Methods currently used to provide care for mothers and infants after discharge include telephone calls, nurse-managed postpartum clinics, home visits, and “baby lines” staffed by nurses who provide information and guidance for callers (see Chapters 1 and 23). Comprehensive psychosocial support including telephone calls, home and clinic visits, and breastfeeding and parenting education has been shown to decrease the incidence of hospital readmission of normal newborns (Barilla, Marshak, Anderson et al., 2010). Some programs use postpartum doulas or paraprofessionals to help extend the work of nurses in providing support to postpartum women. All methods have advantages and disadvantages.

The overlap between nursing care in the birth facility and home makes communication among nurses extremely important. Nurses in the birth facility, who perform the initial assessments, should make information such as nursing diagnoses available to nurses who provide follow-up care.

APPLICATION OF THE NURSING PROCESS

Maternal Adaptation

Assessment

Several factors such as the mother’s progress through the puerperal phases, her mood, her interaction with the infant, and unanticipated events affect maternal adaptation to the birth (Table 18-1).

Nursing Diagnosis

Parenting may be altered when one or more caregivers experience difficulty creating or continuing a nurturing environment. Therefore a common nursing diagnosis is “Risk for Impaired Parenting related to multiple factors such as fatigue, discomfort, and lack of knowledge of infant care” (Box 18-1).

Planning

Expected outcomes for this nursing diagnosis are that the mother will:

- Verbalize feelings of comfort and support as she progresses through the phases of recovery.
- Demonstrate progressive attachment behaviors by (specific date).
- Participate in care of the newborn by discharge.

Interventions

Assisting the Mother through Recovery Phases

“Mother” the Mother. The early, taking-in phase is a time to “mother” the mother to help her transition to more complex tasks of maternal adjustment. During the first few hours after childbirth, she has a great need for physical care and comfort. Provide ample fluids and favorite foods. Keep linens dry, tuck warm blankets around her until chilling has stopped, and use warm water for perineal care.

Monitor and Protect. The new mother depends on nurses to monitor and protect her. Remind her of the need to void and assist her to ambulate. Assess her level of comfort frequently and offer analgesia before discomfort is severe and analgesia is less effective. Instruct her not to delay requesting analgesia because it is more effective and the postpartum course is smoother if her pain stays well controlled. At the first signs of fatigue, encourage her to sleep.

Listen to the Birth Experience. Be prepared to listen to details of the birth experience and offer sincere praise for her efforts during labor. Use open-ended questions to determine the woman’s perception of the birth. The opportunity to discuss her feelings about the experience helps her to integrate it and clarify concerns.

Many mothers spend so much time on the telephone that completing nursing care is difficult. The mother’s need to relate her experiences to family and friends is important, and nurses may be reluctant to interrupt. When assessments and care are necessary for the mother’s physical safety, a compromise can be effective. Offering a choice is often helpful: “Excuse me for a moment. I need to check you soon. I can do it now or come back in 10 minutes.”

Foster Independence

As the mother becomes more independent, allow her to schedule her care as much as possible. Collaborate with her to plan when care such as ambulation or a shower will be performed. Encourage her to assume responsibility for her self-care, and emphasize that the nurse’s role at this point is to assist and teach.

Promote Bonding and Attachment

Early, unlimited contact between parents and infants is of primary importance to facilitate the attachment process. In most hospitals and birth centers, infants remain in the room with the parents unless

TABLE 18-1 ASSESSING MATERNAL ADAPTATION

ASSESSMENTS	NURSING CONSIDERATIONS
<p>Progression through Puerperal Phases</p> <p>Taking-in (passive, dependent)</p> <p>Taking-hold (autonomous, seeks information)</p> <p>Letting-go (relinquishes fantasy baby, begins to see self as mother)</p>	<p>Consider mother's need to rest, her need to tell the details of her labor and childbirth, and her readiness to learn infant care and assume control of her own care.</p>
<p>Maternal Mood</p> <p>Mood and energy level, eye contact, posture, and comfort</p>	<p>Tense body posture, crying, or anxiety (may indicate fatigue, discomfort, or beginning of postpartum blues).</p>
<p>Factors that Affect Maternal Adaptation</p> <p>Age of mother</p> <p>Previous experience</p> <p>Maternal and infant temperaments</p> <p>Other factors</p>	<p>May need additional support if under 18 years of age.</p> <p>Primiparas progress through puerperal phases more slowly and may need more assistance than multiparas. Previous birth of an infant with anomalies or death of an infant may delay adaptation.</p> <p>Mothers who are calm, secure, and free from anxiety need less assistance. More teaching is necessary for parents of infants who are difficult to console.</p> <p>Cesarean birth causes increased discomfort and longer recovery. Attachment problems may occur with birth of a preterm or ill infant or more than one infant.</p>
<p>Interaction with Infant</p> <p>Maternal touch</p> <p>Verbal interaction</p> <p>Response to infant cues or signals</p>	<p>Progresses from fingertipping to enfolding and other comforting behaviors.</p> <p>Mother may call infant "it" initially but progresses quickly to using given name and identifying specific characteristics.</p> <p>Prompt, gentle, consistent response indicates progressive adaptation to parenting role.</p>
<p>Preparation for Parenting</p> <p>Classes in breastfeeding, parenting, and infant care</p>	<p>Many mothers feel more prepared after completing classes and participate in care sooner.</p>

complications intervene. This arrangement may be called mother-baby care, couplet care, or dyad care. One nurse is responsible for both the mother and the baby and provides teaching and help with bonding as part of ongoing nursing care (Figure 18-8). The mother participates as she is able. The nurse assists as the mother learns to care for her baby and gradually takes over all care. This provides continuity of care and helps prepare the parents for discharge.

Prolonged contact between mothers and infants leads to more touching and caring for infants as mothers learn their infants' characteristics and needs. Nursing measures to promote bonding and attachment include:

- Assist the parents in unwrapping the baby to inspect the toes, fingers, and body. Inspection fosters identification and allows the parents to become acquainted with the "real" baby, which must

FIG 18-8 By teaching about the newborn and family, the nurse helps parents develop confidence in their ability to provide care for the infant.

replace the fantasy baby that many parents imagined during the pregnancy.

- Position the infant in an en face position and discuss the infant's ability to see the parent's face. Face-to-face and eye-to-eye contact is a first step in establishing mutual interaction between the infant and parent.
- Point out the reciprocal bonding activities of the infant: "Look how she holds your finger." "He hasn't taken his eyes off you."
- Encourage the parents to take as much time as they wish with the infant. This allows them to progress at their own speed through the discovery or getting-acquainted phase.

- Assist the mother in putting the infant to the breast if she plans to breastfeed. If necessary, reassure her that many infants do not latch onto the breast at first. If she is using formula, assist her in positioning the infant securely and reassure her that holding and cuddling the infant provide comfort and security. Answer her questions about feeding.
- Model behaviors by holding the infant close, making eye contact with the infant, and speaking in high-pitched, soothing tones.
- Point out the characteristics of the infant in a positive way: “She has such pretty little hands and beautiful eyes.”
- Provide comfort and ample time for rest because the mother must replenish her energy and be relatively free of discomfort before she can progress to initiating care of the infant. A mother who seems uninterested may just need a period of rest or pain intervention to be comfortable enough to focus on the infant.

Involve Parents in Infant Care

Providing care for the infant fosters feelings of responsibility and nurturing and is an important component of attachment. In addition, it allows parents to develop confidence in their ability to care for their infant before they go home. Begin with demonstrations, as necessary, and provide assistance while the parents gradually assume all infant care as their confidence in their abilities grows.

Although teaching begins during pregnancy, review information and repeat demonstrations if time allows. Demonstrate the simpler tasks such as care of the cord before progressing to more complicated procedures such as bathing. When the parents receive positive reinforcement for the simple tasks, they are more willing to try the more complicated ones (see [Chapters 21](#) and [23](#)).

Agreement among the entire staff about how to teach basic care is important. Mothers seek confirmation of information, and they become confused and lose faith in the credibility of the staff if information varies. Allow time for practice and repeated encouragement. Parents become easily discouraged if they feel unsuccessful with early attempts to care for their infants.

Suggestions for care must be tactfully phrased to avoid the implication that the parents are inept. “You burped that baby like a professional. There are a couple of little hints I can share about diapering.”

Evaluation

The expected outcomes are met when the mother independently performs self-care and verbalizes feelings of comfort and support during her progression through the phases of recovery. She should show progressive attachment behaviors, including enfolding the infant, calling the infant by name, and responding gently when the infant cries. Her participation in infant care should include diapering, feeding, and care of the umbilical cord and circumcision.

APPLICATION OF THE NURSING PROCESS

Family Adaptation

Assessment

Fathers

The father’s emotional status and interaction with the infant are particularly important because he usually serves as the mother’s primary support person. Is the father involved with the mother and infant? How does he interact with the infant? How much information does he have about infant characteristics and care? What are his expectations about his partner’s recovery? Unrealistic expectations of the infant (will sleep through the night, smile, be easily consoled) may lead to problems. In addition, if he expects the mother to recover her energy

and libido rapidly, he may become resentful if her recovery takes longer than anticipated.

Siblings

Note the ages of siblings and their reactions to the newborn. Are they interested and helpful? Are they hostile and aggressive? How do the parents respond to sibling behaviors?

Support System

Family members often provide a powerful support system, and their involvement is important to the adaptation of the family. Are grandparents available and involved? Do sisters and brothers live nearby? Are they available to help the new parents? If the family is unavailable, who provides support? What arrangements have been made for assistance?

Nonverbal Behavior

Nonverbal behavior is equally important. Are the parents’ words congruent with their actions? For example, does the mother verbalize satisfaction with her infant’s characteristics but respond slowly to infant signals?

Validate impressions and conclusions during a psychosocial assessment. One of the best ways to do this is to ask questions such as, “How much experience have you had with newborns?” “How are newborns fed in Vietnam until the mother’s milk comes in?” “What are your plans when you go home?” “How long can your mother stay?”

Intersperse questions over time during normal caregiving. The mother should not be made to feel she is being interrogated because the nurse asks so many questions at once. [Table 18-2](#) summarizes family assessment.

Nursing Diagnosis

Family assessment identifies family strengths and areas in which nursing interventions could promote family adaptation or prevent disruptions in family functioning. Sometimes a family that usually functions effectively is unable to cope because of a specific event, such as the birth of a baby. An appropriate nursing diagnosis is “Risk for Interrupted Family Processes related to lack of knowledge of infant needs and behaviors, stress during the early weeks at home, and sibling rivalry.”

Planning

Goals and expected outcomes for this nursing diagnosis may overlap with care after discharge because they often cannot be evaluated before the family leaves the birth facility.

By (specific date) the family will:

- Verbalize understanding of the infant’s needs and behaviors.
- Identify methods for reducing stress during the early weeks at home.
- Describe measures to reduce sibling rivalry.
- Identify external resources and the family’s support system.

Interventions

Teaching the Family about the Newborn

Many women access the Internet for information about infant care. One study found that women were interested in information about postpartum weight and parenting from the Internet or by mail. Generally high-income women were more interested in Internet sources and low-income women were interested in information by mail. This may reflect differences in access to the Internet or comfort with computers ([Walker, Im, & Vaughan, 2012](#)).

Mobile phones can also be used for obtaining information. A free service from the National Healthy Mothers, Healthy Babies Coalition

TABLE 18-2 ASSESSING FAMILY ADAPTATION

ASSESSMENT	NURSING CONSIDERATIONS
Characteristics of Infant That May Affect Family Adaptation	
Gender and size of infant	Disappointment about gender or concern about small size may interfere with bonding.
Unexpected characteristics (cephalhematoma, jaundice, cranial molding, newborn rash)	Explain unexpected appearance or behavior in language that parents can comprehend.
Congenital anomaly or illness	Explain the condition to parents; assist them during visits and in learning care.
Infant behavior (irritable, easily consoled, cuddles)	Infants who are easy to manage increase bonding and attachment.
Paternal Adaptation	
Response to the mother and the infant	The father often provides the most important support for the mother. His involvement with the infant indicates acceptance of parenting role.
Knowledge of infant care	The father's knowledge determines the teaching he will need.
Response to infant cues or signals (crying, fussing)	Many fathers feel awkward handling infant but want to become proficient in infant care.
Ages and Developmental Levels of Siblings	
Reaction of siblings	Young children often fear the newborn will replace them in the affection of the parents. Parents may need anticipatory guidance about sibling rivalry.
Support System	
Interest and availability of family or friends to assist during early weeks	Families may need assistance in identifying available support.
Plans for first few days at home	Suggest that parents plan for support and rest. Provide resources such as telephone "baby lines," postpartum clinics, or support groups.
Follow-up plans	Appointments for the mother and infant are generally scheduled at 2 to 6 weeks with clinic or health care provider.
Cultural Factors	
Cultural beliefs and practices that may affect nursing care	Culture-specific care can be planned for hygiene, dietary preferences, usual care and feeding of infants, and role of the partner and family in child care.
Expectations of health care team	Expectations may vary in different cultures.

CASE STUDY 18-1 NURSING CARE PLAN*

ASSESSMENT: During discharge teaching, Dawn states that she does not work outside the home and always has assumed total responsibility for household tasks. She reveals that a perfectly maintained home is important to her and especially to her husband. She wonders about his possible reaction to the disruption the twins will create.

NURSING DIAGNOSIS: Risk for Interrupted Family Processes related to the impact of newborns on family functioning

GOALS/EXPECTED OUTCOMES: The couple will:

1. Share concerns with each other and identify family strengths by (specific date).
2. Identify measures that reduce stress and promote family adjustment to the birth of twins by discharge.
3. Renegotiate responsibilities as necessary during the first few weeks at home.

INTERVENTIONS AND RATIONALES

1. Determine whether Dawn has shared her concerns with her husband. If she has not, suggest that she tell him she is worried about the effect of the twins on their normal life. *Open communication is the first step in identifying stressors and clarifying feelings.*
2. Discuss the ways other family members or friends could help. Attempt to determine overlooked resources such as community resources or the ability to afford hired help with the housework for a few weeks. *Many families develop a higher level of functioning during times of stress, and individual members participate actively. Families often overlook community resources such as neighbors and friends.*
3. Assist the family in identifying measures to reduce stress that may occur when family patterns are disrupted. *During times of stress many parents*

overlook the benefits of good nutrition, exercise, and recreation. Even short periods of recreation can refresh spirits and replenish energy.

- a. Recommend simple meals that are easy to prepare and use of disposable dishes for a few weeks.
 - b. Emphasize the importance of good nutrition and daily exercise.
 - c. Review measures to obtain rest, but point out that fatigue is likely to persist until the twins sleep through the night.
 - d. Recommend that both parents continue to participate in activities that provide recreation and relaxation, both together and separately.
4. Suggest that the couple negotiate sharing household tasks such as meal preparation during the first few weeks, even though this is not part of their usual roles. *Sharing tasks reduces fatigue and helps prevent frustration and arguments during this time of stress.*
 5. Recommend that the couple negotiate child care activities so that both parents are involved in the day-to-day care as much as possible. *When both parents are involved in child care, they co-parent more effectively. Continued shared responsibility for the twins provides each parent with individual time with the infants. It also reduces fatigue.*
 6. Refer Dawn to groups for parents of multiples. Provide her with local phone numbers and websites (such as the Mothers of Twins website: www.nomotc.org). *Interacting with other parents in the same situation may provide information to help Dawn and her husband adjust to their family changes.*

EVALUATION: Dawn discussed with her husband her concerns about the effect of the twins on the usual pattern of family life and was surprised to learn that he was very willing to assume many of the household tasks while the infants required so much care. Dawn's mother is available to babysit, so Dawn and her husband can have some time for exercise and recreation.

*Continued from p. 361.

provides texts with information about pregnancy and infants through one year. The service can be accessed by going to the website at www.text4baby.org or texting BABY to 511411 on a mobile phone.

Infant Needs. Some new parents have unrealistic expectations of the newborn. Provide them with information about the infant's capabilities as well as the infant's emotional and physical needs. For example, parents sometimes are surprised to hear that infants must be fed every 2 to 4 hours and will not sleep through the night for 12 to 16 weeks.

Infant Signals. Discuss the importance of responding promptly and gently to cues such as crying and fussing that indicate the infant needs attention. Reassure parents that responding to cues does not "spoil" their baby but helps the infant learn to trust that the world is a safe, secure place.

Help parents recognize signals that indicate when their infant has had enough interaction and wants to avoid further stimulation. These avoidance cues, such as looking away, splaying the fingers, arching the back, and fussiness, indicate that the infant needs a quiet time.

Helping the Family Adapt

Providing Anticipatory Guidance about Stress Reduction. Help the family plan for the demands of the first weeks at home by providing anticipatory guidance. This is a time when the need for rest is great but the opportunity for uninterrupted sleep is minimal. As a result, fatigue is a common problem for both parents. The nurse should:

- Emphasize that the priority during the first 4 to 6 weeks should be caring for the mother and the baby.
- Recommend that mothers establish a relaxed home atmosphere and flexible meal schedule because attempts to maintain a rigid schedule or meticulous environment increase tension within the family.
- Recommend that the mother sleep when the infant sleeps and conserve her energy for care of the baby.
- Encourage parents to let friends and relatives know sleep and nap times and request that they telephone and visit at other times. Adequate rest is necessary for mental and physical restoration and integration of new information into the memory.
- Advise parents to place a "Do Not Disturb" sign on the door and to set an answering machine to pick up immediately when the phone rings during rest times.
- Suggest the parents limit coffee, tea, colas, and chocolate because they contain caffeine and will interfere with rest.
- Teach breathing exercises and progressive relaxation to reduce stress and energize, especially when a nap is not possible.
- Encourage both parents to delay tiring projects until the infant is older. Remind them that although schedules are chaotic for a while, the infant's behavior is generally more predictable by 12 to 16 weeks of age.
- Encourage open expression of feelings between parents as a first step in coping with stress.

- Remind parents of the need for healthy nutrition and recreation. Fatigue and tension easily can overwhelm the anticipated joys of parenting if no respite is available from constant care.
- Suggest that new parents enlist grandparents, other relatives, and friends to help with cooking, cleaning, shopping, and care of other children.

Helping the Father Co-Parent. Help the father become involved with his infant by including him in teaching. Provide opportunities for him to participate in diapering, comforting activities, and feeding or helping the mother breastfeed. Offer frequent encouragement and praise. If classes or chat rooms for men who are new parents are available, refer the father to them.

Providing Ways to Reduce Sibling Rivalry. Suggest that parents plan time alone with older children. Frequent praise and expressions of love and affection help reassure older children of their places in the family. Suggest that visitors and relatives do not focus exclusively on the infant but include older children in their gift giving and attention.

Emphasize the importance of responding calmly and with understanding when a sibling regresses to more infantile behaviors or expresses hostility toward the infant. Acknowledging the child's feelings and offering prompt reassurance of continued love are the most valuable actions.

Some children, particularly those older than 3 years of age, enjoy being a big brother or sister and respond well when they are included in infant care. This participation may not be possible with younger children, and setting aside separate time with them to participate in a favorite activity may be more worthwhile for the parents.

Identifying Resources. In many homes women assume the major responsibilities of day-to-day homemaking. With the birth of an infant, this task becomes more difficult. A division of labor must be negotiated to prevent undue stress and fatigue. This division of labor is particularly important when other children in the home also need time, attention, and comfort.

Although the mother's primary support often is the father of the baby, extended family members, particularly grandmothers and sisters, also provide valuable support. Community resources such as daycare centers, parenting classes, and breastfeeding support groups are available in many areas. In addition, close friends and neighbors often share solutions to specific problems. Remind the mother that resources are available when she begins to feel isolated and exhausted.

Evaluation

A prompt, gentle response to infant crying and fussing and verbalizations of acceptance of normal newborn behaviors indicate parental understanding of the infant's need. Devising a plan for obtaining rest and lessening anxiety in siblings is a first step in reducing stress and sibling rivalry. Identifying resources in the family, neighborhood, and community may help the family function to meet its needs during the early weeks at home.

SUMMARY CONCEPTS

- Bonding and attachment are gradual processes that begin before childbirth and progress to feelings of love and deep devotion lasting throughout life.
- Nurses foster bonding and attachment by providing early, unlimited contact between the parents and infant and modeling attachment behaviors. Contact is particularly important when the infant is awake and alert and able to interact with the parents.
- Maternal touch changes over time as many mothers progress from exploratory "fingertipping" to enfolding and finally demonstrating a full range of comforting behaviors.
- Verbal behaviors are important indicators of maternal attachment. Nurses often model how to speak to the infant and point out the infant's response to the verbal stimulation.
- Maternal adjustment to parenthood is a gradual process involving restorative phases of taking-in, taking-hold, and letting-go. Nurses play a valuable role in the process by first "mothering the mother" and then fostering independence as the mother becomes ready.
- Parents usually progress through four stages of role attainment—anticipatory, formal, informal, and personal—before they attain a

Continued

SUMMARY CONCEPTS—cont'd

- sense of comfort and can structure their parenting behaviors to mesh with the infant's unique needs.
- The mother develops a “new normal” as she goes through phases of appreciating her body, settling-in with the new baby, and becoming part of a new family.
- Many women experience role conflict when they must leave the infant with a caregiver and return to work. Nurses can offer anticipatory guidance that makes the conflict less difficult.
- Postpartum blues is a temporary, self-limiting period of tearfulness and mood instability. It should not last longer than 2 weeks.
- The birth of a baby requires reorganization of family structure and renegotiation of family responsibilities. Nurses can assist the father in co-parenting the infant and help the new parents identify family resources.
- Siblings may be jealous and fearful that they will be replaced by the newborn in the affection of the parents. Nurses can lessen the negative feelings by providing information about ways to reduce sibling rivalry.
- Attention to cultural concerns of postpartum women is important in helping them meet cultural, physical, and psychosocial needs.
- Nurses recognize that families leave the birth facility with unmet needs and that nursing care in the facility overlaps with follow-up care provided in the home.

Normal Newborn: Processes of Adaptation

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain the physiologic changes that occur in the respiratory and cardiovascular systems during the transition from fetal to neonatal life.
2. Describe thermoregulation in the newborn.
3. Compare gastrointestinal functioning in the newborn and adult.
4. Explain the causes and effects of hypoglycemia.
5. Describe the steps in normal bilirubin excretion and the development of physiologic, nonphysiologic, breastfeeding, and true breast milk jaundice.
6. Describe kidney functioning in the newborn.
7. Explain the functioning of the newborn's immune system.
8. Describe the periods of reactivity and the six behavioral states of the newborn.

At birth neonates must make profound physiologic changes to adapt to extrauterine life and meet their own respiratory, digestive, and regulatory needs. This chapter focuses on these changes and will assist nurses in identification of behaviors that signify problems or abnormalities. It provides a foundation for discussion of nursing assessment and care related to those changes, detailed in [Chapters 20](#) and [21](#).

INITIATION OF RESPIRATIONS

The first vital task the newborn must accomplish is the initiation of respirations. Forces occurring throughout pregnancy and during birth bring about this change.

Development of the Lungs

During fetal life the alveoli produce **fetal lung fluid** that expands the alveoli and is essential for normal development of the lungs. Some of the fluid empties from the lungs into the amniotic fluid. The fluid is continuously produced at a rate of 4 to 5 mL/kg/hour ([Jobe, 2011](#)). As the fetus nears term, the amount of fetal lung fluid produced decreases in preparation for birth, when the fluid must be cleared for the infant

to breathe air. Absorption of lung fluid begins during early labor, and by the time of birth only about 35% of the original amount remains ([Jobe, 2011](#)).

During labor, the fluid begins to move into the interstitial spaces, where it is absorbed. Absorption is accelerated by secretion of fetal epinephrine and corticosteroids but may be delayed by cesarean birth without labor. The removal of the fluid helps reduce pulmonary resistance to blood flow that is present before birth and enhances the advent of air breathing.

Surfactant, a slippery, detergent-like combination of lipoproteins, is detectable by 24 to 25 weeks of gestation ([Blackburn, 2013](#)). Surfactant lines the inside of the alveoli and reduces surface tension within alveoli, allowing the alveoli to remain partially open when the infant begins to breathe at birth. Without surfactant the alveoli collapse as the infant exhales. The alveoli must be reexpanded with each breath, greatly increasing the work of breathing and possibly resulting in atelectasis. By 34 to 36 weeks of gestation sufficient surfactant is usually produced to prevent respiratory distress syndrome ([Gardner, Enzman-Hines, & Dickey, 2011](#)). Surfactant secretion increases during labor and immediately after birth to enhance the transition from fetal to neonatal life.

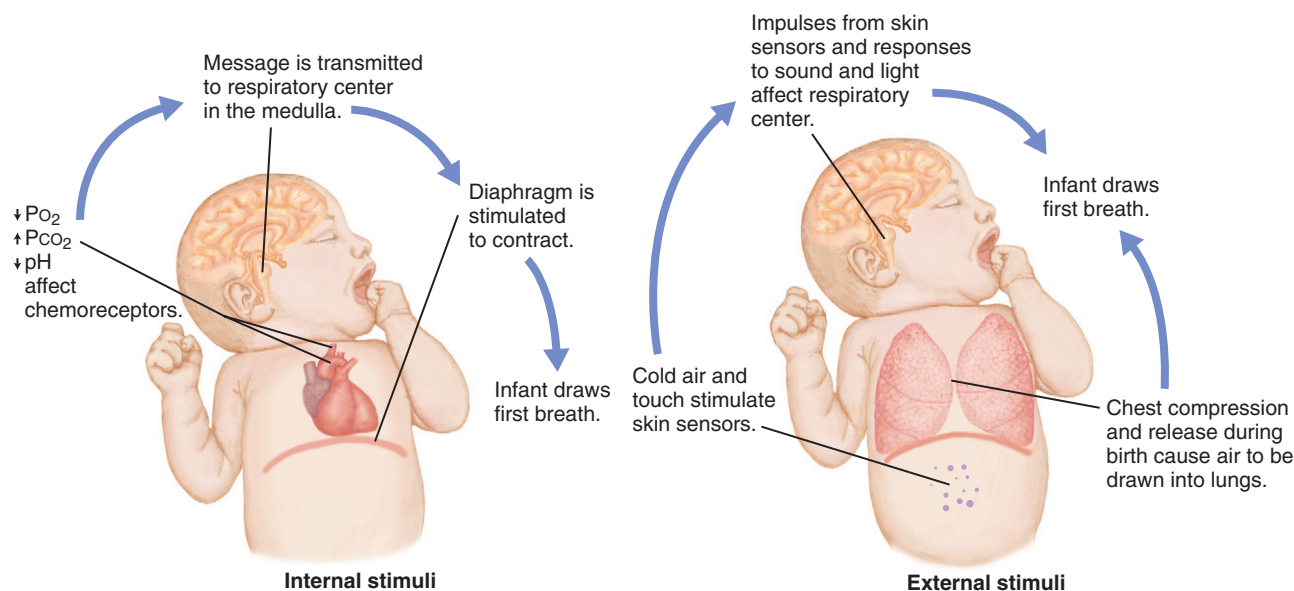

FIG 19-1 Internal causes of the initiation of respirations are the chemical changes that take place at birth. External causes of respirations include thermal, sensory, and mechanical factors.

Steroids given to a woman in preterm labor help increase surfactant production and speed maturation of the lungs. The fetus with intrauterine growth restriction or stressed by conditions such as maternal hypertension, heroin addiction, preeclampsia, or infection; placental insufficiency, or premature rupture of membranes greater than 48 hours may also have accelerated lung maturation. Infants of mothers with diabetes have slower lung maturation (Gardner et al., 2011).

Causes of Respirations

At birth the infant's first breath must force remaining fetal lung fluid out of the alveoli and into the interstitial spaces around the alveoli to allow air to enter the lungs. This requires a much larger negative pressure (suction) than subsequent breathing. Breathing is initiated by chemical, mechanical, thermal, and sensory factors that stimulate the respiratory center in the medulla and trigger respirations (Figure 19-1).

Chemical Factors

Chemoreceptors in the carotid arteries and the aorta respond to changes in blood chemistry caused by the hypoxia that occurs with normal birth. A decrease in the partial pressure of oxygen (PO_2) and pH and an increase in the partial pressure of carbon dioxide (PCO_2) in the blood cause impulses from these receptors to stimulate the respiratory center in the medulla. In addition, occlusion of the vessels in the cord ends the flow of a placental substance that may inhibit respirations. A forceful contraction of the diaphragm results, causing air to enter the lungs. However, stimulation of the respiratory center and breathing do not occur if prolonged hypoxia causes central nervous system depression.

Mechanical Factors

During a vaginal birth the fetal chest is compressed by the narrow birth canal. Approximately one third of the fetal lung fluid is forced out of the lungs into the upper air passages during birth. The fluid passes out of the mouth or nose or is suctioned as the head emerges from the vagina. When the pressure against the chest is released at birth, recoil of the chest draws a small amount of air into the lungs and helps remove some of the viscous fluid in the airways. This reduces the

amount of negative pressure needed for the first breath after birth (Askin, 2008).

Thermal Factors

The temperature change that occurs with birth also stimulates the initiation of respirations. At birth the infant moves from the warm, fluid-filled uterus into an environment where the temperature may be much cooler. Sensors in the skin respond to this sudden change in temperature by sending impulses to the medulla that stimulate the respiratory center and breathing.

Sensory Factors

Tactile, visual, auditory, and olfactory stimuli occur during and after birth to stimulate sensors. Nurses hold, dry, place infants skin-to-skin with the mother or wrap them in blankets, providing further stimulation to skin sensors. The stimulation of the light, sound, smell, and pain at delivery may also aid in initiating respirations.

Continuation of Respirations

As the alveoli expand, surfactant allows them to remain partially open between respirations. About 20 to 30 mL of air from the first breaths remains in the lungs to become the functional residual capacity (FRC) (Carlo, 2011c). Within the first hour after birth 80% to 90% of the FRC is established (Blackburn, 2013). Because the alveoli remain partially expanded with this residual air, subsequent breaths require much less effort than the first one.

As the infant cries, pressure within the lungs increases, causing remaining fetal lung fluid to move into the interstitial spaces, where it is absorbed by the pulmonary circulatory and lymphatic systems. Complete absorption may take several hours. This explains why the lungs may sound moist when first auscultated but become clear a short time later.

3. How is fetal lung fluid removed before and after birth?

CARDIOVASCULAR ADAPTATION: TRANSITION FROM FETAL TO NEONATAL CIRCULATION

During fetal life three shunts—the ductus venosus, foramen ovale, and ductus arteriosus—carry much of the blood away from the lungs and some blood away from the liver. High pressures within the collapsed, fluid-filled lungs permit only a small amount of blood flow into the narrow pulmonary vessels.

Ductus Venosus

Oxygenated blood from the placenta enters the fetal circulation through the umbilical vein. About one third of the blood is directed away from the liver into the ductus venosus (DV) which connects to the inferior vena cava (IVC). The rest of the umbilical vein flow goes through the liver before entering the IVC. Near the end of pregnancy the liver needs more perfusion, and 70% to 80% of the oxygenated blood goes to the liver first and then to the ductus venosus (Blackburn, 2013).

Blood from the DV or the portal system of the liver enters the IVC and joins blood from the lower part of the body. Little mixing of blood from the DV and the lower body occurs because it travels to the heart in separate streams within the IVC. As blood flows into the right atrium, a flap of tissue directs the blood from the more highly oxygenated stream across the atrium to the foramen ovale.

Foramen Ovale

The foramen ovale is a flap valve in the septum between the right and left atria of the fetal heart. As blood flows into the right atrium, 50% to 60% crosses the foramen ovale to the left atrium (Blackburn, 2013). In the left atrium it mixes with the small amount of blood entering from the pulmonary veins, flows to the left ventricle, and leaves through the aorta. The majority of the blood in the ascending aorta flows to the coronary, left carotid, and subclavian arteries. Therefore most of the better-oxygenated blood bypasses the nonfunctioning lungs before birth and travels to the heart, brain, head, and upper body.

Blood that does not cross the foramen ovale moves to the right ventricle, but flow to the lungs is restricted by the narrow pulmonary artery and pulmonary blood vessels, causing a high pressure in the right side of the heart. Pressure is low on the left side of the heart because little resistance occurs as blood leaves the left ventricle to travel to the rest of the body and into the widely dilated placental vessels. This difference in pressures between the right and left atria allows blood to flow through the foramen ovale.

Pulmonary Blood Vessels

Blood from the superior vena cava and the less oxygenated blood from the inferior vena cava flow into the right atrium, to the right ventricle, and into the pulmonary artery. Most of the blood passes through the ductus arteriosus while 10% to 12% of the blood goes to the lungs. After 30 weeks gestation, the amount of blood to the lungs increases (Blackburn, 2013). Blood flow to the lungs is limited because the pulmonary artery and other blood vessels are constricted, causing high pulmonary vascular resistance. Blood perfusing the lungs returns to the left atrium by the pulmonary veins.

Ductus Arteriosus

The ductus arteriosus connects the pulmonary artery and the descending aorta during fetal life. Dilation of the ductus arteriosus is maintained by prostaglandins from the placenta and low oxygen content of the blood.

CRITICAL THINKING EXERCISE 19-1

Understanding the changes that occur during the transition from fetal to neonatal circulation helps in predicting the effect on blood flow of various defects in the heart.

Question

1. What would be the effect on neonatal blood flow of an opening in the septum of the atria of the heart?

Changes at Birth

At birth, the shunts close and the pulmonary vessels dilate. These changes occur in response to increases in blood oxygen and shifts in pressure within the heart, pulmonary, and systemic circulations, as well as clamping of the umbilical cord. The alterations necessary for transition from fetal to neonatal circulation occur simultaneously within the first few minutes after birth. They are discussed separately here (Table 19-1; see also Figure 6-9).

As the newborn takes the first breaths at birth, the rise in oxygen concentration causes the ductus arteriosus to constrict, preventing entry of blood from the pulmonary artery. The pulmonary blood vessels respond to the increased oxygenation by dilating. At the same time, fetal lung fluid shifts into the interstitial spaces and is removed by blood and lymph vessels. These changes decrease pulmonary vascular resistance by 80% and allow the vessels to expand to hold the suddenly increased blood flow from the pulmonary artery.

At birth, pressures between the right and left sides of the heart are reversed. The sudden dilation of the vessels of the lungs allows blood to enter freely from the right ventricle and decreases pressure in the right side of the heart. Clamping of the umbilical cord closes the ductus venosus and further decreases pressure in the right side of the heart. Increased blood flow from the pulmonary veins into the left atrium causes pressure in the left side of the heart to build. Systemic resistance increases as blood flow to the placenta ends with clamping of the cord, and this also elevates pressure in the left heart.

The foramen ovale's flap valve closes when the pressure in the left atrium is higher than that in the right atrium. This change forces the blood from the right atrium into the right ventricle and pulmonary artery. Because the ductus arteriosus is also closing, the blood continues into the lungs for oxygenation and returns to the left atrium through the pulmonary veins. Blood from the left atrium enters the left ventricle and leaves through the aorta to circulate to the rest of the body. Thus blood flow through the heart and lungs changes from fetal to neonatal circulation and is similar to that in the normal adult (see Figure 6-9).

Conditions such as **asphyxia** (insufficient oxygen and excess carbon dioxide in the blood and tissues) and persistent pulmonary hypertension (Chapter 30), however, may reverse the pressures in the heart and cause the foramen ovale to reopen.

The ductus arteriosus closes gradually as oxygenation improves and prostaglandins, which helped keep it open, are metabolized. Until closure is complete, a small amount of blood may shunt through the ductus arteriosus from the aorta to the pulmonary artery, a reverse of flow during fetal life (Rozance & Rosenberg, 2012). This sequence occurs because pressure in the aorta has become higher than that in the pulmonary artery. A murmur may be heard as a result of blood flow through the partially open vessel.

Low levels of oxygen in the blood may cause the ductus arteriosus to dilate and the pulmonary vessels to constrict, increasing resistance to blood flow to the lungs. The result may be opening of the foramen

TABLE 19-1 CIRCULATORY CHANGES AT BIRTH

STRUCTURE	PURPOSE IN FETAL LIFE	CHANGE AT BIRTH	CAUSE OF CHANGE AT BIRTH	RESULTS OF CHANGE AT BIRTH	TIME OF FUNCTIONAL AND PERMANENT CHANGE
Umbilical vessels	Carry blood from placenta to fetus and back	Obstruction of blood flow through vessels	Clamping of cord	Decreased pressure in RA and increased systemic resistance occur.	<i>Functional:</i> immediately when clamped <i>Permanent:</i> 1-2 weeks
Ductus venosus	Shunts one third of blood from umbilical vein to inferior vena cava and away from immature liver	Blood flow occluded with end of umbilical circulation	Occlusion of cord stops flow of blood from placenta through umbilical vein to ductus venosus.	Blood travels through liver to be filtered as in adult circulation.	<i>Functional:</i> when cord is clamped Becomes ligamentum venosum
Foramen ovale	Provides flap valve between RA and LA so blood can bypass nonfunctioning lungs and go directly to LV and aorta; opens in R-to-L direction because of high RA pressure and low LA pressure	Closes when pressure in LA becomes higher than pressure in RA	Cord occlusion elevates systemic resistance; blood returns from PV to LA; both increase L heart pressure. Decreased pulmonary resistance allows free flow of blood into lungs and decreased pressure in RA.	Blood entering RA can no longer pass through to LA; instead it goes to RV and through PA to lungs.	Closes at birth because of pressure changes <i>Functional:</i> 3 months, but may be longer; becomes fossa ovale
Pulmonary blood vessels	Narrowed vessels increase resistance to blood flow to lungs.	Dilation of all vessels in lungs	Elevated blood oxygen and removal of fetal lung fluid	Decreased pulmonary resistance allows blood to enter freely to be oxygenated.	Beginning with first breath
Ductus arteriosus	Is widely dilated to carry blood from PA to aorta and avoid nonfunctioning lungs	Constriction preventing entrance of blood from PA	Increase of oxygen level in blood	Blood in PA is directed to lungs for oxygenation.	<i>Functional:</i> beginning within minutes after birth; complete constriction 1 to 8 days <i>Permanent:</i> 1-4 months; becomes ligamentum arteriosum

L, Left; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary veins; R, right; RA, right atrium; RV, right ventricle.

ovale to allow a right-to-left shunt of blood and flow from the pulmonary artery through the ductus arteriosus and into the aorta. A patent ductus arteriosus may occur in the infant who experiences asphyxia at birth, becomes hypoxic, or is preterm (see [Chapter 30](#)).

CHECK YOUR READING

4. What causes the closure of the ductus arteriosus, foramen ovale, and ductus venosus at birth?
5. What causes the pulmonary blood vessels to dilate and the ductus arteriosus to constrict?

NEUROLOGIC ADAPTATION: THERMOREGULATION

At birth the infant must assume **thermoregulation**, the maintenance of body temperature. Although the fetus produces heat in utero, the consistently warm temperature of the amniotic fluid and the mother's body makes thermoregulation unnecessary. The infant's temperature

may drop as much as 0.2° to 1°C (0.5° to 1.7°F) per minute if not kept warm at birth ([Blackburn, 2013](#)). Neonates must produce and maintain enough heat to prevent cold stress, which can have serious and even fatal effects.

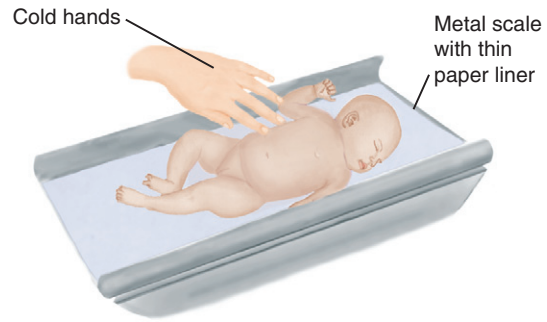

Newborn Characteristics That Lead to Heat Loss

Certain characteristics predispose newborns to lose heat. The skin is thin, and blood vessels are close to the surface. Little subcutaneous or white fat is present to provide a barrier to heat loss. Heat is readily transferred from the warmer internal areas of the body to the cooler skin surfaces and then to the surrounding air. Newborns have three times more surface area to body mass than adults, which provides more area for heat loss. Newborns lose heat at a rate four times greater than that of adults ([Carlo, 2011b](#)).

The healthy full-term infant remains in a position of flexion, reducing the amount of skin surface exposed to the surrounding temperatures and decreasing heat loss. Sick or preterm infants have decreased muscle tone and are unable to maintain a flexed position. Preterm infants also have thinner skin and even less white subcutaneous fat than full-term infants. Therefore they are at increased risk for cold stress (see [Chapter 29](#)).

Evaporation can occur during birth or bathing from moisture on skin, as a result of wet linens or clothes, and from insensible water loss.

Conduction occurs when the infant comes in contact with cold objects or surfaces such as a scale, a circumcision restraint board, cold hands, or a stethoscope.

Convection occurs when drafts come from open doors, air conditioning, or even air currents created by people moving about.

Heat is lost by radiation when the infant is near cold surfaces. Thus, heat is lost from the infant's body to the sides of the crib or incubator and to the outside walls and windows.

FIG 19-2 Methods of heat loss.

Methods of Heat Loss

Heat is lost in four ways: evaporation, conduction, convection, and radiation (Figure 19-2). The nurse can prevent heat loss by each method and must be watchful for situations in which intervention is needed.

Evaporation

Evaporation is air-drying of the skin that results in cooling. Drying the infant, especially the head, as quickly as possible helps prevent loss of heat by evaporation. Insensible water loss from the skin and respiratory tract increases heat loss from evaporation.

Conduction

Movement of heat away from the body occurs when newborns have direct contact with objects that are cooler than their skin. Placing infants on cold surfaces or touching them with cool objects causes this type of heat loss. The reverse is also true: Contact with warm objects increases body heat by conduction. Warming objects that will touch the infant or placing the unclothed infant against the mother's skin ("skin to skin") helps prevent conductive heat loss.

Convection

Transfer of heat from the infant to cooler surrounding air occurs in convection. When infants are in incubators, the circulating warm air helps keep them warm by convection. Providing a warm, draft-free environment avoids convective heat loss.

Radiation

Radiation is the transfer of heat to cooler objects that are not in direct contact with the infant. Infants in incubators transfer heat to the walls of the incubator. If the walls of the incubator are cold, the infant is cooled, even when the temperature of the air inside the incubator is warm. To combat this problem, incubators have double walls. Placing

CRITICAL THINKING EXERCISE 19-2

Look at a newborn's environment and the care given over a day.

Question

1. What are possible causes of each method of heat loss for the infant?

FIG 19-3 Radiant warmers allow easy access to the infant without increasing heat loss resulting from exposure. The nurse is careful not to come between the infant and the overhead source of heat when caring for the infant.

cribs and incubators away from windows and outside walls minimizes radiant heat loss. Newborns can gain heat by radiation, too. Using a radiant warmer transfers heat from the warmer to the cooler infant (Figure 19-3).

Nonshivering Thermogenesis

When adults are cold, they shiver, increasing muscle activity to produce heat. Shivering is not an important method of **thermogenesis** (heat production) for newborns who rarely shiver except during prolonged exposure to low temperatures (Blackburn, 2013). Instead, they become restless and cry. Their increased activity and flexion help generate some warmth and reduce the loss of heat from exposed surface areas of the body.

Exposure to cool temperatures also results in peripheral vasoconstriction, decreasing flow of warm blood to the skin. This helps prevent heat loss from the skin and causes the skin to feel cool to the touch. Acrocyanosis (bluish discoloration of the hands and feet) may occur. In addition, a drop in temperature increases the metabolic rate as much as 200% to 300%, causing above-normal oxygen and glucose use (Blackburn, 2013).

The primary method of heat production in infants is **nonshivering thermogenesis** (NST), the metabolism of brown fat to produce heat. Newborns can increase heat production by 100% using NST (Blackburn, 2013). **Brown fat** (also called *brown adipose tissue* or *BAT*) contains an abundant supply of blood vessels, which cause the brown color. Brown fat is located primarily around the back of the neck; in the axillae; around the heart, kidneys, and adrenals; between the scapulae; and along the abdominal aorta (Figure 19-4). As brown fat is metabolized, it generates more heat than white subcutaneous fat. Blood passing through brown fat is warmed and carries heat to the rest of the body.

NST begins when thermal receptors in the skin detect a skin temperature of 35° to 36°C (95° to 96.8°F) (Blackburn, 2013). Thermal

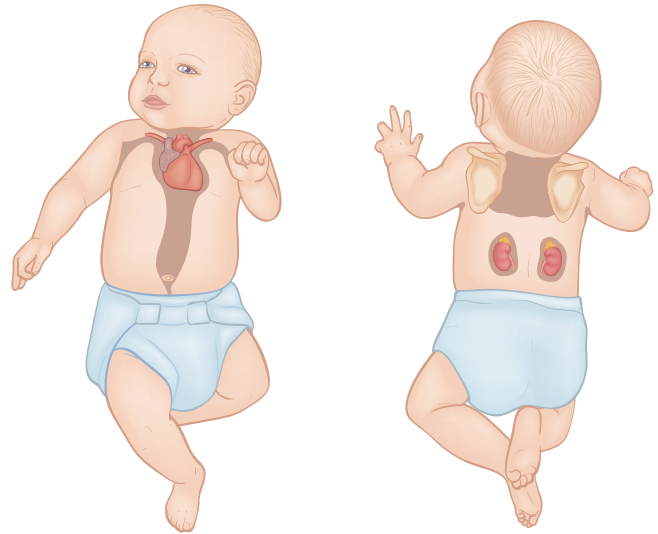

FIG 19-4 Sites of brown fat in the neonate.

receptor stimulation is transmitted to the hypothalamic thermal center. As a result, norepinephrine is released in brown fat, initiating its metabolism.

NST goes into effect even before a change occurs in core (interior) body temperature, as measured with a rectal thermometer. Activating thermogenesis before core temperature decreases allows the body to maintain internal heat at an even level. Therefore NST may begin in an infant when skin temperature has been cooled, even though core measurements show normal readings. A decreased core temperature will not occur until NST is no longer effective.

Some infants have inadequate brown fat stores. It is accumulated mainly during the third trimester, so preterm infants may be born before adequate stores of brown fat have accumulated (Wood, 2009). Intrauterine growth restriction may deplete brown fat stores before birth. Hypoxia, hypoglycemia, and acidosis may interfere with the infant's ability to use brown fat to generate heat. These infants are not able to raise their body temperature if they are subjected to cold stress and may have serious complications.

CRITICAL TO REMEMBER

Hazards of Cold Stress

- Increased oxygen need
- Decreased surfactant production
- Respiratory distress
- Hypoglycemia
- Metabolic acidosis
- Jaundice

Effects of Cold Stress

Cold stress causes many body changes (Figure 19-5). The increased metabolic rate and metabolism of brown fat that result from cold stress can cause a significant rise in the need for oxygen. If an infant is having even mild respiratory distress, the problem may be exacerbated if added oxygen is used for heat production. Cold stress also causes a diminished production of surfactant, impeding lung expansion and leading to more respiratory distress.

Glucose is also necessary in larger amounts when the metabolic rate rises to produce heat. When glycogen stores are converted to glucose,

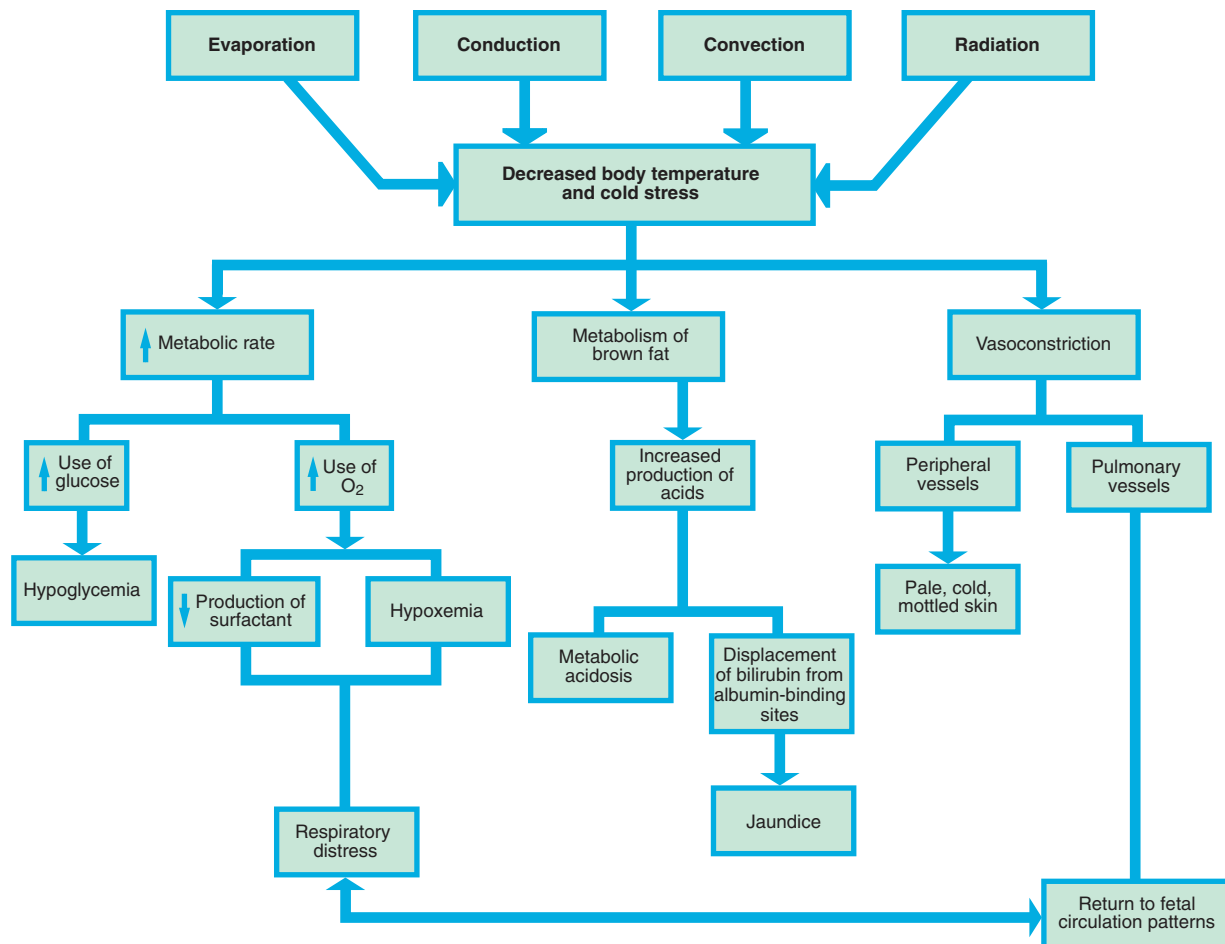

FIG 19-5 Effects of cold stress.

they may be quickly depleted, causing hypoglycemia. Continued use of glucose for temperature maintenance leaves less available for growth.

Metabolism of glucose in the presence of insufficient oxygen causes increased production of acids. Metabolism of brown fat also releases fatty acids. The result can be metabolic acidosis, which can be a life-threatening condition. Elevated fatty acids in the blood can interfere with transport of **bilirubin** to the liver, increasing the risk of **jaundice** (yellow discoloration of the skin and sclera caused by excessive bilirubin in the blood).

As the infant's body attempts to conserve heat, vasoconstriction of the peripheral blood vessels occurs to reduce heat loss from the skin surface. Decreased oxygen concentration in the blood, however, may also cause vasoconstriction of the pulmonary vessels, leading to further respiratory distress.

Neutral Thermal Environment

A **neutral thermal environment** is one in which the infant can maintain a stable body temperature with minimal oxygen need and without an increase in metabolic rate. The range of environmental temperature that allows this stability is called the *thermoneutral zone*. In healthy, unclothed, full-term newborns, an environmental temperature of 32° to 33.5°C (89.6° to 92.3°F) provides a thermoneutral zone. When the infant is dressed, the thermoneutral range is 24° to 27°C (75.2° to 80.6°F) (Blackburn, 2013). The thermoneutral zone for each infant varies according to the infant's gestational age, size, and postnatal age.

Hyperthermia

Infants also respond poorly to hyperthermia. With an elevated temperature the metabolic rate rises, causing an increased need for oxygen and glucose and possible metabolic acidosis. In addition, peripheral vasodilation leads to increased insensible fluid losses. Sweating may occur but is often delayed because sweat glands are immature.

Newborns may be overheated by poorly regulated equipment designed to keep them warm. When radiant warmers, warming lights, or warmed incubators are used, the temperature mechanism must be set to vary the heat according to the infant's skin temperature and thus prevent heat that is too high or too low. Alarms to signal that the infant's temperature is too high or too low should be functioning properly.

- What are the effects of low temperature in newborns?

HEMATOLOGIC ADAPTATION

Factors That Affect the Blood

The blood volume of the term newborn is 80 to 100 mL/kg, but this varies according to the time of cord clamping, the gestational age of the infant, and the position of the infant when the cord is clamped

TABLE 19-2 LABORATORY VALUES IN THE NEWBORN

TEST, SPECIMEN, AND UNIT OF MEASUREMENT	AGE	NORMAL RANGES
Erythrocyte (red blood cell [RBC]) count, whole blood	Newborn	4.8-7.1 (million/microliter)
Hemoglobin, whole blood	Newborn	15-24 g/dL
Hematocrit, whole blood	Newborn	44%-70%
Leukocytes, whole blood	Birth	9.1-34 (thousand/mm ³)
Leukocyte differential count, whole blood		
Myelocytes		0%
Neutrophils ("bands")		3%-5%
Neutrophils ("segs")		54%-62%
Lymphocytes		25%-33%
Monocytes		3%-7%
Eosinophils		1%-3%
Basophils		0-0.75%
Platelet count, whole blood	Newborn	84-478 (thousand/mm ³)
Glucose, serum	Cord	45-96 mg/dL
	Newborn at 1 day	40-60 mg/dL
	Newborn >1 day	50-90 mg/dL
Calcium, total serum	Cord	9-11.5 mg/dL
	3-24 hr	9-10.6 mg/dL
	24-48 hr	7-12 mg/dL
	4-7 days	9-10.9 mg/dL
Magnesium, plasma	0-6 days	1.2-2.6 mg/dL
Bilirubin	Cord	< 2 mg/dL
	0-1 day	1.4-8.7 mg/dL
	1-2 days	3.4-11.5 mg/dL
	3-5 days	1.5-12 mg/dL
	>5 days-adult	0.3 mg/dL

(Diehl-Jones & Askin, 2010). Preterm infants have a greater blood volume per kilogram than term infants. Blood samples drawn from the heel, where the circulation is sluggish, show higher hemoglobin, hematocrit, and erythrocyte values than samples taken from central areas (Blackburn, 2013). Venous blood samples are more accurate and are taken when precise measurement is essential. (See Table 19-2 for specific newborn laboratory values.)

Blood Values

Erythrocytes and Hemoglobin

At birth the infant has comparatively more erythrocytes (4.8 million/microliter to 7.1 million/microliter) and higher hemoglobin (15 to 24 g/dL) levels than the adult (Pagana & Pagana, 2011; Lo, 2011). This difference is necessary because the partial pressure of oxygen in

fetal blood is much lower than the normal adult level. Adequate oxygenation of the cells is possible because fetal hemoglobin (hemoglobin F) carries 20% to 50% more oxygen than adult hemoglobin (Hall, 2011).

Hematocrit

The hematocrit level in the normal newborn is 44% to 70% for the first month (Lo, 2011). A level above 65% from a central site indicates **polycythemia** (an abnormally high erythrocyte count) (Luchtman-Jones & Wilson, 2011). Polycythemia increases the risk of jaundice and injury to the brain and other organs as a result of blood stasis. Respiratory distress and hypoglycemia are more common in these infants (see Chapter 30).

Leukocytes

The leukocyte (white blood cell [WBC]) count at birth is 9100/mm³ to 34,000/mm³ (Lo, 2011). The average WBC count is 15,000/mm³ in term infants. The WBC count falls to 12,000/mm³ by 4 to 5 days after birth (Blackburn, 2013). In newborns an elevated WBC count does not necessarily indicate infection. In fact, the WBC count may decrease in infections (Lott, 2010). Increased numbers of immature leukocytes are a sign of infection or sepsis in the neonate. The number of platelets (thrombocytes) may also decrease as a result of infections.

Risk of Clotting Deficiency

Newborns are at risk for clotting deficiency during the first few days of life because they have low levels of vitamin K, which is necessary to activate several of the clotting factors (factors II [prothrombin], VII, IX, and X). Vitamin K is synthesized in the intestines, but food and normal intestinal flora are necessary for this process. At birth the intestines are sterile and therefore unable to produce vitamin K (Luchtman-Jones & Wilson, 2011). To decrease the risk of hemorrhagic disease of the newborn, vitamin K is administered intramuscularly to most newborns in the United States during initial care. Drugs such as phenytoin (Dilantin), phenobarbital, and antituberculosis drugs taken by the mother during pregnancy interfere with clotting ability in the infant after birth (Blackburn, 2013).

The platelet (thrombocyte) count ranges from 84,000/mm³ to 478,000/mm³ at birth. After the first week platelet levels are the same as in the adult—150,000/mm³ to 400,000/mm³ (Lo, 2011). Although platelet counts in term newborns are near adult levels, platelet response to stimuli is decreased during the first few days of life.

GASTROINTESTINAL SYSTEM

Newborns must begin to take in, digest, and absorb food after birth because the placenta no longer performs these functions for them.

Stomach

The newborn's stomach capacity is about 6 mL/kg at birth. Gastric emptying may be delayed at first. It is twice as rapid after ingestion of human milk than after formula and slower if the infant has swallowed mucus (Blackburn, 2013). The gastrocolic reflex is stimulated when the stomach fills, causing increased intestinal peristalsis. Infants frequently pass a stool during or after a feeding. The cardiac sphincter between the esophagus and the stomach is relaxed, which explains the tendency to regurgitate feedings easily.

Intestines

The intestines of the newborn are long in proportion to the infant's size and compared with those of the adult. The added length allows more surface area for absorption but makes infants more prone to

water loss should diarrhea develop. Air enters the gastrointestinal tract soon after birth, and bowel sounds may be heard beginning at 15 minutes after birth (Goodwin, 2009).

The digestive tract is sterile at birth. Once the infant is exposed to the external environment and begins to take in fluids, bacteria enter the gastrointestinal tract. Normal intestinal flora are established within the first few days of life.

Digestive Enzymes

Maturation of the ability to digest and absorb occurs at different rates for various nutrients. Pancreatic amylase, needed to digest complex carbohydrates, is deficient for the first 4 to 6 months after birth (Blackburn, 2013). Amylase is also produced by the salivary glands, but in low amounts until about the third month of life. Amylase is present in breast milk.

The newborn is also deficient in pancreatic lipase, limiting fat absorption significantly. Lipase present in the mouth and stomach helps with some digestion of fat. Lipase is present in breast milk, which may make it more digestible for the newborn than formula. Protein and lactose, the major carbohydrate in the infant's milk diet, are both well digested.

Stools

Meconium is the first stool excreted by the newborn. It consists of particles from amniotic fluid such as vernix, skin cells, and hair, along with cells shed from the intestinal tract, bile, and other intestinal secretions. Meconium is greenish black with a thick, sticky, tarlike consistency. The first meconium stool is usually passed within 12 hours of life, and 99% of neonates pass meconium within 48 hours (Carlo, 2011a). If meconium is not passed within that time, obstruction is suspected.

Meconium stools are followed by transitional stools, a combination of meconium and milk stools. They are greenish brown and of a looser consistency than meconium. Milk stools characteristic of the type of feeding given to the infant occur next.

The stools of infants fed with breast milk are seedy and the color and consistency of mustard, with a sweet-sour smell. The breastfed infant generally has more frequent stools than the infant who is formula fed. A stool may be passed with each feeding. Some older infants pass only one stool every 2 to 3 days. The normal breastfed newborn should have at least four or more stools daily (Lawrence & Lawrence, 2011).

The formula-fed infant has pale yellow to light brown stools. They are firmer in consistency than those of the breastfed infant. The infant may excrete several stools daily, or only one or two. The stools have the characteristic odor of feces.

HEPATIC SYSTEM

The liver assumes many different functions after birth. Some of the most important include maintenance of blood glucose levels, conjugation of bilirubin, production of factors necessary for blood coagulation, storage of iron, and metabolism of drugs.

Blood Glucose Maintenance

Throughout gestation, glucose is supplied to the fetus by the placenta. During the third trimester, glucose is stored as glycogen primarily in the fetal liver and skeletal muscles for use after birth. These stores are almost completely depleted within 12 hours after birth (Rozance & Rosenberg, 2012). They are used for energy during the stress of delivery and for breathing, heat production, movement against gravity, and activation of all the functions that the neonate must assume at birth.

Until newborns begin regular feedings and their intake is adequate to meet energy requirements, the glucose present in the body is used. As the blood glucose level falls, stored glycogen in the liver is converted to glucose for use. Although the brain can use alternative fuels such as ketones and fatty acids if necessary, glucose is the primary source of energy. Glucose concentration in the blood commonly falls to the lowest levels by 60 to 90 minutes after birth but rises and stabilizes in 2 to 3 hours after birth (Blackburn, 2013).

In the term infant, glucose levels should be 40 to 60 mg/dL on the first day and 50 to 90 mg/dL thereafter (Lo, 2011). There is no general consensus about the level of blood glucose that defines hypoglycemia, but a level below 40 to 45 mg/dL in the term infant is often used (Blackburn, 2013; Kubicka & Little, 2009; McGowan, Rozance, Price-Douglas et al., 2011).

Many newborns are at increased risk for hypoglycemia. In the preterm, late preterm (born between 34 weeks and 36 ½ weeks of gestation), and small-for-gestational-age infant, adequate stores of glycogen or even fat for metabolism may not have accumulated. Stores may be used up before birth in the postterm infant because of poor intrauterine nourishment from a deteriorating placenta. Large-for-gestational-age infants and those with diabetic mothers may produce excessive insulin that consumes available glucose quickly.

Infants exposed to such stressors as asphyxia or infection may exhaust their stores of glycogen. The cold-stressed infant may deplete glycogen to increase metabolism and raise body temperature (see "Critical to Remember: Signs of Neonatal Hypoglycemia," Chapter 20).

Conjugation of Bilirubin

A major function of the liver is the conjugation of bilirubin (Figure 19-6). The newborn's liver may not be mature enough to prevent jaundice during the first week of life. Jaundice results from **hyperbilirubinemia**, excessive bilirubin in the blood. It occurs in 60% of term newborns and 80% of preterm infants (Ambalavanan & Carlo, 2011).

Source and Effect of Bilirubin

The principal source of bilirubin is the hemolysis of erythrocytes. This is a normal occurrence after birth, when fewer erythrocytes are needed than during fetal life. The breakdown of RBCs releases their components into the bloodstream to be reused by the body. Only bilirubin remains as an unusable residue in the blood. This substance is toxic to the body and must be excreted.

Bilirubin is released in an unconjugated form. Unconjugated bilirubin, also called *indirect bilirubin*, is soluble in fat but not in water. Before excretion can occur, the liver must change it to a water-soluble form by a process called *conjugation*. The bilirubin is then known as *conjugated* or *direct bilirubin*. Conjugated bilirubin is not toxic to the body and can be excreted.

Because unconjugated bilirubin is fat soluble, it may be absorbed by the subcutaneous fat, causing the yellowish discoloration of the skin called *jaundice*. If enough unconjugated bilirubin accumulates in the blood, staining of the tissues in the brain may occur. This may cause acute **bilirubin encephalopathy**, a neurologic condition resulting from bilirubin toxicity. If this condition becomes chronic, it causes

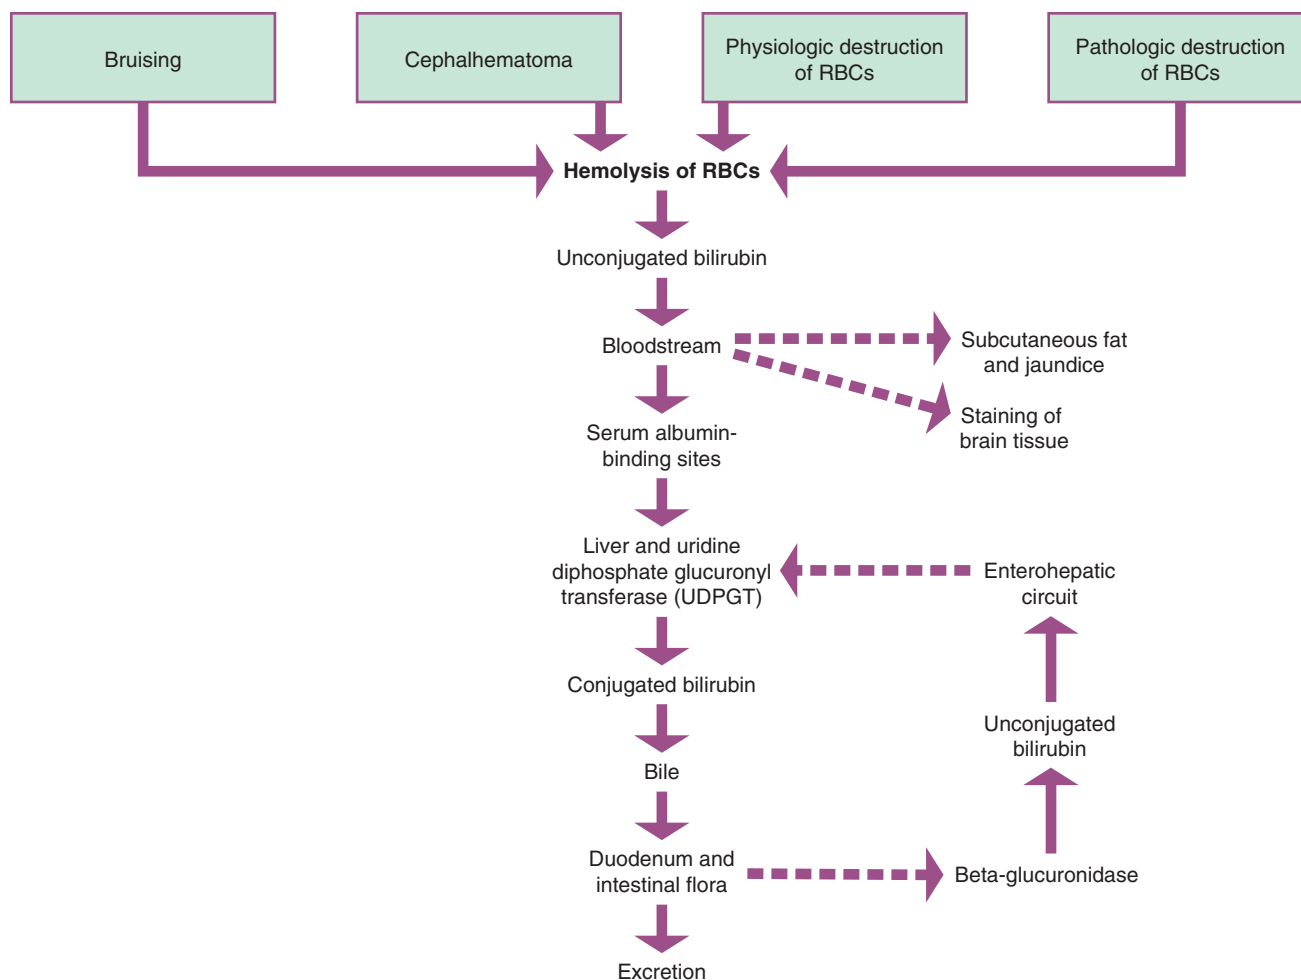

FIG 19-6 Sources of bilirubin and how it is removed from the body.

permanent neurologic injury known as **kernicterus**. The level of bilirubin necessary to cause injury to the central nervous system is unknown and may be different for various infants.

Normal Conjugation

When unconjugated bilirubin is released into the bloodstream, it attaches to binding sites on albumin in the plasma and is carried to the liver. If an adequate number of albumin-binding sites are not available, bilirubin circulates as unbound or free unconjugated bilirubin. Bilirubin can be displaced from albumin by some medications. Free fatty acids, acidosis, and infection also decrease albumin binding of bilirubin (Kamuth, Thilo, & Hernandez, 2011). It is the free, unbound unconjugated bilirubin that can move into the tissues and cross the blood-brain barrier.

When the albumin-bound bilirubin reaches the liver, it is changed to the conjugated form of bilirubin by the enzyme *uridine diphosphate glucuronyl transferase (UDPGT)*. Conjugated bilirubin is excreted into the bile and then into the duodenum. In the intestines the normal flora act to reduce bilirubin to urobilinogen and stercobilin, which are excreted in the stools. Some urobilinogen is excreted by the kidneys.

A small percentage of conjugated bilirubin may be deconjugated, or converted back to the unconjugated state, by the intestinal enzyme beta-glucuronidase. This enzyme is important in fetal life because only unconjugated bilirubin can be cleared by the placenta for conjugation by the mother's liver. In the newborn, deconjugated bilirubin in the intestines is reabsorbed into the portal circulation and carried back to

the liver, where it again undergoes the conjugation process. This recirculation of bilirubin is called the *enterohepatic circuit* and it creates additional work for the liver.

Blood tests for bilirubin measure total serum bilirubin (TSB) and direct (conjugated) bilirubin in the serum. TSB is a combination of indirect (unconjugated) and direct bilirubin.

Factors in Increased Bilirubin

A number of factors lead to the production of excessive amounts of bilirubin or interfere with the normal process of conjugation. These increase the incidence of jaundice during the first week of life.

Excess Production. Approximately 8 to 10 mg/kg of bilirubin is produced in newborns each day, a rate twice that in adults. The rate of production remains higher for 3 to 6 weeks (Blackburn, 2013). Newborns have more RBCs per kilogram than adults.

Red Blood Cell Life. Fetal RBCs break down more quickly than adult erythrocytes. They last 80 to 100 days in term infants and 60 to 80 days in preterm infants, as compared with RBCs in adults, which have a typical life span of 120 days (Blackburn, 2013). In addition, neonate erythrocytes are more fragile and susceptible to injury than those in the adult. Compared to adults, for their size neonates have more RBCs breaking down faster and producing greater amounts of bilirubin to excrete.

Albumin. Newborns have less albumin, decreased albumin-binding capacity, and decreased albumin affinity for bilirubin than adults (Kaplan, Wong, Sibley et al., 2011).

Liver Immaturity. The newborn's immature liver may not produce adequate amounts of UDPGT and other substances during the first few days of life. This limits the amount of bilirubin that can be conjugated.

Blood Incompatibility. Rh, ABO, or other incompatible blood between the mother and the infant may increase RBC breakdown.

Gestation. Preterm and late preterm infants have immature conjugation abilities.

Intestinal Factors. At birth the intestines of the newborn are sterile. Conjugated bilirubin cannot be reduced to urobilinogen or stercobilin for excretion without the action of intestinal flora. In addition, the newborn intestines have a large amount of the enzyme beta-glucuronidase, which changes bilirubin back to the unconjugated state. Intestinal motility is decreased, allowing more time for the enzyme to act. These factors may result in high levels of unconjugated bilirubin, which is reabsorbed into the blood circulation.

Delayed Feeding. Feeding the newborn helps establish the normal intestinal flora and promotes passage of meconium, which is high in bilirubin. When feedings are delayed or taken poorly, normal flora are not established, and passage of meconium, which is high in bilirubin, is delayed. Delayed passage of stools allows more time for exposure to beta-glucuronidase, increasing the chance that conjugated bilirubin will be converted to the unconjugated state and absorbed into the blood.

Trauma. Trauma during birth, such as bruising or a cephalhematoma, causes increased hemolysis of RBCs. As the RBCs in the traumatized areas break down, they add to the bilirubin load.

Fatty Acids. Fatty acids have a greater affinity than bilirubin for the binding sites on albumin and bind to albumin in place of bilirubin. Fatty acids are released when brown fat is used to increase heat during cold stress. During asphyxia, anaerobic metabolism also produces free fatty acids. Therefore the level of unbound unconjugated bilirubin is increased in these infants and jaundice may develop.

Family Background. Infants who are Asian, Native American, or Eskimo or have a sibling who had jaundice are more likely to be affected. Infants of diabetic mothers are also at increased risk of jaundice.

Other Factors. Some drugs (such as sulfisoxazole) given to the mother during pregnancy or to the infant increase jaundice. Blood swallowed during birth, hypoglycemia, infection, and hemolytic anemias also increase jaundice.

CRITICAL TO REMEMBER

Factors That Increase Risk of Hyperbilirubinemia

- Hemolysis of excessive erythrocytes
- Short red blood cell life span
- Lack of albumin-binding sites
- Liver immaturity
- Lack of intestinal flora
- Breastfeeding
- Delayed or inadequate feedings
- Blood incompatibility
- Preterm or late preterm birth
- Trauma resulting in bruising or cephalhematoma
- Polycythemia
- Fatty acids from cold stress or asphyxia
- Sibling with jaundice
- Male gender
- Asian, Native American, Eskimo heritage
- Maternal diabetes or preeclampsia

Hyperbilirubinemia Physiologic Jaundice

Physiologic jaundice, also called *nonpathologic* or *developmental jaundice*, is a transient hyperbilirubinemia (excess bilirubin in the blood) and is considered normal. The jaundice is not present during the first 24 hours of life in term infants but appears on the second or third day after birth. Jaundice becomes visible when the bilirubin level is greater than 5 mg/dL (Pan & Rivas, 2009). The rate at which the bilirubin level in the blood rises and falls is important because it helps determine whether the rate for a particular infant is following the expected curve for age and birth weight. In physiologic jaundice, the bilirubin peaks at between the second and fourth days of life and falls to normal levels by 5 to 7 days (Ambalavanan & Carlo, 2011). The bilirubin level rises higher and falls more slowly in Asian infants.

Nonphysiologic Jaundice

Jaundice that is physiologic or normal must be differentiated from nonphysiologic or pathologic jaundice that requires further investigation. One of the most important differences is the time at which jaundice appears: Pathologic jaundice may occur in the first 24 hours. When bilirubin rises higher or more rapidly than expected or stays elevated for longer than expected, earlier treatment is needed to prevent severe hyperbilirubinemia.

Nonphysiologic jaundice is a result of abnormalities causing excessive destruction of RBCs or problems in bilirubin conjugation. These include incompatibilities between the mother's and the infant's blood types (see Chapter 25), infection, and metabolic disorders. Nonphysiologic jaundice is often treated with phototherapy (see Chapter 30).

Charts are available that show the rise and fall of bilirubin and the degree of risk at various levels of TSB according to the age of the infant in hours. For example, a full-term infant with no complications who is 24 hours old is considered at low risk if the TSB is 5 mg/dL or less and at high risk if the TSB is greater than 8 mg/dL. At 48 hours of age, that infant would be low risk if the TSB were 8.5 mg/dL but high risk if the TSB were that high before 48 hours. Infants who are preterm, late preterm, or who have other risk factors may receive treatment for hyperbilirubinemia at lower TSB levels than full-term infants.

Jaundice Associated with Breastfeeding

The breastfed infant has a higher risk of developing jaundice, which may begin early or late after birth.

Breastfeeding or Early-Onset Jaundice. Bilirubin levels greater than 12 mg/dL develop in 13% of breastfed infants by 1 week of age (Ambalavanan & Carlo, 2011). The most common cause of jaundice in breastfed infants is insufficient intake. Jaundice begins within the first week of life, and serum bilirubin may reach dangerous levels if intake is not increased.

Infants who are sleepy, have a poor suck, or nurse infrequently may not receive enough colostrum—the substance that precedes true breast milk—to benefit from its normal laxative effect in eliminating bilirubin-rich meconium. When meconium is not eliminated, the bilirubin may be deconjugated by beta-glucuronidase in the intestine, absorbed, and recirculated to the liver for conjugation again.

Lack of adequate suckling depresses production of breast milk and increases the problem further. Helping the mother with breastfeeding to increase the infant's intake and stimulate milk production may be the most important treatment. Supplementing with formula interferes with the mother's milk production. However, if breastfeeding is inadequate and the infant is dehydrated or losing excessive weight, supplements of expressed breast milk or formula may be necessary. Glucose-water will not reduce bilirubin levels and should be avoided.

True Breast Milk Jaundice. True breast milk jaundice, also called *late-onset breast milk jaundice*, occurs after the first 3 to 5 days of life. It lasts 3 weeks to as long as 3 months for some infants. The TSB usually peaks at 5 to 10 mg/dL and falls gradually over several months. Some infants reach levels of 20 to 30 mg/dL (Kaplan et al., 2011).

The exact cause of true breast milk jaundice is unknown. Substances in the breast milk may increase absorption of bilirubin from the intestine or interfere with conjugation. This may be a form of physiologic jaundice in breastfed infants. Infants have no signs of illness.

Treatment of breast milk jaundice includes close monitoring of TSB and at least 8 to 12 feedings each 24 hours. If bilirubin levels become too high, phototherapy is begun while the mother continues frequent breastfeeding. Interruption of breastfeeding is generally not recommended. However, if the TSB levels are dangerously high, the health care provider may order formula feeding be given for 1 to 3 days while the mother uses a breast pump to maintain milk supply. Temporarily switching to formula causes a rapid drop in bilirubin level. If the level rises while breastfeeding is interrupted, jaundice from another cause should be investigated. The level may rise again when breastfeeding is resumed but generally not high enough to interfere with further breastfeeding.

Blood Coagulation

Prothrombin and coagulation factors II, VII, IX, and X are produced by the liver and activated by vitamin K, which is deficient in the newborn (see p. 375).

Iron Storage

Iron is stored in the fetal liver and spleen during the last weeks of pregnancy. Full-term infants who are breastfeeding usually do not need added iron until 6 months of age (Lawrence & Lawrence, 2011). At that time, they should begin iron-containing foods or iron supplements. All infants who are not breastfeeding should be given iron-fortified formula (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012; Holt, Wooldridge, Story et al., 2011).

Metabolism of Drugs

The liver metabolizes drugs inefficiently in the newborn. This must be considered when drugs are given to the neonate. In addition, a breastfeeding mother should alert her primary caregiver before taking medications, as harmful amounts may be transferred to the infant via the breast milk.

URINARY SYSTEM

Kidney Development

By 34 to 36 weeks' gestation, the fetal kidneys have as many nephrons as an adult (Frost, Fashaw, Hernandez et al., 2011). Blood flow to the kidneys increases after birth, and resistance in the renal vessels decreases. The improved perfusion results in a steady improvement in kidney function during the first few days of life.

Kidney Function

The newborn's kidney function is immature compared with that of the adult. The ability of the glomeruli to filter and the renal tubules to reabsorb is considerably less than in adults. The glomerular filtration rate doubles or triples during the first weeks of life but does not reach adult levels until 1 to 2 years of age (Frost et al., 2011). Therefore infants have a decreased ability to remove waste products from the blood.

Small amounts of substances such as glucose and amino acids may escape into the urine of the neonate (Blackburn, 2013; Frost et al., 2011). They disappear within the first few days of life as kidney function improves. Uric acid crystals may give a reddish color to the urine that is sometimes mistaken for blood.

Voiding occurs within 12 hours for 50% of newborns; 92% void within 24 hours, and 99% void within 48 hours of life (Frost et al., 2011). Failure to void within that time may be a result of hypovolemia from inadequate intake of fluids. Absence of kidneys or anomalies that interfere with excretion of urine are usually discovered before birth because they cause oligohydramnios, low amniotic fluid volume. This generally prompts investigation into the cause during pregnancy. Only one to two voidings may occur during the first 2 days of life, although a higher number is common. The infant voids at least six times a day by the fourth day.

Fluid Balance

Newborns have a lower tolerance for changes in total volume of body fluid than do older infants. This is because of the location of water within the newborn's body and the inability of the kidneys to adapt to large changes in fluid volume. In addition, the fluid turnover rate is greater than that in adults. To maintain fluid balance, full-term infants need 60 to 100 mL/kg (27 to 45 mL/lb) daily during the first 3 to 5 days of life and 150 to 175 mL/kg (68 to 80 mL/lb) a day by 7 days of age (Halbardier, 2010) (Box 19-1).

Water Distribution

Seventy-eight percent of the newborn's body is composed of water. Intracellular water constitutes 34% of the body and extracellular water comprises 44% of the body. Interstitial water volume is three times greater than in adults (Blackburn, 2013).

Although fluid within the cells is relatively stable, extracellular water is easily lost from the body. Because infants have more fluid for their size than adults, and because a larger proportion of it is located outside the cells, total body water is easily depleted. Conditions such as vomiting and diarrhea can quickly result in life-threatening dehydration. At birth, normal diuresis causes a 5% to 10% weight loss as excess extracellular water is lost (Halbardier, 2010; Jones et al., 2011).

BOX 19-1 DAILY INTAKE AND OUTPUT IN THE NEWBORN

First 3-5 Days of Life

Intake: 60 to 100 mL/kg (27 to 45 mL/lb)
Output: At least 1 to 2 voidings

After the First 3-5 Days

Intake: 150 to 175 mL/kg (68 to 80 mL/lb)
Output: At least 6 voidings by the fourth day

Insensible Water Loss

Water lost from the skin and respiratory tract contributes to insensible water loss. Insensible water losses are increased in the newborn because of the large surface area of the body and the rapid respiratory rate. Fluid losses increase greatly when infants are placed under radiant warmers or phototherapy lights, which accelerate evaporation from the skin. An elevated respiratory rate or low humidity in the air surrounding the infant raises insensible water losses even further.

Urine Dilution and Concentration

The ability of a newborn's kidneys to dilute urine is similar to that of adults, but they have only half the adult's ability to concentrate urine (Blackburn, 2013). However, a newborn's kidneys cannot handle large increases in fluids, which result in fluid overload. This is most likely to happen if infants receive too much intravenous fluid. Normal urine output is 2 to 5 mL/kg/hr, and urine specific gravity is 1.002 to 1.01 (Jones et al., 2011). When abnormal conditions such as diarrhea cause excessive loss of fluid, the newborn's limited ability to conserve water may result in dehydration more quickly than in the older infant or child.

Acid-Base and Electrolyte Balance

The maintenance of acid-base and electrolyte balance is a primary function of the kidneys and may be precarious in neonates. Newborns tend to lose bicarbonate at lower levels than adults, increasing their risk for metabolic acidosis. The excretion of solutes also is less efficient in newborns. Although newborns conserve needed sodium well, they are limited in excretion of sodium (Blackburn, 2013). This is especially a problem if they receive excessive amounts.

IMMUNE SYSTEM

The neonate is less effective in fighting infection than the older infant or child. Leukocytes are delayed in moving to the site of invasion and are inefficient in destroying the invader. The infant's decreased ability to localize infection leads to a tendency toward generalized sepsis.

Fever and leukocytosis, which occur during infection of the older child, are often not present in the newborn with infection. This lack of response occurs because the hypothalamus and inflammatory responses are immature. Nonspecific signs such as changes in activity, color, tone, or feeding may be the only signs of sepsis.

Because of their immature immune system, infants are susceptible to some pathogens that do not usually affect older children. Full-term newborns receive antibodies from their mothers during the last trimester of pregnancy. The mother continues to provide passive antibodies to the infant in her milk if she chooses to breastfeed. Immunoglobulins (serum globulins with antibody activity) help protect the newborn from infection. The major immunoglobulins are IgG, IgM, and IgA, each of which performs a different function. At birth the infant's total immunoglobulin levels range from 55% to 80% of the adult levels (Blackburn, 2013).

Immunoglobulin G

Only immunoglobulin G (IgG) crosses the placenta with passage beginning in the first trimester. Preterm infants have less IgG because transfer is greatest during the third trimester. IgG provides the fetus with passive temporary immunity to bacteria, bacterial toxins, and viruses to which the mother has developed immunity. The full-term infant has IgG levels that are as high as or higher than those of the mother (Stoll, 2011).

Although the fetus makes some IgG, significant production of IgG is delayed until after 6 months of age (Blackburn, 2013). The infant

gradually produces larger quantities of the immunoglobulin to replace IgG from the mother, which is being catabolized. The passive immunity gradually disappears reaching the lowest level at 2 to 4 months of age (Empey & Kolls, 2011).

Immunoglobulin M

Immunoglobulin M (IgM) is the first immunoglobulin produced by the body when the newborn is challenged. This immunoglobulin helps protect against gram-negative bacteria. Rapid production of IgM begins a few days after birth as a result of exposure to environmental antigens. IgM cannot cross the placenta because the molecules are too large. If IgM is found in cord blood, exposure to infection in utero has occurred.

Immunoglobulin A

Immunoglobulin A (IgA) also does not cross the placenta and must be produced by the infant. IgA is important in protection of the gastrointestinal and respiratory systems, and newborns are particularly susceptible to infections of those systems. Secretory IgA is present in colostrum and breast milk (Kapur, Yoder, & Polin, 2011). Therefore breastfed infants may receive protection that formula-fed infants do not.

PSYCHOSOCIAL ADAPTATION

Periods of Reactivity

In the early hours after birth, the infant goes through changes called *periods of reactivity*. The two periods of reactivity are separated by a period of sleep or decreased activity (Gardner & Hernandez, 2011).

First Period of Reactivity

The **first period of reactivity** begins at birth and lasts for 30 minutes. Infants are active at this time and appear wide awake, alert, and interested in their surroundings. Parents enjoy watching the infant gaze directly at them when held in the *en face* (face-to-face) position. Infants move their arms and legs energetically, root, and appear hungry. If allowed to nurse, many infants latch on to the nipple and suck well.

The temperature may be decreased during this period. Respirations may be as high as 80 breaths per minute. The heart rate may be elevated to 180 beats per minute. Crackles, grunting, retractions, and nasal flaring may be present. The pulse and respiratory rates gradually slow, and the infant becomes sleepy.

Period of Sleep or Decreased Activity

After the first period of reactivity, infants become quieter or fall into a deep sleep. During this time the pulse and respirations drop into the normal range. Bowel sounds are audible and meconium may be passed.

Second Period of Reactivity

The **second period of reactivity** lasts 4 to 6 hours. Infants have alert periods, and parents may enjoy the opportunity to get to know their infant at this time. Infants become interested in feeding and may pass meconium. There may be tachycardia and rapid respirations. Mucous secretions increase, and infants may gag or regurgitate.

Behavioral States

Six gradations in the behavioral state of the infant have been identified, ranging from quiet sleep to crying (Blackburn, 2013; Gardner & Goldson, 2011). The amount of time infants spend in the different sleep-wake states varies and is a key to their individuality.

Deep or Quiet Sleep State

During the quiet sleep state the infant is in a deep sleep with closed eyes and no eye movements. Respirations are quiet, regular, and slower than in the other states. Although startles occur at intervals, the infant's body is quiet. The infant is very difficult to arouse and will not feed.

Light or Active Sleep State

The active sleep state is a lighter sleep in which infants' eyes are closed. They move their extremities, stretch, change facial expressions, make sucking movements, and may fuss briefly. During this period, respirations tend to be more rapid and irregular and rapid eye movements occur. Infants are more likely to startle from noise or disturbances and may return to sleep or move to an awake state.

Drowsy State

The drowsy state is a transitional period between sleep and waking similar to that experienced by adults as they awaken. The eyes may remain closed or, if open, appear glazed and unfocused. Infants startle and move their extremities slowly. They may go back to sleep or, with gentle stimulation, gradually awaken.

Quiet Alert State

The quiet alert state (also called *alert inactivity*) should be pointed out to parents because it is an excellent time to increase bonding. Infants

focus on objects or people, respond to the parents with intense gazing, and seem bright and interested in their surroundings. They respond to stimuli and interaction with others. Body movements are minimal as infants seem to concentrate on the environment.

Active Alert State

In the active alert state infants seem restless, have increased motor movements, and may be fussy. Infants have faster and more irregular respirations, may hiccup or regurgitate, and seem more aware of feelings of discomfort from hunger or cold. Although their eyes may be open, infants seem less focused on visual stimuli than during the quiet alert state.

Crying State

The crying state may quickly follow the active alert state if no intervention occurs to comfort the infant. The cries are continuous and lusty, active body movement occurs, and the infant does not respond positively to stimulation. Respirations are irregular and rapid. It may take a period of comforting to move the infant to a state in which feeding or other activities can be accomplished.

SUMMARY CONCEPTS

- Chemical, mechanical, thermal, and sensory factors combine to stimulate the respiratory center in the brain and initiate respirations at birth.
- Surfactant lines the alveoli and reduces surface tension to keep the alveoli open. Fetal lung fluid moves into the interstitial spaces before, during, and after birth and is absorbed by the lymphatic and vascular systems.
- Increases in blood oxygen levels, shifts in pressure in the heart and lungs, and clamping of the umbilical vessels cause closure of the ductus arteriosus, foramen ovale, and ductus venosus at birth.
- Neonates must produce and maintain heat (thermogenesis) to prevent the effects of cold stress.
- Infants are predisposed to heat loss because they have thin skin with little subcutaneous (white) fat, blood vessels close to the surface, and a large skin surface area. They lose heat by evaporation, conduction, convection, and radiation.
- Heat is produced in newborns by increased activity, flexion, and metabolism, vasoconstriction, and nonshivering thermogenesis. These factors increase oxygen and glucose consumption and may cause respiratory distress, hypoglycemia, acidosis, and jaundice.
- Laboratory values for erythrocytes, hemoglobin, and hematocrit are higher for newborns than for adults because less oxygen was available in fetal life than after birth.
- The stools progress from thick, greenish black meconium to loose, greenish brown transitional stools to milk stools. Stools of breastfed infants are frequent, soft, seedy, and mustard-colored. Those of formula-fed infants are pale yellow to light brown, firmer, and less frequent.
- The neonate uses glucose rapidly and is at risk for hypoglycemia. Infants at risk for hypoglycemia include those who are preterm, late preterm, small-for-gestational age, large-for-gestational age, born to diabetic mothers, or exposed to stressors.
- Physiologic jaundice occurs in normal newborns after the first 24 hours of life as a result of hemolysis of red blood cells and immaturity of the liver. Nonphysiologic (pathologic) jaundice begins within the first 24 hours and often requires treatment with phototherapy. Breastfeeding jaundice is often caused by insufficient intake. True breast milk jaundice begins later than physiologic jaundice and may be caused by substances in the milk.
- The newborn's kidneys filter, reabsorb, and maintain fluid and electrolyte balance less efficiently than the adult's kidneys. The newborn's body is composed of a greater percentage of water, with more located in the extracellular compartment, and fluid is more easily lost.
- Newborns receive passive immunity when IgG crosses the placenta in utero. After birth, IgM and IgA are produced to protect against infection.
- During the first and second periods of reactivity, newborns are active and alert and may be interested in feeding. They may have a low temperature, elevated pulse and respiratory rates, and excessive secretions.
- Newborns progress through six behavioral states: quiet sleep, active sleep, drowsy, quiet alert, active alert, and crying.

Assessment of the Normal Newborn

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the initial assessments of the newborn.
2. Explain the nurse's responsibilities in cardiorespiratory and thermoregulatory assessments.
3. Describe nursing assessments of newborn body systems.
4. Explain the importance and components of gestational age assessment.

A very important role of the nurse is assessing the newborn to identify abnormalities and problems in adapting to life outside the uterus. The first complete assessment of the newborn often is called an *admission assessment*. Subsequent assessments are less detailed. [Appendix B](#) ("Keys to Clinical Practice") describes the order of initial assessments and care.

EARLY FOCUSED ASSESSMENTS

As soon as the infant is born, the nurse performs assessments that are most immediately crucial to determining the neonate's health status. These include the cardiorespiratory status, thermoregulation, and the presence of anomalies. The nurse determines whether resuscitation (see [Chapter 30](#)) or other immediate interventions are necessary. When the infant is stable and oxygenating well, a more thorough assessment can be performed.

SAFETY ALERT

After newborns are dried at birth, it is easy to forget that their skin is contaminated with blood and amniotic fluid. The nurse should wear gloves when handling newborns until they are bathed and all blood is removed from the skin and hair. Wearing gloves helps protect the nurse from bloodborne infections.

History

Information about the pregnancy, labor, and delivery is important in assessing the likelihood of problems at birth. The maternal age, health

problems, and any complications during the pregnancy or birth may affect the neonate's adaptation at birth. For example, if the mother received narcotic analgesics late in labor, depression of the fetal central nervous system may interfere with initiation of respirations in the neonate. Preterm infants may not produce adequate amounts of surfactant, and atelectasis may occur because the alveoli do not remain open.

Assessment of Cardiorespiratory Status

Assessments of respiratory and cardiovascular status are performed together because transitional changes take place simultaneously in both systems. Problems of adaptation in one system are likely to result in problems in the other system.

Airway

During birth, some fetal lung fluid is forced into the upper airway and expelled. Excessive fluid and mucus in the infant's respiratory passages may cause respiratory difficulty for several hours after birth.

Respiratory Rate. The nurse assesses respirations at least once every 30 minutes until the infant has been stable for 2 hours after birth ([American Academy of Pediatrics \[AAP\] & American College of Obstetricians and Gynecologists \[ACOG\], 2012](#)). If abnormalities are noted, respirations are assessed more often.

The normal respiratory rate is 30 to 60 breaths per minute ([Verklan, 2010](#)). The average rate is 40 to 49 breaths per minute. The infant may breathe faster immediately after birth, during crying, and during the first and second periods of reactivity. Respirations should not be labored, and the chest movements should be symmetric. Because the

PROCEDURE 20-1 ASSESSING VITAL SIGNS IN THE NEWBORN

PURPOSE: To obtain an accurate measurement of newborn vital signs

Respirations

1. Assess respirations when the infant is quiet or sleeping and before disturbing the infant for other assessments, if possible. *Allows the lung sounds to be heard more clearly.*
2. Observe, auscultate, and palpate the chest and abdomen. *The rapid, shallow, irregular respirations can be confused with other movements in an active infant. A combination of methods increases accuracy of the assessment.*
3. Lift the infant's blanket and shirt to see the chest and abdomen. Observe the pattern of respirations before beginning to count. *Respirations are often irregular, but a basic pattern is present. Observation of the pattern makes it easier to count the rate.*
4. If desired, place a hand lightly to the side of the infant's chest or abdomen to feel the movement. Avoid covering the chest completely so chest excursions can be watched as well as palpated. *Palpation helps keep track of the rate.*
5. To auscultate respirations, move a stethoscope over the chest until the respirations are easily heard. This is often toward the right side of the infant's chest. After counting, move the stethoscope to listen to breath sounds in all areas. *Allows the sounds of the lungs to be heard with less interference from heart sounds.*
6. Count for a full minute. *Respirations are normally irregular in the newborn. Counting for a full minute increases accuracy.*
7. If the infant is crying, allow the infant to suck on a pacifier or gloved finger. If crying continues, count the respirations and make a note on the chart that the infant was crying. Recheck later when the infant is calm. *Sucking may quiet the infant. Although respirations are most easily assessed on a quiet infant, they can be counted when the infant is crying. Respirations may be faster on a crying infant.*
8. Expect the respiratory rate to be 30 to 60 breaths/min with an average rate of 40 to 49 breaths/min when the infant is at rest. Report signs of respiratory distress, including tachypnea, retractions, flaring, cyanosis, grunting, seesawing, apneic periods, and asymmetry of chest movements. Continue to watch infants whose respiratory rate is near the extremes of the normal range. *Allows early identification and follow-up of abnormalities. Rates near abnormal may become abnormal in a short time.*

Pulse

1. Listen to the apical pulse while the infant is quiet and before disturbing the infant for other assessments, if possible. *The heart sounds are heard more clearly in a quiet or sleeping infant.*
2. Use a stethoscope with a pediatric head, if available, to listen to the apical pulse. *Although a larger head may be used, the small head allows better contact between the stethoscope and the chest wall and eliminates some of the sounds from the lungs and intestines.*
3. If the infant is crying, insert a pacifier or a gloved finger into the infant's mouth. *Sucking often quiets infants.*
4. If the infant cannot be quieted, increase concentration and time spent listening. *Concentration helps separate the sounds heard and focus on the heart sounds.*
5. Listen briefly before beginning to count. Tapping a finger in rhythm with the beat may be helpful. Count for a full minute. Expect the heart rate to be 120 to 160 bpm at rest. *Listening to the pattern allows time to become accustomed to the rapid heartbeat before counting. Counting for a full minute increases chances of identifying abnormalities.*
6. Move the stethoscope to listen over the entire heart area. Assess for arrhythmias, murmurs, or other abnormal sounds. Refer any abnormalities. *Listening over the entire area increases chances of hearing abnormal sounds. Reporting abnormalities to the pediatrician allows further investigation.*

Temperature

Axillary

1. Place the thermometer vertically along the chest wall with the tip of the thermometer against the skin in the center of the axillary space and the infant's arm held firmly against the body over the probe. *If the thermometer is held horizontally, it may protrude behind the axilla and give an inaccurate reading. Holding the arm keeps the thermometer positioned correctly and prevents accidental injury if the infant moves unexpectedly.*
2. Read the thermometer at the proper time: electronic or digital, when indicator sounds; other types according to manufacturer's directions. Normal range: 36.5° to 37.5°C (97.7° to 99.5°F). *Ensures an accurate reading.*

pattern and depth of respirations are irregular, they must be counted for a full minute for accuracy (see [Procedure 20-1](#)).

Counting the rapid, shallow, irregular respirations of a newborn can be a challenge at first. Differentiating between the respirations and other movements while observing the infant's chest may be difficult. Observation, auscultation, or palpation, alone or in combination, may be used to obtain an accurate respiratory rate.

The nurse observes for **periodic breathing**, pauses in breathing lasting 5 to 10 seconds without other changes followed by rapid respirations for 10 to 15 seconds. This occurs in some full-term infants during the first few days but is more common in preterm infants. **Apnea** is a pause in breathing lasting 20 seconds or more, or accompanied by cyanosis, pallor, bradycardia, or decreased muscle tone ([Goodwin, 2010](#)). Apnea is abnormal and requires prompt intervention.

Breath Sounds. The anterior and posterior lung fields are auscultated for breath sounds, which should be present equally throughout. Breath sounds should be clear over most areas. However, hearing sounds of moisture (crackles) in the lungs during the first hour or two after birth is not unusual because fetal lung fluid has not been completely absorbed. Infants born by cesarean not preceded by labor do

not experience the changes that occur in the lungs during labor and birth and are more likely to have coarse breath sounds for a short time. Wheezes, crackles, rhonchi, or stridor that persists should be reported.

Abnormal and diminished sounds always should be reported to the primary care provider if they continue. They may indicate a pneumothorax. Bowel sounds in the chest may be a sign of diaphragmatic hernia.

Signs of Respiratory Distress. Throughout the assessment, the nurse must be alert for signs of respiratory distress, which may be present at birth or develop later. Whenever one sign of labored breathing is present, the assessment must be carefully expanded to identify others.

Tachypnea. **Tachypnea**, a respiratory rate of more than 60 breaths per minute, is the most common sign of respiratory distress. It is not unusual during the first hour after birth and during the periods of reactivity, but continued tachypnea is abnormal.

Retractions. Retractions occur when the soft tissue around the bones of the chest is drawn in with the effort of pulling air into the lungs. Xiphoid (substernal) retractions occur when the area under the sternum retracts each time the infant inhales. When the muscles between the ribs are drawn in so that each rib is outlined, intercostal

FIG 20-1 Acrocyanosis. (Courtesy Todd Shires.)

retractions are present. The muscles above the sternum and around the clavicles also may be used to aid in respirations (supraclavicular retractions). Retractions may be mild or severe, depending on the degree of respiratory difficulty. Occasional mild retractions are common immediately after birth but should not continue after the first hour.

Flaring of the Nares. A reflex widening of the nostrils occurs when the infant is receiving insufficient oxygen. Nasal flaring helps decrease airway resistance and increase the amount of air entering the lungs. Intermittent flaring may occur in the first hour after birth. Continued flaring indicates a more serious respiratory problem.

Cyanosis. Cyanosis is a purplish blue discoloration indicating the infant is not getting enough oxygen. It may be preceded by a dusky or gray hue to the skin. Central cyanosis involves the lips, tongue, mucous membranes, and trunk and indicates true hypoxia. This means that not enough oxygen is reaching the vital organs and requires immediate attention.

Bruising of the face may occur from a tight nuchal cord or pressure during birth and may look like central cyanosis. To differentiate cyanosis from bruising, apply pressure to the area. A cyanotic area will blanch, but a bruised area remains blue. Central cyanosis in infants with dark skin tones can be checked by looking at the color of the mucous membranes. A pulse oximeter is used to determine oxygen saturation in infants with cyanosis.

Central cyanosis must be differentiated from **acrocyanosis**, which is peripheral cyanosis involving only the extremities. Acrocyanosis is normal during the first day after birth and if the infant becomes cold. It results from poor perfusion of blood to the periphery of the body (Figure 20-1).

Cyanosis may be present at birth or may become apparent later. It is normal to see a cyanotic infant at birth whose color quickly turns pink as the infant begins to breathe. Cyanosis occurs whenever the infant's breathing is impaired. It may occur during feedings because of difficulty in coordinating sucking, swallowing, and breathing. Infants who become cyanotic on exertion or when crying may have a congenital heart defect.

Grunting. Grunting describes a noise made on expiration when air crosses partially closed vocal cords. This increases the pressure within the alveoli, which keeps the alveoli open and enhances the exchange of gases in the lungs. Grunting may be very mild and heard only with a stethoscope, or loud enough to be heard unaided in an infant having severe respiratory difficulty. Persistent grunting is a common sign of respiratory distress syndrome and necessitates expanded assessment and referral for treatment.

Seesaw or Paradoxical Respirations. Normally the chest and abdomen rise and fall together during respiration. In the infant with severe respiratory difficulty, the chest falls when the abdomen rises and the chest rises when the abdomen falls, causing a seesaw effect.

Asymmetry. Chest expansion should be equal on both sides. Asymmetry or decreased movement on one side may indicate the collapse of a lung (pneumothorax).

Choanal Atresia. Choanal atresia is blockage or narrowing of one or both nasal passages by bone or tissue. Assessment for choanal atresia is important because newborns are preferential nose breathers for approximately the first 4 to 6 weeks of life (Sprecher & Arnold, 2011). This means that they breathe mostly through the nose except when crying. Bilateral choanal atresia causes severe respiratory distress and requires surgery. Blockage of one side puts the infant at risk for respiratory distress if the other side becomes occluded by mucus or edema.

The nurse can assess for choanal atresia by closing the infant's mouth and occluding one nostril at a time. The infant is observed for breathing, and breath sounds are auscultated while each nostril is occluded. Another method of assessment is to pass a catheter through each nostril to check for patency. Infants with choanal atresia may become cyanotic when quiet but pink when crying because air is then drawn in through the mouth.

Color

In addition to cyanosis, the nurse assesses for pallor and ruddiness.

Pallor. Pallor can indicate that the infant is slightly hypoxic or anemic. A laboratory examination of hemoglobin and hematocrit or a complete blood count may be ordered.

Ruddy Color. A ruddy or reddish skin color (plethora) may indicate polycythemia, an excessive number of red blood cells. A hematocrit value above 65% confirms polycythemia. Infants with elevated hematocrit levels are at increased risk for jaundice from the normal destruction of excessive red blood cells that occurs after birth.

Heart Sounds

The heart is auscultated for rate, rhythm, and the presence of murmurs or abnormal sounds. The nurse should count the apical pulse for a full minute for accuracy and listen for abnormalities. The rate should range between 120 and 160 beats per minute (bpm) with normal activity. It may elevate to 180 bpm when infants are crying or drop to as low as 100 bpm when they are in deep sleep.

If no problems are present at birth, the heart rate should be recorded at least once every 30 minutes until the infant has been stable for 2 hours after birth (AAP & ACOG, 2012). Monitoring is more frequent if abnormalities are present. Once stable the heart rate is checked once every 8 to 12 hours or according to hospital policy unless a reason for more frequent assessment develops.

Position. The apex of the heart is located at the **point of maximum impulse**, where the pulse is most easily felt and the sound is loudest. This is at the third or fourth intercostal space, lateral to the midclavicular line (a line drawn from the middle of the left clavicle). Conditions that affect the position of the heart include pneumothorax and dextrocardia (a right-to-left reversal from the normal heart position).

Rhythm and Murmurs. The rhythm of the heart should be regular, and the first and second sounds should be heard clearly. Abnormalities in rhythm and sounds such as murmurs should be noted. Murmurs are sounds of abnormal blood flow through the heart and may indicate openings in the septum of the heart or problems with blood flow through the valves. They occur in approximately 10% of newborns (Gardner & Hernandez, 2011). Most murmurs in the newborn are temporary and result from incomplete transition from fetal to neonatal circulation. A murmur is common until the ductus arteriosus is functionally closed. Although it may be a normal or functional murmur, any abnormal sounds of the heart are investigated because

they may be signs of cardiac defects. Pulse oximetry screening for cardiac defects is often performed before discharge (Chapter 21).

Brachial and Femoral Pulses

The brachial and femoral pulses should be present and equal bilaterally. The brachial pulse is located over the antecubital space, and the femoral pulse is located at the groin. Pulses should be equal bilaterally and the brachial and femoral pulse rates should be the same. Femoral pulses that are weaker than the brachial pulses may result from impaired blood flow in coarctation of the aorta, a congenital heart defect. In this condition, a narrowed area of the aorta impedes blood flow to the lower part of the body and causes weaker pulses in the lower extremities (see Chapter 30).

Blood Pressure

Measurement of blood pressure (BP) is not a necessary part of a routine assessment of the newborn. The BP is taken on all extremities, however, if the infant has unequal pulses, murmurs, or other signs of cardiac complications. Doppler ultrasonography or other electronic measurement techniques are used. For accurate measurement, the infant should be quiet when the BP is taken because crying elevates it. The width of the BP cuff should be 40% to 50% of the circumference of the arm or leg or 25% to 50% wider than the diameter of the limb (Vargo, 2009). A cuff that is too narrow gives a false high reading, whereas a cuff that is too wide gives a false low reading.

The average BP for full-term newborns is 65 to 95 mm Hg systolic and 30 to 60 mm Hg diastolic (Gardner & Hernandez, 2011). Blood pressure varies according to the infant's age, weight, and gestational age. Hypotension may occur in the sick infant.

The blood pressure of the lower extremities should be the same or slightly higher than that of the upper extremities. A systolic blood pressure in the upper extremities that is greater than 20 mm Hg higher than that in the lower extremities may indicate coarctation of the aorta (Vargo, 2009).

Capillary Refill

Capillary refill is assessed to help determine if perfusion is adequate. It is checked by depressing the skin over the chest, abdomen, or an extremity until the area blanches. The color should return within less than 3 to 4 seconds (Vargo, 2009).

Assessment of Thermoregulation

The neonate's temperature is taken soon after birth while the infant is being held by the mother or in a radiant warmer with a skin probe attached to the abdomen. The probe, which should not be attached over bony prominences or areas of brown fat, allows the warmer to measure and display the infant's skin temperature continuously. The temperature control is set to regulate the amount of heat produced according to the infant's skin temperature. The temperature should be assessed at least once every 30 minutes until the infant has been stable for 2 hours after birth (AAP & ACOG, 2012). It is often checked again at 4 hours and then once every 8 to 12 hours or according to facility policy as long as it remains stable (see Procedure 20-1).

The most common method of taking the neonate's temperature is axillary measurement (Figure 20-2). The normal range for axillary temperature is 36.5° to 37.5°C (97.7° to 99.5°F) (Brown & Landers, 2011) (Box 20-1). Taking axillary temperatures is safer than taking rectal temperatures because it avoids the possibility of irritation or injury to the rectum, which turns at a right angle approximately 3 cm (1.2 inches) from the anal sphincter (Gardner & Hernandez, 2011). The location should always be charted along with the temperature measurement.

FIG 20-2 The infant is held securely to prevent injury and obtain an accurate reading when taking the temperature.

BOX 20-1 NORMAL VITAL SIGNS IN THE NEWBORN

- Temperature: 36.5° to 37.5°C (97.7° to 99.5°F) axillary
- Apical pulse: 120 to 160 bpm (100 sleeping, 180 crying)
- Respirations: 30 to 60 breaths/min

If a rectal temperature is necessary, the nurse should use great care because inserting the thermometer too far could cause potentially fatal perforation of the intestinal wall. A thermometer should never be forced into the rectum because of the possible presence of an imperforate (closed) anus.

Temperatures are usually measured with an electronic digital thermometer. Mercury thermometers are no longer used because of the possibility of injury or contamination with mercury if the thermometer breaks. Inexpensive digital thermometers used while the infant is in the hospital are often given to the parents for home use. Disposable plastic strips that change color to indicate temperature readings are used less often than electronic models. Tympanic thermometers, used in some facilities for older infants and children, are not recommended for newborns at this time (Gardner & Hernandez, 2011). Some agencies use temporal artery thermometers (Haddad, Smith, Philips et al., 2012).

2. What is included in assessment of the newborn's cardiovascular status?
3. Why is taking a rectal temperature dangerous in an infant?

General Assessment

If major abnormalities are present at birth, the nurse must maintain a calm, quiet demeanor to avoid frightening the parents. The physician should be alerted quietly and will explain the condition and possible plan of treatment to the parents.

Head

The newborn's head and neck comprises one fourth of the body surface (Gardner & Hernandez, 2011). It is much larger in proportion

to the rest of the body than that of the adult. The head is palpated to assess the shape and identify abnormalities. The newborn who was delivered by cesarean not preceded by labor usually has a round head, whereas the infant born vaginally usually has some molding. The head of infants who were in a breech position may be flattened on the top. The degree of molding, size of the fontanel, and presence of caput succedaneum or later development of a cephalhematoma are noted.

The hair should be fine with a consistent pattern. Abnormal hair growth patterns may indicate genetic abnormalities. The nurse separates the hair, if necessary, to display bruises, rashes, or other marks on the scalp. A small, red mark is apparent if a fetal monitor electrode was inserted into the skin of the scalp. Later, a small scab forms. Occasionally this area becomes infected and a topical antibiotic is applied.

Molding. **Molding** refers to changes in the shape of the head that allow it to pass through the birth canal. It is caused by overriding of the cranial bones at the sutures and is common, especially after a vaginal delivery. The parietal bones often override the occipital and frontal bones, and a ridge can be felt at those areas. The condition generally resolves within a few days to 1 week after birth. Often, dramatic improvement is seen by the end of the first day of life. Parents may need reassurance that the infant's head is normal.

All sutures should be palpated. Separation may be the temporary result of molding or, if it persists or widens, may indicate increased intracranial pressure. If no space is found between suture lines, it may be the result of molding and overriding of the bones. However, a hard, ridged area not resulting from molding may indicate premature closure of the sutures. This condition, called **craniosynostosis**, may impair brain growth and the shape of the head and requires surgery.

Fontanels. The fontanels are the areas of the head where sutures between the bones meet. In the newborn the areas are not calcified but are covered by membrane to allow space for the brain to grow.

The nurse palpates the fontanels and notes the position in relation to the other bones of the skull (Figure 20-3). The infant's head is elevated during palpation for accurate assessment. The infant may be placed in a semisitting position or held in an upright position. The fontanel should be palpated when the infant is quiet because vigorous crying may cause it to protrude.

The anterior fontanel is a diamond-shaped area where the frontal and parietal bones meet. It measures 4 to 6 cm from bone to bone, although this varies because of molding and individual differences. The fontanel closes by 18 months of age (Furdon & Benjamin, 2010).

FIG 20-3 Palpation of the anterior fontanel. Note elevation of the head.

The anterior fontanel should be soft and flat (level with the surrounding bones) or only slightly sunken. After molding resolves, a depressed fontanel may be a sign of dehydration. Although the anterior fontanel may bulge slightly when the infant cries, bulging at rest may indicate increased intracranial pressure. A fontanel that is between flat and bulging is termed full. A larger-than-normal fontanel may be a sign of increased pressure within the skull. Abnormal signs are reported to the primary care provider.

The posterior fontanel is a triangular area where the occipital and parietal bones meet. It is much smaller than the anterior fontanel, measuring 0.5 to 1 cm and feels like a dimple at the juncture of the occipital and parietal bones. This fontanel closes by the time the infant is 2 months of age (Furdon & Benjamin, 2010).

Caput Succedaneum. A **caput succedaneum** is an area of localized edema that appears over the vertex of the newborn's head as a result of pressure against the mother's cervix during labor (Figure 20-4). The pressure interferes with blood flow from the area, causing localized edema at birth. The edematous area crosses suture lines, is soft, and varies in size. It resolves quickly and generally disappears within 12 to 48 hours after birth (Furdon & Benjamin, 2010). Caput also may occur when a vacuum extractor is used to assist birth. When a vacuum is used, the caput corresponds to the area where the extractor was placed on the skull. The amount of edema and presence of bruising are assessed.

Cephalhematoma. A **cephalhematoma**, bleeding between the periosteum and the skull, is the result of pressure during birth (Figure 20-5). It occurs on one or both sides of the head, usually over the parietal bones. The swelling may not be present at birth but may develop within the first 24 to 48 hours.

The area is carefully palpated to determine whether the swelling crosses suture lines. A cephalhematoma has clear edges that end at the suture lines. It does not cross the suture lines, unlike a caput succedaneum, because the bleeding is held between the bone and its covering, the periosteum. A cephalhematoma reabsorbs slowly and may take 2 to 3 months to completely resolve (Mangurten & Puppala, 2011). Because of the breakdown of the red blood cells within the hematoma, affected infants are at greater risk for jaundice. Bruising also increases the risk of jaundice.

Both caput succedaneum and cephalhematoma may be frightening to parents. They need reassurance that the conditions are not harmful to the infant. Even if parents do not ask, they need information about the causes and length of time required for the areas to resolve.

FIG 20-4 Caput succedaneum is an edematous area on the head from pressure against the cervix. It may cross suture lines.

FIG 20-5 A cephalhematoma is characterized by bleeding between the bone and its covering, the periosteum. It may occur on one or both sides and does not cross suture lines.

FIG 20-6 A, The nurse palpates the clavicles to identify fractures. A fracture of the left clavicle is present. **B**, The arm on the side of the fractured clavicle is immobilized by pinning the sleeve to the shirt.

Face. The face is examined for symmetry, positioning of the facial features, movement, and expression. A transient asymmetry from intrauterine pressure may occur, lasting a few weeks or months. Drooping of the mouth appears as a one-sided cry and may be caused by facial nerve trauma. Irregularities of the facial features should be reported.

Neck and Clavicles

The nurse assesses the infant's neck visually and notes the ease with which the head turns from side to side. The neck is very short. Webbing may indicate Turner's syndrome or Down syndrome (trisomy 21) (see [Chapter 5](#)). An unusually large fat pad between the occiput and the shoulders may indicate a chromosomal anomaly. No masses should be present. When lying in a prone position, the term newborn should be able to raise the head briefly and turn it to the other side.

Fractures of the clavicle are more likely to occur in large infants, especially when shoulder dystocia occurred. Sliding the fingers along

each clavicle while moving the infant's arm helps identify a fractured clavicle. If a fracture is present, a lump, swelling, or tenderness over the bone may be observed. Crepitus (grating of the bone) and movement of the bone may be felt during palpation. Decreased movement of the affected arm also may occur. A difference in the movement of the arms is especially noticeable when the Moro reflex is elicited.

Injury to the brachial plexus may cause paralysis of the arm on the side of the fracture. Treatment of a fractured clavicle includes immobilization of the affected arm for a short time. The fracture heals quickly ([Figure 20-6](#)).

Cord

The umbilical cord should contain three vessels. The two arteries are small and may stand up at the cut end. The single vein is larger than the arteries and resembles a slit because its walls are more easily compressed. If only one artery is present, the infant is carefully assessed for other anomalies. A two-vessel cord may be an isolated abnormality or

associated with chromosomal and renal defects. The amount of Wharton's jelly in the cord is noted. If the cord appears thin, the infant may have been poorly nourished in utero. A yellow-brown or green tinge to the cord indicates that meconium was released at some time before birth, perhaps as a result of fetal compromise. No redness or discharge from the cord should be present.

Extremities

The infant should actively move the extremities equally in a random manner. The extremities of a term infant should remain sharply flexed and resist extension during examination. Poor muscle tone results in a limp or "floppy" infant, which may occur from inadequate oxygen during birth but should resolve within a few minutes as oxygen intake increases. Continued poor muscle tone may result from prematurity or neurologic injury. Infants with previously good muscle tone may show decreased flexion if they become hypoglycemic or experience respiratory difficulty.

All extremities are examined for signs of fractures such as crepitus, redness, lumps or swelling. Lack of use of an extremity may indicate nerve injury that may occur with or without fractures.

Injury to the brachial nerve plexus may result in Erb's palsy (Erb-Duchenne paralysis), paralysis of the shoulder and arm muscles. Instead of the usual flexed position, the affected arm is extended at the infant's side with the forearm prone. Movement of this arm is diminished during the Moro reflex. The condition is treated by splinting, exercise, or both.

Hands and Feet. The fingers and toes are examined for extra digits (**polydactyly**) and webbing between digits (**syndactyly**). Extra digits are often small and may not have bones. Tying the extra digits with sutures causes them to atrophy and fall off. The presence of a bone in the extra digit requires surgical removal. Webbed fingers or toes may be corrected by surgery. Nails in a term infant should extend to the end of the fingers or slightly beyond.

The creases in the hands also are examined. Normally, two long transverse creases extend most of the way across the palm. A single crease parallel with the base of the fingers that crosses the palm without a break is called a *simian crease* or *line*. It may be seen with incurving of the little finger in Down syndrome (trisomy 21). The simian line alone is not diagnostic of trisomy 21, however, and may occur in 5% to 10% of normal infants (Kaur & Campbell, 2009).

The feet are assessed for talipes equinovarus, or clubfoot, a common malformation of the feet. If a foot looks abnormal, it should be gently manipulated. If it moves to a normal position, the abnormality is probably temporary, resulting from the position of the infant in the uterus. In true clubfoot, the foot turns inward and cannot be moved to a midline position. Casting and manipulation are the usual treatment, but sometimes surgery is necessary.

Hips. The hips are examined for signs of developmental dysplasia. In this condition, instability of the hip joint occurs and the head of the femur can be moved in and out of the acetabulum. Partial dislocation and inadequate development of the acetabulum may occur. Identifying a hip problem early is important to prevent permanent damage to the joint.

Barlow and Ortolani tests are methods of assessing for hip instability in the newborn period (Figure 20-7). Both legs should abduct equally in normal infants. Abducting the affected hip may be difficult. A hip click may be felt or heard but is usually normal and is different from the "clunk" of hip dysplasia when the femoral head moves in the hip socket (Sankar, Horn, Wells et al., 2011).

The infant's knees should be bent with the feet flat on the bed to compare the height of the knees. If the hip is dislocated, the knee on the affected side is lower. The legs are extended with the infant in a

FIG 20-7 Assessment of the hips. Place the fingers over the infant's greater trochanter and thumbs over the femur. Flex the knees and hips. **A**, Barlow test. Adduct the hips, and apply gentle pressure down and back with the thumbs. In hip dysplasia the examiner can feel the femoral head move out of the acetabulum. **B**, Ortolani test. Abduct the thighs, and apply gentle pressure forward over the greater trochanter. A "clunking" sensation indicates a dislocated femoral head moving into the acetabulum. A hip click is from ligament movement and is not a problem.

prone position to determine whether they are equal in length and if the thigh and gluteal creases are symmetric (Figure 20-8). If the hip is dislocated, the leg on the affected side is shorter and the creases are asymmetric. Because the hip may be unstable but not yet dislocated, these signs are not usually present at birth.

Treatment of developmental dysplasia of the hip involves immobilizing the leg in a flexed, abducted position, usually with a harness. Early identification and treatment are essential to provide the best results in correcting the problem. Treatment may involve casting or surgery if the condition is not discovered early.

Vertebral Column

The nurse palpates the entire length of the newborn's vertebral column to discover any defects in the vertebrae. An indentation is a sign of spina bifida occulta (failure of a vertebra to close). The defect is not obvious on visual inspection because it is covered with skin, but sometimes a tuft of hair grows over the area. Other more obvious neural tube defects include a meningocele (protrusion of spinal fluid and meninges) or a myelomeningocele (protrusion of spinal fluid, meninges, and the spinal cord) through the defect in the vertebrae. They appear as a sack on the back and may be covered by skin or only the

FIG 20-8 Note the symmetry of gluteal and thigh creases.

meninges. The tissue should be covered with moist, sterile, saline dressings immediately after birth. A pilonidal dimple may be present at the base of the spine. It should be examined for a sinus and the depth noted.

Measurements

Measurements provide information about the infant's growth in utero. The weight, length, and head and chest circumferences are part of the initial assessment (see [Procedure 20-2](#)). The measurements are compared with the norms for the infant's gestational age. When a difference is noted between the expected and actual values, expanded assessments are necessary.

Weight

The newborn's weight ranges between 2500 and 4000 g (5 lb, 8 oz and 8 lb, 13 oz) ([Cheffer & Rannalli, 2011](#)). If the infant's weight is outside the normal range, possible causes are assessed. Factors affecting weight include gestational age, placental functioning, genetic factors such as race and parental size, and maternal diabetes, hypertension, and substance abuse.

Infants are weighed each day they are in the birth facility and at follow-up visits. They can be expected to lose up to 10% of their birth weight during the first week of life ([Feigelman, 2011](#)). The loss results

PROCEDURE 20-2 WEIGHING AND MEASURING THE NEWBORN

PURPOSE: To obtain accurate measurements of the newborn

Weight

1. Cover the scale with a blanket. Place a paper cover over the blanket if desired. *Prevents conductive heat loss from contact between the infant and a cold surface, helps prevent cross-contamination, and makes cleaning easier.*
2. Balance or adjust the scale to zero after the covering is placed. Electronic scale: Push the "on" button, and check to see that the digital readout is at zero. The electronic scale is usually self-adjusting. Balance scale: Adjust until the balance arm is horizontal. *Results in accurate weighing of the infant without including weight of the scale covering.*
3. Remove clothing and blankets from the infant, and place the infant in a supine position on the scale. Keep one hand just above the infant and watch him or her carefully throughout the procedure. *Infants often are upset when first placed on the scale, and the startle or Moro reflex may occur. They may be in danger of sliding off the scale.*

4. Wait until the infant is somewhat quiet. The electronic scale displays weight in pounds and ounces or in grams. Some electronic scales display an indicator when an accurate weight has been obtained. For a balance scale, move weights slowly until the arm is level. *Waiting until the infant is quiet increases accuracy.*
5. Record the numbers immediately. If the scale is covered with paper, the weight can be written on the paper. Enter the infant's weight in the nurses' notes when the infant is safely settled. *Prevents forgetting the weight.*
6. Compare weight with the normal range for term infants: 2500 to 4000 g (5 lb, 8 oz to 8 lb, 13 oz). *Shows whether the infant is within expected range.*

Length

Ruler Printed on Scale or Crib

1. Place the infant in supine position with his or her head at the upper edge of the ruler. *Places the infant in the proper position.*
2. While holding the infant with one hand so that the head does not move, use the other hand to fully extend the infant's leg along the ruler. Note the length at the bottom of the heel. *Holding the infant firmly ensures safety and allows an accurate measurement.*

PROCEDURE 20-2 WEIGHING AND MEASURING THE NEWBORN—cont'd

Tape Measure

1. Check that a paper tape has no partial tears in it. *A torn measuring tape would give an inaccurate measurement.*
2. Place tape beside the infant, with the upper end at the top of the head. Tuck it beneath the shoulder, and extend it down to the feet. *Helps prevent movement of the tape and ensures accurate measurements.*
3. Hold the tape straight along the side of the infant's body while extending one of the infant's legs to its full length. Be sure that the tape has not moved from the top of the head. *Careful attention to tape placement ensures accurate measurement.*
4. Another method is to mark the paper on which the infant is lying at the top of the head and the heel. Then measure the distance between the two marks. *Makes measuring more accurate when the infant is very active.*

5. Compare with the normal range of 48 to 53 cm (19 to 21 inches). *Helps determine abnormalities.*

Head and Chest Circumference

1. Measure around the fullest part of the head, with the tape placed around the occiput and just above the eyebrows. *Allows measurement of the largest diameter of the head.*

2. Move tape down to measure the chest at the level of the nipples. Keep the tape even and taut. *Ensures accurate measurement.*

3. Remove the tape by lifting or rolling the infant instead of pulling the tape. *Pulling the tape could cut the infant's skin.*
4. Compare measurements with normal range. Head: 32 to 38 cm (13 to 15 inches). Chest: 30 to 36 cm (12 to 14 inches). *Determines whether the infant's measurements are normal.*

from excretion of meconium, normal loss of extracellular fluid, and inadequate intake of calories during the first few days. Infants normally regain or exceed their birth weight by 14 days of life. Thereafter they gain approximately 30 g per day during the early months (Keane, 2011).

Length

The infant's length is measured from the top of the head to the heel of the outstretched leg. The average length of a full-term newborn is 48 to 53 cm (19 to 21 inches) (Cheffer & Rannalli, 2011). Some agencies also record the crown-to-rump measurement, which is approximately equal to the head circumference.

Head and Chest Circumference

The diameter of the head is measured around the occiput just above the eyebrows. The normal range of head circumference for the term

newborn is 32 to 38 cm (13 to 15 inches) (Furdon & Benjamin, 2010). The measurement may be affected by molding of the skull during the birth process. If a large amount of molding occurred, the head is remeasured when it regains its normal shape. An abnormally small head may indicate poor brain growth and microcephaly. A very large head may be a sign of hydrocephalus.

The chest is measured at the level of the nipples. It usually is 2 to 3 cm smaller than the head. The normal circumference of the chest is 30 to 36 cm (12 to 14 inches) (Creehan, 2008). If molding of the head is present, the head and chest measurements may be equal at birth.

CHECK YOUR READING

4. What are the differences among molding, caput succedaneum, and cephalhematoma?
5. Why are measurements of the neonate important?

ASSESSMENT OF BODY SYSTEMS

Neurologic System

Reflexes

Assessment of the reflexes is important to determine the health of the newborn's central nervous system. The nurse notes the presence and strength of the reflexes and whether both sides of the body respond symmetrically (Figure 20-9). A diminished overall response occurs in preterm and ill infants. Absence of reflexes may indicate a serious neurologic problem. Asymmetric responses may indicate that trauma during birth caused nerve injury, paralysis, or fracture. Some newborn reflexes gradually weaken and disappear over a period of months (Table 20-1).

CRITICAL THINKING EXERCISE 20-1

1. What might be the effect on normal development if reflexes are retained beyond the age when they should disappear?

Sensory Assessment

Ears. The ears are assessed for placement, overall appearance, and maturity. An imaginary horizontal line drawn from the outer canthus of the eye should be even with the area where the upper ear (helix) joins the head (Figure 20-10). Low-set ears may indicate chromosomal abnormalities. The ears should be almost vertical in placement on the head. An angle greater than 10° is abnormal (Parikh & Wiesner, 2011).

The nurse examines the ears for skin tags and preauricular sinuses and dimples. If they occur with any other abnormalities, a renal ultrasound is often performed (Kaur & Campbell, 2009). Abnormalities of the ear may indicate chromosomal abnormalities, hearing problems, or kidney defects. The stiffness of the cartilage and degree of incurving of the pinna are checked as part of the gestational age assessment.

Hearing begins to develop by 23 to 24 weeks gestation (Blackburn, 2013). Infants can hear by the last trimester of pregnancy, and their hearing is very good after birth. Hearing is assessed by noting the infant's reaction to sudden loud noises, which should cause a startle response. Infants should respond to the sound of voices and prefer a high-pitched tone of voice and rhythmic sounds. They will turn toward the sound of the mother's voice or another interesting sound. A hearing screening is performed before discharge from most birth facilities (see Chapter 21).

Eyes. The eyes are examined for abnormalities and signs of inflammation. They should be symmetric and of the same size. The iris is dark gray, blue, or brown but may change color by 6 months of age (Johnson, 2009). Slanting epicanthal folds in a non-Asian infant may be a sign of trisomy 21 or other abnormal conditions.

Edema of the eyelids and subconjunctival hemorrhages (reddened areas of the sclera) result from pressure on the head during birth, which causes capillary rupture in the sclera. The edema diminishes in a few days, and the hemorrhages resolve in 7 to 10 days (Johnson, 2009). The sclera should be white or bluish white. A yellow color indicates jaundice. A blue color occurs in osteogenesis imperfecta, a congenital bone condition.

TABLE 20-1 SUMMARY OF NEONATAL REFLEXES

REFLEX	METHOD OF TESTING	EXPECTED RESPONSE	ABNORMAL RESPONSE/ POSSIBLE CAUSE	TIME REFLEX DISAPPEARS
Babinski	Stroke lateral sole of foot from heel to across base of toes.	Toes flare with dorsiflexion of the big toe.	No response. Bilateral: CNS deficit. Unilateral: local nerve injury.	8-9 mo
Gallant (trunk incurvation)	With infant prone, lightly stroke along the side of the vertebral column.	Entire trunk flexes toward side stimulated.	No response: CNS deficit.	4 mo
Grasp reflex (palmar and plantar)	Press finger against base of infant's fingers or toes.	Fingers curl tightly; toes curl forward.	Weak or absent: neurologic deficit or muscle injury.	Palmar grasp: 2-3 mo Plantar grasp: 8-9 mo
Moro	Let infant's head drop back approximately 30 degrees.	Sharp extension and abduction of arms followed by flexion and adduction to "embrace" position.	Absent: CNS dysfunction. Asymmetry: brachial plexus injury, paralysis, or fractured bone of extremity. Exaggerated: maternal drug use.	5-6 mo
Rooting	Touch or stroke from side of mouth toward cheek.	Infant turns head to side touched. Difficult to elicit if infant is sleeping or just fed.	Weak or absent: prematurity, neurologic deficit, depression from maternal drug use.	3-4 mo
Stepping	Hold infant so feet touch solid surface.	Infant lifts alternate feet as if walking.	Asymmetry: fracture of extremity, neurologic deficit.	3-4 mo
Sucking	Place nipple or gloved finger in mouth, rub against palate.	Infant begins to suck. May be weak if recently fed.	Weak or absent: prematurity, neurologic deficit, maternal drug use.	1 yr
Swallowing	Place fluid on the back of the tongue.	Infant swallows fluid. Should be coordinated with sucking.	Coughing, gagging, choking, cyanosis: prematurity, tracheoesophageal fistula, esophageal atresia, neurologic deficit.	Present throughout life
Tonic neck reflex	Gently turn head to one side while infant is supine.	Infant extends extremities on side to which head is turned, with flexion on opposite side.	Prolonged period in position: neurologic deficit.	May be weak at birth; disappears 4 mo

CNS, Central nervous system.

A

Moro reflex

The Moro reflex is the most dramatic reflex. It occurs when the infant's head and trunk are allowed to drop back 30 degrees when the infant is in a slightly raised position. The infant's arms and legs extend and abduct, with the fingers fanning open and thumbs and forefingers forming a C position. The arms then return to their normally flexed state with an embracing motion. The legs may also extend and then flex.

B

Palmar grasp reflex

The palmar grasp reflex occurs when the infant's palm is touched near the base of the fingers. The hand closes into a tight fist. The grasp reflex may be weak or absent if the infant has injury to the nerves of the arms.

C

Plantar grasp reflex

The plantar grasp reflex is similar to the palmar grasp reflex. When the area below the toes is touched, the infant's toes curl over the nurse's finger.

D

Babinski reflex

The Babinski reflex is elicited by stroking the lateral sole of the infant's foot from the heel forward and across the ball of the foot. This causes the toes to flare outward and the big toe to dorsiflex.

FIG 20-9 Reflexes.

Continued

Rooting reflex

The rooting reflex is important in feeding and is most often demonstrated when the infant is hungry. When the infant's cheek is touched near the mouth, the head turns toward the side that has been stroked. This response helps the infant find the nipple for feeding. The reflex occurs when either side of the mouth is touched. Touching the cheeks on both sides at the same time confuses the infant.

Sucking reflex

The sucking reflex is essential to normal life. When the mouth or palate is touched by the nipple or a finger, the infant begins to suck. The sucking reflex is assessed for its presence and strength. Feeding difficulties may be related to problems in the infant's ability to suck and to coordinate sucking with swallowing and breathing.

Tonic neck reflex

The tonic neck reflex refers to the posture assumed by newborns when in a supine position. The infant extends the arm and leg on the side to which the head is turned and flexes the extremities on the other side. This response is sometimes referred to as the "fencing reflex" because the infant's position is similar to that of a person engaged in a fencing match.

Stepping reflex

The stepping reflex occurs when infants are held upright with their feet touching a solid surface. They lift one foot and then the other, giving the appearance that they are trying to walk.

FIG 12-9, cont'd

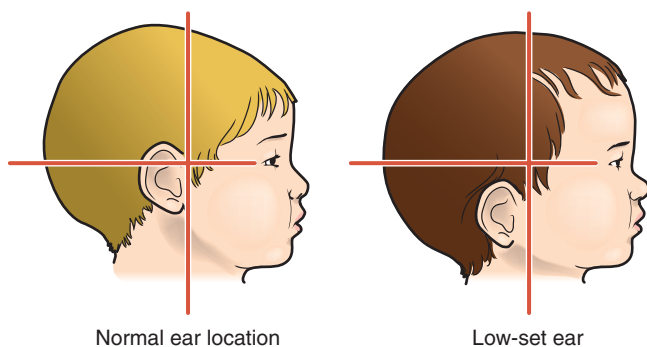

FIG 20-10 An imaginary line is drawn from the outer canthus of the eye to the ear. The line should intersect with the area where the upper ear joins the head.

Conjunctivitis may result from infection or a chemical reaction to medications. *Staphylococcus*, *Chlamydia*, and *Neisseria gonorrhoeae* are common organisms that cause infection. Maternal gonorrhea can cause infection of the infant during birth. The resulting ophthalmia neonatorum may cause blindness. To prevent this condition, all newborns are treated prophylactically with antibiotics to the eyes. Any discharge from the eyes is reported for possible culture and treatment.

Transient **strabismus** (crossed eyes) is common for the first 3 to 4 months after birth because infants have poor control of their eye muscles (Kaufman, Miller, & Gupta, 2011). The doll's-eye sign is a normal finding in the newborn: When the head is turned quickly to one side, the eyes move toward the other side. The setting-sun sign (the iris appears low in the eye and part of the sclera can be seen above the iris) may be an indication of hydrocephalus.

The pupils should be equal in size and react equally to light. Cataracts (opacities of the lens) appear as white areas over the pupils. They may develop in infants of mothers who had rubella or other infections during the pregnancy. When a light is directed into the eyes, the normal red reflex may not be seen if large cataracts are present. Tears are scant or absent for the first 2 months of life (Kaur & Campbell, 2009). Excessive tearing may indicate a plugged lacrimal duct, which is treated with massage or surgery.

Visual acuity is approximately 20/400 (Olitsky, Hug, Plummer et al., 2011). The eyes cannot accommodate well, but newborns should show a visual response to the environment. They should make eye contact when held in a cradle position during a period of alertness. Although they focus best on objects that are 20 to 30 cm (8 to 12 inches) away, they can see objects to a distance of 76 cm (2.5 feet) (Blackburn, 2013). They should respond well to human faces and geometric patterns of black and white or medium bright colors but show little interest in pastel colors.

Newborns should blink or close their eyes in response to bright lights. Any infant who does not respond to visual stimuli should be reported to the physician or nurse practitioner for further investigation.

Sense of Smell and Taste. The sense of smell is demonstrated when infants recognize breast pads soaked with their mother's milk and differentiate them from pads soaked in water. Their ability to distinguish taste is shown by their preference for sweet liquids and aversion to sour or bitter tastes (Blackburn, 2013).

Other Neurologic Signs

The newborn is assessed for tremors or jitteriness. If tremors are present, the blood glucose should be checked because hypoglycemia is

the most common cause. If blood glucose is within normal range, the cause may be low calcium or prenatal exposure to drugs. Tremors increase each time the infant is touched or moved but stop briefly if the extremity is flexed and held firmly.

Seizures indicate central nervous system or metabolic abnormality. To differentiate between tremors and seizures, the infant's extremities are held in a flexed position. This causes tremors to stop, but a seizure continues. Seizure activity may also include abnormal movements of the eyes and mouth and other subtle signs. Any infant thought to be having seizures is referred for further assessment and treatment.

⚡ SAFETY ALERT

Jitteriness or Tremors

- Stop when the extremities are held firmly in a flexed position.
- Are commonly caused by low glucose or calcium levels.

Seizures

- Continue even if extremities are held.
- May include abnormal mouth or eye movements.
- Indicate central nervous system or metabolic abnormality.

The pitch of the cry is important. Cries that are shrill, high-pitched, hoarse, and catlike (mewing) are abnormal. These cries may indicate a neurologic disorder or other problem.

Normal infants respond to holding and are quiet and appear content when their needs are met. Rocking motions are often effective in quieting an irritable infant. Most infants nestle or mold their bodies to that of the people holding them, making them easy to hold and cuddle. Neonates who stiffen the body, pull away from contact, or arch the back when held may be showing signs of central nervous system injury.

Infants should react to painful stimuli with crying and an increase in vital signs. Excessive irritability also may be a sign of injury to the central nervous system. All such abnormal signs are reported for further neurologic assessment.

Hepatic System

The major early assessments of the hepatic system are related to blood glucose and bilirubin conjugation.

Blood Glucose

The nurse must be alert for newborns at increased risk for hypoglycemia, which can cause brain damage. Factors that might have caused the infant to deplete available glucose are noted (Box 20-2). A quick estimate to determine whether the newborn appears to be near term and of appropriate size for gestational age is performed at birth.

BOX 20-2 RISK FACTORS FOR NEONATAL HYPOGLYCEMIA

- Prematurity
- Postmaturity
- Late preterm infant
- Intrauterine growth restriction
- Large or small for gestational age
- Asphyxia
- Problems at birth
- Cold stress
- Maternal diabetes
- Maternal intake of terbutaline

Observing for signs of hypoglycemia is necessary throughout routine assessment and care. Early signs include jitteriness and other central nervous system signs and signs of respiratory difficulty, a decrease in temperature, and poor feeding. Some infants with hypoglycemia show no signs at all.

CRITICAL TO REMEMBER

Signs of Neonatal Hypoglycemia

- Jitteriness, tremors
- Poor muscle tone
- Diaphoresis (sweating)
- Poor suck
- Tachypnea
- Tachycardia
- Dyspnea
- Grunting
- Cyanosis
- Apnea
- Low temperature
- High-pitched cry
- Irritability
- Lethargy
- Seizures, coma
- No signs (some infants may be asymptomatic)

Screening for blood glucose is not necessary for normal term infants (Bloomfield, Dinolfo, & Kokotos, 2009; AAP, 2011; AAP & ACOG, 2012). Those in risk categories or showing early signs should be screened. Normal blood glucose for the term infant during the first day of life is 40 to 60 mg/dL and 50 to 90 mg/dL thereafter (Lo, 2011). Because capillary blood is used in screening tests, these tests are less accurate than laboratory tests using venous blood. Therefore a laboratory analysis (per agency policy) should be used to verify readings of 40 to 45 mg/dL or below.

Avoiding injuries to the infant's foot is important when taking blood from the heel (see Procedure 20-3). If the lancet goes into the calcaneus bone, osteomyelitis may result. Commercial devices for heel puncture are designed to puncture the heel to the proper depth. They are available for full-term and preterm infants. The site chosen must avoid injury to major nerves and arteries in the area. Other complications include cellulitis, abscess, scarring, bruising, and pain.

Infants are often fed if the reading is 40 to 45 mg/dL or less to prevent a further decrease in glucose, especially if the infant shows signs of hypoglycemia. The blood glucose is rechecked 30 to 60 minutes after the feeding and again before feedings until the results are acceptable or according to hospital policy. Infants who are in risk categories are usually monitored for at least 24 hours after birth (Adamkin, 2011).

Bilirubin

The nurse assesses for jaundice at least every 8 to 12 hours and is particularly watchful when infants are at increased risk for hyperbilirubinemia (see Chapter 19). Jaundice is identified by pressing the infant's skin over a firm surface, such as the end of the nose or the sternum. The skin blanches as the blood is pressed out of the tissues, making it easier to see the yellow color that remains. Jaundice is more obvious when the nurse assesses in natural light. Jaundice begins at the head and moves down the body, and the areas of the body involved should be documented. Jaundice becomes visible when the bilirubin is greater than 5 mg/dL (Pan & Rivas, 2009).

Jaundice appearing before the second day of life may indicate the bilirubin level is rising more quickly and to higher levels than normal and may not be physiologic. The physician or nurse practitioner may order laboratory determinations of the bilirubin level based on the nurse's assessment. In many facilities, protocols allow the nurse to obtain transcutaneous bilirubin (TcB) measurements using a bilirubinometer or laboratory measurement of total serum bilirubin (TSB) without the order of a nurse practitioner or physician. A bilirubinometer is a noninvasive device to measure bilirubin in the infant's skin, thus avoiding repeated skin punctures to obtain blood samples. Obtain TSB or TcB measurements on all infants jaundiced within the first 24 hours.

If serial bilirubin assays are ordered, the nurse notes changes from one reading to the next and correlates the results with the infant's age. Abnormal results of TcB should be confirmed by measurement of TSB. Charts are available that show the degree of risk for infants at different ages (in hours) by the level of TSB.

The National Association of Neonatal Nurses (2010) recommends obtaining TSB or TcB measurements on every infant before discharge. This helps determine if discharge should be delayed or early follow-up arranged. All abnormal results should be documented and reported to the nurse practitioner or physician. A plan of care for infants at risk for hyperbilirubinemia is in Chapter 21, and a discussion of phototherapy is in Chapter 30.

CHECK YOUR READING

6. What are some signs of hypoglycemia?
7. Why is it important to use the correct site for heel punctures when obtaining blood samples?

Gastrointestinal System

The initial assessment of the gastrointestinal tract occurs during the first hours after birth, when the nurse visualizes the parts that can be seen and the infant takes the initial feeding.

Mouth

The mouth is inspected visually and by palpation. Some infants are born with precocious teeth, usually lower incisors (Figure 20-11). If the teeth are loose, the physician usually removes them to prevent

FIG 20-11 A precocious tooth.

PROCEDURE 20-3 OBTAINING BLOOD SAMPLES FROM THE NEWBORN BY HEEL PUNCTURE

PURPOSE: To obtain a sample of an infant's blood by heel puncture for analysis of blood glucose level, newborn screening, or other tests. (Instructions are given here for measuring the infant's blood glucose level using a glucometer but the same method applies to other testing.)

1. Wash hands. *Helps prevent spread of infection.*
2. Gather supplies needed. Supplies vary with different glucose meters and for different tests. Common supplies include gloves, alcohol wipes, 2 × 2 inch gauze, glucometer, commercial lancing device, adhesive bandage, cotton balls, and blood-collecting devices (glucose screening reagent strips, blotting paper for metabolic screening tests, capillary tubes). *Having all supplies ready allows efficient performance of the procedure.*
3. If the infant has not received a bath after birth, bathe the infant or thoroughly wash the puncture site before puncturing the skin. *Avoids contamination of the puncture site with maternal blood on the infant's skin. This is especially important should the mother have a known or unknown infection such as hepatitis B or human immunodeficiency virus.*
4. Calibrate or program the glucose meter and use quality control measures according to the manufacturer's guidelines. *Ensures proper functioning of the machine.*
5. Warm the heel with a commercial heel warmer or a warm wet cloth according to agency policy. Take care not to burn the infant. *Warming helps dilate the vessels.*

6. Provide comforting measures (according to hospital policy) such as swaddling, providing a pacifier, allowing the mother to hold the infant or breast-feed, or giving the infant oral sucrose (unless testing blood glucose level). Rate the infant's pain level before, during, and after the procedure using an infant pain scale. *Comfort measures help decrease the infant's pain. Rating the pain before the procedure helps determine the effectiveness of pain-relief measures during and after the procedure.*
7. Apply gloves. *Prevents contamination of the hands with blood.*
8. Hold the heel in one hand and locate the site. Palpate the bone of the heel and place the thumb or finger over the walking surface of the foot. *Stabilizes the heel to prevent movement and inadvertent injury from the lancet. Locating the bone helps avoid puncturing the calcaneus bone, which could result in osteomyelitis. Covering the walking surface avoids damage to nerves and arteries of this area.*
9. Choose a puncture site on the lateral heel that has not been used previously. *Avoiding a site that was punctured previously decreases the chance of infection and scarring.*
10. Clean the lateral heel with alcohol and wipe dry with sterile gauze or allow to air dry. *Alcohol reduces contaminants. Drying prevents irritation to the tissues and dilution of the specimen with alcohol.*
11. Puncture the side of the heel with a lancet that punctures to the appropriate depth. Place the device in a sharps container. *Insertion to the proper depth avoids injury to the infant and ensures blood flow so that further punctures are unnecessary. Proper disposal prevents injury to the infant and injury or unnecessary exposure of others to the infant's blood.*
12. Follow agency policy or manufacturer's directions regarding: using or discarding the first drop of blood, collecting the sample, determining the amount of blood to collect, handling the specimen properly, and reading the results. *Correct procedure promotes accuracy of test results.*
13. Avoid excessive squeezing of the foot. *Excessive squeezing causes bruising and dilution of the sample with fluid from the tissues.*
14. Obtain blood sample. Apply adhesive bandage. Check site frequently and remove the bandage when the bleeding stops. *A bandage helps stop bleeding. Checking the site ensures no further bleeding has occurred.*
15. Document the procedure and the results. Send specimens to the laboratory as appropriate. Report abnormal readings and follow up according to agency policy. Confirm abnormal results by laboratory measurement according to agency policy. *Helps ensure proper handling of specimens and proper care of the infant if results are abnormal.*

aspiration. Epstein's pearls may be present on the hard palate or gums. These small, white, hard, inclusion cysts are accumulations of epithelial cells and disappear without treatment within a few weeks. They are a form of milia.

The nurse examines the tongue for size and movement. A large, protruding tongue is present in hypothyroidism and some chromosomal disorders such as trisomy 21. Paralysis of the facial nerve affects the movement of the tongue and causes unilateral drooping of the mouth noticeable during crying or sucking. The tongue may appear to be tongue-tied because of the short frenulum, but this is normal and usually has no effect on the infant's ability to feed. In a true tongue-tie, there is limited tongue movement. Clipping of the frenulum seldom is practiced because of the potential for infection.

Although candidiasis (thrush) is not apparent in the mouth immediately after birth, it may appear 1 or 2 days later. The lesions resemble milk curds on the tongue and cheeks that bleed if attempts are made

to wipe them away. Newborns may become infected with *Candida albicans* during passage through the birth canal if the mother has a candidal vaginal infection. The infant is treated with antifungal medication such as nystatin suspension.

A cleft lip or palate results if the lip or palate fails to close. Cleft palate may involve the hard or soft palate or both and may appear alone or with a cleft lip. The palate is inspected when the infant cries. A gloved finger is inserted into the mouth to palpate the hard and soft palate. A very small cleft of the soft palate may be missed if only a visual examination is done.

Suck

The normal full-term infant should have a strong suck reflex, which is elicited when the lips or palate are stimulated. The reflex is weaker in the neonate who is preterm, is ill, or has just been fed. The newborn's cheeks have well-developed muscles and sucking pads that enhance the

ability to suck. These fatty sucking pads last until late in infancy, when sucking is no longer essential. Blisters may be present on the newborn's hands or arms from strong sucking before birth.

Initial Feeding

The initial feeding is an opportunity to further assess the newborn. If the mother is breastfeeding, she should begin in the first hour after the birth. The nurse can observe the infant's response unobtrusively while assisting the mother to position the infant. To decrease regurgitation from overdistention of the stomach, an initial formula feeding should be no more than 1 oz.

The nurse evaluates the infant's ability to suck, swallow, and breathe in a coordinated manner. Although the fetus sucks and swallows in utero, these acts may not have been performed together. The addition of breathing to sucking and swallowing is a new experience. Some newborns choke or gag during the first feeding. Others may become dusky or cyanotic because they become apneic while feeding. In either case the nurse should stop the feeding immediately, suction if necessary, and stimulate the infant to cry by rubbing the back. Most full-term infants learn to coordinate sucking, swallowing, and breathing very quickly.

Choking, coughing, cyanosis, or excessive oral secretions may indicate closure of the esophagus (esophageal atresia) or a connection between the trachea and esophagus (tracheoesophageal fistula). Neonates who continue to have difficulty with cyanosis during feedings may have a cardiac anomaly. Further assessment and referral are necessary.

Abdomen

The abdomen should be soft, rounded, and should protrude slightly, but should not be distended. The stomach may be distended by mucus, blood, and amniotic fluid swallowed during birth. An abdomen so distended that the skin is stretched and shiny may indicate obstruction. If the abdomen is distended, the nurse should measure the abdominal circumference periodically to note changes. The measurements should be recorded and reported to the health care provider. Loops of bowel should not be visible through the abdominal wall. Visible loops could indicate that air and meconium are not passing through the intestines normally.

A sunken or scaphoid appearance of the abdomen occurs in diaphragmatic hernia, in which intestines are located in the chest cavity instead of the abdomen. This condition interferes with development of the lungs, resulting in respiratory difficulty at birth. The nurse listens over the abdomen for bowel sounds, which usually appear about 15 minutes after birth (Goodwin, 2009). Bowel sounds heard in the chest may indicate diaphragmatic hernia.

An umbilical hernia occurs when the intestinal muscles fail to close around the umbilicus, allowing the intestines to protrude through the weak area. The condition is more common in low-birth-weight, male, and African-American infants. By the time the infant is walking well, the muscles are usually strong enough that the hernia no longer is present. Some umbilical hernias require surgical repair.

Palpating the abdomen is easiest when the infant is relaxed and quiet. The abdomen should feel soft because the muscles are not yet well developed. Masses may indicate tumors of the kidneys. Palpation of the liver and kidneys is usually not part of routine nursing assessment of the abdomen but is performed by the primary care provider. The liver is normally 1 to 2 cm below the right costal margin. If the organ seems large, it should be reported to the physician or nurse practitioner because it may be a sign of congestive heart failure or congenital infection.

Stools

Stools should be assessed for type, color, and consistency. By the third to fourth day, stools reflect the type of feeding the infant receives. A "water ring" should never be present around the solid part of any stool. A water ring is a wet, stained area on the diaper where watery stool has been absorbed. There may be an area of more solid stool in addition, or all stool may have soaked into the diaper. A water ring indicates diarrhea and may be caused by formula intolerance or infection.

The first stool should be passed within 12 to 48 hours after birth. The nurse should be aware of whether any stools have been passed since birth and, if so, when the infant's last stool occurred. If there is a question about whether the infant has had a stool, the nurse must investigate further. Feeding may cause the infant to pass a stool. Although rectal temperatures are not recommended, the physician may gently insert a thermometer into the rectum to determine patency and stimulate stool passage.

CRITICAL THINKING EXERCISE 20-2

You are caring for an infant who was born 20 hours ago, and you hear on report that the infant has not passed meconium yet.

Question

1. What should you do?

CHECK YOUR READING

8. Why is assessment of newborn reflexes important?
9. Why is it important for the nurse to observe the first feeding carefully?

Genitourinary System

Kidney Palpation

Palpation of the kidneys is not usually performed as part of the routine nursing assessment. The health care provider palpates the kidneys just above the level of the umbilicus on each side of the abdomen during the first hours after birth. Abdominal masses may indicate enlargement or tumors of the kidneys.

Kidney anomalies may accompany other defects because a problem early in fetal development may affect several organs vulnerable at that time. For example, infants with only one umbilical artery or defects involving the ears may have renal anomalies. The nurse should observe carefully for urinary output in these infants to determine if the kidneys are functioning adequately.

Urine

Most newborns void within 12 to 24 hours of birth and a few within 48 hours of birth. Because absence of urine output during this time may indicate anomalies, the first void should be carefully noted on the chart. The newborn's bladder empties as little as once or twice during the first 2 days, although more frequent voiding is common. Because of the small amount, the first void may be missed. Sometimes it occurs in the delivery room but goes unnoticed because attention is focused on the infant's overall condition.

If there is a concern about whether the newborn has urinated, the delivery notes should be carefully read to see if the infant voided at birth. The nurse should ask the mother if she has changed a wet diaper. Increasing the infant's fluid intake often can initiate urination. If no void occurs in the expected time, the infant's fluid intake should be increased and the physician or nurse practitioner alerted.

By the fourth day of life, at least six wet diapers can be expected daily. Each void is recorded in the infant's chart, including the number of diapers changed by the mother. The total number is correlated with that appropriate for the age of the infant. Mothers should be taught that at least six wet diapers by the fourth day indicate the infant is taking adequate fluid.

If an infant is having feeding difficulties, noting the number of wet diapers is especially important. Disposable diapers are very absorbent and the pale color of the newborn's urine may cause very little color change on the diaper. Wet diapers generally feel heavier than dry ones. If necessary, the nurse can put on gloves and take the diaper apart to examine it. The absorbent inner lining is damp if urine is present. Cotton balls or tissue placed in the diaper also may be used to increase visibility of small amounts of urine.

The newborn's urine may contain uric acid crystals that cause a reddish or pink stain on the diaper. This is known as *brick dust staining* and may be frightening to parents, who may think the infant is bleeding. It does not continue beyond the first few days as the kidneys mature.

Genitalia

The nurse examines the newborn's genitalia for size, maturation, and presence of any abnormalities.

Female. In the full-term female infant, the labia majora should be large and completely cover the clitoris and labia minora. The labia may be darker than the surrounding skin, a normal response to exposure to the mother's hormones before birth. Edema of the labia and white mucous vaginal discharge are normal. A small amount of vaginal bleeding, known as **pseudomenstruation**, may occur from the sudden withdrawal of the mother's hormones at birth. Hymenal (vaginal) tags are small pieces of tissue at the vaginal orifice. These are normal and disappear in a few weeks. The urinary meatus and vagina should be present.

Male. The scrotum should be pendulous at term and may be dark brown from maternal hormones. Pressure during a breech delivery may cause it to be edematous. Rugae (creases in the scrotum) are deep and cover the entire scrotum in the full-term infant.

Enlargement of one or both sides of the scrotum may result from a hydrocele. This collection of fluid around the testes may make palpating the testes difficult. Placing a flashlight against the sac may outline the testes. Parents should be told that hydroceles are not painful and often reabsorb within 1 year. Some require later surgery.

Palpation of the scrotum determines whether the testes have descended (Figure 20-12). Testes feel like small, round, movable objects that "slip" between the fingers. If the testes are not present in the scrotal sac, they may be felt in the inguinal canal. An empty scrotal sac appears smaller than one with testes.

Undescended testes (**cryptorchidism**) occurs on one or both sides. Approximately 50% to 70% of undescended testes in full-term infants will descend within 3 months. If the testes do not descend within 12 months, surgery is performed to preserve fertility (North & Gearhart, 2009).

The meatus should be at the tip of the glans penis. It may be abnormally located on the underside of the penis (**hypospadias**), on the upper side (**epispadias**), or on the perineum. The prepuce or foreskin of the penis covers the glans and is adherent to it. Attempts to retract it in the newborn are unnecessary and can cause injury. Abnormal placement of the meatus may not be visible because it is covered by the prepuce, but often the prepuce in these infants is incompletely formed. Hypospadias may be accompanied by **chordee**, a condition in which fibrotic tissue causes the penis to curve downward. These conditions are later corrected by surgery.

FIG 20-12 The testes are palpated from front to back with the thumb and forefinger. Placing a finger over the inguinal canal holds the testes in place for palpation.

Parents are very concerned about any abnormalities of the genitalia. If the meatus is abnormally positioned, they need an explanation of the condition and why the infant should not be circumcised. The foreskin may be needed for later plastic surgery to repair the defect.

Integumentary System

Skin

The newborn's skin is fragile and shows marks easily, especially in infants with fair coloring. Because the skin is so sensitive, reddened areas and rashes may develop during the early days of life. The nurse must examine every inch of skin surface carefully during the initial assessment and at the beginning of each shift. Marks should be documented and explained to parents who may be worried and need emotional support.

Color. The skin color should be pink or tan. Red, thin skin occurs in preterm infants. Redness (ruddy color or plethora) in the full-term infant may indicate polycythemia. Acrocyanosis is common during the first day as a result of poor peripheral circulation. The infant's mouth and central body areas should not be cyanotic at any time. Blanching the skin over the nose or chest shows the presence of jaundice. Jaundice is abnormal during the first day of life but common during the first week.

A greenish-brown discoloration of the skin, nails, and cord results if meconium was passed. The discoloration may indicate that the infant was compromised at some time before birth, and it is more common in the postterm infant. These infants must be watched for other complications such as respiratory difficulty.

Harlequin Color Change. Harlequin coloration is a clear color division over the body with one side deep pink or red and the other half pale or of normal color. The cause is vasomotor instability and it is usually transient and benign.

Mottling (Cutis Marmorata). Mottling is a lacy, red or blue pattern from dilated blood vessels under the skin. It is usually normal from vasomotor instability, occurring when the infant is exposed to cold, stressed, or overstimulated. If persistent, it may indicate a chromosomal abnormality.

Vernix Caseosa. **Vernix caseosa**, a thick, white substance that resembles cream cheese, provides a protective covering for the fetal skin in utero. The full-term infant has little vernix left on the body except small amounts in the creases. A thick covering of vernix may indicate a preterm infant and a postterm infant may have none at all.

FIG 20-13 Lanugo is abundant on this slightly preterm infant.

FIG 20-15 Erythema toxicum. (From Hurwitz, S. [1993]. *Clinical Pediatric Dermatology* [2nd ed., p. 13]. Philadelphia: Saunders.)

FIG 20-14 Milia.

FIG 20-16 Mongolian spots.

Yellow-tinged vernix may result from elevated bilirubin in utero, and green-tinged vernix is caused by meconium staining.

Lanugo. Lanugo is fine, soft hair that covers the fetus during intra-uterine life (Figure 20-13). As the fetus nears term, the lanugo becomes thinner. The term infant may have a small amount of lanugo on the shoulders, forehead, sides of the face, and upper back. Dark-skinned infants often have more lanugo than infants with lighter coloring, and their darker hair is more visible. Lanugo is assessed as part of the gestational age assessment.

Milia. Milia are white cysts, 1 to 2 mm in size, that disappear without treatment (Morelli, 2011). They occur on the face over the forehead, nose, cheeks, and chin (Figure 20-14).

Erythema Toxicum. The nurse notes the presence of erythema toxicum—red, blotchy areas with white or yellow papules or vesicles in the center (Figure 20-15). It is commonly called *flea bite rash* or *newborn rash* and resembles small bites or acne. The rash occurs in as many as 70% of newborns. It appears during the first 24 to 48 hours after birth and can continue for several days to several months (Witt, 2009). It is most common over the face, back, shoulders, and chest. The condition does not result from infection but should be differentiated

from a pustular rash caused by staphylococcal infection or vesicles from herpes simplex.

Birthmarks. The nurse inspects all areas of the skin for birthmarks or other changes. The size, color, location, elevation, and texture of all birthmarks should be carefully documented. All marks should be explained to parents, who are often concerned.

- **Mongolian spots** are bluish-gray marks that resemble bruises on the sacrum, buttocks, arms, shoulders, and other areas (Figure 20-16). Mongolian spots occur most frequently in newborns with dark skin: they are seen in 96% of African-Americans, 85% of Asians, and 46% of Hispanics (Trevino, Bakos, & Janik, 2009). Although they usually disappear after the first few years of life, some continue into adulthood.
- A **nevus simplex** is also called *salmon patch*, *stork bite*, or *telangiectatic nevus* (Figure 20-17). It is a flat, pink discoloration from dilated capillaries that occurs on the eyelids, just above the bridge of the nose, or at the nape of the neck. The color blanches when the area is pressed and is more prominent during crying. The lesions disappear by 2 years of age, although those at the nape of the neck may persist.
- **Nevus flammeus** (port-wine stain) is a permanent, flat, pink to dark reddish-purple mark that varies in size and location and does not blanch with pressure (Figure 20-18). The lesion may darken and may become nodular as the child gets older. If it is large and in a visible area, it can be lightened by laser surgery, which is often begun in infancy. Lesions located over the forehead and upper

FIG 20-17 Nevus simplex, salmon patch, or stork bite.

FIG 20-18 Port-wine stain (nevus flammeus).

eyelid may be associated with Sturge-Weber syndrome, a serious neurologic condition.

- **Nevus vasculosus** (strawberry hemangioma) consists of enlarged capillaries in the outer layers of skin. It is dark red and raised with a rough surface, giving a strawberry-like appearance. The hemangioma usually is located on the head. It may be present at birth or develop by 6 months of age. After growing larger for 6 months, the hemangioma regresses over several years and disappears. No treatment is necessary unless it becomes infected or ulcerated.
- **Café-au-lait spots** are permanent, light-brown areas that may occur anywhere on the body. Although they are harmless, the number and size are important. Six or more spots or spots larger than 0.5 cm are associated with neurofibromatosis, a genetic condition of neural tissue.

Marks from Delivery. The nurse inspects the infant for marks that may have occurred from injury or pressure during labor or birth.

- Bruises may appear on any part of the body where pressure occurred during birth. Bruising or petechiae of the face may be present if the cord was wrapped tightly around the neck during birth (nuchal cord). Bruising on the head may result from use of a vacuum extractor.

- Petechiae, pinpoint bruises that resemble a rash, may appear on the back, face, and groin. They result from increased intravascular pressure during the birth process. Widespread or continued formation of petechiae may indicate infection or a low platelet count.
- A small puncture mark is present on the newborn's head if a fetal monitor scalp electrode was attached. The area should scab and heal normally but is observed for signs of infection.
- Forceps marks occur over the cheeks and ears where the instruments were applied. Their size, color, and location are carefully documented. Asymmetry or lack of movement of the face may indicate injury of the facial nerve.

Other Skin Assessments. The nurse records other aspects of the skin that may indicate abnormalities. Localized edema may be caused by trauma from birth. Generalized edema shows a more serious condition such as heart failure. Peeling of the skin is normal in full-term newborns. Excessive amounts of peeling may indicate a postterm infant.

Documentation

All marks, bruises, rashes, and other abnormalities of the skin must be recorded in the nurses' notes. The location, size, color, elevation, and texture of each mark are described. Subsequent changes in appearance from previous descriptions also are noted on the chart.

The nurse may not always know the proper name for each type of mark on the infant's skin. Most agencies have books with pictures of the common skin variations.

When in doubt about the name of a mark, a description is sufficient. For example, a nevus simplex (stork bite) might be described as a "flat, pink area 1 × 2 cm in size over nape of the neck that blanches with pressure."

Breasts

The nurse notes the placement of the nipples and looks for extra (supernumerary) nipples, which may appear on the chest or in the axilla. Occasionally, the breasts become engorged and secrete a small amount of white fluid (sometimes called *witch's milk*) a few days later. This condition is caused by maternal hormones and resolves within a few weeks without treatment. The breasts should not be expressed or manipulated, as this could cause infection.

Hair and Nails

The hair on the full-term infant should be silky and soft, whereas hair on the preterm infant is woolly or fuzzy. The nails come to the end of the fingers or beyond. Very long nails may indicate a postterm infant. A green-brown staining of the nails may occur if the infant passed meconium before birth. It is a sign of possible fetal distress. The umbilical cord may also be stained (Table 20-2).

ASSESSMENT OF GESTATIONAL AGE

The gestational age assessment is an examination of the newborn's physical and neurologic characteristics to determine the number of weeks from conception to birth. It is important because neonates born before or after term and those whose size is not appropriate for gestational age are at increased risk for complications. Although the gestational age may be calculated from the mother's last menstrual period and by ultrasonography during the pregnancy, the date of the last menstrual period is not always accurate, and ultrasonography is not always performed.

Because the times of development for various fetal characteristics are known, the presence or absence of these characteristics can help estimate gestational age. The estimated age then can be compared with

Text continued on p. 406

TABLE 20-2 SUMMARY OF NEWBORN ASSESSMENT

NORMAL	ABNORMAL (POSSIBLE CAUSES)	NURSING CONSIDERATIONS
Initial Assessment		
Assess for obvious problems first. If infant is stable and has no problems that require immediate attention, continue with complete assessment.		
Vital Signs		
Temperature		
Axillary: 36.5°-37.5°C (97.7°-99.5°F). Axilla is preferred site.	Decreased (cold environment, hypoglycemia, infection, CNS problem). Increased (infection, environment too warm).	Decreased: Institute warming measures and check in 30 min. Check blood glucose. Increased: Remove excessive clothing. Check for dehydration. Decreased or increased: Look for signs of infection. Check radiant warmer or incubator temperature setting. Check thermometer for accuracy if skin is warm or cool to touch. Report abnormal temperatures to physician.
Pulses		
Heart rate 120-160 bpm (100 sleeping, 180 crying). Rhythm regular. PMI at third to fourth intercostal space lateral to the midclavicular line. Brachial, femoral, and pedal pulses present and equal bilaterally.	Tachycardia (respiratory problems, anemia, infection, cardiac conditions). Bradycardia (asphyxia, increased intracranial pressure). PMI to right (dextrocardia, pneumothorax). Murmurs (normal or congenital heart defects). Dysrhythmias. Absent or unequal pulses (coarctation of the aorta).	Note location of murmurs. Refer abnormal rates, rhythms and sounds, pulses.
Respirations		
Rate 30-60 (average 40-49) per min. Respirations irregular, shallow, unlabored. Chest movements symmetric. Breath sounds present and clear bilaterally.	Tachypnea, especially after the first hour (respiratory distress). Slow respirations (maternal medications). Nasal flaring (respiratory distress). Grunting (respiratory distress syndrome). Gasping (respiratory depression). Periods of apnea more than 20 seconds or with change in heart rate or color (respiratory depression, sepsis, cold stress). Asymmetry or decreased chest expansion (pneumothorax). Intercostal, xiphoid, or supraclavicular retractions or seesaw [paradoxical] respirations (respiratory distress). Moist, coarse breath sounds (crackles, rhonchi) (fluid in lungs). Bowel sounds in chest (diaphragmatic hernia).	Mild variations require continued monitoring and usually clear in early hours after birth. If persistent or more than mild, suction, give oxygen, call physician, and initiate more intensive care.
Blood Pressure		
Varies with age, weight, activity, and gestational age. Average systolic 65-95 mm Hg, average diastolic 30-60 mm Hg.	Hypotension (hypovolemia, shock, sepsis). BP 20 mm Hg or more higher in arms than legs (coarctation of the aorta).	Refer abnormal blood pressures. Prepare for intensive care if very low.
Measurements		
Weight		
Weight 2500-4000 g (5 lb, 8 oz to 8 lb, 13 oz). Weight loss up to 10% in early days.	High (LGA, maternal diabetes). Low (SGA, preterm, multifetal pregnancy, medical conditions in mother that affected fetal growth). Weight loss above 10% (dehydration, feeding problems).	Determine cause. Monitor for complications common to cause.

TABLE 20-2 SUMMARY OF NEWBORN ASSESSMENT—cont'd

NORMAL	ABNORMAL (POSSIBLE CAUSES)	NURSING CONSIDERATIONS
Length		
48-53 cm (19-21 in).	Below normal (SGA, congenital dwarfism). Above normal (LGA, maternal diabetes).	Determine cause. Monitor for complications common to cause.
Head Circumference		
32-38 cm (13-15 in). Head and neck are approximately one fourth of infant's body surface.	Small (SGA, microcephaly, anencephaly). Large (LGA, hydrocephalus, increased intracranial pressure).	Determine cause. Monitor for complications common to cause.
Chest Circumference		
30-36 cm (12-14 in). Is 2 cm less than head circumference.	Large (LGA); Small (SGA).	Determine cause. Monitor for complications common to cause.
Posture		
Flexed extremities move freely, resist extension, return quickly to flexed state. Hands usually clenched. Movements symmetric. Slight tremors on crying. "Molds" body to caretaker's body when held, responds by quieting when needs met. Breech: extended, stiff legs.	Limp, flaccid, "floppy," or rigid extremities (preterm, hypoxia, medications, CNS trauma). Hypertonic (neonatal abstinence syndrome, CNS injury). Jitteriness or tremors (low glucose or calcium). Opisthotonos, seizures, stiff when held (CNS injury).	Seek cause, refer abnormalities.
Cry		
Lusty, strong.	High pitched (increased intracranial pressure). Weak, absent, irritable, catlike "mewing" (neurologic problems). Hoarse or crowing (laryngeal irritation).	Observe for changes, report abnormalities.
Skin		
Color pink or tan with acrocyanosis. Vernix caseosa in creases. Small amounts of lanugo over shoulders, sides of face, forehead, upper back. Skin turgor good with quick recoil. Some cracking and peeling of skin. Normal variations: Milia. Skin tags. Erythema toxicum ("flea bite" rash). Puncture on scalp (from electrode). Mongolian spots.	Color: Cyanosis of mouth and central areas (hypoxia). Facial bruising (nuchal cord). Pallor (anemia, hypoxia). Gray (hypoxia, hypotension). Red, sticky, transparent skin (very preterm). Ruddy (polycythemia). Greenish brown discoloration of skin, nails, cord (possible fetal compromise, postterm). Harlequin color (normal transient autonomic imbalance). Mottling (normal or cold stress, hypovolemia, sepsis). Jaundice (pathologic if first 24 hr). Yellow vernix (blood incompatibilities). Thick vernix (preterm). Delivery marks: Bruises on body (pressure), scalp (vacuum extractor), or face (cord around neck). Petechiae (pressure, low platelet count, infection). Forceps marks. Birthmarks: Mongolian spots. Nevus simplex (salmon patch, stork bite). Nevus flammeus (port-wine stain). Nevus vasculosus (strawberry hemangioma). Café-au-lait spots (6 or more larger than 0.5 cm in size (neurofibromatosis)). Other: Excessive lanugo (preterm). Excessive peeling, cracking (postterm). Pustules or other rashes (infection). "Tenting" of skin (dehydration).	Differentiate facial bruising from cyanosis. Central cyanosis requires suction, oxygen, and further treatment. Refer jaundice in first 24 hr or more extensive than expected for age. Watch for respiratory problems in infants with meconium staining. Look for signs and complications of preterm or postterm birth. Record location, size, shape, color, type of rashes and marks. Differentiate mongolian spots from bruises. Check for facial movement with forceps marks. Watch for jaundice with bruising. Point out and explain normal skin variations to parents.

TABLE 20-2 SUMMARY OF NEWBORN ASSESSMENT—cont'd

NORMAL	ABNORMAL (POSSIBLE CAUSES)	NURSING CONSIDERATIONS
Head		
<p>Sutures palpable with small separation between each.</p> <p>Anterior fontanel diamond-shaped, 4-6 cm, soft, and flat. May bulge slightly with crying.</p> <p>Posterior fontanel triangular, 0.5-1 cm.</p> <p>Hair silky and soft with individual hair strands.</p> <p>Normal variations: Overriding sutures (molding).</p> <p>Caput succedaneum or cephalhematoma (pressure during birth).</p>	<p>Head large (hydrocephalus, increased intracranial pressure) or small (microcephaly). Widely separated sutures (hydrocephalus) or hard, ridged area at sutures (craniosynostosis).</p> <p>Anterior fontanel depressed (dehydration, molding), full or bulging at rest (increased intracranial pressure).</p> <p>Woolly, bunched hair (preterm).</p> <p>Unusual hair growth (genetic abnormalities).</p>	<p>Seek cause of variations.</p> <p>Observe for signs of dehydration with depressed fontanel; increased intracranial pressure with bulging of fontanel and wide separation of sutures.</p> <p>Refer for treatment.</p> <p>Differentiate caput succedaneum from cephalhematoma, and reassure parents of normal outcome.</p> <p>Observe for jaundice with cephalhematoma.</p>
Ears		
<p>Ears well formed and complete.</p> <p>Area where upper ear meets head even with imaginary line drawn from outer canthus of eye.</p> <p>Startle response to loud noises. Alerts to high-pitched voices.</p>	<p>Low-set ears (chromosomal disorders).</p> <p>Skin tags, preauricular sinuses, dimples (may be associated with kidney or other abnormalities).</p> <p>No response to sound (deafness).</p>	<p>Check voiding if ears abnormal.</p> <p>Look for signs of chromosomal abnormality if position abnormal.</p> <p>Refer for evaluation if no response to sound.</p>
Face		
<p>Symmetric in appearance and movement.</p> <p>Parts proportional and appropriately placed.</p>	<p>Asymmetry (pressure and position in utero). Drooping of mouth or one side of face, "one-sided cry" (facial nerve injury).</p> <p>Abnormal appearance (chromosomal abnormalities).</p>	<p>Seek cause of variations.</p> <p>Check delivery history for possible cause of injury to facial nerve.</p>
Eyes		
<p>Symmetric. Eyes clear.</p> <p>Transient strabismus.</p> <p>Scant or absent tears.</p> <p>Pupils equal, react to light.</p> <p>Alerts to interesting sights.</p> <p>Doll's-eye sign, red reflex present.</p> <p>Normal variations: May have subconjunctival hemorrhage or edema of eyelids from pressure during birth.</p>	<p>Inflammation or drainage (chemical or infectious conjunctivitis).</p> <p>Constant tearing (plugged lacrimal duct).</p> <p>Unequal pupils.</p> <p>Failure to follow objects (blindness).</p> <p>White areas over pupils (cataracts).</p> <p>Setting-sun sign (hydrocephalus).</p> <p>Yellow sclera (jaundice).</p> <p>Blue sclera (osteogenesis imperfecta).</p>	<p>Clean and monitor any drainage; seek cause.</p> <p>Reassure parents that subconjunctival hemorrhage and edema will clear.</p> <p>Refer other abnormalities.</p>
Nose		
<p>Both nostrils open to air flow.</p> <p>May have slight flattening from pressure during birth.</p>	<p>Blockage of one or both nasal passages (choanal atresia).</p> <p>Malformations (congenital conditions).</p> <p>Flaring, mucus (respiratory distress).</p>	<p>Observe for respiratory distress.</p> <p>Report malformations.</p>
Mouth		
<p>Mouth, gums, tongue pink.</p> <p>Tongue normal in size and movement.</p> <p>Lips and palate intact.</p> <p>Sucking pads. Sucking, rooting, swallowing, gag reflexes present.</p> <p>Normal variations: precocious teeth, Epstein's pearls.</p>	<p>Cyanosis (hypoxia).</p> <p>White patches on cheeks or tongue (candidiasis).</p> <p>Protruding tongue (Down syndrome).</p> <p>Diminished movement of tongue, drooping mouth (facial nerve paralysis).</p> <p>Cleft lip or palate, or both.</p> <p>Absent or weak reflexes (preterm, neurologic problem).</p> <p>Excessive drooling (tracheoesophageal fistula, esophageal atresia).</p>	<p>Oxygen for cyanosis.</p> <p>Expect loose teeth to be removed.</p> <p>Obtain order for antifungal medication for candidiasis.</p> <p>Check mother for vaginal or breast infection. Refer anomalies.</p>
Feeding		
<p>Good suck/swallow coordination. Retains feedings.</p>	<p>Poorly coordinated suck and swallow (prematurity).</p> <p>Dusky or cyanosis during feeding (cardiac defects).</p> <p>Choking, gagging, excessive drooling (tracheoesophageal fistula, esophageal atresia).</p>	<p>Feed slowly. Stop frequently if difficulty occurs.</p> <p>Suction and stimulate if necessary.</p> <p>Refer infants with continued difficulty.</p>

TABLE 20-2 SUMMARY OF NEWBORN ASSESSMENT—cont'd

NORMAL	ABNORMAL (POSSIBLE CAUSES)	NURSING CONSIDERATIONS
<p>Neck/Clavicles</p> <p>Short neck, turns head easily side to side. Infant raises head when prone. Clavicles intact.</p>	<p>Weakness, contractures, or rigidity (muscle abnormalities). Webbing of neck, large fat pad at back of neck (chromosomal disorders). Crepitus, lump, or crying when clavicle or other bones palpated, diminished or absent arm movement (fractures).</p>	<p>Fracture of clavicle more frequent in large infants with shoulder dystocia at birth. Immobilize arm. Look for other injuries. Refer abnormalities.</p>
<p>Chest</p> <p>Cylinder shape. Xiphoid process may be prominent. Symmetric. Nipples present and located properly. Normal variation: May have engorgement, white nipple discharge (maternal hormone withdrawal).</p>	<p>Asymmetry (diaphragmatic hernia, pneumothorax). Supernumerary nipples. Redness (infection).</p>	<p>Report abnormalities.</p>
<p>Abdomen</p> <p>Rounded, soft. Bowel sounds present within 15 min after birth. Liver palpable 1-2 cm below right costal margin. Skin intact. Three vessels in cord. Clamp tight and cord drying. Meconium passed within 12-48 hr. Urine generally passed within 12-24 hr. Normal variation: "Brick dust" staining of diaper (uric acid crystals).</p>	<p>Sunken abdomen (diaphragmatic hernia). Distended abdomen or loops of bowel visible (obstruction, infection, enlarged organs). Absent bowel sounds after first hour (paralytic ileus). Masses palpated (kidney tumors, distended bladder). Enlarged liver (infection, heart failure, hemolytic disease). Abdominal wall defects (umbilical or inguinal hernia, omphalocele, gastroschisis, exstrophy of bladder). Two vessels in cord (other anomalies). Bleeding (loose clamp). Redness, drainage from cord (infection). No passage of meconium (imperforate anus, obstruction). Lack of urinary output (kidney anomalies) or inadequate amounts (dehydration).</p>	<p>Refer abnormalities. Assess for other anomalies if only two vessels in cord. Tighten or replace loose cord clamp. If stool and urine output abnormal, look for missed recording, increase feedings, report.</p>
<p>Genitals</p> <p>Female</p> <p>Labia majora dark, cover clitoris and labia minora. Small amount of white mucous vaginal discharge. Urinary meatus and vagina present. Normal variations: Vaginal bleeding (pseudomenstruation). Hymenal tags.</p>	<p>Clitoris and labia minora larger than labia majora (preterm). Large clitoris (ambiguous genitalia). Edematous labia (breech birth).</p>	<p>Check gestational age for immature genitalia. Refer anomalies.</p>
<p>Male</p> <p>Testes within scrotal sac, rugae on scrotum, prepuce nonretractable. Meatus at tip of penis.</p>	<p>Empty scrotal sac (cryptorchidism). Testes in inguinal canal or abdomen (preterm, cryptorchidism). Lack of rugae on scrotum (preterm). Edema of scrotum (pressure in breech birth). Enlarged scrotal sac (hydrocele). Small penis, scrotum (preterm, ambiguous genitalia). Urinary meatus located on upper side of penis (epispadias), underside of penis (hypospadias), or perineum. Ventral curvature of the penis (chordee).</p>	<p>Check gestational age for immature genitalia. Refer anomalies. Explain to parents why no circumcision can be performed with abnormal placement of meatus.</p>

TABLE 20-2 SUMMARY OF NEWBORN ASSESSMENT—cont'd

NORMAL	ABNORMAL (POSSIBLE CAUSES)	NURSING CONSIDERATIONS
Extremities		
Upper and Lower Extremities		
Equal and bilateral movement of extremities. Correct number and formation of fingers and toes. Nails to ends of digits or slightly beyond. Flexion, good muscle tone.	Crepitus, redness, lumps, swelling (fracture). Diminished or absent movement, especially during Moro reflex (fracture, nerve injury, paralysis). Polydactyly (extra digits). Syndactyly (webbing). Fused or absent digits. Poor muscle tone (preterm, neurologic injury, hypoglycemia, hypoxia).	Refer all anomalies, look for others.
Upper Extremities		
Two transverse palm creases.	Simian crease (normal or Down syndrome). Diminished movement (injury). Diminished movement of arm with extension and forearm prone (Erb-Duchenne paralysis).	Refer all anomalies, look for others.
Lower Extremities		
Legs equal in length, abduct equally, gluteal and thigh creases and knee height equal, no hip “clunk.” Normal position of feet.	Ortolani and Barlow tests abnormal, unequal leg length, unequal thigh or gluteal creases (developmental dysplasia of the hip). Malposition of feet (position in utero, talipes equinovarus).	Refer all anomalies, look for others. Check malpositioned feet to see if they can be gently manipulated back to normal position.
Back		
No openings observed or felt in vertebral column. Anus patent. Sphincter tightly closed.	Failure of one or more vertebrae to close (spina bifida), with or without sac with spinal fluid and meninges (meningocele) or spinal fluid, meninges, and cord (myelomeningocele) enclosed. Tuft of hair over spina bifida occulta. Pilonidal dimple or sinus. Imperforate anus.	Refer abnormalities. Observe for movement below level of defect. If sac, cover with sterile dressing wet with sterile saline. Protect from injury.
Reflexes		
See Table 20-1.	Absent, asymmetric, or weak reflexes.	Observe for signs of fractures, nerve injury, or injury to CNS.

BP, Blood pressure; bpm, beats per minute; CNS, central nervous system; LGA, large for gestational age; PMI, point of maximum impulse; SGA, small for gestational age.

the newborn's weight, length, and head circumference to determine whether the neonate is large, appropriate (average), or small in size for gestational age.

Assessment Tools

The New Ballard Score (Figure 20-19) is often used to assess gestational age based on neuromuscular and physical characteristics. It is designed to assess gestational age from 20 to 44 weeks and provides accurate information within 2 weeks. It is most accurate when performed within 12 hours of birth (Furdon & Benjamin, 2010). A score is given to each assessment and the total score is used to determine the gestational age of the infant. The New Ballard Score is described in the following section.

Neuromuscular Characteristics

Posture

The posture and degree of flexion of the extremities are scored before disturbing the quiet infant (Figure 20-20). Preterm neonates have immature flexor muscles and little energy or muscle tone. Therefore they have extended, limp arms and legs that offer little resistance to movement by the examiner. Flexor tone improves as the gestational age increases, and it moves in a cephalocaudal manner down the infant's

body. Full-term infants hold their arms close to the body with the elbows sharply flexed. The legs should be flexed at the hips, knees, and ankles. Posture is scored from zero for a limp, flaccid posture to 4 if the newborn demonstrates good flexion of all extremities. The legs of infants who were in a frank breech position may be more extended than flexed even when they are full term.

Square Window

The square window sign is elicited by flexing the hand at the wrist until the palm is as flat against the forearm as possible with gentle pressure (Figure 20-21). The angle between the palm and forearm is measured. If the palm bends only 90° (which is the extent of flexion in the adult wrist and looks like a square window), the score is zero. The gestational age of the infant is probably 32 weeks or less. The more mature the neonate, the smaller the angle until the palm folds flat against the forearm at term, the result of maternal hormones at the end of pregnancy.

Arm Recoil

Full-term infants resist extension of the arms. In testing for arm recoil, the nurse holds the neonate's arms fully flexed at the elbows for 5 seconds, then pulls the hands straight down to the sides (Figure 20-22).

FIG 20-19 New Ballard Score. (Courtesy Bristol-Myers Co., Evansville, Ind. From Ballard, J.L., Khoury, J.C., Wedig, K., Wang, L., Eilers-Walsman, B.L., & Lipp, R. [1991]. New Ballard Score, expanded to include extremely premature infants. *Journal of Pediatrics*, 19[3], 417-423.)

The hands are quickly released and the degree of flexion is measured as the arms return to their normally flexed position. Preterm infants may move the arms slowly or not at all and receive a score of zero. Somewhat older infants have a sluggish recoil, with only partial return to flexion. If the arms move briskly to an angle of less than 90° at the elbows, the score is 4.

Popliteal Angle

To measure the popliteal angle, the newborn's lower leg is folded against the thigh, with the thigh on the abdomen (Figure 20-23). With the thigh still flexed on the abdomen, the lower leg is straightened just until resistance is met. Continued pressure causes the infant to further extend the leg and results in an inaccurate score. The angle at the

FIG 20-20 Posture in newborns. **A**, The healthy full-term infant remains in a strongly flexed position. **B**, The preterm infant's extremities are extended.

popliteal space when resistance is first felt is scored on a scale of zero (if the leg can be fully extended) to 5 (if the angle at the popliteal space is less than 90°). The preterm infant extends the leg farther than the full-term infant. The leg may extend with little resistance if the infant was in a frank breech position at birth.

Scarf Sign

For the scarf sign, the nurse grasps the infant's hand and brings the arm across the body to the opposite side, keeping the shoulder flat on the bed and the head in the middle of the body (Figure 20-24). The position of the elbow in relation to the midline of the infant's body is noted. The infant receives a score of zero if muscle tone is so poor that the arm wraps across the body like a scarf with the elbow beyond the edge of the body. A top score (4) shows that the elbow fails to reach the midline.

Heel to Ear

The heel-to-ear assessment is similar to the measurement of the popliteal angle. However, in this case, the nurse grasps the infant's foot and pulls it straight up alongside the body toward the ears while the hips remain flat on the surface of the bed (Figure 20-25). When resistance is felt, the position of the foot in relation to the head and the amount of flexion of the leg are compared with the diagrams. The more resistance and flexion, the more mature the infant.

Record the position when resistance is first felt because the neonate may relax the leg if pressure continues. This assessment also may be inaccurate in infants who were in a breech position at birth.

Physical Characteristics

Skin

The skin is assessed for color, visibility of veins, peeling, and cracking. The very preterm infant's skin is translucent because it is thin and has little subcutaneous fat beneath the surface. The skin is red, sticky, and fragile, with easily visible veins. In the mature newborn, the skin is thicker and the color is paler. Few veins are visible, usually over the chest and abdomen (see Figure 20-24). At term, vernix is present only in the creases.

FIG 20-21 The square window sign is performed on the arm without the identification bracelet. The nurse flexes the wrist and measures the angle. **A**, Infant near full term. **B**, Preterm infant.

FIG 20-22 Arm recoil. **A**, Arms flexed. **B**, Arms extended. **C**, Recoil for the full-term infant.

FIG 20-23 The popliteal angle is measured by flexing the thigh against the abdomen and extending the lower leg to the point of resistance. **A**, Full-term infant. **B**, Preterm infant.

The full-term infant exhibits some peeling and cracking of the skin, especially around areas with creases, such as the ankles and feet. The postmature infant has deeply cracked skin that appears as dry and thick as leather. Peeling becomes even more apparent during the hours after birth as the skin loses moisture.

Lanugo

Lanugo appears at 20 weeks of gestation and increases in amount until 28 weeks (see [Figure 20-13](#)) when it begins to disappear. Most is shed by 32 to 36 weeks ([Gardner & Hernandez, 2011](#)). A small amount may remain over the upper back and shoulders, on the ears, or on the sides of the forehead. The infant receives a score based on the amount of lanugo present on the back.

Plantar Surface

Plantar creases begin to appear at 28 to 32 weeks of gestation and cover the entire foot by term ([Trotter, 2009](#)) ([Figure 20-26](#)). Although the creases are only red lines near the toes at first, they gradually spread down toward the heel and become deeper. The plantar creases must be assessed during the early hours after birth because creases appear more prominent as the infant's skin begins to dry. For the very preterm infant, the length of the foot is measured to help determine gestational age.

Breasts

The nipples, areolae, and size of the breast buds are assessed and scored. In very preterm infants, the structures are not visible.

FIG 20-24 Scarf sign. The nurse determines how far the arm will move across the chest and observes the position of the elbow when resistance is felt. **A**, Full-term infant. **B**, Preterm infant. (Note the many visible veins in the preterm infant and the absence of visible veins in the full-term infant.)

Gradually, they grow larger and the areolae become raised above the chest wall. The breast buds enlarge until they are approximately 1 cm at term. To determine their size, the nurse places a finger on each side and measures the diameter (Figure 20-27). Use of the thumb and forefinger may cause excess tissue to be drawn together, resulting in an inaccurate score.

Eyes and Ears

The eyelids are fused until 26 to 28 weeks of gestation (Trotter, 2009). When the ear is assessed, the incurving and thickness of each pinna are rated (Figure 20-28). At about 34 weeks of gestation, the upper pinnae, which have been flat, begin to curve over. The incurving continues around the ear until it reaches near the earlobe at 40 weeks of gestation (Furdon & Benjamin, 2010).

The amount of cartilage present in the ears is a more accurate guide to gestational age than the incurving of the pinnae because of individual differences in ear shape. As cartilage is deposited in the pinnae, the ears become stiff and stand away from the head. The ear is folded longitudinally and horizontally to assess the resistance and speed with which the ear returns to its original state. In infants less than 34 weeks of gestation, the ear has little cartilage to keep it stiff. When folded, it remains folded over or returns slowly. In the term neonate, the ear springs back to its original position immediately.

FIG 20-25 Heel-to-ear assessment. The nurse grasps the foot and brings it up toward the ear. The score is recorded when resistance is felt. **A**, Full-term infant. **B**, Preterm infant.

FIG 20-26 Plantar creases begin to develop at the base of the toes and extend to the heel. **A**, The postterm infant has deep creases. **B**, The preterm infant has few creases on the entire foot.

Genitals

In the female infant, the relationship in size of the clitoris, labia minora, and labia majora is noted (Figure 20-29). In the preterm infant, the labia majora are small and separated, and the clitoris and labia minora are large by comparison. As the infant nears term, the labia majora enlarge until the clitoris and labia minora are completely covered. Because the size of the labia majora is affected by the amount of fat

deposited, the infant who is malnourished in utero may have genitalia with an immature appearance.

In the male infant, the location of the testes and the rugae on the scrotum are assessed (Figure 20-30). The testes originate in the abdominal cavity and begin to descend at 28 weeks of gestation. By 37 weeks of gestation, they are located high in the scrotal sac, and they are generally completely descended by term. Rugae cover the surface of the scrotum by 40 weeks of gestation (Furdon & Benjamin, 2010). Once the testes are completely down into the scrotum, the scrotum appears large and pendulous.

FIG 20-27 The nurse places a finger on either side of the breast bud and measures the size. In the full-term infant, breast tissue is raised and the nipple is easily distinguished from surrounding skin. (Note the peeling skin.)

Scoring

As each part of the gestational age assessment is performed, the infant's response is matched with the diagrams and descriptions on the assessment tool. The total score is compared with the corresponding gestational age. It is important to understand that one or two characteristics alone are not enough to assign a gestational age. It is the total score of all assessed characteristics that determines the gestational age.

A difference of 2.5 points is necessary to change the gestational age by 1 week. Therefore slight differences in the scores of different examiners are not likely to cause significant differences in the outcome of the examination.

Gestational Age and Infant Size

The appropriateness of the neonate's size for gestational age is determined by plotting the weight, length, head circumference, and gestational age on a graph of intrauterine development. This score determines how well the infant has grown for the amount of time spent in the uterus. An infant may be small, large, or of appropriate size for gestational age. The infant whose size is appropriate for gestational age falls between the 10th and 90th percentiles on the graph. The large-for-gestational-age (LGA) infant is above the 90th percentile, whereas the small-for-gestational-age (SGA) infant is below the 10th percentile.

Further Assessments

When an infant's gestational age or measurements fall outside the expected range, the nurse monitors for complications. Specific complications are common to preterm, postterm, SGA, and LGA infants. For example, pregnancy complications may cause a poorly functioning placenta and an SGA infant. LGA infants are also prone to complications (see Chapter 29).

ASSESSMENT OF BEHAVIOR

Assessment of the infant's behavior helps determine intactness of the central nervous system and provides information about the ability to respond to caretaking activities. Because behavior differs at various times after birth, the nurse should be aware of the periods of reactivity

FIG 20-28 Ear maturation. **A**, The nurse folds the ears and notes how quickly they return to position. **B**, Ears in the full-term infant are well formed and have instant recoil. **C**, In the preterm infant, ears show less incurving of the pinna and recoil slowly or not at all.

FIG 20-29 Female genitals. As the female matures, the labia majora cover the labia minora and clitoris completely; in the preterm infant, these structures are not covered. **A**, Near-term infant. **B**, Preterm infant.

FIG 20-30 Male genitals. **A**, The full-term infant has a pendulous scrotum with deep rugae. **B**, In the preterm infant, the testes may not be descended and rugae are few.

and the six different states of behavior so that nursing care can be adapted appropriately.

Periods of Reactivity

During the first and second periods of reactivity, newborns may have elevated pulse and respiratory rates, low temperatures, and excessive respiratory secretions. Careful observation is important at this time but can usually be done unobtrusively so that parents can continue to enjoy the newborn. During the time between the first and second periods of reactivity, newborns cannot be awakened easily and are not interested in feeding.

Behavioral Changes

Nurses assess the infant's behavior and alert the physician to abnormalities. Assessment includes the six different behavioral states: quiet sleep, active sleep, drowsy, quiet alert, active alert, and crying. Movement between states should be smooth and not abrupt. The Brazelton Neonatal Behavioral Assessment Scale is often used when detailed knowledge about the infant is needed. In addition to assessing behavioral states, the scale analyzes other aspects of the newborn's behavior, such as orientation, habituation, self-consoling behaviors, social behaviors, and the appropriateness of the amount of time in each of these activities.

Orientation

The nurse notes the infant's orientation (ability to pay attention) to interesting visual or auditory stimuli. It is most prominent during the quiet alert state. Infants focus their eyes and turn their heads toward a stimulus in an attempt to prolong contact with it. Preterm and ill neonates have less ability to orient to stimuli.

Habituation

The infant's response to a visual, auditory, or tactile stimulus is an important assessment. Generally, the first response of a healthy newborn to an interesting stimulus, such as a brightly colored object or bell, is a period of alertness. If the stimulus is disturbing, like a bright light flashed in the eyes, the infant startles and attempts to escape by averting the eyes.

Infants gradually stop responding to continued unpleasant stimuli. This gradual habituation allows them to ignore the stimuli and save energy for physiologic needs. Newborns may display a dull, drowsy state or fall into a deep sleep. Those who seem unresponsive in a bright, noisy environment may be in a state of habituation. The preterm infant or one with damage to the central nervous system may not be able to habituate.

Self-Consoling Activities

Normal newborns are able to console themselves for short periods. Self-consoling activities include bringing their hands to their mouth,

sucking on their fists, listening to voices, and watching objects in the environment. Infants who are ill, preterm, or exposed to drugs prenatally have less ability to console themselves.

Parents' Response

The parents' growing ability to respond to the infant's behavioral cues should be noted. The nurse can point out the infant's behavioral changes to facilitate bonding and help the parents learn to interpret the infant's cues. The methods that the parents use to meet the infant's needs during different behavior states also are noted.

SUMMARY CONCEPTS

- Nurses assess newborns immediately after birth to detect serious abnormalities. If no problems are detected with a quick assessment, a more comprehensive examination is performed.
- Assessment of cardiorespiratory status includes history, airway, color, heart sounds, pulses, and blood pressure.
- Because they are safer, axillary temperatures are preferred to rectal temperatures.
- Molding of the head is normal during birth and may cause the head to appear misshapen. Caput succedaneum (localized swelling from pressure against the cervix) or a cephalhematoma (bleeding between the periosteum and the bone) may be present.
- Measurements are an important way to learn about growth before birth. Abnormal measurements alert the nurse that complications may occur.
- Reflexes are an indication of the health of the central nervous system. Asymmetry or retention of reflexes beyond the time when they should disappear is abnormal.
- Early signs of hypoglycemia include jitteriness, poor muscle tone, respiratory distress, sweating, low temperature, and poor suck.
- In performing heel sticks to obtain blood samples, the nurse must choose the site carefully to avoid injury to the bone, nerves, or blood vessels of the heel.
- The initial feeding provides information about the neonate's ability to coordinate sucking, swallowing, and breathing and tolerance to feeding.
- Newborns pass the first stool within 12 to 48 hours of birth. Absence of stool for 48 hours may indicate an obstruction.
- The newborn's first void occurs within 12 to 48 hours. Infants may void only one to two times during the first 2 days and at least six times daily by the fourth day.
- Marks on the skin should be documented, including location, size, color, elevation, and texture. Because marks can be upsetting, they should be explained to the parents.
- The gestational age assessment provides an estimate of the infant's age from conception. It alerts the nurse to possible complications related to age and size.

Care of the Normal Newborn

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the purpose and use of routine prophylactic medications for the normal newborn.
2. Explain the nurse's responsibility in ongoing cardiorespiratory and thermoregulatory assessments and care.
3. Describe collaborative interventions for hypoglycemia.
4. Discuss prevention and parent teaching for jaundice.
5. Compare the risks and benefits of circumcision.
6. Describe the care of circumcised and uncircumcised male infants.
7. Explain ongoing nursing assessments and care of the newborn.
8. Describe methods to protect newborns by proper identification.
9. Explain how nurses can help prevent infant abductions.
10. Describe methods to prevent infections and falls in newborns.
11. Discuss important considerations in parent teaching.
12. Explain the importance of newborn screening tests.

The role of the nurse in ongoing assessments and care of the newborn is to help the newborn and parents have a successful transition after birth. The nurse identifies and responds to changes in the condition of newborns as they adapt to life outside the uterus, keeps infants safe, and teaches parents how to provide care.

EARLY CARE

Early care after birth involves assignment of Apgar scores and assessment and stabilization of the infant as necessary. Immediate care is discussed in [Chapter 13](#) (pp. 246-249) and infant resuscitation in [Chapter 30](#) (p. 652). Once the infant's condition is stable, prophylactic medications are given.

Because of blood and amniotic fluid on the infant's skin from birth, the nurse wears gloves during all contact with the infant until the bath is completed. After the bath, gloves are necessary only when contact with body fluids will occur.

Administering Vitamin K

Vitamin K is given to neonates because they cannot synthesize it in the intestines without bacterial flora. This places them at risk for hemorrhagic disease of the newborn (vitamin K–deficiency disease). One

dose of vitamin K intramuscularly after birth prevents bleeding problems until the infant is able to produce vitamin K in sufficient amounts. Although the injection is usually given within the first hour after birth, it can be delayed until the infant has finished breastfeeding in the delivery room ([American Academy of Pediatrics \[AAP\] & American Academy of Obstetricians and Gynecologists \[ACOG\], 2012](#)) (see [Procedure 21-1](#) and [Drug Guide: Vitamin K₁ \[Phytonadione\]](#)).

Providing Eye Treatment

Infants also receive prophylactic treatment to prevent ophthalmia neonatorum in case the mother is infected with gonorrhea ([Figure 21-1](#) and [Drug Guide: Erythromycin Ophthalmic Ointment](#)). Erythromycin 0.5% is most commonly used. Tetracycline 1% ophthalmic ointment also may be used. Topical antibiotics are not effective against chlamydia, which often occurs with gonorrhea ([AAP & ACOG, 2012](#)).

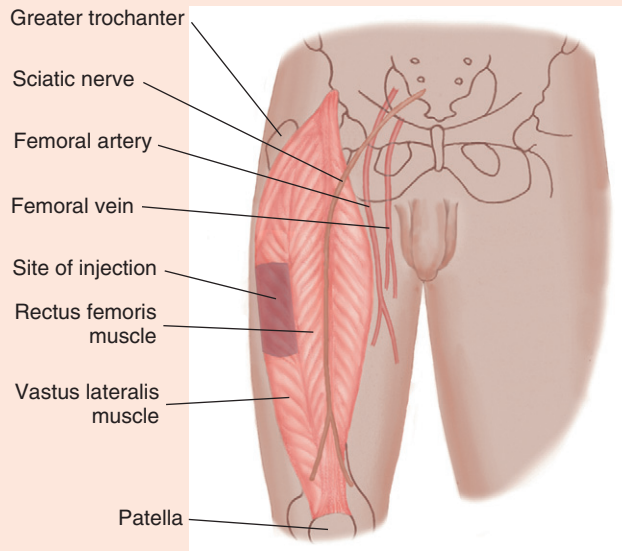

Because the ointment may temporarily blur the infant's vision, parents may wish to delay treatment for a short time during initial bonding. It may be delayed until the end of the first hour after birth or after the first breastfeeding in the delivery room ([AAP & ACOG, 2012](#)).

Some infants develop a mild inflammation a few hours after prophylactic treatment. Any discharge from the eyes, especially if it is

PROCEDURE 21-1 ADMINISTERING INTRAMUSCULAR INJECTIONS TO NEWBORNS

PURPOSE: To place medication into the muscle without injury

1. Wash the infant's thigh if the bath has not yet been given. *Blood from the mother is present on the infant's skin. Washing prevents that blood from being carried into the infant's tissues during the needle insertion.*
2. Prepare medication for injection. Use a 1-mL syringe and a $\frac{3}{8}$ -in, 25-gauge needle. If the medication is in a glass ampule, use a filter needle to draw it up. Remove the filter needle, and place a 25-gauge needle on the syringe to give the injection. *Use of a filter needle prevents particles of glass from being drawn into the syringe. A small needle reaches the newborn's muscle but avoids the bone.*
3. Put on gloves. *Gloves protect the nurse from contamination by blood.*

4. Locate the correct site. The best site for newborn intramuscular injections is the vastus lateralis muscle. Divide the area between the greater trochanter of the femur and the knee into thirds. Give the injection in the middle third of the muscle, lateral to the midline of the anterior thigh. *The large vastus*

lateralis is located away from the sciatic nerve and the femoral artery and vein. The rectus femoris muscle is nearer to these structures and poses more of a danger. (Note: The gluteal muscles are never used until a child has been walking for at least a year. These muscles are poorly developed and dangerously near the sciatic nerve.)

5. Cleanse the area with an alcohol wipe. *Cleansing removes organisms and prevents infection.*
6. Stabilize the leg firmly while grasping the thigh between the thumb and fingers. *Holding the leg prevents sudden movement by the infant and possible injury.*
7. Insert the needle at a 90-degree angle. Inject the medication. *This places the medication into the muscle rather than into the subcutaneous tissue.*

8. Withdraw the needle, and apply gentle pressure to the site with an alcohol wipe. *Massaging promotes absorption of the medication.*
9. Discard the needle and syringe in the appropriate place, and comfort the infant. *The needle and syringe must be placed in the proper container to prevent injury or contamination to others. Infants must always be comforted after painful procedures.*

DRUG GUIDE

VITAMIN K₁ (PHYTONADIONE)

Classification: Fat-soluble vitamin, antihemorrhagic.

Other Names: AquaMEPHYTON, Konakion, Mephyton.

Action: Promotes the formation of factors II (prothrombin), VII, IX, and X by the liver for clotting; provides vitamin K, which is not synthesized in the intestines until intestinal flora necessary for vitamin K production are established.

Indication: Prevention or treatment of vitamin K–deficiency bleeding (hemorrhagic disease of the newborn).

Neonatal Dosage and Route: 0.5 to 1 mg (0.25 to 0.5 mL of solution containing 1 mg/0.5 mL) given once intramuscularly within 1 hour of birth for prophylaxis. May be delayed for breastfeeding in delivery room.

Absorption: Readily absorbed after intramuscular injection; effective within 1 to 2 hours; metabolized in the liver.

Adverse Reactions: Erythema, pain, and edema at injection site; anaphylaxis; hemolysis; or hyperbilirubinemia, especially in a preterm infant or when a large dose is used.

Nursing Considerations: Protect the drug from light until just before administration to prevent decomposition and loss of potency. Observe all infants for signs of vitamin K deficiency (ecchymoses or bleeding from any site). Check that the infant has had vitamin K before a circumcision is performed.

DRUG GUIDE

ERYTHROMYCIN OPHTHALMIC OINTMENT**Classification:** Antibiotic.**Other Name:** Ilotycin ophthalmic ointment.**Action:** Inhibits protein synthesis in bacteria; bacteriostatic.**Indications:** Prophylaxis against the organism *Neisseria gonorrhoeae*; helps prevent ophthalmia neonatorum in infants of mothers infected with gonorrhea; prophylaxis against gonorrhea, required by law for all infants, even if the mother is not known to be infected.**Neonatal Dosage and Route:** A “ribbon” of 0.5% erythromycin ointment, 1 cm (0.4 inch) long, is applied to the lower conjunctival sac of each eye within 1 hour after birth.**Adverse Reactions:** Burning, itching; irritation may result in chemical conjunctivitis lasting 24 to 48 hours; ointment may cause temporary blurred vision.**Nursing Considerations:** Do not rinse. Ointment may be wiped from the outer eye after 1 minute. Observe for irritation.

FIG 21-1 Administration of Ophthalmic Ointment. The nurse wears gloves and gently cleans the eyes of blood or vernix. Then, placing a finger and thumb near the edge of each lid, the nurse gently presses against the periorbital ridges to open the eyes, avoiding pressure on the eye itself. The tube is held horizontally as a ribbon of ointment is squeezed into each conjunctival sac from the inner canthus to the outer canthus. The tube should not touch any part of the eye. Use a new tube for each infant.

purulent, should alert the nurse to the possibility of infection. A culture may be ordered, and the drainage should be removed with sterile saline and a cotton ball. If the mother is infected, the infant needs additional antibiotics because routine prophylactic treatment may not completely prevent infection.

APPLICATION OF THE NURSING PROCESS

■ **Cardiorespiratory Status**

The transition from fetal life to neonatal life may include temporary problems in cardiorespiratory status.

Assessment

Assess the newborn for signs of difficult transition. Note the rate and character of the heart rate, pulses, respirations, and breath sounds. Look for signs of respiratory distress, including tachypnea, retractions, flaring of the nares, pallor or cyanosis, grunting, seesaw respirations, and asymmetry of chest movements. Check blood pressure, if indicated.

Nursing Diagnosis

Fluid from the lungs must be removed by absorption or drainage from the respiratory passages after birth. This does not happen immediately and may cause a temporary problem during the early hours after birth. The nursing diagnosis “Ineffective Airway Clearance related to excessive secretions in the respiratory passages” addresses this problem.

Expected Outcomes

The expected outcomes for this nursing diagnosis are that the newborn will:

1. Maintain a patent airway as evidenced by a respiratory rate within the normal range of 30 to 60 breaths per minute.
2. Show no signs of respiratory distress.

Interventions**Positioning and Suctioning Secretions**

Position the infant on the back with the head in a neutral position or to the side. Use the bulb syringe, as necessary, to suction secretions as they drain into the infant’s mouth or nose. Suction the mouth first because the infant may gasp when the nose is suctioned, causing aspiration of mucus or fluid in the mouth (Kattwinkel, 2011). Then, suction the nose gently and only if necessary. Suctioning is traumatic to the delicate tissues and may cause edema of the nasal passages.

Keep the bulb syringe in the crib near the infant’s head, where it is available if needed quickly. Teach both parents how to use the bulb syringe correctly (see Procedure 21-2). Send the syringe home with the infant so the parents can use it if the infant experiences a problem.

If mechanical suctioning is necessary to remove deeper secretions, choose a small catheter to avoid damaging the tissues of the respiratory tract. Suction for no more than 5 seconds at a time, using minimal negative pressure to avoid trauma, laryngospasm, and bradycardia. Apply suction only as the catheter is being withdrawn.

Providing Continuing Care

Continue monitoring the infant for problems throughout the stay in the birth facility. By the second period of reactivity, the infant may be alone with the mother. Although nurses know that regurgitation, gagging, and brief episodes of cyanosis are normal during this time, these may be very frightening to the mother.

Teach the appropriate responses to the behaviors common to this phase. Remind the mother to use the bulb syringe and call for help, if needed. Check frequently to see if the infant is having difficulty. Assess the parents’ ability to use the bulb syringe and their comfort with its use.

Evaluation

The normal newborn has little difficulty clearing the airway after the first few hours of life. The expected outcomes are met if:

- The respiratory rate is between 30 and 60 breaths per minute.
- The infant shows no signs of respiratory distress.

PROCEDURE 21-2 USING A BULB SYRINGE

PURPOSE: To provide an open airway by removing secretions or regurgitated feeding from the infant's mouth and nose

1. Position the infant's head to the side. *Positioning allows fluids to pool in the lower cheek.*
2. Compress the bulb before inserting it into the mouth. *This removes air from the syringe so that it will suction. (Do not compress the bulb while it is in the infant's mouth, or secretions in the bulb will be expelled back into the mouth.)*
3. Gently insert the tip of the syringe into the side of the infant's mouth between the gums and the cheek. Do not insert it straight to the back of the throat. *Inserting the bulb to the back of the throat could stimulate the gag reflex, causing regurgitation, or could cause a vagal response that results in bradycardia or apnea.*
4. Release the bulb slowly while it is in the infant's mouth. Remove and empty it by compressing several times before using again. *Releasing the bulb draws secretions into the bulb. Emptying it prepares it for use again.*
5. Suction the nose, only if necessary, after the mouth is suctioned. *Infants often gasp when the nose is suctioned and might aspirate secretions in the mouth if it is not cleared first.*
6. Suction the nose gently, and avoid unnecessary suction. *Trauma could cause edema and obstruction of delicate nasal passages. Infants have respiratory difficulty if nasal passages are blocked.*

CASE STUDY 21-1 INTRODUCTION

Nicholas, a full-term newborn, was delivered after his mother, Vicki, had a normal labor of 18 hours. Nicholas receives Apgar scores of 8 at 1 minute and 9 at 5 minutes. He weighs 3402 g (7 lb, 8 oz) and is 50 cm (20 inches) long. Vicki's pregnancy was normal; she is happy and excited about her first baby. Her husband Paul was with her throughout the birthing process.

*Continues on p. 420.

APPLICATION OF THE NURSING PROCESS

■ Thermoregulation

Because any neonate may have difficulty with thermoregulation, the nurse must identify problems and intervene to prevent complications related to this vital function.

Assessment

Assess the newborn's temperature shortly after birth and then according to agency policy. Generally, the temperature is assessed every half hour until it has been stable for 2 hours. It is checked again at 4 hours and then every 8 to 12 hours or according to agency policy. Assess the temperature more often if it is abnormal.

Nursing Diagnosis

Newborns often have temporary difficulty maintaining a stable temperature. Therefore, the appropriate nursing diagnosis is "Risk for Ineffective Thermoregulation related to immature compensation for changes in environmental temperature."

Expected Outcome

The expected outcome for this diagnosis is that the infant will maintain an axillary temperature within the normal range of 97.7°F to 99.5°F (36.5°C to 37.5°C).

Interventions

Preventing Heat Loss

Preparing the Environment before Birth. Begin preventive measures before the infant is born. Prepare a neutral thermal environment with a radiant warmer to use during initial assessments. This ensures that excess oxygen and glucose are not used to maintain body temperature. Check the radiant warmer to ensure that it is functioning properly. Turn it on early enough to warm the bed before the birth.

Providing Immediate Care. Immediately after birth, place the infant on the mother's abdomen to provide warmth from skin-to-skin contact or under a radiant warmer to counteract the cool temperature of the delivery room. Routine assessment and care can be performed while the infant is on the mother's abdomen, and breastfeeding can begin if the mother so desires and both mother and infant are stable. Infants placed skin-to-skin with the mother immediately after birth are more likely to have stable temperatures (Haxton, Doering, Gingras et al., 2012).

Dry the wet infant quickly with warm towels to prevent heat loss by evaporation. Pay particular attention to drying the hair because the head has a large surface area and hair that remains damp increases heat loss. Remove towels or blankets as soon as they become wet and replace them with dry, warmed linens. Cover the head with a cap when the infant is not under a radiant warmer. Do not use a hat when the infant is under the warmer because it interferes with transfer of heat to the infant's head.

When the infant is placed under a radiant warmer, set the servo-control (the mechanism that regulates the amount of heat produced) between 96.8°F and 97.7°F (36°C and 36.5°C) (Brown & Landers, 2011). This setting regulates the heat from the warmer to maintain the infant's skin temperature at the normal level. Attach the skin probe to the infant's abdomen to allow the warmer to monitor and display the infant's temperature continuously. Check frequently to see if the infant's skin temperature is increasing as expected.

Providing Ongoing Prevention. Warm objects that will come in contact with the infant to avoid conduction of heat away from the

infant's body. Pad cool surfaces such as scales or circumcision restraint boards before placing infants on them. Warm stethoscopes and clothing before using them. Before touching the infant, run warm water over your hands if they are cold.

To prevent heat loss by radiation in cold weather, position the newborn's crib or incubator away from exterior walls or windows of the building. These sources of heat loss are easily overlooked when the objects and air around the infant seem warm, but infants may lose heat to objects not in close contact with them. Keep this possibility in mind when positioning cribs in mothers' rooms, which are often short of space. Place the crib between the beds (in a two-bed room) or near the head of the mother's bed and away from windows or doors, if possible. Avoid areas with drafts such as those near hall doors or air conditioners. Keep traffic low around radiant warmers because movement increases air currents.

When assessing or caring for newborns, avoid exposing more of their bodies than necessary. Remove clothing and blankets only from areas being assessed. Keep the upper part of the infant's body covered when changing diapers. Wrap newborns in blankets, and place a stockinette or insulated hat on the infant to prevent heat loss from the large surface area of the head.

Restoring Thermoregulation

If an infant with a previously normal temperature develops a low temperature, institute nursing measures to assist thermoregulation immediately. If the axillary temperature is low, some nurses check the rectal temperature to determine core temperature. However, the process of nonshivering thermogenesis begins before the core temperature becomes abnormal. Core temperature changes indicate that the infant's thermoregulatory resources are exhausted. Nurses must intervene before this happens.

First, look for obvious causes. The blankets around the infant may have come loose or the infant's diapers or clothing may have become wet. The mother's room may be too cold, or the crib may have been placed near the air conditioner. These causes can be corrected easily.

A slight drop in temperature may only require placing the infant, dressed in just a diaper and hat, next to the mother's bare skin. This skin-to-skin contact is very effective in using the mother's body heat to warm the infant. Place a warm blanket over both mother and infant.

If skin-to-skin contact is not possible, add extra clothing. Put a shirt on the infant upside down by placing the legs in the sleeves for added warmth. Use two blankets, each wrapped separately around the infant, to increase insulation of heat by trapping air between the layers. Place another blanket over the infant in the crib and a hat on the infant's head. Warm linens in a warmer before use if more warmth is desired.

A greater drop in the infant's body temperature or a temperature that has not improved within an hour of using skin-to-skin contact requires additional measures. Place the infant under a radiant warmer for a short time. For an infant with a markedly decreased temperature, set the temperature control on the warmer to warm the infant slowly. Gradually increase the temperature until the infant's temperature is within the normal range. Warming the infant too rapidly can cause complications such as apnea (Sedin, 2011).

Performing Expanded Assessments

Expanded assessments are necessary whenever the body temperature decreases in a newborn. Assess the respiratory rate, and observe for signs of respiratory distress because nonshivering thermogenesis increases the need for oxygen.

Because the cold infant uses more glucose to produce heat, test the blood glucose when the temperature is abnormal, following agency

protocol. Help the mother to breastfeed or use formula. Ingestion of warm colostrum or breast milk helps warm the infant. Notify the physician or nurse practitioner if the infant does not respond to these measures. Place the infant under a radiant warmer or in an incubator for close observation until the temperature stabilizes. Because low temperature may be a sign of infection, look for other signs that might indicate sepsis (Sedin, 2011).

Evaluation

When the infant's body temperature has been maintained within the normal range for several hours, the infant can be considered stable in thermoregulation. Monitoring of thermoregulation continues throughout the stay in the birth facility.

2. How can nurses prevent heat loss in newborns?

APPLICATION OF THE NURSING PROCESS

■ Hepatic Function

The major early assessments and care of the hepatic system are related to blood glucose and bilirubin conjugation.

BLOOD GLUCOSE

Assessment

Assess all infants for risk factors and signs of hypoglycemia (see Chapter 20, pp. 395-396). Perform screening tests for blood glucose according to the signs exhibited and according to agency policy.

Nursing Diagnosis

For infants who have glucose levels below 40 to 45 milligrams per deciliter (mg/dL) (or the value according to agency policy), the diagnosis "Potential Complication: Hypoglycemia" is appropriate.

Expected Outcomes

Patient-centered outcomes for hypoglycemia are not created because this problem requires collaboration between the nurse and the physician. Agency protocols usually allow the nurse to intervene for hypoglycemia and then notify the physician of the infant's response. Planning revolves around the nurse's role, including the following:

1. Assessing for signs of hypoglycemia
2. Notifying the physician about signs of hypoglycemia or following hospital protocol for infants with hypoglycemia and then notifying the physician
3. Intervening to minimize hypoglycemia

Interventions

Maintaining Safe Glucose Levels

Follow agency policy and physician orders regarding feeding infants with low glucose levels. A common practice is to feed the newborn if the glucose screening shows 40 to 45 mg/dL or less to prevent further depletion of glucose. Infants with severe hypoglycemia may need intravenous feedings to provide glucose rapidly.

For most infants, breastfeeding or giving formula is sufficient. Glucose water alone is not recommended for newborns because the rapid rise in glucose results in increased insulin production, causing a further drop in blood glucose. Milk provides a longer-lasting supply of glucose.

CASE STUDY 21-1 NURSING CARE PLAN*

ASSESSMENT: Nicholas' temperature is stable during initial assessments, but later, the axillary temperature is 97.2°F (36.2°C). Vicki is eager to hold him and frequently unwraps him to admire him. She sometimes leaves the blankets off after changing a diaper. When reminded about the need to keep Nicholas warm, she states, "It seems hot in here to me. Won't he be too warm with so many blankets?"

NURSING DIAGNOSIS: Risk for Ineffective Thermoregulation related to parental lack of knowledge of newborn thermoregulation abilities and needs

EXPECTED OUTCOMES

1. Nicholas will maintain a temperature within the normal range of 97.7°F to 99.5°F (36.5°C to 37.5°C) axillary throughout his stay at the birth facility.
2. Vicki will verbalize and practice methods of preventing heat loss by the end of the first day.

INTERVENTIONS AND RATIONALES

1. Explain to Vicki why newborns have problems with thermoregulation. *When parents understand the reasons behind precautions they are more likely to practice them.*
2. Place Nicholas, who is wearing only a diaper and a cap, next to his mother's skin. Cover them both with a warm blanket. Continue teaching Vicki about thermoregulation while she holds her baby. *Skin-to-skin contact with the mother uses conduction to warm the infant. The mother needs adequate education about maintaining thermoregulation.*
3. Teach Vicki to keep Nicholas wrapped as much as possible unless she is holding him skin-to-skin. Show her how to look at him and change his diaper while exposing only small areas of his body at a time. *Exposing the skin to the surrounding air increases heat loss by convection and radiation.*
4. Teach Vicki to dry Nicholas promptly whenever he is wet, such as during bathing and when changing wet diapers or clothing. *Heat loss from evaporation occurs when the infant's skin is wet.*
5. Instruct Vicki to keep the infant's crib away from cold walls, windows, or drafts from air conditioners and open doors or windows. *Heat loss by radiation and convection occurs from exposure to cold objects or air drafts.*
6. Point out commonly used objects that may be cold when they touch Nicholas. Explain the effect of this contact, and suggest methods to warm them before use. *Heat can be gained or lost by conduction.*
7. Assess the infant's axillary temperature every 30 minutes until it has been stable for 2 hours. Report progress to Vicki. *Frequent assessment shows*

response to interventions. Keeping the parents aware of the infant's progress involves them in his care.

8. Check the blood glucose level according to facility routine if Nicholas becomes jittery or lethargic. If the blood glucose level is low, help Vicki breastfeed or use formula if she prefers. *Nonshivering thermogenesis may cause hypoglycemia. Feeding provides calories for heat production. Skin contact with the mother during breastfeeding helps warm the infant by conduction.*
9. Monitor for tachypnea or other signs of respiratory distress. Suction and administer oxygen, if needed. *Nonshivering thermogenesis increases oxygen need and work of the respiratory system, and may lead to hypoxia.*
10. If his temperature is still low or if he has repeated episodes of low temperature, place Nicholas in a radiant warmer or an incubator. Alert the physician or nurse practitioner if the problem continues. *Radiant heaters and incubators warm infants and can be adjusted according to their needs. Temperature instability is one sign of infection in newborns. The health care provider may order further tests for continued low temperature.*
11. When Nicholas is ready to go into an open crib, dress him in warmed clothes, and place two warmed blankets, wrapped separately, around him. After he is swaddled, place one or two blankets over him. *Warming clothing and blankets keeps Nicholas warm by conduction. Wrapping blankets separately traps air between layers, which acts as an insulating agent.*
12. Apply a stockinette or insulated cap over the infant's head. *Covering the head decreases heat loss from this large surface area.*
13. Remove extra blankets according to the infant's temperature. *Overheating increases oxygen and glucose consumption.*
14. After transfer to an open crib, assess the infant's temperature every 30 to 60 minutes until it remains stable. *Continued monitoring provides prompt identification of further problems that may develop.*
15. Teach Vicki how to wrap Nicholas and to expose only small areas of the body at a time when bathing or diapering him. Also, teach her how to take an axillary temperature at home. *Teaching increases parents' competence in infant care.*

EVALUATION: The infant's axillary temperature increases to 98.6°F (37°C). Nicholas has no further problems with temperature instability during his stay at the birth facility. Vicki is conscientious in using correct measures to keep Nicholas warm.

*Continued from p. 418; continues on p. 421.

Assist the breastfeeding mother with the first feeding. If she is unable to nurse the infant immediately (because of pain or exhaustion from delivery), feed the infant formula and help her breastfeed at the next feeding. Help formula-feeding mothers with positioning the infant and the bottle. Explain the need for prompt feeding in infants with hypoglycemia.

Repeating Glucose Tests

Until blood glucose is stable, closely observe newborns who have shown signs of hypoglycemia. Repeat glucose screenings may be performed according to agency policy. Keep the physician or nurse practitioner aware of the newborn's status. If the blood glucose does not remain at an adequate level, other causative factors are investigated. The infant may be transferred to an intensive care nursery for more treatment, including intravenous feedings, until the blood glucose is stabilized.

Providing Other Care

Watch for signs of other complications. Infants who do not have enough glucose may experience a drop in temperature that could lead to respiratory distress as oxygen is used for nonshivering thermogenesis. The parents will be distressed over the multiple heel sticks their infant must endure. Explain the importance of maintaining adequate blood glucose and why the tests and frequent feedings are necessary. Encourage parents to feed the newborn as instructed to provide glucose to meet the infant's needs. Discuss the plans for blood testing and criteria for discontinuing it.

Evaluation

In evaluating collaborative interventions for hypoglycemia, note the infant's response to interventions and the presence or absence of continued signs of hypoglycemia. The blood glucose should remain above 40 to 45 mg/dL.

CASE STUDY 21-1 CRITICAL THINKING EXERCISE*

Sue, an RN on the mother-baby unit, is caring for Vicki and Nicholas the next day. Both mother and baby have been doing well. As you enter the room after lunch, Vicki says, "My baby's hands and feet are so cold! His hands are shaky, too. Is he all right? Am I doing something wrong? I keep him covered up."

Questions

1. What are the nursing priorities in this situation?
2. What expanded assessments are necessary?
3. What interventions are necessary?
4. How will you respond to Vicki?

*Continued from p. 420; continues on p. 423.

BILIRUBIN

Because elevated bilirubin is common in newborns, be alert to situations that require intervention. Infants who need treatment for hyperbilirubinemia are discussed in [Chapter 30](#). Prevention, however, is an important aspect of care.

Assessment

Assess for jaundice by blanching the infant's skin on the nose or sternum. Assess for jaundice every 8 to 12 hours along with vital signs. Determine how far down the body the jaundice extends. Because visual assessment of jaundice is unreliable to determine the degree of hyperbilirubinemia accurately, obtain transcutaneous or serum bilirubin measurements in any jaundiced infant. Compare the results with what is expected for the infant's age and previous results.

Nursing Diagnosis

Hyperbilirubinemia may not occur until after discharge, especially if discharge was early. A nursing diagnosis for this situation is "Risk for Neonatal Jaundice related to lack of parental knowledge about hyperbilirubinemia."

Expected Outcomes

The expected outcomes for this diagnosis are as follows:

1. Parents will identify methods for preventing or reducing jaundice.
2. Parents will seek treatment if jaundice develops or worsens after discharge.

Interventions

Determine which infants are at increased risk for hyperbilirubinemia (see [Chapter 19](#), p. 378). Pay particular attention to preterm or late preterm infants because parents may not realize their increased risk for jaundice. Explain the significance of jaundice to parents and show them how to assess for color changes in the skin. Answer parents' questions about blood tests, phototherapy, and other care.

Discuss the importance of adequate feedings to stimulate passage of stools and prevent high levels of bilirubin. If a newborn is feeding poorly, determine the reasons, and intervene appropriately. Help mothers wake sleeping infants to feed, encourage them to spend extra time with the infant with a poor suck, and explain the appropriate amount to give at each feeding. Explain that giving water to jaundiced infants does not stimulate stool excretion and should be avoided.

If the infant is breastfeeding, evaluate the infant's suck and the mother's understanding of positioning and other techniques. Instruct mothers to nurse at least 8 to 12 times each 24 hours for adequate lengths of time. Assist mothers having difficulty to ensure infants are feeding well before discharge.

Instruct parents to contact their care provider if they see an increase in jaundice when they are at home or if the infant is not eating well, voiding at least six times daily by the fourth day, and producing stools appropriately (at least one stool per day for formula-fed infants and at least four stools daily for breastfeeding infants).

Stress the importance of making and keeping follow-up appointments with the infant's health care provider. Offer written materials about jaundice for the parents to take home. Provide materials in the parent's language, or provide an interpreter, if necessary.

Continue to check the infant for jaundice during early clinic or home visits. Transcutaneous or serum bilirubin levels may be used to determine the degree of jaundice. Reinforce teaching about identification of jaundice and importance of feedings and stooling. Answer questions that have occurred to parents since discharge from the birth facility.

If an infant develops true breast milk jaundice, explain it to the parents. The mother who must discontinue breastfeeding for 1 or 2 days will be very concerned. Reassure her that her milk is adequate and not harmful to the infant. Help her maintain her milk supply by using a breast pump during the time the infant is taking formula.

Evaluation

With proper nursing observation and parent teaching, infants with hyperbilirubinemia are identified early to allow for appropriate treatment and prevention of injury. Parents are able to discuss signs, prevention, and management of jaundice at home.

CHECK YOUR READING

3. What should the nurse do when an infant shows signs of hypoglycemia?
4. What are some interventions for preventing jaundice in newborns?

ONGOING ASSESSMENTS AND CARE

A complete assessment is necessary every 8 hours or according to birth facility policy, but the nurse should always watch for signs of change in the newborn's condition (see Appendix B for daily nursing activities for meeting newborn needs). Vital signs are assessed more often if they are abnormal. The infant is weighed once daily, and weight loss or gain is documented.

Providing Skin Care

The skin should be assessed for new marks or changes in old ones. Marks on the scalp may not be obvious if covered by abundant hair. To assess skin turgor, the nurse pinches a small area of skin over the chest or abdomen and notes how quickly it returns to its normal position. The return should be immediate in the normal newborn, with no "tenting." Skin that remains "tenting" (raised in the pinched position) is an indication of dehydration.

Bathing

The infant receives a bath to remove blood and amniotic fluid as soon after birth as the temperature is stable. A temperature of 98°F (36.7°C) or higher is often used to determine when to bathe the infant. Removal of all vernix is unnecessary. Early bathing decreases exposure to maternal blood and possible bloodborne organisms on the infant's skin. The bath is given before any invasive procedures such as injections or heel sticks that might draw organisms on the skin into the infant's tissues or bloodstream. If the skin must be punctured before the bath is given, the area is washed well first.

The infant may be bathed by immersion in a tub. Studies have shown that tub bathing does not increase infection or decrease cord healing. Infants maintain their temperatures better during tub bathing than during sponge bathing. To be kept warm, infants should be immersed in water that covers their shoulders. Water temperature should be approximately 100°F to less than 104°F (38°C to 40°C) (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2013).

If a sponge bath is given, it can be done with the infant under the radiant warmer to help maintain the infant's temperature. The bath should be performed quickly and the infant thoroughly dried to prevent heat loss by evaporation. While shampooing the hair, the nurse combs through it to remove dried blood. Combing the infant's hair hastens drying.

The infant remains under the radiant warmer until the hair is dry and the temperature returns to the previous level. The infant is dressed and wrapped in two warm blankets, and a cap is placed on the infant's head before he or she is removed from the radiant warmer. The temperature should be rechecked within 1 hour to ensure that the infant is maintaining thermoregulation adequately.

Bathing the infant in the presence of the parents allows the nurse to point out infant characteristics in addition to demonstrating the bath procedure. It is also a good time to teach parents about safety precautions.

After the initial bath, the infant may not receive another full bath during the stay in the birth facility. The skin is cleansed at diaper changes and to remove regurgitated milk. Clear water or a mild soap solution is used, according to agency policy.

EVIDENCE-BASED PRACTICE

The Newborn's First Bath

Thermoregulation is always a concern for newborns and particularly so for preterm infants. Bathing infants can lower temperature because of evaporative heat losses. Loring, Gregory, Gargan et al. (2012) studied the effect of the first bath after birth on thermoregulation for late preterm infants (born between 34 and 36½ weeks of gestation).

The authors used a randomized controlled trial including 100 late preterm infants in a well-baby nursery. The infants were healthy and without complications or previous problems with thermoregulation. They were randomly divided into two groups of 50 and received either an immersion tub bath or a sponge bath. Baths were given under warming lights in the nursery with the nearest door closed to prevent drafts. The temperature of the water used ranged from 100°F to 103.9°F. Tub baths were given in water that covered the infant's body from the shoulders down. Baths were limited to 10 minutes or less.

After the bath, the infants were dried and wrapped in warm linens, then diapered, dressed in a shirt and hat, and wrapped in 2 warmed blankets. The infant's axillary temperatures were taken 10 minutes before the bath, 10 minutes after the bath, and 30 minutes after the bath. If a postbath axillary temperature was less than 97.7°F the infant was placed back under the warmer.

Temperature measurements after the baths showed that infants who were tub bathed experienced significantly less variability in body temperature. They were warmer at 10 minutes and 30 minutes after the bath compared with infants who were sponge bathed.

Do you think the results of this study of late preterm infants would apply to full-term infants? How are infants bathed in your facility? What could be done to minimize heat loss for the infants you bathe?

Reference: Loring, C., Gregory, K., Gargan, B. et al. (2012). Tub bathing improves thermoregulation of the late preterm infant. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 41(2), 171-179.

Providing Cord Care

The cord should be checked for bleeding or oozing during the early hours after birth. The cord clamp must be securely fastened with no skin caught in it. Purulent drainage or redness or edema at the base indicates infection. The cord begins to dry shortly after birth. It becomes brownish black within 2 to 3 days and falls off within approximately 10 to 14 days.

Evidence-based practice guidelines show that cleaning the cord with water when necessary and keeping it clean and dry is the best method of cord care. This natural treatment of cords may shorten the time to cord separation and does not lead to increased infections (AWHONN, 2013). The diaper is folded below the cord to keep the cord dry and free from contamination by urine. The cord clamp is removed about 24 hours after birth if the end of the cord is dry (Figure 21-2). Although the base of the cord is still moist, there is no danger of bleeding if the end is dry and crisp.

Cleansing the Diaper Area

Because contact with body fluids is likely, it is important to wear clean gloves while changing diapers. Meconium is very thick and sticky and can be difficult to remove from the skin. Plain water or mild soap solutions may be used for cleaning the diaper area. If commercial

FIG 21-2 The cord clamp is removed when the end of the cord is dry and crisp. The clamp is cut (A) and separated (B).

diaper wipes are used, they should be free of detergent and alcohol (AWHONN, 2007).

Assisting with Feedings

The nurse must ensure the infant is eating well and that parents understand their chosen feeding method. This is particularly important for breastfeeding infants (see Chapter 22). A short period of observation at the start of feedings followed by another check during the feedings will help the nurse identify any problems that may have developed.

Positioning for Sleep

Parents need to understand how to position infants properly. Placing infants in the prone position for sleep is associated with an increased risk for sudden infant death syndrome (SIDS). The AAP (2011) recommends that mothers be taught to place infants on the back for sleep, as this position is associated with the lowest rate of SIDS. The side-lying position is not recommended because of the possibility that the infant may roll to the prone position. It is important for nurses to model correct positioning for sleep for parents. If parents see infants placed on the abdomen in the hospital, they are likely to use prone positioning when at home.

Parents should also be taught to use a firm sleep surface without bumper pads and to avoid loose or soft bedding that might interfere with breathing. Sacklike sleepers that take the place of blankets are available. The infant should not sleep in a bed or couch with another person. However, placing the infant's bed in the parents' room is recommended. Giving a pacifier when putting the infant to sleep is also recommended, but this may be delayed for 1 month in infants who are breastfeeding to help establish breastfeeding. Overheating during sleep should be avoided (AAP, 2011; Jana & Shu, 2011). See Chapter 23 for more information about SIDS.

Positioning and Head Shape

Infants who spend long periods in the supine position may develop flattening or asymmetry of the back of the head (positional plagiocephaly). This occurs because the bones are not fully developed and can be molded by positioning.

To prevent flattening of the head, infants should be placed on the abdomen several times each day while they are awake. This “tummy time” is an opportunity for play and interaction with the parents. It is essential that infants be supervised at all times when in the prone position and they should be moved to the supine position if they fall asleep.

Infants tend to turn their heads toward the center of the room or the door. Therefore, they should be placed toward alternate ends of the crib when put down to sleep. Changing the position changes the side of the head that receives the most pressure. For bottle feeding, infants should be held on alternating sides for feedings to vary pressure points on the head.

CASE STUDY 21-1 CRITICAL THINKING EXERCISE*

Vicki's mother-in-law comes to visit. When Sue enters the room to assess Nicholas, the grandmother says, “I always put my babies on their tummies to sleep, and they did just fine. Are you sure he should sleep on his back? Some babies get a flat head because they sleep on their back. I don't want that to happen to my grandson.”

Question

1. How should you respond to the grandmother?

*Continued from p. 421.

Protecting the Infant

Safeguarding the infant is a major nursing role. Primary ways nurses protect newborns are by (1) ensuring that infants always go to the correct parents, (2) taking precautions to prevent infant abductions, (3) preventing infections or recognizing early signs, and (4) preventing infant falls.

Identifying the Infant

Methods to identify the infant, mother, and a support person are used to ensure that an infant is never given to the wrong person. This type of mistake could result in interference with bonding, exposure to infection, lack of confidence in the reliability of the staff, and lawsuits.

Electronic devices or identification bands with imprinted numbers are used. The electronic device is designed to set off an alarm if removed or the infant is taken beyond a certain area of the facility. With some systems, all exits lock automatically if an alarm is activated. The devices or bands are used to identify the mother and the infant at any time the infant is brought to the mother after a period of separation, however brief (Figure 21-3). All staff must follow the facility protocol for identification of infants.

Other methods to identify infants include taking footprints of the infant and a fingerprint of the mother or photographs of the infant. Birthmarks or other distinguishing features are carefully documented in the nurses' notes. Cord blood may be used for deoxyribonucleic acid (DNA) analysis if the need for identification arises later.

Preventing Infant Abduction

An essential nursing role is protecting the infant from abduction (kidnapping). Between 1983 and 2012, 130 infants were abducted from health care facilities, 115 were abducted from homes, and 39 were abducted from other places. Many of the abductions from health care facilities (58%) were from the mother's room. Hospital abductions have also occurred from the nursery, from the pediatrics unit, and on hospital grounds. Infants have been safely returned to their parents in

FIG 21-3 The nurse unwraps the infant to compare the infant's identification band with the mother's band.

BOX 21-1 PRECAUTIONS TO PREVENT INFANT ABDUCTIONS

- All personnel must wear picture identification that is easily visible at all times. No one without appropriate identification should handle or transport infants.
- Enlist parents' help in preventing kidnapping. Teach them to allow only hospital staff with proper identification to take their infants from them.
- Teach parents and staff to transport infants only in their cribs and never by carrying them. Question anyone carrying an infant outside the mother's room.
- Question anyone with a newborn near an exit or in an unusual part of the facility.
- Be suspicious of anyone who does not seem to be visiting a specific mother, asks detailed questions about maternity or discharge routines, asks to hold infants, or behaves in an unusual manner.
- Be suspicious of unknown people carrying large bags or packages that could contain an infant.
- Respond immediately when an alarm signals that a remote exit has been opened or an infant has been taken into an unauthorized area.
- Never leave infants unattended. Teach parents that infants must be observed at all times. Infants may be taken into the bathroom with the mother, if necessary. Suggest that mothers have the nursing staff take care of the infant if the mother wants to nap or feels unwell and no family members are present.
- If infants need to be moved to another area, take one infant at a time. Never leave an infant in the hall while the nurse is in a room with another mother. Never leave an infant unsupervised.
- When infants are in mothers' rooms, position the crib away from the doorways, preferably on the side of the mother's bed opposite the door.
- Protect codes or card keys that allow entrance to maternity units or nurseries so unauthorized people cannot use them.
- When a parent or family member comes to a nursery to take their infant, always match the infant and adult identification. Never give an infant to anyone who does not have the correct identification.
- Alert hospital security immediately of any suspicious activity.
- Suggest that parents do not place announcements in the paper or signs in their yard that might alert an abductor that a new baby is in the home.

96% of the hospital abductions ([National Center for Missing & Exploited Children, 2012](#)).

Newborns are usually abducted by women who are familiar with the birth facility and its routines. Abductors often live near the birth facility. They usually visit more than one agency several times to learn the routines so that they can impersonate birth facility staff to gain access to a newborn. They often know the layout of the facility and the locations of exits well.

The profile of the abductor is a woman of childbearing age, often overweight, who may want an infant to solidify her relationship with her husband or boyfriend. She may be pretending to be pregnant, have had a previous pregnancy loss, or be unable to have a child of her own. Although the woman plans the kidnapping, she waits for an appropriate opportunity to take any infant available. She may wear a uniform to impersonate hospital staff and tell the parents that she is taking the baby to have a test performed ([Rabun, 2009](#)).

Many precautions are necessary to protect infants from abduction ([Box 21-1](#)). Staff members who are working temporarily on the unit must have a special means of identification that is recognized by parents and other staff members. Temporary identification badges are carefully monitored each shift so that none can be removed from the premises without alerting the regular staff.

FIG 21-4 The nurse uses a code to open the door to the nursery.

Written and verbal information, including a picture of identification badges worn by staff, should be given to parents. Parents must be cautioned never to give their infant to anyone who does not have proper identification. They should be encouraged to feel free to ask for identification at any time and praised for their actions. If they feel unsure about anyone asking to remove their baby, they should call the primary nurse for assistance.

People entering and leaving maternity units or nurseries should be observed at all times. Entrances are locked and equipped with video cameras and alarms. Visitors are required to press a call signal or use a telephone, and staff must use a card-key or a code to enter the unit ([Figure 21-4](#)). Visitors to maternity units may be checked in by security guards or other staff members and wear special visitor identification tags.

Staff must respond quickly whenever an alarm sounds. Although alarms usually are triggered accidentally, it is always possible that a kidnapper is using a remote exit for a quick getaway.

The nurse should make parents a part of the abduction prevention effort without frightening them. Infant abductions have taken place at parents' homes as well as in birth facilities. Parents should avoid public displays such as yard signs that might inform a kidnapper of the birth. Personal websites should not be easily accessible to the general public and should never include the infant's address.

Additional information about abduction is available for parents and professionals at the National Center for Missing and Exploited Children website, <http://www.missingkids.com>.

Preventing Infection

Because the newborn has a limited ability to combat infection, prevention is of utmost importance and constitutes a major part of parent teaching.

Many nursing actions help prevent infection. At the beginning of their shift, nurses wash their hands and arms thoroughly. Throughout the day, handwashing is important before and after touching any infant. It is essential not to handle one neonate and then another without washing the hands in-between. An infection that develops in one infant could quickly spread to others if these precautions are not taken.

A special disinfectant for cleansing the hands may be used in place of handwashing when the hands are not visibly soiled. Dispensers of the special disinfectant may be placed in each mother's room and at other locations throughout the unit.

To avoid cross-contamination, each infant's supplies are kept separate from those used for other infants. Supplies in drawers or

cupboards of each crib unit should be used only for that infant because they are likely to be touched by nurses giving care. Using them for another neonate could result in the transfer of infectious organisms.

The nurse should instruct parents and visitors to wash their hands before touching infants. Parents should be instructed to discourage visitors with colds or other infections from visiting the mother and the newborn at the birth facility or during the early weeks at home.

When the mother has an infection, the health care provider decides whether it is safe for the newborn to remain with her. Although mothers and infants may well share the same organisms, the infant of a mother who is acutely ill may need to stay in the nursery until the mother is no longer contagious and feels able to perform infant care. Often, the degree of the mother's fever is one of the determining factors. The separation of mother and infant should be as short as possible, of course, to promote attachment.

Nurses must be vigilant for signs of infection during assessment and care of the infant. These signs are often different from those in the older infant or child and may be subtle (see [Chapter 30, p. 663](#)). Instead of a fever, the infant's temperature may decrease. The infant may feed poorly, be lethargic, or have periods of apnea without obvious cause. Any change in behavior that is unexplained should be recorded and investigated. The same holds true, of course, for the more obvious signs of infection such as drainage from the eyes, cord, or circumcision site.

Preventing Infant Falls

Infant falls are another concern. They are most likely to happen when mothers are feeding infants during the night. Because the mothers are often exhausted, they may fall asleep, loosening their hold on the infant who then slips from the bed. Nurses should offer to help mothers who are very tired and encourage them to put infants into their cribs when they become sleepy. Checking frequently on mothers who are feeding during the night can reinforce this.

5. How can the nurse prevent a baby being given to the wrong parent?
6. What can nurses and parents do to prevent infant abductions?
7. What is the most important method of preventing infection in newborns?

CIRCUMCISION

In the United States, circumcision is the most common surgical procedure performed on males ([Swanson, 2009](#)). It is the removal of the prepuce (foreskin), a fold of skin that covers the glans penis. Although it can be retracted easily for cleaning in the older child, the prepuce may not be fully retractable until 3 to 6 years of age ([Smith, 2012](#)). The prepuce should never be forcibly retracted in any infant because trauma and adhesions can result.

Circumcision is a controversial issue, and parents may have questions about choosing it for their son. The AAP recently stated that the health benefits of circumcision outweigh the risks of the procedure but that the benefits are not so great that it should be recommended as a routine for all newborns. Parents should have access to circumcision if they decide to choose it for their infants ([AAP Task Force, 2012a](#)).

Reasons for Choosing Circumcision

The major benefits of circumcision are that it reduces penile cancer, urinary tract infections in the first year of life, human immunodeficiency virus (HIV) infection, and transmission of other sexually transmitted diseases ([AAP Task Force, 2012b](#)). Some parents choose

circumcision for religious, cultural, or social reasons. Jewish parents may have their infants circumcised on the eighth day after birth as part of a special ceremony. Muslims may also circumcise their sons ([D'Avanzo, 2008](#)). Some parents want their son to look like his circumcised father or peers. Others feel that circumcision is an expected part of newborn care and some do not realize that they have a choice in the matter.

Parents may be concerned that when the child is older, he might develop **phimosis**, a tightening of the prepuce, which prevents retraction and thus requires circumcision. Although the number of such cases is small, surgery after the newborn period involves hospitalization and anesthesia and can be psychologically disturbing to the young child.

Lack of knowledge about care of the prepuce leads to some circumcisions. Poor hygiene may increase the risk of infections and other problems. Teaching parents and children about proper care of the uncircumcised penis can prevent surgery and complications related to inadequate cleanliness.

Reasons for Rejecting Circumcision

Parents decide against circumcision for various reasons. Some parents believe that the incidence of conditions more common in uncircumcised males is too low to warrant the pain and risks associated with surgery. Others believe that having the infant circumcised to look like the father or peers is cosmetic surgery and therefore unnecessary. These parents especially object to subjecting their son to pain during and after surgery. Circumcision is less often practiced by families from Asian, Hispanic, and Native American cultures. It is less common in Europe, Asia, South and Central America, Canada, and Australia ([Swanson, 2009](#)).

Parents may be concerned about removing the prepuce, which serves to protect the glans. The glans is more prone to irritation from constant exposure to urine and rubbing against diapers when unprotected by the prepuce.

Complications of circumcision are rare but include hemorrhage and infection. Removal of too much or too little of the prepuce, an unsatisfactory cosmetic result, urinary retention, stenosis or fistulas of the urethra, adhesions, necrosis, or other injury to the glans penis may also occur.

Only healthy newborns should undergo circumcision. The preterm or sick infant should not be circumcised until he is healthy enough to tolerate the procedure. Infants with blood dyscrasias may experience excessive bleeding if circumcised. For the repair of anatomic abnormalities of the penis such as hypospadias or epispadias, an intact prepuce may be needed for use in plastic surgery.

Pain Relief

Relief of pain during circumcision is an important consideration. At one time, it was believed that newborns do not feel pain. It is now known that pain stimuli pass along fetal nerve pathways during the second and third trimesters of pregnancy. Pain responses include changes in vital signs, oxygen saturation levels, intracranial pressure, and catecholamine and cortisol levels. Infants may show irritability, altered sleep-wake states, and abnormal feeding patterns after the painful event ([Gardner, Enzman-Hines, & Dickey, 2011](#)).

The AAP recommends that adequate pharmacologic pain relief be given to newborns during circumcision ([AAP Task Force, 2012b](#)). A dorsal penile nerve block (anesthetic injected into the dorsal penile nerve) is a safe method to eliminate pain during circumcision. It has been found to be more effective compared with other methods of pain relief. EMLA (eutetic mixture of local anesthetics) cream may be applied to anesthetize the skin before the procedure, but it is less

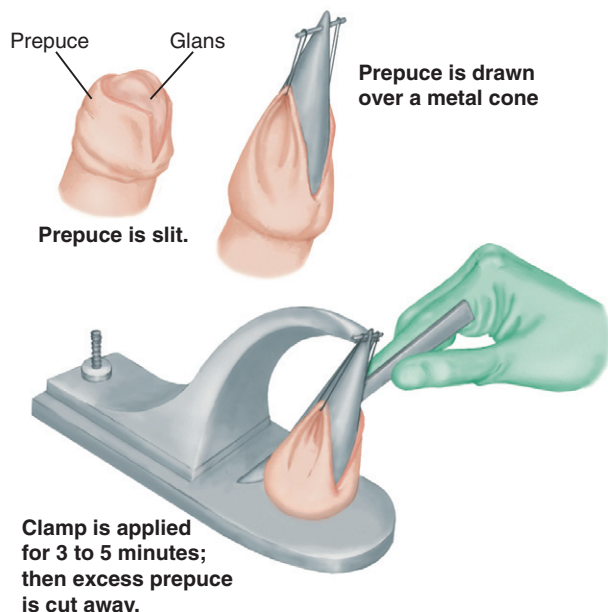

FIG 21-5 Circumcision Using the Gomco (Yellen) Clamp. The physician pulls the prepuce over a cone-shaped device that rests against the glans. A clamp is placed around the cone and the prepuce and tightened to provide enough pressure to crush the blood vessels. This prevents bleeding when the prepuce is removed after 3 to 5 minutes.

effective than anesthetic injection and requires a longer waiting period before it is effective. Acetaminophen may be given throughout the first day for postprocedure pain (Gardner et al., 2011).

Nonpharmacologic pain relief methods include pacifiers, oral sucrose, soothing music, recordings of intrauterine sounds, decreased lights, and talking softly to the infant. All have shown some success in reducing an infant's pain responses to circumcision but are not as effective as anesthetics. They are especially helpful at decreasing the stress of the procedure when combined with regional anesthesia. Pain and pain management in newborns is discussed further in Chapter 29.

Methods

The Gomco (Yellen) clamp (Figure 21-5) and the PlastiBell (Figure 21-6) are two devices used for performing circumcisions. In both methods, the prepuce is first separated from the glans with a probe and incised to expose the glans. A Mogen clamp may also be used for circumcisions, especially for ritual circumcisions of Jewish infants.

Nursing Considerations

Assisting in Decision Making

Ideally, parents decide about circumcision early in pregnancy on the basis of a careful consideration of risks and benefits. However, some parents are not well informed about circumcision. Although the physician is responsible for explaining the risks and benefits of circumcision to parents, the nurse may be asked to answer questions or clarify misconceptions.

Although nurses generally teach parents of circumcised infants how to care for the penis, they may not think about providing teaching for parents who decide against circumcision. Proper care of the intact penis should be included in the teaching plan for these parents and should be discussed with parents who are undecided about the procedure as well.

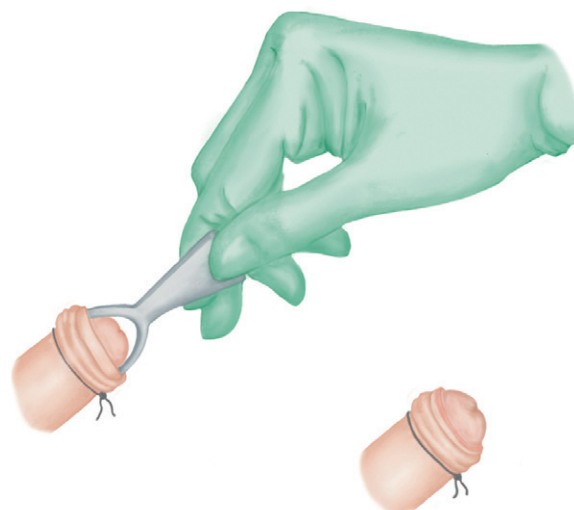

FIG 21-6 Circumcision Using the PlastiBell Ring. The physician places the PlastiBell, a plastic ring, over the glans, draws the prepuce over it, and ties a suture around the prepuce and the PlastiBell ring. This prevents bleeding when the excess prepuce is removed. The handle is removed, leaving only the ring in place over the glans.

PARENTS WANT TO KNOW

How to Care for the Uncircumcised Penis

- Wash your baby's penis daily and when soiled diapers are changed. Do not retract the foreskin because it does not separate from the glans (or end of the penis) for 3 to 6 years.
- Occasionally, gently pull back on the foreskin to see how much separation has occurred. However, *never* force the foreskin to retract because it would be painful and might cause bleeding, infection, and adhesions.
- As your son gets older and is able to take care of himself, teach him to wash under the foreskin by gently pulling it back as far as it retracts easily. This should become a part of his daily bath.

Nurses must be certain that their own biases about circumcision do not interfere with their ability to give objective information to parents. Once the parents reach a decision, the nurse should support it.

Providing Care during Circumcision

As with any surgical procedure, informed consent from parents is necessary before a circumcision is performed. The nurse sees that the consent has been signed, the infant is stable, and that vitamin K has been given to prevent excessive bleeding. The physician is informed of any problems that might impair the infant's ability to withstand circumcision.

The nurse gathers equipment and supplies before the procedure. To prevent regurgitation and possible aspiration while the infant is restrained in the supine position, feedings may be withheld for 2 to 4 hours before the procedure. A bulb syringe should be placed nearby in case suction is necessary.

When the physician and equipment are ready, the infant is placed on the circumcision board. This plastic holder is molded to fit the infant's body and has restraints for his arms and legs (Figure 21-7). A blanket is placed under the infant, and a surgical drape provides warmth and maintains sterility. A heat lamp or radiant warmer helps prevent cold stress.

FIG 21-7 The infant is placed on the circumcision board just before the procedure is begun.

The nurse should comfort the infant during the procedure. The physician administers the anesthesia. The nurse may provide a pacifier or sucrose, talk to the infant, or play soft music or recordings of intra-uterine sounds to help distract the infant from pain.

Evaluating Pain

Nurses should evaluate the infant's pain with one of the pain scales available for use with newborns. An example is the Neonatal Inventory Pain Scale (NIPS) (Lawrence, Alcock, McGrath et al., 1993). This scale measures facial expression, crying, breathing pattern, muscle tone of the extremities, and state of arousal. The infant's pain responses should be measured before, during, and after the procedure.

Providing Postprocedure Care

The infant should be removed from the restraints immediately after the circumcision is completed. If a Gomco clamp was used, the nurse squeezes petroleum jelly on the circumcision site to prevent the diaper from sticking to it. A small piece of gauze may be placed over the area. Petroleum jelly should not be used with a PlastiBell because it may cause the ring to be displaced. The diaper is attached loosely to prevent pressure. The infant should be comforted and returned to his mother, who may be anxious about her son.

The nurse watches carefully for signs of complications after the circumcision (Figure 21-8). The wound is checked frequently for bleeding during the first few hours after the procedure. If the infant is to be discharged after the circumcision, he should be observed for at least 2 hours before release (AAP & ACOG, 2012).

If excessive bleeding occurs, pressure is applied to the site. The nurse notifies the physician, who may apply Gelfoam or epinephrine or may suture the small blood vessels. Even a small amount of blood loss may be significant in an infant, who has a small total blood volume.

Noting the first urination after circumcision is important because edema could cause obstruction. If the infant goes home before voiding, the mother is instructed to call the physician if the baby does not urinate within 6 to 8 hours.

SAFETY ALERT

Signs of complications of circumcision include the following:

- Bleeding more than a few drops with first diaper changes
- Failure to urinate
- Signs of infection: fever or low temperature, purulent or foul-smelling drainage
- Displacement of the PlastiBell ring

FIG 21-8 An infant with a recently circumcised penis. (Courtesy of Cheryl Briggs, RNC, Annapolis, MD).

Teaching Parents

Because circumcision is often performed on the day of discharge, the parents take over care of the site. Each time the site is checked for bleeding, the nurse should show the parents the amount of blood on the diaper to help them understand how much to expect. The normal yellowish exudate that forms over the site should be described and differentiated from purulent drainage. Signs of complications should be discussed thoroughly with parents.

PARENTS WANT TO KNOW

How to Care for the Circumcision Site

- Observe the circumcision site at each diaper change, and check the amount of bleeding. Call the physician if more than a few drops of blood are present with diaper changes on the first day or any bleeding thereafter.
- Continue to apply petroleum jelly to the penis with each diaper change for the first 4 to 7 days or as directed by your pediatrician. If a PlastiBell ring was used, do not use petroleum jelly because it might make the ring fall off too soon.
- Keeping the circumcision site clean is important for healing. Squeeze warm water from a clean washcloth over the penis to wash it. Pat gently to dry the area. Fasten the diaper loosely to prevent rubbing or pressure on the incision site.
- Expect a yellow crust or scab to form over the circumcision site. This is a normal part of healing and should not be removed. The scab will fall off within 7 to 10 days. If a PlastiBell ring was used, the plastic rim will fall off in 10 to 14 days (AAP, 2011). If it does not fall off by that time or falls off sooner, notify your physician. Watch for signs of infection such as fever or drainage that smells bad or has pus in it. *Call your physician if you suspect any abnormalities.* The circumcision site should be fully healed in approximately 10 days.

8. What are the reasons parents decide for or against circumcision?
9. What information do parents need about care of the intact and circumcised penis?

APPLICATION OF THE NURSING PROCESS

■ Parents' Knowledge of Newborn Care

New mothers often feel anxious about taking over total care of their newborn. Mothers dealing with exhaustion and physiologic changes from childbirth may have difficulty remembering the extensive information they are given. Therefore, finding creative teaching methods is especially important. The nurse must use every contact with the parents as an opportunity for further teaching.

Assessment

Assess parents' changing learning needs throughout the birth facility stay. Consider the mother's and infant's physical conditions and any special concerns the mother may have.

Determine the learning needs of experienced mothers. They may be unaware of information that has changed since the birth of the last infant. For example, they may not know about the need for hepatitis B immunization for all infants. Concerns about helping other children adjust to the newborn may be especially important.

Assess the father's learning needs and his plans for involvement in infant care. Determine if there are cultural dictates about the father's participation in infant care. In some cultures, the father participates little in the care of the young infant. In other families, fathers actively participate in child care, even during the stay in the birth facility. They often have many questions and are eager to learn about care of their infant.

Nursing Diagnosis

A common nursing diagnosis for the family with learning needs is "Readiness for Enhanced Knowledge: Infant Care." See [Box 21-2](#) for other nursing diagnoses commonly used for newborns.

Expected Outcomes

The primary expected outcomes for this diagnosis are that before discharge the parents will:

1. Identify their own information needs and seek assistance from nurses to meet those needs.
2. Correctly demonstrate infant care.
3. Express confidence in their ability to meet their infant's needs.

Interventions

Determining Who Teaches

Several different nurses will care for the mother and infant during the time they are in the birth facility. Coordinate the teaching so that all

concerns are addressed. Many facilities use a checklist of major teaching topics to ensure that all important areas are covered ([Box 21-3](#)).

Setting Priorities

Because of the short time available for teaching, set priorities in determining what to teach. After assessing the parents' learning needs, make a teaching plan with them. Use a topic list to help them point out major concerns regarding infant care to ensure effective use of the precious teaching time. Begin by discussing their most pressing concerns to decrease anxiety so that they can concentrate on the information. Then, as time allows, proceed to other subjects.

Using Various Teaching Methods

Use a variety of teaching methods to increase effectiveness, make the subject more interesting, and increase retention of the material. Use verbal and written methods, demonstrations, and return demonstrations. Parents often learn best by seeing skills performed correctly and then practicing them while the nurse gives suggestions. To increase the likelihood that parents will follow instructions, explain the rationale for each point made during teaching sessions.

Discuss information with the mother alone or with her family members, roommate, or a group of mothers. Group teaching allows nurses to make more efficient use of time and allows mothers to learn from each other's questions. However, some women learn better with one-on-one teaching.

Use audiovisual materials, including pamphlets, magazines, DVDs, television programs, and Internet sites. Highlight the most important areas in written material, discuss the programs with the new mother, and clarify information, as necessary, to reinforce learning.

Many parents use the Internet to obtain information about child care. Suggest that they look for websites provided by well-known organizations such as the American Academy of Pediatrics (www.healthychildren.org). Warn them to be wary of sites with unclear sources or information that seems contrary to generally accepted knowledge. Suggest that they have their health care provider confirm the validity of the information if they are unsure about it. Commend

parents for their interest in obtaining information to increase their parenting skills.

Texts to cell phones are another source of information. One source that provides tips for infant care during the first year is Text4baby from the National Healthy Mothers Healthy Babies Coalition (see [Chapter 18](#), p. 366).

Modeling Behavior

Mothers watch closely when nurses handle infants. Nurses model mothering behavior by the way they hold, care for, and talk to infants. Modeling is particularly important for the mother with no experience in infant care.

Use every opportunity during general care of the infant to point out infant characteristics and behavior states and to model how to calm crying infants. Teach mothers to use progressive consoling interventions such as talking to the infant, folding the infant's arms across the chest, holding, swaddling, and facilitating sucking of the infant's finger or a pacifier. Point out the different behavior states and how to help infants move to a more awake state for feeding. Instruct parents to intervene before infants reach the point of frantic crying.

Teaching Intermittently

Plan teaching in small segments that are interspersed with infant care. Check the parents' understanding often. Encourage them to take over various tasks until they are performing all of the infant's routine care.

Including the Father

Identify fathers who would like to participate in the care of their infants but hesitate because they lack experience. Offer them the same teaching given to the inexperienced mother. Give praise liberally to increase confidence when the fathers practice their new infant care skills.

Documenting Teaching

Document all teaching performed and the parents' abilities to carry out infant care. This information shows other nurses what teaching has been completed and what is still needed. It also provides legal proof that teaching was completed before discharge.

Providing for Follow-Up Care

If the mother and infant will be seen by a clinic or home visit nurse, provide information about unmet learning needs. Reinforcement can then be provided at a time when the mother's memory has improved after the stress of birth.

Give as much information as possible in written form so that parents can refer to it later if they have concerns. Also, provide telephone numbers that they can call for further help. Offer written information in the parents' primary language, if possible. Even if they speak English as a second language, they may prefer to read the information in their native language.

Remind parents about timing of follow-up care. Suggest that they call early for an appointment so that the infant can receive care on time.

Incorporating Cultural Considerations

Consider the family's cultural beliefs about child care when teaching. Asian parents may be uneasy when caregivers are too complimentary about the baby or casually touch the infant's head. Mexican parents, however, may prefer that a person who compliments the infant touch the infant to ward off the *mal ojo* or "evil eye" ([Owen, Gonzalez, & Esperat, 2013](#)).

Women from India may tie a black thread around the infant's wrist, ankle, or waist to ward off evil spirits ([Grewal, Bhagat, & Balneaves,](#)

[2008](#)). Amulets may be placed on the baby or in the room by parents from Israel, Italy, Kuwait, Iran, Iraq, Malaysia, Greece, and Russia ([Spector, 2009](#)).

The baby may be named before the birth or as long as 30 days later, depending on the culture of the family ([Grewal et al., 2008](#)). Care of the cord differs in various cultures, too. Women from Mexico may strap a coin to the navel to keep it attractive ([Spector, 2009](#)). Other women may use a binder or belly-band or put a raisin or oil on the cord ([Callister, 2008](#)).

Ask the parents who will be helping them care for the baby to determine family members who should be included in the teaching. This varies according to the culture and availability of the traditional caregiver. In addition to the father of the infant, the woman's mother is often the major support person. However, in the Korean culture the husband's mother is the primary caregiver for both the infant and the mother in the early weeks ([Callister, 2008](#)). Family members of women from Vietnam, India, and Pakistan also care for the newborns so that the mother can rest ([Galanti, 2008](#)).

If the mother will not be the primary caregiver of the infant, she may appear uninterested in the instructions given by the nurse. Nurses must not assume that she is not bonding with her infant because she is following the role prescribed by her culture. Sometimes, a woman with other children appears to lack knowledge as she tries to assume care of her infant in the birth facility. The reason for this lack of knowledge may be that past caregivers are no longer available and the mother will have to assume infant care herself. These mothers will need more help than is usually given to experienced mothers.

Elicit questions during the discussions. However, be aware that women from some cultures will not ask questions. For many Native Americans, asking questions is considered rude. Other women may be too shy or uneasy about their limited English. When questions are not asked, discuss questions often asked by other parents.

Evaluation

Ongoing evaluation of parents' learning is necessary throughout the birth facility stay and during the follow-up home, clinic, or office visits. Determine whether the parents feel that their questions have been answered and they can demonstrate important aspects of infant care safely and correctly. As they learn more caregiving skills, they should verbalize more confidence in their abilities.

IMMUNIZATION

Immunization for hepatitis B is now included with other routine childhood vaccinations. Newborns of mothers with acute or chronic hepatitis B infection (hepatitis B surface antigen [HBsAg] positive) may become infected from exposure to the mother's blood at birth. Infected infants have a very high chance of developing chronic infection, which may later cause cancer or other serious liver disease.

These infants should receive both the vaccine and hepatitis B immune globulin (HBIG). HBIG provides passive immunity against hepatitis to protect infants until they develop their own antibodies and should be given within 12 hours of birth. The vaccine promotes antibody formation to protect infants from further exposure to the disease. The rest of the vaccine series is given in the health care provider's office or in a clinic.

Newborns of uninfected mothers also receive hepatitis B vaccine. It is often given during the stay in the birth facility but may also be given later in the pediatrician's office. A national voluntary standard for perinatal care is that all infants receive the appropriate hepatitis prophylaxis before discharge ([National Quality Forum, 2009](#)). Parents should be referred to their pediatrician for two more doses of the

PARENTS WANT TO KNOW

Techniques of Infant Care

This guide is written in language that the nurse might use when teaching parents about infant care. Adapt the subjects to meet the needs of individual parents.

Handling the Infant

Head Support

- An infant's head is the heaviest part of the body. Infants are unable to support the head when held in an upright position for the first few months of life. You must place one hand behind the infant's head to support it when you pick up or carry the baby.

Positions

- Most mothers hold the infant in the cradle position. For the "football" position, support the baby's head in the palm of your hand with the body held along your arm and supported against your side (see [Figure 22-4](#)). This position allows one hand to be free when washing the baby's hair or breastfeeding.
- The shoulder hold is good for burping the baby. Or sit the baby on your lap, and support the head and chest with one hand while gently patting or rubbing the infant's back with the other hand. This allows you to see the baby's face in case of spit-ups.

- Always place your baby on the back for sleep. This position is recommended by the American Academy of Pediatrics because it helps prevent sudden infant death syndrome (SIDS), the sudden unexplained death of an infant. The baby should sleep on a firm mattress and have no loose blankets or pillows in the bed. The baby should not sleep with anyone else. Use a pacifier when you put the baby down to sleep. If you are breastfeeding, you can wait 1 month to fully establish breastfeeding and then give the baby a pacifier.
- Place your baby on the abdomen for play when the infant is awake and will be observed. This "tummy time" helps the infant develop muscles in the back and neck and prevents flattening of the back of the head. If the infant becomes sleepy, change the position to lying on the back for safety during sleep.

Wrapping

- Young infants seem to feel secure when wrapped firmly in a blanket (swaddled). Fussy babies often respond well to swaddling. To swaddle the infant, turn down one corner of a blanket, and position the baby's head over the edge. Fold one side of the blanket over the body and arm. Bring the lower corner up, and fold it over the chest. Then bring the other side around the infant, and tuck it underneath snugly.

Normal Body Processes

Breathing

- Newborns normally breathe about 30 to 60 times a minute. Their breathing is irregular and may vary from loud to very soft. Sneezing is normal and not likely to be from a cold unless there are other signs.

Using a Bulb Syringe

- Use the bulb syringe if the infant has excessive mucus in the mouth or nose or spits up milk. Be very gentle, and use the bulb only if necessary. Squeeze the bulb before you gently insert the tip into the side of the mouth. Do not aim it to the back of the mouth as the baby might gag. Do not suction the nose unless necessary. Always suction the mouth before the nose. Extra mucus is common in the first days of life but is usually not a problem thereafter.
- Clean the bulb with soap and water. Rinse and dry well before using again. Call your physician if the baby's skin becomes blue or the baby stops breathing for more than 15 seconds, has difficulty breathing, or has yellow or green drainage from the nose.

Regulating Temperature

- Newborns have difficulty regulating their body temperature. If they become cold, they need more calories and oxygen than when they are warm. Dress your baby as you would like to be dressed. Add a light receiving blanket, except in very hot weather.

Using a Thermometer

- Check your baby's temperature during illness. Place the thermometer in the pit of the arm so that the bulb does not stick out the other side of the arm. Hold the arm firmly over the thermometer. Read it according to the manufacturer's directions. Call your physician if the baby has a temperature higher than 100°F (37.8°C) or lower than 97.7°F (36.5°C).

Urine Output

- Your baby will have at least one or two wet diapers a day during the first day or two and at least six wet diapers a day by the fourth day. Counting the number of wet diapers helps you know if the baby is getting enough milk. Call your baby's doctor if the baby has no wet diapers for more than 12 hours.

Stool Output

- Breastfed infants pass at least four soft, seedy stools that have a sweet-sour odor and are mustard yellow each day. Formula-fed infants pass one to several stools each day that are pale yellow to light brown and formed. Babies are not constipated when they turn red and seem to strain when passing a stool. Constipated stools are dry with small, hard pieces like marbles.

Diarrhea

- Babies with diarrhea pass more frequent stools that are greener and more liquid than usual. There may be a water ring, an area in the diaper where the watery stool has been absorbed, sometimes around an area of more solid stool. Call your physician if the infant passes more than two diarrhea stools because serious dehydration can occur very quickly in infants.

Skin Care

- A number of normal marks occur on the newborn's skin. A normal newborn rash called erythema toxicum resembles small insect bites or pimples. Small whiteheads called milia are normal and disappear without treatment. Do not squeeze them, or they may become infected. Newborns have dry, peeling skin that will be soft after peeling. Lotions or creams are unnecessary and may cause irritation.

PARENTS WANT TO KNOW—cont'd

Cord

- Clean the cord with plain water, if necessary, and keep it dry. Fold the diaper below it so that it is not wet by urine. The cord generally falls off in about 10 to 14 days. Some care providers suggest waiting for the cord to fall off before tub bathing, but others allow tub baths. Check with your health care provider. When the cord detaches, there may be a few drops of blood or a slight odor, which is normal. Notify your physician if you see more bleeding or signs of infection, such as redness, drainage, or a foul odor.

Diaper Area

- Clean the diaper area with each diaper change. For girls, separate the labia (folds), and remove all stool. Wipe the diaper area from front to back. Wiping back and forth may move stool into the vagina or urethra and cause an infection. For boys, wash under the scrotum to help prevent rashes. Changing the diaper frequently, avoiding commercial diaper wipes, and using absorbent diapers may help prevent diaper rash. If the diaper area becomes red, change the diaper more often. Leaving the diaper off to expose the area to air is also helpful. Petroleum jelly or a barrier-type zinc oxide ointment may be used. If redness persists, ask your baby's doctor for suggestions.

Bathing

- Because infants are washed as needed after they spit up and with diaper changes, baths are not necessary every day. Fathers often enjoy giving the infant a bath and make this their special time with the baby.

Sponge Baths

- Before the bath, gather all the supplies: a container or sink for warm water, washcloth, towel, baby shampoo, and clean clothes. Soap is not necessary for the young infant, but if used, it should be gentle and nonalkaline to protect the natural acids of the infant's skin.
- Give the bath in a room that is warm and free of drafts. Bathe the baby on a safe surface at a comfortable height for you. If you use a counter, pad it with blankets or towels.
- Never leave the infant alone on an unprotected surface, even for a moment. Keep one hand on the infant at all times to prevent falls. Avoid answering the phone during bath time to avoid distractions. If you must leave the room, take the baby along, or place the baby in the crib.
- Before fully undressing the baby, use the football position to shampoo the baby's head. Although the fontanel or "soft spot" may seem delicate, it is covered with a tough membrane and is not injured by washing. Pulse movements in the fontanel are normal. Dry the hair well to prevent heat loss.
- Keep the baby warm by uncovering only the area you are washing. Wash and dry one part of the baby's body at a time. Wash the face with clear water. Use a separate clean area of the washcloth to wipe across each eyelid and around each eye. Use a washcloth to clean in and around the ears, where milk may accumulate. Do not use cotton-tipped swabs in the infant's ears or nose, as injury may occur if the baby moves suddenly.
- To clean the neck folds, put one hand under the baby's shoulders and lift slightly to cause the head to drop back enough that the creases in the neck can be washed. Clean the diaper area last.

Tub Bath

- For a tub bath, use a plastic tub or a clean sink. Pad the bottom with a towel or foam pad to make it more comfortable and prevent the infant from slipping. Place enough warm water in the tub to cover the shoulders to prevent chilling. Wash the baby's face and hair before placing the baby in the tub. Keep the infant dressed until after the hair is washed to prevent chilling.
- It may be easier, at first, to lather the infant's body and then immerse the baby in the tub for rinsing. It is not unusual for infants to be frightened when

they are first put into the water. To help your baby adjust to this new experience, talk softly and calmly while holding the baby securely.

- Keep the bath short so the baby does not get cold. Dry quickly, dress, and wrap the infant in two blankets for a short while to help the baby maintain heat.

Feeding

- See [Chapter 22](#) for information on breastfeeding and formula feeding.

Behavior

Knowing infants' different behavioral states helps you learn about your baby's individual characteristics.

Sleep Phases

- During quiet sleep the infant sleeps soundly with quiet breathing and little movement. Your baby will not be disturbed by noises from appliances or other children at this time. In active sleep, the baby moves or fusses while still asleep. During the drowsy state, the baby is beginning to wake but may go back to sleep if not disturbed. However, if it is time for feeding or other activities, talk softly to help the baby awaken.

Awake Phases

- The quiet alert state is a good time for infant stimulation and "play time." The quiet alert state lasts only a short time, and infants often need a break from interaction. Signs of overstimulation are present if the infant turns the head away; begins to cough, sneeze, hiccup, or spit up; or becomes fussy. They show the infant needs a short quiet time.
- The active alert or "fussy" phase is a time when the infant may show hunger, discomfort, or fatigue. With intervention the baby may move back to the quiet alert state or eat and then go to sleep. If you do not intervene, the baby soon moves to the crying state.
- The baby may use self-consoling measures such as sucking on a finger. However, if these efforts are not effective, parents should comfort the infant quickly. Babies who cry too long may not respond at first to care activities. A few minutes of rocking and holding close may be necessary before the infant settles down.

Continued

PARENTS WANT TO KNOW—cont'd

Socialization

- Infants are social beings who enjoy contact with people. The baby should be part of family life. Use an infant seat or carrier to keep the baby near you and the rest of the family. Infants enjoy watching the human face. Hold your baby close, and talk to your baby to provide social stimulation.

Stimulation

- Babies respond best to gentle stimulation and enjoy a variety of types. They enjoy music that is not too loud. They focus their eyes best at a distance of

8 to 12 inches. Items such as mobiles should be placed within this range. Infants especially like black and white geometric figures and bright colors. Infants respond to gentle stimulation when they are in the quiet alert state. Do not try to use stimulation techniques with a fussy infant. Overstimulation causes the baby to be irritable and have difficulty going to sleep.

DRUG GUIDE

HEPATITIS B VACCINE

Classification: Vaccine.

Other Names: Engerix-B, Recombivax HB.

Action: Immunization against hepatitis B infection.

Indications: Prevention of hepatitis B in exposed and unexposed infants.

Neonatal Dosage and Route**Recombivax HB**

5 mcg

Engerix-B

10 mcg

The first dose of hepatitis B vaccine is given to newborns before hospital discharge. The second dose of vaccine is given at age 1 to 2 months. The third dose is given at 6 to 18 months (at least 16 weeks after the first dose)

Infants of HBsAg-Negative Mothers: The usual routine is followed.

Infants of HBsAg-Positive Mothers: The vaccine is given within 12 hours of birth along with hepatitis B immune globulin (HBIG), which is given at a different site. The usual routine is followed for the rest of the series. The infant should be tested for HBsAg and antibody to HBsAg after completing three doses of vaccine.

Infants of Mothers Whose HBsAg Status Is Unknown: The vaccine is given within 12 hours of birth and the mother is tested. If the HBsAg test is positive, the infant should receive HBIG as soon as possible and no later than 1 week of age. The usual routine is followed for the rest of the series. Give intramuscularly in the anterolateral thigh.

Absorption: Absorbed slowly; not affected by maternal antibodies.

Contraindications: Hypersensitivity to yeast.

Adverse Reactions: Pain or redness at site, fever, fatigue, headache.

Nursing Considerations: If a vial is used, shake the solution well before preparing. Give vaccine within 12 hours of birth to infants of infected mothers. Do not inject intravenously or intradermally. Obtain parental consent before administering.

vaccine after discharge (see Drug Guide: Hepatitis B Vaccine and Drug Guide: Hepatitis Immune Globulin [HBIG]).

NEWBORN SCREENING TESTS

Each year greater than 98% of the four million newborns in the United States undergo screening tests, and 12,500 are diagnosed with a problem (Centers for Disease Control and Prevention [CDC], 2012a). Prompt identification and treatment of these infants is essential. Each

DRUG GUIDE

HEPATITIS B IMMUNE GLOBULIN (HBIG)

Classification: Immune globulin.

Other Names: HBIG, Hep-B-Gammagee, HyperHEP.

Action: Provides antibodies and passive immunity to hepatitis B.

Indications: Prophylaxis for infants of hepatitis B surface antigen-positive mothers.

Neonatal Dosage and Route: 0.5 mL within 12 hours of birth if possible but no later than 1 week of age; given intramuscularly in the anterolateral thigh; should not be given intravenously.

Absorption: Absorbed slowly.

Contraindications: None known.

Adverse Reactions: Pain and tenderness at the site, urticaria, anaphylaxis.

Nursing Considerations: Do not shake or give intravenously. Hepatitis vaccine series should begin within 12 hours of birth. Give injections of vaccine and immune globulin at separate sites.

state determines which tests are performed, and they vary among states. Tests are performed before discharge from the birth facility to identify infants who need more complex diagnostic testing.

Critical Congenital Heart Defect Screening

It is essential that critical congenital heart defects (CCHD) be identified early after birth to prevent injury or death to infants. The AAP (2012) recommends pulse oximetry as a part of normal screening for all infants before discharge from the birth facility. The screening should be done on the right hand and either foot with motion-tolerant oximeters after the first 24 hours of life. An oximetry reading of 95% or less in either extremity or 3% or more absolute difference between the upper and lower extremity requires further testing.

Hearing Screening

In 2010, 97.9% of newborns were screened for hearing impairment, and 8.5% were found to have a hearing impairment (CDC, 2012c). Approximately 12,000 infants are born in the United States each year with hearing impairment (CDC, 2011). It is the most common congenital abnormality in newborns (Cunningham & Sydlowski, 2009).

Because early detection and treatment can prevent or reduce developmental delays and help the child communicate better, auditory screening of all newborns within the first month is recommended. Infants who do not pass the screening should be rescreened, and if they still do not pass, they should have audiologic and medical evaluations by no later than 3 months of age (AAP, 2012).

A goal of *Healthy People 2020* is to increase the proportion of newborns who are screened for hearing impairment by age 1 month, have audiologic evaluation by age 3 months, and are enrolled in appropriate intervention services by age 6 months (U.S. Department of Health and Human Services, 2010). To accomplish this goal, a screening test is usually given to infants before discharge from the birth facility.

Otoacoustic emissions and acoustic brainstem response tests are used for screening. The tests can be done while the infant sleeps. The nurse ensures that infants receive screening and explains the testing to the parents. An infant who fails the first screening is often retested in the birth facility. Parents of infants referred for further testing after discharge need more explanation and emotional support.

Other Screening Tests

Blood tests to screen for metabolic, hematologic, or genetic disorders are also performed. With early identification and treatment, infants with these conditions may avoid severe intellectual disability or other serious problems. Common disorders often included are phenylketonuria (PKU) (see Chapter 30), hypothyroidism, galactosemia, hemoglobinopathies such as sickle cell disease and thalassemia, and congenital adrenal hyperplasia.

Screening tests are easy and inexpensive. They require a blood sample taken from the infant's heel, and only one blood sample is needed for all tests. The tests are performed at 24 to 48 hours after birth. Further testing is necessary to confirm any abnormal test results.

Parents may have questions for the nurse about the purpose of the tests. A pamphlet with information about the tests may be given to parents. Nurses often refer to the tests as "PKU tests," but they should call them "screening tests" instead to emphasize that a number of conditions are included.

Tests performed within the first 24 hours of life are less sensitive than those performed after 24 hours. Infants tested before age 12 to 24 hours should have repeat tests at age 1 to 2 weeks so that disorders are not missed because testing was done too early (Drake & Gibson, 2010).

Commonly Screened Conditions

Phenylketonuria

PKU is a genetic condition in which the infant cannot metabolize the amino acid phenylalanine, which is common in protein foods such as milk. Although some phenylalanine is essential to growth, accumulations of it can result in severe intellectual disability. Treatment should be started by the third week of life (Braverman & Hamosh, 2009). PKU is treated with a special low-phenylalanine diet, in which the amount of the amino acid is carefully regulated. (See Chapter 30.)

Congenital Hypothyroidism

Congenital hypothyroidism occurs when the thyroid does not produce enough thyroid hormones, which affect the entire body. Symptoms in an untreated infant include a hoarse cry, large fontanel and tongue, slow reflexes, abdominal distention, lethargy, and feeding problems, and can lead to intellectual disability. Infants may have no signs in the early weeks, but early treatment with thyroid hormones is necessary to ensure normal growth and intellectual function.

Galactosemia

Absence of the enzyme necessary for the conversion of the milk sugar galactose to glucose causes galactosemia. The condition results in damage to the liver, increased susceptibility to infection, intellectual disability, and other developmental problems. Treatment includes a diet free of lactose and galactose. Long-term complications such as

delayed growth and neurologic impairment may occur even with treatment.

Hemoglobinopathies

Hemoglobinopathies include sickle cell anemia, thalassemia, and other disorders. The conditions are most often found in infants of African, Mediterranean, Indian, or South and Central American background. In sickle cell anemia, erythrocytes may become sickle shaped, resulting in obstruction of blood vessels and erythrocyte destruction. The hemoglobinopathies cause chronic anemias, sepsis, and other serious conditions.

Congenital Adrenal Hyperplasia

The term *congenital adrenal hyperplasia* refers to a group of disorders with an enzyme defect that prevents adequate adrenal corticosteroid and aldosterone production and increases production of androgens. Infants may have ambiguous genitalia or masculinization of female infants at birth. Salt-wasting crisis with low sodium and glucose and high potassium levels may occur within the first week of life. Treatment is administration of corticosteroids and mineralocorticoids for the remainder of the child's life.

Other Conditions

Screening may also be performed for maple syrup urine disease, biotinidase deficiency, homocystinuria, cystic fibrosis, and other conditions. Each of these conditions can be accurately diagnosed in newborns so that treatment can begin early. Knowing that many conditions are included in testing allows the nurse to explain its importance to the parents.

DISCHARGE AND NEWBORN FOLLOW-UP CARE

Discharge

Although state and federal legislation allows women and infants to stay in the birth facility for 48 hours after vaginal birth and 96 hours after cesarean birth, some women choose to go home earlier. The time of discharge varies according to the wishes and needs of the mother and the primary caregiver's assessment of conditions of the mother and baby.

Discharge is considered when term newborns who are appropriate for gestational age have normal physical examination results and show that they are making the transition from fetal to neonatal life without difficulty. Infants should have normal stable vital signs for the 12 hours before discharge, have fed successfully at least twice, passed urine and stool, and have no excessive bleeding at the circumcision site for at least 2 hours. Newborn laboratory and screening tests and evaluation for sepsis should have been completed. Hepatitis B vaccine should have been given or plans for administration made.

If infants have significant jaundice, plans for follow-up after discharge should be made, or the infant's discharge may be delayed. The mother should have received teaching about infant care and should demonstrate knowledge, ability, and confidence to provide adequate care to the newborn. An appropriate infant car seat should be available at discharge. Family, environmental, and social risk factors should have been assessed and plans made to safeguard the infant as necessary. The

family should have an adequate support system and have plans for continued care from a health care provider (AAP & ACOG, 2012).

Follow-Up Care

Care after discharge from the birth facility is very important. The AAP recommends that follow-up by a health care professional be provided

within 48 hours for all newborns who are taken home from the birth facility less than 48 hours after birth. This care can be provided in the home, clinic, or office (AAP & ACOG, 2012). Any infant who is breast-feeding or has other risk factors should be seen within the first week and usually within 2 to 3 days of discharge (Sullivan & Dela Cruz-Rivera, 2009). See Chapters 18 and 23 for more information about follow-up care.

SUMMARY CONCEPTS

- Prophylaxis against vitamin K–deficiency bleeding (hemorrhagic disease of the newborn) and ophthalmia neonatorum is necessary shortly after birth. It is provided by an injection of vitamin K and use of erythromycin ophthalmic ointment.
- Newborns may need help with clearing the airway. Positioning, suction, and close observation may be necessary.
- Nurses can prevent heat loss in newborns by keeping them dry and covered, avoiding contact between newborns and cold objects or surfaces, and keeping newborns away from drafts and exterior windows and walls.
- The nurse must identify actual or potential hypoglycemia and intervene appropriately.
- Important interventions for jaundice are to assess for its presence, to ensure that the infant is feeding well, and to explain the condition to the parents.
- Parents should be taught to place infants supine for sleep to prevent SIDS. Infants should have supervised periods of lying prone while awake each day.
- The nurse must prevent mistaken identification of infants by checking the mother's and infant's identification whenever they have been separated.
- Parents and nurses must work together to prevent infant abductions. Parents must know how to identify hospital staff. Nurses should be alert for suspicious behavior.
- Infection can best be prevented by scrupulous handwashing by staff and all who come in contact with newborns.
- Reasons parents may choose circumcision are to prevent certain conditions, for religious reasons, parental preference, or lack of knowledge about care of the foreskin.
- Parents reject circumcision because of belief that uncommon conditions do not necessitate surgery and pain in infants and concerns about the complications that can occur.
- Risks of circumcision include hemorrhage, infection, unsatisfactory cosmetic effect, urinary retention, urethral stenosis or fistulas, adhesions, necrosis, injury to the glans, and pain during and after surgery.
- Infants who are circumcised should have pain relief provided. Dorsal penile nerve block along with nonpharmacologic methods of pain relief such as oral sucrose are often used.
- Parents of uncircumcised infants should be taught not to retract the foreskin until it becomes separated from the glans later in childhood.
- Parents of circumcised infants should be taught signs of complications and how to care for the area.
- Every nursing contact with parents should be used as an opportunity to teach.
- Screening tests are commonly performed to rule out cardiac and hearing abnormalities, phenylketonuria, hypothyroidism, galactosemia, congenital adrenal hyperplasia, and hemoglobinopathies.

Infant Feeding

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Identify the nutritional and fluid needs of the infant.
2. Compare the composition of breast milk with that of formula.
3. Describe the benefits of breastfeeding for the mother and the infant.
4. Explain important factors in choosing a method of infant feeding.
5. Explain the physiology of lactation.
6. Describe nursing management of initial and continued breastfeeding.
7. Describe nursing assessments and interventions for common problems in breastfeeding.
8. Describe nursing assessments and interventions in formula feeding.

Infant feeding is an important part of parenting, and a woman may derive much satisfaction from her perception of success with feeding. Helping women choose and feel comfortable with a feeding method is an important nursing contribution that requires knowledge of the newborn's nutritional needs and the techniques to meet those needs.

NUTRITIONAL NEEDS OF THE NEWBORN

Calories

The full-term newborn needs 39 to 45 kilocalories per pound of body weight (kcal/lb) (85 to 100 kilocalories per kilogram of body weight [kcal/kg]) each day if breastfed and 45 to 50 kcal/lb (100 to 110 kcal/kg) if formula fed (Blackburn, 2013). The infant must consume sufficient calories to meet energy needs, prevent the use of body stores, and provide for growth.

Breast milk and formulas used for the normal newborn contain 20 kilocalories per ounce (kcal/oz). During the early days after birth, infants may lose up to 10% of their birth weight (Halbardier, 2010; Jones, Hayes, Starbuck et al., 2011). This loss is a result of normal excretion of extracellular water and meconium and newborns consuming fewer calories than needed. Newborns have a small stomach

capacity and may fall asleep before feeding adequately or may sleep through feeding times in the early days.

Infants should be evaluated for feeding problems if weight loss exceeds 7%, if weight loss continues beyond 3 days of age, or if the birth weight is not regained by 10 days of age in the term infant (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012). This information should be explained to parents.

Nutrients

Nutrients needed by the newborn are provided by carbohydrates, proteins, and fat in breast milk or formula. Full-term neonates digest simple carbohydrates and proteins well. Complex carbohydrates and fats are less well digested because of the lack of pancreatic amylase and lipase in the newborn. Vitamins and minerals are provided by both breast milk and formula.

Water

The newborn needs larger amounts of fluid in relationship to size than the adult because infants lose water more easily from the skin, kidneys, and intestines. The normal newborn needs approximately 27 to 45 milliliters per pound (mL/lb) (60 to 100 milliliters per kilogram [mL/

BOX 22-1 DAILY CALORIE AND FLUID NEEDS OF THE NEWBORN

Calories

39 to 45 kcal/lb (85 to 100 kcal/kg) if breastfed
45 to 50 kcal/lb (100 to 110 kcal/kg) if formula fed

Fluid

27 to 45 mL/lb (60 to 100 mL/kg) for the first 3 to 5 days of life;
gradually increasing to 68 to 80 mL/lb (150 to 175 mL/kg)

kg]) during the first 3 to 5 days of life (Box 22-1). This gradually increases to 68 to 80 mL/lb (150 to 175 mL/kg) a day (Halbardier, 2010). Breast milk or formula supplies the infant's fluid needs. Additional water is unnecessary.

BREAST MILK AND FORMULA COMPOSITION

Breast Milk

Breast milk is species specific (made for human infants) and offers many advantages compared with formula. The nutrients in breast milk are proportioned appropriately for the neonate and vary to meet the newborn's changing needs. Breast milk provides protection against infection and is easily digested. Maternal immunoglobulins, leukocytes, antioxidants, enzymes, and hormones important for growth are present in breast milk but are not available in formula.

Changes in Composition

The composition of breast milk changes in three phases: **lactogenesis** (the production of milk) stages I, II, and III.

Lactogenesis I. Lactogenesis I begins during pregnancy and continues during the early days after giving birth. At this time, the breasts secrete **colostrum**—a thick, yellow substance. Colostrum is higher in protein and some vitamins and minerals compared with mature milk. It is lower in carbohydrates, fat, lactose, and some vitamins. It is rich in immunoglobulins, especially secretory immunoglobulin A (IgA), which helps protect the infant's gastrointestinal (GI) tract from infection. Colostrum helps establish the normal flora in the intestines, and its laxative effect speeds the passage of meconium. Colostrum is sometimes referred to as “liquid gold” because of its many benefits (U.S. Department of Health and Human Services [USDHHS], 2011b).

Lactogenesis II. Lactogenesis II begins 2 to 3 days after birth. **Transitional milk**, milk that gradually changes from colostrum to mature milk, appears over about 10 days (Lawrence & Lawrence, 2011). The amount of milk increases rapidly as the milk “comes in.” Immunoglobulins and proteins decrease and lactose, fat, and calories increase. The vitamin content is approximately the same as that of mature milk.

Lactogenesis III. **Mature milk** replaces transitional milk during lactogenesis III. Because breast milk is bluish and not as thick as colostrum, some mothers think their milk is not “rich” enough for their infants. Nurses should explain the normal appearance of breast milk to mothers. Mature milk contains approximately 20 kcal/oz and nutrients sufficient to meet the infant's needs. It continues to provide immunoglobulins and other antibacterial components. Discussions of breast milk and its contents refer to mature milk unless otherwise stated.

Nutrients

The nutrients provided in breast milk are present in the amounts and proportions needed by the infant.

Protein. The concentrations of amino acids in breast milk are suited to the infant's needs and ability to metabolize them. Breast milk is high in taurine, which is important for bile conjugation and brain development. Tyrosine and phenylalanine levels are low in breast milk to correspond to the infant's low levels of enzymes to digest them (Lawrence & Lawrence, 2011). Milk proteins produce a lower solute load (the amount of nitrogenous waste and minerals excreted by the kidneys) for the infant's immature kidneys.

Casein and whey are the proteins in milk. Casein forms a large, insoluble curd that is harder to digest than the curd from whey, which is very soft (Riordan, 2010b). Breast milk is easily digested because it has a high ratio of whey to casein, especially in early lactation. Commercial formulas must be adapted to increase the amount of whey so that the curd is more digestible. A large amount of the protein in formula is not digested but passes in the stools (Eiger, 2009).

The body's immune system recognizes and may react to the protein in cow's milk, making it one of the most common allergens. Because breast milk is made for the human infant, it is unlikely to cause allergies. However, antigens in foods the mother has eaten may pass into her milk. If the infant reacts to the mother's diet, the offending food should be identified and eliminated. Foods in the mother's diet that may cause a problem for some infants include cow's milk or milk products, chocolate, cola, corn, citrus fruit, wheat, and peanuts (Bronner, 2010).

Studies have been inconclusive in determining if avoiding common antigens in the mother's diet will protect against allergies in the infant. General recommendations are that the infant be exclusively breastfed for at least 4 months and that allergic foods be avoided by the mother if her infant under 6 weeks of age has colic (List & Vonderhaar, 2010).

Carbohydrate. Lactose is the major carbohydrate in breast milk. It improves absorption of calcium and provides energy for brain growth. Other carbohydrates in breast milk increase intestinal acidity and impede growth of pathogens (Riordan, 2010b).

Fat. Fat provides 50% of the calories in breast milk (Kleinman, 2009). The fat in breast milk is more easily digested by the newborn than that in cow's milk. The amount of fat in breast milk varies during the feeding, between feedings, and on the same or different days. Hind-milk, the milk produced at the end of the feeding, produces satiety and helps the infant gain weight.

Triglycerides form the majority of fat content. Cholesterol and essential fatty acids such as the long-chain polyunsaturated fatty acids docosahexaenoic acid (DHA) and arachidonic acid (ARA) are also present. These nutrients are important for vision and for the growth of the brain and the nervous system.

Vitamins. Levels of vitamins A, E, and C are high in breast milk. The vitamin D content of breast milk is low and daily supplementation with 400 international units (IU) is recommended within the first few days of life (Wagner, Greer, & AAP Section on Breastfeeding and Committee on Nutrition, 2008; AAP & ACOG, 2012). Breastfeeding infants who are not exposed to the sun and those with dark skin are particularly at risk for insufficient vitamin D. Formula-fed infants who drink less than 1 quart of vitamin D–fortified milk per day should also be supplemented. Infants receiving adequate amounts of formula do not need added vitamin D because it is present in formula.

The presence of water-soluble vitamins in breast milk varies according to the mother's intake. The infant of a vegan mother may need supplementation with vitamin B₁₂.

Minerals. The casein protein in cow's milk interferes with iron absorption. Although the level of iron in breast milk is lower than that in formula, it is absorbed five times as well and breastfed infants are rarely deficient in iron (Riordan, 2010b).

The full-term infant who is breastfed exclusively maintains iron stores for the first 6 months of life (Lawrence & Lawrence, 2011). Generally, iron is added when the infant begins eating solids. Preterm infants need iron supplements earlier. All formula-fed infants should receive iron-fortified formula (AAP & ACOG, 2012; Holt, Wooldridge, Story et al., 2011).

Sodium, calcium, and phosphorus levels are higher in cow's milk than in human milk. This difference could cause an excessively high renal solute load if formula is not diluted properly. Fluoride supplements may be given starting at 6 months of age to improve dental health, depending on fluoridation of water in the area (AAP & ACOG, 2012; Kleinman, 2009).

Enzymes. Breast milk contains enzymes that aid in digestion. The amount of pancreatic amylase, necessary for digestion of carbohydrates, is low in the newborn but present in breast milk. Breast milk also contains lipase to increase fat digestion.

Infection-Preventing Components

Other factors present in human milk help prevent infection in the newborn. Bifidus factor promotes the growth of *Lactobacillus bifidus*, an important part of the intestinal flora that helps produce an acid environment in the GI tract. This protects the infant against infection from common intestinal pathogens.

Leukocytes present in breast milk also help protect against infection. Macrophages are most abundant and secrete lysozyme and lactoferrin. Lysozyme is a bacteriolytic enzyme that acts against gram-positive and enteric bacteria. Lactoferrin is a protein that binds iron in iron-dependent bacteria, preventing their growth. It also makes the iron in milk absorbed more easily. Giving infants supplementary iron may interfere with the effectiveness of lactoferrin (Riordan, 2010b).

Immunoglobulins are present in highest amounts in colostrum but also are present throughout lactation. Higher levels occur when the infant is born prematurely. Lymphocytes in the milk produce secretory IgA, which helps prevent viral or bacterial invasion of the intestinal mucosa, resulting in fewer intestinal infections. Infants who are breastfed have a decreased incidence of respiratory, GI, and urinary tract infections, otitis media, asthma, diabetes, some cancers, obesity, sudden infant death syndrome (SIDS), and necrotizing enterocolitis (Lawrence & Lawrence, 2011).

Effect of Maternal Diet

Although the fatty acid content of breast milk is influenced by the mother's diet, malnourished mothers' milk has about the same proportions of total fat, protein, carbohydrates, and most minerals as milk from those who are well nourished. Levels of water-soluble vitamins in breast milk, however, are affected by the mother's intake and stores (Lawrence & Lawrence, 2011). It is important for breastfeeding women to eat a well-balanced diet to maintain their own health and energy levels (see Chapter 9, p. 138).

Formulas

Commercial formulas are produced to replace or supplement breast milk. They are sometimes called "breast milk substitutes" or "artificial breast milk" because manufacturers must adapt them to correspond to

the components in breast milk as much as possible. However, an exact match is impossible. Changes in formula composition are made when a substance in human milk is found to be important enough to add to infant formulas. A variety of formulas, which differ in price and ingredients, is available.

Cow's Milk

Unmodified cow's milk (whole milk, low-fat milk, or fat-free milk) is not recommended for infants under 12 months of age. It contains too much protein, potassium, chloride, and sodium and lacks essential fatty acids, vitamin E, iron, zinc, and other nutrients (Kleinman, 2009).

Modified cow's milk is the source of most commercial formulas. Manufacturers specifically formulate it for infants by reducing protein content to decrease renal solute load. Saturated fat is removed and replaced with vegetable fats. Vitamins and other nutrients are added to simulate the contents of breast milk. Formula with added iron should be used for all infants receiving formula (AAP & ACOG, 2012).

Formulas for Infants with Special Needs

Soy formula may be given to infants with galactosemia or lactase deficiency and to those whose families are vegetarians. Soy milk is derived from the protein of soybeans and supplemented with amino acids. As many as 50% of infants allergic to cow's milk are also allergic to soy protein (Nguyen & Kerner, 2009). Protein hydrolysate formulas are better tolerated by infants with allergies. The protein is treated to make it less allergenic. The formulas are also used for infants with malabsorption disorders. Amino acid formulas are used for allergic infants who do not thrive on hydrolyzed protein formulas.

The preterm infant may require a more concentrated formula with more calories in less liquid. Modifications of other nutrients are also made. Human milk fortifiers can be added to breast milk to adapt it for preterm infants. Lactose-free formula uses primarily glucose instead of lactose for infants who do not tolerate lactose. Low-phenylalanine formulas are needed for infants with phenylketonuria (PKU), a deficiency in the enzyme to digest phenylalanine found in standard formulas.

CONSIDERATIONS IN CHOOSING A FEEDING METHOD

Many women decide on a feeding method well before the infant's birth. Some may not have questions about which method is best for them until late in pregnancy. Nurses can help undecided parents choose a method and gain confidence in feeding their infants.

For women who are undecided, nurses should explain the many benefits of breastfeeding for both mother and infant. However, nurses must be sensitive to mothers' feelings about feeding. Although nurses should encourage breastfeeding as the best method of feeding in most circumstances, they should be supportive of the mother's chosen method once a decision has been made. The early days of parenting are a very vulnerable time for new mothers, who may feel that their feeding abilities reflect their mothering abilities. The nurse's teaching and encouragement about the chosen feeding method are essential.

Breastfeeding

Mothers choose breastfeeding because it offers many advantages for the mother and the infant (Box 22-2). It has been increasingly recognized that formula feeding can never fully equal breastfeeding in terms of providing for the infant's optimal growth and development.

The American Academy of Pediatrics (AAP) recommends that infants receive only breast milk for the first 6 months after birth. Breastfeeding should continue until the infant is at least 12 months old

BOX 22-2 BENEFITS OF BREASTFEEDING**For the Infant**

- Allergies are less likely to develop.
- Immunologic properties help prevent infections.
- Decreased incidence of necrotizing enterocolitis and respiratory tract, ear, urinary tract, and gastrointestinal tract infections.
- Lower incidence of diabetes, asthma, obesity, some cancers, sudden infant death syndrome (SIDS).
- Composition meets the infant's specific nutritional needs.
- Nutritional and immunologic properties change according to the infant's needs.
- Easily digested, with nutrients that are well absorbed.
- Protein, fat, and carbohydrate occur in the most suitable proportions.
- No possibility of improper and potentially dangerous dilution.
- Unlikely to be contaminated, decreases growth of bacteria, not affected by water supply.
- Less likely to result in overfeeding.
- Constipation less likely.

For the Mother

- Oxytocin release enhances uterine involution.
- Mother loses less blood because of delayed return of menses.
- Resumption of ovulation delayed.
- Reduction in the incidence of some cancers.
- Mother more likely to rest while feeding.
- A balanced maternal diet that improves healing is more likely.
- Frequent skin-to-skin contact enhances bonding.
- Convenient: available, no bottles to wash or formula to buy, prepare, or heat.
- Economical: eliminates cost of formula and bottles and time spent in preparation.
- Infant is less likely to be ill, reducing medical care costs.
- Working mothers miss fewer days of work to care for sick infants.
- Travel easier: no bottles to prepare, carry, refrigerate, and warm.

with the addition of complementary foods (AAP, 2012). Breastfeeding and support to help mothers achieve it are also recommended by the American Dietetic Association (2009) and the U.S. Surgeon General (USDHHS, 2011a).

A goal set by the U.S. Department of Health and Human Services (USDHHS) for the year 2020 is for 81.9% of all infants to be breastfed at some time, for at least 60.5% to be breastfeeding at 6 months, and 34.1% at 1 year. Additional goals are to increase the number of mothers who exclusively breastfeed their infants through 3 months to 44.3% and through 6 months to 23.7% (USDHHS, 2010). One study found that if 90% of women breastfed exclusively for 6 months, the United States would prevent 911 infant deaths and save \$13 billion per year in health care costs (Bartick & Reinhold, 2010).

The Centers for Disease Control and Prevention (CDC, 2012) reports that in 2009 76.9% of infants were ever breastfed. At 6 months, 47.2% of mothers were breastfeeding and at 12 months the rate was 25.5% breastfeeding. These statistics show a gradual but steady increase over previous years, but continued improvement is needed.

In an effort to promote breastfeeding, the United Nations Children's Fund (UNICEF), the World Health Organization (WHO), and the U.S. Surgeon General advocate that birth facilities become certified as "baby-friendly" hospitals with policies to actively encourage breastfeeding. Guidelines to becoming certified as a baby-friendly hospital emphasize education of staff and parents about breastfeeding, early initiation of breastfeeding, demand feedings, rooming-in, no pacifiers,

and avoidance of formula unless medically indicated. In 2012, 6.7% of U.S. hospitals are certified as baby-friendly (Baby Friendly, USA, 2012). (More information is available at www.babyfriendlyusa.org.)

The Joint Commission has issued a brochure titled "Speak Up" for women who want to breastfeed. They encourage mothers to ask for help with breastfeeding. Skin-to-skin contact, breastfeeding as soon as possible after birth, and avoidance of formula or water unless medically indicated are emphasized. The brochure is available at www.jointcommission.org/speakup_breastfeeding.

Formula Feeding

Parents choose formula feeding for many reasons. Some women are embarrassed by breastfeeding, seeing their breasts only in the sexual context. Many mothers have few relatives or friends who have had breastfeeding experiences. A woman may feel a need to maintain a strict feeding schedule and be uneasy not knowing exactly how much milk the infant consumes at each feeding. Her partner or mother may not be supportive of breastfeeding. Occasionally, a woman must take medications that might harm the infant. A frequent reason mothers choose formula feeding instead of breastfeeding is lack of understanding and education about the two methods.

Combination Feeding

Some parents prefer a combination of breastfeeding and formula feeding. Unless medically indicated, it is best to delay giving formula until lactation has been well established when the infant is 3 to 4 weeks of age. Giving formula to breastfeeding infants leads to a decrease in breastfeeding frequency and milk production, making successful breastfeeding less likely (AAP & ACOG, 2012; Newton, 2012). If the mother chooses combination feeding, however, the nurse should be supportive so that the infant receives the benefits of breast milk at least part of the time.

The mother may give a bottle each day or only occasionally, such as when a babysitter is with the infant. Some mothers feel this allows them to be away from the infant for longer periods, yet allows the closeness with the infant they enjoy and the physical advantages of breastfeeding to continue. Either breast milk or formula may be given in the bottle feedings.

Factors Influencing Choice

Many factors influence a woman's choice of feeding method. These factors must be considered when educating women about their choices.

Support from Others

Family members and friends may share in the decision-making process. Women with a support system are more likely to begin breastfeeding and continue longer than those without a perceived support system (Brand, Kothari, & Stark, 2011). The woman's partner and the baby's grandmothers are often important influences in determining whether women breastfeed (USDHHS, 2011a). Advice from friends who have breastfed may also influence the woman's decision. The woman with little support or active discouragement from her family is more likely to have a difficult time breastfeeding. Some women choose not to breastfeed because of their partner's objection.

Involvement of the father in infant care is important in some families, and some may think it is possible mainly with feedings. Nurses can suggest other ways fathers can participate in infant care, for example, holding, rocking, and bathing infants. Educating family members about the advantages of breastfeeding may lead to their encouragement and support as well.

Prenatal classes that include breastfeeding information may help a woman decide to breastfeed and may help her develop confidence that

she will be successful. Fathers should also attend the classes so that they can learn techniques to help cope with any difficulties that might occur. Some breastfeeding classes just for fathers are available. Both prenatal classes and new mother support groups led by lactation consultants are associated with higher breastfeeding rates at 6 months postpartum (Rosen, Krueger, Carney et al., 2008).

Encouragement from the woman's health care provider may be a powerful influence in the woman choosing to breastfeed (Newton, 2012). The support the mother receives from the nursing staff plays a significant part in whether she feels comfortable with her choice of feeding method. The mother who does not feel confident in her ability to breastfeed before she leaves the birth facility is less likely to continue breastfeeding if she encounters difficulties at home.

Other support is also important. *Doulas*, trained lay-women who make home visits to assist women with breastfeeding after discharge, have been shown to increase the rate of breastfeeding at 6 weeks postpartum (Nommsen-Rivers, Mastergeorge, Hansen et al., 2009). One study of African-American women found that breastfeeding self-efficacy, a woman's belief that she will be able to breastfeed successfully, was associated with a longer period of breastfeeding and more exclusive breastfeeding at 1 and 6 months postpartum (McCarter-Spaulding & Gore, 2009).

Culture

Cultural influences may dictate decisions about how a mother feeds her infant. Women who are most likely to breastfeed are Asian, Pacific Islander, or Hispanic. Those with the lowest breastfeeding rates include women who are non-Hispanic black (USDHHS, 2011a).

However, immigrants from countries in which breastfeeding is the norm may breastfeed for shorter durations or not at all because they lack the support system they had in their own country. Hispanic women who are new immigrants are more likely to begin breastfeeding and continue for a longer period than more acculturated immigrants (Gill, 2009).

Some women may think that formula feeding is the preferred method in the United States because it is available in birth facilities. They may also believe breastfeeding is inferior to formula feeding and consider formula a way to help their infants grow larger and become stronger. Nurses must emphasize the superiority of breastfeeding and encourage these women to continue their cultural tradition of breastfeeding.

Nurses should be particularly watchful for ways to help mothers from other cultures wishing to breastfeed but fail to do so because of lack of support. Some Southeast Asian, Hispanic, and Arab women are hesitant to breastfeed in the birth facility and prefer to wait until they are home and the milk comes in. Mexican women may believe colostrum is bad because it is old milk, and they may delay breastfeeding until they go home. They may express colostrum and discard it before they begin to breastfeed the infant. This practice may be caused by modesty about breastfeeding in front of others in the birth facility as well as lack of understanding about the value of colostrum. Women from Laos believe colostrum causes diarrhea (Spector, 2009). Nurses should educate mothers about the importance of giving colostrum to their infants.

Rituals may be important to some woman. Women from the Philippines may participate in *lihi*, a ritual of stroking the breasts with papaya leaves and sugar cane stalks to ensure adequate rich milk (Wambach & Riordan, 2010). Hispanic women may believe that they can transmit negative emotions to their breastfeeding infants. Navajo women may believe they pass maternal attributes and model good behavior by breastfeeding (Kleinman, 2009).

Some mothers who plan to wait until after discharge to begin breastfeeding may be amenable to breastfeeding the infant with help while in the birth facility, especially if the antibody and laxative properties of colostrum are explained. Breastfeeding involves a learning process for both mother and infant, which is best started where assistance is available. Nurses can help women learn by offering to help them "practice" breastfeeding at least a few times before discharge. This helps build the woman's confidence and allows for early identification and correction of problems.

If the mother is firm in her desire to wait until discharge to begin breastfeeding, nurses can teach her what she will need to know when she goes home and refer her to sources of help should she need it. Cultural values about feeding, as in other areas of health care, must be respected.

Employment

The need to return to roles outside the home soon after giving birth may cause concern about feeding methods. Unfortunately, returning to work or school is a major cause of discontinuation of breastfeeding. The mother may choose formula from the beginning, plan a short period of breastfeeding before weaning the infant to formula, or use a combination of breastfeeding and bottle feeding with breast milk or formula.

The nurse should encourage women to continue to breastfeed when they return to work and point out the advantages. The decreased incidence of illness in breastfed infants means mothers are less likely to miss work to care for a sick infant. This is an advantage for the employer as well as the breastfeeding family.

Nurses who provide practical information about options, breastfeeding and working, use of breast pumps, and storage of breast milk help a mother continue breastfeeding for a longer period. Pamphlets and books for the working breastfeeding mother are particularly helpful. Referral to a lactation consultant can provide a mother with continued education and support after she goes home.

Staff Knowledge

It is important that all birth facility staff members have education about how to help women breastfeed and not provide inaccurate or conflicting information to new mothers. Educational programs are effective in helping to ensure that all staff have the same basic knowledge and skills to help breastfeeding mothers. Programs may involve formal classes, protocols, and self-paced learning modules (Bernaix, Beaman, Schmidt et al., 2010; Mellin, Poplawski, & Gole, 2011).

Other Factors

Other factors may also influence a woman's decision. Her knowledge and past experience with infant feeding are important. Modesty may be an issue for some women who are concerned about breastfeeding in public situations.

Women who receive assistance from the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), those with less than a high school education, and those who live in rural areas or the southeastern United States have lower breastfeeding rates compared with other women (USDHHS, 2011a). One study found that women were more likely to breastfeed exclusively in the hospital if they began prenatal care in the first trimester and had expressed an intention during pregnancy to breastfeed exclusively. Women who were overweight or obese were half as likely to breastfeed exclusively during the hospital stay (Tenfelde, Finnegan, & Hill, 2011).

NORMAL BREASTFEEDING

The anatomy and physiology of the breast are discussed in [Chapter 4](#), and breast changes occurring in pregnancy are discussed in [Chapter 7](#) (see [Figures 4-8](#) and [7-3](#)).

Breast Changes during Pregnancy

Breast changes begin early in pregnancy in preparation for the production of milk. The ducts, lobules, and alveoli develop in response to the hormones estrogen, progesterone, human chorionic somatomammotropin (hCS), and prolactin. Prolactin levels are high but milk production is prevented by estrogen, progesterone, and hCS, which inhibit breast response to prolactin. Colostrum is present by 16 weeks of gestation ([Bond, 2011](#)).

Changes, such as increase in breast size, indicate that the breasts are responding adequately to hormonal stimulation in preparation for lactation. Women who have no breast changes during pregnancy may have more difficulty with lactation. Seeing a lactation consultant may be helpful for these women.

Milk Production

Milk is produced in the alveoli of the breasts through a complex process by which materials from the mother's bloodstream are reformulated into breast milk. Thus, amino acids, glucose, lipids, enzymes, leukocytes, and other materials are used to manufacture the nutrients needed by the infant.

The milk is ejected from the secretory cells of the alveoli into the alveolar lumen by contraction of the myoepithelial cells. From there, it travels through the lactiferous ducts to the nipple. The infant compresses the areola during breastfeeding to move a stream of milk through pores in the nipple ([Blackburn, 2013](#)).

Hormonal Changes at Birth**Prolactin**

At birth, loss of placental hormones results in increasing levels and effectiveness of prolactin and activates milk production. The tactile stimulation of **suckling** and the removal of colostrum or milk cause continued increased levels of prolactin. Prolactin is secreted at the highest levels with suckling and during the night ([Lawrence & Lawrence, 2011](#)). Levels are high during the early months and then gradually decrease until weaning.

Oxytocin

Oxytocin increases in response to nipple stimulation and causes the **milk-ejection reflex** or **let-down reflex**, the release of milk from the alveoli into the ducts. During feeding, the milk-ejection reflex occurs several times. Some mothers have a tingling sensation of the breast when the let-down occurs.

When mothers see, hear, or think about their infants, they often have an increase in oxytocin, resulting in let-down of milk, causing milk to drip or spurt from the breasts. Pain or lack of relaxation can inhibit oxytocin release. Oxytocin also causes the uterine contractions mothers may feel at the beginning of breastfeeding sessions. These contractions are beneficial because they hasten involution of the uterus ([Figure 22-1](#)).

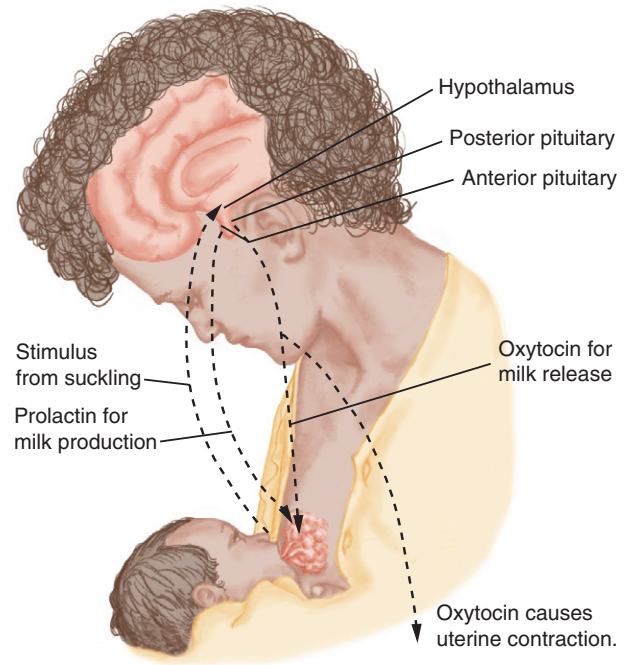

FIG 22-1 Effect of Prolactin and Oxytocin on Milk Production. When the infant begins to suckle at the breast, nerve impulses travel to the hypothalamus, causing the anterior pituitary to secrete prolactin to increase milk production. Suckling causes the posterior pituitary to secrete oxytocin, producing the let-down reflex, which releases milk from the breast. Oxytocin also causes the uterus to contract, which aids in involution.

Continued Milk Production

The amount of milk produced depends primarily on adequate stimulation of the breast and removal of the milk by suckling or a breast pump, which causes production of prolactin. This “supply-and-demand” effect continues throughout lactation. Early and frequent suckling may increase prolactin receptors in the breast, making milk production more effective. Therefore, increased demand with more frequent and longer breastfeeding results in more milk being available.

If milk (or colostrum) is not removed from the breasts, components in the milk cause a feedback that decreases prolactin secretion and milk production. The milk in the ducts is absorbed, the alveoli become smaller, the cells return to a resting state, and milk production ends.

Preparation of Breasts for Breastfeeding

Little preparation is needed during pregnancy for breastfeeding. The mother should avoid applying soap on her nipples because it removes the natural protective oils secreted by the Montgomery tubercles of the breasts. The use of creams and nipple rolling, pulling, and rubbing to “toughen” nipples does not decrease nipple pain after birth and may cause irritation or uterine contractions from release of oxytocin.

Breasts should be assessed during pregnancy to identify flat or inverted nipples ([Figure 22-2](#)). Normally, nipples protrude. Flat nipples appear soft, like the areola, and do not stand erect unless stimulated by rolling them between the fingers. Inverted nipples are retracted into the breast tissue. Both conditions make it more difficult for infants to **latch** (attach) onto the nipples.

Some nipples appear normal but draw inward when the areola is compressed in the infant's mouth. Compressing the areola between the thumb and forefinger determines whether the nipple projects normally

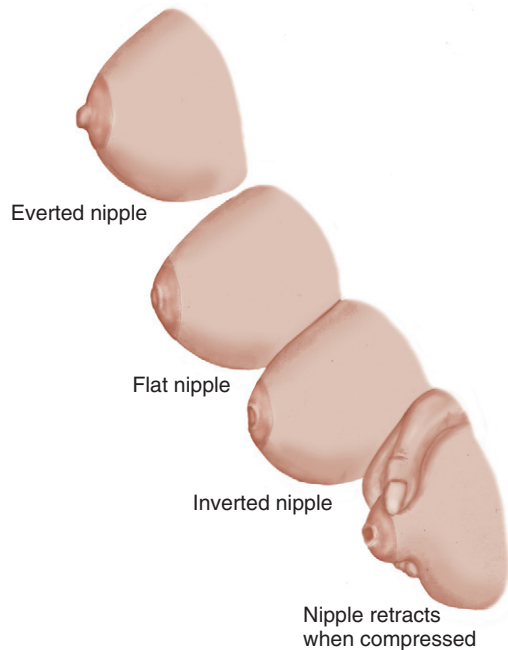

FIG 22-2 Normal everted nipple and other types of nipples that may cause the infant difficulty in latching on.

or becomes inverted. Nipples that appear inverted early in pregnancy may be improved near the end (Riordan & Wambach, 2010).

The helpfulness of breast shells for flat or inverted nipples is debated. Some authors find them helpful for some women and others feel they decrease motivation to breastfeed and do not improve nipple eversion (Lawrence & Lawrence, 2011; Riordan & Wambach, 2010). The dome-shaped devices are worn during the last weeks of pregnancy and between feedings after birth. The shells are placed in the bra with the opening over the nipple. They exert slight pressure against the areola to help the nipples protrude. Pumping the breasts for a few minutes before feeding helps the nipples protrude and may be more effective.

8. What preparation of the breasts is needed during pregnancy?

APPLICATION OF THE NURSING PROCESS

■ Breastfeeding

Assessment

Assess both the mother and the infant during the breastfeeding process. Various scoring tools have been developed to assess breastfeeding, but none is completely satisfactory. One method often used is the LATCH breastfeeding assessment tool (Table 22-1).

Maternal Assessment

Breasts and Nipples. Assess the condition of the breasts and nipples and the mother's knowledge about breastfeeding to determine her need for assistance.

Examine the breasts and nipples during late pregnancy to identify problems that might interfere with feeding. If this assessment did not occur before birth, examine the breasts and nipples before the initial feeding. Assess the protrusion of the nipples to identify flat or inverted nipples.

Ongoing assessments after birth include identification of breast fullness and breast engorgement. Fullness is the swelling of the breasts that may occur early in lactation as a result of increased blood and lymph circulation. It may progress to engorgement if feedings are delayed, too short, or not frequent enough. Palpate the breasts to see if they are soft, filling, or engorged.

Soft breasts feel like a cheek. If milk is beginning to fill the breasts or “come in,” they may be slightly firmer, which is charted as “filling.” **Engorgement** is congestion and increased vascularity, edema from obstruction of lymphatic drainage, and accumulation of milk as lactation is established. Engorged breasts may be hard and tender, with taut, shiny skin. Note any redness, tenderness, and lumps within the breasts. Engorged breasts are usually not seen until after discharge from the birth facility.

Assess the nipples, which may be red, bruised, blistered, fissured, or bleeding. Ask about nipple tenderness and when it occurs. Evaluate breastfeeding techniques of the mother having problems with her nipples.

Knowledge. The mother who is breastfeeding for the first time may have many questions and need substantial guidance during her first attempts. If she has nursed before, she has more knowledge but may have forgotten some aspects and may be unaware of current information that was unavailable when she breastfed her last infant. It is particularly important that all staff give the same instructions to mothers. Conflicting advice is very confusing to mothers trying to learn how to breastfeed.

Infant Feeding Behaviors

Before initiating a breastfeeding session, assess the infant's readiness for feeding (Box 22-3). The infant should be awake and hungry. Trying to feed an infant in a deep sleep period is frustrating to both mother and infant. Sucking on the hands, rooting when the cheek or side of the mouth is touched, smacking the lips, and hand to mouth movements are common hunger cues. Feeding should begin before crying, which is a late sign of hunger. Crying infants must be calmed before they are ready to feed. Continue to assess for problems throughout the feeding.

Nursing Diagnosis

Women with and without experience often need information to have a successful breastfeeding experience. A woman's confidence in her ability to breastfeed may be an important determinant of her success. Therefore, nurses should help women increase their confidence and help prevent early weaning by using the nursing diagnosis “Risk for Ineffective Breastfeeding related to lack of understanding of breastfeeding techniques and confidence in using them.”

Expected Outcomes

The expected outcomes for this nursing diagnosis are as follows:

1. The infant will breastfeed using nutritive suckling for 10 to 15 minutes or more on each breast for most feedings before discharge.
2. The mother will demonstrate breastfeeding techniques (such as positioning) as taught before discharge.
3. The mother will verbalize satisfaction and confidence with the breastfeeding process before discharge.

TABLE 22-1 THE LATCH SCORING TOOL*

	0	1	2
L			
Latch	Infant too sleepy or reluctant No sustained latch achieved	After repeated attempts is able to sustain latch and suck Must hold nipple in infant's mouth Must stimulate infant to suck	Grasps breast Tongue down Lips flanged Rhythmic sucking
A			
Audible swallowing	None	A few with stimulation	Spontaneous and intermittent <24 hr old Spontaneous and frequent >24 hr old
T			
Type of nipple	Inverted	Flat	Everted (after stimulation)
C			
Comfort (breast or nipple)	Engorged Cracked, bleeding, large blisters, or bruises Severe discomfort	Filling Reddened or small blisters or bruises Mild to moderate discomfort	Soft Nontender
H			
Hold (positioning)	Full assist (staff holds infant at breast)	Minimal assist (e.g., elevate head of bed; place pillows for support) Teach one side; mother does other Staff holds and then mother takes over	No assist from staff Mother able to position or hold infant

*The nurse can use the LATCH scoring system to assess and document the need for assistance with breastfeeding. Each assessment area is scored 0 to 2. A score of 7 or less indicates the mother needs more assistance in feeding.

Modified from Jensen, D., Wallace, S., & Kelsay, P. (1994). LATCH: A breastfeeding charting system and documentation tool. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 23(1), 27–32. Reprinted with permission of Sage Publications.

THERAPEUTIC COMMUNICATIONS

Anxiety about Breastfeeding

Brianna gave birth to her second baby, Luis, by cesarean birth. She tells her nurse, Chela, that she breastfed her first infant for a week and then switched to bottle feeding because she did not have enough milk. Luis is a sleepy baby but does nurse at times. Brianna's breasts are engorged, and her nipples are sore.

Brianna: I really wanted to nurse Luis, but I don't know if it's worth the effort. My breasts hurt, and I don't know if he's getting enough milk. I probably should just use the bottle again.

Chela: You sound really discouraged! *(Reflecting the feelings expressed.)*

Brianna: When I couldn't nurse my daughter, I was so disappointed. I had this "Mother Earth" view of the kind of mother I was going to be. But the baby wouldn't stop crying, so I went to the bottle.

Chela: That must have been hard for you! *(Reflecting the feelings expressed.)*

Brianna: It was awful, and now it looks like I'm going to fail again. Luis won't nurse half the time, and I'm going home this afternoon.

Chela: And you're worried about what's going to happen at home. *(Seeking clarification of the mother's concerns.)*

Brianna: What if he won't nurse at home? I don't know what to do!

Chela: Breastfeeding isn't always easy. Mothers and babies both have to learn the process, and that takes time and a lot of patience. Luis seems hungry now—would you like to try again? I'll stay with you and answer your questions. *(Offering realistic encouragement and assistance in techniques.)*

Brianna: That would be great! Maybe I'll get the hang of this yet! *(By allowing Brianna to express her feelings of discouragement and disappointment before beginning to teach, the nurse learns how important breastfeeding is to Brianna and how best to go about teaching her. Brianna feels accepted, even though she is discouraged.)*

BOX 22-3 HUNGER CUES IN INFANTS

- Licking or sucking movements
- Lip smacking
- Rooting
- Hand to mouth movements
- Sucking on the hands
- Increased activity
- Crying (a late sign)

Interventions

Interventions are focused on the teaching the nurse should provide all breastfeeding mothers and their support persons. Inexperienced mothers may need detailed teaching. Experienced mothers often need only a review or clarification about techniques they have used previously. Interventions used for the first feeding session are summarized in "Keys to Clinical Practice: Assisting the Inexperienced Breastfeeding Mother" (see [Appendix B](#)).

Assisting with the First Feeding

In the United States, nurses are encouraged to help mothers begin breastfeeding within the first hour after birth if both mother and infant are in stable condition. The expectation in Canada is that mothers will breastfeed within 30 minutes of giving birth (Morin, 2009; AAP & ACOG, 2012).

The AAP recommends that all infants be placed skin to skin with the mother immediately after delivery and until the first feeding has occurred (AAP, 2012). At this time, infants are in an alert state, and many begin to nurse. Others may nuzzle, lick, or suck intermittently at the breast. Infants placed on the mother's trunk after birth will work their way to the nipple and begin to nurse (Henderson, 2011).

Breastfeeding within the first hour in the delivery room is associated with a higher breastfeeding rate at 2 to 4 weeks and 2 to 4 months postpartum (DiFrisco, Goodman, Budin et al., 2011; Schanler, 2009). Early breastfeeding provides stimulation for milk production, improves suckling, and may increase the duration of breastfeeding. Feeding at this time also helps increase early bonding. The mother may be very gratified to see her infant nurse right after birth.

Help the mother move to her side or into Fowler's position. Show her how to hold the breast, and explain proper positioning of the infant. This is a short session, and teaching should be repeated at the next feeding for reinforcement. Observe the infant's response to the feeding, and watch for signs such as cyanosis or choking, which may indicate the presence of problems. Stay with the mother for a short time during the first few feedings to help with problems that may occur. For subsequent feedings, check back with her frequently to answer questions that may arise.

Teaching Feeding Techniques

Position of the Mother and Infant. Both the mother and the infant must be positioned properly for optimal breastfeeding. Make the mother as comfortable as possible before the feeding begins. Provide pain medications, if necessary. Pain or an awkward position may interfere with the let-down reflex and cause her to tire. Provide privacy and prevent interruptions so that she can concentrate on learning techniques.

The cradle, football (or clutch), and cross-cradle holds and the side-lying position are commonly used (Figures 22-3 to 22-6). To increase her comfort, use pillows behind the mother's back, over the abdominal incision (if any), and to support her arms. Her shoulders should be relaxed, and she should not be in a hunched position. Arrange folded blankets or pillows to elevate the infant to the level of the nipple and to prevent pulling and tension on the nipple.

The infant's head and body should directly face the breast with the infant's nose, cheeks, and chin lightly touching the breast. If the infant must turn the head to reach the breast, swallowing is difficult. The neck should be flexed because hyperextension also makes swallowing difficult. The infant's body should be aligned so that the ear, shoulder, and hips are in a straight line.

Position of the Mother's Hands. The mother's hand position is also important. In the palmar or "C" hand position, the mother holds her breast with her thumb on top and her fingers under the breast. Her little finger is against the chest wall and the other fingers provide support to the breast (Figure 22-7). Her fingers should be behind the areola and her thumb should not press on the breast enough to make the nipple tip upward, or the infant will suck improperly, and the nipple may become sore.

Some women use the "V" hold. The woman uses her index and middle fingers to support the breast. She must be careful to place her

FIG 22-3 For the cradle hold, the mother positions the infant's head at or near the antecubital space and level with her nipple, with her arm supporting the infant's body. Her other hand is free to hold the breast. Once the infant is positioned, pillows or blankets can be used to support the mother's arm, which may tire from holding the baby.

FIG 22-4 For the football or clutch hold, the mother supports the infant's head and neck in her hand, with the infant's body resting on pillows alongside her hip. This method allows the mother to see the position of the infant's mouth on the breast, helps her control the infant's head, and is especially helpful for mothers with heavy breasts. This hold also avoids pressure against an abdominal incision.

fingers well behind the areola or they may slip down the wet areola and interfere with the placement of the infant's mouth.

The mother should support her breast in place for the first few weeks if the weight of the breast makes it difficult for the infant to hold on to it. As the infant becomes more adept at breastfeeding, the mother no longer needs to hold the breast.

Although mothers worry about the infant's ability to breathe while breastfeeding, indenting the breast tissue near the infant's nostrils is unnecessary. This might cause improper positioning of the nipple in the infant's mouth, interfere with the grasp of the nipple, or interfere

FIG 22-5 The cross-cradle or modified cradle hold is helpful for infants who are preterm or have a fractured clavicle. The mother holds the infant's head with the hand opposite the side on which the infant will feed and supports the infant's body across her lap with her arm. The other hand holds the breast. The mother can guide the infant's head to the breast and see the mouth on the breast during the feeding.

FIG 22-6 The side-lying position avoids pressure on episiotomy or abdominal incisions and allows the mother to rest while feeding. She lies on her side, with her lower arm supporting her head or placed around the infant. Pillows behind her back and between her legs provide comfort. Her upper hand and arm are used to position the infant on the side at nipple level and hold the breast. When the infant's mouth opens to nurse, the mother draws the infant to her to insert the nipple into the mouth. A small blanket or towel can be placed over an abdominal incision to protect it from infant movement.

with milk flow. Unless the mother's breasts are very heavy and the infant's nose is buried in the breast, the infant's breathing is not occluded. Bringing the infant's hips closer to the mother and lifting the body to a more horizontal position are usually sufficient if there is concern about the infant's ability to breathe while breastfeeding.

FIG 22-7 "C" Position of Hand on Breast. The hand is positioned so that the thumb is on top of the breast while the fingers support the breast from below. Note the flaring of the infant's lips.

Latch-On Techniques. Teach the mother techniques to help the infant latch on to the breast. The infant should be awake and hungry. Talking and cuddling can help a sleepy infant awaken and calm an upset infant.

Eliciting Latch-On. After positioning the infant to face the breast, instruct the mother to hold her breast so that the nipple brushes against the infant's lips. A hungry infant usually opens the mouth, but some need a minute of stroking the area around the mouth. The breast should not be inserted until the infant's mouth is opened widely, or the infant will compress the end of the nipple, causing pain, trauma, and little milk flow.

When the infant's mouth is wide open with the tongue down and forward over the gum, the mother should quickly bring the infant close to her so that the infant can latch on to the areola. The angle of the open mouth should be approximately 120 to 160 degrees (Smith & Riordan, 2010). Suggesting to the mother that during latch-on the infant opens the mouth as though yawning or eating a large sandwich may help her understand what is needed.

Position of the Mouth. Assess the position of the infant's mouth on the breast (Figure 22-8). The infant's lips should be positioned on the areola about 1 to 1½ inches (2.5 to 3.8 cm) from the base of the nipple to allow the nipple to be drawn toward the back of the mouth (Lawrence & Lawrence, 2011). This prevents the infant from sucking on the nipple only, which leads to sore nipples and insufficient milk production. It also places the infant's gums over the ducts so that the milk is released into the mouth as the gums compress the breast.

Assess the position of the infant's tongue by gently pulling down on the lower lip. The tongue should be forward, cupped under the breast and over the top of the lower gums. The lips should be flared outward. Be sure that the lower lip is not turned in, which may result in a friction burn on the lower side of the nipple.

Suckling Pattern. Teach the mother about the infant's suckling pattern. During **nutritive suckling (sucking)**, the infant sucks with smooth, continuous movements with occasional pauses to rest. The infant may swallow after each suck or may suck several times before swallowing. **Nonnutritive sucking**, in which little or no milk flow is obtained, often occurs when the infant is falling asleep. A fluttery or

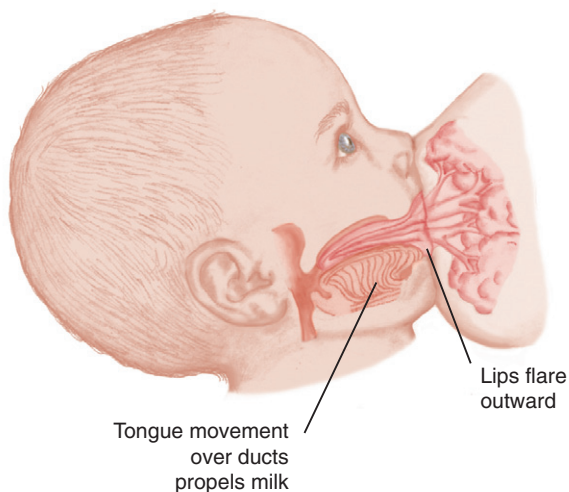

FIG 22-8 Position of the Infant's Mouth While Suckling. When the nipple and areola are properly positioned in the infant's mouth, the gums compress the areola instead of the nipple. The tongue is between the lower gum and breast. The infant's lips are flared outward.

choppy motion of the jaw not accompanied by the sound of swallowing indicates nonnutritive sucking.

Explain the milk-ejection reflex to the mother. Many mothers learn to recognize a feeling of tingling in the nipples as the let-down occurs. The reflex occurs several times throughout the feeding. She will see the infant begin to swallow more rapidly each time a new let-down brings more rapid expulsion of milk. Milk may drip from the opposite breast when the reflex occurs.

Mothers often wonder whether their infants are actually receiving milk from the breast. Point out the sound of swallowing when it occurs. A soft “ka” or “ah” sound indicates the infant is swallowing colostrum or milk.

Short pauses are normal during breastfeeding. Caution mothers not to jiggle the breast in the infant's mouth in an effort to start the suckling again. Moving the breast in the mouth may cause the infant to lose the grasp on the nipple and areola, resulting in “chewing” on the nipple and soreness. If necessary, she should take the infant off the breast for awakening and then start again.

Removal from the Breast. Teach the mother to remove the infant from the breast when suckling becomes nonnutritive. Show her how to avoid trauma to the breast by inserting her finger into the corner of the infant's mouth between the gums to break the suction. She then removes the breast quickly before the infant begins to suck again. Another method is to indent the breast tissue with a finger near the infant's mouth and remove the infant when suction is released.

Frequency of Feedings. Breast milk moves through the stomach twice as fast as formula (Blackburn, 2013). Therefore, infants are usually breastfed every 1.5 to 3 hours with 8 to 12 feedings in 24 hours (Schanler, 2009). Frequent feedings are especially important in the early days after birth, while lactation is being established and the infant's stomach capacity is small. Explaining that the hormone prolactin, which is responsible for milk production, is released in increased amounts while the infant is suckling helps the mother understand the relationship between frequent feeding and milk supply. Long periods between feedings increase the likelihood of breast engorgement.

An infant may vary in the length of feedings and time between each feeding. Several feedings close together (sometimes called “cluster feedings”) are followed by a longer interval between feedings. Cluster

feedings may occur on the second or third night at home or in later weeks when an appetite spurt occurs in the infant (Academy of Breastfeeding Medicine [ABM], 2009). An infant's frequent need to nurse may cause the mother to think that her milk supply is inadequate, when, in fact, it may be normal. Strict scheduling of infant feedings is unnecessary and leads to frustration for both mother and infant. A mother should take her cues from her infant.

Length of Feedings. Early feedings were once limited to only a few minutes per breast to prevent sore nipples; however, improper positioning, rather than time at breast, is the usual cause of nipple trauma. When feedings are too short, infants receive little or no colostrum or milk. It may take as long as 5 minutes for the milk-ejection (let-down) reflex to occur during the early days after birth.

Generally, mothers can allow infants to set the length of feedings. The infant should suckle vigorously for a certain period. When choppy, nonnutritive suckling without the sound of swallowing occurs, the mother should burp the infant and complete the feeding at the other breast. When the infant is satisfied, the suckling pattern changes, and the infant may fall asleep.

Mothers who are uneasy without a specific length of time for feedings can be instructed to start with feedings that last approximately 10 to 15 minutes on each side, or longer if the infant continues to nurse vigorously (Schanler, 2009; AAP & ACOG, 2012). Although variations in the length of feedings occur, early feedings that last less than an average of 20 minutes and occur less than eight times in 24 hours may not be enough (Riordan & Hoover, 2010). Feeding time increases as needed by the infant over the next few days. Teach the mother that longer feedings do not cause sore nipples if the infant is positioned properly.

Explain the differences between **foremilk**, the watery first milk that quenches the infant's thirst, and **hindmilk**, which comes at the end of the feeding. Hindmilk is richer in fat, more satisfying, and leads to weight gain. Feeding for too short a time prevents the infant from getting the hindmilk and decreases weight gain.

Switching back and forth between breasts several times during a feeding increases the amount of foremilk the infant receives but decreases the amount of hindmilk. Therefore, the mother should continue feeding on the first side as long as the infant nurses vigorously before burping and continuing on the other breast. Mothers should alternate the breast offered first at each feeding to provide equal stimulation of the breasts.

Preventing Problems. Women who intend to breastfeed but encounter difficulties that cause them to switch to formula feeding may express guilt and disappointment for months after the experience. Nurses can help prevent early problems in several ways.

Teaching. Once women leave the birth facility, they often have no one to advise them about breastfeeding. Help prevent problems after discharge by intensive teaching during the short stay at the birth facility. Check the woman frequently as she feeds her infant so that her questions can be answered as she thinks of them.

Include suggestions on how to improve positioning and techniques. Discuss common problems that may occur after discharge and offer solutions. Some facilities hold classes for groups of women during the birth facility stay. Pamphlets and DVDs provide another means of teaching. Review them before use, however, to ensure that the information is correct and that they contain no advertisements for formula. If the birth facility provides classes, telephone calls, support groups, or home visits, explain those services.

Minimizing Interruptions. Once the mother is breastfeeding well, keep interruptions to a minimum. Ask her if she would like visitors to wait until she has finished feeding. Hang a “Do Not Disturb” sign on the door to advise staff and visitors that the mother should not

EVIDENCE-BASED PRACTICE

Mothers experience many interruptions during the postpartum period in the birth facility. Morrison and Ludington-Hoe studied the interruptions experienced by breastfeeding mothers on their first postpartum day. They included the number and duration of interruptions and time alone, the number and length of breastfeeding sessions, maternal perceptions of success and satisfaction with breastfeeding and the influence of interruptions on their experiences. A convenience sample of 30 breastfeeding mother–infant dyads was used for the study. Mothers were given a receiving blanket for participating in the study.

The authors observed the hospital room door of each mother to count and time each interruption from 8 A.M. to 8 P.M. on the first postpartum day. The length of time when the mother was alone or when she was with the father, infant, or both was also recorded. Mothers used a “Breastfeeding Success and Satisfaction Log” to record the length of each feeding, her perception of the success, and her satisfaction with each session. At the end of the day mothers used the “End of Day Satisfaction Questionnaire” to record their perception of the first postpartum day. A visual analog scale with markings from 0 to 10 was used for the mothers to describe their experiences.

Results of the study showed a total of 1596 interruptions for the 30 mothers. The mean number of interruptions throughout the 12 hours was 53.2 \pm 13.4

with durations of 19.1 \pm 36.6 minutes per dyad. Mothers had an average of 23.4 \pm 5.5 intervals of 15.8 \pm 19.4 minutes alone or with the father, infant, or both. Each mother averaged 4.6 \pm 1.5 breastfeeding sessions that lasted 25.6 \pm 17.2 minutes during the 12-hour observation period.

The mothers scoring of perceived breastfeeding success and perceived satisfaction with sessions ranged from 6.23 to 6.6 on the 10-point scale. The breastfeeding frequency was moderately negatively correlated with the frequency of interruptions, showing that mothers needed more time alone. Mothers regarded the breastfeeding sessions as moderately successful and satisfying, even though there were more than four interruptions per hour. They were highly satisfied with interactions with their infants but indicated interruptions somewhat interfered with breastfeeding.

The authors suggested use of door signs to allow mothers privacy during breastfeeding sessions, clustering care to minimize interruptions, and planning nursing care activities with the mother so that she can predict quiet periods.

Do you think mothers on your postpartum unit experience excessive interruptions? How many times have you interrupted postpartum mothers during a shift? Is it possible to allow them more privacy and time alone with their infants?

be interrupted. Tell the mother to use her call light to notify the nurse if she needs help or when she is ready for interruptions.

Formula Gift Packs. Although there is lack of agreement about the effects of formula gift packs given to mothers at discharge, it is likely that having formula available leads to an expectation in some mothers that formula will be necessary. This is contrary to the message nurses should give to parents about breastfeeding. Gift packs that do not have formula are more appropriate for breastfeeding mothers. “Baby-friendly” hospitals do not give formula gift packs and the *AAP and ACOG (2012)* recommend against them for breastfeeding mothers.

Formula Supplementation. Avoid use of formula supplementation in the hospital unless there are medical indications. Avoidance of supplements of any kind during the first 72 hours is a nursing care quality measure being introduced by the Association of Women’s Health, Obstetric, and Neonatal Nurses (*AWHONN, 2013*). Supplements may lessen the success of breastfeeding because they decrease feeding from the breast and decrease milk production (*AAP & ACOG, 2012; Schanler, 2009*). A national goal is to reduce the proportion of breastfed newborns who receive formula in the first 2 days of life to no more than 15.6% (*USDHHS, 2010*). Some progress has been made with 24.6% of breastfed infants receiving formula before they are 2 days old (*CDC, 2012*). Teach mothers that supplementing with formula will not necessarily result in their getting more sleep during the night. Breastfed infants do not need water or glucose water either as they will interfere with adequate intake of breast milk.

Insufficient Milk Supply. One of the major reasons for early weaning to formula is parents’ perception of insufficient milk supply. Women with positive attitudes toward breastfeeding and confidence that they will produce enough milk are less likely to wean early because of perceived insufficiency of milk. Explain the normal course of breastfeeding and the methods of handling problems to help mothers feel more confident in their abilities.

Teach the parents how to assess swallowing and nutritive suckling. Discuss ways to determine if the infant is receiving enough milk. Suggest that the mother count the number of wet and soiled diapers to help her determine whether the infant is receiving enough milk. A

simple chart can be used to record the time and duration of each feeding along with the number of voids and stools each day.

Infants should have at least three to four wet diapers and three or four stools a day by the third day (*Janke, 2008*). After that time, the normal breastfed infant should have at least four or more stools daily (*Lawrence & Lawrence, 2011*). Stools should be yellow by day 5 (*Jana & Shu, 2011*). There should be at least six wet diapers by day 4.

Intake can also be gauged when weight gain is assessed at well-baby checkups. Following the initial weight loss after birth, infants generally gain approximately 0.7 to 1 oz (20 to 30 g) each day during the early months (*Keane, 2011*).

Common causes of decreased milk supply include ineffective suckling by the infant, feedings that are infrequent or too short, maternal fatigue, low maternal thyroid function, preterm or late preterm infants, and some medications including oral contraceptives containing estrogen. Intervene appropriately if any common causes are present.

Although women were once taught to drink large quantities of liquids to maintain milk supply, fluid intake sufficient to satisfy the mother’s thirst and to keep her urine light yellow is adequate.

Because the breasts are soft and the mother does not see large amounts of milk during the first few days, she may believe that little or none is present. This may lead her to give the infant formula before or after the feeding, decreasing milk production. Teach mothers who need to increase milk supply to feed more often and to use a breast pump after feedings.

If problems persist, refer the woman to a lactation consultant. Lactation professionals are often available in the birth facility and in the community. They can help with breastfeeding techniques and special problems.

Getting Help from Family. Fathers often feel there is nothing they can do to help the mother during breastfeeding. Give suggestions on how the father can be involved. Helping the mother to recognize early hunger signs can alert the mother to get ready to feed. Fathers can prepare the infant for feeding by changing the diaper and calming the infant. Assisting the mother to position the infant so both mother and baby are comfortable and burping the infant after feedings are other methods of support. Caring for other children, helping with

MOTHERS WANT TO KNOW

Is My Baby Getting Enough Milk?

Your baby is probably getting enough milk if:

- You hear the baby swallow frequently during feedings. It sounds like a soft “ka” or “ah” sound.
- You see nutritive suckling—a smooth series of suckling and swallowing with occasional rest periods. This is different from short, choppy sucks that occur when the baby is falling asleep and not getting milk. After the first few days, you may feel a tingling of your nipples each time a new let-down reflex occurs. This sensation is followed by more nutritive suckling as the infant swallows the increased milk available.
- Your breast is getting softer during the feeding. (However, your breasts do not have to be hard [engorged] for you to have enough milk.)
- You can see milk in the baby’s mouth or dripping from your breast occasionally.
- You feed your baby 8 to 12 times every 24 hours. More milk is produced when you nurse more often. (Keep track, at first, by writing down the time you start

each feeding. Once breastfeeding is well established, keeping close track of the time is not necessary. Your baby will let you know when it is time for feedings.)

- Your baby has at least one or two wet diapers per day for the first 2 days after birth, at least 3 to 4 wet diapers a day by day 3, and at least 6 wet diapers per day by day 4. Disposable diapers are very absorbent, and knowing whether they are wet is sometimes hard. If you are unsure, place a tissue or cotton ball inside the diaper to show even small amounts of urine. Urine should be light yellow, not dark yellow.
- Your baby has at least 3 to 4 bowel movements per day by day 3, and 4 stools per day after that time. The bowel movements are yellow by day 5.
- Your baby seems satisfied after feedings. Babies remain quietly awake or go to sleep for at least an hour after most feedings. (An occasional fussy time is not unusual and does not mean that the baby is not getting enough to eat.)
- Well-baby checkups show that your baby is gaining weight.

housework, and giving the infant occasional bottles of expressed milk may enable the mother to get more rest (Mitchell-Box & Braun, 2012).

Increasing Confidence. Use every opportunity to offer praise and reinforcement of the woman’s ability to breastfeed her infant. Point out the infant’s positive response to the mother’s handling and feeding. Mention the improvements she makes in recognizing hunger cues, positioning, latch-on, and other aspects of care. The nurse’s support and encouragement will help the woman feel more confident with each feeding and may lead to a longer duration of breastfeeding.

Providing Resources. Women who stop breastfeeding before they originally planned to stop often cite nipple pain, problems with latch-on, belief that their milk supply was insufficient, and need to return to work as their reasons. Give them contact information for lactation consultants, the local La Leche League (www.llli.org), and other breastfeeding resources in their area that may help them continue breastfeeding. Providing written material and Internet resources such as www.breastfeeding.com or www.womenshealth.gov/breastfeeding is also helpful.

Evaluation

Evaluation of interventions should be continued throughout the birth facility stay. Before discharge, the infant should be feeding well for 10 to 15 minutes at each breast most of the time. The woman should correctly demonstrate feeding techniques and voice her satisfaction with breastfeeding and confidence in her ability. Satisfaction and confidence are major determinants of whether she continues breastfeeding at home.

9. How can the nurse help the mother establish breastfeeding during the initial feeding sessions?
10. What should the nurse teach the mother about frequency and length of feedings?

COMMON BREASTFEEDING CONCERNS

Because mothers may be discharged from the birth facility before problems arise, nurses should teach them how to prevent and treat common concerns. When the mother seeks help for problems that have developed after discharge, the nurse should ask what the mother has

CASE STUDY 22-1 INTRODUCTION

Marina, age 26 years, had a normal pregnancy but had a cesarean birth because of fetal distress. Her son, Martin, was admitted to the neonatal care unit. She is disappointed that she did not have the birth she had planned during this, her first pregnancy, but has been told that Martin is progressing well so far in spite of some complications.

*Continues on p. 450.

done to solve the problem and whether she has used any complementary or alternative therapies. The safety of any therapy should be determined.

Teas made from herbs such as orange spice, fenugreek, and raspberry are considered safe during lactation. However, no herbal tea should be consumed in large quantities (Lawrence & Lawrence, 2011; Skidmore-Roth, 2010). The mother may have used other herbs to promote milk production. Because research on the use of these therapies is inadequate, she should be referred to a health care provider for information before using any substances as some may be harmful.

Problems may be divided into those originating with the infant and those pertaining to the mother.

Infant Problems

Infant problems require prompt attention to ensure successful breastfeeding.

SAFETY ALERT

Signs an infant is having breastfeeding problems include the following:

- Falling asleep after feeding for less than 5 minutes
- Refusal to breastfeed
- Tongue thrusting
- Smacking or clicking sounds
- Dimpling of the cheeks
- Failure to open the mouth widely at latch-on
- Lower lip turned in
- Short, choppy motions of the jaw
- No audible swallowing
- Use of formula

Sleepy Infant

During the first few days after birth, infants often sleep longer than expected or fall asleep at the breast after feeding for only a short time. They may be tired from the birth process and may not recognize or respond appropriately to hunger.

The nurse should show mothers how to arouse sleepy infants for breastfeeding (see “Breastfeeding Mothers Want to Know: Solutions to Common Breastfeeding Problems,” p. 453). If infants start the feeding fully awake, they are more likely to stay awake to finish the feeding. Pointing out the various behavioral states to the mother helps her develop a greater understanding of her infant and recognize when her attempts to feed will be most successful.

When the infant falls asleep during feedings, the nurse should evaluate whether the infant has fed adequately, should be awakened to feed longer, or should be fed again sooner than usual. Emphasizing that wake-up techniques should be gentle is important. The mother should avoid techniques that are excessively irritating to the infant because feeding should be associated with pleasurable sensations. Infants who continue to be excessively sleepy or nurse poorly need further evaluation. Poor feeding may be an early sign of a complication such as sepsis (see Chapter 30).

Nipple Confusion

Nipple confusion (or nipple preference) may occur when an infant who has been fed by bottle confuses the tongue movements necessary for bottle feeding with the suckling of breastfeeding. Some infants may refuse to breastfeed or use tongue movements that push the breast out of the mouth.

Movements of the mouth and tongue are different in breastfeeding and bottle feeding. During breastfeeding, the infant uses suction to hold the nipple in place near the soft palate. The tongue cups around the nipple and areola with the tip over the lower gum. With each compression of the lower jaw, the tongue presses against the breast, causing the milk to move forward from the ducts and into the infant's mouth.

To feed from a bottle, infants must push the tongue over the nipple to slow the flow of milk and prevent choking. This constant flow can be demonstrated by noting the steady drip of milk when a bottle is held upside down. The infant's lips are relaxed because there is no need to hold the nipple in place. If the infant uses the same thrusting tongue motion and relaxed lips while breastfeeding, the breast may be pushed out of the mouth.

Nurses should discourage use of formula in normal breastfeeding infants. It reduces breastfeeding time, which decreases prolactin secretion and, therefore, milk production. Formula takes longer to digest, and the infant is not hungry again for about 4 hours. The increased time between feedings limits breast stimulation and may lead to engorgement.

Some parents find pacifiers helpful, but early pacifier use may be associated with suckling problems and an earlier weaning from the breast for some infants. Pacifiers are advised as one way to decrease the risk of SIDS, but their use can be delayed for the first month until breastfeeding is well established (AAP, 2011a).

Suckling Problems

Suckling problems may occur when the nipple is poorly positioned in the infant's mouth. Dimpling of the cheeks and smacking or clicking sounds may indicate that the infant is sucking on the tongue or nipple only. Some infants do not open their mouths widely enough and suck on the end of the nipple.

Inserting a gloved finger into the infant's mouth helps assess suckling. The motion of the tongue should be felt as the infant sucks. The

infant who is thrusting the tongue may have become confused by the use of artificial nipples, which should be avoided until the problem is resolved.

The tongue should be cupped under the breast and should cover the lower gum. If the infant tends to place the tongue on top of the nipple, inserting a finger in the mouth and pressing the infant's tongue down just before latch-on may be effective. Helping the infant open the mouth wide before attachment may improve suckling. More complicated suckling problems may require assistance from a lactation consultant.

Infant Complications

Infant complications may be minor and cause minimal interference with breastfeeding or may prevent the infant from breastfeeding for a long period.

Jaundice. Jaundice (hyperbilirubinemia) in the infant does not necessarily interfere with breastfeeding. Even when infants receive phototherapy, they usually can be removed from the lights for feedings. Concern about adequate intake may be more prevalent in caring for the infant with jaundice. Insensible water loss from the skin is increased as a result of the heat and lights used in treatment and could lead to dehydration.

Infants receiving phototherapy should not be given water, which may decrease the intake of breast milk. Decreased intestinal motility from insufficient milk intake allows reabsorption of bilirubin through the intestinal wall into the bloodstream, increasing the work of the immature liver. Frequent breastfeeding increases the number of stools, which aids in bilirubin excretion and provides adequate intake of protein and fluid. In some cases, supplementary formula may be necessary, but breastfeeding should usually continue (ABM, 2010).

Prematurity. If the preterm infant cannot breastfeed immediately after birth, the mother needs encouragement and instruction on how to use a breast pump to establish and maintain her milk supply. Breast milk offers immunologic and nutritional benefits and is adapted to the preterm infant's needs. It may help prevent or minimize the severity of necrotizing enterocolitis, a serious complication of prematurity. It also helps the mother feel that she is providing care for her infant even when she is not able to take the baby home with her.

The woman can pump her milk and take it to the nursery for the infant's feedings. The nurse should provide sterile containers for the woman to take home and instruct her in special nursery requirements. The containers should be labeled with the infant's name and the date and time the milk was pumped.

Some preterm infants or those with breastfeeding problems respond well to the use of supplementary feeding devices. These consist of a container of milk with a small plastic feeding tube attached to the breast. When the infant begins to breastfeed, milk is drawn from both the container and the breast, increasing the infant's intake and motivation to continue suckling. As the infant gains weight and feeding ability increases, use of the device is gradually decreased until it can be discontinued completely.

Women who provide breast milk for their preterm infants may feel something is wrong with their milk when additions such as human milk fortifier are used. They should be reassured that their milk is very important in providing nutrition and protection against infection but that the infant needs more of some nutrients during the period of very rapid growth.

Late preterm infants (born between the beginning of the 34th week of gestation and the end of the 36th week) may have difficulty feeding. Although they may look like full-term infants, they are immature. Coordination of sucking, swallowing, and breathing may be poor and they may be sleepier than full-term infants.

A lactation consultant should be involved in teaching the mother her late preterm infant's special needs and monitoring the effectiveness of feedings (AWHONN, 2010; Radke, 2011). The infants need to be positioned in such a way that the head is supported, as in a football hold. Infants should be seen by a health care provider within 1 to 2 days after discharge to check the weight, adequacy of feeding, and jaundice. Frequent visits and weight checks should be made for any infants having feeding difficulties. Weekly weight checks should be performed until the infant reaches 40 weeks postconceptional age (ABM, 2011).

Illness and Congenital Defects

Infant illness and congenital defects such as a cleft palate may cause breastfeeding problems. If the mother is not able to nurse the infant at first, she will need assistance to maintain lactation until breastfeeding is possible. Referral to support groups can be particularly helpful. Some groups focus on particular congenital defects, and others focus on breastfeeding infants with special problems.

Maternal Concerns

Early nursing intervention can help the mother overcome common breast problems.

Common Breast Problems

Engorgement, nipple trauma, flat or inverted nipples, plugged ducts, and mastitis (infection of the breast) are common problems involving the breasts.

Engorgement. Many women experience a temporary swelling or fullness of the breasts, which peaks at 72 to 96 hours after giving birth when the production of milk begins to increase or the milk “comes in” (Lawrence & Lawrence, 2009). This normal temporary engorgement is the result of congestion, increased vascularity, accumulation of milk, and edema. It should not interfere with breastfeeding.

Engorgement may become a problem if feedings are delayed, too short, or infrequent. Engorged breasts become edematous, hard, and tender, making feeding and even movement painful. The areola may become so hard that the infant cannot compress it for feeding. An engorged areola causes the nipple to become flat, making it more difficult for the infant to draw it into the back of the mouth. Engorgement may lead to nipple trauma, mastitis, and even the discontinuation of breastfeeding.

Nurses help prevent engorgement by assisting women to begin breastfeeding early and to feed frequently. Encouraging mothers to breastfeed at night, unless extenuating circumstances are present,

CASE STUDY 22-1 NURSING CARE PLAN*

ASSESSMENT: Marina has looked forward to breastfeeding her infant, but Martin will probably not be able to feed at the breast for a few days. Although Marina understands the situation, she sounds disappointed and discouraged. She states that she will probably have to use formula after Martin is better because “it will be too late to start breastfeeding.”

NURSING DIAGNOSIS: Interrupted Breastfeeding related to separation from infant secondary to illness

GOALS OR EXPECTED OUTCOMES: Within 2 days Marina will:

1. Verbalize the importance of breastfeeding her infant and her desire to maintain lactation.
2. Pump her breasts as taught.
3. Breastfeed Martin successfully when it becomes possible.

INTERVENTIONS AND RATIONALES

1. Explore Marina's perception of the problem and her understanding of the cause for separation and its effect on breastfeeding. *Discussion of the problem identifies misconceptions and determines what teaching and support are required.*
2. Use therapeutic communication to help Marina express her feelings of disappointment with the unexpected change in plans. *Expression of feelings helps a person cope with situations.*
3. Explain to Marina how valuable breast milk is for her infant and that she can use a breast pump to maintain lactation until Martin is able to breastfeed. *Reinforcing the value of breastfeeding and offering encouragement increase the chance of success.*
4. Teach Marina how to use a breast pump and store her milk. Instruct her to pump her breasts for 15 to 20 minutes every 2 to 3 hours or at least 8 times in 24 hours. *Frequent use of a breast pump helps establish lactation by causing release of prolactin and oxytocin so that milk is produced and released from the breasts.*
5. Explain prevention and treatment of engorgement. *Frequent pumping should prevent engorgement. If it does not, the mother will need assistance in treating it.*

6. Feed Martin breast milk, if possible, whether by bottle or gavage. Teach Marina how to store her milk and prepare it for use for her infant. *Breast milk has properties that are especially valuable for the sick infant.*
7. Arrange for Marina to spend as much time with Martin as possible. Stay with her during the early visits and when she begins to breastfeed to answer her questions and provide support. *Bonding occurs more easily if a mother is able to be with her baby. The nurse's presence provides an opportunity to offer support, encouragement, and teaching, as needed.*
8. When Marina begins to breastfeed, offer the same teaching given to mothers of well infants. In addition, provide continued support if she has concerns. *Women who must delay breastfeeding may be more anxious about the process.*
9. Offer praise and realistic encouragement frequently. *Reassurance of her abilities increases a mother's confidence. Encouragement must be suited to actual circumstances.*
10. If Marina must go home before Martin is ready for discharge, provide her with information about purchase or rental of an electric breast pump. A hospital-grade electric pump is most effective. Give her containers to bring her milk into the nursery. *The mother who must pump her breasts for a longer period may find that an electric pump is more efficient.*

Critical Thinking: What other interventions might be necessary if Marina had flat nipples?

Answer: Reassure Marina that she can breastfeed even if her nipples are flat. Teach her to roll her nipples just before Martin latches on to begin feeding.

EVALUATION: Marina talks about her determination to provide breast milk for her son. She pumps her breast to maintain lactation and brings breast milk for Martin at each visit. At 3 days of age, Martin is ready to begin breastfeeding. Marina is very patient in helping Martin learn to breastfeed with the nurses' help. Martin has nursed well by discharge the next day.

*Continued from p. 448; continues on p. 452.

ensures that the breasts are emptied regularly. The use of water and formula should be discouraged.

⚡ SAFETY ALERT

Maternal signs of breastfeeding problems:

- Hard, tender breasts
- Painful, red, cracked, blistered, or bleeding nipples
- Flat or inverted nipples
- Localized edema or pain in either breast
- Fever, generalized aching, or malaise

Nipple Pain. Nipple pain is common during early breastfeeding. Pain for 1 minute or less may occur at the beginning of feedings because of tissue stretching and suction on the ductules before they fill with milk. Nipple pain is common during the first week, usually peaks at the third to sixth day, and resolves soon afterward (Smith & Riordan, 2010). Nipple trauma causes more sustained pain. Traumatized nipples appear red, cracked, blistered, or bleeding (Figure 22-9). Minor nipple trauma can be treated by independent nursing interventions. Redness of breast tissue, purulent drainage, and fever indicate mastitis or breast abscess and require antibiotic treatment (see Chapter 28, p. 612).

Improper positioning or latch-on techniques and exposure to soaps, prolonged moisture from wet breast pads, or irritating creams may cause sore nipples. Using a breast pump too long or with the suction set on high may be traumatic.

Flat and Inverted Nipples. Nipple abnormalities should be identified during pregnancy, if possible, but interventions can begin after birth, if necessary. Nipple rolling just before feeding helps flat nipples become more erect so the infant can grasp them more readily (Figure 22-10). A breast pump used for a few minutes before feedings or a breast shield may help draw out inverted nipples.

Plugged Ducts. Although the exact cause of occlusion of a lactiferous duct is unknown, engorgement, missed feedings, or a constricting bra may be involved. Localized edema and tenderness are present, and a hard area may be palpated. A tiny, white area may be present on the nipple. Massage of the area (Figure 22-11), heat application, and continued breastfeeding are helpful. Positioning the infant's nose or chin in line with the lump will improve drainage of the area (Orr, 2011). A plugged duct may progress to mastitis if not treated promptly. Mastitis involves localized pain accompanied by fever, generalized aching, and malaise.

FIG 22-9 Note the cracked area on this nipple.

CHECK YOUR READING

11. What wake-up techniques should the nurse teach the mother of a sleepy infant?
12. How does sucking from a bottle differ from suckling from the breast?
13. What help can the nurse offer the mother with engorged breasts?
14. How should the nurse advise the mother with sore nipples?

FIG 22-10 Rolling helps flat nipples become erect in preparation for latch-on.

FIG 22-11 To massage the breasts, the mother places her hands against the chest wall with her fingers encircling the breasts. She gently slides her hands forward until the fingers overlap. The position of the hands is rotated to cover all breast tissue. Massaging with the fingertips in a circular motion over all areas of the breast is also helpful.

CASE STUDY 22-1 NURSING CARE PLAN*

ASSESSMENT: A home health nurse visits Marina 2 days after discharge. She finds Marina very frustrated. Her nipples are everted but red and sore. There are no blisters, fissures, or bleeding. Martin latches onto the breast after a number of attempts at each feeding. Marina says, "I'm going to give a bottle for the next few feedings. I'm just too sore to nurse anymore today." Marina says she has been breastfeeding for about 5 minutes per side every 4 to 4½ hours. She holds Martin lying on his back with his hips and legs lower than the rest of his body during feedings. A few swallowing sounds are heard during breastfeeding.

Critical Thinking: Evaluate the preceding information and assign a LATCH score that can be used in planning care for Marina and Martin. (See Table 22-1.)

Answer: The LATCH score is 5. One point is given for latch, one for audible swallowing, one for comfort. Two points are given for type of nipple. No points are given for hold because she holds the infant incorrectly. The focus of teaching will be on improving the areas where there are problems.

NURSING DIAGNOSIS: Impaired Skin Integrity related to incorrect positioning and engorgement

GOALS OR EXPECTED OUTCOMES: Marina will:

1. Demonstrate correct positioning by the next feeding.
2. Describe prevention and treatment of sore nipples by the end of the visit.
3. Have no redness of the nipples within 2 days.

INTERVENTIONS AND RATIONALES

1. Suggest that Marina shower or apply warm compresses (such as clean, wet disposable diapers) to her breasts before feeding. *Heat dilates blood vessels and milk ducts, encourages the let-down reflex, and relieves pain.*
2. Suggest Marina take her pain medication just before feedings. *Medication relieves pain that could interfere with the let-down reflex, yet only minimal amounts reach breast milk within the feeding time.*
3. Demonstrate gentle massage of the breasts before feedings. *Massage causes release of oxytocin, resulting in the let-down reflex. The infant gets milk more quickly, reducing nonproductive time on a painful breast.*
4. Demonstrate correct positioning of the infant. For the cradle and cross-cradle positions, place Martin on his side so he faces the nipple with his abdomen against Marina. *If the infant must turn his head to feed, it interferes with swallowing and causes traction on the nipple.*
5. Suggest that Marina use a variety of positions for feeding and demonstrate each. *Changing the area of stress on the nipple allows healing of the sore area.*
6. Have Marina begin the feeding on the less sore side. *The let-down reflex occurs in both breasts at once. Vigorous suckling on the sore side before let-down increases nipple trauma.*

7. Assess Martin's mouth position by gently pulling down the lower lip to see that his tongue covers the lower gum. If the lower lip is turned in, gently pull it out so the lips flare. Assess the position of the nipple. *The tongue cushions the lower gum compression of the areola. A turned-in lower lip causes a friction rub on the nipple and areola. If the lips are 1 to 1½ inches from the base of the nipple, the nipple should be at the back of the infant's mouth.*
8. Teach Marina to feed Martin every 1.5 to 3 hours during the day and for a total of 8 to 12 feedings per day. She should feed an average of at least 20 minutes of effective suckling per feeding. *Frequent feedings empty the breasts, prevent stasis, stimulate milk production, and reduce the risk of mastitis. Adequate length allows time for the let-down reflex, which may be delayed at first.*
9. Teach Marina to apply warm water compresses or colostrum to the sore nipples after feedings. Instruct her to leave the flaps of her nursing bra down between feedings. Ice packs can be used on the breasts after feeding for engorgement. *Warm water compresses are soothing. Colostrum has lysosomes and healing properties. Increased air circulation promotes healing. Ice packs help reduce edema of the breast tissue.*
10. Teach Marina to avoid creams that must be removed before feeding or to which she may have allergies. If she uses breast pads, suggest that she change them frequently. Tell her to avoid soap on her nipples. *Cream removal, allergies, and wet pads increase irritation. Prolonged exposure to wet pads can cause maceration and breakdown of skin. Soap removes protective oils from nipples.*

Critical Thinking: Should Marina use a bottle for the next few feedings?

Answer: If Marina skips feedings, her engorgement will increase. Martin will not be ready to feed again for 3 to 4 hours after taking formula, increasing the time between feedings. The lack of suckling decreases milk production. Using the interventions listed, Marina should be able to breastfeed with less discomfort and prevent further problems.

EVALUATION: Marina nurses Martin during the visit and follows instructions on positioning well. She is glad to hear about ways to prevent and treat nipple pain. The nurse visits again 2 days later to check Marina's progress. Marina breastfeeds Martin every 2 to 3 hours for approximately 15 minutes per side during the day and every 4 hours at night. She positions Martin correctly and discusses causes and care for sore nipples. Her engorgement, nipple redness, and tenderness have resolved. Marina verbalizes methods she will use to prevent further problems.

*Continued from p. 450.

Illness in the Mother

It is seldom necessary for a mother to stop breastfeeding when she is ill. If breastfeeding must be temporarily stopped because of the mother's condition or the drugs she receives, the nurse should help the mother use a breast pump, if she wishes, until she resumes breastfeeding. Abrupt weaning may lead to mastitis.

Drug Transfer to Breast Milk

Most medications taken by the mother cross into the breast milk to some degree, but many pass in small amounts and are safe during

lactation. Some drugs interfere with milk production. Therefore, both prescription and over-the-counter drugs should be approved by the health care provider. Another drug can often be substituted for one that adversely affects the infant. If a mother must take a drug that will be harmful to her infant, she should pump her breasts while she is taking the medication. Once the drug clears her bloodstream, she may resume breastfeeding (see Appendix A). Some drugs may not reach the infant in harmful amounts if taken after a feeding or at night when there is a longer time between feedings. The U.S. National Library of Medicine has a website for information about drugs during lactation at www.toxnet.nlm.nih.gov.

BREASTFEEDING MOTHERS WANT TO KNOW**Solutions to Common Breastfeeding Problems****Problem: Sleepy Infant**

An infant is sleepy at feeding time or falls asleep shortly after beginning feeding.

Prevention

- Look for signs your baby is ready to wake up, such as movement of the eyes through closed eyelids, small twitches of the face, sucking movements, stretching, and increased movements of the entire body.
- Gently awaken your baby when you see those signs. Talk, gently move the infant's arms and legs, and play with the infant for a short time before beginning the feeding.
- Unwrap the baby's blankets and change the diaper. Swaddling infants by wrapping them tightly with blankets is a calming technique that often helps them sleep. Leave the blanket and shirt off as you begin the feeding with the baby skin-to-skin against your chest. Your body and a blanket draped over both of you after your baby begins to nurse will provide adequate warmth.

Solutions

If your baby goes to sleep during the feeding and has fed less than 5 minutes, try the following:

- Rub the baby's hair or cheeks gently, stroke around his or her mouth, or shift the baby's position slightly to see if the infant will wake up.
- Remove the baby from the breast. Rub the infant's back to bring up bubbles of air that may cause a sensation of stomach fullness. Rubbing the back also stimulates the central nervous system and arouses the baby.
- Change the diaper.
- Undress the baby (except for the diaper) and place the infant against your skin (if you have not done this already).
- Express a few drops of colostrum onto the nipple. The baby tastes the colostrum when the nipple is offered and often resumes suckling.
- Wipe the baby's face gently with a lukewarm washcloth to help the infant wake up.
- If your baby cannot be aroused with a few of these gentle techniques, a longer sleep period may be needed. Let the infant sleep another half hour; then begin again. Watch for signs the baby is in a lighter phase of sleep and can be awakened more easily.

Problem: Nipple Confusion

An infant who has taken bottles pushes the nipple out of the mouth and sucks poorly during breastfeeding. The infant has become confused about the way to suckle from the breast and is using sucking movements for bottle feeding.

Prevention

- Avoid all bottles and pacifiers unless absolutely necessary. If they are necessary, stop as soon as possible.
- Do not give the baby formula during the night. The extra sleep is not worth the possibility of later feeding difficulties.
- Avoid giving formula before or after breastfeeding because it is unnecessary for healthy newborns. It may cause the infant's stomach to become distended causing more "spitting up." Adding formula will cause the infant to wait longer before breastfeeding again, which decreases milk production.

Solution

- Stop all bottle feeding and pacifier use so that the baby becomes accustomed to suckling from the breast instead of the bottle. Nurse more often to stimulate milk production and help the baby learn what to do.

Problem: Latch-On Difficulty

The infant sucks on the end of the nipple or fails to open his or her mouth widely enough.

Prevention

- Do not insert the breast into the infant's mouth until the infant opens the mouth widely with the tongue down and forward (like biting into a large sandwich). Then bring the baby to the breast.
- Pull down gently on the infant's chin to help the infant open the mouth wider, if necessary.
- Be sure the nipple is at the back of the mouth with 1 to 1½ inches of the areola in the mouth.

Solutions

- Stop the feeding and start again if the infant is sucking on the end of the nipple, you see dimples in the infant's cheeks, or hear smacking, slurping, or clicking sounds. Short, choppy movement of the jaw means that the infant is going to sleep or has finished feeding.
- If you believe the infant should nurse longer, awaken the infant and begin again.

Problem: Engorgement

The mother's breasts are hard and tender from engorgement.

Prevention

- Breastfeed the infant every 2 to 3 hours day and night. Do not give bottles during the day or night, as this increases the risk of engorgement. Waiting even 4 hours between feedings may increase the risk of engorgement, but frequent breastfeeding often can prevent it.

Solutions

- To reduce edema and pain, apply cold packs to the breasts between feedings. Use commercial cold packs or make inexpensive cold packs from frozen washcloths, packages of frozen vegetables, or plastic bags filled with crushed ice. Cover cold packs with a washcloth before applying to the skin. A disposable diaper with crushed ice placed between the layers may also be used.
- Some women find application of cool cabbage leaves are helpful. Studies on their use have had mixed results (Lawrence & Lawrence, 2011; Riordan & Hoover, 2010).
- Just before feedings, apply heat with washcloths or disposable diapers wet with warm water. Apply the diaper over each breast and fasten the tabs to keep it in place and prevent dripping. Or take a warm shower so that the heat can stimulate milk flow.
- Massage the breasts before and during feedings to stimulate the let-down reflex so that the baby can nurse more easily. Massaging the breasts in the shower provides comfort and helps prepare for feeding.
- If the areola is engorged and hard, making it difficult for the baby to latch on, express a little milk by hand or with a breast pump. Or apply gentle pressure on the areola to move some swelling back into the breast and soften the areola to allow the infant to latch on. As soon as the areolae are soft, begin to feed.
- Feed more often, such as every 1.5 to 2 hours.
- Wear a well-fitting bra for support during the day and at night for comfort.
- Take prescribed pain medication just before feedings to make you more comfortable.

Problem: Sore Nipples

The nipples are sore and may be cracked, blistered, or bleeding.

Prevention

- Position the baby at the breast with enough of the areola in the mouth that the nipple is not compressed between the baby's gums during breastfeeding.

Continued

BREASTFEEDING MOTHERS WANT TO KNOW—cont'd

- Avoid engorgement by breastfeeding frequently. Express enough milk to soften the areola if engorgement makes the areola too hard for the infant to grasp.
- Vary the position of the baby to change the areas of pressure on the nipple.
- Do not use soap on the nipples because it removes the protective oils and causes drying.
- If you use breast pads for leaking milk, remove them when they become wet to prevent irritation of the skin. Avoid pads with plastic linings that retain moisture. Use a handkerchief or pieces of cotton cloth as inexpensive, washable substitutes for commercial breast pads.

Solutions

- Using warm compresses before feedings will help the milk to flow more quickly. Use them between feedings to soothe nipples.
- Express a small amount of milk before feeding to begin the let-down reflex.
- Begin each feeding with the less sore breast first. The hungry baby nurses more vigorously at first, which may be painful. The let-down reflex is started, causing milk to flow more quickly from the second breast.
- Massage the breasts when the infant pauses during feedings to enhance milk flow.
- Vary the position of the infant during feedings. The area of the nipple directly in line with the infant's nose and chin is most stressed during the feeding.
- Nipple shields (artificial nipples that fit over your own nipples) may be helpful in some situations. A lactation consultant should help you use them temporarily.
- Breast creams may cause sensitivity and irritation. If you choose to use lanolin, use only purified lanolin to protect against allergens and pesticides.

Creams that have to be removed before each feeding may increase soreness. Hydrogel may also be used to soothe nipples.

- Apply colostrum or breast milk to the nipples after feedings because they have healing properties.
- Expose the nipples to air between feedings by lowering the flaps of your nursing bra.
- If you have burning, itching, or stabbing pain throughout your breast, look in the baby's mouth for white patches of thrush, a yeast infection that can infect the nipples. Call the health care provider for medication to treat both you and your baby.
- Take prescribed pain medication just before feedings to help you relax.

Problem: Flat or Inverted Nipples

The mother's nipples are flat or inverted, and the baby has difficulty drawing them into his or her mouth.

Prevention

None.

Solutions

- Some women find wearing breast shells in the bra helps make the nipples protrude.
- Just before beginning breastfeeding, roll the nipple between your thumb and forefinger to help it protrude (see [Figure 22-10](#)).
- Use a breast pump for a few minutes just before feedings. Put the baby to your breast immediately after the pump causes the nipple to become erect. The normal suckling process usually causes the nipple to stay erect.
- A nipple shield may be used for a short time with the help of a lactation consultant to help the infant latch on to inverted nipples.

Conditions in which Breastfeeding Should be Avoided. In some situations such as a mother's serious illness that can be transmitted to the infant, breastfeeding is contraindicated. Women who take methadone or buprenorphine for opiate addiction are allowed to breastfeed because only minimal amounts of the drugs pass to breast milk (ACOG, 2012). Other types of drug abuse, active untreated tuberculosis, human immunodeficiency virus (HIV) infection, galactosemia, and maternal chemotherapy, and mothers who must take drugs that are unsafe for the infant are situations in which breastfeeding is not advised.

Mothers with hepatitis A, B, or C may breastfeed. Infants of mothers with hepatitis B should receive hepatitis B vaccine and immunoglobulin. Herpes simplex does not preclude breastfeeding if the mother does not have a lesion on her breast and uses thorough handwashing (AAP & ACOG, 2012; Stettler et al., 2011; Holt et al., 2011). Women who smoke can breastfeed but should stop smoking if possible or not smoke around the infant.

Previous Breast Surgery

Women who have had surgery for breast reduction, augmentation, or other conditions may have difficulty with lactation. The ability to produce and transfer milk to the nipple depends on the surgical technique used and the amount of tissue involved. Surgery may disrupt the neural pathways, ducts, and blood supply. Some women can breastfeed without problems. Others may be able to do so by pumping to help build up milk supply or by using a supplementation device when the breasts are unable to produce a sufficient amount of milk.

Women with pierced nipples should not have difficulty with breastfeeding. They should remove the rings or studs before feeding the

infant. Milk may leak from the pierced hole, but that should not be a problem (Huggins, 2010; Meek, 2011).

Employment

Although some women remain at home for 6 or more weeks after giving birth, others must return to work earlier. With some advance planning, breastfeeding can be efficiently combined with working. Breastfeeding classes and support groups are often helpful in providing practical advice on how to merge employment with lactation.

The mother will need to purchase a breast pump. The expense of a pump is covered under most insurance plans. A week or two before she returns to work, the mother should use a breast pump once or twice a day to practice pumping her breasts and to build up a small supply of frozen breast milk. This avoids the stress of having to learn the technique or worry about having enough milk while adjusting to the work situation. Giving the infant a bottle occasionally about 2 weeks before returning to work makes the transition smoother.

Most working mothers use a pump two or three times a day during lunch or breaks at work. Some mothers pump for only a short time (5 minutes) during breaks to relieve engorgement and then pump longer at meal time. The woman needs a clean, private place to pump. A national goal is to increase the proportion of employers that have worksite lactation support programs (USDHHS, 2010). The law now requires employers to provide reasonable break time for a nursing employee to express milk for 1 year after her child's birth. A place to express milk, other than a bathroom, is also to be provided and must be shielded from view and intrusions (U.S. Department of Labor, 2010).

FIG 22-12 To express milk from the breast, the mother places her hand just behind the areola, with the thumb on top and the fingers supporting the breast. The tissue is pressed back against the chest wall; then the fingers and thumb are brought together and toward the nipple. This compresses the ducts and causes milk to flow. The action is repeated to simulate the suckling of the infant. Moving the hands around the areola allows compression of all areas and increases removal of milk from the breast. Compression should be gentle to avoid trauma. Application of heat and massage before expression increase the flow of milk.

The milk should be refrigerated or placed in an insulated container with ice to be used for the next day's feedings by the caregiver. Breast-feeding just before the mother leaves for work and again when she returns home keeps the time between feedings at a minimum. Frequent breastfeedings throughout the evenings and on weekends help her maintain her milk supply.

Some mothers choose to use formula during work hours but breastfeed when at home. They should prepare for this by gradually eliminating the feedings that occur during work hours and substituting a bottle. Although the total milk supply is diminished, breastfeeding can continue in the mornings and evenings.

Milk Expression and Storage

When milk expression is needed, the nurse helps the mother use hand expression (Figure 22-12) or a breast pump (Figure 22-13).

Hand Expression. Hand expression can be performed without other equipment but is usually not as effective as a breast pump. Hand expression or manual pumps are useful for the mother who wants to save breast milk for another feeding occasionally or whose areolae are so engorged that the infant cannot grasp them.

Use of a Breast Pump. The mother who plans to pump her milk for a prolonged period should use an electric breast pump. Battery-operated pumps are small, portable, and relatively inexpensive for short-term use. Large electric hospital-grade pumps can be rented for home use. They are more efficient than hand pumps or battery-operated pumps and are indicated when the mother plans to pump for a long time. A double pump allows the mother to pump both breasts at once, saving time and increasing milk production.

FIG 22-13 The nurse helps the mother use an electric breast pump.

Use of the breast pump should begin as soon as possible after birth for the woman who cannot breastfeed her infant. She should pump her breasts as often as the infant would nurse or at least eight times a day if she plans to breastfeed for a prolonged time. Sessions should last approximately 15 to 20 minutes (Hurst & Meier, 2010).

The mother should wash her hands before using the pump and before preparing the pumped milk for storage or feeding. Breast massage and application of heat before pumping help initiate the flow of milk. Massaging the breast during pumping may increase the volume of milk obtained at each session. Pumping before or after the first morning feeding often produces the greatest volume. Relaxation during pumping increases volume, but tension or discomfort may reduce the output. The mother should plan enough time for pumping so that she does not feel hurried, as that would increase tension and decrease the output.

Moistening the breast before attaching the pump improves suction. The amount of suction should be set at a low level in the beginning and gradually increased, if necessary. Too much negative pressure traumatizes the breast. If the woman needs to increase her milk supply, pumping more often, rather than for longer periods, is most effective. The pump should be cleaned according to the manufacturer's instructions after each use.

Milk Storage. Milk should be stored in clean (sterile for a hospitalized infant) glass or rigid polypropylene containers with a tight cap (Hurst & Meier, 2010). A nipple should not be used to cover the container during storage because the hole allows passage of organisms that can contaminate the milk.

Fresh unrefrigerated breast milk should generally be used within 3 to 4 hours of pumping. Under very clean conditions using it within 6 to 8 hours is acceptable. It may be stored in a refrigerator at 4°C (39°F) or below for 72 hours in usual circumstances or for 5 to 8 days under very clean situations (ABM, 2010). Milk that is fresh or has been refrigerated rather than frozen should be used as much as possible so that the leukocytes are available for the infant (Hurst & Meier, 2010).

If the milk is to be frozen, it should be placed in the back of the freezer and kept at -17°C (0°F) or below. It should optimally be used by 6 months, although use within 12 months is acceptable (ABM, 2010). Milk should be frozen in amounts that are likely to be used for one feeding. Containers should be marked with the date and the oldest used first. Newly pumped milk should not be added to containers of previously pumped milk.

Breast milk can be thawed and warmed by holding the container under running water. Cool water should be used first to defrost it; then the milk can be warmed by placing it under warm running water or in a bowl of warm water. It can also be thawed in the refrigerator and used within 24 hours. It should not be refrozen.

Milk should not be heated in a microwave because the microwave heats unevenly. The infant might be burned because the container may be cool but the milk may have hot spots. Thawed breast milk should be gently inverted a few times to mix the foremilk and hindmilk. Milk that is not finished in one feeding should be discarded within 1 hour.

Breastfeeding after Multiple Births

Mothers who have more than one newborn have many questions about breastfeeding and need help and support from nurses and family members to be successful. Explain to the mother that her milk supply adjusts to the demand and that she can produce enough milk for her infants. Breastfeeding every 2 to 3 hours to build up the milk supply is important. If the infants cannot breastfeed at first, the woman will need help using a breast pump.

If the woman decides to feed two infants simultaneously, the nurse helps position them in the football (clutch) hold, cradle hold, or a combination of both. She should be encouraged to eat well, get enough rest, and ask for help from family and friends.

Weaning

Mothers are sometimes subjected to opinions and pressure from family and friends about weaning. There is no one “right” time to wean the

infant. The AAP suggests breastfeeding only for at least 6 months and continuing breastfeeding for 1 year or longer, while adding solids (AAP, 2012). Mothers choose to wean their infants for various reasons. The nurse should provide information so women can make informed decisions about weaning and should support the woman once her decision is made. Explaining that even a short period of breastfeeding offers her infant many advantages is reassuring.

Mothers may need help in planning a slow weaning process to help avoid engorgement and allow the infant to become accustomed to a bottle or cup gradually. Mothers who are not in a hurry to wean may allow the infant to take the lead. Omitting one breastfeeding session a day and waiting several days or a week before omitting another will allow the mother and the infant to adjust to the change more easily. Weaning too rapidly increases the risk of plugged ducts or mastitis. Infants who are weaned before 12 months of age should be given iron-fortified formula instead of cow’s milk (AAP & ACOG, 2012; Holt et al., 2011).

Home Care

Many infants have not breastfed well by the time of discharge from the birth facility, placing them at risk for failure to gain weight, dehydration, and hyperbilirubinemia. Problems with engorgement and sore nipples are more likely to occur after discharge. These families need continued support by nurses during home, clinic, or office visits (Figure 22-14). The infant should be seen by the physician or other health care provider 3 to 5 days after birth or within 48 hours of

BREASTFEEDING MOTHERS WANT TO KNOW

Breastfeeding after the Birth of More than One Infant

Ensuring Adequate Milk Production

Because the amount of milk produced depends on the amount of suckling the breasts receive, mothers can produce enough milk for more than one baby. Breastfeeding frequently (every 2 to 3 hours) helps build up the milk supply. Production of milk may be more evenly stimulated if you alternate breasts for each infant, especially if one baby has a weaker suck.

Using a Breast Pump

If your infants are not ready for breastfeeding, use a breast pump to build up your milk supply and provide milk for them until they are ready to nurse. Use the pump every 2 to 3 hours while you are awake and once or twice during the night. Pump for 15 to 20 minutes during at least 8 to 12 pumping sessions daily. Use a double pump to decrease the time spent pumping and increase the production of milk.

If one baby is ready to breastfeed before the other(s), nurse the baby and pump your breasts after each feeding to stimulate milk production. An alternative is to nurse the infant on one breast and use a breast pump on the other at the same time.

Feeding Simultaneously or Individually

You can feed each baby separately or feed two infants at once. Simultaneous breastfeeding shortens feeding times, but both infants must be awake at once. You need help positioning the infants at first. Individual feeding can be done without help and on each infant’s own schedule, but a larger portion of your day will be spent feeding. It may be necessary to feed the infants separately at first and begin simultaneous feedings when each infant is feeding well at the breast.

Positioning Infants for Simultaneous Feeding

Use a variety of positions for breastfeeding two infants at once. Place pillows under both infants to lift them to the right height and keep them in

place. Use pillows under your arms and behind your back to make yourself comfortable.

- Football (clutch) hold—Place each infant’s head on your lap and support each infant’s body with pillows along your side. Place a hand under each infant’s head and bring the infants to the nipples.
- Football and cradle hold—Place one infant in a cradle position on pillows across your lap. Place the other infant in a football position with the body supported on pillows alongside you. Once the infants are in position, help one and then the other latch onto the breast.
- Crisscross hold—Place pillows on your lap and hold each baby in the cradle position. The infants’ legs crisscross over one another.

Keeping Track

Keep track of when and for how long each baby eats, especially if you feed them individually. Record the number of wet diapers and bowel movements each infant has each day. The babies should have at least six wet diapers and four bowel movements by day 4 if the infants’ intakes are adequate.

You can assign each infant one breast without changing to the opposite breast, if you choose. Mothers often alternate the breast each infant nurses from at each feeding to keep stimulation of the breasts similar. Alternating breasts every 24 hours may be easier to remember.

Care for Yourself

Eating well and getting enough rest are important. Ask for help from family and friends. Pamper yourself as much as possible, and leave care of the house and cooking to others if you can. Your major responsibility during this time should be to care for yourself and your new babies!

BREASTFEEDING MOTHERS WANT TO KNOW

How to Wean from Breastfeeding

Deciding When to Wean

Breastfeeding has many benefits, and you can continue to breastfeed as long as you wish. Only you can make the decision about when to wean your baby. Before you decide to begin weaning, evaluate the reasons for continuing breastfeeding or beginning weaning.

How to Proceed

Gradual weaning is best for both you and your baby. Abrupt weaning can lead to engorgement and mastitis for you and can upset your baby. You both need to get used to this change slowly.

- Eliminate one feeding at a time. Replace it with a bottle for the young infant who needs to continue sucking. Infants generally do not drink as much from a cup as they do from a bottle. They may need a bottle to get enough milk

to meet their nutritional requirements. The older infant who has learned to use a cup may not need a bottle at all. Use formula instead of cow's milk until the infant is at least 1 year old because formula is more suited to an infant's needs.

- Omit a middle of the day feeding first. Begin with the feeding in which the baby seems least interested, and then gradually eliminate others.
- Wait several days before eliminating another feeding. This allows time for your milk production to adjust and the baby to accept the changes.
- Eliminate the baby's favorite feedings last. Many infants are particularly fond of morning and bedtime feedings.
- Expect your infant to want to nurse again when tired, ill, or hurt during the weaning process. This is sometimes called "comfort breastfeeding." A few minutes of breastfeeding may be all that are necessary to comfort the baby.

FIG 22-14 The nurse offers suggestions on hand position during the clinic visit.

discharge and again at 2 to 3 weeks of age to assess for any problems that might occur early after discharge (Noble, 2012; AAP & ACOG, 2012).

A mother may be concerned when her infant suddenly seems to want to nurse much more often. She may assume she is not producing enough milk. Nurses can teach mothers that this behavior shows their infants are experiencing growth spurts. They can expect growth spurts at approximately 10 days, 2 weeks, 6 weeks, 3 months, and 6 months after birth (Grodner, Long, & Walkingshaw, 2012).

Guidance for dealing with breastfeeding problems can be continued after discharge by referring the mother to lactation consultants or organizations such as La Leche League, a support group that gives assistance to breastfeeding mothers. La Leche League chapters are available in most communities and are listed in the telephone book. Support groups also may be provided by the birth facility.

FORMULA FEEDING

Formula feeding requires less knowledge and skill than breastfeeding, but the inexperienced parent often has many questions and may need assistance in learning to use formula correctly. Although breastfeeding

is preferable in most situations, the nurse should support the woman who has decided to use formula.

APPLICATION OF THE NURSING PROCESS

■ Formula Feeding Assessment

Assess both the mother and the infant during the feeding process.

Mother's Knowledge

Assess the mother's knowledge of bottle feeding. Ask her if she has fed an infant before and whether she has questions. Observe her technique during the initial and subsequent feedings. Note how she holds the infant and the bottle, and evaluate her burping technique to identify areas where she seems unsure.

Infant Feeding Behaviors

Point out infant feeding cues, which are the same regardless of how infants are fed. Waiting until the infant is frantic may result in a feeding taken too fast, with excess swallowing of air or choking. Assess the way the infant sucks to identify problems.

Nursing Diagnosis

Because improper formula preparation and feeding techniques could harm the infant, an appropriate nursing diagnosis for the mother using formula feeding is "Risk for Ineffective Health Maintenance (Infant) related to mother's lack of understanding of formula preparation and feeding techniques."

Expected Outcomes

The mother will demonstrate correct techniques in holding the infant and bottle during feedings and will correctly describe how to prepare formula and the frequency of feedings.

Interventions

Teaching about Formula

The mother must learn about types of formula to use and how to prepare it.

Types of Formula. The physician or nurse practitioner prescribes the type of formula the mother is to use. Infants should receive iron-fortified formula. Formula may be purchased in three different forms: ready-to-use formula, concentrated liquid formula, and powdered formula.

Ready-to-Use Formula. Ready-to-use formula is available in bottles to which a nipple is added or in cans to be poured directly into a bottle. It should not be diluted. The container should be shaken before pouring it into a bottle. Although expensive, it is practical when traveling, when there is difficulty in mixing formula, or if the water supply is in question. Refrigeration is not necessary until the container is opened. An open can should be refrigerated and used within 48 hours.

Concentrated Liquid Formula. Explain to the parents how to dilute concentrated liquid formula. Equal parts of concentrated liquid formula and water are mixed together and poured into a bottle to provide the amount desired for each feeding. Opened cans should be stored in the refrigerator and used within 48 hours (Kleinman, 2009).

Powdered Formula. Powdered formula is more economical and is particularly useful when a breastfeeding mother plans to give an occasional bottle of formula. Usually one level scoop of powder is added to each 2 oz (60 mL) of water in a bottle. Single portion packets of powder are convenient when away from home. Because powdered formula is not sterile, it is not recommended for preterm or immunocompromised infants.

Formula should be well mixed to dissolve the powder and make the solution uniform. New formula should be prepared for each feeding and used immediately or refrigerated for no more than 48 hours. Cans of powdered formula should be kept covered and used within 4 weeks after opening (Kleinman, 2009).

⚡ SAFETY ALERT

Formulas must be properly diluted to prevent serious, possibly fatal, illness (such as fluid and electrolyte imbalance) and to promote weight gain and growth in the infant. It is essential that the label be followed accurately.

- Ready-to-use preparations: Use as is without dilution.
- Concentrated formulas: Dilute with equal parts of water.
- Powdered formulas: Mix one level scoop of powder with 2 oz (60 mL) of water.

Equipment. Many different types of bottles and nipples are available. Mothers may use glass or plastic bottles or a plastic liner that fits into a rigid container. Selection of type of bottles and nipples depends on individual preference. Although bisphenol-A (BPA) was once a concern, it is no longer used in baby bottles in the United States.

Preparation. Discuss preparation of formula with the mother. Instruct the mother to wash her hands as well as the top of the can and the can opener (if needed). Infection may occur if the equipment, milk, or water used for preparation is contaminated. Emphasize the importance of following the directions on the label when mixing the formula. Improper dilution of the formula may cause undernutrition, imbalances of sodium level, and an excessively high renal solute load, which can be dangerous to the infant.

The mother can prepare a single bottle or a 24-hour supply. If the water supply is safe, sterilization of the milk and equipment is not

necessary for normal newborns. However, all water mixed with formula should be boiled for 1 minute. Longer boiling time is not advised because the minerals in the water may become too concentrated (Kleinman, 2009). If water from a well is used, it should be tested for high levels of nitrates, which can be harmful to infants.

Bottles and nipples can be washed in hot, sudsy water using a brush to clean well, then rinsed, and allowed to air-dry. They may also be washed in a dishwasher. The formula and water are poured into the bottles, which then are capped. Emphasize that the proportion of water and liquid or powdered formula must be followed exactly to avoid causing illness in the infant.

Explain that if safety of the water supply is questionable, sterilization by the aseptic or terminal method is necessary. In both methods all equipment is washed and rinsed well before beginning. In the aseptic method, equipment needed for the procedure is boiled for 10 to 12 minutes in a sterilizer or deep pan (Nickols-Richardson, 2011). Water for diluting the formula is boiled separately. The bottles are then assembled using sterilized tongs. The formula and boiled water are added, and the bottles are capped and refrigerated until needed.

In the terminal sterilization method, the formula is prepared in clean, loosely capped bottles. The bottles are then placed in the sterilizer or pan of water and the pan is covered. After boiling for 25 minutes, the bottles are allowed to cool (Eiger, 2009). The caps are then tightened and the bottles refrigerated. Prepared bottles should be used within 24 hours (Kleinman, 2009).

Explaining Feeding Techniques

Positioning. Show the parents how to position the infant in a semi-upright position such as the cradle hold. This allows them to hold the infant close in a face-to-face position. The bottle is held with the nipple kept full of formula to prevent excessive swallowing of air (Figure 22-15). Placing the infant in the opposite arm for each feeding provides varied visual stimulation during feedings.

Burping. For the first few days, the infant should be burped or “bubbled” after every 0.5 oz (15 mL) of formula. Gradually, the infant is able to take more milk before burping and should be burped halfway through feeding. Show the parents how to burp the infant over the shoulder or in a sitting position with the head supported while patting or rubbing the infant’s back (Figure 22-16).

FIG 22-15 This mother holds her infant close during bottle feeding. The bottle is positioned such that the nipple is filled with milk at all times. The father offers encouragement.

FIG 22-16 The mother burps the infant by holding him in the sitting position. She supports the infant's head and chest with one hand and gently pats the back with the other hand.

Frequency and Amount. Instruct the parents to feed the infant every 3 to 4 hours but to avoid rigid scheduling and take cues from the infant. Hunger signs are the same as for breastfed infants. Explain that the bottle-fed infant takes 0.5 to 1.5 oz (15-45 mL) at a time at first and 12 to 24 oz/24 hr (360-720 mL) after the first few days (Jana & Shu, 2011).

Cautions. Instruct the mother not to heat formula in a microwave oven because the heating will be uneven. This may result in some parts of the liquid being very hot even when the outside of the bottle feels

only warm. Formula can be heated by placing it in a container of warm water for 5 to 10 minutes. Suggest that the mother test the formula temperature by allowing a few drops from the bottle to fall on her inner arm.

Sometimes, formula flow is too fast for infants. If this occurs, the infant may choke, gag, sputter, drool, or bite the nipple. Some infants suck without stopping to breathe frequently enough. To provide a rest period, the mother should tip the baby forward to stop the flow of milk.

Caution parents not to prop the bottle. Propping increases the likelihood of choking if regurgitation occurs and eliminates the holding and cuddling that should accompany feeding. Some mothers put an infant to bed with a bottle propped. This not only increases the danger of aspiration but also allows milk to pool in the mouth. Prolonged contact of teeth with milk promotes growth of bacteria and leads to cavities once teeth erupt. Otitis media is also more common in infants who sleep with a bottle or feed from a propped bottle.

The parents should not try to coax the infant to finish every bottle because it could cause regurgitation and excessive weight gain. The mother should not save formula from one feeding to the next because of the danger of rapidly growing bacteria. Any formula not used within 1 hour should be discarded.

Infant Variations. Infants vary in their feeding preferences. Some infants drink from the bottle reluctantly. Although formula is usually given at room temperature, some infants take heated or cool formula better. The mother of a sleepy infant needs to use the same wake-up techniques described for the breastfeeding mother.

Angling the tip of the nipple so that it rubs the palate triggers the suck reflex in most infants. It may take patience and persistence to find the most effective techniques.

Evaluation

The mother should hold the infant and bottle correctly during feedings. She should be able to correctly describe formula preparation and the amount and frequency of feedings.

SUMMARY CONCEPTS

- Full-term breastfed infants need 39 to 45 kcal/lb (85 to 100 kcal/kg) and formula-fed infants need 45 to 50 kcal/lb (100 to 110 kcal/kg) daily. They may lose weight in the first few days after birth as a result of insufficient intake and normal loss of extracellular fluid and meconium.
- Lactogenesis I begins during pregnancy and continues after birth with the secretion of colostrum. Lactogenesis II begins 2 to 3 days after birth when transitional milk appears. Lactogenesis III is the time when mature milk replaces transitional milk.
- Colostrum is rich in protein, vitamins, minerals, and immunoglobulins. Transitional milk appears between colostrum and mature milk. Mature milk continues to provide immunoglobulins and antibacterial components.
- Breast milk has nutrients in proportions required by the newborn and in an easily digested form. Most commercial formulas are cow's milk adapted to simulate human milk.
- Breast milk contains factors that help establish the normal intestinal flora and prevent infection. These include bifidus factor, leukocytes, lysozymes, lactoferrin, and immunoglobulins.
- A variety of commercial formulas is available. They include modified cow's milk formula, soy-based or hydrolyzed formulas, and formulas for preterm infants or those with special problems.
- The American Academy of Pediatrics recommends exclusive breastfeeding for the first 6 months and continued breastfeeding with the addition of complementary foods until the infant is 12 months old or longer.
- Factors that influence the mother's choice of feeding method include knowledge about each method, support from family and friends, cultural influences, and employment.
- Suckling at the breast causes release of oxytocin, which triggers the let-down reflex. It also causes the release of prolactin, which increases milk production.

Continued

SUMMARY CONCEPTS—cont'd

- The principle of supply and demand applies to breastfeeding. Milk production increases when the infant feeds frequently. When breastfeeding ceases, prolactin is decreased and eventually the alveoli of the breasts stop producing milk.
- Flat and inverted nipples should be identified during pregnancy. Creams and methods to toughen the nipples are not necessary.
- The nurse should assess the mother's knowledge and the condition of her breasts and nipples. The LATCH score can be used to identify problems.
- The nurse can help the mother establish breastfeeding by initiating early feeding, assisting her to position the infant at the breast, and showing her how to position her hands. The nurse should teach the mother how to help the infant latch onto the breast, assess the position of the mouth on the breast, and how to remove the infant from the breast.
- The mother should feed the infant 8 to 12 times each day for an average of at least 10 to 15 minutes of effective suckling on each side, or until the infant is satisfied.
- Wake-up techniques for sleepy infants include unwrapping the blankets, placing the infant skin to skin with the mother, talking to the infant, changing the diaper, rubbing the infant's back, and expressing colostrum onto the breast.
- When infants suck from a bottle, they must push the tongue against the nipple to slow the flow of milk. When they suckle at the breast, they position the nipple far into the mouth so that the gums compress the areola.
- The nurse can help the woman with engorged breasts by encouraging her to nurse frequently, apply heat and cold, massage the breasts, and express milk to soften the areola.
- The nurse teaches the mother with sore nipples how to check the positioning of the infant at the breast. The mother should vary the position of the infant at the breast and apply breast milk and warm-water compresses to the nipples. She should also expose the nipples to air.
- Teaching for the mother who plans to work and breastfeed includes expression of breast milk by hand or pump and proper storage of the milk.
- Mothers who use formula need information about the types of formula available, correct preparation, and feeding techniques.
- Formula should be diluted exactly according to directions. It should not be heated in a microwave.

Home Care of the Infant

WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain why nurses need knowledge about care of the infant during the early weeks after birth.
2. Describe postdischarge nursing care included in home visits, clinic visits, and telephone follow-up.
3. Explain the safety features of infant equipment that parents must consider.
4. Explain methods of resolving common problems involving infant crying and sleep patterns during the early weeks of parenting.
5. Answer common questions that parents might have about care of the young infant.
6. Describe the normal changes in growth and development of the infant during the first 12 weeks of life.
7. Explain the purpose and importance of well-baby checkups and immunizations for infants.
8. List the signs that indicate illness in the infant.
9. Discuss current knowledge about sudden infant death syndrome.

Nurses often receive questions from parents about care of infants after discharge from the birth facility. This chapter provides information about caring for infants during the first 12 weeks of life. The focus is on teaching parents beyond the usual birth facility discharge teaching, which is included in [Chapter 21](#). Detailed information about ill or older infants can be found in pediatrics textbooks.

INFORMATION FOR NEW PARENTS

Needs

The early weeks after birth are often stressful for new parents. The mother is tired from the pregnancy and birth, both parents may be anxious about their new role, and the newborn may be awake much of the night or may behave in unexpected ways. Parents have concerns about ongoing care of the infant and adjustment to parenthood.

Sources of Information

In the birth facility, parents often receive more information about care of the newborn than they can absorb in the short time available. New mothers' physical needs and anxieties often interfere with their ability to learn. This may leave parents inadequately prepared to cope with the multiple demands of early parenting.

Family members, once the primary source of support for new parents, frequently live far away, and parents must rely on friends, health care personnel, child care classes, television, books, and magazines. Many people get information from the Internet. Parents should determine if the source of information obtained online is valid because if it is from nonprofessional sources, it may not be accurate. Friends can be important sources of support and information, but their knowledge may be incorrect or outdated. Nurses are ideal sources of assistance in these situations.

CARE AFTER DISCHARGE

Various programs have been instituted to provide after-discharge care for mothers and infants. They may include nursing contact with the family in the home, in the clinic, or by telephone.

Home Visits

The home visit is ideally scheduled during the first 24 to 72 hours after discharge. This timing allows early assessment and intervention for problems in nutrition, jaundice, newborn adaptation, and mother–infant interaction. Nurses may visit low-risk mothers and infants or may follow high-risk infants after discharge from the neonatal

intensive care nursery (Figures 23-1 to 23-4). Visits usually are 60 to 90 minutes to allow enough time for assessment and teaching. Home visits are expensive and are not available in all areas, but they do provide the most comprehensive care.

Nurses who care for patients in the home setting have a great deal of autonomy. They should be experienced in patient care and be able to function independently. Nurses who work in the community have several years of experience in the acute care setting and gain skill in a variety of areas.

Visits to Low-Risk Families

During the home visit, the nurse performs a physical examination of the mother and the infant. Family adaptation to the addition of a new member and the adequacy of the mother's support system is also assessed. Reinforcement of the teaching that was begun at the birth facility is important. A feeding session should be observed, especially if the mother is breastfeeding. The nurse may take blood for metabolic screening if the infant went home too early to have had reliable testing in the birth facility. Safety in the home is often discussed, and questions about infant care and general parenting are answered.

Home visits provide reassurance for parents and may increase a woman's confidence and competence in caring for herself and her infant. The visits are especially valuable in recognizing jaundice and intervening before bilirubin levels become dangerously high. When jaundice is found, the nurse can discuss the implications and check the transcutaneous bilirubin level or draw blood for testing serum

bilirubin levels. Appropriate care, including hydration and phototherapy, is discussed, as necessary.

Feeding is an area of concern for many mothers, especially if they are breastfeeding. When the nurse helps a woman cope with problems, the infant's intake may increase. Increased intake leads to greater bilirubin excretion, which may help avoid the need for phototherapy.

FIG 23-1 During the home visit, the nurse performs a complete assessment of the infant. Here, she is checking the apical pulse and listening to breath sounds.

FIG 23-2 Jaundice is especially of concern when infants are discharged early after birth. The nurse shows the mother how to blanch the skin to check for jaundice and discusses what the mother should do if she sees jaundice in her baby.

FIG 23-3 The nurse discusses thermoregulation with the mother and demonstrates swaddling.

FIG 23-4 The nurse observes a feeding during the visit to assess feeding techniques and provide a chance for parents to ask questions about feeding. This is a good time to assess parent–infant interaction. The infant is weighed to help determine adequacy of intake.

Visits to Families with High-Risk Infants

High-risk infants (see [Chapters 29](#) and [30](#)) often need special care after discharge. Parents may be very anxious about assuming the care of an infant who has had a prolonged hospitalization. Many hospitals have programs that enable parents to take over their infant's care gradually before discharge.

A nurse may visit the home before the infant's discharge to help the family plan for accommodating the equipment and the type of care the infant needs. The home is checked for the availability of electricity, heat, and a telephone. If the family has a technology-dependent infant, the nurse checks that they have notified the utility companies and have battery backup to ensure that no disruption of services occurs.

After the infant is discharged, nursing visits can help the family maintain the infant's health and decrease the need for rehospitalization. Components of each visit vary according to the infant's needs. The nurse provides assessment of the infant and the parents' caregiving ability in addition to necessary teaching and nursing care.

Medically fragile infants may require home treatment with mechanical ventilation, oxygen therapy, or apnea monitors. Parents may have to perform such nursing skills as tracheostomy care, tube feedings, suctioning, and care of intravenous sites. Mothers often have concerns about feeding the infant, which may differ greatly from feeding a healthy full-term infant. Follow-up telephone calls from nurses between visits help families adapt to the needs of these infants and may also decrease the need for rehospitalization.

The home health nurse may be part of an interdisciplinary team of health care providers working with families in the home. The nurse may help coordinate care by different professionals. Some infants are eligible for home health aides who provide direct care in the home. The aide is supervised by a nurse.

Infants with complications often need more frequent visits to the pediatrician or nurse practitioner or are rehospitalized during the early months after birth. Common problems include respiratory illness, infections (gastroenteritis, sepsis, urinary tract infections, otitis media), and need for surgery. These parents need information on preventive measures and care of the infant with an acute illness.

Although parents' greatest concerns involve the infant's health, other problems may also exist. Finding a babysitter who is qualified to care for an infant who must receive oxygen or who might need

resuscitation may be difficult. Siblings often have difficulty adjusting to the needs of the infant and may resent not having the parents' full attention. The nurse can make suggestions and help parents contact parent groups that offer practical help in caring for a high-risk infant.

General Considerations in Home Visits

The nurse making a home visit is a guest of the family and must adapt nursing care to the home setting. The needs of other family members must be considered. For example, the examination of the infant may need to wait for a short time while the mother meets the needs of her other small children.

Careful planning before the visit is essential to make the most of the limited time available. The nurse calls to schedule the visit at a time convenient for the family and to obtain directions to the home. Setting priorities based on the needs identified by the nurse and the family is important, especially when only one visit is planned. Communication skills are particularly important when the setting is the home and the patient is the family. The nurse must develop rapport with family members quickly and work with them to meet shared goals. A brief social interaction may be beneficial at the beginning of the visit to develop a trusting relationship. The purpose of the visit should be explained and the family's expectations and desires discussed. Open-ended questions and therapeutic communication techniques help the nurse identify and address the family's needs. Making suggestions in a positive manner is important.

The nurse should be aware of any cultural practices affecting the family's view of care. In patriarchal cultures, the father is the head of the family and teaching should be performed through him. In some cultures, one or both grandmothers are important influences in the care of the mother and the infant.

After the visit, additional visits may be planned or the family may be given a telephone number to call to receive further help, if needed. The results of the assessments, teaching, nursing care, referrals, and plans for follow-up should be recorded. Copies of the record usually are sent to the primary caregiver. If problems are identified that need to be discussed with the primary care provider, a report is made by telephone.

Outpatient Visits

Outpatient visits may be provided in a pediatrician's office or in a birth facility clinic often managed by nurses. Assessment and care are essentially the same as those provided for home visits. A feeding session is often observed for the lactating mother so that the nurse may offer assistance.

The advantage of outpatient visits is that the nurse does not have to travel to the home and can see more patients each day, thereby reducing the cost of the service. Assessment of the home setting and family interaction, however, is not possible. Clinic visits usually last 30 to 45 minutes.

Parenting Classes

Nurses often provide classes in child care and parenting. See [Chapter 11](#) for information about these classes.

Telephone Counseling

Telephone counseling may be provided during follow-up calls to discharged patients or when parents call "warm lines" for help with problems or questions. Telephone calls are much less expensive than home or clinic visits. The major disadvantage is that the nurse cannot perform an in-person assessment of the mother, baby, or home environment and must rely on the caller to present an accurate picture of the situation.

Follow-Up Calls

Follow-up calls are placed by nurses in the first few days after discharge. The nurse asks a series of questions to assess the physical condition of the mother and infant and to identify any needs or problems. All mothers may receive calls or only those considered at risk for problems. If problems are discovered, the nurse may schedule another call or a home visit, if available, or refer the woman to her primary care provider.

Warm Lines

Warm lines, also called *help lines* or *information lines*, provide parents with an opportunity to ask a nurse questions arising from the daily challenges of parenting. Warm lines are used for troubling, but not emergency, situations. The service should be available 24 hours a day and should be staffed by qualified nurses. Parents often call about infant feeding, breastfeeding concerns, postpartum blues, and basic care of the mother and infant. Calls last about 15 to 20 minutes. The nurse answers the caller's questions and assesses for other problems. The nurse may call back later to find out if the issue has been resolved.

Telephone Techniques

Nurses caring for patients by telephone must understand telephone counseling techniques. They need special education in telephone communication and triage.

Open-ended questions or statements help the mother describe any problems in her own terms. Some examples are as follows:

“How have you been getting along since you left the hospital?”

“Tell me about any situations where you weren't quite sure what to do.”

“What has been most difficult?”

Telephone triage involves determining the existence of and solution to a serious problem. Callers may not describe the situation accurately. The nurse must be skilled at soliciting information to identify problems and determining the priority of the problems identified. For instance, does the information obtained indicate that the family should come to the office or clinic for a more thorough assessment by their health care provider? Should they come now, or can they wait? Can their problem be solved by information or advice?

The nurse should help the caller describe the major concerns, which may not be those discussed first. “What worries you most?” may help the caller focus on the most important problems. Although most problems discussed are concerns about normal infants, the nurse must be alert for “red flags” that signal serious situations needing immediate referral.

The patient should be allowed enough time to avoid feeling hurried. Lay terminology should be used and questions asked to elicit detailed description of the problems. Parents should be reassured that their questions are valued so that they do not feel hesitant to ask what they may see as a “silly” question.

Guidelines and Documentation

When nurses give care by telephone, they must have written protocols and policies that provide guidelines for care to ensure that all who perform this service provide patients with similar information. A list of common questions can be compiled to help nurses give appropriate information when parents call about a problem.

Parents should always be told when and how to seek more care if problems are not resolved. If the infant seems ill, referral to the pediatrician or hospital emergency department is most appropriate. The nurse's judgment, based on education, expertise, and experience, determines how helpful the service is to patients.

CRITICAL TO REMEMBER

Red Flags of Telephone Triage

- An emergency situation (such as respiratory difficulty, bleeding). Tell the parent to call 9-1-1 or take the infant to a hospital emergency department immediately. Call back in 5 minutes to ensure that parents did seek help.
- Illness (fever, dehydration, change in feeding or behavior, unusual rashes).
- Severe feeding problems (infant may become dehydrated or jaundiced or may fail to thrive).
- Problem has been present for longer than usual or usual remedies are ineffective (such as prolonged crying or sleeping, rash is spreading).
- Parent's affect seems inappropriate for situation (extremely emotional with apparently minor situation or unconcerned when situation could be serious).
- *Note:* Callers should be referred to the primary health care provider or the hospital emergency department, if necessary, when a serious problem may be present. Being overcautious is preferable. Refer parents to the primary care provider early rather than miss a serious situation.

All calls should be documented so that accurate legal records are available for future reference. The nurse may use a checklist or a simple written description of the call. Documentation should include identifying information for the caller, reason for the call, problems described, advice given, and any referrals given. A copy of the information is sent to the primary caregiver to provide continuity of care.

CHECK YOUR READING

1. Where do parents obtain information about caring for their infant during the early weeks after birth?
2. What are some ways in which nurses offer follow-up services to new parents?

INFANT EQUIPMENT

Generally, parents obtain most of their baby equipment before the infant is born, but nurses may receive questions in the weeks after the birth. Although nurses should never recommend specific brand names of equipment, their guidance about features and safety is helpful.

Safety Considerations

Parents, especially those of limited means, need to understand that few, if any, pieces of equipment are absolutely essential for newborns. Infants sleep in padded dresser drawers and designer cribs with equal comfort. Safety is the most important consideration.

New equipment sold in the United States is generally safe because manufacturers are required to follow certain governmental standards for safety. A recent ruling by the U.S. [Consumer Protection Safety Commission](#) (2011) has banned the sale of cribs with a side rail that drops down. Other changes included in the ruling have made cribs more durable and safer for infants.

Hand-me-down equipment may have been recalled by the manufacturer for safety defects. Parents can check with the Consumer Product Safety Commission (CPSC) for a list of recalled products at www.cpsc.gov. Older equipment should be checked carefully to ensure that all parts are strong and working properly ([Box 23-1](#)). All nuts, screws, bolts, and hooks should be checked periodically to ensure that they are tight.

Car Safety Seats

Child safety seats for cars are essential to reduce injury and death to infants and children when accidents occur. An infant carried by an

BOX 23-1 SAFETY CONSIDERATIONS FOR INFANT EQUIPMENT

Cribs

- Cribs that meet the new Consumer Protection Safety Commission guidelines should be used for infants.
- If parents choose to use an older crib, an immobilizer should be added to prevent drop sides from moving. The crib should be checked frequently to be sure hardware is secured tightly and no loose, missing, or broken parts are present.
- The crib mattress should fit snugly with less than two fingers able to fit into the space between the mattress and the sides of the crib. More room could allow the infant to become wedged in that space and possibly suffocate. The mattress should be firm. The crib should contain no loose bedding, pillows, or stuffed animals because they increase the risk of suffocation.
- Crib toys or mobiles should be firmly attached, with no straps or strings within the infant's reach. Mobiles should be removed when the infant can reach them.
- Cribs should be placed away from hanging cords of blinds or drapes, which could become wrapped around an active infant.
- Cribs should be placed away from windows.

Other Equipment

- Paint used to refurbish infant equipment should be marked "lead-free" and "safe for children's equipment" to prevent lead poisoning.
- All parts should function properly: highchair trays must stay firmly in place, latches must remain fastened, and so on. The frame and basic construction of all equipment should be sturdy.
- All moving parts should be examined carefully to see whether little fingers could get caught or whether the infant could trigger a catch that would cause the equipment to become unsafe.
- Safety straps for infant seats, swings, changing tables, high chairs, or other equipment must be in good condition. Straps should fit around the infant but not be long enough that the infant could become entangled.
- Automatic swings should have legs that are stable so that the swing does not tip over. Note how difficult it is to put the infant into the swing and to remove the infant from the swing safely.
- All toys should be examined carefully for parts that can be removed and swallowed. Small toys should have a diameter of more than 3.5 cm (1 $\frac{3}{8}$ inches) and be at least 6.35 cm (2 $\frac{1}{2}$ inches) long to prevent the infant from choking on them.

adult while in a car is never safe. A sudden stop or accident could cause the baby to be hurled against the dashboard or crushed by the adult, who would be thrown forward by the force of the impact. Legislation has been passed in all 50 states in the United States requiring restraint of infants and young children in car seats when they are riding in automobiles.

Laws vary with regard to when and at what weight or height an infant or child can move from one type of car seat to another. The American Academy of Pediatrics (AAP) had earlier recommended that infants be placed in a rear-facing seat until 12 months of age. The current recommendation is that rear-facing seats be used for infants until they are 2 years of age or have reached the highest weight or height allowed by the car seat manufacturer (AAP, 2011b).

Discharge teaching should include information about state car seat laws and the change in the age at which infants can move to a forward-facing seat. Infants should be placed in a rear-facing car seat when they are discharged from the hospital. The seat should recline at approximately a 45-degree angle (Figure 23-5).

FIG 23-5 A car seat for an infant under 2 years should face the rear of the car. Note the clip that holds the straps together for a snug fit.

The harness of the car seat should firmly restrain the infant and yet be quick and easy to fasten. The shoulder straps should be in the lowest position at or slightly below the shoulder level. In forward-facing seats, the straps should be at or slightly above the shoulders. Straps should be snug and should not be twisted. The restraint clip should be placed at the mid-chest or axillary level to keep the straps in place on the infant's shoulders.

Blankets should never be placed under the infant or behind the infant's back or head. If a blanket is needed for warmth, it should be placed over the infant after the harness and clip are in place. After the infant is restrained, rolled blankets can be placed at the sides or special bolsters positioned around the head to increase comfort by preventing slouching of the head.

All car seats should be secured tightly in the car, according to manufacturer's instructions, to prevent the infant from being thrown forward on impact. If the seat can be moved 1 inch forward, backward, or side to side, it is too loose. Car seats are safest when they are placed in the center back seat of the car. They should never be placed in the front passenger seat in a car with air bags because serious injury or death may occur when air bags inflate and hit the car seat. If placing a car seat in the front seat is absolutely necessary, the air bags should be disengaged. Even with the air bags turned off, however, the front seat of the car is not as safe as the back seat for infants and children.

Preterm and small infants may need special adaptations. Blankets or bolsters placed at the head, along the sides, and between the legs may improve the fit. Blankets and bolsters should not be placed under the infant. Some infants have low oxygen levels, bradycardia, or apnea when in a car seat. Facilities often have parents of infants who are less than 37 weeks of gestation or low birth weight bring their car seat to the hospital to test the infant's response to being placed in the seat. During testing, the infant's vital signs and oxygen level are monitored. Infants who have respiratory compromise in car seats may need to use special seats or beds designed specifically for preterm or low-birth-weight infants (Daily, Carter, & Carter, 2011).

Although most parents believe they are using their car seats correctly, the seats are often used improperly. Such misuse could result in injury or death of the child. An incorrectly fastened harness may not restrain the infant in an accident and could cause serious injuries such as laceration of the liver. If the automobile seat belt is not routed through the correct area of the car seat, the seat may tip or become a flying missile during an accident. Car seats should be used only according to manufacturer's directions (Box 23-2).

BOX 23-2 SAFETY CONSIDERATIONS FOR INFANT CAR SEATS

- Use only car seats that are approved for use in automobiles. Seats designed for use in the home do not provide adequate protection in a car.
- Use car seats that are appropriate for the infant's age and size. Place the seat in the center of the back seat of the car, never where an air bag is installed.
- Use a rear-facing car seat placed in the back seat until your baby is at least 2 years old or reaches the highest height and weight recommended by the manufacturer. Never place the baby in the front seat of a car if there are passenger-side air bags.
- Follow the manufacturer's directions for fastening the seat in the car and the infant in the car seat. Recheck the restraint straps each time the seat is used.
- Be certain that the straps are tight enough to prevent the infant from getting out of the restraints or turning over in the seat. Infants who turn over can suffocate in the padding of the seat.
- Be certain that the infant cannot become caught with the straps tightly around the neck.
- Use car seats only in an automobile. Do not place them on a soft surface such as a bed, where they might turn over and suffocate the infant.
- Do not place car seats on surfaces from which they might fall, for example, grocery carts.
- Never leave infants alone in a car, even for a few minutes. They could be kidnapped or injured in an accident involving the car even though it is parked. Cars quickly become very warm, and the infant could become dangerously overheated.

In many agencies, nurses are not allowed to install car seats for parents. Some agencies have technicians on site who have special training to help parents determine if car seats are correctly installed. Car seat fitting stations are available in some areas to determine if car seats are used properly and to provide teaching for parents. A list of such stations is available at www.nhtsa.dot.gov/cps/cpsfitting/index.cfm. Further information about proper use of car seats, recall of seats, and a rating system of car seat brands is available on the Internet from sources such as the National Transportation Safety Board at www.nhtsa.gov.

EARLY PROBLEMS

Crying

Crying is a major parental concern during the early weeks after birth. Crying peaks at approximately 6 weeks of age at up to 3 hours per day. It usually decreases to 1 hour or less each day by 3 months (Feigelman, 2011). Crying is most frustrating to parents when they cannot find the cause for it. Infants cry for many reasons, including hunger, discomfort, fatigue, overstimulation, and boredom. Parents can often identify the problem on the basis of the type of sound made during crying. Sometimes no specific cause can be determined.

When the cause for crying is not obvious, some parents are afraid that responding may spoil the infant. If the infant stops crying when picked up, their concern may increase. However, changing the infant's

position may help gas move in the intestines, relieve tired muscles, or distract the infant by changing the scenery, bringing about a temporary end of crying.

Infants cannot signal that they have unmet needs in any other way but by crying and are not spoiled when parents meet their needs. In fact, their needs must be met in a consistent, warm, and prompt manner for the development of trust to occur. Infants who are consistently held when in distress cry less at 1 year and are less aggressive at 2 years of age (Feigelman, 2011). Therefore parents should be taught the importance of consistently and quickly answering infant cries.

Some families develop creative methods for dealing with crying infants. Others benefit from a nurse's suggestions about appropriate techniques to use.

Colic Description

Colic is characterized by irritable crying for no obvious reason for 3 hours or more per day. It usually takes place during the late afternoon or evening on at least 3 days per week, lasting at least 3 weeks. It occurs in 10% to 20% of infants under 3 months of age. Colic begins at 2 to 3 weeks, peaks at 6 to 8 weeks, and ends at 3 to 4 months of age (Grover, 2012a). Some infants continue to have colic until 6 months of age. The infant is in good health, eats well, and gains weight appropriately despite the daily crying episodes. Both breastfed and formula-fed infants have colic.

Infants with colic cry as though in pain, draw their knees onto the abdomen or rigidly extend the legs, and may pass flatus. The crying is intense and may last until the infant falls asleep, exhausted. Because crying causes so much parental distress and may interfere with bonding or be a factor in parenting disorders or child abuse, nurses should find ways to provide support to parents of infants with colic.

Although many theories have been investigated, the cause of colic remains unknown. Allergies to cow's milk or to substances in the breastfeeding mother's diet, abnormal intestinal peristalsis, gastrointestinal tract or nervous system immaturity, feeding techniques such as overfeeding, and parental stress have all been considered. The cause is probably a combination of factors. Actual disease states must be ruled out before a diagnosis of colic can be made.

Interventions

Nursing interventions include using therapeutic communication to help parents express their frustrations and teaching techniques for coping with the problem. Parents should be encouraged to talk about their feelings and should be reassured that colic is temporary and does not indicate poor parenting. They often feel inadequate because of their failure to manage the problem and guilty if their frustration develops into anger.

The nurse should explain that it is not abnormal to have ambivalent feelings or even anger toward the infant. It is essential to take time away from infant care to rest and recoup energy needed to cope with the demands of a crying infant. Parents should leave the infant with a babysitter for short periods or take turns consoling the infant to provide breaks from the crying.

The techniques listed in "Parents Want to Know: Methods to Relieve Crying in Infants" may temporarily alleviate crying caused by colic, but generally no technique gives prolonged relief. Feeding the infant in an upright position and burping frequently may help relieve discomfort caused by swallowed air. Use of the "5S's" technique may be helpful (Grover, 2012a). Chamomile tea is often given to infants, as it has an antispasmodic effect. Any herbs the parents are using should be checked with the health care provider to ensure they are safe. Studies have not proven effectiveness for any herbs (Perry, Hunt, & Ernst,

PARENTS WANT TO KNOW

Methods to Relieve Crying in Infants**Treating Common Causes**

Hunger—Try feeding the infant if it has been more than 30 minutes since the last feeding. A bubble of air may have caused a feeling of fullness too soon during the last feeding. The infant may be experiencing a “growth spurt” and need more frequent feedings for a day or two to provide necessary nutrients for rapid growth. However, avoid overfeeding the baby, as that may cause discomfort.

Air bubbles—Fussy infants may need more frequent burping during and after feedings compared with other infants. Try burping during crying spells because the infant may swallow air.

Diapers—Although most infants do not mind wet or soiled diapers, they may become cold or their skin may be irritated when diapers are not changed frequently enough.

Clothing—Check the infant’s clothing for anything that could cause discomfort. Look for stiff seams, tags that are scratchy, or elastic that is too tight.

Warmth—Be sure that the infant is warm enough, but not too warm. The abdomen should feel warm even if the hands and feet are slightly cool. Dress a newborn as warmly as an adult would want to be dressed, but add a receiving blanket. Infants who are overdressed rarely perspire but often cry because of their discomfort.

Overstimulation—Too many visitors handling the infant or too much noise and commotion in the household may be overstimulating the infant. Holding the infant in a quiet environment, rocking, or walking with the infant may be helpful.

Quieting Techniques

Rocking—The gentle motion of rocking, reminiscent of intrauterine life, is often soothing for infants.

Automatic swings—The continued motion of automatic swings may be helpful. Be sure they move smoothly and are not noisy. Getting the baby into and out of the swing should be easy to avoid awakening the infant. All parts of the body should be supported. Small infants may need padding with blankets for safety and comfort. Observe the baby throughout the time in the swing.

Walking, jiggling, swaying—Sometimes, newborns prefer a particular style of motion. Rocking sideways with the infant held in an upright position is helpful for some infants, whereas others prefer vertical rocking. Taking a walk outside with new sights and sounds may provide distraction.

Skin-to-skin contact—Remove the baby’s clothes and leave just the diaper. Place the baby against the parent’s bare skin and cover both with a blanket. This skin-to-skin contact is often soothing to a young infant.

Swaddling—Wrap the infant snugly. This is comforting because infants are used to restricted activity in the uterus. Swaddling is especially helpful during the first few weeks after birth.

5S’s Technique—A combination of soothing techniques that includes *swaddling* with the infant in the *side* or stomach position, making *shushing* sounds while *swinging* the baby in the arms, and having the baby *suck* on a pacifier has been found to be calming for babies (Grover, 2012a; Harrington, Logan, Harwell, et al., 2012).

Stroller rides—The motion of a stroller may be soothing to some infants. The ride can be inside or outside the house. A parent can move a stroller back and forth with one foot while eating meals. The stroller should allow the infant to lie down rather than sit. Padding the stroller may increase comfort.

Car rides—Some infants go to sleep in a moving car. A short ride may put the infant to sleep. The infant may stay asleep when carried into the house.

Music—The sound of a parent singing or humming may be reassuring to the infant. Some newborns respond well to a music box, radio, or CD. Soft music with a steady beat or classical music may be particularly effective.

White noise—Background noise sometimes puts infants to sleep by diffusing other noises. A radio set on low volume, a clock ticking, an indoor fountain, a fan, or the sound of a dishwasher, dryer, vacuum cleaner, or shower may be effective. Tapes of sounds heard in utero are available.

Heat—A blanket warmed in the clothes dryer for a few minutes held against the infant’s skin may be soothing. (Take care not to burn the infant’s skin.) Do not use a heating pad. Placing the newborn in an infant seat on top of a dishwasher or clothes dryer provides heat and background noise. Be sure that the infant is well secured and watched at all times, of course.

Bathing—Although older infants love baths, young infants may not yet have reached that stage. However, giving a bath may be a distraction for both parent and infant, and the infant may fall asleep after the bath.

Infant carriers or packs—Front carriers are designed for the young infant and may be especially helpful during crying episodes. A parent’s warm body, soothing voice, and gentle swaying motion can often put an infant to sleep. At the same time, the parent can accomplish other tasks. Backpacks should be used only for older infants who are able to support the head well.

Pacifiers—Parents may find pacifiers useful for an irritable infant. The infant may be comforted by sucking even though not hungry.

Position changes—Try varying the infant’s position. Laying the infant prone across a parent’s lap (or over a warmed blanket) may help expel gas. Placing the infant in the supine position and gently flexing the knees on the abdomen may also help.

Massage—Gentle massage may be soothing for some infants. Massage of the abdomen may help infants with colic.

Taking turns—Ask your partner to take turns comforting the baby. This provides each partner with a chance to rest, and sometimes a different approach is effective.

2011). Simethicone, an antifatulent, has not been found effective, although some parents have reported that it helps (Baum, 2009; Grover 2012a).

A quiet environment, a calm approach, and a fairly regular schedule may help some infants with colic. Increasing the time spent carrying the infant often results in some improvement. Parents should be assured that spoiling does not result from responding to the infant’s cries.

One possible result of crying in infants is abusive head trauma (AHT), formerly known as *shaken baby syndrome*. AHT results from blunt trauma or shaking an infant vigorously enough to cause the soft tissue of the brain to bounce against the skull. Subdural or subarachnoid hemorrhage, retinal hemorrhage or detachment, skull and other

fractures, and damage to the spinal cord may result. The infant may show little sign of external trauma.

AHT is the leading cause of deaths from child abuse in the United States. It causes death in 25% of babies who are shaken violently. The primary cause of AHT is inconsolable crying in an infant, usually 4 months of age or less (Centers for Disease Control and Prevention [CDC], 2012a).

Nurses can help prevent AHT by making parents aware of the danger in shaking infants and by helping parents learn methods to cope with infant crying and their own anger that may result from it. Parents are encouraged to share information about the dangers of AHT with other caregivers.

THERAPEUTIC COMMUNICATIONS

Coping with Crying

Linda tells her nurse, Daniel, about her daughter, Rebecca, who has been having crying spells every day lasting 4 hours or longer. Linda looks tired and worried. Rebecca, age 4 weeks, eats well, shows good weight gain, and is developing appropriately for her age.

Linda: It seems like all I do is try to stop Rebecca's crying. I can't get anything else done.

Daniel: You spend a lot of time trying to find ways to comfort her. *(Paraphrasing to encourage the mother to continue.)*

Linda: I've tried everything! I rock her, walk with her, feed her, and change her. We go for car rides and put her in her swing, but nothing works for long. She just starts crying again.

Daniel: It's so frustrating when nothing seems to work! *(Reflecting mother's feelings shows that the nurse is trying to understand them.)*

Linda: Sometimes I wonder if I was cut out to be a mother. I never thought it would be like this.

Daniel: Being a mother is so much harder than you expected that sometimes you aren't sure you made the right choice. *(Reflecting the content of what the mother said helps her focus and shows acceptance.)*

Linda: But I really do love her. I just don't know how to help her. I must be a terrible mother *(becomes teary)*.

Daniel: Parents often feel guilty when they can't find a way to help an upset baby. Yet we really don't know all the reasons why babies cry. You've tried very hard to help Rebecca. Maybe we can work together to think of some other techniques to use. *(Gives reassurance that what the mother is feeling is normal, then offers information and further help.)*

Linda: I'd love that. It worries me to have Rebecca so unhappy. What else can I do for her?

Birth facilities often include pamphlets and other information on AHT with discharge teaching. Various educational programs have been held in hospitals, middle and high schools, daycare facilities, and other community centers to increase the public awareness of the problem. Further information on AHT may be found at Internet sites such as the National Center on Shaken Baby Syndrome at www.dontshake.org.

- Why should parents respond to crying without fear of spoiling the infant?
- How can nurses help parents of crying infants?

Sleep Parents

During the early months after birth, parents often wonder whether they will ever get a full night's sleep again. Because they are so often up during the night, they should try to make up for lost sleep at other times. If the mother is not employed, she may be able to sleep during the day when the infant naps. If she is working, parents can alternate responsibility for night or early morning feedings. When mothers are breastfeeding, fathers can change the diaper, bring the infant to the mother for night feedings, and settle the infant back in bed when the feeding is finished. This allows the mother more time to sleep and lets the father share the middle-of-the-night care.

Infant Sleep Patterns

Although many newborns sleep 16 to 17 hours per day, there is wide variation in the amount of time infants spend sleeping. Infants sleep

PARENTS WANT TO KNOW

How to Help Infants Sleep through the Night

- Allow infants to fall asleep at bedtime on their own instead of always rocking or feeding the infant. If rocking is used, place the infant into the bed when the infant is drowsy but not fully asleep. This may help the infant go back to sleep after awakening in the night even when alone.
- Allow the infant who wakes during the night to cry for a few minutes before responding. The infant may not be completely awake and often returns to sleep if left undisturbed. However, once the infant is awake, respond quickly to meet the infant's needs.
- Keep night feedings for feeding only. Avoid unnecessary activity, or the infant may learn to think of this as a playtime.
- Use a soft light that provides only the amount of light essential for care.
- Give night feedings in the infant's room to further avoid stimulation.
- Keep sounds subdued. Soft music or humming may help the infant return to sleep, but talking should be kept to a minimum.
- Keep night feedings short, and put the infant back to bed immediately.
- Change diapers before beginning the feeding to avoid awakening the infant after feeding.
- As infants near 12 weeks, when sleeping 5 or more hours is more likely, try patting them on the back instead of feeding. Offer water instead of milk.

less deeply than adults and spend 50% of their sleep time in rapid eye movement (REM) sleep (Grover, 2012c). During this type of sleep, they sometimes make noises loud enough to wake parents in the same room, and they move about as if awakening. Going to them at this time is likely to wake them, but they may return to quiet sleep if left alone.

Infants should be positioned on the back for sleep. The nurse should explain that the prone position has been associated with sudden infant death syndrome (SIDS). (See discussion of SIDS on p. 473.) No pillows or soft stuffed animals should be placed in the crib because they could cause suffocation.

Sleeping through the Night

Parents are often confused about when infants should sleep through the night. Newborns are not ready to sleep through the night during the early weeks of life because of their neurologic immaturity. By 12 weeks of age, many infants sleep at least 5 hours at night and most infants sleep that long by 4 months. By 12 months of age, infants take two naps during the day and sleep about 10 hours at night (Grover, 2012c).

Once infants establish longer sleep patterns, they often awaken at night again when they are teething or ill. Therefore, parents can expect to be awakened frequently during the early years. Parents should be taught methods of helping their infants achieve longer sleep periods at night.

Concerns of Working Mothers

Although it has been traditional for women who work to have at least 6 weeks of maternity leave, this is not always possible. Some women must return to work as early as 3 weeks after childbirth. The problems of working mothers are different from those of mothers who remain at home. They must find adequate child care, identify methods of managing the household, and try to find enough time and energy to meet the needs of the infant, other family members, and themselves (see Chapter 18, pp. 355-356).

Working mothers should not become so involved in their many responsibilities that they have little time for their own needs. Some

mothers regularly schedule time for themselves and for family activities. Many working mothers find that the time they can spend with their infant is particularly precious.

Concerns of Adoptive Parents

Although adoptive parents have not experienced pregnancy and childbirth, they must make many of the same adjustments made by biologic parents. In some cases, adoptive parents meet the biologic mother during pregnancy and may even be with her during the birth. Other adoptive parents receive a call after months of waiting to be told that their new infant is ready for them. In both cases, the lives of the adoptive parents change abruptly.

In some agencies, adoptive parents receive the same teaching given to biologic parents. However, their ability to absorb information may be impaired by the excitement of the situation. Although adoptive mothers have not been pregnant or undergone childbirth, they are still tired from the loss of sleep and sudden changes they experience. This may be surprising and worrisome to some. They may have many questions that nurses can answer.

Adoptive parents sometimes feel a greater need than biologic parents to be “perfect,” and they may feel guilt if they do not meet their own expectations. These parents need reassurance and emotional support as they experience this happy but exhausting time in their lives.

CRITICAL THINKING EXERCISE 23-1

Mary and Skip received their adopted daughter, Susan, 3 days ago. They bring the 5-day-old infant to the pediatrician’s office and discuss their concerns with the nurse. They received basic discharge teaching at the hospital where Susan was born but have many questions about infant care. The last two nights Susan slept very little, and both parents are exhausted. “We’ve waited so long to get Susan,” Mary says, “but I’m beginning to wonder if she’s all right and if I’ll be a good mother.”

Questions

1. What are the priorities in this situation?
2. How should the nurse support Mary and Skip?
3. What information should the nurse include in teaching these parents?
4. How should the nurse address Susan’s nighttime wakefulness?

COMMON QUESTIONS AND CONCERNS

Dressing and Warmth

The infant should be dressed as the parents would like to be dressed, with a receiving blanket added. The abdomen should be checked to see if the infant is warm enough. The infant’s hands and feet may be slightly cooler than the rest of the body but should not be mottled or blue. The infant’s head should be kept warm because many thermal skin sensors are located in the scalp. A hat is appropriate if the infant is outside when it is cold or windy.

Stool and Voiding Patterns

Formula-fed infants generally pass at least one stool each day. Breastfed infants may pass a stool after every feeding or, occasionally in the older infant, only one stool every 2 to 3 days. Infants may get red in the face and appear to be straining when having a bowel movement, but this is normal behavior and does not indicate constipation. Stools that are dry, hard, and marbled indicate constipation.

Watery stools indicate diarrhea. A watery stool is absorbed into the diaper with little or no solid material left at the surface. A “water ring”

remains on the diaper, showing where the liquid was absorbed. Diarrheal stools occur more frequently compared with the infant’s normal stool pattern and are greenish from bile moving quickly through the intestines. Diarrhea can be serious because life-threatening dehydration develops rapidly. Infants should be taken to the pediatrician or nurse practitioner for treatment.

The infant should have at least six wet diapers by the fourth day of life. If there are fewer voidings, feedings should be assessed. The infant may not be feeding frequently enough or for a long enough period, if breastfed. The mother should be nursing 8 to 12 times daily, and the formula-fed infant should be fed 6 to 8 times each day.

Smoking

Many mothers quit smoking before or during pregnancy but may not realize that preventing infant exposure to smoke is just as important after birth as before. Infants exposed to smoke from parents’ cigarettes are more likely to develop frequent respiratory tract problems. Smoking is a risk factor in SIDS. Smoke absorption by infants occurs even when smoking is done in another room. Parents who continue to smoke should do so outside the house and away from the infant.

Eyes

Parents can remove small amounts of mucus that accumulate in the corners of the eyes with a damp, clean washcloth, using a separate section for each eye. A large amount of mucus, redness, or excessive tearing indicates an infection or a blocked lacrimal duct. The infant should be seen by the pediatrician or nurse practitioner.

Transient **strabismus**—misalignment or deviation of one or both eyes—is sometimes called “crossing” of the eyes. Although the condition is normal for the first 2 to 3 months, it can be frightening to parents. The nurse should reassure them that it will end after the first few months, when the infant gains control of the small muscles of the eye. It does not indicate that the infant will have later problems. Strabismus that continues after 4 months should be evaluated by an ophthalmologist (Rosales, 2012).

Baths

Bathing, cord care, and care of the circumcision site are discussed in Chapter 21. If the infant is washed well at diaper changes and when milk is regurgitated, bathing the child every day is not necessary. Bathing should be a time for infant stimulation and parent–infant interaction. It can be done at any time of the day that is convenient for parents.

Nails

Nails should be cut straight across with either blunt-ended scissors or clippers. Pressing down on the skin at the fingertip makes it easier to avoid cutting the skin. Nail edges can be carefully smoothed with an emery board. Some mothers prefer to cut nails while the infant is sleeping. Others have someone else hold the baby’s hand steady while cutting nails. Nails grow rapidly and may need trimming once a week.

Sucking Needs

Parents often have questions about pacifiers and thumb sucking or finger sucking. Nurses should explain that all infants have an urge to suck, although the amount of sucking needed varies with individual infants. Some infants seem satisfied by feedings, but others suck their fingers or a pacifier even when not hungry. The AAP recommends the use of pacifiers for sleep and to help prevent SIDS. Use may be delayed until 1 month in breastfeeding infants (AAP Task Force on Sudden Infant Death Syndrome, 2011).

Parents may be concerned that sucking on a pacifier or thumb will cause the teeth to become maloccluded. The nurse should reassure them that sucking that is not all day long, or on an upside down pacifier, and that ends before the secondary teeth begin to erupt is unlikely to cause malocclusion (Berkowitz, 2012).

In some infants, nonnutritive sucking increases because the time they spend sucking during feedings is too short. Breastfed infants should be allowed to continue sucking at the breast long enough to meet basic sucking needs. A short time of sucking after the end of feeding generally satisfies the infant's sucking needs and increases production of milk. For formula-fed infants, bottle nipples should have small holes and be replaced every couple of months before they get soft.

When infants use a pacifier, parents should be instructed to examine it often to see if it is in good condition. Cracked, torn, or sticky nipples or nipples that can be pulled away from the shield should be discarded. Pacifiers should be replaced every month or two because they may come apart as they deteriorate and cause aspiration of parts. The shield on the pacifier should be large enough that it cannot be pulled into the mouth. Pacifiers should not have any decorations that might come off and cause a choking hazard.

Pacifiers should be kept clean by frequent washing, and parents should buy several so that a clean one is always available when needed. Pacifiers should never be placed on a string around the infant's neck. The string could become tangled tightly around the neck and cause strangulation. Clips with a short band to attach pacifiers to the infant's clothing without danger are available, or several pacifiers can be placed in the bed for the infant to find.

Some parents find that one advantage of pacifier use is that the infant gives it up more quickly than a thumb or finger because it is not so easily accessible. Parents who resort to the use of a pacifier as the first response when the infant is fussy are likely to reinforce its use and increase dependence on it. Pacifiers used only after other causes of distress are ruled out may be given up sooner by the infant. Because the need for nonnutritive sucking begins to diminish between 4 and 6 months of age, pacifier use may begin to decrease at that time with parents' help.

Common Rashes

Diaper Rash (Diaper Dermatitis)

Diaper rash occurs as a result of prolonged exposure of skin to wetness, urine, and feces and friction against the diaper. A rash is more likely to develop when infants begin to sleep for longer periods and the time between diaper changes increases. Another cause may be sensitivity to commercial disposable wipes or components of paper diapers.

Diaper rash is primarily treated by keeping the diaper area clean and dry. The nurse should instruct the parents to change diapers as soon as they are wet or soiled. They should gently wash the perineum with mild soap and warm water but should avoid excessive washing or scrubbing. If commercial wipes are used, they should be free of alcohol, perfumes, or preservatives. Removing the diapers and exposing the perineum to warm air helps healing.

Applying a thin layer of zinc oxide or petrolatum may speed healing and help prevent recurrence. Vigorous rubbing to remove the skin barrier product is not necessary. Gentle cleansing to remove the soiled layer of barrier in the skin folds is adequate (Association of Women's Health, Obstetric, and Neonatal Nurses [AWHONN], 2013). Low-potency corticosteroid preparations may be necessary for severe cases. Talc-based powders should not be used because they can cause pneumonia if they get into the infant's lungs.

Secondary infection of diaper rash with organisms such as *Candida albicans* or *Staphylococcus* is common. When infection occurs, severe

rash, pustules, or crusted areas may appear. The infant should be taken to a pediatrician or nurse practitioner for treatment. Antifungal or antibiotic creams may be necessary for infections.

Miliaria (Prickly Heat)

Although most common during hot weather, **miliaria**, or prickly heat, develops in infants who are too warmly dressed in any weather. It may also occur in infants with a fever. This rash results from occlusion and inflammation of the sweat (eccrine) glands. It has a red base with papules or clear vesicles in the center.

Treatment involves cooling the infant by removing excess clothing or by giving a soothing lukewarm bath. The condition clears quickly with removal of the cause, and ointments or other skin preparations should be avoided. The nurse should discuss the appropriate amount of clothing with parents when infants develop prickly heat.

Seborrheic Dermatitis (Cradle Cap)

Seborrheic dermatitis is a chronic inflammation of the scalp or other areas of the skin characterized by yellow, scaly, oily lesions. It sometimes results when parents do not wash the anterior fontanel for fear that they will hurt the infant.

Treatment is application of oil or shampoo to the area to help the lesions soften and then removal with a comb or soft brush before shampooing the head. The nurse should teach parents how to shampoo the scalp and explain that they will not injure the fontanel by normal gentle shampooing. The scalp should be rinsed well to remove all soap, which otherwise may cause irritation. A persistent problem may be treated with hydrocortisone cream or special shampoos recommended by the pediatrician or nurse practitioner.

FEEDING CONCERNS

Breastfeeding, formula feeding, and weaning are discussed in [Chapter 22](#). This section addresses only regurgitation and introduction of solid foods.

Regurgitation

Infants often regurgitate ("spit up") because they may eat more than the stomach can easily hold and because the immature lower esophageal sphincter allows the stomach contents to flow into the esophagus easily. "Wet burps" result when air is trapped under the stomach contents. As the air is expelled, a small amount of milk comes with it.

The nurse should teach parents to differentiate normal spitting up from vomiting, which is a sign of illness. Regurgitation may occur frequently but is usually only a small amount at a time. Vomiting may involve the entire feeding, and it is expelled forcefully. Parents should always seek treatment for the infant with projectile vomiting, in which the vomitus is expelled with such force that it travels some distance. This is a sign of pyloric stenosis, which may require surgery, and other serious conditions.

If an infant has frequent regurgitation, place the infant in a more upright position during and for a short time after feedings. Small, more frequent feedings may also help. Some infants swallow excessive air because they feed rapidly. Nurses can instruct parents to feed infants before they get too hungry and to stop often for burping. If the hole in a bottle nipple is too small, an infant may swallow the air around the nipple. Enlarging the nipple hole slightly with a hot needle may prevent this. The hole should not be too big or the flow of milk may be too fast and cause choking.

The infant who has excessive regurgitation or vomiting should be referred for follow-up with the pediatrician or nurse practitioner.

Introduction of Solid Foods

Infants do not need solid foods until 4 to 6 months of age. It is recommended that breastfed infants should have only breast milk for the first 6 months (AAP & ACOG, 2012). Some mothers introduce solids earlier in the hope that the infant will sleep longer at night. This is seldom successful because the infant receives no more calories from the small amounts of solids taken than from milk. When infants are started on solids, they drink less milk, thus replacing a food that meets their nutrient needs well with a food that is poorly digested.

The **extrusion reflex**, in which infants push the tongue out against anything that touches it, continues until approximately 4 to 6 months of age (Eiger, 2009). This makes feeding a younger infant difficult because the infant pushes almost all of every spoonful out of the mouth. The nurse should explain the problems involved with early introduction of solid foods and encourage parents to wait until the infant is physiologically ready, at 4 to 6 months of age. The concerns that made the parents consider changing the feeding routine should also be discussed.

GROWTH AND DEVELOPMENT

Anticipatory Guidance

Parents often have questions about normal patterns of growth and stages of development. Nurses provide anticipatory guidance about these areas to help parents develop realistic expectations about infants' abilities at various ages.

Growth and Developmental Milestones

A brief summary of the changes that can be expected during the infant's first 12 weeks is included here. More in-depth information is found in pediatrics textbooks. The nurse should emphasize to parents that guidelines are only averages, the range of normal is often broad, and individual differences are expected.

Growth proceeds at a predictable rate in normal infants. The weight lost after birth is usually regained by 14 days of age. In the first 3 months, the average infant gains approximately 1 oz (30 g) each day and 2 lb (0.9 kg) per month. Each month they grow 1.4 inches (3.5 cm) and have an increase in head circumference of 0.8 inch (2 cm) (Keane, 2011). The posterior fontanel closes by 2 months and the anterior fontanel by 18 months of age (Furdon & Benjamin, 2010). Tears are scant or absent for the first 2 months of life (Kaur & Campbell, 2009).

Parents are especially interested in the Moro, grasp, and rooting reflexes. The nurse should point out that their gradual disappearance helps prepare the infant to learn new skills such as voluntary grasping or turning over, which are impossible if the reflexes continue. The infant gradually develops more control of the heavy head and has less bobbing or head lag by the end of the third month.

Infants are social beings. They stare at objects of interest and focus best within a range of 8 to 12 inches (20 to 30 cm) as newborns (Blackburn, 2013). By 3 months, infants can follow interesting objects horizontally across the midline (Gundy, 2009). A social smile begins at 1 to 3 months. Infants start making vowel sounds ("cooing") at 1 to 4 months and laugh at 3 to 6 months (Grover, 2012b).

Accident Prevention

Knowing what infants can do helps prevent accidents. In the first 3 months after birth, they are totally helpless. Although they can communicate their needs through crying, someone must be available at all times to care for them. Parents must be taught the dangers of leaving the infant on any unprotected surface, even for seconds. In a short time, an infant can wiggle from the middle to the edge of a large bed and fall.

If parents must turn away, they should keep one hand on an infant lying on an unprotected surface. Infants should never be left, even for an instant, in even 1 inch of water because of the danger of drowning. Parents should take the telephone off the hook or take a portable phone with them and ignore the doorbell while bathing the infant. If they must leave the room, parents should take the infant out of the water and with them.

As infants learn to grasp objects with increasing accuracy (4 months), parents must be certain that nothing that could be swallowed or otherwise cause harm is within the infant's reach. Help parents think ahead to the time when the infant will be crawling and walking and make plans for how they will "child-proof" their home.

WELL-BABY CARE

Well-Baby Checkups

Well-baby checkups are an opportunity for the pediatrician or nurse practitioner to assess the infant's growth and development, answer questions about feeding and infant care, observe for abnormalities, and give immunizations. These checkups may be provided by a private practitioner or in a well-baby clinic where examinations and immunizations are free or at reduced cost. Infants are usually taken to their first checkup anywhere from 48 hours to 2 weeks after discharge from the birth facility. They generally receive well-baby checkups at 1, 2, 4, 6, 9, and 12 months of age (Hagan & Duncan, 2012).

Well-baby checkups are a good time for mothers to learn what is normal for their infants in terms of growth and behaviors. Anticipatory guidance is a major part of well-baby visits. Many mothers are reassured to find that such problems as wakefulness at night or changes in feeding habits are normal. Safety is discussed as parents are taught about skills infants will soon develop that might place them in danger.

Immunizations

Nurses often receive questions about the need for immunizations for uncommon diseases such as diphtheria, which parents have never seen. Parents may consider a condition such as varicella (chickenpox) to be a harmless childhood illness. When they do not understand the need for immunizations, parents may be reluctant to have their infants undergo painful procedures.

The nurse must explain to parents the importance of immunizations, briefly describing the serious illnesses that are prevented by immunizations. Discuss the age at which each immunization is given and when boosters are needed. Because recommendations for immunizations change from time to time, parents should be referred to their pediatrician for the latest information. Another source is the AAP website (www.aap.org), which offers information for parents as well as professionals.

In the United States, national health objectives for the year 2020 include achieving and maintaining effective vaccination coverage levels for universally recommended vaccines among young children with targets of 85% to 90% depending on the vaccine (U.S. Department of Health and Human Services [USDHHS], 2010). Maintaining a high level of immunization is important to prevent the rise of

communicable diseases, as has happened in the past when a resurgence of measles occurred in many U.S. communities.

10. How can parents use their knowledge about infant development to prevent accidents in the first 12 weeks of life?
11. What is the purpose of well-baby checkups?
12. Why are immunizations important?

ILLNESS

Parents have many questions about illnesses in the infants. They have concerns about how to recognize an illness and when to call the pediatrician or nurse practitioner.

Recognizing Signs

Parents may need help in recognizing signs of illness in infants (Box 23-3). The nurse should explain that any time the infant appears sick or parents believe that something is wrong with the infant, they should call the pediatrician or nurse practitioner. Office staff is usually educated to help parents determine whether the infant is sick enough to need an appointment.

Calling the Pediatrician or Nurse Practitioner

When calling the health care provider about an illness, parents should prepare by writing down the information about the illness to avoid forgetting something. They should have the name and telephone number of a pharmacy available in case a prescription drug is needed, and they should be ready to write down instructions (Box 23-4).

Office staff members are usually able to answer questions on the telephone about common concerns and simple illnesses. They can help determine if an infant should be seen by the health care provider, but parents should be assertive in asking for an appointment if they believe that one is needed. They have a more complete picture of the infant's condition than can be given over the telephone. Parents should immediately identify emergencies so that the staff can act accordingly. Parents can expect the pediatrician or nurse practitioner to return calls about acute illness as soon as possible and calls about other concerns near the end of the day.

Knowing When to Seek Immediate Help

Parents should take the infant to the pediatrician or to a hospital if signs of dyspnea are present. An infant from birth to 3 months of age should not have a sustained respiratory rate above 60 breaths per minute. If retractions, cyanosis, or extreme pallor is present, parents should get immediate help. If respiratory difficulty occurs suddenly in

an infant who is well, the infant may have aspirated a feeding or small object. Parents should call the emergency medical services (EMS). Nurses should encourage all parents to take classes in cardiopulmonary resuscitation.

If an infant's respiratory rate is below 30 breaths per minute, parents should stimulate the infant and see if the respirations increase and stay within the normal range of 30 to 60 breaths per minute. If the respiratory rate continues to be below normal, the infant should be seen by a pediatrician, by a nurse practitioner, or at a hospital.

Parents should call the pediatrician if the infant is hard to arouse and keep awake. The infant could be semicomatose and showing signs of a central nervous system disease such as meningitis or encephalitis.

Learning about Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is the abrupt death of an infant less than 1 year of age that is unexplained by history, autopsy, or examination of the scene of death. In the United States, approximately 2250 infants die of SIDS each year. It is the third leading cause of death in infants from birth to 1 year of age and the most common cause of death in infants from 1 month to 1 year of age (CDC, 2012b).

SIDS occurs in apparently healthy infants during sleep and more often in male infants. It peaks in infants who are 2 to 3 months of age, and 90% of SIDS cases occur before 6 months of age (Smith, 2012). African-American, American Indian, and Alaska Native infants are two to three times more likely to have SIDS. The incidence is lower in Asian, Pacific Islander, and Hispanic infants (Hunt & Hauck, 2011).

There have been many studies, but the cause of SIDS remains unknown. Sleeping in the prone position; sleeping on a soft surface; overheating; maternal smoking or drug use during or after pregnancy;

BOX 23-4 CALLING THE PEDIATRICIAN OR NURSE PRACTITIONER

Write down pertinent information before calling. Have your pharmacy name and telephone number handy, along with a pen and paper to write down instructions.

1. Give the infant's name and age first.
2. Describe the illness or problem.
 - a. When did it start?
 - b. How often does it occur (e.g., the number of times the infant vomits or passes stool)?
 - c. How does this compare with the infant's normal patterns?
 - d. What does it look like (e.g., appearance of rash, color and consistency of stools)?
3. Describe any fever.
 - a. How high is it? (Take the axillary temperature.)
 - b. How long has the fever been present?
 - c. Has it been higher than it is now?
4. Describe other signs of illness.
 - a. Has eating behavior changed?
 - b. Have sleep patterns changed?
5. Describe the infant's behavior.
 - a. Does the infant seem sick? How?
 - b. Is the infant irritable, lethargic, acting differently from normal? How?
6. Describe what has been done so far to treat the condition (e.g., medicines, herbs) and the results.
7. Discuss other relevant information.
 - a. Is there a similar illness in family members?
 - b. Was the infant treated recently for a similar or different illness?
 - c. Is the infant given any other medications?

BOX 23-3 COMMON SIGNS OF ILLNESS IN INFANTS

- Axillary temperature above 100.4°F (38°C)
- Vomiting all of a feeding more than once or twice in a day
- Watery stools or significant increase in number of stools over what is normal for the infant
- Blisters, sores, or rashes that are unusual for the infant
- Unusual changes in behavior: listlessness or sleeping much more than usual, irritability or crying much more than usual
- Coughing, frequent sneezing, runny nose (occasional sneezing is not a problem)
- Pulling or rubbing at the ear, drainage from the ear

young maternal age; low socioeconomic status; late or no prenatal care; prematurity, low birth weight, and male gender; and prenatal exposure to nicotine, alcohol, and illicit drugs have been associated with SIDS. Risk of SIDS is increased when infants sleep in the same bed with another person; on adult beds or sofas; or with pillows, stuffed toys, or loose bedding; or become overheated during sleep. Bed-sharing with a parent is controversial and not recommended at this time (AAP Task Force on Sudden Infant Death Syndrome, 2011; Hunt & Hauck 2011).

The current AAP (2011a) recommendation is that a healthy infant be placed in the supine position for sleep because the prone position may increase the risk of upper airway obstruction, rebreathing of expired air, and hyperthermia. A national goal for the year 2020 is to reduce the number of SIDS deaths by increasing to at least 75.9% the number of infants who are put to sleep on their backs (USDHHS, 2010). Approximately 20% of SIDS cases occur when the caregiver is not the parent (Smith, 2012). Parents should ensure that all caregivers of their child are aware of the risk associated with the prone position and follow the guidelines.

Nurses should teach parents about the AAP recommendations for the supine position for sleep and give parents educational material about the position. It is important for nurses to model this behavior in addition to teaching about it. For suggestions on modifying some risk factors, see “Parents Want to Know: How Can I Help Prevent SIDS?”

Parents may be concerned about abnormalities in head shape that may occur in some infants from sleeping on the back. Flattening of the head (**plagiocephaly**), which was rounded at birth, may result from prolonged lying in the supine position. This can be prevented by the parents placing the infant in the prone position on a firm surface during awake periods several times a day while watching the infant.

Parents should be taught the importance of “tummy time” to help develop the shoulder muscles as well as to prevent plagiocephaly. The prone position helps the infant develop neck, shoulder, and arm muscles. Toys placed within reach can help infants focus and begin to reach for objects. The position also helps the infant attain developmental milestones such as rolling over and crawling.

Infants tend to look toward the center of the room or the door when in their beds. Placing the infant at alternating ends of the crib often influences the direction of turning the head and distributes pressure more evenly. Avoiding prolonged time in car seats or other seats and holding the baby in an upright position some of the time may also help. Infants who develop flattening of the head should spend very little time in infant seats, swings, or car seats because these put pressure on the back of the head.

Because parents often have many concerns about SIDS, therapeutic communication techniques may assist them to talk about their fears. They may need reassurance that the chance that any one infant will experience SIDS is small. When parents have experienced loss of an

infant from SIDS, they need appropriate counseling. One organization that provides this is First Candle, which can be reached at 1-800-221-SIDS or www.firstcandle.org.

PARENTS WANT TO KNOW

How Can I Help Prevent SIDS?

The following are suggestions that may help prevent sudden infant death syndrome (SIDS):

- Always place the baby on his or her back for sleep, whether for naps or at night. Never allow the infant to be placed on the abdomen or side for sleep.
- Ensure that all other caregivers (babysitters, daycare workers, relatives) position the baby properly for sleep.
- The infant’s sleep surface should be firm. Do not put the baby to sleep on a couch, armchair, soft mattress, or waterbed.
- Do not let the baby sleep with any other person, whether an adult or a child. Bed-sharing with the parent is controversial.
- If you feed your infant while you are in bed, put the baby back into the infant’s bed when you are ready to sleep.
- The infant’s bed should be placed in the parent’s room.
- Do not put any loose bedding, comforters, quilts, pillows, bumper pads, sheepskins, positioning devices, stuffed toys, or any soft items in the baby’s bed.
- Dress the baby in pajamas, sleepers, or a sleep sack instead of using blankets.
- If blankets are used, place them no higher than the baby’s waist and tuck the edges under the mattress to prevent blankets from covering the infant’s face.
- Do not let the infant get overheated. Dress the baby appropriately.
- Consider giving the baby a pacifier for sleep. If you are breastfeeding, wait until the baby is 1 month old and breastfeeding is well established before giving the pacifier for sleep, if you wish. If the pacifier falls out during sleep, it is not necessary to reinsert it.
- Do not smoke during or after birth or let anyone smoke around your baby.
- Avoid alcohol and illicit drug use during pregnancy or after birth.
- If possible, breastfeed your baby, as it has been found to protect infants from SIDS.
- To prevent flattening of the head, several times each day place your baby on his or her abdomen for “tummy time” when the baby is awake and you can watch the baby. This also helps develop the muscles of the baby’s upper body.
- Do not let infants sleep routinely in sitting devices such as car seats, strollers, and swings as infants may slump enough to obstruct the airway.

CHECK YOUR READING

13. When should immediate help be sought for an infant?
14. What should nurses teach parents about SIDS?

SUMMARY CONCEPTS

- Nurses assist parents after discharge by way of home or clinic visits and telephone calls.
- Careful planning, good communication skills, and knowledge of cultural practices are necessary during home visits.
- Outpatient visits include the same assessment and teaching as home visits but do not allow the nurse to assess the home. They are, however, more cost-effective.
- Telephone calls after discharge from the birth facility are less expensive than home or clinic visits but do not allow the nurse to assess the patient or home environment in person.
- All equipment, particularly older, used articles, should be checked by parents for safety.
- Infants should use a rear-facing car seat until they are 2 years old or have reached the greatest weight and height recommended by

Continued

SUMMARY CONCEPTS—cont'd

- the manufacturer. Older infants need car seats that face forward. All should be placed in the back seat of the car.
- Crying is a major source of concern for parents. They should be reassured that infants are not spoiled by prompt attention to their needs.
- Colic—crying without obvious cause that lasts 3 or more hours a day—usually occurs in the afternoon or evening and often disappears after 3 to 4 months. The cause is unknown, and infants with colic grow and develop normally.
- The nurse can help prevent abusive head trauma (shaken baby syndrome) by teaching parents not to shake their baby and helping them cope with crying.
- Infants may sleep 5 or more hours at night by about 12 weeks.
- Diaper rash may be caused by prolonged exposure to wet and soiled diapers or sensitivity to substances in diapers or disposable wipes. The rash can become infected.
- Solid foods should be started at 4 to 6 months of age when the extrusion reflex is gone and solids can be digested by infants.
- Well-baby checkups are important for assessment of growth and development and to provide guidance and immunizations. Immunizations safeguard infants and communities from spread of communicable diseases.
- Parents should learn signs of illness in the infant and when immediate medical care is necessary. They should seek immediate medical attention if infants have respiratory difficulty or are difficult to arouse from sleep.
- The nurse should teach parents about current knowledge about SIDS and the fact that the cause remains unknown. Parents should be taught to place their infants in the supine position for sleep in their own beds.

The Childbearing Family with Special Needs

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Discuss the incidence and factors that contribute to teenage pregnancy.
2. Identify the effects of pregnancy on the adolescent mother, her infant, and her family.
3. Explain the role of the nurse in the prevention and management of teenage pregnancy.
4. Relate the major implications of delayed childbearing in terms of maternal and fetal health.
5. Describe the effects of substance abuse on the mother, the fetus, and the newborn.
6. Explain nursing interventions to reduce or minimize the effects of substance abuse in the antepartum, intrapartum, and postpartum periods.
7. Discuss parental responses when an infant is born with congenital anomalies and identify nursing interventions to assist the parents.
8. Describe parental responses to pregnancy loss and identify nursing interventions to assist parents through the grieving process.
9. Examine the role of the nurse when the mother places her infant for adoption.
10. Identify the factors that promote violence against women and describe the role of the nurse in assessment, prevention, and interventions.

All families must make major changes as they adapt to pregnancy and childbirth. For some families, however, the changes are particularly difficult. Such families have special needs related to parental age, substance abuse, birth of an infant with congenital abnormalities, perinatal loss, adoption, or intimate partner violence. Perinatal nurses can make a difference in the lives of these families and particularly in the lives of infants born into them.

ADOLESCENT PREGNANCY

Incidence

In 2011, in the United States, there were 31.3 births per 1000 women 15 to 19 years old. This is the lowest rate ever recorded and a decrease of 8% from the rate in 2010. There is still a large disparity between groups. Asian and Pacific Islander adolescents have the lowest rate of teen pregnancy. The birth rates for Hispanic and African-American teenagers were more than twice as high as the birth rate for non-Hispanic white teens (Hamilton, Hoyert, Martin et al., 2013).

The pregnancy rate for U.S. teenagers is higher than that of European teens (Alan Guttmacher Institute, 2012). A *Healthy People 2020* goal is to reduce the rate of pregnancy for women 15 to 17 years of age to 36.2 pregnancies per 1000. Another goal is to reduce the pregnancy rate for women 18 to 19 years of age to 105.9 per 1000 (U.S. Department of Health and Human Services [USDHHS], 2010). The current rate for women age 15 to 17 years is 15.4 per 1000, and the rate for women age 18 to 19 is 54.1 per 1000 which surpass the Healthy People 2020 goals (Hamilton et al., 2013). Approximately 20% of pregnant teens have had one or more births previously (Elfenbein & Felice, 2011) (Figure 24-1).

Factors Associated with Teenage Pregnancy

Adolescents tend to have a high rate of sexual activity and low incidence of consistent, correct contraceptive use. In 2011, 47% of high school students reported ever having had sexual intercourse, and 34% reported being sexually active (having sex in the last 3 months). Sixty

FIG 24-1 Pregnant Adolescent. Approximately 20% of pregnant adolescents have had one or more previous births.

BOX 24-1 FACTORS THAT CONTRIBUTE TO TEENAGE PREGNANCY

- Peer pressure to begin sexual activity
- High rate of sexual activity
- Limited access to contraceptive devices
- Lack of accurate information about how to use contraceptives correctly
- Incorrect or lack of use of contraceptives
- Fear of reporting sexual activity to parents
- Ambivalence toward sexuality; intercourse not “planned”
- Feelings of invincibility
- Low self-esteem and consequent inability to set limits on sexual activity
- Desire to attain love or escape present situation
- Lack of appropriate role models

percent said they used a condom the last time they had sex, and 18% used birth control pills (Centers for Disease Control and Prevention [CDC], 2012d).

Pregnancy occurs because many adolescents fail to recognize their vulnerability to the consequences of their sexual activity and believe that pregnancy cannot happen to them. Increased abstinence and more effective contraceptive practices have helped prompt the recent declines in adolescent pregnancies.

Some adolescents risk pregnancy and parenthood as a means of gaining or maintaining a love relationship. They may see themselves as lacking power in their relationships and defer to their partners' wishes. Still others see pregnancy as a means to gain independence. Factors that contribute to teenage pregnancy are listed in [Box 24-1](#).

Adolescents who give birth are more likely to have a low income, which may mean that they have less access to contraception and abortion. These teenagers may not believe that finishing education and obtaining a good job are possibilities for them and may see little reason to postpone pregnancy.

Sex Education

Sex education for teens should help them clarify their own values and beliefs about sexuality, understand how to set limits on sexual activity, and learn effective measures to prevent pregnancy and sexually transmitted diseases (STDs) when they decide to become sexually active (see [Chapter 31](#)).

Learning how to set limits on sexual behavior is particularly important for younger teenagers, who may be pressured to become sexually active before they have developed the maturity to deal responsibly with intercourse, contraception, or unplanned pregnancy. They need information about ways to handle pressure so that they can postpone sexual intercourse until they are emotionally and physically ready. Adolescent females may need help in learning how to say “not now,” “not yet,” and “not you.”

When providing sex education, nurses must keep in mind that adolescent males and females mature at different rates and may be more comfortable learning in separate groups. In talking with teenagers, nurses should use simple but correct language such as “uterus,” “testicles,” “penis,” and “vagina.”

Because adolescents are often seen by a health care provider for various reasons before they become pregnant, counseling to improve health for a future pregnancy should be offered them during any health care visit. Smoking cessation, attaining optimal weight, folic acid intake, and screening for violence are all topics that should be discussed with all young women so that a future pregnancy has the most positive outcome (Heavey, 2010).

Studies have shown that programs that provide education about teen pregnancy and provide contraceptive counseling have reduced the level of unintended pregnancy (Oringanje, Meremikwu, Eko et al., 2009). Teens want information about sexuality and the positives and negatives of becoming parents. They need to hear from adolescent parents about the rewards and problems in parenting and the impact of adolescent pregnancy on their relationships with friends and family, the effect on school and work, and the need for suddenly increased maturity.

Options When Pregnancy Occurs

An adolescent who becomes pregnant must choose one of three options: (1) terminate the pregnancy, (2) continue the pregnancy and place the infant for adoption, or (3) keep the infant. Some pregnant teens choose abortion, but this is not an acceptable alternative for others. Teenagers who might consider termination may not acknowledge the pregnancy or know how to seek care until it is too late for abortion.

The choice of abortion or adoption leaves the adolescent with no tangible evidence of her pregnancy and mixed messages from society regarding her decision. Unlike the teenager who decides to keep her infant, these adolescents may receive less assistance about ways to cope with their experiences. They need recognition of the significance of the experience to them and assistance in dealing with their feelings about their decision.

Few teenagers choose to continue the pregnancy and place the infant for adoption. Those who do may have complicated feelings of grief, relief that a “bad” experience is over, and anger at parents who were unwilling to provide assistance and thus made adoption the only realistic option. For some young women, the autonomous decision to relinquish the child “for the child’s good” may be an important step toward maturity.

Socioeconomic Implications

The medical expenses of adolescent pregnancy are often not covered by the family’s health insurance, so public services become necessary.

It is estimated that the public cost of adolescent pregnancy is nearly \$11 billion each year. The cost includes funds for health care, foster care, incarceration of children of teen parents, and lost tax revenues because teen mothers achieve lower educational levels and have lower incomes (CDC, 2012a). Teenage mothers are more likely than older mothers to be nonwhite, poor, less educated, and unmarried, and many of the negative effects of early childbearing are related to these factors (SmithBattle, 2009). Because they are more likely to have larger families at an earlier age, adolescent mothers have more children to feed and clothe on an already inadequate income.

Although the financial cost of teenage pregnancy is enormous, the cost in human terms is often tragic. The developmental tasks of

adolescence such as achieving independence from parents and establishing a lifestyle that is personally satisfying may be interrupted when a pregnancy increases the need for financial and emotional support from parents (Table 24-1). Instead of becoming independent, they often become more dependent on parents or their boyfriends as a result of pregnancy.

Educational goals may be curtailed for some young mothers, limiting employment opportunities and resulting in reliance on the welfare system. Only about 50% of adolescent mothers finish high school by age 22 years compared with their peers who have not given birth (CDC, 2012a). Parenthood is the leading cause of school dropout in adolescent girls. Less than 2% of teen mothers achieve a college degree

TABLE 24-1 IMPACT OF PREGNANCY ON THE DEVELOPMENTAL TASKS OF ADOLESCENCE

DEVELOPMENTAL TASK*	IMPACT OF PREGNANCY	NURSING CONSIDERATIONS
<i>Achievement of a Stable Identity:</i> How the person sees himself or herself and how the person perceives that others see and accept him or her. Peer group approval provides confirmation and is a major component of identity development.	The ability to adapt and respond to stress is a good indicator of identity development. Adolescents who become pregnant before a stable identity is developed may not be able to accept the responsibilities of parenthood and to plan for the future.	Explore the availability of a school-based mothers' program that will provide the peer support that is very important. Emphasize the importance of prenatal classes and the effect of prenatal care on pregnancy. Encourage both parents to attend parenting classes, and describe the expected growth and development of infants. Focus on the infant's need to develop trust and on the parenting behaviors that promote this.
<i>Achievement of Comfort with Body Image:</i> Requires internalization of mature body size, contour, and function.	The adolescent must learn to cope with body changes of pregnancy (increasing size, contour, pigmentation changes, and striae) before she has learned to accept the body changes of puberty. May deny pregnancy or severely restrict calories to avoid gaining weight. May be disgusted with the physical changes of pregnancy that make her look different from her peers.	Allow time for the teenager to verbalize her feelings about the body changes of pregnancy. Emphasize that dieting is harmful to the infant and will not stop the changes in body size and contour. Provide exercises that will help her regain her figure after the birth of the infant.
<i>Acceptance of Sexual Role and Identity:</i> Requires internalization of strong sexual urges and achievement of intimacy with others.	The adolescent may need to achieve an intimate relationship with another person and to form an exclusive relationship before she is ready. The pregnant teenager will also need to cope with changes in relationships with friends. She often has difficulty seeing herself as a sexual being or as a mother.	Allow the teenager to express her feelings about sexuality and about motherhood. Initiate groups designed specifically for adolescents (e.g., childbirth education, parenting classes, groups focused on nutrition). This will help her deal with changing relationships with her peers and move toward a mothering role.
<i>Development of a Personal Value System:</i> Able to consider the rights and feelings of others.	Pregnancy may occur before the adolescent is able to move from following rules to considering the rights and feelings of others and developing ethical standards. She may experience conflict when she must adjust to the responsibilities of premature motherhood.	Initiate a discussion of the teenager's feelings of conflict about her role as mother versus her role as student. Explore her views about motherhood: How does she expect it to change her life? What are her future plans? Present options and assist her to explore her goals.
<i>Preparation for Vocation or Career:</i> Completing educational or vocational goals; youths living in poverty may not have the means or encouragement to accomplish this.	Pregnancy often interrupts school for both parents. This may be a major frustration, and it may result in permanent withdrawal from school and limited access to jobs that pay more than the minimum wage.	Discuss the importance of continued education, and elicit the teenager's feelings and plans to accomplish this. Determine the amount and availability of support from her parents. Refer her to social services for needed assistance.
<i>Achievement of Independence from Parents:</i> Competent in the social environment and able to function without parental guidance.	Must adjust to the need for continued financial assistance and dependence on parents at a time when achieving independence is a major priority.	Assist the teenager to verbalize her feelings about continued dependence on parents. Discuss the reality of the situation and her need for financial support and help with the care of the infant. Determine the reaction of her parents to the pregnancy and if she will continue to live at home. How much support will they provide? What are the conditions for her remaining in her parents' home with the infant?

*Modified from Mercer, R.T. (1990). *Parents at risk*. New York: Springer.

by age 30 years (National Campaign to Prevent Teen and Unplanned Pregnancy [NCPTP], 2010).

Children born into this situation do not escape unscathed. They may show a higher incidence of impaired intellectual functioning and poor school adjustment. Approximately one third of these children drop out of school early, and they are 50% more likely to repeat a grade (NCPTP, 2010). The negative cycle often is repeated: 25% of children of adolescent parents become teenage parents (Elfenbein & Felice, 2011). As a result, children of adolescent parents often are among the poorest people in the United States.

However, positive outcomes from the pregnancy may also occur. For some adolescents, pregnancy motivates a desire to do well in school so that they can provide for their infants. Pregnancy and birth may have a stabilizing effect on adolescents who change past poor lifestyle choices and become more goal directed than they had been. They may become more determined to get an education to enable them to get jobs that allow them to provide for their children. Nurses can help adolescent mothers by focusing on their strengths, recognizing the adversities they face, and helping them develop a new sense of purpose in mothering (SmithBattle, 2009).

Implications for Maternal Health

Most pregnant teens have no medical complications during pregnancy. However, they are at increased risk for anemia, nutritional deficiencies, pregnancy-associated hypertension, human immunodeficiency virus (HIV) infection and other STDs, short interval until next pregnancy, and depression (Elfenbein & Felice, 2011; Wildschut, 2011).

Adolescents are often in abusive relationships and should be screened to identify violence so the nurse can help them access available resources. A Canadian study found adolescents were more likely to have experienced physical abuse in the last 2 years compared with older women (Kingston, Heaman, Fell et al., 2012). The high incidence of STDs among pregnant teenagers is another concern, so STD screening is important during prenatal care.

The reason for complications among teenagers is unclear. It may be related to delayed or inconsistent prenatal care and economic or socio-cultural problems rather than age. Pregnant adolescents generally begin prenatal care later compared with older women (Kingston et al., 2012). Six percent of pregnant teenagers have late or no prenatal care at all (Alan Guttmacher Institute, 2012). Delayed prenatal care may result from denial of the pregnancy, lack of knowledge of how to get care, or a negative view of health care providers. Early prenatal care that includes counseling about nutritional needs and close observation for complications is especially important when the expectant mother is very young.

Some pregnant adolescents are homeless. They have difficulty meeting the basic needs for food and shelter and are more likely to have complications of pregnancy. They need access to prenatal care and social services to help them cope with the multiple problems in their lives.

Implications for Fetal and Neonatal Health

Infants of teenage mothers have an increased risk of two major complications: prematurity and low birth weight (less than 2500 g or 5.5 lb). Preterm infants are more likely to have low birth weight and the added risks associated with immature organs. Low birth weight may be related to fetal growth restriction (failure of the fetus to grow at the rate to be expected for the gestational age). This may result from a variety of causes such as poor placental perfusion or the underdeveloped vasculature of the uterus in young primigravidas. When placental perfusion is decreased, the newborn may have a low birth weight even if the pregnancy goes to term because transport of nutrients and

oxygen to the fetus has been inadequate. Cigarette smoking is another cause of low birth weight. Teens are more likely to smoke during pregnancy compared with women in other maternal age groups (Grassley, 2010). Other problems include an increased risk of neonatal death and sudden infant death syndrome (SIDS) (Wildschut, 2011).

The Teenage Expectant Father

The majority of teenage mothers have partners who are within 2 years of their age, but some may have partners who are older. These men may accept responsibility for the child, or they may become “phantom fathers,” who are absent and rarely involved in raising the child.

Almost all adolescent expectant fathers indicate that they are not ready for fatherhood. Many are depressed as they grapple with the conflicting roles of adolescence and fatherhood. Although some express interest in learning about childbirth and child care, those who do not want to be fathers are less likely to be supportive. Some do not wish to be involved in the child’s life, leaving the pregnant girl to seek support elsewhere. Others are involved to some degree during the pregnancy and early years of the child’s life but become less involved over time. Many adolescent mothers perceive that support from their partners is inadequate.

A disproportionate number of teenage expectant fathers are from environments of poverty and lack job skills or educational preparation. Many need job training before they can earn enough money to contribute to the support of their children. To help provide financial support, the father may have to interrupt his education to find a job.

Impact of Teenage Pregnancy on Parenting

Adolescent mothers are at risk of becoming non-nurturing parents and having negative parent–infant interactions. It is difficult to determine whether this risk results from adolescence per se, the higher incidence of premature births, the lower socioeconomic status, or the particular home environment. Having to focus on an infant at a time when most teenagers are absorbed in their own thoughts and activities may make parenting difficult. Teenage mothers tend to respond in a less sensitive manner to their infants (Grassley, 2010).

The ability to handle stress plays an important part in mothering skills. Because of their immature coping mechanisms, young adolescents may be unable to separate the stress of other life events from that which occurs when the infant cries and cannot be consoled. They may respond with immature or punitive measures toward the infant when the source of stress is other factors such as social isolation or inadequate financial resources.

Adolescent parents are likely to be surprised and dismayed at how difficult and time-consuming parenting can be. The fatigue that is such a part of the early weeks after childbirth may be especially difficult for teens because they need more sleep than adults. Previous fantasies with a romantic view of love and family life with the father of the baby may give way to feelings of confusion and being overwhelmed by the realities of infant care (DeVito, 2010).

Adolescents often have little understanding of the expected growth and development of infants and may have unrealistic expectations of their children. For instance, they may expect that an infant will sleep through the night or complete toilet training before infants are able to do so. In addition, the infant may be in a neonatal intensive care unit for some time, and the mother may have to learn to care for a baby with problems.

Preparing for parenthood is important. Although adolescents may want to be good mothers, they often do not actively seek information about infant care and development. The mother’s relationship with the father of the baby may affect her parenting abilities. A close and satisfying relationship with the baby’s father may increase attachment

behaviors in the mother. Therefore, the father should be included, when appropriate, in care of the mother and the baby. However, many adolescent mothers do not have a good relationship with the father of their baby, which increases their need for support in coping.

APPLICATION OF THE NURSING PROCESS

■ The Pregnant Teenager

Assessment

Physical Assessment

Assessment of pregnant teenagers is similar to that of older women in many respects. At the initial visit, obtain a thorough health and family history to determine whether conditions such as diabetes or infectious diseases increase the risk for the mother and the fetus. Monitor closely for signs of iron-deficiency anemia, preeclampsia, or STDs. Attempt to identify behavioral risk factors such as poor nutrition, smoking, alcohol or drug use, or unprotected sex, which could harm the mother or the fetus. Screen for physical or sexual abuse, which is more common in pregnant teenagers.

Teenagers are sometimes defensive and inconsistent in their responses. Because they may not volunteer information about nutrition, exercise, and the use of alcohol or other drugs, the nurse needs to press for details. The teenager's statement "I eat okay, and I'm pretty active" requires follow-up questions worded to obtain specific information: "What foods do you especially like? What did you eat yesterday?" "What kind of things do you like to do?"

Structure the interview so that questions can be interspersed in a more general conversation that explores the teenager's likes and concerns. For example, a question such as "Will you be able to continue on the swim team after the baby is born?" may help the nurse establish rapport, gain a better understanding of the teenager, and determine if she is making plans for the future.

Cognitive Development

Determine the teenager's level of cognitive development and ability to absorb health counseling. The three most important areas of cognitive development are as follows:

1. **Egocentrism** (interest centered on the self), which involves the ability to defer personal satisfaction to respond to the needs of the infant: "What will you do when the baby gets sick?" "How will you help the baby get better?"
2. Present-future orientation, which involves the ability to make long-term plans: "What are your plans for finishing high school?" "What will you and the infant need in the first year of the infant's life?"
3. Abstract thinking, which involves identifying cause and effect: "Why is it important to keep clinic appointments?" "Why should condoms be used during sex even though you're pregnant?"

Knowledge of Infant Needs

Assess knowledge of infant needs and parenting skills. How does the teenager plan to feed the infant? What will she do when the infant cries? How will she know when the infant is ill and should be taken to a pediatrician? Does she know how much the infant should sleep? What plans have been made to provide for the safety needs of the infant?

Family Assessment

Begin assessment of the family unit by determining the degree of participation by the father of the infant. The father may deny responsibility for the pregnancy, be married to or plan to marry the expectant mother, participate in the pregnancy and rearing of the child without marriage, or be totally uninvolved.

Assessing the adolescent without the presence of her parents is important, yet it is crucial to determine the availability and amount of family support. Will the pregnant teenager continue to live with her parents? How do her parents feel about the pregnancy? How will they incorporate the mother and her infant into the family?

Families generally respond in one of three ways:

1. A family member (often the adolescent's mother) assumes the mothering role, which the teenager may abdicate willingly.
2. All care and responsibilities are left to the adolescent mother, although shelter and food are provided.
3. The family shares care and responsibilities, which allows the teenager to grow in the mothering role while completing the developmental tasks of adolescence.

It is particularly important to assess the perceptions of the pregnant teenager's mother. How does she feel about becoming a grandmother? Many women feel embarrassed and disgraced. She may feel that she has "failed" as a mother, or she may resent the new cycle of child care in which the pregnancy involves her. Is communication with her daughter open? Is she aware of the difficult role conflict (as adolescent and mother) that her daughter will experience? Many pregnant adolescents live with their mothers who provide various levels of support.

If the family is unable or unwilling to provide care for an adolescent with an infant, what other social support can be identified? In some situations, the family of the baby's father may be of assistance.

Nursing Diagnosis

Many adolescents wait until the second or third trimester to seek prenatal care because they either do not realize they are pregnant, continue to deny they are pregnant, or want to hide the pregnancy. They may not know where to go for care and may fear the effects of pregnancy on their lives and relationships. In addition, many teenagers have little information about physiologic demands such as the increased need for nutrients that pregnancy imposes on their bodies. As a result they may have a pattern of sporadic prenatal care and missed appointments (see [Nursing Care Plan](#)). One of the most relevant nursing diagnoses is "Risk for Ineffective Health Maintenance related to lack of knowledge of measures to promote health during pregnancy and increased family stress."

Expected Outcomes

The expected outcomes for this nursing diagnosis are as follows:

1. The expectant mother will keep prenatal appointments and will follow health care instructions throughout pregnancy.
2. She will communicate her concerns throughout pregnancy and participate in learning about infant care.
3. The family will verbalize emotions and concerns and maintain functional support of the expectant mother and her infant.

Interventions

Eliminating Barriers to Health Care

The two major barriers to health care are (1) scheduling conflicts and (2) negative attitudes of some health care workers. Help the adolescent locate the clinic closest to her that offers appointments when she (and her partner, if they wish) is available. Provide information about public

NURSING CARE PLAN

Adolescent Responses to Pregnancy and Birth

ASSESSMENT: Ann, 16 years old, visits the prenatal clinic during the 20th week of her pregnancy. She lives with her mother and father, who both work long hours, and a younger sister. Ann sees her boyfriend sporadically but is unsure if he will be involved in the baby's life. She remains in school but discusses her concern about how she looks: "I'm so fat! How much bigger am I going to get?" "Why is my face so blotchy?" "My feet swell, and it looks gross."

NURSING DIAGNOSIS: Disturbed Body Image related to perceived negative effects of pregnancy as evidenced by verbalized concern about appearance

GOALS/EXPECTED OUTCOMES: Ann will:

1. Verbalize her feelings about pregnancy and her perception of herself during each antepartum visit.
2. Make two positive statements about herself during the next antepartum visit.

INTERVENTIONS AND RATIONALES

1. Allow time at each prenatal visit for Ann to express concerns about weight gain and other physiologic changes of pregnancy such as hyperpigmentation and stretch marks. *The adolescent is often ashamed of and uncomfortable with her pregnant body. She feels more comfortable if she is allowed to share these feelings and is reassured that they are a normal part of pregnancy.*
2. Initiate interaction about body changes by asking open-ended questions such as "How do you feel about your weight gain?" *Adolescents may be intimidated by health care professionals and may think their own feelings are not important enough to discuss.*
3. Provide anticipatory guidance about normal changes such as the pattern of weight gain during pregnancy. *Most adolescents do not know what to expect during pregnancy, and their fears often are unexpressed. Anticipatory guidance reduces fear and provides needed information.*
4. Explain the reason for changes that are most troublesome at each prenatal visit (weight gain, hyperpigmentation, stretch marks, breast changes). *Knowing that some changes are temporary and increasing weight indicates the fetus is growing and developing often is helpful. This may become a source of pride for the teenager as well as for the older woman.*
5. Involve Ann in scheduling follow-up prenatal appointments and other activities related to the birth of the infant (classes, plans for childbirth). *Participation in decision making promotes a positive sense of self.*
6. Promote a positive self-image by praising grooming, posture, and responsible behavior such as keeping prenatal appointments and following recommendations: "You have never missed an appointment, and your baby is growing so well." *Positive reinforcement is particularly important to help the adolescent meet the developmental tasks of developing a sense of identity and self-worth.*
7. Near the end of pregnancy, discuss postpartum weight loss and exercise planning. *Adolescents may expect instant weight loss after delivery. They need information about healthy and realistic measures to lose weight.*

EVALUATION: Ann discusses her concerns about how she looks and feels about herself and begins to make positive statements about herself at each prenatal visit.

ASSESSMENT: Ann reveals that her father says she has "shamed the family." She discusses her fears that her friends, none of whom have been pregnant, will reject her because she is pregnant. Ann states that she will have to "drop out of everything." She tearfully confides that she feels guilty for "putting my family through this."

NURSING DIAGNOSIS: Situational Low Self-Esteem related to feelings of rejection by family and friends as manifested by statements indicating guilt and uncertainty about future support for herself and the infant

GOALS AND EXPECTED OUTCOMES: Ann will:

1. Identify at least two new measures to cope with anxiety by the end of the current antepartum visit.
2. Discuss her implementation of these measures during subsequent antepartum visits.

INTERVENTIONS AND RATIONALES

1. Use therapeutic communication techniques to help Ann continue to express her feelings about her pregnancy and the reactions of significant others. *Listening to the adolescent helps her see her feelings as important to others and helps the nurse prioritize nursing interventions.*
2. Help Ann identify what she can do to overcome anxiety about rejection by her family and friends. *Planning how to approach the family and friends reduces anxiety.*
 - a. Suggest that Ann talk to family members about her feelings of guilt for the unhappiness she is causing and her fear that they will not assist her through the pregnancy and birth. *Although adolescents strive for independence, family values continue to be a significant influence. Rejection by the family at this time would leave her vulnerable to stress beyond her coping ability.*
 - b. Role play how she can initiate a conversation with friends to discuss activities that they can continue to share. *Acceptance by the peer group and participation in group activities are major concerns of the adolescent. A change in status within the group is a threat to self-concept that precipitates acute anxiety.*
 - c. Recommend that she share her feelings with the father of the infant if she continues to see him. *Expectant fathers may be a source of emotional and financial support.*
3. Assist Ann in locating and joining the school-age mothers' program if available through her school district. *Teenagers who are either mothers or expectant mothers often replace the pregnant teenager's previous peer group. The shared concerns and activities provide an opportunity for growth.*
4. Help Ann discuss her economic needs and plans for continuing school after the infant is born. *Developing plans for the future provides some sense of control over the situation and increases feelings of competency.*
5. Point out and praise any positive actions that Ann takes, such as keeping prenatal appointments or eating a nutritious diet. *Sincere praise helps reinforce a positive self-image.*

EVALUATION: Ann makes plans to talk with her family and friends about her concerns. In later visits, she reports that relationships are somewhat improved. She enters a school-age mothers' program and is very pleased. She states that her best friend has been very supportive.

ASSESSMENT: Ann has a normal vaginal birth of a 6-lb, 3-oz girl she names Berlyn at 38 weeks of gestation. She does not want to breastfeed because she feels uncomfortable with it and plans to go back to school as soon as possible. Ann will live at home, and her parents have agreed to pay for childcare while Ann is in school. Ann is very concerned about caring for Berlyn. Although she participated in infant care classes, she seems unsure how to respond when the infant cries and handles Berlyn only during feedings.

NURSING DIAGNOSIS: Risk for Impaired Parenting related to lack of knowledge about the infant's needs and little confidence in her ability to care for the infant, as evidenced by uncertain responses to the infant

GOALS AND EXPECTED OUTCOMES: Ann will:

1. Demonstrate basic infant care (feeding, burping, bathing, swaddling) by discharge.

🕒 NURSING CARE PLAN—cont'd

2. Verbalize infant needs for gentle, prompt response to crying on the first postpartum day.
3. Demonstrate attachment behaviors (eye contact, gazing, holding, calling by name, and positive comments about the infant) before discharge.

INTERVENTIONS AND RATIONALES

1. Demonstrate infant care on the first postpartum day, and have Ann perform a return demonstration by the second postpartum day. *Confidence is increased when the mother shows the nurse what she has learned and continues to care for the infant.*
2. Model how to respond when Berlyn cries, and emphasize the importance of promptness and gentleness. Explain that infants develop a sense of trust when needs are met promptly and that crying does not indicate the infant is spoiled. *Observing how nurses respond to the infant increases the likelihood that adolescents will respond in the same manner. Prompt, gentle responses help the infant develop trust.*
3. Include the grandparents and infant's father (if involved) in as many demonstrations as possible. *When all caregivers are included, family cohesiveness and consistency of care are enhanced.*
4. Emphasize the importance of touch and verbal stimulation, and point out reciprocal bonding behaviors such as the infant following the mother with her eyes. Teach Ann signs that show Berlyn is overstimulated and needs a

period of rest. *Many teenage parents do not provide adequate tactile and verbal stimulation for their infants. The infant has many behaviors that stimulate mutual attachment between parent and child. Learning how to recognize and handle overstimulation is important.*

5. Instruct Ann regarding early growth and development of the infant (how often newborns need to eat, how much they sleep, what to do when they cry). *Some teenage parents expect too much too soon from infants. Anticipatory guidance helps parents have more realistic expectations.*
6. Encourage Ann to continue in her school-age mothers' program and to attend parenting classes with other teenage mothers. *Learning along with her peers helps the adolescent increase parenting skills and provides a continuing peer support group.*
7. Discuss Ann's future plans for her education and for avoiding another pregnancy before she is ready. Provide information about contraceptives and refer her to her primary provider. *Helping the teen make realistic plans for her future is important. Providing information about avoiding pregnancy may help her meet her goals.*

EVALUATION: Ann responds quickly when Berlyn cries. She gives basic care as she was taught and discusses Berlyn's expected growth and development. She shows attachment behaviors frequently and often makes positive comments about her daughter.

transportation to that location, if necessary. Some clinics are open in the evening or on Saturday.

Communicating with adolescents requires special skills. Nurses must match their teaching with the teenager's cognitive development. Those who are 15 years old or younger need concrete explanations because their ability to understand abstract reasoning is not yet developed. Nurses should avoid seeming authoritarian because teens may see this behavior as interfering with their independence and may not return for care. When nurses work with adolescents as partners in care, adolescents are more likely to follow nursing recommendations.

Applying Teaching and Learning Principles

The lives of adolescents change greatly during pregnancy and even more after the infant is born. They often feel isolated from peers who may not understand the responsibilities of parenthood. They may no longer be able to participate in activities with their friends because of child care obligations.

Teens often are hesitant to ask questions. Discuss concerns that are common to pregnant adolescents, and ask the pregnant teenager if she has other questions. Because peers are important to adolescents, arrange for them to participate in small groups with common concerns. Being with peers may make her feel more comfortable in asking questions and voicing concerns. Specific needs that might be addressed are the benefits of prenatal care or help in eliminating unhealthy habits such as smoking, drug use, or alcohol consumption. Find common goals that may be discussed in groups in which the teens can assist each other to have a healthier pregnancy. As pregnancy progresses, needs and group focus change and preparation for labor and delivery and infant care become priorities.

Repetition is an important method of teaching and clarifying misinformation. Allow ample time for discussions. Although teenagers often do not read or benefit from printed materials to the same degree that older parents do, material that is prepared with adolescents in mind may be helpful. Teens often respond well to audiovisual aids. Numerous well-made DVDs are available that deal with all aspects of prenatal and infant care.

BOX 24-2 RECOMMENDED METHODS FOR TEACHING PREGNANT ADOLESCENTS

- Identify and correct barriers to prenatal care.
- Communicate with kindness and respect.
- Form small groups with similar concerns.
- Allow ample time for clarification and discussion.
- Use audiovisual materials.
- Provide information in appropriate language easily understood by teens.
- Convey empathetic concern by using nonverbal communication skills.
- Include other family members or support persons when appropriate.

It is particularly important that the nurse does not sound like a parent when working with adolescents. Avoid using the words "should" and "ought," offering unwanted advice, and making decisions for the teenagers. Maintain an open, friendly posture, and convey empathy by using attending behaviors such as eye contact, frequent nodding, and leaning toward the speaker. **Box 24-2** summarizes additional recommended methods for teaching adolescents.

Counseling

Allow time to counsel teenagers about their specific concerns such as nutrition, stress reduction, and infant care.

Nutrition. Nutrition counseling is one way to help reduce the incidence of low-birth-weight infants. Determine the adolescent's general nutritional status and assess for eating disorders that would reduce caloric intake and possibly affect fetal growth. Emphasize that she is still growing and her intake must be adequate for her own growth as well as that of the fetus. Discuss nutrition during lactation, pointing out the advantages for both mother and baby.

Tailor information to suit the individual adolescent's likes and peer group habits. Teach her how to make the most nutritious selection

from fast-food menus or select and plan for healthy snacks when she is away from home (see [Chapter 9](#), pp. 137–138). Nutrition education must be socially and culturally appropriate.

Refer the teen to food stamp providers; the Special Supplemental Food Program for Women, Infants, and Children (WIC); surplus food distributors; and food banks, if necessary. Many teenagers have limited access to food and lack the ability to store or prepare it.

Self-Care. Provide the same teaching about self-care that would be given to an older woman (see [Chapter 7](#)). In addition, emphasize the importance of using a condom for prevention of STDs even though she is pregnant. Counsel the adolescent about lifestyle changes such as cessation of smoking or substance abuse, which will benefit her and the fetus, and refer her to resources that offer help with these problems. One Internet resource for smoking cessation that is designed for pregnant adolescents is www.smashoutcigarettes.org. The site uses pictures, videos, and information to show the immediate effects of smoking on the teen and her baby ([Comer & Grassley, 2010](#)).

Stress Reduction. Identify the stressors in the adolescent's life. Stress may be related to basic needs such as food, shelter, and health care. Fear of labor and delivery and fear of being single, alone, and unsupported all create stress. Meeting the developmental tasks of adolescence while working on the tasks of pregnancy is another stressor.

A variety of measures may be used to reduce stress, depending on the teenager's age, situation, and available support. Refer adolescents with chronic life stress to a social worker for help to achieve stability. If the girl is very young or the pregnancy is a result of rape or incest, social service and law enforcement agencies must become involved to provide protection and assistance.

The pregnant teenager often experiences stress because she has not told her parents or the father of the infant about the pregnancy. Explore her reluctance to do this, and role-play the encounter with her to help her work out a plan for breaking the news. Although there is strain on the relationship when the teen first tells her parents, their relationship may improve over time if her parents are supportive. If appropriate, encourage her to tell the expectant father so that he can work out his role.

Teens who experience high levels of stress during pregnancy and the postpartum period may spend less time on infant care activities, feel less competent as parents, and have a more difficult time adjusting to being mothers compared with teens with lower levels of stress during pregnancy and postpartum. Therefore, interventions to reduce stress in pregnant adolescents impact the infant as well as the mother.

Help the teen think ahead to how her life will change as a result of the pregnancy and what may interfere with the mother role. Help her identify possible solutions to the problems presented. Assistance with resolving conflict with support persons and identifying new sources of support are other important interventions.

Attachment to the Fetus. Because attachment begins during pregnancy, helping the adolescent begin this process is important. Seeing the fetus move during an ultrasound often changes any pregnant woman's perceptions about the fetus. Hearing the fetal heartbeat and feeling the baby move may also increase attachment. Looking at illustrations of the fetus at different gestational ages increases the mother's interest. A heightened awareness of the fetus may make her more likely to follow suggestions that will enhance fetal well-being. Discussion of the fetal changes month to month may lead to discussion of the capabilities and needs of the neonate.

Infant Care. The priorities for teaching gradually change from maternal needs to infant needs, with particular emphasis on infant care and normal growth and development. Discuss common early developmental changes to help the young mother understand the normal progression of infant abilities.

Explain and demonstrate infant cues (using behaviors of the infants in videos or in the group as examples) in terms of gaze, vocalization, facial expression, body position, and limb movement. Describe the way that infants use these behaviors to “talk” without words and ways in which parents can use the behaviors to respond to their infants. Emphasize that eye contact, holding, cuddling, and verbal stimulation are important for the child's development.

Because adolescents tend to have a more rigid and punitive approach to child care, explain that infants develop a sense of trust when their needs are met promptly and gently. In addition, their future development depends on attaining a sense of trust during infancy. Emphasize that crying does not indicate that the infant is spoiled but simply that the infant has a need for food, warmth, or comfort and love.

If a support person will be involved in helping care for the infant, include that person in teaching, especially if the support person has little experience with babies. Having a support person learn with her may help the teenager remember the information better.

Breastfeeding. Adolescents who decide to breastfeed their infants need much support in their endeavor. Adapt teaching to the mother's level of understanding. Encourage questions as they may have much misinformation. Privacy is important to adolescents as they often feel embarrassed to breastfeed in front of others. Provide help with correct positioning and latching-on of the infant. Show her how to drape a blanket to cover her breast and the nursing infant.

Check on the mother frequently during feedings to identify any problems and intervene appropriately and in a timely manner. Discuss problems that may occur so that she has a realistic understanding of them and knows when and where to seek help, if necessary. Offer praise liberally. Success in the baby latching onto the breast and seeing the infant gain weight may be very rewarding for the mother.

Promoting Family Support

The pregnant teenager needs encouragement to include her family in her decision making and problem solving. The involvement of her mother, older sister, or other close relative is particularly important in terms of future plans. Discuss topics such as who will care for the infant, whether the teenager will return to school, and what financial assistance is available from the family and the infant's father. Adolescent mothers who have adequate emotional support are more likely to learn appropriate parenting techniques.

However, if the family has multiple problems such as substance abuse or family violence, involving them may be inappropriate. In such situations, the teenager should be encouraged to communicate instead with a family friend or another trusted adult.

Providing Support during Labor

The needs of the pregnant adolescent during labor are similar to those of the older woman. Nursing support at this time is especially important in helping them to feel safe and cared for so that they can have a successful childbirth experience (see [Evidence-Based Practice](#) box).

Providing Referrals

Make referrals to conveniently located national and community resources for pregnant adolescents. Include well-baby clinics offered by the Public Health Service and assistance programs offered by state social service agencies. Church and community organizations also may provide needed assistance. Childbirth education classes specifically for teenagers are often available.

Programs for school-age mothers are offered by many school districts and provide an opportunity to complete high school education and take the much-needed classes in childbearing and parenting. Some

EVIDENCE-BASED PRACTICE

Labor Support for Adolescents

Labor support is an important part of the childbirth experience for all pregnant women. [Sauls \(2010\)](#) conducted a study to learn what behaviors adolescents found most supportive during their childbirth experience. A convenience sample of 185 adolescents ranging in age from 13 years to 19 years were recruited for the study. All of the young women spoke English or Spanish and had had vaginal or cesarean deliveries within the past 48 hours when they participated in the study.

The researcher used the Bryanton Adaptation of the Nursing Support in Labor Questionnaire. This is a 26-item questionnaire, which requires participants to rate various support behaviors on a 1-to-5 scale (“not at all” to “very helpful”). Two open-ended questions were added to the questionnaire: (1) What other things did the nurse do that helped you with labor? (2) Was there anything that you wanted or wished that the nurse would have done, but did not, while you were in labor?

In answering the first open-ended question, the behaviors mentioned most often (62%) were helping the woman to feel respected, encouraging her, and making her feel wanted and safe. The second most common (20%) theme was assistance with pain control. These were also highly ranked behaviors on the behavior scale.

The most common (85%) theme in answers to the second open-ended question was that the adolescents wanted the nurse to support their support persons. The other most common theme (12%) was that they wanted the nurses to provide more guidance with the process of childbirth.

When the behavior scale questions and the open-ended questions were analyzed together, the most important supportive behavior was pain management, followed by treating the teens with respect and caring about them. The third most important behavior was support and encouragement of the involvement of the adolescent’s support person.

What supportive behaviors have you seen used to support adolescents during labor and delivery as well as after birth? What other nursing behaviors might you use the next time you care for a pregnant or newly delivered teenage mother?

Reference: Sauls, D.J. (2010). Promoting a positive childbirth experience for adolescents. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 39(6), 703-712.

schools include pregnant adolescents in regular classes and add other classes to meet their special needs.

Evaluation

Nursing care has been effective if the pregnant adolescent keeps prenatal appointments and participates actively in her plan of care, as demonstrated by asking questions, sharing concerns, and adhering to the recommended program of care. She should demonstrate basic knowledge of the infant’s needs and care of the infant. Family support should be available, but if it is not, referrals to agencies that can provide assistance should be made.

4. What should prospective teenage parents be taught about infant growth and development?

DELAYED PREGNANCY

An increasing number of women become pregnant relatively late in their reproductive lives. In 2011, the birth rate for women aged 40 to 44 increased to 10.3 per 1000 women, an increase over previous years

([Hamilton et al., 2013](#)). Advances in contraception have given women the freedom to time the births of their children. Some women may delay childbearing to pursue a career, marry later, or establish financial security. Specialized infertility techniques available today provide women with infertility a chance to have children.

Maternal and Fetal Implications

When the mature woman decides to conceive, she may experience a delay in becoming pregnant. This is particularly true after the age of 35 years because of the normal aging of the ovaries and the increased incidence of reproductive tract disorders. For instance, pelvic inflammatory disease can cause pelvic and tubal adhesions that interfere with fertilization and implantation (see [Chapters 32 and 34](#)).

Although most pregnancies in mature women are normal, they are at increased risk for complications. Possible problems include genetic disorders, conditions related to preexisting medical conditions, and obstetric complications. The increased risk of fetal chromosomal abnormalities such as trisomy 21 (Down syndrome) with advancing maternal age is well documented. Genetic abnormalities also increase when the father is older than 55 years ([Gregory, Niebyl, & Johnson, 2012](#)).

The most common examples of preexisting diseases that increase maternal or fetal jeopardy are hypertension and diabetes mellitus. Uterine myomas (fibroids) occur with greater frequency in women older than 35 years. Myomas may be associated with postpartum hemorrhage.

Obstetric complications such as spontaneous abortion, gestational diabetes, cesarean birth, preterm delivery, stillbirth, preeclampsia, multifetal gestation, placenta previa, abruptio placentae, and low-birth-weight infants may occur ([Bayrampour & Heaman, 2010](#); [Cunningham, Leveno, Bloom et al., 2010](#); [Lu, Williams, & Hobel, 2010](#)).

In spite of some increased risk with childbearing after age 35 years, most women have few problems during their pregnancy and deliver healthy neonates. Those who do have complications can often have a successful pregnancy with good medical and nursing care.

Advantages of Delayed Childbirth

Mature gravidas come to the parenting role with a range of personal resources: psychosocial maturity, self-confidence, and a sense of control over their lives ([Figure 24-2](#)). They demonstrate high levels of empathy and flexibility in child-rearing attitudes. In addition, mature primigravidas are capable of solving complex problems and are often adept at maintaining interpersonal relationships. Because they are more likely to be financially secure, they can afford good care for their infants. They are experienced at setting priorities and developing plans. They usually are able to manage stress and will seek support and assistance when needed ([von Kohler, 2011](#)).

Disadvantages of Delayed Childbirth

Pregnancy complications that the mature woman did not expect may occur causing a need for activity restrictions or missed work. They may need more time to recover from childbirth, and they have less energy compared with their younger counterparts. They may find child care an exhausting experience during the first few weeks. This is particularly true if they had a cesarean birth or other complications of pregnancy.

Some older women choose to have a child without a partner and lack the support that women with partners have ([Mandel, 2010](#)). Peer support may be less available for mature primigravidas. Many of their friends have teenage children instead of infants and do not relate to the concerns of a new mother. Younger mothers have some of the same concerns, but they often do not share the perspective of older mothers.

FIG 24-2 Older primigravidas bring maturity and problem-solving skills to the maternal role, but they are at somewhat increased risk for physiologic problems related to pregnancy and birth.

Family support also may be lacking for the older woman. Her parents are usually in their 60s or 70s or older and may not be able to assist with child care to the extent that younger grandparents can. In addition, they may be ill and need help from the expectant mother instead of being able to provide it to her.

Nursing Considerations Preconception Care

Preconception care is particularly important for the older woman planning to become pregnant. A visit to the midwife, nurse practitioner, or obstetrician can identify risk factors and correct them, when possible. Chronic conditions should be well treated before conception. The preconception visit is essentially the same for the older woman as for a younger woman but pays particular attention to any medical conditions more likely to occur in the older woman. (See “Preconception Care” in [Chapter 7](#).)

Reinforcing and Clarifying Information

Because the fetus of a mature gravida is at increased risk for chromosomal anomalies, the woman will be informed about available diagnostic tests. Professionals with special preparation in genetics provide genetic counseling, but all nurses must be prepared to reinforce and clarify the information that has been provided. The tests most often recommended are multiple-marker screening, chorionic villus sampling, amniocentesis, and ultrasonography (see [Chapter 10](#)).

The family’s beliefs and attitudes about abortion may determine whether to have the recommended tests. The woman who would not consider abortion regardless of the condition of the fetus may refuse diagnostic studies or have them to help prepare for the problems that will occur at birth. Nurses must respect their decision and acknowledge that it may have been difficult to make.

Facilitating Expression of Emotions

Several days or weeks may pass between performance of some diagnostic studies and receipt of the results. This is a particularly difficult time for many expectant parents, and nurses often assist the couple to express their concerns and emotions.

A broad statement such as “Many couples find it difficult to wait for the results” will often elicit free expression of the parents’ feelings. Follow-up questions such as “What concerns you most?” may reveal anxiety about the procedure itself or about the possible effects of the procedure on the fetus. Simply acknowledging that it is a stressful time helps the couple cope with their emotions.

Women who have undergone many tests and procedures for infertility may be especially anxious. Once pregnancy is achieved, they worry about their ability to carry the fetus to term and may see themselves as being at higher risk than they actually are. If they have had unsuccessful pregnancies in the past, the fear that the present pregnancy may also be lost makes it hard for them to be optimistic about success.

Mature gravidas also worry about complications that may affect the fetus or their own health. They are aware that they may not have another opportunity for pregnancy because of their age. They may also be concerned about their ability to balance their careers with increased family responsibilities.

Providing Parenting Information

Nurses often help the mature primipara prepare for effective parenting by pointing out her individual strengths and advantages. Anticipatory guidance about measures that will help conserve energy after childbirth is very useful. These include meal planning and setting realistic housekeeping goals. In addition, many older mothers need to mobilize all available support so that they can reserve their energy for care of the infant.

When giving suggestions about conserving energy and obtaining support, avoid using terms like “elderly primipara” when referring to the expectant mother. It is important not to make her feel abnormal because of her age. Unless she has complications, she should know that her prenatal course will be the same as that for any other pregnant woman.

During the first weeks after childbirth the mother may experience feelings of social isolation, particularly if her friends have children who are much older. She may miss the mental stimulation of a job while staying at home. If she elects to return to work, she is likely to experience guilt and grief because she must leave her infant (see [Chapter 18](#)). Balancing the needs of the infant and the challenges of what may be a demanding career or occupation may be difficult.

Older mothers are likely to seek out information they need from a variety of sources. They are particularly interested in learning how the infant grows and develops and what they can do to provide nurturing care for the infant. Meeting other older expectant parents in classes may provide friendships that can continue after the birth and help women provide support for each other. Play groups are another source of support where mothers can compare notes on parenting.

Older parents may interview care providers before choosing one. They may have special concerns and ask many questions. They often adopt health-promoting activities such as improving nutrition and eliminating harmful substances. Printed materials that can be used to reinforce teaching are often helpful.

SUBSTANCE ABUSE

Chemical dependence is the physical and psychological dependence on a substance such as alcohol, tobacco, or drugs, either legal or illicit. When present during pregnancy, it increases the risk of medical complications in the mother and poor birth outcomes in the infant.

Incidence

In 2010 and 2011, approximately 1 in 6 pregnant women had smoked cigarettes in the past month. About 9.4% of women reported current drinking during pregnancy, 0.4% reported heavy drinking, and 2.6% reported binge (four or more drinks on one occasion) drinking. Illicit drugs were used by 5.5% of pregnant women (Substance Abuse and Mental Health Services Administration, 2012).

Although tobacco, alcohol, and marijuana are the most commonly abused drugs, the use of drugs such as opioids, cocaine, and amphetamines has had a major impact on health care for pregnant women and their offspring. A *Healthy People 2020* goal is to increase abstinence in pregnant women to 98.6% for cigarette smoking, 98.3% for alcohol, and 100% for use of illicit drugs (USDHHS, 2010).

Maternal and Fetal Effects

When a pregnant woman uses a substance by drinking, smoking, snorting, or injecting it, the fetus experiences the same systemic effects as the expectant mother but often more severely and for a longer time. Because the fetus is unable to metabolize drugs efficiently, a drug that causes intoxication in the woman causes it for prolonged periods in

the fetus. Therefore, substances taken by the woman can have great impact on the fetus and interfere with normal fetal development and health.

Maternal, fetal, and neonatal effects of commonly abused substances are summarized in [Table 24-2](#).

Tobacco

Cigarette smoking is the most common form of substance abuse by pregnant women. The active ingredients of cigarette smoke are nicotine, tar, and harmful gases such as carbon monoxide and cyanide. Nicotine causes vasoconstriction, transfers readily across the placenta, and reduces placental blood circulation. Carbon monoxide inactivates fetal and maternal hemoglobin. Together these substances reduce the amount of oxygen delivered to the fetus (Pitts, 2010). Suggestions for helping women stop smoking are provided in [Chapter 7](#).

Maternal and Fetal Effects. Indirect effects of cigarette smoking include decreased maternal appetite, which results in inadequate intake of calories as well as decreased absorption of some nutrients.

Pregnant women who smoke have a higher rate of spontaneous abortion, infants with low birth weight and length, abruptio placentae, placenta previa, premature rupture of membranes, and perinatal mortality than women who do not smoke (Cunningham et al., 2010; Lu, Williams, & Hobel, 2010).

Neonatal Effects. Infants of smokers have a 30% higher chance of prematurity. In addition, exposure to tobacco smoke before or after birth increases the odds of learning disabilities in children (Anderko, Braun, & Auinger, 2010). The risk of asthma, infantile colic, and

TABLE 24-2 MATERNAL AND FETAL OR NEONATAL EFFECTS OF COMMONLY ABUSED SUBSTANCES

SUBSTANCE	MATERNAL EFFECTS	FETAL OR NEONATAL EFFECTS
Caffeine (coffee, tea, cola, chocolate, cold remedies, analgesics)	Stimulates CNS and cardiac function, causes vasoconstriction and mild diuresis, half-life triples during pregnancy	Crosses placental barrier and stimulates fetus; teratogenic effects are undocumented
Tobacco	Decreased placental perfusion, abruptio placentae, anemia, PROM, preterm labor, spontaneous abortion	Prematurity, LBW, neurodevelopmental problems, increased incidence of SIDS, perinatal mortality
Alcohol (beer, wine, mixed drinks, after-dinner drinks)	Spontaneous abortion, abruptio placentae	Fetal demise, FGR, fetal alcohol spectrum disorders, FAS (facial and cranial anomalies, developmental delay, cognitive impairment, short attention span)
Marijuana ("pot" or "grass")	Often used with other drugs: tobacco, alcohol, cocaine; exact effects undetermined	Unclear; more study needed; may be related to problems in motor development; increased risk of anomalies or mortality unproven
Cocaine ("crack")	Hyperarousal state, euphoria, generalized vasoconstriction, hypertension, tachycardia, STDs, spontaneous abortion, abruptio placentae, preeclampsia, PROM, preterm labor, precipitous delivery	Fetal hypoxia, tachycardia, meconium staining, stillbirth, prematurity, irritability, sleep followed by agitation, poor response to comforting or interaction, possible attention and language problems,
Amphetamines and methamphetamines ("speed," "crystal," "glass," "ice," "ecstasy")	Malnutrition, vasoconstriction, tachycardia, hypertension, spontaneous abortion, preterm labor, abruptio placentae, preeclampsia, retroplacental hemorrhage	Increased risk for FGR, prematurity, abnormal sleep patterns, agitation, poor feeding, vomiting
Opioids (heroin, methadone, morphine)	Malnutrition, anemia, increased incidence of STDs, HIV exposure, hepatitis, thrombosis, cardiac disease, spontaneous abortion, preterm labor	FGR, LBW, perinatal asphyxia, meconium aspiration syndrome, fetal or neonatal death, SIDS, child abuse and neglect; long-term developmental effects unclear
Antidepressants such as selective serotonin reuptake inhibitors	Relief of anxiety and depression; risk of anomalies with paroxetine, small risk of anomalies with other antidepressants	Transient respiratory problems, irritability, poor tone, persistent pulmonary hypertension

CNS, Central nervous system; FAS, fetal alcohol syndrome; FGR, fetal growth restriction; HIV, human immunodeficiency virus; LBW, low birth weight; NAS, neonatal abstinence syndrome; PROM, premature rupture of membranes; SIDS, sudden infant death syndrome; STDs, sexually transmitted diseases.

childhood obesity is increased for children of mothers who smoke during pregnancy (AAP & ACOG, 2012). Exposure to secondhand smoke is also a problem. It increases the risk for stillbirth, preterm birth, congenital anomalies, respiratory distress syndrome, and neonatal intensive care unit (NICU) admissions (Ashford, Hahn, Hall et al., 2010; Leonardi-Bee, Britton, & Venn, 2011).

Newborns of mothers who smoke weigh approximately 200 g less than infants born to women who do not smoke and are 1.4 to 3 times more likely to die of SIDS (CDC, 2011a). The degree of fetal growth restriction varies with the number of cigarettes smoked daily. Women who stop smoking during pregnancy reduce the amount of growth restriction suffered by the fetus (Walker & Walker, 2011). If they stop smoking during the first trimester, their chance of having preterm and small-for-gestational-age infants is similar to that of nonsmokers (Polakowski, Akinbami, & Mendola, 2009).

Alcohol

Alcohol is the most commonly used drug. It passes easily across the placenta. During pregnancy, it can cause spontaneous abortion and abruptio placentae (Bandstra & Accornero, 2011). It is a teratogen that can cause **fetal alcohol spectrum disorders**, conditions resulting from maternal use of alcohol during pregnancy. The disorders include fetal alcohol syndrome (FAS), partial FAS, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects. **Fetal alcohol syndrome**, a group of physical, behavioral, and mental abnormalities resulting from fetal exposure to alcohol, is the most severe of these disorders. Alcohol is the leading cause of birth defects and developmental disabilities (CDC, 2012b).

The amount and timing of alcohol intake influence the specific effects on the fetus. During the first trimester, it is believed to affect cell membranes and alter the organization of tissue, causing structural defects. Throughout pregnancy, alcohol interferes with the metabolism of nutrients and thus retards cell growth and division. Although binge drinking is especially harmful, drinking in any amount and at any time may cause adverse fetal effects.

The teratogenic effects of alcohol include FAS, which is characterized by three clinical features: prenatal and postnatal growth restriction, central nervous system (CNS) impairment, and a recognizable combination of facial features. Growth restriction is noted in length, weight, and head circumference. CNS impairment includes intellectual disability, learning disabilities, high activity level, short attention span, and poor short-term memory.

Common facial anomalies associated with FAS include microcephaly, short palpebral fissures (the openings between the eyelids), epicanthal folds, flat midface with a low nasal bridge, indistinct philtrum (groove between the nose and upper lip), and a thin upper lip.

Not every infant exposed to alcohol during pregnancy has all the characteristics of FAS. A range of defects may be exhibited. Because no safe level of alcohol consumption during pregnancy has been established, it is recommended that women abstain from drinking alcohol both when planning a pregnancy and throughout the pregnancy.

Marijuana

Marijuana is the most commonly used illicit drug in the United States (Pitts, 2010). The active constituent of marijuana is tetrahydrocannabinol, which crosses the placenta and accumulates in the fetus. Because it is often used with other drugs such as cocaine and alcohol, its precise effects are difficult to determine. Studies are conflicting regarding the results of marijuana use in pregnancy. It increases blood carbon monoxide content of the mother's blood and may reduce oxygen available to the fetus. There may be neurobehavioral problems in the infant such as tremors and sleep disturbances. Research has not

shown an increased risk of anomalies or infant mortality (Bandstra & Accornero, 2011).

Cocaine

Cocaine is a powerful short-acting CNS stimulant. It blocks the reuptake of the neurotransmitters *norepinephrine* and *dopamine* at the nerve terminals, producing a hyperarousal state that results in euphoria, sexual excitement, increased alertness, and a heightened sense of well-being. Physical effects of cocaine use are related to cardiovascular stimulation and vasoconstriction. Hypertension, tachycardia, arrhythmias, tremors, anemia, and anorexia occur. Complications include myocardial infarction, convulsions, and death (Bandstra & Accornero, 2011; Pitts, 2010).

When the initial euphoria wears off, a period of irritability, exhaustion, lethargy, depression, and anxiety occurs. This state elicits a strong desire for additional cocaine so that the initial feelings can be recaptured.

Maternal and Fetal Effects. Because many women who use cocaine also use other drugs such as alcohol, tranquilizers, heroin, or marijuana to “come down” from the hyperarousal state that cocaine produces, it is difficult to define the exact effects of cocaine on the fetus. Women who abuse cocaine are less likely to seek prenatal care or to eat a diet that contains adequate nutrition. Sex may be exchanged for drugs, increasing the risk for STDs.

Because cocaine causes vasoconstriction of placental vessels, the incidence of abruptio placentae increases. It stimulates uterine contractions resulting in increased incidence of spontaneous abortion, premature rupture of membranes, preterm labor, and precipitous delivery. Additional complications include preeclampsia, fetal hypoxia, meconium staining, and stillbirth (Bandstra & Accornero, 2011; Pitts, 2010).

Neonatal Effects. Neonates exposed to cocaine in utero may exhibit CNS signs such as irritability followed by lethargy, alternating between sleep and agitation, and poor response to interaction with others or comforting by caregivers (Pitts, 2010). Long-term effects are unclear but may include attention and language problems (Bandstra & Accornero, 2011).

Amphetamines and Methamphetamines

These drugs produce effects similar to those of cocaine but are longer acting. Common names include speed, crystal, glass, crank, ice, and ecstasy.

Maternal and Fetal Effects. Amphetamines and methamphetamines are CNS stimulants that create a perception of pleasure. They cause vasoconstriction, hypertension, and tachycardia. Effects on the mother and the fetus are similar to those of cocaine. Spontaneous abortion, fetal growth restriction, low birth weight, preterm labor, abruptio placentae, preeclampsia, and retroplacental hemorrhage may occur (ACOG, 2011; Pitts, 2010; Walker & Walker, 2011). Because these drugs are appetite depressants, the mother may not eat well, and thus the fetus may not receive required nutrients.

Neonatal Effects. Infants may be preterm or have congenital defects such as cleft palate; abnormal sleep patterns, agitation, diaphoresis, poor feeding, and vomiting may occur during withdrawal.

Antidepressants

Antidepressants such as the selective serotonin reuptake inhibitors (SSRIs) are being prescribed more often in pregnancy for women with depression and anxiety. In some cases, the benefits of treatment outweigh any adverse effects known.

Maternal and Fetal Effects. Paroxetine (Paxil) is no longer recommended for use during pregnancy because there have been

reports of congenital malformations. Further research is needed but the risk for anomalies with other antidepressants appears to be small (Buhimschi & Weiner, 2011).

Neonatal Effects. Transient respiratory distress, poor tone, irritability, and persistent pulmonary hypertension have been reported (Buhimschi & Weiner, 2011). Long-term effects are unknown at this time.

Opiates

In the United States, there has been an increase in recent years in the incidence of maternal opiate use and **neonatal abstinence syndrome** (infant withdrawal from maternal use of opiates during pregnancy) (Patrick, Schumacher, Benneyworth et al., 2012). Opiates include drugs such as morphine, heroin, methadone, meperidine (Demerol), hydromorphone hydrochloride (Dilaudid), and oxycodone (Oxy-Contin). Heroin is used here as an example of this class of drugs. Heroin is an illegal **opiate** (drug containing opium or an opium derivative) and produces severe physical dependence. Like all opiates, heroin is a CNS depressant that produces a feeling of mental dullness, drowsiness, and finally stupor. Dependence is present when discontinuing the drug causes withdrawal symptoms (**abstinence syndrome**), which are quickly relieved by a dose of heroin.

Women who abuse heroin have poor general health with multiple medical problems associated with their chemical dependence and the associated lifestyle. Heroin is an appetite suppressant that also interferes with absorption of nutrients, and many women begin pregnancy malnourished and anemic. Additional problems include a high incidence of STDs, hepatitis, and exposure to HIV from sharing unclean needles.

Fetal Effects. The fetus suffers both direct and indirect effects of heroin use by the expectant mother. The woman's supply of heroin usually is not steady, resulting in episodes of maternal overdose alternating with periods of withdrawal from the drug. These episodes expose the fetus to intermittent hypoxia, which increases the risk of meconium aspiration syndrome. Fetal growth restriction, preterm labor, premature rupture of membranes, fetal distress, and stillbirth are other risks (Buhimschi & Weiner, 2011; Pitts, 2010; Walker & Walker, 2011).

Neonatal Effects. Infants born to mothers dependent on opioids exhibit neonatal abstinence syndrome (NAS), physical signs that affect all body systems as a result of fetal exposure to opioids. Most signs involve the neurologic and gastrointestinal systems. Infants may also have low birth weight and an increased incidence of SIDS (Buhimschi & Weiner, 2011; Walker & Walker, 2011). Studies of long-term developmental and learning problems have produced conflicting results. The lifestyle of parents who are substance abusers is often associated with child neglect and abuse. (See Chapter 30 for a discussion of management of the infant.)

Diagnosis and Management of Substance Abuse

In addition to toxicology screening, the pregnant woman who uses illicit drugs must be assessed throughout pregnancy for STDs, hepatitis, and exposure to HIV. Fetal diagnostic tests such as ultrasonography, nonstress tests, and biophysical profiles help identify problems. Nurses monitor weight gain and provide guidance in nutrition at each opportunity to prevent maternal anemia and inadequate weight gain.

Therapeutic management depends on the type of drug used and the problems presented. In the case of opioids such as heroin, withdrawal during pregnancy has been associated with significant fetal stress, fetal seizures, and even fetal death. Pregnant women who use heroin are often prescribed an alternative drug such as **methadone**, a synthetic opiate. Methadone can be taken orally once daily and is long

acting, providing consistent blood levels to decrease the adverse fetal effects of wide swings in blood level found with heroin use. Methadone also reduces the risk of infections from contaminated needles and drug-seeking behavior such as prostitution. At therapeutic levels, it does not produce the euphoria or sedation of heroin and allows the woman to live a relatively normal lifestyle.

The woman who receives a daily dose of methadone in a drug treatment program is more likely to receive prenatal care. However, the newborn must withdraw from methadone after birth. Some women who use methadone also use other illicit drugs such as heroin, cocaine, or marijuana.

Buprenorphine may be used instead of methadone. Although neonatal withdrawal still occurs, it is shorter and less severe than with methadone (Walker & Walker, 2011).

Treatment is aimed at establishing abstinence and preventing relapse. Outpatient or residential treatment provide education and individual and group therapy sessions. Peer support groups (such as Alcoholics Anonymous, Narcotics Anonymous, Cocaine Anonymous) are helpful. Written contracts that focus on abstinence for 1 day at a time are often used to help the woman who has relapsed and experiences feelings of guilt and self-blame.

APPLICATION OF THE NURSING PROCESS

Maternal Substance Abuse ANTEPARTUM PERIOD

Assessment

Polydrug abuse appears to be the most common substance abuse problem among women, and all women must be screened at the first prenatal visit for tobacco, alcohol, and other drug use. Because substance abuse occurs in all populations, the nurse must not make assumptions based on class, race, or economic status.

Certain behaviors are strongly associated with substance abuse: seeking prenatal care late in the pregnancy, failing to keep appointments, and following recommended regimens inconsistently.

SAFETY ALERT

Signs of Possible Drug Use

- Seeking prenatal care late in pregnancy
- Failure to keep prenatal appointments
- Inconsistent follow-through with recommended care
- Poor grooming, inadequate weight gain
- Needle punctures, thrombosed veins, cellulitis
- Defensive or hostile reactions
- Anger or apathy regarding pregnancy
- Severe mood swings

Women who use drugs have low self-esteem. They are dealing with conflicting issues: the physical and psychological need for the substance, the need to deny that the substance is harming the fetus, and guilt that they may be responsible for harming the fetus. Fear of prosecution for use of illegal drugs may prevent the woman from seeking prenatal care, increasing risk for the woman and her fetus. In addition, many women with substance abuse problems face discrimination and resentment from health care professionals who direct their frustration at the woman rather than the problem.

Given the powerful deterrents to self-disclosure, extensive history taking provides the best opportunity to determine current and past substance use. The nurse taking the health history must exhibit patience, empathy, and tolerance and use a blend of approaches that reinforce concern for the woman and her infant. When women receive nonjudgmental, supportive care from knowledgeable health care workers, they are more likely to keep appointments for prenatal care (Lefebvre, Midmer, Boyd et al., 2010).

Medical History

Determine whether the woman has medical conditions that are prevalent among women who use drugs, for example, seizures, hepatitis, cellulitis, STDs, hypertension, depression, and suicide attempts. Current problems may include insomnia, panic attacks, exhaustion, heart palpitations, depression, and suicidal ideation.

Obstetric History

Evaluate for past and current complications of pregnancy. Spontaneous abortions, premature deliveries, abruptio placentae, and stillbirths are associated with substance abuse. Current complications may include STDs, vaginal bleeding, and an inactive or hyperactive fetus. Fundal height may be inconsistent with gestational age, suggesting fetal growth restriction.

Investigate emotional responses such as anger or apathy regarding the pregnancy. These feelings are particularly significant during the latter half of the pregnancy, when the normal feelings of ambivalence are usually resolved. Negative feelings toward the pregnancy may interfere with prenatal compliance with recommended care.

History of Substance Abuse

Obtaining an accurate history of substance abuse is difficult and depends in large part on the way the health care worker approaches the woman. A sincere, nonjudgmental, and empathic approach promotes an open exchange of information. (Suggestions for interviewing are given in Box 24-3.)

Ask about all forms of drug use, including cigarettes, over-the-counter drugs, prescription medications, alcohol, and illicit drugs. Examine patterns of drug use, which can range from occasional recreational use to weekly binges to daily dependence on a particular drug or group of drugs.

Nursing Diagnosis

Some women acknowledge the use of harmful substances but do not fully understand the adverse effects. Other women are aware of the risks but are unable to stop using these substances. A nursing diagnosis that addresses both factors is “Ineffective Health Maintenance related to lack of knowledge of the effects of substance abuse on self and fetus and inability to manage stress without the use of drugs.”

Expected Outcomes

Expected outcomes are that the woman will do the following:

1. Identify the harmful effects of substances on herself and her infant.
2. Verbalize feelings related to continued use of harmful substances.

BOX 24-3 TECHNIQUES FOR INTERVIEWING A WOMAN ABOUT SUBSTANCE ABUSE

To determine whether the woman abuses substances:

- Display an accepting and nonjudgmental attitude.
- Explain why it is important to know about substance abuse: “We need to know about anything that might affect you or your baby during the pregnancy.”
- Let her know that the questions are asked of all pregnant women.
- Acknowledge that women may be reluctant to disclose information: “I know it’s difficult to talk to us about this, but we need to know so that we can give you and your baby the best care possible.”
- Begin with questions about over-the-counter or prescription drugs and lead up to use of tobacco, alcohol, and, finally, illicit drugs.
- Demonstrate knowledge of types and forms of drugs commonly used in the community: “Do you have friends who are using ecstasy?”

When substance abuse is acknowledged, the important points in the drug history include the following:

- The type of drug used
- The amount of drug used
- The frequency of use
- The time of last dose

Ask specific questions:

- How often have you taken over-the-counter medications?
- What drugs did you take last month? Were they prescribed?
- How many cigarettes do you smoke on a daily basis? Are there times when you smoke more?
- How many times a week do you drink alcoholic beverages (beer, wine, mixed drinks)?
- How many in a day? Are there times when you have more drinks?
- How often did you use [drug used] before becoming pregnant? How often do you use it now? Do you snort? Smoke crack? Shoot cocaine? How many lines do you use? How long do you stay high?

3. Identify personal strengths and accept resources offered by the health care delivery system to stop using drugs.

Interventions

Effective interventions for substance abuse require the combined efforts of nurses, physicians, social workers, and numerous community and federal agencies. Nurses must realize that progress is slow and frustrating. The major priority is to protect the fetus and the expectant mother from the harmful effects of drugs.

Examining Attitudes

When working with pregnant women with substance abuse problems, nurses must identify their own knowledge level, feelings, and prejudices. They may have limited knowledge about perinatal substance abuse and negative attitudes toward mothers who abuse substances. Nurses may be angry at the woman who not only engages in self-destructive behavior but also may be inflicting harm on an innocent victim. Maintaining feelings of empathy or concern without becoming judgmental or even unknowingly punitive to the pregnant woman may be difficult. Nurses also may feel helpless and discouraged when the pregnant woman continues to abuse drugs despite the best efforts of the health care team.

Inservice education, professional consultation, and peer support are all helpful when working with pregnant women who abuse drugs. These processes can allow opportunities for discussion and sharing of feelings, problems, and particularly troublesome treatment issues.

Preventing Substance Abuse

Participate in campaigns to prevent substance abuse throughout the community. Provide accurate information in terms that patients can easily understand. Use posters, diagrams, pamphlets, and other visual aids to describe the effects of tobacco, alcohol, and other drugs on the fetus. Post visual aids in schools, supermarkets, shopping centers, and other areas where women of childbearing age will be exposed to them.

Focus on the benefits of remaining drug free, which include a decrease in maternal and neonatal complications. For example, the effects of smoking tobacco are dose related and cumulative, and nurses need to encourage and support cessation at any point during pregnancy.

Women who use alcohol but not other drugs during pregnancy may not realize the effect on the fetus. Social drinkers will often stop drinking once they know about the dangers. Those with heavy alcohol use need counseling and referral for further treatment.

Communicating with the Woman

Ask the expectant mother about stressors in her life that may be contributing to her substance abuse. Additional stressors may include inadequate housing, economic predicaments, intimate partner violence, and emotional or physical illness.

Be honest at all times while displaying a patient, nonjudgmental attitude as well as genuine interest and concern. This is especially important when the woman relapses into substance-abusing patterns. Allow her to express guilt, and reassure her that abstinence is possible and that she can and must begin again.

Helping the Woman Identify Strengths

Assist the pregnant woman with substance abuse problems in identifying personal strengths because she generally has a poor self-image. Acknowledge her actions when she abstains from drugs or alcohol for even a short time. Praise for maintaining an adequate weight gain and attending prenatal classes may increase her confidence and compliance with the recommended regimen of care.

Providing Ongoing Care

At each antepartum visit, consider the current status of substance use, social service needs, education needs, and compliance with treatment referrals. In particular, address current drug use because women may change their pattern of drug use during pregnancy. For example, they may stop using cocaine but may increase their use of heroin or alcohol.

Verify compliance with recommended treatment regimens such as antepartum clinics and chemical-dependence referral programs. Coordinate care among various service providers such as group therapy and prenatal classes. Establish communication with all agencies that provide care, and facilitate communication that helps the woman with a chaotic lifestyle meet treatment objectives.

Provide continuing prenatal education about the anatomy and physiology of pregnancy and consequences of prenatal substance abuse. Describe how the newborn benefits when the mother abstains from using drugs, including tobacco and alcohol. Drug screens will be performed periodically throughout the pregnancy. Praise any attempts at abstinence, and encourage the expectant mother to try again if she relapses.

Assess signs of maternal attachment to the fetus because it may help her to reduce or eliminate her substance use. Fetal movement often increases the woman's awareness of the fetus and may lead to a discussion about her plans for the infant and changes in her life that have occurred and will occur. Help her to make realistic plans for care of the baby. Include support persons if possible.

When the woman's partner abuses substances, she is more likely to continue to use them or to stop during the pregnancy but start again after delivery. Explain to the partner the importance of avoiding use for both members of the couple to enhance the outcome of the pregnancy and to avoid exposure of children to the adverse effects of substances.

When women take drugs during pregnancy, child welfare services may be involved to ensure the safety of the infant after discharge. The infant may become a ward of the courts, and be placed in foster care until the mother can show she is in rehabilitation. Use therapeutic communication techniques to help the mother express her feelings about this loss. Help her to make plans for implementing changes that will allow her to be with her infant.

Evaluation

Interventions have been successful if the expectant mother identifies the harmful effects of substance abuse on herself and on the fetus, discusses her strengths and her feelings about continued use of substances, and is receptive to assistance to stop using drugs.

INTRAPARTUM PERIOD

Assessment

Nurses who work in labor and delivery units must become skilled at identifying drug-induced signs and symptoms.

Cocaine

Behaviors associated with frequent or recent use of cocaine include profuse sweating, hypertension, tachycardia, and irregular respirations combined with a lethargic response to labor and apparent lack of interest in the necessary interventions. Additional signs include dilated pupils, increased body temperature, and sudden onset of severely painful contractions. Fetal signs often include tachycardia and excessive fetal activity. Fetal bradycardia and late decelerations may occur.

Emotional signs of recent cocaine use may include angry, caustic, or abusive reactions to those attempting to provide care. Emotional lability and paranoia are signs of cocaine intoxication.

Heroin

Typically, the pregnant woman dependent on heroin comes to the labor and delivery unit intoxicated from a recent drug use. When the effects of the drug begin to wear off, withdrawal symptoms may be observed. These include yawning, diaphoresis, rhinorrhea, restlessness, excessive tearing of the eyes, nausea, vomiting, and abdominal cramping.

Nursing Diagnosis

One of the most relevant nursing diagnoses during the intrapartum period is "Risk for Injury related to physiologic and psychological effects of recent drug use."

Expected Outcomes

The major goal or expected outcome for this nursing diagnosis is that the woman and the fetus will remain free from injury during labor and childbirth.

Interventions Preventing Injury

When a laboring woman has recently used a substance such as cocaine, the nurse must intervene to meet the needs of the woman and the fetus for safety, oxygen, and comfort.

Admitting Procedure. Two nurses may be needed to admit the woman into the labor unit and to persuade her to assume a safe position. One nurse helps the woman into bed, initiates electronic fetal monitoring, and begins administration of oxygen, as needed. The other nurse acts as the communicator.

Because the woman who has recently used a drug may have difficulty following directions, she should hear only one voice telling her what to do. This nurse states firmly what is happening and exactly what the woman must do: “Lie on your left side.” “This helps us watch how the baby is doing.” “This gives you more oxygen.” Maintain eye contact with the woman while giving her instructions.

Setting Limits. It is essential to set limits to protect the safety of the mother and the fetus. For instance, the mother cannot smoke. The nurse may say, “It’s difficult not to smoke, but there is real danger to everyone if you smoke when oxygen is being used.” The mother who must remain in bed may become agitated. The nurse may say, “I know it’s hard to stay in bed, but we can’t take good care of the baby when you walk.” If walking is safe for the woman, the nurse must set limits about where she can walk (in the labor room, not to the cafeteria).

Initiating Seizure Precautions. The laboring woman who recently used cocaine is at risk for seizures. Take the following seizure precautions:

- Keep the bed in a low, locked position.
- Pad the side rails, and keep them up at all times.
- Make sure that the suction equipment functions properly to prevent aspiration.
- Reduce environmental stimuli (lights, noise) as much as possible.

Maintaining Effective Communication

Establishing a therapeutic pattern of communication is essential. Avoid confrontation. Instead, acknowledge feelings: “I know you hurt and are frightened. I’ll do everything I can to make you comfortable.” When the woman is abusive, be careful not to take the abuse personally or react in a nontherapeutic manner.

Examine your own feelings when women are abusive and acknowledge when anger is getting in the way of providing care. Another nurse may need to assume care of the woman for a time to allow some relief from being the target of unrelenting abusive comments.

Providing Pain Control

Pain control for women who are substance abusers poses a difficult problem because it is often impossible to determine the type or combination of drugs that were used before admission. If pain medication can be administered safely, do not withhold it under the false assumption that the woman does not need it or that medication will contribute to her chemical dependence. Include nonpharmacologic comfort measures such as sacral pressure, back rubs, a cool cloth on the forehead, and continual support and encouragement as for any other woman in labor.

Preventing Heroin Withdrawal

To prevent heroin withdrawal during labor, give methadone to the woman who usually receives it at a chemical-dependence center if she did not receive her daily dose. Administer it intramuscularly, as ordered, if the woman is nauseated or vomiting. It is essential to avoid the use of drugs such as butorphanol (Stadol) in women who are opiate dependent because acute withdrawal signs and symptoms will occur in the woman and the fetus.

Evaluation

Both the expectant mother and the fetus may have experienced the harmful effects of drugs throughout pregnancy. However, the

interventions for this nursing diagnosis can be considered effective if neither the woman nor the fetus sustains additional injury during labor and childbirth.

POSTPARTUM PERIOD

During the postpartum period, nursing care is focused on helping the mother with bonding, providing infant care, and planning to provide care of herself and the infant after discharge. Observe for signs of recent drug use, and continue to assess the vital signs and level of consciousness of the mother.

Observe the mother–infant interaction so that bonding and attachment can be promoted. This is a major concern at this time (see Chapter 30). Encourage the woman to continue her efforts to stop taking substances. Women who stop or reduce use during pregnancy may return to using at previous levels after pregnancy and need support to continue abstinence. Referral to social services and child protective agencies may be necessary for the follow-up care of the mother and the infant.

BIRTH OF AN INFANT WITH CONGENITAL ANOMALIES

Even when everything goes according to plan, childbirth is a time of stress for parents. Their anxiety about the condition of the infant is obvious as they carefully trace the features and count the fingers and toes of their newborn. When the infant is not perfect but is born with anomalies, the parents are often overwhelmed with shock and grief. What may appear to be a minor defect to health care workers may seem a severe impairment to parents (Gardner & Dickey, 2011). Because nurses are with the parents more than other members of the perinatal team, they have an opportunity to help the family adjust and cope with their feelings.

Factors Influencing Emotional Responses of Parents Timing and Manner of Being Told

At one time, common practice was to remove the infant from the delivery area before parents could see a congenital anomaly and to tell them about it later. This practice changed, however, when it was realized that parents experienced less stress if they were told at once and were permitted to hold their baby if the physical status of the infant allowed. The manner of presenting information also changed. Physicians and nurses became aware of the importance of helping the parents accept and bond with the newborn.

Prior Knowledge of the Defect

Although ultrasonography does not identify all fetal anomalies, many parents become aware of congenital anomalies during ultrasound examinations performed during pregnancy. These parents have time for anticipatory grieving before the birth. They may not demonstrate the shock and disbelief at the birth that are seen in parents who are unprepared. Their reactions should not be interpreted to mean that they do not experience grief but rather that they have completed some of the early phases of grieving before the birth. Their grief is real and profound, even though it is expressed differently.

One couple was aware from 18 weeks of gestation that the fetus had hydrocephalus and protrusion of brain tissue from the skull. The mother elected to carry the fetus to term so that the infant would have “every chance at life.” When the infant died within minutes after birth, the parents calmly held their child and called the infant by the name they had selected several weeks previously. The only overt signs of grief were silent tears and a request to see their clergyman.

Once the anomaly is discovered by ultrasound, the pregnancy is no longer seen as normal and the focus may be on specialized care for the mother in preparation for the birth. Parents may feel isolated from those with normal pregnancies. Some parents seek information from parents who have a child with a similar anomaly. The full extent of the problem may not be known until after the birth. There may be a long period of worry and fear between the ultrasound diagnosis and the birth.

Type of Defect

Although any defect in a newborn produces extreme concern and anxiety, certain defects are associated with long-term parenting problems. Accepting an infant with facial or genital anomalies is particularly difficult for the family and the community.

The face is visible to everyone, and parents are fearful about whether the child will be accepted. If the defect is cleft lip and palate, the parents are extremely concerned about surgical repair. They are often anxious about how grandparents and siblings will accept the child. With time and support, parents often work out unique methods to help the family develop strong feelings of attachment.

Gender is at the core of a person’s identity, and any defect of the genitals, however slight or correctable, arouses deep concern in both parents. Some anomalies such as hypospadias (opening of the urethra on the underside of the penis) are repaired in early childhood. Other genital anomalies such as ambiguous genitalia (when assignment of gender is in doubt) cause extreme concern in the family and affect such basic issues as what to name the infant, how to dress the infant, and how to respond to questions about the infant’s gender.

Irreparable Defect

Although the initial impact of any defect is profound disappointment and concern, when the defect is irreparable, the parents must grapple with the knowledge that the infant will have a lifelong disability. Examples of irreparable defects include Down syndrome, microcephaly, and amelia (absence of an entire limb).

Grief and Mourning

Grief describes the emotional response to loss. Mourning is the process of going through the phases of grief until the loss can be accepted and resolved. Birth of an infant with an anomaly evokes a grief response. The family must mourn the loss of the perfect infant they imagined during pregnancy. They must detach from and mourn the fantasy baby to be able to attach to the actual infant (Gardner & Dickey, 2011). Early emotions include denial, anger, and guilt.

Denial and disbelief are the initial reactions of most parents to the birth of an infant with a congenital defect. “How could this happen?” Anger is often a pervasive response and may take the form of fault-finding or resentment. Anger may be directed toward the family, the medical personnel, or the self, but it is seldom directed toward the infant. Guilt may be expressed as a question of responsibility for the defect as many parents search for a cause: “I shouldn’t have worked so much while I was pregnant.”

Other emotions include fear, which may be expressed as concern about what must be done in the immediate or distant future (surgical procedures, complicated care, the infant’s potential for a normal life).

Sadness and depression, manifested by crying, withdrawal from relationships, lack of energy, inability to sleep, and decreased appetite, may precede acceptance and resolution. Gradually—often after a prolonged time—the feelings of sadness abate and the family is able to adapt to the loss and resolve its grief.

Nursing Considerations

Assisting with the Grieving Process

Both parents should be present when they are told about the infant’s condition (Freda, 2009). The nurse should use therapeutic communication techniques to help them discuss their feelings and fears. They should be given as much information as possible about the anomaly before the birth. If the infant will go to the NICU, a tour before the birth may help them understand the type of care their infant will receive.

At birth, the parents continue to grieve the loss of the perfect infant they expected and begin to form an attachment with this newborn. Whether the parents learned about the problem before or after the birth, it is helpful if the nurse remains with them as they go through the initial phase of shock and disbelief. The nurse maintains an atmosphere that encourages them to express their feelings by listening carefully to what the parents say and reflecting the content and feelings that they express.

For example, the mother of an infant girl with cleft palate says, “How could this happen? I should have gone to the doctor earlier.” A helpful response might be, “It sounds like you feel responsible for this problem. Actually, we don’t know the exact causes of cleft palate, but let’s talk about how you are feeling.” This offers reassurance but keeps the interaction open to explore the underlying feelings of guilt the mother may be expressing.

Nurses must recognize that grief responses vary among individuals, and cultural and religious beliefs affect the expression of grief. Members of some groups express grief openly by crying, becoming angry, or seeking comfort from a support group. Those in other cultures (such as Asian and Native American) may appear stoic and may not reveal the depths of their grief. In some cultures (such as Hispanic), it is acceptable for women, but not for men, to grieve publicly. The couple should be offered a private room, if possible. The infant should be examined in front of the parents so that they can ask questions. Information about normal needs of the newborn should be given at the same time as information about the anomaly.

Promoting Bonding and Attachment

A priority nursing intervention is to promote bonding and attachment, which may be disrupted when parents who expected a perfect infant give birth to an infant with an abnormality. The process is facilitated when the nurse communicates acceptance of the infant.

To promote bonding, the nurse handles the newborn gently and presents the infant as someone precious. Parents are particularly sensitive to facial expressions of shock or distress. The infant should be called by name. Many nurses emphasize the normal aspects of the infant’s body: “She’s so alert, and she has beautiful eyes.” Perhaps it is most important to help the parents hold their infant as soon as possible. Touching and cuddling are essential to caring (Figure 24-3).

FIG 24-3 Touching and cuddling by a mother whose infant has a congenital anomaly fosters attachment and helps them cope with the grieving process. This infant has anomalies of the hand and arm. (Courtesy of Cheryl Briggs, RNC, Annapolis, MD).

Providing Accurate Information

Nurses who work in perinatal settings are responsible for becoming informed about follow-up treatment and timing of surgical procedures for common anomalies so they can clarify and reinforce the information provided by the physician. This involves discussing the plan of care with the physician as well as researching the nursing care that will be required. Parents develop trust in the health care team when consistent information is presented clearly and explained fully.

If possible, one primary nurse or a team of nurses should work with the family throughout the hospital stay. The nurse should assess the parents' understanding of the condition and the treatment plan. Parents often need information repeated frequently because it is difficult for them to absorb all they are told at this time of intense emotions.

Facilitating Communication

Nurses are sometimes fearful of being asked questions they are unable to answer, or they fear they will say the wrong thing.

The most helpful course of action is to answer questions as honestly as possible. If uncertain about information, say so: "I'm not sure about that, but I'll find out about it for you." In addition to answers, parents need kindness, support, and genuine concern.

It is crucial that family members communicate with one another as well as with the health care professionals. Information and empathy should be offered consistently to both parents. Fathers should be included in all discussions, demonstrations, and care of the infant. Without this attention, the father cannot be expected to support his partner, explain the infant's condition to relatives and friends, or begin to deal with his own shock and sadness.

The nurse should assess the mother for signs of postpartum depression (see [Chapter 28](#)). The support person should be made aware of the mother's increased risk for prolonged depression. The signs of depression and the differences among normal "baby blues," normal grieving, and postpartum depression should be explained.

Participating in Infant Care

Parents should be involved in giving care to the infant as soon as possible to increase bonding and to help them feel that they can be real parents to the infant. Providing care for the infant also helps reduce parental anxiety as they get to know their baby (Klaus, Kennell, & Edwards, 2011).

Planning for Discharge

Teach parents the special feeding, holding, and positioning techniques that their infant needs. For example, parents may need to learn about cast care for the infant with clubfoot (talipes equinovarus). Early participation in infant care fosters feelings of attachment and responsibility for the infant as well as increasing feelings of confidence. They should also know what type of follow-up care with the health care provider is necessary and what other services may be needed.

Provide other anticipatory guidance that may help prevent problems when the infant is discharged. The reaction and behavior of siblings depend on their ages and abilities to understand the needs of the infant. Young children, who are often jealous of the attention and care the infant requires, may regress to infantile behaviors such as bedwetting and thumb sucking. Remind parents that this indicates a need for attention rather than naughtiness.

Although grandparents can be a great source of strength and support, they may also have difficulty adjusting to the infant with an abnormality. When appropriate and if the parents are willing, include grandparents when teaching the special care the infant will need.

Providing Referrals

Initiate referrals to national and community resources, as needed. In addition to a referral to the social worker or grief counselor in the hospital, parents may also benefit from information about the Easter Seal Disability Services, the March of Dimes, or the disabled children's services of the public health department. In addition, organizations such as the Shriners provide funds for the care of children. Support groups vary among communities, and perinatal nurses may wish to make a list of the names, addresses, and telephone numbers of these organizations.

PERINATAL LOSS

Perinatal death can occur at any time. Early spontaneous abortion, ectopic pregnancy, fetal demise at any point in pregnancy, stillbirth, or neonatal death when the infant survives for a few days or weeks can be equally devastating for the parents. The death may occur after a complicated pregnancy or one in which all seemed well until the baby died. Parents may have a short time with their baby while it still lives or none at all.

Because many people do not consider perinatal loss to be on the same level as the loss of an older child or adult, parents experiencing perinatal death often feel alone in their grief. In addition, friends and family members may be hesitant to discuss the loss for fear of saying the wrong thing. They may be uncomfortable with the topic and change the subject when parents want to talk.

Early Pregnancy Loss

Early pregnancy loss from spontaneous abortion or ectopic pregnancy may precipitate intense grief in the parents. The parents may not yet have told family and friends about the pregnancy. Those who do know may minimize the grief that occurs at this time. Comments such as “You shouldn’t have any problems getting pregnant again” discount the intensity of the parents’ feelings.

When ectopic pregnancy is the reason for the loss, the woman has to cope with the loss of the pregnancy and the loss of or damage to a fallopian tube. Health care workers mean well when they say, “You still have one fallopian tube left; you’ll get pregnant again,” but this does not acknowledge to the mother that a child has been lost. Ectopic pregnancy is more frequent in women older than 35 years, increasing the impact if the woman has experienced infertility problems.

Concurrent Death and Survival in Multifetal Pregnancy

Parents experience conflicting and complex feelings of joy and grief when one or more infants in a multifetal pregnancy live and one or more infants in the same gestation die. Contrary to common belief, parents do not grieve less for the dead infant because of the joy they experience in the surviving child.

For parents experiencing survival of one infant and death of another, the grieving process may be more complicated. They may have fears about the health of the surviving infant, especially if the infant is preterm or ill. They may be unable to grieve for the dead child because of their concerns and responsibilities for the surviving child. They also may experience problems with attachment to the surviving infant because of grieving and fear that they will lose that infant as well. In addition, they may receive less support from others compared with parents who have lost their child in a single gestation.

Parents who experience the death of one infant and the survival of another need the same interventions as those offered for parents who lose the child in a single gestation. These interventions include allowing the parents to hold the dead infant and gathering mementos. In addition, nurses must be prepared to confirm the cause of death, if known, and the health status of the surviving infant.

Perinatal Palliative or Hospice Care Services

Some parents learn that the fetus has a condition that is terminal. They may choose to continue the pregnancy and deliver at term, knowing that the infant will survive only a short time. Perinatal palliative or hospice care services provide care by nurses experienced in hospice or palliative care. These nurses assist the family through the processes of birth, death, and grief. The emphasis of care is on promoting quality of life, minimizing suffering, and supporting parents in their grief. It allows parents to plan for the birth and death of their baby. They make choices about care and make memories that make their parenting more meaningful, even though it lasts only a short time (Kobler & Limbo, 2011).

Previous Pregnancy Loss

Women who have experienced previous pregnancy losses often have higher levels of anxiety compared with women who have not suffered such loss. They may also have symptoms of depression, which are correlated with increased concern about the well-being of a healthy infant born after a previous loss (Armstrong, Hutti, & Myers, 2009). Many tend to be pessimistic about the chance of a successful outcome near the beginning of pregnancy but gradually become more positive as the pregnancy progresses. They may be particularly fearful near the time in gestation when the previous loss occurred. Fathers may hide their

worries about a new pregnancy in an effort to decrease worry in the mother.

Having other, healthy children does not reduce the degree of anxiety during a pregnancy that follows a perinatal loss. Parents may delay telling family and friends about the pregnancy until they feel more confident about the outcome. They may not tell those who do not already know about the loss of the previous pregnancy. Some do not prepare the baby’s room at all during the pregnancy. Others wait until near the end of pregnancy to make preparations to bring an infant into the home. Conflicting emotions of excitement, fear, and doubt occur as the pregnancy progresses normally.

Early prenatal care is especially important during a pregnancy following a loss. Both parents may be more comfortable with more frequent contact with the health care provider. Women tend to be extra careful to do what is recommended in pregnancy and hypervigilant about signs that might indicate something is wrong. Less fetal activity than usual is very worrying, and feeling the baby move is reassuring. They need frequent reassurance about the status of the fetus and emotional support throughout the pregnancy.

Although mothers may request extra diagnostic testing to help relieve their anxiety, they may not always feel as reassured by normal test results as they had hoped. Nurses who provide them with an opportunity to express their distress and fears are essential. Making referrals to support groups or mental health providers as appropriate may provide better relief of anxiety and a better use of health care resources (Hutti, Armstrong, & Myers, 2011).

APPLICATION OF THE NURSING PROCESS

■ Pregnancy Loss Assessment

Nursing assessment of the family that has experienced the loss of a fetus or infant requires great sensitivity. In the case of infant death, collect as much information as possible before meeting the woman and her family for the first time so that hurtful mistakes can be avoided. Knowing the child’s gender, weight, length, gestational age, and whether any abnormalities were noted will help the nurse communicate effectively.

Many perinatal units design a sticker or symbol to place on the door, chart, and Kardex so that all staff who come in contact with the family, including auxiliary, housekeeping, and laboratory personnel, will be alerted that the infant has not survived. Designs include a fallen leaf, teardrop, flower, butterfly, or rainbow. This visual symbol diminishes the chance that an uninformed person will make inadvertent comments that cause pain.

Nurses are often unsure about how to interact with a family that has experienced the loss of an infant. It is helpful to acknowledge the situation and clarify the nurse’s role at once: “I’m Dawn, and I’ll be your nurse today. I’m so sorry for your loss. What can I do today that would be most helpful to you?” This is not an appropriate time for self-disclosure or for false reassurance. Keep the focus on the family’s response and their ability to support one another.

Initial grief responses are similar to those expressed by parents of infants with anomalies. Crying and expressions of anger often occur during the woman’s stay in the birth facility. Guilt is often an underlying feeling as the parents search for a reason for their infant’s death.

Nurses who provide home care or make follow-up telephone calls must be aware of subtle cues of grief such as sighing, excessive sleeping, apathy, poor hygiene, and loss of appetite. These signs are especially important when assessing members of cultural groups that do not display grief publicly. In addition, nurses must observe for signs of

postpartum depression, post-traumatic stress disorder, and panic disorder, which may occur after perinatal loss.

Evaluate the availability of a support system that includes family members or clergy. Ask whether the family would like a spiritual advisor called. The family may want the infant baptized or blessed.

Assess the father's needs as well because they are sometimes perceived as needing less support than the mother and they may not receive the support they need. Many feel a need to appear strong so that they can support their partners. As a result, they often hold back their own feelings of grief and pain in an attempt to avoid increasing the mother's grief. In addition, each member of the couple may grieve differently and may be perceived as being unsupportive by others (Coverston, 2011). Mothers feel a sense of failure but often find it easier to express feelings of sadness. Fathers may express sadness as anger and may focus their attention on their work to help them cope with their grief.

Nursing Diagnosis

Because perinatal loss affects the whole family, the nursing diagnosis "Interrupted Family Processes related to grief over newborn (or fetal) death" is discussed here.

Expected Outcomes

Expected outcomes for this diagnosis are that the parents will:

1. Acknowledge their grief and express the meaning of the loss.
2. Share their grief with significant others.
3. Provide support to each family member.

Interventions

Allowing Expression of Feelings

Stay with the parents as they express their feelings. Allow them to cry or respond as they wish. Parents may want to have some time alone but may also appreciate having the nurse sit quietly nearby. When they are ready to talk, listen attentively.

Acknowledging the Infant

It was once believed that when an infant was stillborn or died shortly after birth, the less parents knew of the infant, the less they would grieve. The infant often was whisked away so that the parents never saw their newborn. Relatives disposed of the clothes and infant equipment before the mother returned home, and the parents were left with very few memories of the infant's birth.

The response to perinatal death changed as nurses discovered that the most helpful interventions for grieving parents were those that acknowledged the rights of the baby. These include the right to:

- Be recognized as a person who was born and died
- Be named
- Be seen, touched, and held by the family
- Have life-ending acknowledged
- Be put to rest with dignity (Primeau & Lamb, 1995)

Allow the parents to talk about the baby as much as they wish. Refer to the infant by name. If the infant lived for a time, talk about what happened during that time, and answer any questions the parents have. If the infant is dying, allow parents to hold and care for their baby. Take pictures of the infant if the parents wish.

Presenting the Infant to the Parents

When the baby dies, the way in which the infant is presented to the parents is extremely important because these are the memories they will retain. Parents should be prepared for the appearance of the infant, especially if maceration (peeling) of the skin is present or there are disfigured areas. If necessary, wash the infant, and apply baby lotion or powder. Wrap the infant in a soft, warm blanket. Some parents may wish to participate in bathing and dressing the baby.

If possible, bring the parents and the infant together while the infant is still warm and soft. Keeping the infant in a warmed incubator may be necessary if some time elapses before the parents have contact with the infant. If this is not possible, tell the parents that the skin may feel cool. Allow the parents to keep the infant as long as they wish, and tell them to feel free to unwrap the infant if they wish.

When the stillborn infant has severe deformities, explain the defect briefly and gently. Wrap the infant to expose the most normal aspects. When the infant has deformities of the head and face, wrap the infant with the blanket draped loosely over the most severely affected areas so that the parents do not see those areas first. Use diapers to cover genital defects and booties and mittens to cover abnormalities of the hands and feet.

It is not advisable, however, to try to hide the defects completely. Allow parents to progress at their own speed in inspecting the infant. Parents may look at the abnormality or choose to leave the infant wrapped. They may quietly discuss positive features of the infant: "He has your ears." "Look at her long fingers."

Some parents may provide care before their baby dies. If death is near, ventilators and other equipment may be removed so that the parents can feel closer to the infant. They may hold the infant during the dying process. Many feel that this is very helpful to them, as it provides a chance to say goodbye and is the only opportunity they will have to parent their baby. Other family members may also be present at this time. Stay with the family, if they wish, to help them at this difficult time.

Allow as much privacy and time as the parents and other family members need to be together. Remain sensitive to cues that members of the family want to talk or prefer silence. A sympathetic smile or a promise to return at a certain time and then returning at that time are equally important. It is all right to say, "Do you want to talk?" Then all that is required is listening quietly and reflecting the mother's or father's feelings. Allow the parents to be alone if they wish, and check intermittently to see if they need assistance.

Although many parents want to spend time caring for or holding their baby before or after death, others may not. It is important not to make the parents feel guilty or that they should behave in a certain way. Nurses must accept that each family needs to go through this difficult experience in their own way.

Preparing a Memory Packet

Mourning requires memories. Nurses have explored measures that help the family create memories of the infant so that the existence of the child is confirmed and the parents can complete the grieving process. Helping families create memories and providing support are part of a perinatal grief support nursing care quality measure being introduced by the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN, 2013).

Most parents treasure a memory packet. Prepare one that includes a photograph; a birth identification band with the date and time of birth; the crib card with the infant's name, weight, and length; a tape measure; and a blanket and cap used for the baby. If the baby has enough hair, ask the parents for permission to cut a lock of hair from the nape of the neck where it will not be noticeable. Some hospitals offer commercial remembrance materials to parents. The packets or boxes may contain clothing for the baby to wear and provide a place to keep baby items. Make paper handprints or soft modeling material impressions of the infant's hands and feet.

Take photographs of the infant to help parents remember the baby's features, and assist them through the grieving process. Take photos of the infant dressed and undressed, wrapped and unwrapped, and of the parents and other family members with the infant. Professional photographers may be available from Now I Lay Me Down To Sleep Foundation, a nonprofit organization that provides bereavement photos to

families. A list of photographers and their locations is available at www.nowilaymedowntosleep.org. A website that offers help to caregivers who take pictures for the family is www.todddhochberg.com.

Keep the memory packet and photographs on file if the parents do not wish to take them home because they may want them at a later time. Many couples feel that these concrete forms of remembrance are invaluable in helping them remember the baby as a person who really existed when they have no other signs of that life.

Respecting Cultural Practices

In some cultures, seeing or holding the baby after death is not acceptable. Cutting a lock of hair may not be permissible in some Muslim families. It is culturally unacceptable in certain groups to take photographs of a person after death. Therefore, ask permission before taking pictures. Pictures taken before death occurs may be more acceptable. Expression of grief may be loud and open, or parents may appear stoic, depending on cultural expectations. The nurse must be accepting of the family's method of coping with their loss.

Assisting with Other Needs

If the family includes other children, help the parents plan how to tell them about the death of the expected infant. Give them information about sibling responses and needs based on the ages of their other children. Provide the parents with written information about perinatal loss, grieving, and children's responses to death for later use. Other family members and close friends may be important in helping care for siblings as the parents cope with their own grief.

Offer to call clergy, and discuss plans for a funeral or memorial service, if the family wishes. Parents may want to discuss this with their own clergy, or a hospital chaplain may assist them. Discuss the normal grieving process, and explain that a considerable amount of time is involved. Describe common reactions that family members and friends might have. For example, some family members or friends may minimize the loss, whereas others, in a misguided attempt to offer comfort, may urge the couple to have another baby. Let them know that grandparents also go through grief because of the loss of their grandchild as well as the pain their children must endure.

Providing Follow-Up Care

Parents may find that friends and relatives expect them to recover quickly from perinatal loss and cannot understand their continued grief. Suggest that they allow the parents to "tell the story" of the infant as often as they want because this helps them in the grief process. Suggest that they help parents collect and talk about mementos to help establish memories of the infant.

Siblings are often expecting to be a "big brother" or "big sister" and need help understanding why that will not occur. Help the parents explore how they will tell their other children that the new baby will not be coming home. Explain that some young children think they have done something to cause the death and need reassurance. They may have questions (such as "Is the baby still dead?" or "Is the baby alive?") that should be answered simply but truthfully (Limbo & Kobler, 2009).

Because the mother and the father experience grief in different ways, they may not understand each other's responses. Mothers who want to talk about the loss repeatedly may have partners who deal with their grief by being stoic and brooding or by focusing their energy on work. Emphasize the individuality of grief and that no single method or duration of grieving is right for everyone.

Couples usually want to know the cause of their infant's death. An autopsy may be recommended even if the cause of death is obvious. This gives parents the most accurate diagnosis for risk of recurrence in a future pregnancy. In some cases, the cause may never be found.

Referral for genetic counseling may be appropriate for some parents who are concerned about the risk of a repeated tragedy. Future pregnancies will be stressful, and the woman will need closer follow-up than usual to identify any problems as soon as possible. The anxiety may continue in the neonatal period, and parents may need education and emotional support during this time.

Providing Referrals

Many birth agencies offer bereavement programs or counselors to provide ongoing help to parents. A social services referral is important. Telephone calls made during the first week, 1 to 2 weeks later, at the time of the postpartum checkup, and at the 1-year anniversary are helpful. Sympathy cards may be sent by agency staff with a list of resources that may be helpful. The greatest help often comes from contact with people who have experienced a similar loss, and a variety of support groups have been formed.

Refer parents to resources at the birth facility or in the community designed to help parents cope with loss. Many Internet resources are available. Examples are M.I.S.S. Foundation at www.misschildren.org, or Helping After Neonatal Death (HAND) at www.handonline.org.

Some women join Internet perinatal loss support groups. Such groups may be particularly helpful after the immediate period surrounding the death. Extended family and friends may no longer be as supportive at this time and do not realize the length of time involved in grieving. Gaining a feeling of control over their lives and being able to make decisions gradually develop as the parents move toward healing.

Evaluation

Nursing care has been successful if the family members share their feelings of loss and grief, communicate them to their significant others, and are supportive of one another.

21. What is a memory packet, and what should it include?

ADOPTION

Some women carry a pregnancy to term and then relinquish the newborn to the care of another family by adoption. The decision to place the infant for adoption is a painful one that can produce long-lasting feelings of ambivalence and chronic sorrow. On the one hand, the expectant mother may be satisfied that the infant is going into a stable home where the child is wanted and will receive excellent care. On the other hand, the social pressures against giving up one's child are often intense.

The relationship between the birth mother and the adoptive parents varies greatly. The adoptive parents may be unknown to the birth mother, or she may have chosen them after interviewing many candidates. Some adoptive mothers participate at the birth and act as coach or support person during the birth. The birth mother may never see the infant again or may keep in contact with the child and participate in the child's life.

Nurses are sometimes unsure about how to communicate with the woman who is placing her infant for adoption. First, the nursing staff who come in contact with the woman must be informed of her decision. This information prevents inadvertent comments that could cause distress. Second, nurses must remember that adoption is an act of love, not one of abandonment, because the woman relinquishes the

newborn to a family that is better able to provide financial and emotional support to the child.

Nurses must also be prepared to respect any special wishes the mother may have about the birth. Most birth mothers make plans for how much they want to be involved with the infant and with the adoptive parents. Many want to know all about the infant—how big he or she is, how healthy, how beautiful, and so on. Encourage birth mothers to see and hold the newborn and give the baby a name. Many mothers take photographs or save mementos such as the crib card. Such actions provide memories of the infant and help the mother through the grieving process that accompanies placing the child for adoption.

The nurse should try to establish rapport and a trusting relationship with the birth mother. It is helpful to acknowledge the situation at the initial contact with the woman: “Hello, my name is Kate, and I’ll be your nurse today. I understand the adoptive family is coming this morning. What can I do to help you get ready?” This is much more helpful than providing care without reference to an event that is of utmost concern to the mother. It also provides an opening for her to express feelings that may include strong attachment and love for the infant, ambivalence about her decision, and profound sadness.

Therapeutic communication techniques are useful to help the mother explore her feelings. Although the mother has chosen to give up her baby, the grief she experiences may be similar to loss by death. Her grief may not be shared with family and friends, who may not understand her feelings. The nurse should acknowledge the feelings the mother may have, avoid offering advice, and remain nonjudgmental.

Nurses also teach adoptive families how to care for the newborn and what to expect in growth and development. Teaching requires adequate time and a private place be provided. This family benefits from all the teaching that is provided for other new parents. They may be anxious, and demonstrations as well as return demonstrations are appropriate.

23. What are the nurse’s responsibilities to the adoptive parents?

INTIMATE PARTNER VIOLENCE

Intimate partner violence (IPV) is defined as abuse by a current or former partner or spouse. It includes physical, sexual, and emotional abuse (e.g., threatening a partner’s loved ones or possessions or harming a partner’s self-worth). Approximately 42.4 million (35.6%) of women in the United States have experienced rape, physical violence, or stalking by an intimate partner. Severe violence has been suffered by 24.3% of women (Black, Basile, Breiding, et al., 2011). Adolescents as well as older women are victims of IPV. Although some studies show an increased incidence in economically disadvantaged groups, IPV is seen at all socioeconomic levels.

Physical abuse may involve threats, slapping, and pushing. It may escalate to punching, kicking, and beating that result in internal injury, wounds from weapons, or death (Figure 24-4). Sexual abuse, including rape, often is part of physical abuse, with many abused women reporting being forced into sex by their male partner.

Physical violence occurs within the context of continuous mental abuse, threats, and coercion, and the abuser blames the victim for causing the abuse. As a result, women feel shame, loss of self-respect, and powerlessness. They are often isolated from friends and family. Abused women often report that their partner is unwilling to use contraception or makes it difficult for them to use it, causing unwanted

FIG 24-4 The woman who is abused by her partner lives with an ever-present risk of violence. Because an abused woman may not seek help, all women should be asked about abuse whenever they receive health care.

pregnancies (Gee, Mitra, Wan et al., 2009). This reproductive coercion involves interfering with a woman’s use of contraception or threatening to leave her if she does not become pregnant (Miller, Jordan, Levinson et al., 2010).

Factors that are associated with violence include abuse of alcohol and other substances by the woman and her partner, depression, unwanted pregnancy, repeat pregnancy within 24 months, and frequent need for treatment for various problems including vague complaints, chronic pain, gynecologic problems, recurrent STDs, and inadequately explained injuries (Bacchus & Bewley, 2011; Ettinger & Gambone, 2010).

Effects of Intimate Partner Violence during Pregnancy

Violence may start or escalate in frequency and severity during pregnancy and the postpartum period. Pregnancy adds more stress to the relationship. The partner may feel trapped in the relationship and under increased pressure to provide emotional and financial support for the woman and the infant. Up to 20% of women may be physically abused during pregnancy. Abuse is more common during pregnancy than preeclampsia, diabetes, or other commonly screened pregnancy complications (Lu, Williams, & Hobel, 2010). The greatest risk occurs during the postpartum period (Bacchus & Bewley, 2011).

Abuse during pregnancy is correlated with health problems for the mother and the infant. Abused women are likely to have multiple injury sites, particularly on the face, arms, buttocks, abdomen, and breasts (Beckmann, Ling, Barzansky et al., 2010; Records, 2011). They are more likely than nonabused women to start prenatal care late and may miss appointments because the abuser will not let them leave the house or they want to hide the signs of injury. They may have health problems such as STDs. In addition, they have an increased risk of postpartum depression (Certain, Mueller, Jagodzinski et al., 2008).

Infants born to abused mothers are more likely to have a low birth weight and be born preterm. Trauma to the abdomen can cause spontaneous abortion, abruptio placentae, premature rupture of membranes, preterm labor and birth, and fetal death (Bacchus & Bewley, 2011; Cunningham et al., 2010).

In addition, physical abuse of the mother may be an indication of what life holds for the unborn child. Some men who batter women

also batter children, and some women who are victims of violence abuse their children. Approximately 27% of abused women abuse their children. Child abuse occurs in 33% to 77% of homes where there is IPV (AAP & ACOG, 2012). Children who witness violence in the home may have emotional, behavioral, developmental, and medical problems. They may have anxiety, depression, aggressiveness, sleep disorders, hyperactivity, school difficulties, bedwetting, failure to thrive, and other difficulties (Sherman & Rice, 2009). Adults who abuse others often were abused as children.

Factors That Promote Violence

Family violence occurs in cultures in which roles are gender based and little value is placed on the woman's role. Men hold the power, and women are viewed as less worthy of respect than are men. Women usually earn less than men do in the job market, and they are often victimized by marriage. For example, women who hold full-time jobs continue to carry the major responsibilities for housekeeping and child care. They may remain in unhealthy relationships because they are financially dependent on their partners. If they divorce, women often become single parents with a standard of living much lower than that of their former husbands.

The woman's role in her own culture is important. For example, in many cultures, women believe that they must be submissive to men and must sacrifice for their families because it is their duty to keep the family together. They may not have the education to be able to access help or obtain a job to provide a means of support if they should leave their partners. If the woman is an illegal immigrant, she is less likely to seek help from authorities for fear of being deported.

Stereotyping males as powerful and females as weak and without value has a profound effect on the self-esteem of women. Many women internalize these messages and come to believe that they are less worthy than their partners and that they are the cause of their own punishment. They accept the implication from some members of society that women who are battered or raped "got what they deserved."

The woman may come to accept her partner's statements that she is the cause of the violence. She may minimize the abuse or indicate to others that it is unusual. Women often feel a need to help the abuser and hope that the partner will change and the abuse will end. As the relationship becomes more and more abusive, the woman may begin to look for help.

Although alcohol is often stated as a cause of violence against women, chemical dependence and IPV are two separate problems. Chemical dependence is a disease of addiction, but abuse is a learned behavior that can be unlearned. However, violence may become more severe or bizarre when alcohol or drugs are involved. See Table 24-3 for a summary of the myths and realities of violence against women.

Characteristics of the Abuser

Physical abuse is about power, and it is only one of many tactics that abusive men use to control their partners. Other tactics include isolation, intimidation, and threats. Extreme jealousy and possessiveness are typical of the abuser. An abusive man often attempts to control every aspect of the woman's life, such as where she goes, to whom she speaks, and what she wears. He controls access to money and transportation and may force the woman to account for every moment spent away from him.

The abusive man often has a low tolerance for frustration and poor impulse control. He does not perceive his violent behavior as a problem and often denies responsibility for the violence by blaming the woman. Most abusive men come from homes in which they witnessed the abuse of their mothers or were themselves abused as children.

Cycle of Violence

Although IPV may be random, there is often a pattern. The violence occurs in a cycle that consists of three phases: (1) a tension-building phase, (2) a battering incident, and (3) a "honeymoon or calm phase." Being aware of the behaviors that accompany each phase will enable the nurse to counsel the woman (Figure 24-5).

Nurse's Role in Prevention of Abuse

Nurses can do a great deal to prevent physical abuse of women. First, they must examine their own beliefs to determine whether they accept the attitude that blames the victim: "Why was she wearing that?" "She shouldn't have flirted with someone else." "Why does she stay with him?" Second, nurses can consciously practice ways that empower women. They should make it clear that the woman owns her body and has the right to decide how it should be treated. Nurses must use language that indicates the woman is an active partner in her care: "You understand your body; what do you think?"

TABLE 24-3 MYTHS AND REALITIES OF VIOLENCE AGAINST WOMEN

MYTHS	REALITIES
The battered-woman syndrome affects only a small percentage of the population.	Battering is a major cause of injury to women. Approximately 24.3% of women have experienced severe violence from IPV.
Violence against women occurs only in lower socioeconomic classes and minority groups.	Violence occurs in families from all social, economic, educational, racial, and religious backgrounds.
The problem is really "partner abuse," couples who assault each other.	Women experience IPV more often than men. Violence against women is about control and power.
Alcohol and drugs cause abusive behavior.	Substance abuse and violence against women are two separate problems. Substance abuse is a disease, but violence is a learned behavior that can be unlearned.
The abuser is "out of control."	He is not out of control. Instead, he is making a decision because he chooses who, when, and where he abuses.
The woman "got what she deserved."	No one deserves to be beaten. No one has the right to beat another person. Violent behavior is the responsibility of the violent person.
Women "like it," or they would leave.	Women are threatened with severe punishment or death if they attempt to leave. Many have no resources and are isolated, and they and their children are dependent on the abuser.
Couples' counseling is a good recommendation for abusive relationships.	Couples' counseling not only is ineffective for the couple, but also can be dangerous for the abused woman.

IPV, Intimate partner violence.

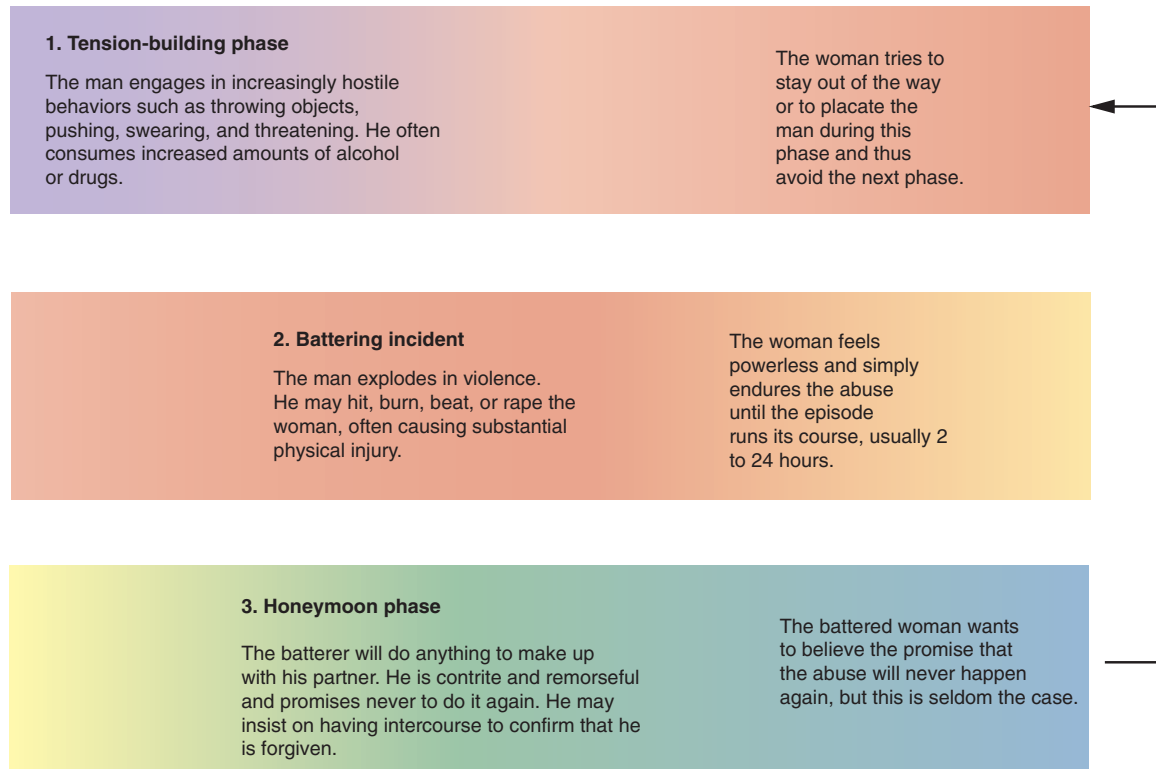

FIG 24-5 Types of behaviors that are evident in each step of the cycle of violence.

During examinations, nurses can introduce aspects of care that increase the woman's control over the situation. For example, make sure that when the woman first meets the physician or nurse practitioner who is to examine her, she is seated and clothed instead of being unclothed and in a lithotomy position.

School nurses are in an excellent position to influence how teenagers define gender roles: "Real men don't beat up women." "Girls don't have to put up with verbal or physical abuse from anyone." "Use a condom; it's not cool to give STDs or an unwanted pregnancy to someone you care about."

Nurses should be familiar with national resources that are designed to provide health care workers with technical assistance, training materials, posters, bibliographies, and relevant articles. The National Domestic Violence Hotline offers information on crisis assistance throughout the United States. They have interpreters for 170 different languages and are available 24 hours a day. The other sources listed here provide information but are not crisis lines.

- National Domestic Violence Hotline, 800-799-SAFE, www.ndvh.org
- National Coalition against Domestic Violence, 303-839-1852, www.ncadv.org
- National Resource Center on Domestic Violence, 800-537-2238, www.nrcdv.org

Women who are being abused should be warned not to use their home computers to access the Internet for sources of information

about abuse because their partners may be able to find out about recently used Internet sites.

APPLICATION OF THE NURSING PROCESS

■ The Battered Woman Assessment

During pregnancy, a woman is likely to have more frequent contact with health care providers than at any other time in her life. Because of the prevalence of IPV during pregnancy, women should be asked about IPV at each prenatal visit, on admission to the hospital, and again at the postpartum checkup. After pregnancy, visits to the pediatrician usually occur frequently during the infant's first year and provide other opportunities for screening. The *American Academy of Pediatrics (2010)* recommends assessment for IPV during office visits as a means to preventing child abuse.

Unfortunately, few women identify themselves as victims of IPV, and many remain unrecognized. When they are first approached, women may deny that abuse has occurred. They may feel judged and stigmatized because they do not want to leave the relationship and are fearful that their children will be taken away if they reveal the situation. The woman who is not ready to seek help when she is first asked may be ready at a later time. Asking in a nonjudgmental way, and especially asking more than once, may lead the woman to seek help at a later time.

Place written information about abuse in areas such as restrooms, where it will not be seen by the partner. This implies that discussion of violence is encouraged and safe.

Many nurses are unsure about how to approach the issue of suspected abuse. Women often seek care during the "honeymoon phase" of the violence cycle. During this phase, the man is often overly solicitous ("hovering husband syndrome") and eager to explain any injuries the woman exhibits. He often answers questions directed at the woman.

24. What is the effect of pregnancy on battering behavior?
25. How can nurses alter their practice to help prevent violence against women?

CRITICAL THINKING EXERCISE 24-1

Mandy, a 28-year-old primigravida, is admitted to the labor, delivery, recovery unit with contractions at 34 weeks of gestation. The right side of her face is swollen, old bruises that look like fingerprints are present on her upper arms, and a large bruised area is apparent on her abdomen. She is accompanied by her husband, who is very solicitous. He verbalizes concern about her labor status and remains close beside her at all times. Mandy appears lethargic and avoids eye contact with the nurse who is admitting her. She states that she fainted at home and hurt herself when she fell against the bathtub. The nurse accepts the explanation and asks no further questions.

Questions

1. What assumptions has the nurse made?
2. What should make the nurse question whether the injuries resulted from falling?

At the change of shifts, Mandy is assigned to another nurse. The nurse waits for a time when Mandy's husband is out of the room and she can be alone with Mandy. The nurse asks, "Did you get these injuries from being hit?" Mandy appears extremely anxious and says, "Don't say anything to him! He got so mad when I was late getting home from shopping. It was my fault."

Questions

3. Why did the nurse wait for time alone with Mandy before asking questions?
4. How should the nurse respond? What bias must the nurse resist?
5. How can Mandy be protected?

Introducing the subject of violence in the presence of the man who may be responsible for it places the woman in danger. It is absolutely essential to separate the woman from the man for the discussion of violence. No other family members should be present for that part of the interview. Even children as young as 2 years may reveal to the partner or family members that abuse was discussed (Bacchus & Bewley, 2011).

A common concern about discussing IPV is having time with the woman without her partner. Sometimes the partner can be sent to another area to give insurance information. Telling the partner that the nurse plans to discuss "feminine hygiene" and needs privacy may also be a way to have time alone with the woman.

Other reasons nurses cite for not discussing IPV include lack of time, not knowing what to do if IPV is discovered, and language barriers. If language barriers are present, a professional interpreter should be used to translate and never a family member or friend.

When a private, secure place has been found, explain to the woman that many women experience abuse. For example, "Because abuse is very common and can affect the woman's health, it is the policy at this hospital to ask every woman about abuse situations." This lets the woman know that she is not being singled out for questioning. Reassure her that her privacy will be protected and that confidentiality will be maintained.

Common screening questions include the following:

- Have you been threatened, hit, slapped, kicked, choked, or otherwise physically hurt by anyone within the last year?
- Has this happened since you have been pregnant?
- Has anyone forced you to have sexual activities?
- Are you ever afraid of anyone?

A "yes" answer should prompt questions about who hurt the woman and the frequency and kinds of abuse. If a woman has old or new signs that might be from abuse, ask questions such as "Did someone hurt you?" and "Did you receive these injuries from being hit?"

The abused woman often appears hesitant, embarrassed, or evasive. She may speak in a low tone of voice, be unable to look the nurse in the eye, and appear guilty, ashamed, jumpy, or frightened. She may have a flat affect (absence of facial response) or one that is inappropriate for the situation.

CRITICAL TO REMEMBER

Cues Indicating Violence Against Women

Nonverbal—Facial grimacing, slow and unsteady gait, vomiting, abdominal tenderness, absence of facial response

Injuries—Welts, swelling, burns, vaginal or rectal bleeding; bruises or lacerations in various stages of healing; evidence of old or new fractures of the nose, face, ribs, or arms; injuries to the face, breasts, abdomen, or genitals

Vague somatic complaints—Anxiety, depression, panic attacks, sleeplessness, anorexia

Discrepancy between history and type of injuries—Wounds that do not match the woman's story; multiple bruises in various stages of healing; bruising on the arms (which she may have raised while trying to protect herself); old, untreated wounds

Evaluate and document all signs of injury, both past and present. This includes areas of welts, bruising, swelling, lacerations, burns, and scars. Injuries are most commonly noted on the face, breasts, abdomen, and genitalia. Many women have new or old fractures of the face, nose, ribs, or arms. A photograph or a drawing may be used to record areas of injury. These may be important for future legal action.

If sexual abuse has occurred, a gynecologic examination is necessary because trauma to the labia, vagina, cervix, or anus often is present. Types of forced sex may include vaginal intercourse, anal intercourse, and insertion of objects into the vagina and anus.

Be particularly alert for nonverbal cues that indicate that abuse has occurred. Facial grimacing or a slow, unsteady gait may indicate pain. Vomiting or abdominal tenderness may indicate internal injury. A flat affect is indicative of women who mentally withdraw from the situation to protect themselves from the horror and humiliation they experience. Keep in mind that the woman may fear for her life because abusive episodes tend to escalate. Open-ended questions help prompt full disclosure and the expression of feelings. Record direct quotes of what the woman says about her experience.

Nursing Diagnosis

A variety of nursing diagnoses might apply, depending on assessment data. The most meaningful diagnosis may be "Fear related to possibility of severe injury to self and/or children during unpredictable cycles of violence" (Box 24-4).

Expected Outcomes

The abused woman may have difficulty developing a long-term plan of care without a great deal of specialized assistance. She often is unwilling to leave the abusive situation, and nurses must focus on working with the woman to make short-term plans that will protect her from future injury. The expected outcomes are that the woman will:

1. Acknowledge the physical assaults.
2. Develop a specific plan of action for when the abusive cycle begins.
3. Identify community resources that can provide protection for her and her children.

Interventions

Listening

Use therapeutic communication techniques to listen and encourage the woman to share her feelings. Assure her that you understand her situation is a difficult one and that she has been surviving as well as she can. Praise even small positive steps she has taken to ensure safety for herself and her children. The woman must make her own decisions about whether to continue the relationship and should not feel coerced to end it.

Developing a Personal Safety Plan

Ask the woman what she does to decrease or avoid violence from her partner. Help her make concrete plans to protect her safety and that of her children. For example, if the woman insists on returning to the shared home, describe the cycle of behavior that culminates in physical abuse and factors such as drug or alcohol use that precipitate a violent episode. Discuss behaviors that indicate that the level of frustration and anger is increasing to the point where the danger is escalating.

Assist her to:

- Locate the nearest shelter, safe house, or another safe place and make specific plans to go there once the cycle of violence begins.
- Identify the safest, quickest routes out of the home.
- Hide extra keys to the car and house, money, personal information (social security numbers, birth certificates, insurance policy information, driver's license, bank account numbers, passport), medications, some clothes for herself and her children, and personal necessities. She should not hide them in the house but find another place such as the house of a friend or relative.
- Devise a code word and prearrange with someone to call the police when the word is used.
- Memorize the telephone number of the shelter or hotline because time is often a crucial element in the decision to leave. An easy number to remember is the one for the National Domestic Violence Hotline (1-800-799-SAFE), which provides immediate crisis assistance in the caller's community.

- Review the safety plan frequently because leaving the partner is one of the most dangerous times. Women are more likely to be injured or killed when they are leaving than at any other time.

Affirming She Is Not to Blame

The abused woman often believes that she is responsible for the abuse. Let her know that no one deserves to be hurt for any reason. The one who hurt her is the person responsible. She did not provoke it or cause it and could not have prevented it. Nurses are often responsible for teaching basic family processes such as the following:

- Violence is not normal.
- Violence usually is repeated and escalates.
- Battering is against the law.
- Abused women have alternatives.

She also needs nonjudgmental acceptance and recognition of the difficulties involved in making changes in her situation. Praise her for any actions she takes, even if they are only minor steps toward making her life safer. Reassure her that she is doing the right thing for herself and her children when she seeks help and makes plans for escape.

Providing Education

The pregnant woman is likely to worry about the effect of abuse on her pregnancy. Discuss the increased incidence of preterm labor with her and explain the signs. If she is using substances, explain the effects of smoking and of the use of alcohol and drugs and help her make plans to decrease or stop her use. Help her identify stressors and explore ways to reduce them wherever possible.

Providing Referrals

When contact with the battered woman is a short-term one, many interventions are outside the scope of nursing practice. Refer the family to community agencies such as the police department, legal services, community shelters, counseling services, and social service agencies, as needed. Include mental health referrals, if necessary, for treatment of depression or for counseling. Document that referrals were made and whether the woman accepted them.

It is essential to accept the decisions of the battered woman and acknowledge that she is on her own timetable. She may not take any actions at the time they are recommended. Therefore, listening to her, believing her, and providing information about resources may be the only help the nurse can provide until the woman is ready to do more.

Do not become negative or pass judgment on the partner of an abused woman. She is often tied to the man by both economic and emotional bonds and may become defensive if her partner is criticized. Tell her that resources are available for her partner but he must first admit abuse and seek assistance before help can be offered. *Initiating referrals for the partner before he asks for help will increase the danger to the woman if he believes he has been betrayed.*

Evaluation

The plan of care can be deemed successful if the woman acknowledges the violent episodes in the home, makes concrete plans to protect herself and her children from future injury, and makes plans to use the community resources available to her.

26. What major cues indicate that a woman has been physically abused?
27. How can nurses intervene to help women protect their safety if they choose to remain in a home situation with a partner who physically abuses them?

SUMMARY CONCEPTS

- Teenage pregnancy is a major health problem in the United States. Adolescents need to receive accurate information about contraceptives and how to set limits on sexual behavior.
- Adolescent pregnancy imposes serious physiologic risks that result in a higher incidence of complications for the mother and the fetus.
- Teenage pregnancy interrupts the developmental tasks of adolescence and may result in childbirth before the parents are capable of providing a nurturing home for the infant without a great deal of assistance.
- The mature primigravida often has financial and emotional resources that younger women do not have. She may experience anxiety, however, about recommended antepartum testing and her ability to parent effectively.
- Polydrug abuse is a widespread problem that can have devastating fetal and neonatal effects, which may persist and become long-term developmental problems for the child.
- The lifestyle associated with illicit drug abuse includes inadequate nutrition, inadequate prenatal care, and increased incidence of STDs. It requires interdisciplinary interventions to prevent injury to the expectant mother and the fetus.
- The birth of an infant with congenital anomalies produces strong emotions of shock and grief in the family. It calls for a sensitive response from the health care team to help the family grieve for the loss of the perfect or “fantasy” infant and form an attachment to the newborn.
- Pregnancy loss at any stage produces grief that must be acknowledged and expressed before it can be resolved. Nurses realize that mourning requires memories, and they intervene to arrange unlimited contact between the family and the stillborn infant and gather a memento packet for the family.
- Nursing care for the mother who is placing her infant for adoption is based on the knowledge that adoption is an act of love, not abandonment.
- Multiple factors are associated with IPV, which is deliberate, severe, and generally repeated in a predictable cycle that often causes severe physical harm (or death) to the woman.
- All perinatal nurses come into contact with abused women who require assistance to protect themselves and their children from serious injury.

Complications of Pregnancy

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the hemorrhagic conditions of early pregnancy, including spontaneous abortion, ectopic pregnancy, and gestational trophoblastic disease.
2. Explain disorders of the placenta such as placenta previa and abruptio placentae, which may result in hemorrhage during late pregnancy.
3. Discuss the effects and management of hyperemesis gravidarum.
4. Describe the development and management of hypertensive disorders of pregnancy.
5. Compare Rh and ABO incompatibility in terms of etiology, fetal and neonatal complications, and management.
6. Explain nursing considerations for each complication of pregnancy.

Although childbearing is a normal process, numerous maternal and fetal adaptations must occur in an orderly sequence. If problems develop in these physiologic processes, complications may arise threatening the well-being of the woman, the fetus, or both. A nurse-midwife or family physician may manage some mild conditions, or the woman may be referred to an obstetrician or a **perinatologist** (medical specialist in high-risk pregnancy care from about 20 weeks of gestation through 4 weeks postpartum) for management of severe complications.

Nurses who work at a primary care site or perinatal center frequently fill the role of case manager or coordinator of services provided for the woman. The nurse is often the only consistent provider involved in the woman's care and therefore is the person on whom the woman relies to guide her through the system.

Conditions that complicate pregnancy are divided into two broad categories: (1) those that are related to pregnancy and are not seen at other times and (2) those that could occur at any time but when they occur concurrently with pregnancy may complicate its course. Concurrent conditions that affect pregnancy are covered in [Chapter 26](#).

The most common pregnancy-related complications are hemorrhagic conditions that occur in early pregnancy, hemorrhagic complications of the placenta in late pregnancy, hyperemesis

gravidarum (HEG), hypertensive disorders of pregnancy, and blood incompatibilities.

HEMORRHAGIC CONDITIONS OF EARLY PREGNANCY

The three most common causes of hemorrhage during the first half of pregnancy are abortion, ectopic pregnancy, and gestational trophoblastic disease.

Abortion

Abortion is the loss of pregnancy before the fetus is viable, or capable of living outside the uterus. The medical consensus today is that a fetus of less than 20 weeks of gestation or one weighing less than 500 g is not viable. Ending of pregnancy before this time is considered an abortion. Abortion may be either spontaneous or induced. *Abortion* is an accepted medical term for either a spontaneous ending or an induced ending of pregnancy, although the lay term *miscarriage* is becoming an accepted medical term to denote spontaneous abortion. Elective termination of pregnancy, or induced abortion, is described in [Chapter 34](#).

FIG 25-1 Three types of spontaneous abortion, also called *miscarriage*.

Spontaneous Abortion

Spontaneous abortion is a termination of pregnancy without action taken by the woman or another person.

Incidence and Etiology. Determining the exact incidence of spontaneous abortion is difficult because many unrecognized losses occur in early pregnancy, but it averages about 15% to 20% with any pregnancy. Pregnancies lost during the first trimester are estimated to be 50% to 70%, and many of these may occur before implantation or during the first month after the last menstrual period. The incidence of spontaneous abortion increases with parental age. The incidence is 12% for women younger than 20 years, rising to 26% for women older than 40 years. At a maternal age of 45 years, abortion risk is greater than 50%, about double the risk at 40 years. Paternal age younger than 20 years is associated with a spontaneous abortion rate of 12%, rising to 20% for fathers older than 40 years. Most spontaneous abortions occur in the first 12 weeks of pregnancy, with the rate declining rapidly thereafter (Cunningham, Leveno, Bloom et al., 2010; Porter, Branch, & Scott, 2008; Simpson & Jauniaux, 2012).

The most common cause of spontaneous abortion is severe congenital abnormalities that are often incompatible with life. Chromosomal abnormalities account for about 50% to 60% of spontaneous abortions within the first 12 weeks. Additional causes include maternal infections such as syphilis, listeriosis, toxoplasmosis, brucellosis, rubella, and cytomegalic inclusion disease. Intraabdominal infections also increase the risk. Maternal endocrine disorders such as hypothyroidism and abnormalities of the reproductive organs have also been implicated. Some women who have repeated early pregnancy losses appear to have immunologic factors that play a role in their higher-than-expected spontaneous abortion incidence. Anatomic defects of the uterus or cervix may contribute to pregnancy loss at any gestational age (Cunningham et al., 2010; Porter, Branch & Scott, 2008; Simpson & Jauniaux, 2012).

Spontaneous abortion is divided into six subgroups: threatened, inevitable, incomplete, complete, missed, and recurrent. Figure 25-1 illustrates threatened, inevitable, and incomplete abortion.

Threatened Abortion

Clinical Manifestations. The first sign of threatened abortion is vaginal bleeding, which is rather common during early pregnancy. About 25% of pregnant women experience “spotting” or bleeding in early pregnancy, and up to 50% of these pregnancies end in spontaneous abortion. Vaginal bleeding, which may be brief or last for weeks, may be accompanied by uterine cramping, persistent backache, or feelings of pelvic pressure. These added symptoms are more likely to be associated with loss of pregnancy.

Therapeutic Management. Bleeding during the first half of pregnancy should be considered a threatened abortion, and women must be advised to notify their physician or nurse-midwife if brownish or red vaginal bleeding is noted. When a woman reports bleeding in early pregnancy, the nurse obtains a detailed history that includes length of gestation (or first day of her last menstrual period) and the onset, duration, and amount of vaginal bleeding. Any accompanying discomfort such as cramping, backache, or abdominal pain also is noted. Ultrasound examination helps verify if the embryo or fetus is present and alive and the approximate gestational age. Determining if the woman’s beta-human chorionic gonadotropin (beta-hCG) levels are normal for the estimated gestational age provides added information about whether the pregnancy is likely to continue.

Vaginal ultrasound examination is performed to determine whether a fetus is present and, if so, whether it is alive. Maternal serum beta-hCG and progesterone levels provide added information about the viability of the pregnancy (that is, whether the levels are appropriate for gestation period and increase with fetal growth).

There is no evidence to support physical activity restrictions to stop spontaneous abortion. The woman may be advised to limit sexual activity until bleeding has ceased. The woman is instructed to count the number of perineal pads used and to note the quantity and color of blood on the pads. She should also look for evidence of tissue passage, which would indicate progression beyond a threatened abortion. Drainage with a foul odor suggests infection.

Bleeding episodes are frightening, so psychological support is important. The woman often wonders whether her actions may have contributed to the situation and is anxious about her own condition and that of the fetus. The nurse should offer accurate information and avoid false reassurance because the woman may lose her pregnancy despite every precaution. Later problems such as prematurity, a small-for-gestational-age infant, abnormal presentation, or perinatal asphyxia may occur in pregnancies that do not end with a spontaneous abortion after early bleeding (Cunningham et al., 2010; Porter, Branch, & Scott, et al., 2008; Simpson & Jauniaux, 2012).

Inevitable Abortion

Clinical Manifestations. Abortion is usually inevitable (that is, it cannot be stopped) when membranes rupture and the cervix dilates. Rupture of membranes generally is experienced as a loss of fluid from the vagina and subsequent uterine contractions and active bleeding. Incomplete evacuation of the products of conception can result in excessive bleeding or infection can occur.

Therapeutic Management. Natural expulsion of uterine contents is common in inevitable abortion. **Vacuum curettage** (removal of uterine contents with a vacuum curet) is used to clear the uterus if the natural process is ineffective or incomplete. If the pregnancy is more advanced or if bleeding is excessive, a **dilation and curettage (D&C)** (stretching the cervical os to permit suctioning or scraping the uterine walls) may be needed. Intravenous (IV) sedation or other anesthesia provides pain management for the procedure.

Incomplete Abortion

Clinical Manifestations. Incomplete abortion occurs when some but not all of the products of conception are expelled from the uterus. The major manifestations are active uterine bleeding and severe abdominal cramping. The cervix is open, and fetal and placental tissues are passed. The products of conception may have been expelled from the uterus but remain in the vagina because of their small size, often no larger than a Ping-Pong ball, in the very early gestation period. Therefore, the initial diagnosis of inevitable abortion would change to complete abortion.

Therapeutic Management. Retained tissue prevents the uterus from contracting firmly, thereby allowing profuse bleeding from uterine blood vessels. Initial treatment should focus on stabilizing the woman's cardiovascular state. A blood specimen is drawn for blood type and screen or crossmatch, and an IV line is inserted for fluid replacement and drug administration. When the woman's condition is stable, a D&C usually is performed to remove the remaining tissue. A later pregnancy and a larger amount of fetal tissue may require a greater cervical **dilation and evacuation (D&E)** with removal of fetal tissue, followed by vacuum or surgical curettage. This procedure may be followed by IV administration of oxytocin (Pitocin) or intramuscular (IM) administration of methylergonovine (Methergine) to contract the uterus and control bleeding.

A D&C may not be performed if the pregnancy has advanced beyond 14 weeks because of the danger of excessive bleeding. In this case, oxytocin or prostaglandin is administered to stimulate uterine contractions until all products of conception (fetus, membranes, placenta, and amniotic fluid) are expelled.

Complete Abortion

Clinical Manifestations. Complete abortion occurs when all products of conception are expelled from the uterus. After passage of all products of conception, uterine contractions and bleeding subside, and the cervix closes. The uterus feels smaller than the length of gestation would suggest. The symptoms of pregnancy are no longer present, and the pregnancy test becomes negative as hormone levels fall.

Therapeutic Management. Once complete abortion is confirmed, no additional intervention is required unless excessive bleeding

or infection develops. The woman should be advised to rest and to watch for further bleeding, pain, or fever. She should not have sexual intercourse until after a follow-up visit with her health care provider. Contraception is discussed at the follow-up visit if she wishes to prevent pregnancy.

Missed Abortion

Clinical Manifestations. Missed abortion occurs when the fetus dies during the first half of pregnancy but is retained in the uterus. When the fetus dies, the early symptoms of pregnancy (nausea, breast tenderness, urinary frequency) disappear. The uterus stops growing and decreases in size, reflecting the absorption of amniotic fluid and **maceration** (discoloration, softening, and eventual tissue degeneration) of the fetus. Vaginal bleeding of a red or brownish color may or may not occur.

Therapeutic Management. An ultrasound examination confirms fetal death by identifying a gestational sac or fetus that is too small for the presumed gestational age. No fetal heart activity can be found. Pregnancy tests for hCG should show a decline in placental hormone production.

In most cases, the contents of the uterus would be expelled spontaneously, but this is emotionally difficult once the woman knows that her fetus is not alive. Therefore, her uterus usually is emptied by the most appropriate method for the size when the diagnosis of missed abortion is made. For a first-trimester missed abortion, a D&C usually can be done. If the missed abortion occurs during the second trimester, when the fetus is larger, a D&E may be done, or vaginal prostaglandin E₂ (PGE₂) or misoprostol (Cytotec) may be needed to induce uterine contractions that expel the fetus. A D&C may be needed to remove the placenta.

Two major complications of missed abortion are infection and disseminated intravascular coagulation (DIC). Signs such as elevation in temperature, vaginal discharge with a foul odor, and abdominal pain indicate uterine infection, and evacuation of the uterus is delayed until cultures are obtained and antimicrobial therapy is initiated.

Recurrent Spontaneous Abortion

Clinical Manifestations. *Recurrent spontaneous abortion* usually is defined as three or more spontaneous abortions, although some authorities now use two or more pregnancy losses as the definition. The primary causes of recurrent abortion are believed to be genetic or chromosomal abnormalities and anomalies of the reproductive tract, such as **bicornuate** uterus (uterus with two horns) or incompetent cervix. Additional causes include an inadequate luteal phase with insufficient secretion of progesterone and immunologic factors that involve increased sharing of human leukocyte antigens by the sperm of the man and the ovum of the woman who conceived. The theory is that because of this sharing, the woman's immunologic system is not stimulated to produce blocking antibodies that protect the embryo from maternal immune cells or other damaging antibodies. Systemic diseases such as systemic lupus erythematosus and diabetes mellitus have been implicated in recurrent abortions. Reproductive infections and some sexually transmitted diseases are also associated with recurrent abortions (Cunningham et al., 2010; Regan, Backos, & Farquharson, 2011).

Therapeutic Management. The first step in management of recurrent spontaneous abortion is examination of the reproductive system to determine whether anatomic defects are the cause. If the cervix and uterus are normal, the woman and her partner are usually referred for genetic screening to identify chromosomal factors that would increase the possibility of recurrent abortions.

Additional therapeutic management of recurrent pregnancy loss depends on the cause. For instance, treatment may involve assisting the woman to develop a regimen to maintain normal blood glucose level

if diabetes mellitus is a factor. Supplemental hormones may be given if her progesterone or other hormone levels are lower than normal. Antimicrobials are prescribed for the woman with infection, or hormone-related drugs may be prescribed if imbalance preventing normal fetal implantation and support is found.

Recurrent spontaneous abortion may be caused by cervical incompetence, an anatomic defect that results in painless dilation of the cervix in the second trimester. In this situation, a **cerclage** procedure—suturing of the cervix to prevent early dilation—may be performed. The cerclage is most likely to be successful if done before much cervical dilation or bulging of the membranes through the cervix has occurred. Sutures may be removed near term in preparation for vaginal delivery, or they may be left in place if a cesarean birth is planned. Prophylactic antibiotics are ordered if the woman is at increased risk for infection. Preterm labor may still occur, but, it is hoped, after the fetus is viable.

Rh immune globulin (RhoGAM) is given to the unsensitized Rho(D)-negative woman to prevent development of anti-Rh antibodies (see p. 532). A microdose (50 mcg) is given to the woman whose fetus is less than 13 weeks of gestational age at the time of the abortion.

Nursing Considerations. Nurses must consider the psychological needs of the woman experiencing spontaneous abortion. Vaginal bleeding is frightening, and waiting and watching are often difficult (although possibly the only treatment recommended). Many women and their families feel an acute sense of loss and grief with spontaneous abortion. Grief often includes feelings of guilt and speculation about whether the woman could have done something to prevent the loss. Nurses may help by emphasizing that abortions usually occur as the result of factors or abnormalities that cannot be avoided.

Anger, disappointment, and sadness are commonly experienced emotions, although the intensity of these feelings may vary. For many people, the fetus has not yet taken on specific physical characteristics, but they grieve for their fantasies of the unseen, unborn child. Recognizing the meaning of the loss to each woman and her significant others is important. Nurses must listen carefully to what the woman says and observe how she behaves. The woman or the couple may want to express their sadness but may feel that family, friends, and often health care personnel are uncomfortable or diminish their loss. Nurses must convey their acceptance of the feelings expressed or demonstrated by the couple. The couple should remain together as much as possible. Providing information and simple brief explanations of what has occurred and what will be done facilitates the family's ability to grieve. Nurses may identify if the clinical facility offers options to dispose of fetal tissue and work to identify improvements (Limbo, Kobler, & Levang, 2010).

The family should realize that grief may last from 6 months to 1 year or even longer. Family support, knowledge of the grief process, spiritual counselors, and support from other bereaved couples may provide needed assistance during this time. Coping with a new pregnancy after pregnancy loss is often more difficult for women. Hutti, Armstrong, and Myers (2011) found that women often attempted to cope with previous perinatal losses by requesting more frequent phone calls, visits, testing, and other interventions during a subsequent pregnancy. The authors propose that better use of health care resources might be compassion, extra education and information, and referrals to mental health care providers and support groups. Chapter 24 provides additional information about pregnancy loss and grief.

Disseminated Intravascular Coagulation

DIC, also called *consumptive coagulopathy*, is a life-threatening defect in coagulation that may occur with several complications of pregnancy such as abruptio placentae (p. 515) or hypertension (p. 519). DIC is

not limited to obstetric conditions. While anticoagulation is occurring, inappropriate coagulation also is occurring in the microcirculation. The second result of DIC is that tiny clots form in tiny blood vessels, blocking blood flow to organs and causing ischemia.

Some factor in one of these disease processes initiates clotting mechanisms inappropriately. The first result is consumption of plasma factors, including platelets, fibrinogen, prothrombin, factor V, and factor VIII. When these plasma factors are consumed, the circulating blood then becomes deficient in clotting factors and is unable to clot. Fibrin degradation products accumulate and further interfere with coagulation.

Diseases that cause DIC fall into three major groups:

1. Infusion of tissue thromboplastin into the circulation, which consumes, or “uses up,” other clotting factors such as fibrinogen and platelets: Abruptio placentae (premature separation) and prolonged retention of a dead fetus cause this because the placenta is a rich source of thromboplastin.
2. Conditions characterized by endothelial damage: Severe preeclampsia and HELLP (*hemolysis, elevated levels of liver enzymes, and low platelet levels*) syndrome (p. 529) are characterized by endothelial damage.
3. Nonspecific effects of some diseases: Diseases such as maternal sepsis or amniotic fluid embolism (see Chapter 27) are in this category.

DIC allows excess bleeding to occur from any vulnerable area such as IV sites, incisions, gums, or the nose and from expected sites such as the site of placental attachment during the postpartum period.

Laboratory studies help establish a diagnosis. Levels of fibrinogen and platelets usually are decreased, prothrombin time (PT) and activated partial thromboplastin time (aPTT) may be prolonged, and levels of fibrin degradation products, the most sensitive measurement, are increased. The D-dimer serum assay, which normally has negative results, confirms fibrin split products (FSP) and is presumptive for DIC when results are positive.

The priority in treatment of DIC is to correct the cause. In the case of a missed abortion, delivery of the fetus and the placenta ends the production of thromboplastin, which is fueling the process. Blood replacement products such as whole blood, packed red blood cells (RBCs), and cryoprecipitate, are administered, as needed, to maintain the circulating volume and to transport oxygen to body cells.

Nursing Considerations

When caring for a woman who has any of the disorders that increase her risk for DIC, the nurse should observe for bleeding from unexpected sites. Sites for IV insertion or lab work, nosebleeds, or spontaneous bruising may be early indicators of DIC and should be reported. Also, if her coagulation studies are severely abnormal, an epidural block may be contraindicated because of possible bleeding into the spinal canal, so other types of labor pain management should be anticipated.

Ectopic Pregnancy

Ectopic pregnancy is an implantation of a fertilized ovum in an area outside the uterine cavity. Although implantation can occur in the

abdomen or cervix, more than 98% of ectopic pregnancies occur in the fallopian tube (Seeber & Barnhart, 2008). Figure 25-2 shows the common sites of ectopic implantation.

Ectopic pregnancy has been called “a disaster of reproduction” despite our greater ability to recognize its occurrence. Ectopic pregnancy remains a significant cause of maternal death from hemorrhage. Tubal damage caused by an ectopic pregnancy reduces the woman’s chances of subsequent pregnancies.

Incidence and Etiology

Ectopic pregnancies have increased in the United States since 1970 from a rate of 4.5 per 1000 pregnancies to 19.7 per 1000 pregnancies. The increase in incidence is attributed to the growing number of women of childbearing age who experience scarring of the fallopian tubes because of pelvic infection, inflammation, or surgery. Additionally, sensitive tests that identify pregnancy earlier and transvaginal ultrasound allow diagnosis of some pregnancies within the fallopian tube that previously might have resolved spontaneously before diagnosis (Seeber & Barnhart, 2008).

Pelvic infection often is caused by *Chlamydia* or *Neisseria gonorrhoeae*. A failed tubal ligation, even if performed many years ago, and a history of previous ectopic pregnancy also increase the risk for an ectopic pregnancy in the fallopian tube. Greater incidences of ectopic pregnancies occur in women who conceived with assisted reproduction, most likely related to the tubal factors that contributed to infertility. Contraception such as intrauterine contraceptive devices or low-dose progesterone agents is associated with increased risk of ectopic pregnancy. However, 40% or more ectopic pregnancies occur in women with no identified risk factors (American College of Obstetricians & Gynecologists [ACOG], 2012c; Cahill, Swingler, & Wardle, 2011; Cunningham et al., 2010; Seeber & Barnhart, 2008).

Additional causes of ectopic pregnancy are delayed or premature ovulation, with the tendency of the fertilized ovum to implant before arrival in the uterus, and altered tubal motility in response to changes in estrogen and progesterone levels that occur with conception. Multiple induced abortions increase the risk for tubal pregnancy, possibly because of salpingitis (infection of the fallopian tube) that occurred after induced abortion (Box 25-1). Regardless of the cause of tubal pregnancy, the effect is that transport of the fertilized ovum through the fallopian tube is hampered.

Clinical Manifestations

The classic signs of ectopic pregnancy include the following:

- Missed menstrual period
- Positive pregnancy test
- Abdominal pain
- Vaginal “spotting”

More subtle signs and symptoms depend on the site of implantation. If implantation occurs in the distal end of the fallopian tube, which can contain the growing embryo longer, the woman may at first exhibit the usual early signs of pregnancy and consider herself to be normally pregnant. Several weeks into the pregnancy, intermittent abdominal pain and small amounts of vaginal bleeding occur, and initially this could be mistaken for threatened abortion. Because routine ultrasound examination in early pregnancy is common, however, it is not unusual to diagnose an ectopic pregnancy before onset of symptoms.

If implantation has occurred in the proximal end of the fallopian tube, rupture of the tube may occur within 2 to 3 weeks of the missed period because the tube is narrow in this area. Symptoms include sudden, severe pain in one of the lower quadrants of the abdomen as the tube tears open and the embryo is expelled into the pelvic cavity, often with profuse abdominal hemorrhage. Radiating pain under the scapula may indicate bleeding into the abdomen caused by phrenic nerve irritation. **Hypovolemic shock** (acute peripheral circulatory failure from loss of circulating blood) is a major concern because

BOX 25-1 RISK FACTORS FOR ECTOPIC PREGNANCY

- History of previous ectopic pregnancies
- Peak age-specific incidence 25-34 years
- History of sexually transmitted diseases (gonorrhea, chlamydia)
- Multiple sexual partners
- Tubal sterilization and tubal reconstruction
- Infertility
- Assisted reproductive techniques such as gamete intrafallopian transfer (GIFT)
- Intrauterine device (IUD)
- Multiple induced abortions

FIG 25-2 Sites of tubal ectopic pregnancy. Numbers indicate the order of prevalence.

systemic signs of shock may be rapid and extensive without external bleeding.

Diagnosis

The combined use of transvaginal ultrasound examination (see [Chapter 10](#)) and determination of beta-hCG usually results in early detection of ectopic pregnancy. An abnormal pregnancy is suspected if beta-hCG is present but at lower levels than expected. If a gestational sac cannot be visualized when beta-hCG is present, a diagnosis of ectopic pregnancy may be made with great accuracy. Visualization of an intrauterine pregnancy, however, does not absolutely rule out an ectopic pregnancy. A woman may have an intrauterine pregnancy and concurrently have an ectopic pregnancy.

The use of sensitive pregnancy tests, maternal serum progesterone levels, and high-resolution transvaginal ultrasound has largely eliminated invasive tests for ectopic pregnancy. **Laparoscopy** (examination of the peritoneal cavity by means of a laparoscope) occasionally may be necessary to diagnose rupture of an ectopic pregnancy. A characteristic bluish swelling within the tube is the most common finding.

Therapeutic Management

Management of tubal pregnancy depends on whether the tube is intact or ruptured. Medical management may be possible if the tube is unruptured. The goal of medical management is to preserve the tube and improve the chance of future fertility. The chemotherapeutic agent methotrexate (a folic acid antagonist) is used to inhibit cell division in the developing embryo.

Surgical management of a tubal pregnancy that is unruptured may involve a **linear salpingostomy** to salvage the tube ([Figure 25-3](#)). Linear salpingostomy also may be attempted if the tube is ruptured

but damage to the tube is minimal. Salvaging the tube is particularly important to women concerned about future fertility, although the same cause may affect both tubes.

When ectopic pregnancy results in rupture of the fallopian tube, the goal of therapeutic management is to control the bleeding and prevent hypovolemic shock. When the woman's cardiovascular status is stable, **salpingectomy** (removal of the tube) with ligation of bleeding vessels may be required. With early diagnosis and medical management, salpingectomy has become uncommon in the treatment of ectopic pregnancy.

Rh immune globulin is given to appropriate Rho(D)-negative women.

Nursing Considerations

Nursing care focuses on prevention or early identification of hypovolemic shock, pain control, and psychological support for the woman who experiences ectopic pregnancy. Nurses monitor the woman for signs and symptoms that suggest tubal rupture or bleeding (e.g., pelvic, shoulder, or neck pain; dizziness or faintness; increased vaginal bleeding). Nurses administer ordered analgesics and evaluate their effectiveness so that pain can be adequately controlled.

If methotrexate is used, the nurse must explain adverse side effects such as nausea and vomiting, and the importance of informing the health care team of any physical changes. Transient abdominal pain occurs during methotrexate therapy, probably because of expulsion of the products of conception from the tube ([Seeber & Barnhart, 2008](#)). The woman must also be instructed to refrain from drinking alcohol (which decreases the effectiveness of methotrexate), taking vitamins that contain folic acid, and having sexual intercourse until beta-hCG is not detectable. If the treatment is successful, this hormone

A linear incision is made in the intact tube.

Forceps are used to remove products of conception.

The tubal incision is left to heal without being sutured.

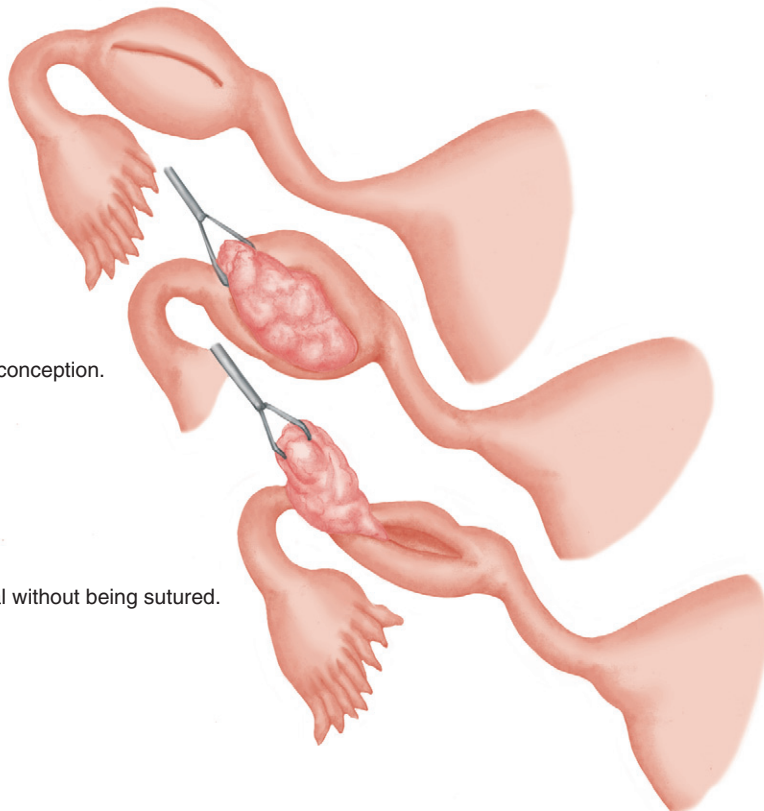

FIG 25-3 Linear salpingostomy.

disappears from plasma within 2 to 3 weeks. Maintaining follow-up appointments is essential to identify whether the hCG titer becomes negative and remains negative. Continued presence of hCG in the serum requires follow-up to identify whether the ectopic pregnancy is still present (Cahill, Swingler, & Wardle, 2011; Cunningham et al., 2010).

The woman and her family will need psychological support to deal with intense emotions that may include anger, grief, guilt, and self-blame. The woman also may be anxious about her ability to become pregnant in the future. Because ectopic pregnancy may occur when a woman has undergone an assisted reproductive procedure, she may be more anxious about when she might become pregnant again and if similar risks exist for another pregnancy. The nurses should clarify the physician's explanation and use therapeutic communication techniques that assist the woman to deal with her anxiety.

Gestational Trophoblastic Disease (Hydatidiform Mole)

Hydatidiform mole is one form of **gestational trophoblastic disease**, which occurs when trophoblasts (peripheral cells that attach the fertilized ovum to the uterine wall) develop abnormally. As a result of the abnormal growth, abnormality of placenta develops, and, if present, a fetus has a fatal chromosome defect. Gestational trophoblastic disease is characterized by proliferation and edema of the chorionic villi. The fluid-filled villi form grapelike clusters of tissue that can rapidly grow large enough to fill the uterus to the size of an advanced pregnancy (Figure 25-4). The mole may be complete, with no fetus present, or partial, in which fetal tissue or membranes are present.

Incidence and Etiology

In the United States and Europe, the incidence of hydatidiform mole is 1 in every 1000 to 1500 pregnancies. Age is a factor, with the frequency of molar pregnancies highest at both ends of reproductive life. The incidence is higher among Asian women. Women who have had one molar pregnancy have a greater risk to have another in a subsequent pregnancy (Cahill, Swingler, & Wardle, 2011; Cunningham et al., 2010; Salani, Eisenhauer, & Copeland, 2012). Persistent gestational trophoblastic disease may undergo malignant change

FIG 25-4 Gestational trophoblastic disease, also called *hydatidiform mole*.

(choriocarcinoma) and may metastasize to sites such as the lung, vagina, liver, and brain.

Complete mole is thought to occur when the ovum is fertilized by a sperm that duplicates its own chromosomes while the maternal chromosomes in the ovum are inactivated. In a partial mole, the maternal contribution is usually present, but the paternal contribution is doubled, and therefore the karyotype is triploid (69,XXY or 69,XYY). If a fetus is identified with the partial mole, it is grossly abnormal because of the abnormal chromosomal composition.

Clinical Manifestations

Routine use of ultrasound allows earlier diagnosis of hydatidiform mole, usually before the more severe manifestations of the disorder develop. Possible signs and symptoms of molar pregnancy include the following:

- Higher levels of beta-hCG than expected for gestation
- Characteristic “snowstorm” ultrasound pattern that shows the vesicles and the absence of a fetal sac or fetal heart activity in a complete molar pregnancy
- A uterus that is larger than expected for gestational age
- Vaginal bleeding, which varies from dark-brown spotting to profuse hemorrhage
- Excessive nausea and vomiting (HEG), which may be related to high levels of beta-hCG from the proliferating trophoblasts
- Early development of preeclampsia, which is rarely diagnosed before 24 weeks in an otherwise normal pregnancy

Diagnosis

Measurement of the beta-hCG levels detects the abnormally high levels of the hormone before treatment. Following treatment, beta-hCG levels are measured to determine if they fall and then disappear.

In addition to the characteristic pattern showing the vesicles, ultrasound examination allows a differential diagnosis to be made between two types of molar pregnancies: (1) a partial mole that includes some fetal tissue and membranes and (2) a complete mole that is composed only of enlarged villi but contains no fetal tissue or membranes.

Therapeutic Management

Medical management includes two phases: (1) evacuation of the trophoblastic tissue of the mole and (2) continuous follow-up of the woman to detect malignant changes of any remaining trophoblastic tissue. At the same time, the woman is treated for any other problems such as preeclampsia or HEG.

Before evacuation, chest radiography, computed tomography (CT), or magnetic resonance imaging (MRI) may be performed to detect metastatic disease. A complete blood count, laboratory assessment of coagulation status, and blood type screening or crossmatching are also necessary in case a transfusion is needed. Blood chemistries are done to evaluate renal, hepatic, and thyroid functions.

The mole usually is removed by vacuum aspiration followed by curettage. After tissue removal, IV oxytocin is given to contract the uterus. Avoiding uterine stimulation with oxytocin before evacuation is important. Uterine contractions can cause trophoblastic tissue to be pulled into the large venous sinusoids in the uterus, resulting in embolization of the tissue and respiratory distress (Cahill, Swingler, & Wardle, 2011; Salani, Eisenhauer, & Copeland, 2012). The tissue obtained is sent for laboratory evaluation. Although a hydatidiform mole is usually a benign process, choriocarcinoma may occur.

Follow-up is critical to detect changes suggestive of trophoblastic malignancy. Beta-hCG is repeated at 6 weeks postpartum. Follow-up protocol involves evaluation of serum beta-hCG levels monthly for 6 months, then every 2 to 3 months for 6 months until normal for three

values. A persistent or rising beta-hCG level suggests continued gestational trophoblastic disease. Pregnancy must be avoided during the follow-up because the normal rise of beta-hCG level in pregnancy would obscure evidence of choriocarcinoma. Oral contraceptives are the preferred birth control method (Cahill, Swingler, & Wardle, 2011; Salani, Eisenhauer, & Copeland, 2012).

Nursing Considerations

Bleeding is a possible complication with a molar pregnancy, but emotional care of the woman is also essential. Women who have had a hydatidiform mole experience emotions similar to those of women who have experienced any other type of pregnancy loss. In addition, they may be anxious about follow-up evaluations, the possibility of malignant change, and the need to delay pregnancy for at least 1 year (DiGiuglio, Weidaseck, & Monchek, 2012).

APPLICATION OF THE NURSING PROCESS

■ Hemorrhagic Conditions of Early Pregnancy

Regardless of the cause of early antepartum bleeding, nurses play a vital role in its management. Nurses are responsible for monitoring the condition of the pregnant woman and for collaborating with the physician to provide treatment.

Assessment

Confirmation of pregnancy and length of gestation are important initial data to obtain. Physical assessment focuses on determining the amount of bleeding and the description, location, and severity of pain. Estimate the amount of vaginal bleeding by examining the linen and peripads. If necessary, make a more accurate estimation by weighing the linen and peripads (1 g weight equals 1 mL volume).

When asking a woman how much blood she lost at home, ask her to compare the amount lost with a common liquid measure such as a tablespoon or a cup. Ask also how long the bleeding episode lasted and what was done to control the bleeding.

CRITICAL THINKING EXERCISE 25-1

All women who have experienced prenatal bleeding and invasive procedures are at increased risk for infection.

Question

1. What common assumptions do nurses make about those who are at risk for developing infections?

Bleeding may be accompanied by pain. Uterine cramping usually accompanies spontaneous abortion; deep, severe pelvic pain is associated with ruptured ectopic pregnancy. Remember that in ruptured ectopic pregnancy, bleeding may be concealed and pain could be the only symptom.

The woman’s vital signs and urine output give a clue to her cardiovascular status. A rising pulse rate and respiratory rate and falling urine

output are associated with hypovolemia. The blood pressure usually falls late in hypovolemic shock. Check laboratory values for hemoglobin and hematocrit and report abnormal values to the health care provider. Check laboratory values for coagulation factors to identify added risks for hemorrhage. Identify women who are Rh-negative so that they receive RhoGAM.

Because vaginal bleeding and necessary medical interventions may be associated with infections, assess the woman for fever, elevated pulse rate, malaise, and prolonged or malodorous vaginal discharge. Determine the family’s knowledge of needed follow-up care and how to prevent complications such as infection.

Nursing Diagnosis

A variety of collaborative problems or nursing diagnoses should be considered in the woman who has a bleeding disorder of early pregnancy. Collaborative problems such as bleeding and potential for infection are present. Current diagnostic techniques often permit early diagnosis before hemorrhage occurs. A nursing diagnosis that would apply to these early pregnancy disorders is “Deficient Knowledge about diagnostic and therapeutic procedures, signs and symptoms of additional complications, dietary measures to prevent infection or reduction in therapeutic drug levels, and importance of follow-up care.”

Planning

Goals and expected outcomes for this nursing diagnosis are that the woman will:

- Verbalize understanding of diagnostic and therapeutic procedures.
- Verbalize measures to prevent infection.
- Verbalize signs of infection to report to the health care provider.
- Maintain follow-up care.

Interventions

Provide Information about Tests and Procedures

Women and their families experience less anxiety if they understand what is happening. Explain planned diagnostic procedures such as transvaginal or transabdominal ultrasonography (see Chapter 10). Include the purpose of the tests, how long they will take, and whether the procedures cause discomfort. Briefly describe the reasons for blood tests such as evaluation of hCG, hemoglobin, hematocrit, or coagulation factors. Explain that diagnostic and therapeutic measures sometimes must be performed quickly to prevent excessive blood loss. If surgical intervention is necessary, reinforce the explanations from the anesthesia professional about planned anesthesia. Obtain needed consents before procedures.

Teach Measures to Prevent Infection

The risk for infection is greatest during the first 72 hours after spontaneous abortion or operative procedures. Personal hygiene should include daily showers and careful handwashing before and after changing perineal pads. Perineal pads, applied in a front-to-back direction, should be used instead of tampons until bleeding has subsided. The woman should consult with the health care provider about safe timing for resuming intercourse.

Provide Dietary Information

Nutrition and adequate fluid intake help maintain the body’s defense against infection, and the nurse must promote an adequate and culturally sensitive diet. The woman who has a hemorrhagic complication is also at risk for infection. She needs foods that are high in iron to increase hemoglobin and hematocrit values. These foods include liver, red meat, spinach, egg yolks, carrots, and raisins (Erick, 2012). Foods high in vitamin C include citrus fruits, broccoli, strawberries,

cantaloupe, cabbage, and green peppers. Adequate fluid intake (2500 mL per day) promotes hydration after bleeding episodes and maintains digestive processes.

Iron supplementation is often prescribed, and the woman may require information on how to lessen the gastrointestinal upset that many people experience when iron is administered. Less gastric upset is experienced when iron is taken with meals. Iron supplements having a slow release may also be better tolerated. A diet high in fiber and fluid helps reduce the commonly associated constipation.

Teach Signs of Infection to Report

Ensure that the woman has a thermometer at home and knows how to use it. Tell her to take her temperature every 8 hours for the first 3 days at home. Teach the woman to seek medical help if her temperature rises above 100.4°F (38°C) or as her physician instructs. She also should report other signs of infection, even if she does not have a fever, such as vaginal discharge with foul odor, pelvic tenderness, or persistent general malaise.

Reinforce Follow-Up Care

A variety of follow-up procedures such as repeat ultrasonic examinations or evaluation of serum beta-hCG levels may be necessary for women with gestational trophoblastic disease such as hydatidiform mole. Immunologic or genetic testing and counseling may be advised for couples having recurrent abortions. All couples who have had a pregnancy loss should be seen by health care professionals and counseled.

CRITICAL THINKING EXERCISE 25-2

Alice, a 24-year-old primigravida, had an incomplete abortion at 12 weeks of gestation. When she was admitted to the hospital, intravenous fluids were administered and blood was taken for blood typing and screening. A vacuum extraction with curettage was performed to remove retained placental tissue. She was discharged home after the bleeding subsided. The nurse providing discharge instructions comments to the woman, "These things happen for the best, and you are so lucky it happened early." "You can have other children."

Questions

1. What assumptions has the nurse made? How might these comments affect the woman who suffered the spontaneous abortion or miscarriage?
2. Is the comment that the woman can have other children comforting? Why, or why not?
3. If the nurse's response was not helpful, what responses from the nurse would be most helpful to Alice?

At this time, acknowledge their grief, which often manifests as anger. Many women have guilt feelings, which must be recognized. They often need repeated reassurance that the loss was not a result of anything they did or anything they neglected to do.

Women who do not desire pregnancy right away will need contraception. Reliable contraception for at least 1 year also will be essential for women who have had a molar pregnancy. Teach the woman how to use the prescribed contraceptive method correctly to enhance effectiveness (see Chapter 31).

Evaluation

Interventions are deemed successful, and the goals and expected outcomes are met if the woman:

- Verbalizes understanding of diagnostic and therapeutic procedures.

- Verbalizes measures to prevent infection.
- Verbalizes signs of infection that should be reported to a health care professional.
- Helps develop and participate in a plan of longer term follow-up care.

HEMORRHAGIC CONDITIONS OF LATE PREGNANCY

After 20 weeks of pregnancy, the two major causes of hemorrhage are the disorders of the placenta called *placenta previa* and *abruptio placentae*. Abruption placentae may be further complicated by DIC, which was discussed earlier.

Placenta Previa

Placenta previa is an implantation of the placenta in the lower uterus. As a result, the placenta is closer to the internal cervical os than to the presenting part (usually the head) of the fetus. The three classifications of placenta previa (total, partial, and marginal) depend on how much of the internal cervical os is covered by the placenta (Figure 25-5). High-resolution ultrasound allows more accurate measurement of the distance between the internal cervical os and the lower border of the placenta:

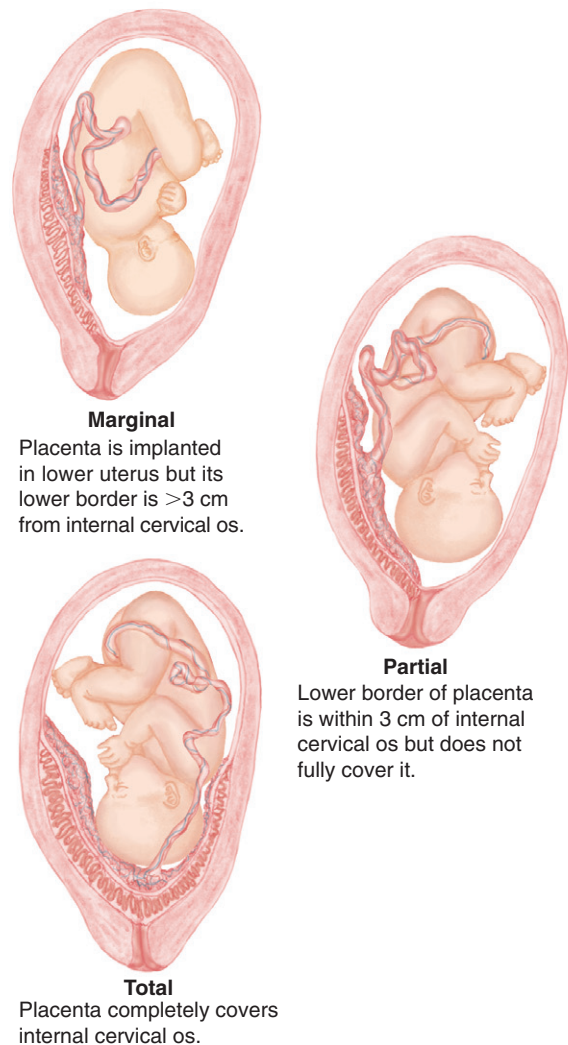

FIG 25-5 Examples of three classifications of placenta previa.

CASE STUDY 25-1 NURSING CARE PLAN*

ASSESSMENT: Beth, a 28-year-old gravida 2, para 1, is admitted to the antepartum unit at 32 weeks of gestation after an episode of vaginal bleeding resulting from total placenta previa. Vital signs are stable, and fetal heart rate is 140 to 150 beats per minute with no nonreassuring signs. Beth and her husband, Bob, appear anxious about the condition of the fetus and the plan of care. Beth is particularly worried about her 5-year-old son, who is at home with a neighbor.

NURSING DIAGNOSIS: Anxiety related to unknown effects of bleeding and lack of knowledge of predicted course of management

Critical Thinking: *Although this diagnosis is correct, what are priority nursing actions for Beth? Why?*

Answer: *To monitor the condition of the fetus and to observe Beth for vaginal bleeding or change in vital signs. These priorities are based on a hierarchy of needs. Physiologic needs and the need for safety must be ensured before psychological needs are fully addressed.*

EXPECTED OUTCOMES: Beth and Bob will:

1. Verbalize expected routines and projected management by the end of the first day after admission.
2. Express less anxiety after the course of management is explained.

INTERVENTIONS AND RATIONALES

1. Remain with the couple, and acknowledge the emotions that they exhibit: "I know this is unexpected, and you must have many questions. Perhaps I can answer some of them." *The nurse's presence and empathetic understanding are therapeutic tools to prepare the family to cope with the unexpected situation.*

2. Determine the couple's level of understanding of the situation and the projected management: "Tell me what you've been told to expect." *This allows the nurse to reinforce the physician's explanations and to identify whether additional explanations are needed.*
3. Provide Beth and Bob with factual information about projected management. *Patient education has proven to be an effective measure for preventing and reducing anxiety. Knowledge reduces fear of the unknown and reinforces medical explanations of care.*
 - a. Explain that Beth will need to remain in the hospital so that her condition and the condition of the fetus can be closely monitored.
 - b. Explain why a cesarean birth is necessary with this pregnancy, even though she delivered vaginally before.
 - c. Provide information about hospital routines (meals, visiting hours) and any fetal surveillance techniques (such as frequent ultrasound examinations and biophysical profiles).
4. Explain corticosteroid therapy ordered to speed fetal lung maturation. Knowing that corticosteroids can speed fetal lung maturity may reduce anxiety if a preterm delivery must occur.
5. Ask Beth and her family if they would like to talk with a nurse from the special care nursery. Continued bleeding or nonreassuring fetal factors are likely to result in a preterm delivery.
6. Allow Beth and her family to participate in the routine as much as possible. This may mean scheduling nursing care around times when Bob and their son can visit. Many women feel a sense of powerlessness when their activities are limited and a course of treatment is prescribed without consultation.

EVALUATION: After talking with the health care staff, Beth and Bob demonstrate understanding of her projected management and why it is necessary. They verbalized less anxiety about why hospital care is needed but still wish their son could visit more often.

*Continues on p. 514.

- Marginal (sometimes called low-lying): The placenta is implanted in the lower uterus, but its lower border is more than 3 cm from the internal cervical os.
- Partial: The lower border of the placenta is within 3 cm of the internal cervical os but does not completely cover the os.
- Total: The placenta completely covers internal cervical os.

Marginal placenta previa is common in early ultrasound examinations and often appears to move upward and away from the internal cervical os (*placental migration*) as the fetus grows, and the upper uterus develops more than the lower uterus. Only about 10% of placenta previas diagnosed in the second trimester remain a previa at term (Francois & Foley, 2012; Navti & Konje, 2011).

Incidence and Etiology

In the United States, the average incidence of placenta previa is 1 in 300 births, and evidence indicates that the rate of placenta previa is increasing. It is more common in older women, multiparas, women who have had cesarean births, and women who have had suction curettage for induced or spontaneous abortion. It is also more likely to recur if a woman has had a placenta previa. African or Asian ethnicity also increases the risk. Cigarette smoking and cocaine use are personal habits that add to a woman's risk for a previa. Previa is more likely if the fetus is male (Cunningham et al., 2010; Francois & Foley, 2012; Navti & Konje, 2011).

Clinical Manifestations

The classic sign of placenta previa is the sudden onset of painless uterine bleeding in the last half of pregnancy. Many cases of placenta

previa are diagnosed by ultrasound examination before any bleeding occurs. Bleeding results from tearing of the placental villi from the uterine wall as the lower uterine segment thins and the internal os begins dilation near term. Bleeding is painless because it does not occur in a closed cavity and does not cause pressure on adjacent tissue. It may be scanty or profuse, and it may cease spontaneously, only to recur later.

Bleeding may not occur until labor starts, when cervical changes disrupt placental attachment. The admitting nurse may be unsure whether the bleeding is just heavy "bloody show" or a sign of a placenta previa, particularly if the woman had no prenatal care.

Digital examination of the cervical os or stimulation of contractions when a placenta previa is present can cause additional placental separation or tear the placenta itself, causing severe hemorrhage and extreme risk to the fetus. *Until the location and position of the placenta are verified by ultrasonography, no manual vaginal examinations should be performed, and administration of oxytocin should be postponed to prevent strong contractions that could result in sudden placental separation and rapid hemorrhage.*

Therapeutic Management

When the diagnosis of placenta previa is confirmed, medical interventions are based on the condition of the expectant mother and the fetus. The woman is evaluated to determine the amount of hemorrhage, and electronic fetal monitoring is initiated to evaluate the fetus. Fetal gestational age is a third consideration.

Options for management include conservative management if the mother's cardiovascular status is stable and the fetus is immature and

CASE STUDY 25-1 NURSING CARE PLAN*

ASSESSMENT: Beth continues to have episodes of light vaginal bleeding, although none has been so heavy as to demand immediate delivery. Her doctor wants the fetus to mature at least 2 more weeks, if possible. Beth cries frequently, telling the nurse, "I miss my son so much. He just started kindergarten and he is so shy. I feel useless and he really needs me now. It's hard on Bob, too; he has to do everything."

NURSING DIAGNOSIS: Situational Low Self-Esteem related to temporary inability to provide care for family

EXPECTED OUTCOMES: Beth will:

1. Identify positive aspects of self during hospitalization.
2. Identify ways of providing comfort and affection to her son during her hospital stay

INTERVENTIONS AND RATIONALES

1. Encourage Beth to express her concerns about the need for hospitalization: "What bothers you most about being away from home?" *Major concerns may not be identified or may be misunderstood unless Beth clarifies them.*
2. After acknowledging feelings, encourage examination of the need for hospitalization and its desired consequences: It provides time for the fetus to mature. *This identifies positive aspects of the situation and her important role. It helps Beth understand that her role in fetal maturity extends beyond*

the corticosteroid therapy given to mature the fetal lungs if birth must occur before 34 weeks.

3. Explore reality of Beth's self-appraisal ("I feel useless") by assisting her to investigate ways to provide nurturing care for her son while she is hospitalized. *Daily involvement in the life of the child helps reduce feelings of isolation and failure to meet obligations to her family.* Examples of involvement might include the following:
 - a. Keeping in close touch by telephone (wake-up, goodnight, and after-school calls).
 - b. Making small handmade items such as bookmarks, games, needlework.
 - c. Explaining in simple, nonfrightening terms why she should stay in the hospital.
 - d. Offering reassurances of continued love
4. Assist Beth to involve her son in the plans for the newborn. He might benefit from sibling classes or playtime with the mother that involves caring for newborn-sized dolls. *Involving siblings provides goals for combined family interaction that increases feelings of self-worth. Young children often benefit from understanding that they can benefit their new sibling's life.*

EVALUATION: Beth is able to make positive comments about the importance of rest to the health of the new baby, and she initiates numerous activities that permit her to continue close, comforting contact with her son during the period of hospitalization.

*Continued from p. 513.

has a reassuring status by ultrasound examination and monitoring. Delaying birth may increase birth weight and maturity and administration of corticosteroids to the mother speeds maturation of the fetal lungs, if needed. Antepartum units are often designed to consider the woman's needs for physical and occupational therapy and for diversion as well as care for her pregnancy complication. Conservative management may take place in the home or the hospital.

Home Care. Making a medical decision on home care versus inpatient care is difficult. General criteria for home care include the following (Francois & Foley, 2012):

- No evidence of active bleeding is present.
- The woman is able to maintain bed rest at home.
- Home is located within a short distance from the hospital.
- Emergency systems are available for immediate transport to the hospital 24 hours a day.
- The woman can verbalize her understanding of the risks associated with placenta previa and how to manage her care.

Nursing Considerations

Home Care. Nurses are often responsible for helping the woman and family understand the physician's plan of care. Nurses help the woman and family develop a workable plan for home care that may include strict bed rest except for elimination and shower, the presence of another adult to manage the home and be present if an emergency arises, and a procedure to follow if heavy bleeding begins. Teaching also includes emphasizing the importance of (1) assessing color and amount of vaginal discharge or bleeding, especially after each urination or bowel movement, (2) assessing fetal activity (kick counts) daily (see Chapter 10), (3) assessing uterine activity at prescribed intervals, and (4) refraining from sexual intercourse to prevent disruption of the placenta. Home care nurses may be responsible for making daily phone contact to assess the woman's perception of uterine activity (cramping, regular or sporadic contractions), bleeding, fetal activity,

and adherence to the prescribed treatment plan. In addition, they may make home visits for comprehensive maternal-fetal assessments with portable equipment, such as nonstress tests. The woman and her family are instructed to report a decrease in fetal movement or an increase in uterine contractions or vaginal bleeding.

Nurses should provide specific, accurate information about the condition of the fetus. For example, parents are reassured when they hear that the fetal heart rate is within the expected range and daily kick counts are normal. Nurses also may need to help the family understand the physician's plan of care. For instance, the nurse may explain why a cesarean birth is necessary and why blood transfusion may be required.

Inpatient Care. Women with placenta previa are admitted to the antepartum unit if they do not meet the criteria for home care or if they require additional care to meet the goal of greater fetal maturity. When the expectant mother is confined to the hospital, nursing assessments focus on determining whether she experiences bleeding episodes or signs of preterm labor. Periodic electronic fetal monitoring is necessary to determine whether there are fetal heart activity changes in association with fetal compromise. A significant change in fetal heart activity, an episode of vaginal bleeding, or signs of preterm labor should be reported immediately to the physician.

At times, conservative management is not an option. For instance, delivery may be scheduled if the fetus is older than 36 weeks of gestation and the lungs are mature. Immediate delivery may be necessary regardless of fetal immaturity if bleeding is excessive, the woman demonstrates signs of hypovolemia, or signs of fetal compromise are present. If cesarean birth is necessary, nurses must prepare the expectant mother for surgery. See Box 16-2 for a summary of care for the woman having a cesarean birth.

The preoperative procedures are often performed quickly if the woman is hemorrhaging, and the family may be anxious about the condition of the fetus and the expectant mother. Nurses must use whatever time is available to keep the family informed.

During the rapid preparations for surgery, the nurse can reassure both the woman and the family by briefly describing the necessary preparations: “I’m sorry we have to rush, but we need to start the IV in case she needs extra fluids.” “Do you have questions I might answer as we prepare for the cesarean?”

Abruptio Placentae

Separation of a normally implanted placenta before the fetus is born (called *abruptio placentae*, *placental abruption*, or *premature separation of the placenta*) occurs in cases of bleeding and formation of a hematoma (clot) on the maternal side of the placenta. As the clot expands, further separation occurs. Hemorrhage may be apparent (vaginal bleeding) or concealed. The severity of the complication depends on the amount of bleeding and the size of the hematoma. If bleeding continues, the hematoma expands and obliterates intervillous spaces. Fetal vessels are disrupted as placental separation occurs, resulting in fetal and maternal bleeding.

Abruptio placentae is a dangerous condition for both the pregnant woman and the fetus. The major dangers for the woman are hemorrhage and consequent hypovolemic shock and clotting abnormalities (see discussion of DIC, p. 507). The major dangers for the fetus are asphyxia, excessive blood loss, and prematurity.

Incidence and Etiology

The incidence of abruptio placentae varies but is about 0.5% to 1% of pregnancies. Abruptio placentae accounts for 10% to 15% of perinatal deaths.

The cause is not always known, but several factors that increase the risk have been identified. Maternal use of cocaine, which causes **vasoconstriction** (narrowing of blood vessel lumen) in the endometrial arteries, is a leading cause of abruptio placentae. Other risk factors include maternal hypertension, maternal cigarette smoking, multi-gravida status, short umbilical cord, abdominal trauma, premature rupture of the membranes, and history of previous premature separation of the placenta. Maternal age is also associated with abruptio placentae, probably associated with a larger number of births for each mother (Cunningham et al., 2010; Francois & Foley, 2012; Navti & Konje, 2011).

Recently identified factors that are associated with abruptio placentae can be grouped under the classification “autoimmune antibodies that result in various coagulopathies.” This group includes anticardiolipin antibodies and lupus anticoagulant. Other coagulopathies may be caused by genetic factors such as a factor V Leiden mutation. Women who have these coagulopathies have a tendency to form clots in the placenta. Hypertension, a frequent companion of abruptio placentae, occurs more frequently in women with some autoimmune disorders as well (Cunningham et al., 2010; Francois & Foley, 2012; Navti & Konje, 2011).

Clinical Manifestations

Although verification of abruptio placentae may be quickly evident, it is not always a dramatic or acute event. Five classic signs and symptoms of abruptio placentae include the following:

- Bleeding, which may be evident vaginally or may be concealed behind the placenta
- Uterine tenderness that may be localized at the site of the abruption
- Uterine irritability with frequent low-intensity contractions and poor relaxation between contractions
- Abdominal or low back pain that may be described as aching or dull
- High uterine resting tone identified with use of an intrauterine pressure catheter

Additional signs include back pain, nonreassuring fetal heart rate patterns, signs of hypovolemic shock, or fetal death.

Cases of abruptio placentae are divided into two main types: (1) those in which hemorrhage is concealed and (2) those in which hemorrhage is apparent. In either type, the placental abruption may be complete or partial. In cases of concealed hemorrhage, the bleeding occurs behind the placenta but the margins remain intact, causing formation of a hematoma. The hemorrhage is apparent when bleeding separates or dissects the membranes from the endometrium and blood flows out through the vagina. Amniotic fluid often has a classic “port wine” color. Figure 25-6 illustrates abruptio placentae with external and concealed bleeding. Apparent bleeding does not always correspond to the actual amount of blood lost, and signs of shock (tachycardia, hypotension, pale color, and cold, clammy skin) may be present when little or no external bleeding occurs. Also, the woman may have an undiagnosed hypertensive disorder that masks hypovolemia until late hypotension occurs.

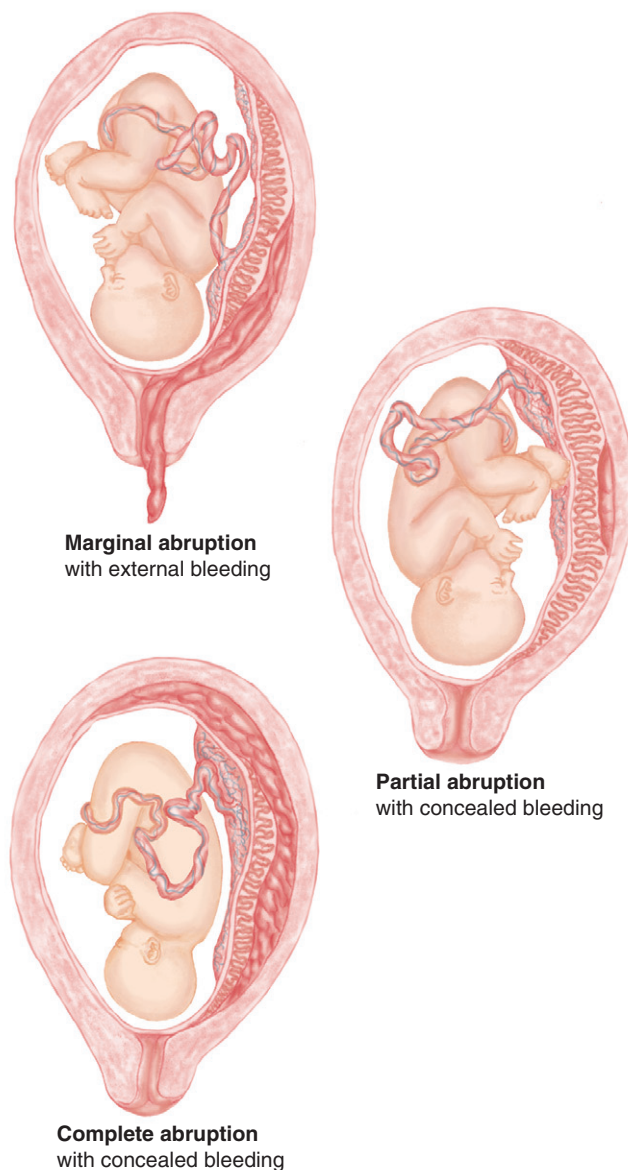

FIG 25-6 Types of abruptio placentae.

Abdominal pain is also related to the type of separation. It may be sudden and severe when bleeding occurs into the myometrium (uterine muscle) or be intermittent and difficult to distinguish from labor contractions. The uterus may become exceedingly firm (boardlike) and tender, making palpation of the fetus difficult. Ultrasound examination is helpful to rule out placenta previa as the cause of bleeding, but it cannot be used to diagnose abruptio placentae reliably because the separation and bleeding may not be obvious on ultrasonography.

Therapeutic Management

Any woman who exhibits signs of abruptio placentae should be hospitalized and evaluated at once. Evaluation focuses on the cardiovascular status of the expectant mother and the condition of the fetus.

If the condition is mild and the fetus is under 34 weeks and shows no signs of distress, conservative management may be initiated. This includes bed rest and possible administration of tocolytic medications to reduce uterine activity and steroids to accelerate fetal lung maturity. Conservative management is rare, however, because of the risks of fetal death and maternal hemorrhage associated with abruptio placentae and lack of research on the topic (Bobrowski, 2011; Cunningham et al., 2011; Francois & Foley, 2012; Navti & Konje, 2011).

Immediate delivery of the fetus is necessary if signs of fetal compromise exist or if the mother exhibits signs of excessive bleeding, either obvious or concealed. Intensive monitoring of both the woman and the fetus is essential because rapid deterioration of either can occur. Blood products for replacement should be available, and two large-bore IV lines should be started for replacement of fluid and blood.

Women who have experienced abdominal trauma are at increased risk for abruptio placentae. They may be observed for up to 24 hours after significant trauma such as a motor vehicle accident, even if they are not having any signs of bleeding, because it may take this long for an abruptio placentae to develop. Serial Kleihauer-Betke (K-B) tests determine if fetal bleeding is worsening. For the Rh-negative woman, RhoGAM is usually ordered to prevent possible maternal Rh sensitization.

Nursing Considerations

Abruptio placentae is frightening for a woman. She experiences severe pain and is aware of the danger to herself and to the fetus. She must be carefully assessed for signs of concealed hemorrhage.

If immediate cesarean delivery is necessary, the woman may feel powerless as the health care team hastily prepares her for surgery. If at all possible in the time available, nurses must explain the anticipated procedures to the woman and her family to reduce their fear and anxiety.

Excessive bleeding and fetal hypoxia are always major concerns with abruptio placentae, and nurses are responsible for continuous monitoring of both the mother and the fetus so that problems can be detected early before the condition of the woman or the fetus deteriorates.

SAFETY ALERT

Signs of concealed hemorrhage in abruptio placentae include the following:

- Increase in fundal height
- Hard, boardlike abdomen
- High uterine baseline tone on electronic monitoring strip, especially when an intrauterine pressure catheter is used
- Persistent abdominal pain
- Systemic signs of early hemorrhage (tachycardia [maternal and fetal], tachypnea, falling blood pressure, falling urine output, restlessness)
- Persistent late decelerations in fetal heart rate or decreasing baseline variability; absence of accelerations
- Slight or absent vaginal bleeding

APPLICATION OF THE NURSING PROCESS

■ Hemorrhagic Conditions of Late Pregnancy Assessment

For hemorrhagic conditions of late pregnancy, some nursing assessments should be performed immediately and others can be deferred until initial interventions have been taken to stabilize the cardiovascular status of the woman. Many nursing assessments are concurrent with medical assessments and include the following:

- Amount and nature of bleeding (time of onset, estimated blood loss before admission to hospital, and description of tissue or clots passed): Peripads and underpads should be saved, as needed, to accurately estimate blood loss.
- Pain (type [constant, intermittent, sharp, dull, severe]; onset [sudden, gradual]; and location [generalized over abdomen, localized in back]): Is uterine tenderness present with gentle palpation? Is the tenderness localized? Where?
- Maternal vital signs: Are these within normal limits, or is hypotension, tachycardia, or both present? A normal blood pressure may be misleading in a woman with abruptio placentae because she may have been hypertensive before the blood loss caused her blood pressure to fall to normal or hypotensive levels.
- Condition of the fetus: An electronic fetal monitor determines fetal heart rate, presence of accelerations, and fetal response to uterine activity. The presence of late decelerations or poor variability is of particular concern.
- Uterine contractions: Application of an external monitor determines frequency and duration of contractions. An intrauterine pressure catheter can identify hypertonic contractions and an increased resting tone associated with abruptio placentae if it is not contraindicated. Palpation can identify that the uterus does not relax fully between contractions. Thick abdominal fat reduces the ability to identify poor uterine relaxation by external means.
- Obstetric history (gravida, para, previous abortions, preterm infants, previous pregnancy outcomes): Does the history include previous abruptio placentae?
- Length of gestation (date of last menstrual period, fundal height, correlation of fundal height with estimated gestation): If bleeding occurs into the myometrium, the fundus enlarges as bleeding progresses. A piece of tape on the abdomen can mark the top of the fundus at a given time, and then the nurse can observe and report increasing fundal size, which suggests that bleeding into uterine muscles is occurring.
- Laboratory data: Laboratory studies include a complete blood count and blood typing and screening. Blood crossmatching is

CHECK YOUR READING

8. What are the signs and symptoms of placenta previa? How is it managed in the home?
9. What are the signs and symptoms of abruptio placentae?
10. What are the major dangers to the mother and the fetus during the placental abruption?

done if transfusion is likely. Type and Rh factor identify possible need for RhoGAM. Other tests may be done serially to identify whether the abruption is stable or worsening. The K-B test identifies fetal blood cells in the maternal circulation. Coagulation studies include fibrinogen, FSP, prothrombin and partial thromboplastin times (PT/PTT), and D-dimer to identify fibrin degradation fragments. A drug screen is done if illegal drug use is suspected or if the woman had no prenatal care.

Despite the emphasis on physical assessment, the emotional response of the mother and her partner must also be addressed. They will most likely be anxious, fearful, confused, and overwhelmed by the activity. They may have little knowledge of expected medical management and may not realize that the fetus will need to be delivered as quickly as possible and that a surgical procedure is necessary. They may fear for the life of the woman and that of the fetus.

Nursing Diagnosis

Nursing diagnoses vary, depending on the cause and severity of the bleeding. The most commonly used nursing diagnoses for antepartum bleeding appear in [Case Study 25-1](#). The most dangerous potential complication is hypovolemic shock, which jeopardizes the life of the mother as well as that of the fetus.

Planning

The nurse does not independently manage hypovolemic shock but must confer with physicians for medical orders for treatment. Planning should reflect the nurse's responsibility to:

- Monitor for signs of hypovolemic shock.
- Consult with the physician if signs of hypovolemic shock are observed.
- Perform actions to minimize the effects of hypovolemic shock.

Interventions

Monitor for Signs of Hypovolemic Shock

Assess for any sign of developing hypovolemic shock. The body attempts to compensate for decreased blood volume and to maintain oxygenation of essential organs by increasing the rate and effort of the heart and lungs and by shunting blood from less essential organs, such as the skin and the extremities, to more essential organs such as the brain and the kidneys. This compensatory mechanism results in the following early signs and symptoms of hypovolemic shock:

- Fetal tachycardia (often the first sign of either maternal or fetal hypovolemia)
- Maternal tachycardia, weak peripheral pulses
- Normal or slightly decreased blood pressure
- Increased respiratory rate
- Low oxygen saturation
- Cool, pale skin and mucous membranes

The compensatory mechanism fails if hypovolemic shock progresses and insufficient blood exists to perfuse the brain, heart, and kidneys. Later signs of hypovolemic shock include the following:

- Falling blood pressure and oxygen saturation levels
- Pallor; skin becomes cold and clammy
- Urine output less than 30 mL/hr
- Restlessness, agitation, decreased mentation

Monitor the Fetus

Use continuous electronic fetal monitoring so that signs of fetal compromise, such as tachycardia, decreasing baseline variability, or late decelerations, can be seen (see [Chapter 14](#)). If nonreassuring patterns are seen, contact the physician at once because the fetus often shows signs of compromise before maternal signs of hypovolemia are obvious.

Give the physician a report on new laboratory data that suggest an increasing degree of placental abruption, such as rising K-B levels after abdominal trauma.

Promote Tissue Oxygenation

To promote oxygenation of tissues:

- Place the woman in a lateral position, with the head of the bed flat to increase cardiac return and thus to increase circulation and oxygenation of the placenta and other vital organs.
- Limit maternal activity to decrease the tissue demand for oxygen.
- Provide simple explanations, reassurance, and emotional support to the woman to reduce anxiety, which increases the metabolic demand for oxygen.

Collaborate with the Physician for Fluid Replacement

To replace fluids:

- Insert IV lines according to hospital protocol. Two lines that use large-gauge catheters (16- to 18-gauge) are often recommended for rapid blood replacement, if needed.
- Administer fluids for replacement as directed by the physician to maintain a urinary output of at least 30 mL/hr.
- Obtain an order for blood typing and screening or crossmatching if not previously done.

Prepare the Woman for Surgery

Quick preparation of the woman for cesarean delivery may be necessary. The neonatal resuscitation team should be notified. See [Chapter 16](#) (pp. 315-323) for common preparations of a woman for cesarean.

Before and after birth assess bleeding from the vagina as well as from any surgical sites or puncture wounds (epidural or IV sites) to identify uncontrolled bleeding or bleeding from unexpected sites that may indicate DIC, requiring prompt medical management.

SAFETY ALERT

Signs and symptoms of hypovolemic shock caused by blood loss include the following:

- Increased pulse rate, falling blood pressure, increased respiratory rate
- Weak, diminished, or "thready" peripheral pulses
- Cool, moist skin; pallor; or cyanosis (late sign)
- Decreased (<30 mL/hr) or absent urinary output
- Decreased hemoglobin, hematocrit levels
- Change in mental status (restlessness, agitation, difficulty concentrating)

Provide Emotional Support

Once the safety of the woman and the fetus is ensured, nursing interventions promote comfort and provide emotional support. Explain what is causing the discomfort, and reassure the woman that pain-relief measures that do not cause harm to the fetus will be initiated as soon as possible. Offering false reassurance about the condition of the fetus is unwise, but remain with the woman, and provide accurate and timely information. Explain your actions to the woman and her family. They can feel overwhelmed by all the activity. Visiting with the woman and her support person after birth helps clarify the problem and reasons for interventions to help put events in perspective.

Evaluation

Patient-centered goals are not developed for collaborative problems but the nurse collects and compares data with established norms and judges whether the data are within normal limits. For hypovolemic shock, the maternal vital signs remain within normal limits and the

fetal heart demonstrates no signs of compromise such as abnormal rate, late decelerations, or decreasing baseline variability.

HYPEREMESIS GRAVIDARUM

Hyperemesis gravidarum (HEG) is persistent, uncontrollable vomiting that begins in the first weeks of pregnancy and may continue throughout pregnancy. HEG may continue throughout pregnancy, although its severity usually lessens. Unlike morning sickness, which is self-limited and causes no serious complications, HEG can have serious consequences. Hyperemesis is associated with loss of 5% or more of pre-pregnancy weight, dehydration, acidosis from starvation, elevated levels of blood and urine ketones, alkalosis from loss of hydrochloric acid in the gastric fluids, and hypokalemia. Short-term hepatic dysfunction with elevated liver enzymes may occur. Deficiency of vitamin K may cause coagulation disorders, and deficiency of thiamine can cause encephalopathy.

Etiology

The cause of HEG is not known, but the condition is more common among unmarried white women, during first pregnancies, and in multifetal pregnancies. Other possible causes include possible allergy to fetal proteins. Elevated levels of pregnancy-related hormones such as estrogen and beta-hCG are considered a possible cause, as is maternal thyroid dysfunction. Association with the organism that causes peptic ulcer disease, *Helicobacter pylori*, is not conclusive. Psychological factors may interact with the nausea and vomiting that occurs during early pregnancy to worsen the condition (ACOG, 2011; Cunningham et al., 2010; Gilbert, 2011; Kelly & Savides, 2009).

Therapeutic Management

Exclusion of other causes of persistent nausea and vomiting, such as cholecystitis, peptic ulcer disease, or gestational trophoblastic disease, should precede diagnosing hyperemesis. Laboratory studies include hemoglobin and hematocrit levels, which may be elevated because of dehydration, resulting in hemoconcentration. Electrolyte studies may reveal reduced sodium, potassium, and chloride levels. Elevated creatinine levels indicate renal dysfunction.

Treatment occurs primarily in the home, where the woman first attempts to control the nausea with methods that are used for morning sickness (see Chapter 7). In addition, some physicians prescribe vitamins such as pyridoxine (vitamin B₆), which may provide some relief. A daily vitamin and mineral supplement may be recommended.

Drug therapy may be required if the vomiting becomes severe. Drugs prescribed may include the following:

- Promethazine (Phenergan)
- Diphenhydramine (Benadryl)
- Histamine-receptor antagonists such as famotidine (Pepcid) or ranitidine (Zantac)
- Gastric acid inhibitors such as esomeprazole (Nexium) or omeprazole (Prilosec)
- Metoclopramide (Reglan)
- Ondansetron (Zofran)

If simpler methods are unsuccessful and weight loss or electrolyte imbalance persists, IV fluid and electrolyte replacement or total parenteral nutrition (TPN) may be necessary. In some women, IV fluid replacement improves the nausea and vomiting quickly. The woman usually can be managed at home with periodic home nursing visits if she must have TPN. Periodic brief hospitalizations may be needed until the hyperemesis problem lessens. Enteral nutrition has also been used successfully (ACOG, 2011; Cunningham et al., 2010).

Nursing Considerations

Because management often occurs in the home, nurses are often responsible for assessing and intervening for the woman with HEG in the hospital. Physical assessment begins with determining the intake and output. Intake includes IV fluids and parenteral or enteral nutrition, as well as oral nutrition, which is resumed with control of vomiting. Output includes the amount and character of emesis and urinary output. As a rule of thumb, the normal urinary output is about 1 mL/kg/hr (1 mL/2.2 lb/hr). A record of bowel elimination also provides significant information about oral nutrition because a woman's intake may have been so minimal that many days have passed since her last normal bowel movement.

Laboratory data may be evaluated to determine fluid and metabolic status. Elevated levels of hemoglobin and hematocrit may occur as a result of dehydration, which results in hemoconcentration. Concentrations of sodium, potassium, and chloride may be reduced, resulting in hypokalemia and alkalosis.

Whether at home or at the hospital, the woman weighs herself daily, first thing in the morning and in similar clothing each day. Weight loss and the presence of ketones in the urine suggest that fat stores and protein are being metabolized to meet energy needs.

Signs of dehydration include decreased fluid intake (less than 2000 mL/day), decreased urinary output, increased urine specific gravity (more than 1.025), dry skin or dry mucous membranes, and nonelastic skin turgor.

Nursing interventions focus on reducing nausea and vomiting, maintaining nutrition and fluid balance, and providing emotional support.

Reducing Nausea and Vomiting

When food is offered to the woman, portions should be small so that the amount does not appear overwhelming. Food should be attractively presented, and foods with strong odors should be eliminated from the diet because food smells often incite nausea. Low-fat foods and easily digested carbohydrates such as fruit, breads, cereals, rice, and pasta provide important nutrients and help prevent low blood glucose levels, which can cause nausea. Soups and other liquids should be taken between meals to avoid distending the stomach and triggering vomiting. Sitting upright after meals reduces gastric reflux.

Maintaining Nutrition and Fluid Balance

Women with nausea and vomiting should eat every 2 to 3 hours. Salting the food helps replace the chloride lost when hydrochloric acid is vomited. Consuming potassium-rich and magnesium-rich foods and fluids should be encouraged when the woman can do so because stores of these nutrients are likely to be depleted and magnesium deficiency can exacerbate nausea. Potassium is found in fruits, vegetables, and meat. Sources of magnesium include seeds, nuts, legumes, and green vegetables. See Chapter 9 for more information on nutrition.

IV fluids and total parenteral nutrition are administered as directed by the physician. IV fluid containing potassium is often ordered until the low serum level returns to normal. Small oral feedings of clear liquids are started when nausea and vomiting subside. When oral fluids and adequate food intake are tolerated, parenteral nutrition is gradually discontinued. Continued inability to tolerate oral feedings or continued episodes of vomiting should be reported to the physician so that continued parenteral fluids and nutrition can be prescribed.

Providing Emotional Support

The woman with HEG needs the opportunity to express how it feels to be pregnant and to live with constant nausea. The woman,

and possibly her significant other, may have been surprised by the pregnancy and may not have accepted it. Helping the woman express reluctance to accept the pregnancy and identifying her sources of support may reduce nausea, although its intensity may remain higher than in most women. HEG can make early pregnancy unpleasant because of its unpredictability.

The woman with HEG needs the opportunity to express how it feels to be pregnant and to live with ever-present nausea, but these women often experience a curious lack of sympathy and support. This attitude may stem from reports that the cause of hyperemesis gravidarum is always psychological. In addition, observation of the woman and her family may provide clues about family dynamics that may be contributing to her response to nausea of pregnancy. Nurses must use critical thinking to examine personal beliefs and biases so that they can provide comfort and support.

HYPERTENSIVE DISORDERS OF PREGNANCY

The terminology used to describe hypertension in pregnancy is often nonuniform and confusing. In an effort to standardize classifications of hypertension occurring during pregnancy and to identify the best management, the National Heart, Lung, and Blood Institute assembled a working group to update older recommendations. Four categories of hypertensive disorders that occur during pregnancy were identified by the group (Table 25-1; ACOG, 2012a, b; Cunningham et al., 2010; Roberts & Funai, 2009).

- Gestational hypertension: Blood pressure elevation after 20 weeks of pregnancy that is not accompanied by proteinuria. Gestational hypertension must be considered a working diagnosis because it may progress to preeclampsia. If gestational hypertension persists after birth, chronic hypertension is diagnosed.

- Preeclampsia: A systolic blood pressure of 140 mm Hg or greater or a diastolic blood pressure of 90 mm Hg or greater occurring after 20 weeks of pregnancy that is accompanied by significant proteinuria (≥ 0.3 g in a 24-hour urine collection, which usually correlates with a random urine dipstick evaluation of $\geq 1+$). Edema, although common in preeclampsia, is now considered to be non-specific because it occurs in many pregnancies not complicated by hypertension.
- Eclampsia: Progression of preeclampsia to generalized seizures that cannot be attributed to other causes. Seizures may occur postpartum.
- Chronic hypertension: The elevated blood pressure was known to exist before pregnancy or before 20 weeks of gestation. Unrecognized chronic hypertension may not be diagnosed until well after the end of pregnancy when the blood pressure remains high.

Preeclampsia

Preeclampsia is a condition in which hypertension develops during the last half of pregnancy in a woman who previously had normal blood pressure. In addition to hypertension, renal involvement may cause proteinuria. Many women also experience generalized edema. The only known cure is birth of the fetus. Maternal and fetal morbidity can be minimized if preeclampsia is detected early and managed carefully.

Incidence and Risk Factors

Preeclampsia is relatively common, affecting 5% to 10% of all pregnancies. Efforts to prevent hypertension in pregnancy have not been successful. It is a major cause of perinatal death, and it is often associated with intrauterine fetal growth restriction (IUGR) (Cunningham et al., 2010; Dekker, 2011; Sibai, 2012).

Although the cause of preeclampsia is not understood, several factors are known to increase a woman's risk (Box 25-2). Many risk factors such as obesity and prepregnancy diabetes may be interrelated.

Preeclampsia is most likely to occur in a first pregnancy, in women older than 35 years, in African-Americans, in those with a positive family history, and in those with chronic hypertension or renal disease. Being overweight increases a woman's risk for preeclampsia, as it does for chronic hypertension. Women with diabetes or multifetal

TABLE 25-1 CLASSIFICATIONS OF HYPERTENSION IN PREGNANCY

CLASSIFICATION	COMMENTS
Gestational hypertension (replaces the term <i>pregnancy-induced hypertension [PIH]</i>)	Systolic blood pressure ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg that develops after 20 weeks of pregnancy but returns to normal within 6 weeks postpartum. Proteinuria (negative or trace on random urine dipstick) is not present.
Preeclampsia	Systolic blood pressure ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg that develops after 20 weeks of pregnancy and is accompanied by proteinuria ≥ 0.3 g in 24-hr urine collection (random urine dipstick is usually $\geq 1+$).
Eclampsia	Progression of preeclampsia to generalized seizures that cannot be attributed to other causes.
Chronic hypertension	Systolic blood pressure ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg that was known to exist before pregnancy or develops before 20 weeks of gestation. Also diagnosed if the hypertension does not resolve during postpartum period.
Preeclampsia superimposed on chronic hypertension	Development of new-onset proteinuria ≥ 0.3 g in 24-hr urine collection in a woman who has chronic hypertension. In women who had proteinuria before 20 weeks, preeclampsia should be suspected if woman has a sudden increase in proteinuria from her baseline levels, a sudden increase in blood pressure when it had been previously well controlled, development of thrombocytopenia (platelets $< 100,000/\text{mm}^3$), or abnormal elevations of liver enzymes (AST or ALT).

ALT, Alanine aminotransferase (formerly SGPT); AST, aspartate aminotransferase (formerly SGOT).

BOX 25-2 RISK FACTORS FOR PREGNANCY-RELATED HYPERTENSION

First pregnancy
 First pregnancy for father of baby or man who has previously fathered one preeclamptic pregnancy
 Age >35 years
 Anemia
 Family or personal history of pregnancy-induced hypertension
 Chronic hypertension or preexisting vascular or renal disease
 Obesity
 Diabetes mellitus
 Antiphospholipid syndrome
 Multifetal pregnancy

From Cunningham, F.G., Leveno, K.G., Bloom, S.L. et al. (2010). *Williams obstetrics* (23rd ed.). New York: McGraw-Hill; Dekker, G. (2011). Hypertension. In D.K. James, P.J. Steer, C.P. Weiner, & B. Gonik (Eds.), *High risk pregnancy: Management options* (4th ed., pp. 599–626). Philadelphia: Elsevier Saunders; Sibai, B.M. (2012). Hypertension. In S.G. Gabbe, J.R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed., pp. 779–824). Philadelphia: Elsevier Saunders.

gestations are also more likely to have preeclampsia. The presence of immunologic or genetic disorders such as lupus or clotting disorders adds to the risk for preeclampsia that is often severe. The woman who had prior pregnancies without hypertension is more likely to have preeclampsia if her partner and his previous partner had a pregnancy that was complicated by the disorder (ACOG, 2012b; Cunningham et al., 2010; Founds, Dorman, & Conley, 2008; Kriebs, 2009; Sibai, 2012).

Pathophysiology

Preeclampsia is a result of generalized vasospasm. The underlying cause of the vasospasm remains unknown, although some of the pathophysiologic processes are known. In normal pregnancy, vascular volume and cardiac output increase significantly. Despite these increases, blood pressure does not rise in normal pregnancy. This is probably because pregnant women develop resistance to the effects of vasoconstrictors such as angiotensin II. Peripheral vascular resistance decreases because of the effects of certain vasodilators such as prostacyclin (PGI₂), PGE, and endothelium-derived relaxing factor (EDRF).

In preeclampsia, however, peripheral vascular resistance increases because some women are sensitive to angiotensin II. They also may have a decrease in vasodilators. For instance, the ratio of thromboxane (TXA₂) to PGI₂ (prostacyclin) increases. TXA₂, produced by kidney and trophoblastic tissue, causes vasoconstriction and platelet aggregation (clumping). PGI₂, produced by placental tissue and endothelial cells, causes vasodilation and inhibits platelet aggregation.

Vasospasm decreases the diameter of blood vessels, which results in endothelial cell damage and decreased EDRF. Vasoconstriction also results in impeded blood flow and elevated blood pressure. As a result, circulation to all body organs, including the kidneys, liver, brain, and placenta, is decreased. The following changes are most significant:

- Decreased renal perfusion reduces the glomerular filtration rate. Blood urea nitrogen, creatinine, and uric acid levels rise.
- Reduced renal blood flow results in glomerular damage, allowing protein to leak across the glomerular membrane, which is normally impermeable to large protein molecules.

- Loss of protein from the kidneys reduces colloid osmotic pressure and allows fluid to shift to interstitial spaces. This may result in edema and a reduction in intravascular volume, which causes increased viscosity of the blood and a rise in hematocrit level. Generalized edema often occurs.
- In response to reduced intravascular volume, additional angiotensin II and aldosterone trigger the retention of both sodium and water. Pathologic processes spiral: Additional angiotensin II results in further vasospasm and hypertension; aldosterone increases fluid retention; edema worsens.
- Reduced liver circulation impairs function and leads to hepatic edema and subcapsular hemorrhage, which can result in hemorrhagic necrosis. This is manifested by elevation of liver enzymes in maternal serum. Epigastric pain is a common symptom.
- Vasoconstriction of cerebral vessels leads to pressure-induced rupture of thin-walled capillaries, resulting in small cerebral hemorrhages. Symptoms of arterial vasospasm include headache and visual disturbances such as blurred vision, “spots” before the eyes, and hyperactive deep tendon reflexes (DTRs).
- Decreased colloid oncotic pressure can lead to pulmonary capillary leak that results in pulmonary edema. Dyspnea is the primary symptom.
- Decreased placental circulation results in infarctions that increase the risk for abruptio placentae and HELLP syndrome (p. 529). In addition, the fetus is likely to experience IUGR and persistent hypoxemia and acidosis when maternal blood flow through the placenta is reduced. Figure 25-7 summarizes the pathologic processes of preeclampsia.

Preventive Measures

Prenatal Care. Early and regular prenatal care with attention to pattern of weight gain and monitoring of blood pressure and urinary protein level may minimize maternal and fetal morbidity and mortality by allowing early detection of the problem.

Attempts at prevention in women at high risk for recurrence have included low-dose aspirin, calcium and magnesium supplements, and fish oil supplements. Low-dose aspirin of 81 mg/day appears to have minimum benefit in high-risk women. Calcium supplementation also appears to reduce the risk of preeclampsia only in high-risk women. However, no consensus on measures to reliably prevent preeclampsia in high-risk women exists at this time (Cunningham et al., 2010; Sibai, 2012).

Clinical Manifestations of Preeclampsia

Classic Signs. The first indication of preeclampsia is usually hypertension. Blood pressure measurements vary with the woman's position, so the blood pressure should be measured uniformly at each office visit. Blood pressure should be measured with the woman seated and her arm supported, and the cuff size should be appropriate for the size of her arm. The diastolic pressure should be recorded at Korotkoff phase V, disappearance of sound. Hospitalizing the woman for serial observations of her blood pressure may identify true elevations from those induced by anxiety. After a 10-minute or longer rest period, blood pressure should be assessed with a sphygmomanometer and a stethoscope to provide best audible identification of Korotkoff sounds (ACOG, 2012b; Dekker, 2011).

Proteinuria can be identified by using a clean-catch specimen of urine to prevent contamination of the specimen by vaginal secretions or blood. Women with a urinary tract infection often have erythrocytes and leukocytes in urine, which would elevate urine protein level in the absence of preeclampsia.

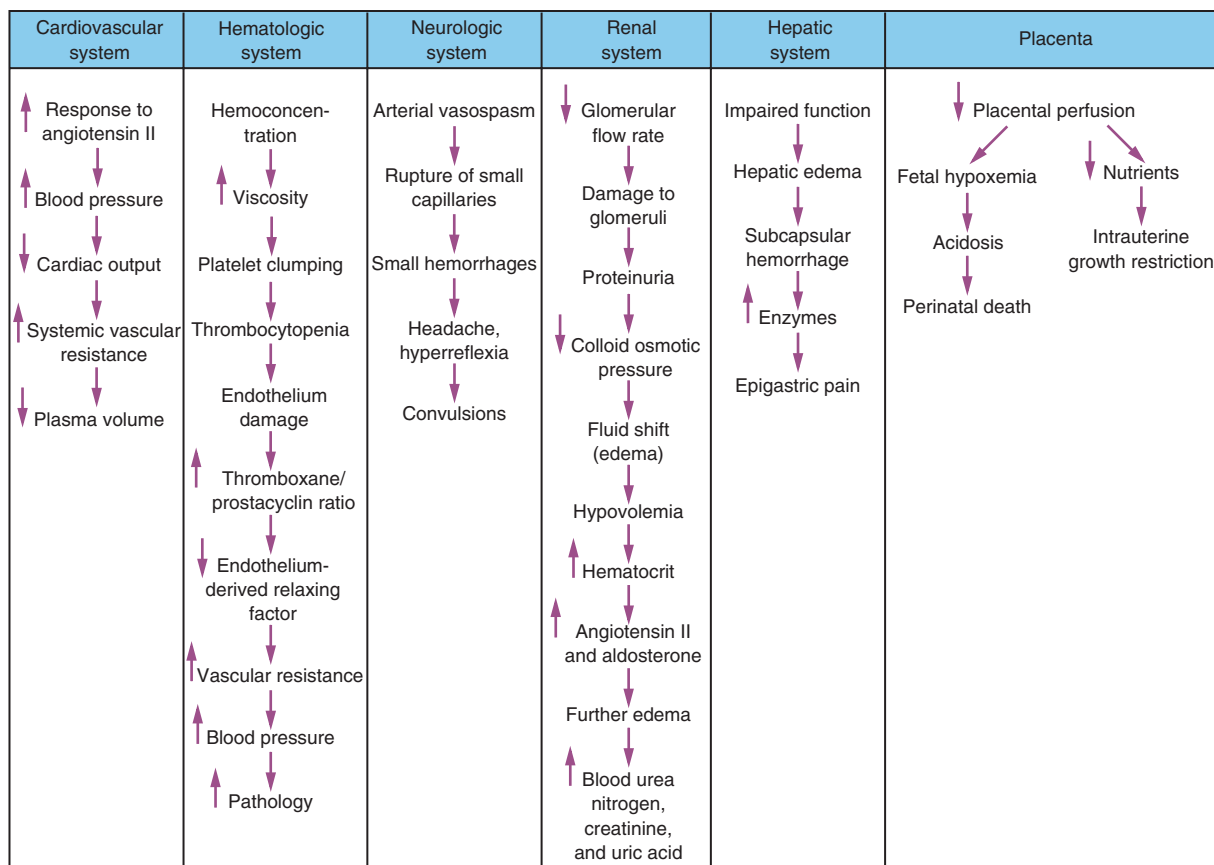

FIG 25-7 The pathologic processes of preeclampsia.

Additional Signs. When the retina is examined, vascular constriction and narrowing of the small arteries are obvious in most women with preeclampsia. The vasoconstriction that can be seen in the retina is occurring throughout the body. DTRs may be very brisk (hyperreflexia), suggesting cerebral irritability secondary to decreased brain circulation and edema.

Laboratory studies may identify liver, renal, and hepatic dysfunction if preeclampsia is severe. Coagulation may be impaired, as evidenced by a decrease in the number of platelets, which are often in the high-normal range in a woman without preeclampsia. See also the earlier discussion of DIC (p. 507).

Although it is a nonspecific sign that may have many causes, generalized edema often occurs with preeclampsia, and it may be severe. Edema may first manifest as a rapid weight gain caused by fluid retention. Edema may be present in the lower legs, which is common in pregnancy, and in the hands and face (Figure 25-8). Edema may be so massive that the woman's appearance is distorted. Edema may not, however, be present in all women who develop preeclampsia, and it may be severe in women who do not have the disorder. Pulmonary edema is also more common in women with massive edema from any cause, including drug therapy such as that given to stop preterm labor (see Chapter 27).

Symptoms. Preeclampsia is dangerous for the woman and the fetus for two reasons: (1) It can develop and worsen rapidly, and (2) the earliest symptoms are often not noticed by the woman. By the time she notices the symptoms, the disease may have progressed to an advanced state and valuable treatment time lost.

Certain symptoms such as continuous headache, drowsiness, or mental confusion indicate poor cerebral perfusion and may be

precursors of seizures. Visual disturbances such as blurred or double vision or spots before the eyes indicate arterial spasms and edema in the retina. Numbness or tingling of the hands or feet occurs when nerves are compressed by retained fluid. Some symptoms such as epigastric pain or "upset stomach" are particularly ominous because they indicate distention of the hepatic capsule and often mean that a seizure is imminent. Decreased urinary output indicates poor perfusion of the kidneys and may precede acute renal failure.

Therapeutic Management of Mild Preeclampsia

The only cure for preeclampsia is delivery of the baby. However, the decision about delivery will be based on the severity of the hypertensive disorder and the degree of fetal maturity. If the fetus is less than 34 weeks of gestation, steroids to accelerate fetal lung maturity will be given and an attempt made to delay birth for 48 hours. However, if the maternal or fetal condition deteriorates, the infant must be delivered, regardless of fetal age or administration of steroids. Vaginal birth is preferred because of the multisystem impairments.

Preeclampsia is categorized as either mild or severe, depending on the presenting signs and symptoms (Table 25-2). However, an apparently mild condition can become severe in a very short time because the disease may progress rapidly.

Home Care. Management in the home may be possible for selected women if the condition is mild and if the women are not good candidates for labor induction, usually because of fetal immaturity. The woman must be in a stable condition with a reassuring fetal status. She must be willing to adhere to a prescribed treatment plan that includes bed rest or reduced activity, home blood pressure monitoring, and follow-up visits to the physician every 3 to 4 days. The woman who is

FIG 25-8 Generalized edema is a possible sign identified with preeclampsia, although it may occur in normal pregnancy or in a pregnancy complicated by another disorder. **A**, Facial edema may be subtle. **B**, Pitting edema of the lower leg.

CASE STUDY 25-2 NURSING CARE PLAN*

ASSESSMENT: Julie, a 16-year-old primigravida, is seen in the prenatal clinic at 30 weeks of gestation. Her first clinic visit was at 20 weeks of gestation. Her mother accompanies her. Her blood pressure is 136/90 mm Hg, and there is some edema of the lower legs and a trace proteinuria. She is given instructions about home care for pregnancy-induced hypertension. The regimen includes bed rest; frequent monitoring of blood pressure, weight, and urine; and recording fetal “kick counts.” Julie is told she should return to the clinic in 1 week. She states that she feels fine and does not want to miss school. She says that she does not see the reason for bed rest.

NURSING DIAGNOSIS: Julie’s readiness for Enhanced Knowledge of her recommended treatment regimen for preeclampsia

EXPECTED OUTCOMES: Julie and her support person (mother) will do the following:

1. Verbalize the benefits of the recommended regimen by the end of the first prenatal appointment.
2. Comply with the recommended care for the next week.
3. Keep prenatal appointments.

INTERVENTIONS AND RATIONALES

1. Allow Julie to verbalize her feelings about the recommended regimen: “What concerns you most about missing school?” Acknowledge her feelings as important: “It must be difficult to think of falling behind in your schoolwork. It isn’t any fun to miss all the after-school activities or time with your friends.”

When feelings are identified and acknowledged as important, anxiety decreases and teaching and learning can begin.

2. Identify family support that is likely to improve compliance with the recommended regimen of bed rest and home care. *Compliance with the regimen for the adolescent is probably impossible without family assistance, which includes assistance with activities of daily living and necessary assessments.*
3. Describe in general terms the pathophysiologic processes that affect Julie and her fetus. *Pregnant women, including teen mothers, are often motivated to comply with a therapeutic regimen that will benefit the fetus. Julie’s support from friends and family can strengthen her motivation and compliance.*
4. Explain to Julie and her mother that she may feel well even if the condition worsens and that she must be observed for signs and symptoms of worsening at home and at the clinic. Julie may not notice hypertension and proteinuria. *Although edema is not always present in hypertensive complications during pregnancy, women may not be aware that it may also be associated with other significant problems.*
5. Tell Julie and her mother to call the clinic if she has headache, double vision, or spots before her eyes *because these signs indicate rapid progression of the disease and the prompt necessity for additional management.*
6. Collaborate with Julie and her mother to arrange for contact with her boyfriend or selected friends and to arrange for ongoing home-bound classes. *Such an agreement will allow a schedule to provide peer support but allow for prolonged periods of quiet. Home-bound classes alleviate the concern that she is falling behind with schoolwork.*

*Continues on p. 524.

prescribed home care should be taught how to check her blood pressure and about reporting the symptoms that suggest worsening preeclampsia, such as visual disturbance, severe headache, or epigastric pain. Symptoms that suggest a nonreassuring fetal status, such as reduced fetal movement, should also be taught. If the woman is hospitalized with mild preeclampsia, the following assessments for home care are adapted for her inpatient care.

Activity Restrictions. The mother should rest frequently, although full bed rest is not required for mild preeclampsia. A lateral position for at least 1½ hours a day decreases pressure on the vena cava, thereby increasing cardiac return and circulatory volume and improving perfusion of the woman’s vital organs and the placenta.

Blood Pressure. If monitoring of blood pressure is prescribed, the family must be taught to use electronic blood pressure equipment, readily available in drug, grocery, and discount stores. Blood pressure should be checked in the same arm and in the same position two to four times each day. A large cuff should be used for a woman with a large upper arm. Although electronic equipment may not provide blood pressure readings with the precision of manual assessment, they are usually sufficiently accurate for home care.

Weight. The woman should weigh herself each morning, preferably on the same scale and in clothing of similar weight.

Urinalysis. A urine dipstick test for protein, using the first voided midstream specimen, should be performed daily. The physician may

request that she test at other times also. Twenty-four hour urine specimens collected at home or in the hospital may be ordered for best accuracy of urine protein levels.

Fetal Assessment. Because vasoconstriction can reduce placental flow, the woman will have increased fetal assessments to observe for evidence of fetal compromise. Fetal compromise can be evidenced by reduced fetal movement noted by the mother (“kick counts”). Additional surveillance includes ultrasonography for fetal growth and quantity of amniotic fluid or as part of a biophysical profile (BPP). A diminishing amount of amniotic fluid suggests placental impairment. If the pregnancy is less than 34 completed weeks and delivery is being considered but is not yet urgent, amniocentesis is often done to evaluate fetal lung maturity. See Chapter 10 for discussion of fetal surveillance methods.

Diet. The diet should have ample protein and calories. A regular diet without salt or fluid restriction is usually prescribed. Women who also have chronic hypertension or diabetes should have diet management appropriate for these disorders.

A nurse should reevaluate the woman’s compliance with prescribed care and signs or symptoms to promptly report at each contact, whether phone or home care visit. The woman should go to the hospital for evaluation promptly if unable to contact her caregiver about signs or symptoms of concern.

Inpatient Management of Severe Preeclampsia

Preeclampsia is severe if the systolic blood pressure is 160 mm Hg or greater, the diastolic blood pressure is 110 mm Hg or greater, or evidence of multisystem involvement is present (see Table 25-2). In such a case, immediate delivery is the usual decision, even if the gestation is less than 34 weeks, because of disease severity. A decreased volume of amniotic fluid is considered significant because it suggests reduced

placental blood flow, even if blood pressures are not high. Ultrasound may be done to evaluate fetal blood flow through the cord and placenta.

Antepartum Management. Goals of management are to improve placental blood flow and fetal oxygenation and to prevent seizures and other maternal complications such as stroke as the woman’s condition is stabilized before birth.

Bed Rest. The woman is prescribed bed rest in the lateral position, and her environment is kept quiet. External stimuli (e.g., lights, noise) that might precipitate a seizure should be reduced. Electronic fetal monitoring (EFM) is usually continuous.

Antihypertensive Medications. If the woman’s systolic blood pressure is 160 mm Hg or greater or her diastolic blood pressure is 110 mm Hg or greater, the risk for stroke or congestive heart failure is higher. Hydralazine (Apresoline) is often used because of its record of safety. Hydralazine’s major advantage over other antihypertensives is that it is a vasodilator that increases cardiac output and blood flow to the placenta. Other antihypertensive medications such as nifedipine (a calcium channel blocker) or labetalol (a beta-adrenergic blocker) may be used. Caution is essential when antihypertensive medications are given to the woman receiving magnesium sulfate because hypotension may result, reducing placental perfusion.

Anticonvulsant Medications. Magnesium sulfate is the drug most often used to prevent seizures. Magnesium acts as a central nervous system (CNS) depressant by blocking neuromuscular transmission and decreasing the amount of acetylcholine liberated. Magnesium is not an antihypertensive medication, but it relaxes smooth muscle, including the uterus, and thus reduces vasoconstriction, possibly resulting in modest blood pressure reduction. Decreased vasoconstriction promotes circulation to the vital organs of the expectant mother and increases placental circulation. Increased circulation to the

TABLE 25-2 MILD VERSUS SEVERE PREECLAMPSIA

PARAMETER EVALUATED	MILD	SEVERE
Systolic blood pressure	≥140 but <160 mm Hg	≥160 mm Hg (two readings, 6 hr apart, while on bed rest)
Diastolic blood pressure	≥90 but <110 mm Hg	≥110 mm Hg
Proteinuria (24-hr specimen is preferred to eliminate hour-to-hour variations)	≥0.3 g but <2 g in 24-hr specimen (1+ or higher on random dipstick)	≥5 g in 24-hr specimen (3+ or higher on random dipstick samples)
Creatinine, serum (renal function)	Normal	Elevated (>1.2 mg/dL)
Platelets	Normal	Decreased (<100,000 cells/mm ³)
Liver enzymes (alanine aminotransferase [ALT] or aspartate aminotransferase [AST])	Normal or minimal increase in levels	Elevated levels
Urine output	Normal	Oliguria common, often <500 mL/day
Severe, unrelenting headache not attributable to other cause; mental confusion (cerebral edema)	Absent	Often present
Persistent right upper quadrant or epigastric pain or pain penetrating to back (distention of liver capsule); nausea and vomiting	Absent	May be present and often precedes seizure
Visual disturbances (spots or “sparkles”; temporary blindness; photophobia)	Absent to minimal	Common
Pulmonary edema; heart failure; cyanosis	Absent	May be present
Fetal growth restriction	Normal growth	Growth restriction; reduced amniotic fluid volume

CASE STUDY 25-2 NURSING CARE PLAN*

EVALUATION: Despite following the recommended regimen of bed rest with the help of her mother and sister and keeping prenatal appointments, Julie's condition worsens. She develops a rise in blood pressure and a rapid gain in weight, indicating generalized edema, at 32 weeks.

ASSESSMENT: Julie is admitted to the hospital at 32 weeks of gestation with a blood pressure of 160/110 mm Hg, heart rate of 92 beats per minute (bpm), and respiratory rate of 22 breaths per min. There is 2+ proteinuria in a random urine specimen and marked edema of the hands and face as well as her lower extremities. Fetal heart rate is 136 bpm with average variability. An intravenous infusion of magnesium sulfate is started, seizure precautions are initiated, and environmental stimuli are reduced. Julie is agitated and verbalizes concern that the procedures are going to hurt her or the fetus. She frequently asks, "How sick am I?" "Is my baby going to be okay?" Her hands are perspiring, and they shake when she reaches for a tissue.

NURSING DIAGNOSIS: Anxiety related to hospitalization and concern about her health and the health of her baby

EXPECTED OUTCOMES: Julie will:

1. Verbalize her concerns and describe the benefits of the treatment while her family is present.
2. Manifest less anxiety (agitation; physiologic signs such as tremors, tachycardia, and perspiration).

INTERVENTIONS AND RATIONALES

1. Initiate measures to reduce anxiety. *Anxiety is an ominous feeling of tension resulting from a physical or emotional threat to the self. It is a global, often unnamed, sense of doom, a feeling of helplessness, isolation, and insecurity. Anxiety needs to be ventilated and then addressed by conveying that the person is not alone and will be protected.*
 - a. Provide positive reassurance that a solution for anxiety can be found: "I can see you are really worried, and I will try to answer all your questions."
 - b. Allow Julie to cry, get angry, or express any feeling that is present.
 - c. Encourage a discussion of feelings: "Tell me more about how you feel."
 - d. Reflect observations: "I see you wringing your hands; do you want to talk about it?"
 - e. Convey empathy and positive regard; use nonverbal behavior, including touch, when appropriate.

2. Provide information about hospital routines and procedures when Julie's anxiety has diminished enough for learning to take place. *When feelings are identified and acknowledged as important, anxiety decreases and teaching and learning can begin.* Examples for Julie include the following:
 - a. Be very specific about procedures such as fetal monitoring, assessment of deep tendon reflexes, measurement of vital signs, and care specific for magnesium sulfate therapy. Explain the reasons for these procedures, who will perform them, and how long they will be continued after birth.
 - b. Focus on Julie's present concerns; she cannot be future oriented at this time.
 - c. Speak slowly and calmly, give very short directions: "Turn on your side." "Breathe slowly."; do not ask Julie to make decisions.
 - d. Allow a friend or family member to remain with Julie, and instruct the person about the need for a low-stimulus environment.

Knowledge of procedures to be performed and the purpose of these procedures provides a sense of control that reduces anxiety. Perception is somewhat narrowed when anxiety is high. Brief instructions are easier for the anxious person to understand than long explanations.

Critical Thinking

1. What two potential complications cause the greatest concern for nurses who care for Julie?
2. Why do nurses not develop goals for these problems?
3. What are the nurses' responsibilities for these complications?

Answers

1. The most common complications that cause the greatest concern are magnesium toxicity and generalized seizures.
2. These are collaborative problems that require collaboration with physicians for management. The nurse does not independently manage magnesium toxicity or seizures.
3. The nurse must monitor for signs of these conditions, administer prescribed medications, observe and report Julie's response to the medications, and collaborate with the physicians to lessen the chance of these complications occurring.

EVALUATION: Julie discusses her feelings with the nurse and with her sister. She feels in control of her anxiety, as manifested by fewer signs of agitation and fewer physiologic signs (tachycardia, tachypnea) and by the ability to use relaxation techniques.

*Continued from p. 522.

maternal kidneys leads to diuresis as interstitial fluid is shifted into the vascular compartment and excreted.

Magnesium is administered by IV infusion, which allows for immediate onset of action and does not cause the discomfort associated with intramuscular administration. Magnesium is administered via a secondary line so that the medication can be discontinued at any time while the primary line remains functional. Two qualified nurses should check the orders to ensure that the ordered grams per hour of magnesium are infused and that the total volume when added to plain IV fluid totals the correct infusion volume ordered.

Although magnesium sulfate is not risk-free, the major advantage of magnesium is its long record of safety for mother and baby while preventing maternal seizures (AAP & ACOG, 2012; Dekker, 2011; Sibai, 2012). Fetal magnesium levels are nearly identical with those of the expectant mother. As a result, the fetal monitor tracing may show decreased fetal heart rate variability. No cumulative effect occurs, however, because the fetal kidneys excrete magnesium effectively.

The therapeutic serum level for magnesium is 4 to 8 mg/dL although it is elevated in terms of normal laboratory values. Adverse reactions to magnesium sulfate usually occur if the serum level becomes too high. The most important is CNS depression, including depression of the respiratory center. Magnesium is excreted solely by the kidneys, and the reduced urine output that often occurs in preeclampsia allows magnesium to accumulate to toxic levels in the woman. Frequent assessment of serum magnesium levels, deep tendon reflexes (Procedure 25-1), respiratory rate, and oxygen saturation can identify CNS depression before it progresses to respiratory depression or cardiac dysfunction. Monitoring urine output identifies oliguria that could allow magnesium to accumulate and reach excessive levels.

Intrapartum Management. Most seizures occur during labor or the first 24 hours after birth. The fetus and the mother must be monitored continuously to detect signs of decreased fetal oxygenation and imminent seizures. The woman should be kept in a lateral position to

DRUG GUIDE

MAGNESIUM SULFATE

Classification: Miscellaneous anticonvulsant.

Action: Decreases acetylcholine released by motor nerve impulses, thereby blocking neuromuscular transmission. Depresses the central nervous system (CNS) to act as an anticonvulsant; also decreases frequency and intensity of uterine contractions. Produces flushing and sweating because of reduced peripheral blood pressure.

Indications: Prevention and control of seizures in severe preeclampsia; prevention of uterine contractions in preterm labor.

Dosage and Route: A common intravenous (IV) administration protocol for preeclampsia includes a loading dose and a continuous infusion using a controlled infusion pump. The loading dose is 4 to 6 g of magnesium sulfate administered in 100 mL of IV fluid over 15 to 20 minutes. The continuing infusion to maintain control is 2 g/hr. Doses are individualized, as needed. Deep intramuscular injection is acceptable but is painful. A primary IV infusion with no medication is maintained if the magnesium must be discontinued.

Magnesium sulfate may also be administered in a similar dose profile to stop preterm labor contractions.

Absorption: Immediate onset after IV administration.

Excretion: Excreted by the kidneys.

Contraindications and Precautions: Contraindicated in persons with myocardial damage, heart block, myasthenia gravis, or impaired renal function. Magnesium toxicity, possibly related to incomplete renal drug excretion, may be evidenced by thirst, mental confusion, or a decrease in reflexes.

Adverse Reactions: Result from magnesium overdose and include flushing, sweating, hypotension, depressed deep tendon reflexes (DTRs), and CNS depression, including respiratory depression.

Nursing Implications: Monitor blood pressure closely during administration. Assess the woman for respiratory rate above 12 breaths per minute, presence of DTRs, and urinary output greater than 30 mL/hr before administering magnesium. Place resuscitation equipment (suction, oxygen) in the room. Keep calcium gluconate, which acts as an antidote to magnesium, in the room, along with syringes and needles.

promote circulation through the placenta, and efforts should focus on controlling pain that may cause agitation and precipitate seizures.

Oxytocin to stimulate uterine contractions and magnesium sulfate to prevent seizures are often administered simultaneously during labor when a woman has preeclampsia. The woman will have two secondary infusions in addition to her primary infusion line, one for oxytocin and one for magnesium. Antibiotics or other drugs may require additional lines. Multiple infusion pumps ensure that different medications and fluids are administered at the prescribed volume and dose. Equipment, IV lines, and IV sites should be checked carefully for correct placement and function.

Opiate analgesics or epidural analgesia may be administered to provide comfort and to reduce painful stimuli that could precipitate a seizure. However, some women with severe preeclampsia have coagulation abnormalities that may contraindicate use of epidural analgesia.

Continuous EFM identifies changes in fetal heart rate patterns that suggest compromise (see Chapter 14). Late decelerations, which are associated with reduced placental perfusion, or decreased variability, which are associated with reduced placental perfusion or magnesium use, is more likely to occur, but any other nonreassuring pattern may occur as well. Interventions are tailored to the nonreassuring fetal heart pattern identified, such as administering oxygen to the mother, stopping the oxytocin infusion, and altering other IV infusion rates as ordered.

A pediatrician, neonatologist, or neonatal nurse practitioner must be available to care for the newborn at birth. A neonatal resuscitation team is often called to the birth.

Postpartum Management. After birth, careful assessment of the mother's blood loss and signs of shock is essential because the hypovolemia caused by preeclampsia may be aggravated by blood loss during the delivery. Assessments for signs and symptoms of preeclampsia must be continued for at least 48 hours, and administration of magnesium along with its associated care usually is continued to prevent seizures for 24 hours.

Signs that the woman is recovering from preeclampsia include the following:

- Urinary output of 4 to 6 L/day, which causes a rapid reduction in edema and rapid weight loss

- Decreased protein in the urine
- Return of blood pressure to normal, usually within 2 weeks

Therapeutic Management of Eclampsia

Eclampsia is a potentially preventable extension of severe preeclampsia marked by one or more generalized seizures, at times occurring before the woman goes to the hospital. Early identification of preeclampsia in a pregnant woman allows intervention before the condition reaches the seizure stage in most cases. Generalized seizures usually start with facial twitching, followed by rigidity of the body. Tonic-clonic movements then begin and last for about 1 minute. Breathing stops during a generalized seizure but resumes with a long, noisy inhalation. The woman is temporarily in a coma and is unlikely to remember the seizure when she resumes consciousness. Transient fetal heart rate patterns such as bradycardia, loss of variability, or late decelerations may be nonreassuring. Fetal tachycardia may occur as the fetus compensates for the period of maternal apnea during the seizures. Eclampsia may occur during pregnancy or in the intrapartum or postpartum period.

Magnesium sulfate is the drug of choice to control eclamptic seizures. Other anticonvulsants or sedatives are not routinely given.

The woman's blood volume is often severely reduced in eclampsia, increasing the risk for poor placental perfusion. Fluid shifts from her intravascular space to the interstitial space, including the lungs, causing pulmonary edema and possibly heart failure as forward blood flow from the maternal heart is impeded. Renal blood flow is severely reduced, with oliguria (<30 mL/hr urine output) and possible renal failure. Cerebral hemorrhage may accompany eclampsia because of the high blood pressure and coagulation deficits. The woman's lungs should be auscultated at regular intervals, usually hourly. A pulse oximeter provides continuous readings of oxygen saturation. Furosemide (Lasix) may be administered if pulmonary edema develops. Administration of oxygen via a face mask at 8 to 10 L/min improves maternal and fetal oxygenation. Digitalis may be needed to strengthen contraction of the heart if circulatory failure results. Urine output should be assessed hourly, and if output drops below 30 mL/hr, renal failure should be suspected.

Because eclampsia stimulates uterine irritability, the woman should be monitored carefully for ruptured membranes, signs of labor, or

abruptio placentae. While the woman is unresponsive, she should be kept on her side to prevent aspiration and to improve placental circulation. The side rails should be padded and raised to prevent injury from a fall. When vital signs have stabilized, delivery of the fetus is considered.

Aspiration of gastric contents is a leading cause of maternal morbidity after an eclamptic seizure. Equipment to suction the woman's airway should be immediately available. After initial stabilization, the nurse should anticipate orders for chest radiography and arterial blood gas determination to identify aspiration.

HELLP syndrome is associated with severe preeclampsia. DIC is an added complication of unexpected bleeding that may occur with coagulation abnormalities of severe preeclampsia or eclampsia. Laboratory studies are performed at frequent intervals to identify both falling and recovering coagulation values as well as to identify hemolysis and elevated levels of liver enzymes.

Eclampsia stimulates uterine irritability. The woman should be monitored for ruptured membranes, signs of labor, and abruptio placentae. While the woman is **postictal** (the unresponsive state after a seizure), she should be kept on her side to prevent aspiration and improve placental circulation. The side rails should be raised to prevent a fall and possible injury. After maternal and fetal conditions have been stabilized, the fetus usually is delivered, either by induction of labor if the woman's cervix is favorable or by cesarean birth if she is farther from term.

APPLICATION OF THE NURSING PROCESS

■ Preeclampsia

Assessment

Nursing assessment is one of the most important components of successful management of preeclampsia. Careful assessment is the only way to determine whether the condition is responding to medical management or whether the disease is worsening. A one-to-one nurse-patient ratio is needed for the woman with severe pregnancy-induced hypertension.

Weigh the woman on admission and daily. Check vital signs, and auscultate the chest at least every 4 hours for moist breath sounds that indicate pulmonary edema. Assess the location and severity of edema at least every 4 hours. [Table 25-3](#) provides a guideline to describe edema. Insert an indwelling catheter to measure hourly urine output.

TABLE 25-3 ASSESSMENT OF EDEMA

CHARACTERISTICS	GRADE
Minimal edema of lower extremities	+1
Marked edema of lower extremities	+2
Edema of lower extremities, face, hands, and sacral area	+3
Generalized massive edema that includes ascites (accumulation of fluid in peritoneal cavity)	+4

Check the urine for protein every 4 hours. Apply an external electronic fetal monitor to identify changes in fetal heart rate, variability, or nonreassuring patterns. Consider maternal medications and their relationship to the fetal monitoring pattern.

Check reflexes such as brachial, radial, and patellar reflexes for hyperreflexia, which indicates cerebral irritability. Determine if clonus is present with hyperactive reflexes by dorsiflexing the woman's foot sharply and then releasing it while her knee is held in a flexed position. Clonus (rapidly alternating muscle contraction and relaxation) may occur when reflexes are hyperactive. If clonus is present, it should be reported to the physician. [Procedure 25-1](#) illustrates how to assess and rate DTRs.

Question the woman carefully about symptoms she may be experiencing, such as headache, visual disturbances, epigastric pain, nausea or vomiting, or a sudden increase in edema.

Detailed questions are needed to identify important symptoms. Ask targeted questions such as "Do you have a headache? Describe it for me." "Do you have any pain in the abdomen? Show me where it hurts, and describe it." "Do you see spots before your eyes? Flashes of light?" "Do you have double vision?" "Is your vision blurred?" "Does the light bother you?" "I see you have removed your rings. Did you do that because your hands were swollen? When did that happen?"

Assessments for Magnesium Toxicity

Obstetric units have protocols that address routine assessments and their frequency when magnesium is being administered. Reflexes may be slightly hypotonic but should not be absent at therapeutic levels of magnesium. Absent reflexes suggest CNS depression that precedes respiratory depression if magnesium levels are too high. Determining the respiratory rate and oxygen saturations by pulse oximetry identifies the adequacy of maternal respirations. Checking urine output identifies oliguria (<30 mL/hr), which may result in magnesium toxicity as the drug accumulates. Assess the woman's level of consciousness (alert, drowsy [expected], confused, oriented, disoriented). [Table 25-4](#) summarizes nursing assessments and their implications.

Psychosocial Assessment

The development of preeclampsia places added stress on the childbearing family. If the condition is mild and the gestation period is early, the woman may have been instructed to reduce her activity at home. She may be hospitalized, complicating care for other children. This creates anxiety about the condition of the fetus and that of the mother. Many families do not understand the seriousness of the disease. After all, the woman often feels well after its onset, especially if her preeclampsia does not advance rapidly. The possibility that a preterm birth may be necessary to reduce harm to mother and infant adds to the family's concerns about the outcome.

Explore how the family will function while the expectant mother is hospitalized. Determine how the woman is adapting to the "sick role" and the need of being dependent on others instead of functioning in her primary role. Ask how much support is available and who is willing to participate. Determine if referrals to manage loss of income are needed. Finally, determine the priority concerns of the family. See [Chapter 27, Preterm Labor \(p. 579\)](#), for additional information on home care.

Nursing Diagnosis

Analysis of the data collected can lead to both nursing diagnoses (see [Case Study 25-2](#)) and collaborative problems for potential complications. Both physician-prescribed and nurse-prescribed interventions are used to minimize the complications. Potential complications for

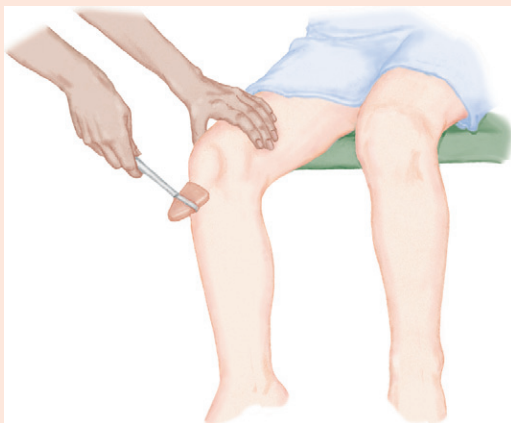

PROCEDURE 25-1 ASSESSING DEEP TENDON REFLEXES

PURPOSE: To identify exaggerated reflexes (hyperreflexia) or diminished reflexes (hyporeflexia)

1. You will need a reflex hammer to best assess the brachial and the patellar reflexes. The patellar reflex is less reliable if the woman has had epidural analgesia, and upper extremity reflexes should be assessed.
2. Support the woman's arm, and instruct her to let it go limp while it is being held so that the arm is totally relaxed and slightly flexed as you assess the brachial reflex. If you have difficulty identifying the correct tendon to tap, have the woman flex and extend her arm until you can feel it moving beneath your thumb. Have her fully relax her arm after you identify the tendon.
3. Place your thumb over the woman's tendon, as illustrated, to allow you to feel as well as see the tendon response when it is tapped. Strike your thumb with the small end of the reflex hammer. The normal response is slight flexion of the forearm.

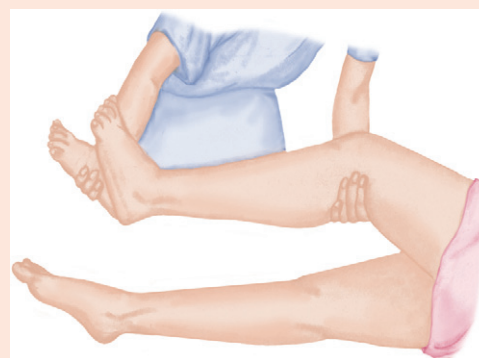

4. The patellar, or "knee-jerk," reflex can be assessed with the woman in two positions, sitting or lying. When the woman is sitting, allow her lower legs to dangle freely to flex the knee and stretch the tendons. If her patellar tendon is difficult to identify, have her flex and extend her lower legs slightly until you palpate the tendon. Strike the tendon directly with the reflex hammer just below the patella.

5. When the woman is supine, the weight of her leg must be supported to flex the knee and stretch the tendons. An accurate response requires that the limb be relaxed and the tendon partially stretched. Strike the partially stretched tendons just below the patella. Slight extension of the leg or a brief twitch of the quadriceps muscle of the thigh is the expected response.

6. To assess for clonus, the woman's lower leg should be supported, as illustrated, and the foot well dorsiflexed to stretch the tendon. Hold the flexion. If no clonus is present, no movement will be felt. When clonus (indicating hyperreflexia) is present, rapid rhythmic tapping motions of the foot are present.

**Deep Tendon Reflex Rating Scale***

0	Reflex absent
+1	Reflex present, hypoactive
+2	Normal reflex
+3	Brisker than average reflex
+4	Hyperactive reflex; clonus may also be present

*The rating scales of some facilities may omit the plus signs.

the woman with preeclampsia are eclamptic seizures and magnesium toxicity.

Planning

Patient-centered goals are inappropriate for the potential complications of eclamptic seizures and magnesium toxicity because the nurse cannot independently manage these conditions but must confer with physicians and use established protocols for treatment. For seizures, planning should reflect the nurse's responsibility to do the following:

- Perform actions that minimize the risk of seizures and prevent injury if seizures do occur.
 - Monitor for signs of impending seizures.
 - Consult with the physician if signs of impending seizures are observed.
 - Support the family of the woman with eclampsia.
- The following steps are necessary in cases of magnesium toxicity:
- Monitor for signs of magnesium toxicity.
 - Consult with the physician if signs of magnesium toxicity are observed.
 - Perform actions that reduce the possibility of magnesium toxicity.

TABLE 25-4 NURSING ASSESSMENTS FOR PREECLAMPSIA AND MAGNESIUM TOXICITY

ASSESSMENT	IMPLICATIONS
Daily weight	Provides estimate of fluid retention.
Blood pressure	Determines worsening condition, response to treatment, or both.
Respiratory rate, pulse oximeter readings	Drug therapy (magnesium sulfate) causes respiratory depression, and drug should be withheld and physician notified if respiratory rate is <12 breaths per minute or as specified by hospital policy. Pulse oximeter readings should be 95% or greater.
Breath sounds	Identifies sounds of excess moisture in lungs associated with pulmonary edema.
Deep tendon reflexes	Hyperreflexia indicates increased cerebral irritability and edema; hyporeflexia is associated with magnesium excess.
Edema	Provides estimation of interstitial fluid.
Urinary output	Output of at least 30 mL/hr indicates adequate perfusion of the kidneys (25 mL/hr is used by some authorities). Magnesium levels may become toxic if urinary output is inadequate.
Urine protein	Normal protein in random dipstick urine sample is negative or trace. Higher protein levels suggest greater leaking of protein secondary to glomerular damage with worsening preeclampsia. A 24-hr urine sample is most accurate for quantitative urine protein level.
Level of consciousness	Drowsiness or dulled sensorium indicates therapeutic effects of magnesium; no responsive behavior or muscle weakness is associated with magnesium excess.
Headache, epigastric pain, visual problems	These symptoms indicate increasing severity of condition caused by cerebral edema, vasospasm of cerebral vessels, and liver edema. Eclampsia may develop quickly.
Fetal heart rate and baseline variability	Rate should be between 110 and 160 beats per minute in a term fetus. Decreasing baseline variability may be caused by therapeutic magnesium level or by inadequate placental perfusion.
Laboratory data	Significant signs of increasing severity of disease are elevated serum creatinine level, elevated levels of liver enzymes, or decreased number of platelets (thrombocytopenia). Serum magnesium levels should be in therapeutic range designated by physician.

Interventions

Interventions for Seizures

Monitor for Signs of Impending Seizures. Signs of impending seizures include the following:

- Hyperreflexia, possibly accompanied by clonus
 - Increasing signs of cerebral irritability (headache, visual disturbances)
 - Epigastric or right upper quadrant pain, nausea, or vomiting
- None of these signs is a predictor of imminent seizure. Nurses must be alert for subtle changes and be prepared for seizures in all women with preeclampsia.

Initiate Preventive Measures. In the presence of cerebral irritability, generalized seizures may be precipitated by excessive visual or auditory stimuli. Nurses should reduce external stimuli by doing the following:

- Admit the woman to a room in the quietest section of the unit and keep the door to the room closed. Intense nursing observation is needed regardless of the specific room location that is available.
- Pad the door to reduce noise when the door must be opened and closed.
- Keep lights low and noise to a minimum. This may include blocking incoming telephone calls and turning the noises of the electronic monitors (fetal monitor, pulse oximeter, IV pump) as low as possible.
- Group nursing assessments and care to allow the woman periods of undisturbed quiet.
- Move carefully and calmly around the room and avoid bumping into the bed or startling the woman.
- Collaborate with the woman and her family to restrict visitors.

Prevent Seizure-Related Injury. Hard side rails should be padded and the bed kept in the lowest position with the wheels locked to prevent trauma during a seizure.

Oxygen and suction equipment should be assembled and ready to use to suction secretions and to provide oxygen if it is not already being

administered. Check equipment and connections at the beginning of each shift because sufficient time for setup will not exist if seizures occur.

A preeclampsia tray or box should be in the room. Typical contents include a medium plastic airway, an Ambu bag with mask, an ophthalmoscope, a tourniquet, a reflex hammer, and syringes and needles. Medications that should be readily available include magnesium sulfate, sodium bicarbonate, heparin, epinephrine, phenytoin, and calcium gluconate.

Protect the Woman and the Fetus during a Seizure. Nurses must protect the woman and the fetus during a seizure. The nurse's primary responsibilities are the following:

- Remain with the woman and press the emergency bell for assistance.
- If she is not on her side already, attempt to turn the woman onto her side when the tonic phase begins. A side-lying position permits greater circulation through the placenta and may prevent aspiration.
- Note the time and sequence of the seizure. Eclampsia is marked by a tonic-clonic seizure that may be preceded by facial twitching that lasts for a few seconds. A tonic contraction of the entire body is followed by the clonic phase, which may last about 1 minute.
- Insert an airway after the seizure, and suction the woman's mouth and nose to prevent aspiration. Administer oxygen by mask at 8 to 10 L/min to increase oxygenation of the placenta and all maternal body organs.
- Notify the physician that a seizure has occurred. This is an obstetric emergency that is associated with cerebral hemorrhage, abruptio placentae, severe fetal hypoxia, and death.
- Administer medications and prepare for additional medical interventions as directed by the physician.

These interventions are also relevant if the woman has a generalized seizure disorder that is unrelated to hypertension.

Provide Information and Support for the Family. Explain to the family what has happened without minimizing the seriousness of the

situation. A generalized seizure is frightening for anyone who witnesses it, and the family often is reassured when the nurse explains that the seizure lasts for only a few minutes and that the woman will be unconscious, then drowsy for some time afterward. Acknowledge that the seizure indicates worsening of the condition and that it will be necessary for the physician to determine future management, which may include delivery of the infant as soon as possible. Vaginal birth is preferred if the maternal and fetal conditions permit because of abnormalities in coagulation and other body systems.

Interventions for Magnesium Toxicity

Monitor for Signs of Magnesium Toxicity. Magnesium excess depresses the entire CNS, including the brainstem, which controls respirations and cardiac function, and the cerebrum, which controls memory, mental processes, and speech. Carbon dioxide accumulates if the respiratory rate is reduced, leading to respiratory acidosis and further CNS depression, which could culminate in respiratory arrest.

Signs of magnesium toxicity include the following:

- Respiratory rate of less than 12 breaths per minute (hospitals may specify a rate of less than 14 breaths per minute)
- Maternal pulse oximeter reading lower than 95%
- Absence of DTRs
- Sweating, flushing
- Altered sensorium (confused, lethargic, slurred speech, drowsy, disoriented)
- Hypotension
- Serum magnesium value above the therapeutic range of 4 to 8 mg/dL

Respond to Signs of Magnesium Toxicity. Discontinue magnesium if the respiratory rate is below 12 breaths per minute, a low pulse oximeter level (<95%) persists, or DTRs are absent. Additional magnesium will make the condition worse. Notify the physician of the woman's condition for additional orders. If the urinary output falls below 30 mL/hr, the physician is notified so that the drug's administration can be adjusted to maintain a therapeutic range.

Calcium opposes the effects of magnesium at the neuromuscular junction, and it should be readily available whenever magnesium is administered. Magnesium toxicity can be reversed by IV administration of 1 g (10 mL of 10% solution) of calcium gluconate at 1 mL/min.

Evaluation

Collect and compare data with established norms and then determine whether the data are within normal limits. For seizures, interventions are deemed successful if the following occur:

- Reflexes remain within normal limits (+1 to +3).
- The woman is free of visual disturbances, headache, and epigastric or right upper quadrant pain.
- The woman remains free of seizures or free of preventable injury if a seizure occurs.

For magnesium toxicity, determine whether respiratory rates remain at least 12 breaths per minute, deep tendon reflexes are present and not hyperactive, and maternal plasma levels of magnesium do not exceed the therapeutic range of 4 to 8 mg/dL.

HEMOLYSIS, ELEVATED LIVER ENZYMES, AND LOW PLATELETS (HELLP) SYNDROME

HELLP syndrome is a life-threatening occurrence, which complicates about 10% of pregnancies. Half of the women affected by HELLP also have severe preeclampsia, although hypertension may be absent. The normotensive woman should be considered to have preeclampsia if she has other signs of this complication. As in preeclampsia, HELLP syndrome may occur during the postpartum period (Cunningham et al., 2010; Dekker, 2011; Sibai, 2012).

Hemolysis is believed to occur as a result of the fragmentation and distortion of erythrocytes during passage through small damaged blood vessels. Liver enzyme levels increase when hepatic blood flow is obstructed by fibrin deposits. Hyperbilirubinemia and jaundice may occur as a result of liver impairment. Low platelet levels are caused by vascular damage resulting from vasospasm; platelets aggregate at sites of damage, resulting in thrombocytopenia, which increases the risk for bleeding, usually in the liver (Dekker, 2011; Sibai, 2012).

The prominent symptom of HELLP syndrome is pain in the right upper quadrant, the lower right chest, or the mid-epigastric area. There may also be tenderness because of liver distention. Additional signs and symptoms include nausea, vomiting, and severe edema. It is important to avoid traumatizing the liver by abdominal palpation and to use care in transporting the woman. A sudden increase in intraabdominal pressure, including that caused by a seizure, could lead to rupture of a subcapsular hematoma, resulting in internal bleeding and hypovolemic shock. Hepatic rupture can lead to fetal and maternal mortality (Dekker, 2011; Sibai, 2012).

Women with HELLP syndrome should be managed in a setting with intensive care facilities. Treatment includes magnesium sulfate to control seizures and hydralazine to control blood pressure. Fluid replacement is managed to avoid worsening the woman's reduced intravascular volume without giving her too much, as that could cause pulmonary edema or ascites. Cervical ripening with labor induction usually is done if the gestation is at least 34 weeks. Delivery may be delayed if the gestation is less than 34 weeks and the woman's condition is stable, and steroids can be administered to stimulate fetal lung maturation (Cunningham et al., 2010; Dekker, 2011; Sibai, 2012).

If the woman is near term and has a favorable cervix, induction of labor is preferred to avoid the bleeding and clotting complications that are more likely to occur with cesarean birth. Anesthesia choices are likely to be complicated by laryngeal edema (intubation difficulties), low platelet counts that may reduce safety of epidural block, and coagulation abnormalities that can impact safety of pudendal blocks. Cesarean birth may be necessary if the woman is far from term or has an unfavorable cervix.

CHRONIC HYPERTENSION

A diagnosis of chronic hypertension is made if evidence suggests that hypertension preceded the pregnancy or when a woman is hypertensive before 20 weeks of gestation. Ninety percent will be diagnosed with primary, or essential, hypertension. Chronic hypertension is seen most often in older women, in those who are obese, and in those with diabetes. Heredity, including race, plays a role in the development of chronic hypertension, which is more common in African-Americans at any age than in people of other races. Late childbearing and rising obesity rates add to the risks for women. However, hypertension may be secondary to another problem, such as renal disease or an autoimmune disorder (Centers for Disease Control & Prevention [CDC], 2012; Cunningham et al., 2010; Dekker, 2011; Sibai, 2012).

Because of the natural fall in blood pressure during early pregnancy, the woman's blood pressure may appear normal when she enters prenatal care. If she already is taking an antihypertensive drug, she usually continues this drug unless her blood pressure becomes low because of the vasodilators of pregnancy. If she is not taking an antihypertensive drug, she may be prescribed one if her diastolic pressure is consistently above 90 mm Hg.

The most common maternal hazard is the development of preeclampsia, which occurs in approximately 25% of pregnant women with chronic hypertension. New-onset proteinuria or a significant rise in preexisting proteinuria identifies the development of superimposed preeclampsia. The rise in blood pressure with preeclampsia is likely to be greater in these women (Cunningham et al., 2010; National Heart, Lung, and Blood Institute [NHLBI], 2001).

A dietitian should be consulted about the appropriate diet and weight gain because many of these women are obese and frequently have diabetes. Adequate intake of protein helps counteract the protein lost in urine. A reduced salt intake may be advised, unlike recommendations for the woman with preeclampsia alone. More frequent prenatal visits will be needed. Regular fetal surveillance by biophysical profile and kick counts (see Chapter 10) is the usual method for identification of poor growth patterns or signs that are nonreassuring, such as a decreasing amount of amniotic fluid.

Antihypertensive medications must be chosen carefully because they may reduce placental blood flow. Antihypertensive medication should be initiated if the diastolic pressure remains higher than 90 mm Hg in early pregnancy. Methyldopa (Aldomet) is the drug of choice because of its record of safety and effectiveness in pregnancy. Beta-blockers and calcium channel blockers also may be used if methyldopa is not effective, but their record of safety in pregnancy is less well established. Angiotensin-converting enzyme (ACE) inhibitors are not recommended in pregnancy but may be used in the postpartum period. Hydralazine is a vasodilator reserved for hypertensive crisis. Diuretics are avoided, if possible, because they may shrink the blood volume, which may already be reduced if preeclampsia exists with the chronic hypertension. If regular diuretics are needed, thiazides are considered safe for pregnancy (Cunningham, 2010; Dekker, 2011; Sibai, 2012).

24. Compare preeclampsia with chronic hypertension in terms of onset and treatment.

INCOMPATIBILITY BETWEEN MATERNAL AND FETAL BLOOD

Rh Incompatibility

Rhesus (Rh) factor incompatibility during pregnancy is possible only when two specific circumstances coexist: (1) the mother is Rh-negative (D-negative), and (2) the fetus is Rh-positive. For such a circumstance to occur, the father of the fetus must be Rh-positive. Rh incompatibility is a problem that affects the fetus; it causes no harm to the mother.

Rh-negative blood is an autosomal recessive trait, and a person must inherit the same gene from both parents to be Rh-negative. About 15% of the white population in the United States is Rh-negative. The incidence is lower in the African-American and Asian populations.

Pathophysiology

People who are Rh-positive have the Rh antigen on their RBCs, whereas people who are Rh-negative do not have the antigen. When blood from a person who is Rh-positive enters the bloodstream of a person who is Rh-negative, the body reacts as it would to any foreign substance: It develops antibodies to destroy the invading antigen. To destroy the Rh antigen, which exists as part of the RBC, the entire RBC must be destroyed. Exposure of the Rh-negative male or female to Rh-positive blood may occur unrelated to a pregnancy, such as during emergency blood transfusion. Destruction of Rh-positive cells occurs in the Rh-negative person after they have become sensitized to the Rh-positive antigens.

Theoretically, fetal and maternal blood do not mix during pregnancy. In reality, small placental accidents occur that allow a drop or two of fetal blood to enter the maternal circulation and initiate the production of antibodies to destroy the Rh-positive blood. Sensitization also can occur during a spontaneous or elective abortion or during antepartum procedures such as amniocentesis and chorionic villus sampling (Figure 25-9). A rapid immune response against Rh-positive blood occurs with an extensive fetal-maternal hemorrhage in complications such as placenta previa or abruptio placentae or with an uncomplicated birth.

Most exposure of maternal blood to fetal blood occurs during the third stage of labor, when active exchange of fetal and maternal blood may occur from damaged placental vessels. In this case the woman's first child is not usually affected because antibodies are formed after the birth of the infant. Subsequent Rh-positive fetuses may be affected, however, unless the mother receives RhoGAM to prevent antibody formation after the birth of each Rh-positive infant.

Fetal and Neonatal Implications

If antibodies to the Rh factor are present in the expectant mother's blood, they cross the placenta and destroy fetal erythrocytes. The fetus becomes deficient in RBCs, which are needed to transport oxygen to fetal tissue. As fetal RBCs are destroyed, fetal bilirubin levels increase (icterus gravis), which can lead to neurologic disease (**kernicterus** [staining of brain tissue], leading to bilirubin encephalopathy). This hemolytic process results in rapid production of erythroblasts (immature RBCs), which cannot carry oxygen. The entire syndrome is termed **erythroblastosis fetalis**. The fetus may become so anemic that generalized fetal edema (hydrops fetalis) results and can end in fetal congestive heart failure. Management of the infant born with erythroblastosis fetalis is discussed in Chapter 30.

Prenatal Assessment and Management

Women should have a blood test to determine blood type and Rh factor at the initial prenatal visit. Rh-negative women should have an indirect Coombs' test to determine whether they are sensitized (have developed antibodies) as a result of previous exposure to Rh-positive blood. If the indirect Coombs' test is negative, it is repeated at 28 weeks of gestation to identify if they have developed subsequent sensitization.

RhoGAM is administered to the unsensitized Rh-negative woman at 28 weeks of gestation to prevent sensitization, which may occur from small leaks of fetal blood across the placenta. RhoGAM is a commercial preparation of passive antibodies against Rh factor. It effectively prevents the formation of active antibodies against Rh-positive erythrocytes if a small amount of fetal Rh-positive blood enters the circulation of the Rh-negative mother during the remainder of the pregnancy. Administration of RhoGAM is repeated after birth if the woman delivers an Rh-positive infant.

FIG 25-9 The process of maternal sensitization to the Rh factor.

SAFETY ALERT

All unsensitized Rh-negative women should receive RhoGAM after abortion, ectopic pregnancy, chorionic villus sampling, amniocentesis, or birth of an Rh-positive infant. RhoGAM prevents the development of Rh antibodies that would result in destruction of fetal erythrocytes in subsequent pregnancies.

If the indirect Coombs' test result is positive, indicating maternal sensitization and the presence of antibodies, it is repeated at frequent intervals throughout the pregnancy to determine whether the antibody titer is rising. An increase in titer indicates that the process is continuing and that the fetus will be in jeopardy.

Amniocentesis may be performed to determine the Rh factor of the fetus and to evaluate change in the optical density, delta-OD (ΔOD), of amniotic fluid. If the fluid optical density remains low, it may indicate that the fetus is Rh-negative or that the fetus is Rh-positive but in no jeopardy. Deoxyribonucleic acid (DNA) analysis allows determination of the Rh factor of the fetus from amniotic fluid cells with high accuracy, reducing uncertainty when other testing results fall in the borderline zone. For example, if the optical density is slightly elevated but DNA testing shows the fetus to be Rh-negative, amniocentesis can eliminate the need to test further for Rh-related problems.

The optical density reflects the amount of bilirubin (that is, the residue of RBC destruction) present in the amniotic fluid. If the fluid optical density remains low, it may indicate that the fetus is Rh-positive but in no jeopardy. An elevated optical density suggests fetal jeopardy.

Ultrasound examination is used to noninvasively evaluate the condition of the fetus. Doppler studies allow evaluation of cardiac function and blood flow in fetal vessels. Generalized fetal edema, ascites, an enlarged heart, or hydramnios occurs when the fetus is very anemic. Percutaneous umbilical blood sampling (PUBS), or cordocentesis (see [Chapter 10](#)), allows invasive sampling of fetal blood from cord vessels to determine the degree of erythrocyte destruction. Because it is invasive, PUBS is reserved for the fetus thought to be significantly affected.

Intrauterine transfusion is the direct infusion of O-negative erythrocytes into the umbilical cord by percutaneous umbilical blood transfusion (see [Chapter 10](#)). The transfused erythrocytes must be compatible with maternal blood to avoid destruction by her antibodies. Whole blood is usually used to replace fetal serum proteins. Erythrocytes may also be transfused into the fetal abdominal cavity, where they are gradually absorbed into the circulation ([Figure 25-10](#)).

Postpartum Management

If the mother is Rh-negative, umbilical cord blood is taken at delivery to determine blood type, Rh factor, and antibody titer (direct Coombs' test) of the newborn. Rh-negative, unsensitized mothers who give birth to Rh-positive infants are given an intramuscular injection of RhoGAM within 72 hours after delivery. If RhoGAM is given to the mother in the first 72 hours after delivery of an Rh-positive infant, Rh antigens present in her blood are destroyed before she forms antibodies to the Rh factor. If the infant is Rh-negative, Rh antibody formation does not occur and RhoGAM is not necessary.

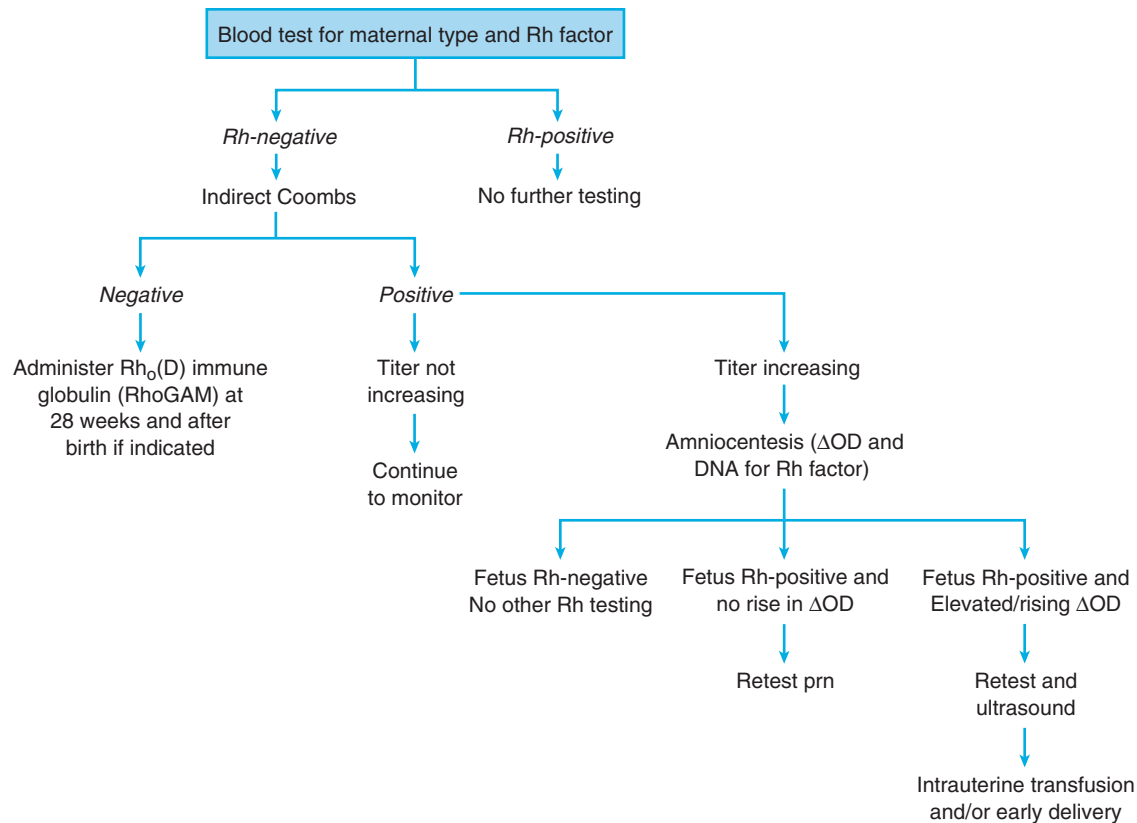

FIG 25-10 Sequence of assessments for Rh sensitization, as needed. Delta-OD (ΔOD), change in optical density of bilirubin.

DRUG GUIDE

RHO(D) IMMUNE GLOBULIN (RHOGAM, HYPRHO-D, GAMULIN RH)

Classification: Concentrated immunoglobulins directed toward the red blood cell (RBC) antigen Rho(D).

Action: Prevents production of anti-Rho(D) antibodies in Rh-negative women who have been exposed to Rh-positive blood by suppressing the immune reaction of the Rh-negative woman to the antigen in Rh-positive blood; prevents antibody response and thereby prevents hemolytic disease of the newborn in future Rh-positive pregnancies; used for both males and females who are Rh-negative but exposed to Rh-positive blood or for immune thrombocytopenic purpura (ITP).

Indications (Pregnancy Related): Administered to Rh-negative women who have been exposed to Rh-positive blood by doing the following:

1. Delivering an Rh-positive infant
2. Aborting an Rh-positive fetus
3. Undergoing chorionic villus sampling, amniocentesis, or intraabdominal trauma while carrying an Rh-positive fetus
4. Receiving inadvertent transfusion of Rh-positive blood

Dosage and Route: One *standard* dose (300 mcg) administered intramuscularly:

1. At 28 weeks of pregnancy and within 72 hours of delivery of a Rh-positive infant

2. Within 72 hours after termination of a pregnancy of 13 weeks or more of gestation

One *microdose* (50 mcg) within 72 hours after the termination of a pregnancy of less than 13 weeks of gestation.

Dose is calculated based on the volume of fetal-maternal hemorrhage or Rh-positive blood administered in transfusion accidents. A standard dose will protect against 30 mL of Rh-positive whole blood or 15 mL of packed RBCs (Weiner & Buhimschi, 2009).

Absorption: Well absorbed from intramuscular sites.

Excretion: Metabolism and excretion unknown.

Contraindications and Precautions: Women who are Rh-positive or women previously sensitized to Rho(D) should not receive Rho(D) immune globulin. It is used cautiously for women with previous hypersensitivity reactions to immune globulins.

Adverse Reactions: Local pain at intramuscular site, fever, or both.

Nursing Implications: Type and antibody screening of the mother's blood and cord blood type of the newborn must be performed to determine the need for the medication. The mother must be Rh-negative and negative for Rh antibodies. The newborn must be Rh-positive. If the fetal blood type after termination of pregnancy is uncertain, the medication should be administered. The newborn may have a weakly positive antibody test if the woman received Rho(D) immune globulin during pregnancy. The drug is administered to the mother, not the infant. The deltoid muscle is recommended for intramuscular administration.

Families often are concerned about the fetus, and nurses must be sensitive to cues that indicate that the family is anxious and must be able to offer honest reassurance. This is especially important if the woman is sensitized and fetal testing is necessary throughout pregnancy.

During labor, the nurse must carefully label the tube of cord blood obtained for analysis of the newborn's blood type and Rh factor. During the postpartum period, nurses are responsible for follow-up to determine whether RhoGAM is necessary and for administering the injection within the prescribed time.

ABO Incompatibility

ABO incompatibility occurs when the mother is blood type O and the fetus is blood type A, B, or AB. Types A, B, and AB blood contain a protein component (antigen) that is not present in type O blood.

People with type O blood develop anti-A or anti-B antibodies naturally as a result of exposure to antigens in the foods that they eat or to infection by gram-negative bacteria. As a result, some women with blood type O have developed high serum anti-A and anti-B antibody titers before pregnancy. The antibodies may be either immunoglobulin G (IgG) or IgM. When the woman becomes pregnant, the IgG antibodies cross the placental barrier and cause hemolysis of fetal RBCs. Although the first fetus can be affected, ABO incompatibility is less severe than Rh incompatibility because the primary antibodies of the ABO system are IgM, which do not readily cross the placenta.

No specific prenatal care is needed; however, the nurse must be aware of the possibility of ABO incompatibility. During the delivery, cord blood is taken to determine the blood type of the newborn and the antibody titer (direct Coombs' test). The newborn is carefully screened for jaundice, which indicates hyperbilirubinemia. See [Chapter 30](#) for medical and nursing management of hyperbilirubinemia in newborns.

PARENTS WANT TO KNOW

About Rh Incompatibility

What does it mean to be Rh-negative?

- Those who are Rh-negative lack a substance that is present in the red blood cells of those who are Rh-positive.

How can the expectant mother be Rh-negative and the fetus be Rh-positive?

- The fetus can inherit the Rh-positive factor from the father.

What does sensitization mean?

- *Sensitization* means that the Rh-negative person has been exposed to Rh-positive blood and has developed antibodies against the Rh factor.

Do the antibodies harm the woman?

- No, because she does not have the Rh factor.

Do Rh-positive men always father Rh-positive children?

- No. Rh-positive men who have an Rh-positive gene and an Rh-negative gene can father Rh-negative children. Two Rh-positive parents can conceive an Rh-negative fetus who inherits the Rh-negative gene from each parent.

Why is Rho(D) immune globulin (RhoGAM) necessary during pregnancy and after childbirth?

- RhoGAM prevents the development of Rh antibodies in the mother, which might be harmful to subsequent fetuses who are Rh-positive. Administering Rho(D) immune globulin during pregnancy to the mother who delivers an Rh-positive or Rh-negative infant is not harmful to the baby.

Why will the next fetus be jeopardized if RhoGAM is not administered?

- If RhoGAM is not administered when the newborn is Rh-positive, the woman may develop antibodies that cross the placental barrier and affect the next Rh-positive fetus.

25. Why do unsensitized Rh-negative expectant mothers receive RhoGAM during pregnancy and after an abortion, amniocentesis, and childbirth?
26. What are the effects on the fetus of maternal Rh sensitization?
27. Why is the first fetus sometimes affected if ABO incompatibility occurs? Why are the effects of ABO incompatibility milder than those of Rh sensitization?

SUMMARY CONCEPTS

- Spontaneous abortion is a leading cause of pregnancy loss. Treatment is aimed at preventing complications such as hypovolemic shock and infection and providing emotional support for the grieving mother and her family.
- The incidence of ectopic pregnancy is increasing in the United States as a result of pelvic inflammation associated with sexually transmitted diseases. The goals of therapeutic management are to prevent severe hemorrhage and to preserve the fallopian tube so that future fertility is retained.
- Management of gestational trophoblastic disease (hydatidiform mole) involves two phases: (1) evacuation of the molar pregnancy and (2) evaluation of serum beta-hCG levels monthly X 6, then every 2 to 3 months for 6 months until normal for three values. Pregnancy must be avoided during the follow-up because the normal rise of beta-hCG level in pregnancy would obscure evidence of choriocarcinoma.
- Disorders of the placenta (placenta previa and abruptio placentae) are responsible for hemorrhagic conditions of the last half of pregnancy. Either condition may result in maternal hemorrhage and fetal or maternal death.
- Disseminated intravascular coagulation is a life-threatening complication of missed abortion, abruptio placentae, and severe hypertension, in which procoagulation and anticoagulation factors are simultaneously activated. DIC may occur with problems unrelated to pregnancy.
- The cause of hyperemesis gravidarum remains unclear, but the goals of management are to prevent dehydration, malnutrition, excess weight loss, and electrolyte imbalance. Emotional support is an important responsibility of nurses, in addition to physical care.
- Classifications of hypertension during pregnancy include pre-eclampsia, eclampsia, gestational hypertension, chronic (preexisting or persistent) hypertension, and preeclampsia superimposed over existing chronic hypertension. The underlying process is generalized vasospasm, which decreases circulation to all organs of the body, including the placenta. Major maternal organs affected include the liver, kidneys, and brain.

Continued

SUMMARY CONCEPTS—cont'd

- Treatment of preeclampsia includes reduced activity, reduction of environmental stimuli, and administration of medications to prevent generalized seizures.
- Magnesium sulfate, used to prevent preeclampsia from progressing to generalized eclamptic seizures, may have adverse effects. The most serious of these is CNS depression, which includes depression of the respiratory center. Adverse effects such as respiratory depression or absent DTRs are more likely to occur if the blood level of magnesium rises over the therapeutic range.
- Nurses monitor the woman with preeclampsia to determine the effectiveness of medical therapy and to identify signs that her condition is worsening, such as increasing hyperreflexia. Nurses also control external stimuli and initiate measures to protect her in case of eclamptic seizures.
- Pregnant women who have chronic hypertension are at increased risk for preeclampsia and should be monitored for worsening

- hypertension, proteinuria, or generalized edema. Antihypertensive medication should be continued or initiated if diastolic blood pressure is consistently greater than 90 mm Hg.
- Rh incompatibility can occur if an Rh-negative woman conceives a child who is Rh-positive. As a result of exposure to the Rh-positive antigen, maternal antibodies may develop that cause hemolysis of fetal Rh-positive RBCs in subsequent pregnancies.
- Administration of RhoGAM prevents production of anti-Rh antibodies, thereby preventing destruction of Rh-positive red blood cells in subsequent pregnancies.
- ABO incompatibility usually occurs when the mother has type O blood and naturally occurring anti-A and anti-B antibodies, which cause hemolysis if the fetus's blood is not type O. ABO incompatibility may result in hyperbilirubinemia of the infant, but it usually presents no serious threat to the health of the child.

CHAPTER

26

Concurrent Disorders during Pregnancy

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the effects of pregnancy on glucose metabolism.
2. Discuss the effects and management of preexisting diabetes mellitus during pregnancy.
3. Explain the effects and management of gestational diabetes mellitus.
4. Describe the major effects of pregnancy on the woman who has heart disease and identify the goals of therapy.
5. Explain the maternal and fetal effects of specific anemias and the required management during pregnancy.
6. Identify the effects, management, and nursing considerations of specific preexisting conditions discussed in this chapter.
7. Discuss the maternal, fetal, and neonatal effects of the most common infections that may occur during pregnancy.

Pregnancy affects the care of women with a medical condition in two ways. First, pregnancy may alter the course of the disease. Second, the disease or its treatment may have unwanted effects on the pregnancy. Antepartum care must be adapted to include increased surveillance of the mother and the fetus. Also, some disorders that are mild or even subclinical in the pregnant woman can produce massive damage to the fetus. This chapter describes some common disorders that can cause significant fetal jeopardy.

DIABETES MELLITUS

Pathophysiology

Etiology

Diabetes mellitus is a complex disorder of carbohydrate metabolism caused primarily by a partial or complete lack of insulin secretion by the beta cells of the pancreas. Some cells, such as those in skeletal and cardiac muscles and adipose tissue, rely on insulin to carry glucose across the cell membranes. Without insulin, glucose accumulates in blood, resulting in hyperglycemia. The body attempts to dilute the glucose load by any means possible. The first strategy is to increase thirst (**polydipsia**), a classic symptom of diabetes mellitus. Next, fluid from the intracellular spaces is drawn into the vascular bed, resulting in dehydration at the cellular level but fluid volume excess in the

vascular compartment. The kidneys attempt to excrete large volumes of this fluid and the heavy solute load of glucose (**osmotic diuresis**). This excretion produces the second hallmark of diabetes, **polyuria**, as well as **glycosuria** (glucose in urine). Without glucose the cells starve, so weight loss occurs, even though the person ingests large amounts of food (**polyphagia**).

Because the body cannot metabolize glucose, it begins to metabolize protein and fat to meet energy needs. Metabolism of protein produces a negative nitrogen balance, and the metabolism of fat results in the buildup of ketone bodies (such as acetone, acetoacetic acid, or beta-hydroxybutyric acid) or **ketosis** (accumulation of acids in the body).

If the disease is not well controlled, serious complications may occur. Hypoglycemia or hyperglycemia can result if the amount of insulin does not match the diet. Fluctuating periods of hyperglycemia and hypoglycemia damage small blood vessels throughout the body. This damage can cause serious impairment, especially in the kidneys, eyes, and heart.

Effect of Pregnancy on Fuel Metabolism

To understand the relationship between diabetes mellitus and pregnancy, an understanding of the way pregnancy and diabetes alter the metabolism of food is necessary.

Early Pregnancy. Metabolic changes can be divided into those that occur early in pregnancy (from 1 to 20 weeks of gestation) and those that occur late in pregnancy (from 20 to 40 weeks of gestation). During early pregnancy, maternal metabolic rates and energy needs change little. During this time, however, insulin release in response to serum glucose levels accelerates. As a result, significant hypoglycemia may occur, particularly in women who experience the nausea, vomiting, and anorexia that often arise during the first weeks of pregnancy.

In an uncomplicated pregnancy, the availability of glucose and insulin, a **lipogenic** substance, favors the development and storage of fat during the first half of pregnancy. Accumulation of fat prepares the mother for the rise in energy use by the growing fetus during the second half of pregnancy.

Late Pregnancy. During the second half of pregnancy, when fetal growth accelerates, levels of placental hormones rise sharply. These hormones, particularly estrogen, progesterone, and human placental lactogen (hPL), create resistance to insulin in maternal cells. This resistance allows an abundant supply of glucose to be available for the fetus. However, the hormones have a **diabetogenic effect** in that they may leave the woman with insufficient insulin and episodes of hyperglycemia.

For most women, insulin resistance is not a problem. The pancreas responds by simply increasing the production of insulin. If the pancreas is unable to respond adequately, the woman will have periods of hyperglycemia.

The fetus continually draws nutrients such as glucose and amino acids from maternal blood during late pregnancy. The result is an earlier-than-normal switch from carbohydrate metabolism to **gluconeogenesis** (formation of glycogen from noncarbohydrate sources such as proteins and fat). Because the fetus uses many of the amino acids, the process becomes predominantly one of fat utilization. This process produces high levels of free fatty acids that further inhibit the uptake and oxidation of glucose, thus preserving glucose for use by the central nervous system (CNS) and for fetal needs. These metabolic changes are similar to those occurring during “accelerated starvation,” when fat is metabolized to meet many of the body’s energy needs.

Birth. Maintenance of normal maternal glucose levels is essential during birth to reduce neonatal hypoglycemia. Women with diabetes usually maintain their glucose testing and continue administration of doses of insulin the day before scheduled induction or cesarean birth. Women with an insulin pump continue using their pump through the night. After admission with nothing by mouth (NPO) after the prescribed time, their glucose level is checked and continuous infusion of insulin and glucose is started based on hourly glucose levels.

Postpartum Period. The need for additional insulin falls during the postpartum period. Breastfeeding is encouraged not only for the newborn’s benefit but also because the added calorie intake by the mother helps lower the amount of insulin needed in women with types 1 and 2 diabetes mellitus. The woman with gestational diabetes mellitus (GDM) usually needs no insulin after birth but the greater risk for later development of type 2 diabetes should be emphasized with teaching before discharge.

Classification

Diabetes that exists before pregnancy is classified as type 1 (insulin deficient) or type 2 (insulin resistant, with a relative deficiency of insulin to metabolize carbohydrate), according to whether the client requires the administration of insulin to prevent ketoacidosis. A third type is one in which any degree of glucose intolerance has its onset or first recognition during pregnancy. The term *gestational diabetes mellitus* refers to the onset of glucose intolerance during pregnancy.

BOX 26-1 CLASSIFICATION OF DIABETES MELLITUS

- **Type 1:** Insulin dependence. Onset in childhood or young adulthood. Involves autoimmune destruction of pancreatic beta cells. Prone to ketosis.
- **Type 2:** May be diet controlled or require insulin related to increasing insulin resistance. Usual onset after age 40 years. Associated with obesity that often occurs in young adults or children. Ketosis less likely to occur than in type 1 diabetes mellitus.
- **Gestational (GDM):** Onset of glucose intolerance first diagnosed during pregnancy. Two subgroups are GDM A₁ (diet control) and GDM A₂ (insulin control with diet).

Data from American Diabetes Association. (2011). Diagnosis and classification of diabetes mellitus. *Diabetes Care*, 34 (Suppl 1), S62–S69; Landon, M.B., Catalano, P.A., & Gabbe, S.G. (2012). Diabetes mellitus complicating pregnancy. In S.G. Gabbe, J.R. Niebyl, J.L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed., pp. 887–921). Philadelphia, PA: Saunders.

An additional classification of diabetes is sometimes used for descriptive purposes. The White classification describes the age at onset of diabetes, its duration based on the woman’s current age, and vascular complications such as retinopathy that are present. GDM descriptions in White’s classification include A-1 (diet controlled) and A-2 (diet and insulin controlled). Another classification for diabetes during pregnancy lists complications that may be found with type 1 or type 2 diabetes (retinopathy, nephropathy, coronary artery disease) and whether GDM is controlled by diet alone or also requires insulin to supplement diet control (Fraser & Farrell, 2011; Landon, Catalano, & Gabbe, 2012) (Box 26-1).

Incidence

Diabetes mellitus is a common medical condition that often affects pregnancy. About 90% to 95% of diagnoses in the total population are of type 2, whereas type 1 accounts for only 5% to 10% of those diagnosed. The pregnant woman may have preexisting diabetes (type 1 or type 2), or she may develop GDM during the course of pregnancy. The pregnant woman may have had undiagnosed type 2 diabetes that is discovered during pregnancy screening for GDM and remains during the postpartum period (Centers for Disease Control and Prevention [CDC], 2011b).

Up to 10% of all pregnancies are affected by GDM but the incidence varies from 1% to 14% among different ethnic groups, with higher rates in African-American, Hispanic or Latino, American-Indian, Asian-American, or Pacific Islanders. Women who have GDM in pregnancy have a 35% to 60% chance of developing diabetes in the next 10 to 20 years (American College of Obstetricians and Gynecologists [ACOG], 2010b; American Diabetes Association [ADA], 2011; CDC, 2011b).

Preexisting Diabetes Mellitus Maternal Effects

The course of pregnancy for women with diabetes mellitus has improved greatly as a result of new treatments and more effective methods of fetal surveillance. However, the incidence of complications affecting the mother and fetus remains higher than that experienced by women who do not have diabetes.

Diabetes can adversely affect a pregnant woman and her developing baby in several ways. During the first trimester, when major fetal organs are developing, the effects of the abnormal metabolic environment such as in hypoglycemia, hyperglycemia, and ketosis may lead to

TABLE 26-1 MAJOR EFFECTS OF DIABETES MELLITUS ON PREGNANCY

EFFECT	PROBABLE CAUSE
Increased Maternal Risks	
Hypertension; preeclampsia	Unknown but increased even without renal or vascular impairment
Urinary tract infections	Increased bacterial growth in nutrient-rich urine
Ketoacidosis (risk for mother and fetus)	Uncontrolled hyperglycemia or infection; most common in women with type 1 diabetes
Labor dystocia; cesarean birth; uterine atony with hemorrhage after birth	Hydramnios secondary to fetal osmotic diuresis caused by hyperglycemia; uterus is overstretched
Birth injury to maternal tissues (hematoma, lacerations)	Fetal macrosomia causing difficult birth
Increased Fetal and Neonatal Risks	
Congenital anomalies	Maternal hyperglycemia during organ formation in first trimester
Perinatal death	Poor placental perfusion because of maternal vascular impairment, primarily in woman with type 1 diabetes
Macrosomia (>4000 g)	Fetal hyperglycemia stimulating production of insulin to metabolize carbohydrates; excess nutrients transported to fetus
Intrauterine fetal growth restriction	Maternal vascular impairment
Preterm labor; premature rupture of membranes; preterm birth	Overdistention of uterus caused by hydramnios and large fetal size at preterm gestation
Birth injury	Large fetal size; shoulder dystocia or other difficult delivery
Hypoglycemia	Neonatal hyperinsulinemia after birth when maternal glucose is no longer available (but insulin production remains high)
Polycythemia	Fetal hypoxemia stimulating erythrocyte production
Hyperbilirubinemia	Breakdown of excessive red blood cells after birth
Hypocalcemia	Transfer of calcium abruptly stopped at birth; reduced fetal parathyroid function
Respiratory distress syndrome	Delayed maturation of fetal lungs; inadequate production of pulmonary surfactant; slowed absorption of fetal lung fluid

increased incidence of spontaneous abortion or major fetal malformations. Preeclampsia is two to three times more likely to develop if the woman has preexisting diabetes (ACOG, 2010b; Cunningham, Leveno, Bloom et al., 2010). The development of ketoacidosis is a threat to women with type 1 diabetes and is most often precipitated by infection or missed insulin doses. In addition, ketoacidosis may develop in these women at lower thresholds of hyperglycemia than those seen in non-pregnant individuals. Untreated ketoacidosis can progress to fetal and maternal death. Urinary tract infections are more common, possibly because of glucose in the urine, which provides a nutrient-rich medium for bacterial growth.

Other effects include **hydramnios**, which may result from fetal hyperglycemia and consequent fetal diuresis, and premature rupture of membranes, which may be caused by overdistention of the uterus by hydramnios or a large fetus. Problems that arise during labor and childbirth if the fetus has **macrosomia** (weighs more than 8.8 lb [4000 g]) may include a difficult labor, shoulder **dystocia** (delayed or difficult birth of fetal shoulders after the head is born), and consequent injury to the birth canal or the infant. Large fetal size also increases the likelihood of a cesarean birth and the risk of postpartum hemorrhage (Table 26-1).

Fetal Effects

Fetal and neonatal effects of preexisting diabetes depend on the timing and severity of maternal hyperglycemia and the degree of vascular impairment that has occurred.

Congenital Malformation. Fewer malformations occur if the woman maintains a normal blood glucose level before conception and throughout pregnancy. The risk for a major congenital malformation is two to six times higher than for the general population of pregnant

women if maternal hyperglycemia is not controlled during the first trimester. The most common major congenital malformations associated with preexisting diabetes are neural tube defects, **caudal regression syndrome** (failure of sacrum, lumbar spine, and lower extremities to develop), and cardiac defects (Fraser & Farrell, 2011; Landon, Catalano, & Gabbe, 2012; Moore & Catalano, 2009).

Variations in Fetal Size. Fetal growth is related to maternal vascular integrity. In women without vascular impairment, glucose and oxygen are easily transported to the fetus. If the mother is hyperglycemic, so is the fetus. Although maternal insulin does not cross the placental barrier, the fetus produces insulin by the tenth week of gestation. Fetal macrosomia results when elevated levels of blood glucose stimulate excessive production of fetal insulin, which acts as a powerful growth hormone. This is a major neonatal effect with consequent increase in the rate of cesarean birth or birth injury from shoulder dystocia.

Conversely, if vascular impairment occurs, placental perfusion may be decreased. Vascular impairment may be caused by complications of the diabetes such as vasoconstriction, which occurs in preeclampsia. Impaired placental perfusion decreases supplies of glucose and oxygen delivered to the fetus. As a result, the infant is likely to be small for gestational age (SGA). This condition is called **intrauterine growth restriction** (IUGR). Amniotic fluid may be reduced (oligohydramnios) as the fetus conserves oxygen for the heart and brain rather than providing normal circulation to the kidneys.

Neonatal Effects

The four major neonatal complications of preexisting diabetes are hypoglycemia, hypocalcemia, hyperbilirubinemia, and respiratory distress syndrome. Maintaining normal maternal levels of glucose reduces the incidence and severity of neonatal complications.

Hypoglycemia. The neonate is at higher risk for hypoglycemia because fetal insulin production would have been accelerated during pregnancy to metabolize the excessive glucose received from the mother. The constant stimulation of hyperglycemia leads to hyperplasia and hypertrophy of the islets of Langerhans in the fetal pancreas. When the maternal glucose supply is abruptly withdrawn at birth, the level of neonatal insulin exceeds the available glucose, and hypoglycemia develops rapidly.

Hypocalcemia. During the last half of pregnancy, large amounts of calcium are transported across the placenta from the mother to the fetus. At the time of birth, this transfer is abruptly stopped, leading to a dramatic decrease in the amount of total and ionized calcium. Hypocalcemia, defined as a calcium concentration less than 7 milligrams per deciliter (mg/dL), most often occurs within the first 3 days of life. It is associated with preterm birth and perinatal asphyxia, which are more likely to occur with poor maternal glycemic control (Landon, Catalano, & Gabbe, 2012; Moore & Catalano, 2009).

Hyperbilirubinemia. The fetus experiencing recurrent hypoxia compensates by production of additional erythrocytes (polycythemia) to carry oxygen supplied by the mother. After birth, the excess erythrocytes are broken down, which releases large amounts of bilirubin into the neonate's circulation. Prematurity, more likely in the infant of a woman with poor glycemic control, further reduces the infant's ability to metabolize and excrete excess bilirubin.

Respiratory Distress Syndrome. Fetal hyperinsulinemia retards cortisol production, which is necessary for the synthesis of surfactant needed to keep the newborn's alveoli open after birth, thereby increasing the risk for respiratory distress syndrome. Reduced lung fluid clearance and delayed thinning of lung connective tissue may also play a part, although some authors believe that gestational age is the primary determinant of respiratory distress syndrome occurring in an infant. Respiratory distress syndrome is more likely to occur if the mother's glycemic control is poor because wide fluctuations in her insulin and glucose levels have slowed lung maturation (Cunningham et al., 2010; Fraser & Farrell, 2011; Landon, Catalano, & Gabbe, 2012). Tests of fetal lung maturity will be done before elective delivery of the fetus by induction or scheduled cesarean birth if questions about maturity exist. (See Chapter 10 for additional information about tests of fetal lung maturity and Chapter 30 for information about care of the infant of a mother with diabetes.)

Complications in a mother and her fetus and then her newborn can be reduced if the mother maintains normal and stable blood glucose levels. The objective of the team providing treatment is to devise a plan that allows the woman to maintain a level as close to normal as possible.

1. What effects do the hormones of pregnancy have on maternal glucose metabolism?
2. What are the maternal effects of type 1 diabetes mellitus? What are possible fetal and neonatal effects?
3. How do insulin needs vary from the first trimester through the postpartum period?

Maternal Assessment

Preconception care is ideal in a woman with preexisting diabetes. If the woman can have her body in the best condition before conception, including diabetes management, pregnancy is likely to have fewer or less severe complications than if she started care after conception. When the woman with preconception care or preexisting diabetes initiates care, a thorough evaluation of her health status must be

completed. This evaluation includes history, physical examination, and laboratory tests.

History. A detailed history should include the onset and management of the diabetic condition. How long has she had the disease? How does she maintain normal blood glucose level? Is she familiar with ways to monitor blood glucose level and administer insulin? The degree of glycemic control before pregnancy is of particular interest. Effective management depends on her adherence to a plan of care. Therefore, her knowledge of how diabetes affects pregnancy and how pregnancy affects diabetes must be determined. The support person's knowledge also must be assessed, and specific learning needs should be identified. In addition, the woman's emotional status should be assessed to determine how she is coping with pregnancy superimposed on preexisting diabetes.

All women with diabetes should be seen by a qualified nurse educator for an individualized assessment to ensure that these women can monitor their blood glucose level accurately. Accurate readings depend on performing the test correctly and at the times recommended by her health care team. In addition to home monitoring of blood glucose level, the nurse must observe the woman's skill in mixing and self-administering insulin, using a sliding scale for added insulin or using an insulin pump if the drug will be given that way. Most pregnant women who need medication to reduce glucose levels take insulin via injection rather than as an oral agent, even if the oral agent had been effective in the woman with type 2 diabetes. An occasional woman refuses to take injectable medication for blood glucose control. Adverse fetal effects of oral agents have not been confirmed, but discontinuing their use during pregnancy is currently recommended.

Physical Examination. In addition to routine prenatal examination (see Chapter 7), specific efforts should be made to assess the effects of diabetes. A baseline electrocardiogram (ECG) should be obtained to determine cardiovascular status. Evaluation for retinopathy should be performed, with referral to an ophthalmologist, if necessary. The woman's weight and blood pressure must be monitored because of the increased risk for preeclampsia. Fundal height should be measured, noting any abnormal increase in size that may indicate macrosomia or hydramnios, which may occur as a result of diuresis by the hyperglycemic fetus. Fundal height less than expected for the gestation may indicate fetal growth restriction or sometimes intrauterine death.

Laboratory Tests. In addition to routine prenatal laboratory examinations (see Chapter 7), baseline renal function should be assessed with a 24-hour urine collection for total protein excretion and creatinine clearance. A random urine sample should be checked at each prenatal visit for possible urinary tract infections, which are common in women with diabetes. Urine also should be checked by using a dipstick for the presence of glucose, ketones, and protein. Thyroid function tests should be performed in the woman with preexisting diabetes because of her risk for coexisting thyroid disease.

Glycemic control should be evaluated on the basis of the level of glycosylated hemoglobin or hemoglobin A_{1c} (HbA_{1c}). With prolonged hyperglycemia, a percentage of hemoglobin will remain saturated with glucose for the life of the red blood cell (RBC). The glycosylated hemoglobin assay is an accurate measurement of the average glucose concentrations during the preceding 2 to 3 months. Unlike tests that reflect the amount of glucose in the plasma at that moment, the HbA_{1c} measurement is not affected by recent intake or restriction of food.

Fetal Surveillance

Because of the increased risk for congenital anomalies or fetal death, surveillance should begin early for women with preexisting diabetes,

ideally with preconception care, to bring her diabetes into the best control. Testing for anomalies includes multiple-marker screening to identify possible neural tube or other open defects and for possible chromosome abnormalities. Testing also includes performing ultrasonography and fetal echocardiography at 20 to 22 weeks of gestation to determine the integrity of the fetal body and cardiac structure (ACOG, 2010b, 2012c; Cunningham et al., 2010; Fraser & Farrell, 2011; Landon, Catalano, & Gabbe, 2012).

During the third trimester, the goal of fetal surveillance is to identify markers that suggest a worsening intrauterine environment with a higher probability of fetal death. Surveillance may include maternal assessment of fetal movement (“kick counts”), biophysical profiles, nonstress tests, and contraction stress tests. Ultrasonography is also used to document fetal growth rates. Doppler velocimetry may identify whether vascular complications exist or if hypertension develops. See Chapter 10 for a description of fetal surveillance methods.

Therapeutic Management

The goals of therapeutic management for a pregnant woman with diabetes are to (1) maintain normal blood glucose levels, (2) facilitate the birth of a healthy baby, and (3) avoid accelerated impairment of blood vessels and other major organs. To achieve this outcome, an intensive, team approach to care is required.

Members of the team often include a diabetologist, who assists in regulation of maternal blood glucose level; an obstetrician, who monitors the mother and fetus and determines the optimal time for birth; a registered dietitian (RD) or registered dietary technician (DTR), who provides a balanced meal plan; and a diabetes educator, often a specialized nurse, who provides ongoing education and support as the therapy changes throughout pregnancy. The team is completed by a neonatologist, who will care for the newborn; the family physician; and the pediatrician, who will provide ongoing care for the infant and the mother. A maternal-fetal medicine specialist (**perinatologist**) and support staff may be added if multiple fetal surveillance procedures are needed.

Preconception Care. Ideally, care should begin before conception. If diabetes exists before pregnancy, both prospective parents should participate in care sessions to learn more about the following measures that need to be taken by the health care team:

- Establishing the optimal time to undertake pregnancy, based on maintenance of normal maternal blood glucose levels, to reduce the risk for major fetal malformations
- Identifying if diabetes complications exist in other organ systems
- Determining the degree of glycemic control based on client records or laboratory studies
- Instructing a woman about how to use a glucometer for blood glucose level measurement and having the woman demonstrate a correct technique
- Having the woman take a daily prenatal vitamin that contains 400 mcg (micrograms) (0.4 mg) of folic acid. A dose of 4 mg per day is recommended for the woman who had a previous child with a neural tube defect.

Diet. Diet recommendations are individualized during pregnancy in a woman with diabetes. The average recommended caloric intake for the pregnant woman with diabetes who is of normal weight is 30 kilocalories per kilogram of body weight per day (kcal/kg/day). Approximately 40% to 45% of the calories should be from carbohydrates, 12% to 20% from protein (about 60 g), and up to 40% from fat. Caloric intake should be distributed among three meals and two or more snacks. The bedtime snack should include a complex carbohydrate and a protein. Women who are overweight or underweight usually have lower or higher caloric goals.

Self-Monitoring of Blood Glucose Level. The best frequency for self-monitoring of blood glucose (SMBG) level of capillary blood has not yet been established. One common testing regimen requires obtaining fasting and 2-hour postprandial levels. Another includes testing six times per day: a fasting capillary glucose level, 1 to 2 hours after breakfast, before and after lunch, before dinner, and at bedtime. Normal fasting and postprandial glucose levels have been associated with better outcomes, including a lower risk for macrosomia, neonatal hypoglycemia, and labor dystocia that results in cesarean birth. Preprandial glucose levels may be needed for smoother control if the glucose level is difficult to control. In addition to regular monitoring, the woman should also perform a glucose test whenever she experiences symptoms of hypoglycemia. The woman should record all test results on a log sheet for review by the health care provider at each visit. Instruments for SMBG level have a memory to provide accurate recall of times and glucose levels and to verify accuracy of log sheet entries (ACOG, 2010b).

Insulin Therapy. The need to maintain rigorous control of maternal metabolism during pregnancy requires more frequent doses of insulin than usual. Most treatment regimens rely on three daily injections, with a combination of short-acting (regular) insulin and intermediate-acting (neutral protamine Hagedorn [NPH]) insulin given before breakfast, regular insulin before dinner, and NPH insulin at bedtime. Lispro and aspart (Humalog and NovoLog, respectively) insulins act rapidly and should be injected just before a meal. Rapid-acting insulins have been shown to control postprandial hyperglycemia with less between-meal hypoglycemia (Landon, Catalano, & Gabbe, 2012). Because placental hormones cause insulin needs to change throughout pregnancy, insulin coverage will need to be adjusted as pregnancy progresses.

First Trimester. Insulin needs generally decline during the first trimester because the secretion of placental hormones antagonistic to insulin remains low. The woman also may experience nausea, vomiting, and anorexia, which results in decreased intake of food; therefore, the woman requires less insulin. In addition, the fetus receives its share of glucose, which reduces maternal plasma glucose levels and decreases the need for maternal insulin.

Second and Third Trimesters. Insulin needs increase markedly during the second and third trimesters when placental hormones, which initiate maternal resistance to the effects of insulin, reach their peak. In addition, the nausea of early pregnancy usually resolves, and the diet includes additional calories per day to meet the increased metabolic demands of pregnancy.

During Labor. Maintenance of tight maternal glucose control during birth is desirable to reduce neonatal hypoglycemia. Continuous infusion of a regular insulin solution combined with a separate intravenous (IV) solution containing glucose, such as 5% dextrose in Ringer’s lactate, allows titration to maintain blood glucose levels between 80 and 110 mg/dL or according to facility policy. The insulin solution is raised, lowered, or discontinued to maintain euglycemia based on hourly capillary blood glucose levels. If blood glucose levels remain too high, the insulin infusion is adjusted, and the primary IV infusion is changed to one without glucose (Cunningham et al., 2010; Pagana & Pagana, 2011).

Women with type 2 or GDM that has been controlled by diet during pregnancy can usually maintain normal glucose levels during labor if glucose-bearing IV solutions are avoided (Cunningham et al., 2010; Landon, Catalano, & Gabbe, 2012).

Postpartum Period. Insulin needs should decline rapidly after the delivery of the placenta and abrupt cessation of placental hormones. However, blood glucose levels should be monitored at least four times daily so that the insulin dose can be adjusted to meet

individual needs. Women with type 1 diabetes usually return to their prepregnancy dosages. Women with type 2 diabetes are monitored, as ordered, and insulin is ordered only if needed.

Oral Therapy. Although insulin remains the only drug widely accepted for treatment of diabetes during pregnancy because it does not cross the placenta, oral agents are being studied more closely for GDM treatment. Landon, Catalano, and Gabbe (2012) summarized recent surveys of glyburide versus insulin treatment for GDM:

- Maternal fasting and postpartum glucose levels were improved with glyburide.
- Glyburide failure rates to control GDM glucose level were 15% to 20%.
- Glyburide failure rates are higher in women with earlier diagnosis of GDM.
- There is no difference in newborn outcomes.
- Significant cost savings have been achieved with glyburide treatment.

Timing of Delivery. If possible, the pregnancy is allowed to progress to 39 weeks or later to allow the fetal lungs to mature, reducing the risk for neonatal respiratory distress syndrome. With evidence of fetal compromise, such as nonreassuring biophysical profile or reduced amniotic fluid, delivery may be required. If delivery before completion of 38 weeks is needed for non-emergency reasons, amniocentesis to determine fetal lung maturity is often performed because lung maturation may be slower than in nondiabetic pregnancies.

Gestational Diabetes Mellitus

Risk Factors

GDM is a carbohydrate intolerance of variable severity that develops or is first recognized during pregnancy. Some women diagnosed with gestational diabetes may actually have unrecognized type 2 diabetes. GDM is an added risk factor that a woman will develop type 2 diabetes later in life, often well after she has finished bearing children. Factors such as obesity, inactivity, abnormal cholesterol levels, vascular disease, or family members with type 2 diabetes further increase a woman's risk to develop type 2 diabetes (ACOG, 2010a; ADA, 2011; CDC, 2011b).

Diagnosis begins with history taking to identify the woman at risk to develop gestational diabetes. Factors known to increase the risk include the following (National Institutes of Health [NIH]: National Diabetes Information Clearinghouse [NDIC], 2011):

- Overweight (body mass index [BMI] ≥ 25 to 25.9) or obesity (BMI ≥ 30 or morbidly obese (BMI ≥ 40 or higher)
- Maternal age older than 25 years
- Previous birth outcome often associated with GDM (neonatal macrosomia, maternal hypertension, infant with unexplained congenital anomalies, previous fetal death)
- Gestational diabetes in previous pregnancy
- History of abnormal glucose tolerance
- History of diabetes in a close (first-degree) relative
- Member of a high-risk ethnic group (African-American, Hispanic or Latino, American Indian, Asian American, or Pacific Islanders)

Women with any of these factors should be screened for type 2 or gestational diabetes at the first prenatal visit (ACOG, 2010a; ADA, 2011; Landon, Catalano, & Gabbe, 2012).

Identifying Gestational Diabetes Mellitus

All pregnant women should be screened by identification of a history or risk factors that are consistent for type 2 diabetes or GDM or by blood glucose testing. Low-risk women include those with no risk factors listed previously. Low-risk women often have the basic glucose challenge screening test (GCT).

Screening

Glucose Challenge Test. A GCT is administered between 24 and 28 weeks of gestation, often to both low- and high-risk antepartum patients. An oral glucose tolerance test (OGTT) may be used as the initial test if a woman is at high risk for GDM, but the test is more likely to be used for diagnosis following abnormally high GCT results.

Fasting is not necessary for a GCT, and the woman is not required to follow any pretest dietary instructions. The woman should ingest 50 g of oral glucose solution. A blood sample is taken 1 hour later. If the blood glucose concentration is 140 mg/dL or greater, a 3-hour oral glucose tolerance test is recommended. Some practitioners use a lower cutoff of 130 or 135 mg/dL to identify more women at risk (ACOG, 2010a; Fraser & Farrell, 2011; Landon, Catalano, & Gabbe, 2012).

Oral Glucose Tolerance Test. The OGTT is the gold standard for diagnosing diabetes, but it is a more complex test. The woman must fast from midnight on the day of the test. After a fasting plasma glucose level is determined, the woman should ingest 100 g of oral glucose solution. Plasma glucose levels are then determined at 1, 2, and 3 hours. GDM is the diagnosis if the fasting blood glucose level is abnormal or if two or more of the following values occur on the OGTT (Fraser & Farrell, 2011; Landon, Catalano, & Gabbe, 2012; NIH: NDIC, 2011):

- Fasting, greater than 95 mg/dL
- 1 hour, greater than 180 mg/dL
- 2 hours, greater than 155 mg/dL
- 3 hours, greater than 140 mg/dL

Maternal, Fetal, and Neonatal Effects

With a few important exceptions, the effects of GDM are similar to those associated with preexisting diabetes. The exceptions are that GDM is not associated with an increased risk for maternal ketoacidosis or spontaneous abortion. Because GDM develops after the first trimester, the critical period of major fetal organ development (organogenesis), it usually is not associated with an increase in major congenital malformations. Nevertheless, poorly controlled GDM, characterized by maternal hyperglycemia during the third trimester, is associated with increased neonatal morbidity and mortality. The major fetal complications are macrosomia, leading to birth injuries or cesarean birth, and neonatal hypoglycemia. Other problems such as hypocalcemia, hyperbilirubinemia, and respiratory distress also may occur. Breast-feeding may reduce later development of type 2 diabetes in the infant (Cunningham et al., 2010; Fraser & Farrell, 2011; Landon, Catalano, & Gabbe, 2012). (See Table 26-1 for a summary of maternal, fetal, and neonatal effects of diabetes mellitus and their probable causes.)

Therapeutic Management

Diet. Ideally, a registered dietitian, registered dietary technician, or diabetes educator determines the dietary needs of the woman with GDM. The diet should provide the calories and nutrients needed for maternal and fetal health, result in euglycemia, avoid ketosis, and promote appropriate weight gain. Calories should be distributed in a way similar to that for preexisting diabetes. Simple sugars, found in concentrated sweets, should be eliminated from the diet. Based on a nonobese prepregnancy weight, an average of 30 kcal/kg/day is recommended. Calorie restriction to 25 kcal/kg each day may be recommended for women who are obese. These may be prescribed a diet with a smaller percentage of carbohydrates than that for women of normal weight to limit hyperglycemia. Carbohydrates at breakfast may be limited to 30 g during pregnancy because of increased levels of cortisol and growth hormones at that time of day. Protein foods at breakfast help satisfy early morning hunger. An evening snack is usually needed to prevent ketosis at night. Calories should be divided among three meals and at least three snacks (Franz, 2012).

CASE STUDY 26-1 NURSING CARE PLAN*

ASSESSMENT: Kathy is a 24-year-old primigravida at 9 weeks of gestation. Today is her first prenatal visit. She was diagnosed with type 1 diabetes mellitus 6 years ago. She has been on a daily regimen of insulin and is comfortable with insulin administration and blood glucose monitoring. She says she experiences daily nausea and vomiting, usually in the first 3 hours of the morning. Kathy states that she is concerned because she is not eating as much as she did before becoming pregnant. She also reveals that she had sometimes “binged” on food before becoming pregnant and did not always monitor her blood glucose level as often as she should have. She does not see why her blood glucose level has to be watched so carefully.

NURSING DIAGNOSIS: Readiness for enhanced knowledge.

EXPECTED OUTCOMES: Kathy will:

1. Describe predicted changes in insulin needs throughout pregnancy.
2. Follow prescribed schedule of blood glucose monitoring, insulin administration, diet, and exercise.
3. Describe the importance of frequent fetal surveillance and follow the prescribed prenatal schedule.

INTERVENTIONS AND RATIONALES

1. Reduce barriers to learning *because motivation and readiness to learn are essential for permanent learning to occur.*
 - a. Allow Kathy to express emotions and concerns before teaching.
 - b. Examine her beliefs and past experiences related to diabetes.
 - c. Assess readiness to learn, based on interest, attention, and participation in scheduled learning sessions *because Kathy will learn only if she sees the value of the information.*
2. Teach Kathy about the predicted changes in diabetes management during pregnancy:
 - a. Explain the importance of blood glucose testing; Kathy will need less insulin because of the nausea and vomiting occurring in the first trimester.
 - b. Emphasize that she will probably need more insulin as the second and third trimesters progress because of the effects of the placental hormones.

Insulin requirements often fall immediately after birth but will reach longer-term levels after the immediate postdelivery period.

- c. Describe the importance of following the prescribed diet and exercise regimen to maintain normal blood glucose levels as the pregnancy progresses.

Behaviors change when learning occurs. Understanding how insulin needs change throughout pregnancy, labor, and the postpartum period increases the likelihood that Kathy will follow the recommended regimen.
3. Inform Kathy about specific fetal surveillance techniques recommended during pregnancy (serial nonstress tests, contraction stress tests, biophysical profiles, kick counts, ultrasound examinations), and explain the importance of the tests. Reinforce or clarify medical explanations.

Some frequently ordered tests are time consuming and expensive, and others are simple. The woman is more likely to comply if she understands the importance of monitoring the fetal condition at frequent intervals.
4. Allow time for Kathy to focus on her feelings and concerns at each teaching session; offer praise and encouragement for her adherence to the prescribed regimen. *Motivation to comply with the regimen is strengthened by praise and the awareness that the woman’s feelings are important.*
5. Explain in simple, positive terms the advantages to the fetus of maintaining a normal maternal blood glucose level. These advantages include an optimal pattern of growth, the increased likelihood that the baby will be born near term and have fewer complications associated with prematurity. *Kathy’s knowledge that her feelings are common to most women may provide some relief from anxiety.*
6. Review the recommended plan for diet and exercise during pregnancy, and determine whether Kathy knows the importance of these factors in her care. *Maintenance of normal blood glucose level depends on coordinating the amount of food, insulin, and exercise. If any of these factors are altered, the others must also be altered to prevent hypoglycemia or hyperglycemia.*

EVALUATION: Kathy verbalizes her understanding of changing insulin needs and the importance of glucose monitoring. Kathy states that she has better control of the diabetes and plans to comply with the recommended schedule of fetal surveillance, diet, and exercise.

*Continues on p. 544.

Exercise. Research results have been mixed about whether exercise reduces the need for insulin in the woman with GDM. Nevertheless, exercise and an active lifestyle can improve cardiorespiratory fitness. A graduated physical exercise program should be recommended by a physician, taking into account each woman’s risk factors, but exercise has been shown to be safe for women with GDM (ACOG, 2010b; Franz, 2012).

Blood Glucose Monitoring. Blood glucose levels should be evaluated to determine whether levels are normal. A common method is measurement of fasting blood glucose level (no food for the previous 4 hours) and postprandial blood glucose level (2 hours after each meal). If fasting capillary blood glucose levels repeatedly exceed 95 mg/dL or postprandial values exceed 120 mg/dL, insulin therapy is started. Additional tests for glucose levels may be performed, as needed.

Fetal Surveillance. Testing to identify fetal compromise may begin as early as 28 weeks of gestation if the woman has poor glycemic control or by 34 weeks of gestation in lower-risk women with GDM. The surveillance testing often includes “kick counts,” ultrasonography for fetal growth and amniotic fluid volume, biophysical profile, nonstress test, contraction stress test, or amniocentesis for fetal lung maturity (Landon, Catalano, & Gabbe, 2012).

Nursing Considerations

The care of a pregnant woman with diabetes mellitus focuses primarily on maintaining normal blood glucose levels. As stated earlier, this maintenance involves a rather rigid schedule of controlling the diet, performing blood glucose tests, administering insulin, and performing regular fetal surveillance. Some women respond calmly to the intense medical supervision. Others respond with anxiety, fear, denial, or anger and may feel inadequate or unable to control the diabetes to the degree expected by the health care team. These feelings may not be shared spontaneously, but they may affect the woman’s ability to achieve the desired outcomes. Also, nurses should remember to provide for normal pregnancy care in addition to monitoring the pregnant woman’s diabetes. Fleming and Corbett (2010) identified evidence-based and theory-based strategies that a nurse might use both before and during pregnancy.

Increasing Effective Communication. A woman often does not volunteer information about her feelings and concerns, especially if she has negative feelings about her care. In addition, the woman and the nurse both may be unaware of any misunderstanding or conflict regarding the plan of care. Nurses must ask specifically about the feelings and concerns the woman and her family have about the pregnancy.

CRITICAL THINKING EXERCISE 26-1

A 28-year-old primigravida is diagnosed with gestational diabetes in her 30th week of pregnancy. The health care team provides her with a diet and exercise regimen and tells her that she will need weekly tests to monitor her condition and that of the fetus. Although she accepts the information without comment, she does not keep the next scheduled appointment.

Questions

1. What assumptions has the health care team made?
2. What could the team have done to improve the woman's compliance with the recommendations?

The woman is located and agrees to return to the clinic for follow-up care. She states she does not "see what all the fuss is about." She understands she may have a large baby but states that her mother had a 10-lb baby who did just fine. She wonders if the weekly tests are necessary and if they could harm the baby.

Questions

3. How can the nurse respond to the woman's comments about having a large baby without frightening her?
4. How can the nurse explain the need for weekly nonstress tests or biophysical profiles?

Broad opening questions such as "What are your major concerns?" and "How do you feel about the plan of care?" are helpful. These should be followed by more specific questions such as "How do you feel about the fetal testing?" and "What would you like to change about the diet?" The woman's responses may provide valuable information about her emotional response to the care plan. One woman remarked, "I can tell you one thing, I don't feel like a person. I feel like an incubator, a faulty incubator." Another woman who had a difficult time achieving the desired blood glucose level said, "I feel as though my whole life has been taken over by diabetes. I'm tired of feeling like a sick person."

The nurse must be an active listener and allow time for the woman and her family to express concerns and feelings. The nurse must convey acceptance of both negative feelings and positive feelings that are expressed. Many women are reassured to hear that their feelings of stress or anger are normal and learn that the health care team understands those feelings. Sharing of emotions will help her avoid or diminish unnecessary guilt, anxiety, and frustration and thus promotes positive feelings about her ability to participate successfully in her plan of care.

Most women benefit from praise when diabetes control is well maintained. They feel competent and trusted by the health care team and are motivated to continue their efforts.

Providing Opportunities for Control. Allowing the woman to make as many decisions as possible increases her sense of being in control. For instance, she can select foods from the exchange list that provide the necessary nutrients but still allow her some choice. A dietitian or dietary technician should be consulted if the list does not include foods she likes or that suit her ethnic or cultural preferences. A regular schedule of exercise and sleep that helps keep the blood glucose level under control is important. The woman can develop the best schedule for rest and exercise that suits her lifestyle. Nurses should allow as much flexibility as possible when scheduling stressful events such as fetal monitoring tests and amniocentesis.

Some women resent being "treated as though ill," even though their diabetes control is excellent. These women may be capable of making

more decisions regarding their care during pregnancy, but they need the support of an understanding team to do this.

Providing Normal Pregnancy Care. Some women express a need for more attention to the normal aspects of their pregnancies. This can be overlooked because of the intense focus on preventing complications that can occur with diabetes. Women with diabetes also experience discomforts such as morning sickness, fatigue, backache, and difficulty sleeping that women without diabetes experience during pregnancy. The nurse caring for women with diabetes should therefore provide the usual education and counseling regarding pregnancy.

5. How does GDM compare with type 1 diabetes mellitus in terms of onset and treatment?
6. What is the difference between GCT and OGTT?
7. How do the maternal, fetal, and neonatal effects of gestational diabetes differ from those of preexisting diabetes?

APPLICATION OF THE NURSING PROCESS**The Pregnant Woman with Diabetes Mellitus****Assessment**

Determine how well the woman understands the prescribed management and how the family plans to carry out the recommended regimen. She may be newly diagnosed and have no experience in the necessary skills and procedures. The woman who had diabetes before becoming pregnant may be skilled in monitoring glucose level and administering insulin. However, the woman with preexisting diabetes may have no knowledge of how diabetes can affect pregnancy or how pregnancy can affect diabetes. She may have been using premixed insulin exclusively and now must begin mixing insulins of different types. A woman with type 2 diabetes may have taken only oral medication and now must learn to mix and inject insulin.

To determine whether the pregnant woman's techniques are accurate, ask her to demonstrate how she monitors blood glucose level and observe as she mixes and injects insulins if she has done that. Verify that she and her family are aware of the need to select appropriate sites and injection techniques that prevent insulin leakage.

Although diet is prescribed by a dietitian or diabetes educator, the nurse should assess how well the family understands the diet. Determine whether special problems with food preferences or availability of recommended foods exist. Diet recommendations include a target number of calories, plus targets for grams of carbohydrate, protein, and fat to meet calorie needs. Any of several methods to count and exchange foods may be used. One method uses exchange lists, in which the listed foods all have about the same number of grams of carbohydrate, protein, and fat. Therefore, one food from the list may be substituted, or exchanged, for another in the same list. Another method uses carbohydrate counting, in which foods on the starch, fruit, or milk list supply about 15 g of carbohydrate, or one carbohydrate choice. The diet plan would prescribe the number of carbohydrate choices for each meal and snack. Insulin is often adjusted according to the carbohydrate count for each meal or snack.

Identify special needs related to food preferences, culturally prescribed foods, or the availability of recommended foods. It may be necessary to review an exchange list and ask the woman how she plans

CASE STUDY 26-1 NURSING CARE PLAN*

ASSESSMENT: At 32 weeks of gestation, Kathy's blood glucose value is consistently above the desired level, and her insulin doses are adjusted. Twice-weekly nonstress tests and fetal ultrasounds for biophysical profiles are prescribed. The tests are reactive, and ultrasounds show appropriate fetal growth and amniotic fluid quantities, indicating no fetal compromise. However, Kathy verbalizes anxiety about the condition of the fetus and asks when it will be safe for the baby to be born.

NURSING DIAGNOSIS: Anxiety related to perceived threat to the health of the fetus, including expected gestation at birth.

EXPECTED OUTCOMES: Kathy will:

1. Relate her perception of the condition of the fetus and the significance of the fetal evaluations as the tests are performed.
2. Describe her concerns about the timing of the delivery at the conclusion of the next fetal evaluation session.

INTERVENTIONS AND RATIONALES

1. Ask Kathy to describe her concern about the fetus and to clarify her feelings. *Kathy's concerns must be identified and clarified so that misconceptions do not occur.*
2. Explain that a reactive nonstress test indicates that the fetal heart rate accelerates whenever the fetus moves, a good sign that the fetus is not in immediate jeopardy. Reinforce medical explanations of how other parts of

the biophysical profile are also reassuring of fetal well-being. *Frequency of testing will be changed if a need is identified. Reassurance that the fetus is not in jeopardy and that the tests will detect early signs if a problem develops reduces anxiety about the fetal condition.*

3. Ask Kathy how she feels about labor and delivery; determine whether she is taking childbirth education classes and whether she has selected her coach. *It is normal for women to become concerned about the birth process and how they will cope with labor during the last few weeks of pregnancy. Medical professionals should not neglect the need for normal pregnancy care for women with high-risk pregnancies.*
4. Help Kathy locate a childbirth education class if she has not done so previously and suggest that she and her coach begin classes. *Knowledge learned at childbirth classes may reduce the anxiety about the birth processes.*
5. Acknowledge that the prospect of labor and birth causes many women some anxiety, even when the infant is not at risk. *Knowledge that her feelings are common to most women may provide some relief from anxiety.*

EVALUATION: Kathy says she is reassured by explanations regarding the tests for fetal well-being but is concerned about how she will do in labor. She initiates plans to attend a childbirth education class with her sister as her coach.

ADDITIONAL NURSING DIAGNOSES TO CONSIDER

Readiness for Enhanced Family Coping
Risk for Injury

*Continued from p. 542.

to substitute and exchange foods to obtain the prescribed number of foods from each list.

Identify the woman's knowledge of potential complications such as hypoglycemia and hyperglycemia so that she and her family can be provided with pertinent information to avoid it or treat it.

Determine her knowledge of fetal surveillance techniques and her response to the need for frequent tests. Some women are highly motivated to continue the treatment regimen when test results indicate that the fetus is thriving. Other women find the frequent testing stressful and inconvenient.

Nursing Diagnosis

A common nursing diagnosis is "Deficient Knowledge of Measures to (1) maintain normal blood glucose levels, (2) manage abnormal glucose levels, and (3) common fetal surveillance procedures."

Planning

Goals for this nursing diagnosis are that the woman and her family will do the following:

- Demonstrate competence in SMBG level and administration of insulin before home management is initiated.
- Describe a plan for meeting dietary recommendations that fits family lifestyle and food preferences.
- Identify signs and symptoms of hypoglycemia and hyperglycemia and the management required for each.
- Verbalize knowledge of fetal surveillance procedures and keep scheduled appointments for testing.

Interventions

Management of diabetes mellitus during pregnancy is a team effort, and the nurse is responsible to provide or reinforce accurate information about the therapeutic regimen and offer consistent support for

the woman's efforts to comply with the recommendations. It may be necessary to demonstrate specific skills that the woman and her support person must master and to review and reinforce information from other members of the health care team.

Teaching Self-Care Skills

Demonstrations and return demonstrations are effective ways to teach and evaluate psychomotor skills. The woman (and her family) must learn to (1) use a meter and obtain a small sample of blood; (2) test for glucose level; and (3) mix and inject insulin. Both procedures are invasive and cause mild discomfort, which may make the woman reluctant to start. Mixing insulins accurately or using a sliding scale may be intimidating at first. Using food exchanges is often unfamiliar to the woman who is newly diagnosed, but it is critical to glucose control. Acknowledge these feelings before teaching begins.

Self-Monitoring of Blood Glucose Level. Spring-loaded lancets make home blood glucose monitoring easier. The side of the fingertip is less sensitive than the pad of the fingertip, so using the side reduces discomfort. Teach the woman to cleanse the area with warm water before obtaining a sample, to prevent infection. The first drop of blood is wiped away, and the second drop is placed on the meter's strip. Each home monitoring kit contains specific instructions for use of the meter and the type of reagent strip or cartridge that should be used. Teach the woman how to record glucose values in a handwritten or other log. Teach her that current glucose monitors have a memory option to provide retrieval of previous glucose readings.

Insulin Administration. The woman is often prescribed a combination of short-acting and intermediate-acting insulins. Teach her about the difference in onset, peak, and duration of action of each type of insulin in her combination. She also needs to learn how to mix the two insulins in the same syringe. If she will use a sliding scale to keep glucose levels close to normal, she will need teaching about how to

determine the additional dose of insulin if she has never used a sliding scale for insulin administration.

Insulin is administered subcutaneously. Common sites include the upper thighs, abdomen, and upper arms. Because the pregnant woman is injecting insulin frequently, emphasize the following precautions:

- To prevent hypoglycemia, a meal should be taken 30 minutes after regular insulin is injected. Because of its 10-minute onset of action, lispro (Humalog) insulin is injected just before eating.
- Unless the woman is very thin, insulin should be injected with the short needle inserted at a 90-degree angle so that the tip of the needle reaches the fatty tissue layer.
- The needle should be inserted quickly to minimize discomfort.
- The tissue pinch, if used, is released after inserting the needle and before injecting insulin because pressure from the pinch can promote insulin leakage from subcutaneous tissue.
- Aspirating is not necessary when injecting into subcutaneous tissue.
- Insulin is injected slowly (over 2 to 4 seconds) to allow tissue expansion and to minimize pressure, which can cause insulin leakage.
- The needle is withdrawn quickly to minimize the formation of a track, which might cause insulin to leak out.

Emphasize the importance of administering the correct dosage at the correct time. Teach the woman and her family about the function of insulin and the importance of following the directions of her physician in regard to coordinating meals with the administration of insulin.

Continuous Subcutaneous Insulin Infusion. Many women who have preexisting diabetes use continuous subcutaneous insulin infusion and wish to continue with this method during pregnancy. The use of programmable insulin infusion pumps allows tailoring of insulin administration to the woman's individual lifestyle. Prompt emergency counseling and assistance must be available 24 hours a day to deal with unexpected problems such as pump malfunction (Hood, 2012).

Teaching Dietary Management

Although a dietitian prescribes the recommended diet, the nurse must be aware of the general requirements and sensitive to the woman's dietary habits and preferences. Often, reviewing and clarifying how exchange lists are used to plan meals and snacks are necessary. Encourage the patient to avoid simple sugars (candy, cake, cookies), which raise the blood glucose levels quickly but may result in wide swings between high and low glucose levels.

It may be necessary to help the woman select foods that are high in nutrients but low in cost or meet cultural or religious constraints. Animal protein is especially expensive, and alternative sources of protein (beans, peas, corn, grains) can be substituted to meet some of the protein needs as well as provide high-quality carbohydrate and fiber. (See Chapter 9 for information about special needs such as types of vegetarian diets.) A registered dietary technician (DTR) can help a pregnant woman who is a vegetarian meet her individual needs depending on what foods are acceptable to her.

Allow the expectant mother to verbalize her frustrations or problems with the diet, and collaborate with the dietitian if she has a particular problem.

Managing Hypoglycemia and Hyperglycemia

Every woman and her family must be aware of signs and symptoms that indicate abnormal glucose levels and how to correct the abnormal levels. Hypoglycemia and hyperglycemia pose a threat to the mother and the fetus if these problems are not identified and corrected quickly.

Hypoglycemia. Treat hypoglycemia at once to prevent damage to the fetal brain, which is dependent on glucose. The woman should take 15 g of carbohydrate if she can swallow food. Examples of foods that supply this are 3 glucose tablets or glucose gel, $\frac{1}{2}$ cup of fruit juice or

regular soft drink, 6 saltine crackers, or 1 tablespoon of syrup or honey. Large quantities of high-carbohydrate foods such as candy will increase the blood glucose excessively, making a sudden fall in the level more likely. The woman should retest 15 minutes after the carbohydrate intake and repeat the treatment if her blood glucose level remains below 70 milligrams per deciliter (mg/dL). If it is more than 1 hour until the next meal or snack, the woman should add an additional 15 g of carbohydrate such as one serving of fruit (Franz, 2012).

SAFETY ALERT

Signs and symptoms of maternal hypoglycemia include:

- Shakiness (tremors)
- Sweating
- Pallor; cold, clammy skin
- Disorientation; irritability
- Headache
- Hunger
- Blurred vision

Teach family members how to inject glucagon in the event that the woman cannot swallow or retain food. Notify the physician at once. IV glucose will be administered if she is hospitalized. If untreated, hypoglycemia can progress to convulsions and death.

To prevent hypoglycemia, instruct the woman to have meals at a fixed time each day and to plan snacks at 10 AM, 3 PM, and bedtime. Suggest that she always carry glucose tablets or gel or some crackers with her.

Hyperglycemia. Because infection is the most common cause of hyperglycemia, pregnant women must be instructed to notify the physician whenever they have an infection of any type.

Untreated hyperglycemia can lead to ketoacidosis, coma, and maternal and fetal death. If signs and symptoms occur, notify the physician at once so that treatment can be initiated. Hospitalization often is necessary to monitor blood glucose levels, for IV insulin administration to normalize glucose levels, and for treatment of any underlying infection.

SAFETY ALERT

Signs and symptoms of maternal hyperglycemia include the following:

- Fatigue
- Flushed, hot skin
- Dry mouth; excessive thirst
- Frequent urination
- Rapid, deep respirations; odor of acetone on the breath
- Drowsiness; headache
- Depressed reflexes

Explaining Procedures, Tests, and Plan of Care

Explain the schedule and the reasons for frequent checkups and necessary tests. Encourage the woman and her family to ask questions if any part of the schedule is confusing. This is particularly important for women who are aware that their prenatal care differs significantly from that of their friends who do not have diabetes. Knowing that the tests provide information about the condition of the mother and fetus reduces frustration and anxiety. Explain why more frequent antepartum surveillance testing is needed when diabetes complicates pregnancy. The woman needs to know that her diabetic care will require more time and effort than it did before pregnancy but that this care greatly improves her likelihood of having a healthy infant.

Evaluation

After procedures, tests, and plan of care have been explained, evaluation should ensure the following:

- The woman and at least one support person can demonstrate competence in home glucose monitoring and administration of insulin.
- The woman can describe a satisfactory plan for meeting her individual dietary requirements.
- The woman and at least one support person can list the signs and symptoms of hypoglycemia and hyperglycemia and describe the initial management of these conditions.
- The woman can verbalize knowledge of the reason for fetal surveillance procedures and keeps appointments for tests.

CARDIAC DISEASE

Alterations in cardiovascular function are necessary in pregnancy to meet additional maternal metabolic demands and the needs of the fetus. Plasma volume, venous return, and cardiac output all increase. Heart rate and stroke volume, the components of cardiac output, increase during pregnancy. Heart rate gradually rises above the baseline during the third trimester. However, increases in stroke volume are primarily responsible for the overall rise in cardiac output during early pregnancy.

A normal heart can adapt to the changes so that pregnancy and birth are tolerated without difficulty. For women with preexisting or underlying heart disease, however, the changes can impose an additional burden on an already compromised heart, which may result in cardiac decompensation and **congestive heart failure** (CHF; failure of heart to maintain adequate circulation).

Incidence and Classification

Heart disease complicates about 1% of pregnancies. Although the overall mortality rate of heart disease has decreased it remains a significant cause of maternal mortality (Cunningham et al., 2010). Pregnancy may unmask a previously asymptomatic heart condition, or it may aggravate known heart disease.

The two major categories of heart disease are rheumatic heart disease and congenital heart disease in the mother. Rheumatic heart disease was once the major cause of heart disease in a childbearing woman but has now become uncommon, with congenital heart disease (CHD) being the main cause in North America. Women with CHD are more likely to survive to reproductive age, possibly adding cardiac risk to their pregnancy. A third category, mitral valve prolapse, is a common but benign condition that usually does not cause problems during pregnancy. Myocardial infarction and conduction defects also may occur in women of childbearing age, especially with the increase in obesity (Cunningham et al., 2010; Easterling & Stout, 2012; Gaddipati & Troiano, 2013; Tomlinson, 2011).

Cardiomyopathy is a rare and often fatal disorder of the muscle structure of the heart and may be considered a diagnosis of exclusion. Cardiomyopathy may occur during late pregnancy to 5 months postpartum with no identifiable cause and no known previous heart disease. Left ventricular systolic dysfunction is demonstrated by echocardiographic criteria. CHF may be secondary to underlying heart disease or damage or may occur secondary to treatment for other conditions. Risk of recurrence with another pregnancy is high. Hess and Weinland (2012) have summarized reports of women's varied experiences obtained from the Internet (Cunningham et al., 2010; Easterling & Stout, 2012; Hess & Weinland, 2012; Tomlinson, 2011).

Rheumatic Heart Disease

Rheumatic heart disease is a complication that sometimes follows streptococcal pharyngitis ("strep throat"). Even one bout of rheumatic fever may cause scarring of the heart valves, resulting in stenosis (narrowing) of the openings between the chambers of the heart. Early diagnosis and treatment of the streptococcal infection has resulted in a near-eradication of rheumatic fever in North America and Europe.

The mitral valve is the most common site of stenosis. Mitral stenosis obstructs free flow of blood from the left atrium to the left ventricle. The left atrium becomes dilated, and as a result, pressure in the left atrium, pulmonary veins, and pulmonary capillaries is chronically elevated. This elevation may lead to pulmonary hypertension, pulmonary edema, or CHF. The first warnings of heart failure include persistent rales at the base of the lungs, dyspnea on exertion, cough, and hemoptysis. Progressive edema and tachycardia are additional signs of heart failure.

Congenital Heart Disease

Congenital heart defects can be grouped into those that cause a left-to-right shunt and those resulting in a right-to-left shunt. Defects that produce left-to-right shunting include atrial and ventricular septal defects and patent ductus arteriosus. In contrast, right-to-left shunting occurs when a cyanotic heart defect such as tetralogy of Fallot is present. Right-to-left shunting also may occur through a septal defect or patent ductus arteriosus when pulmonary vascular resistance exceeds peripheral vascular resistance and pulmonary hypertension (Eisenmenger's syndrome) occurs. The fetus is more likely to inherit congenital defects, although the risk varies with different maternal defects (Easterling & Stout, 2012; Tomlinson, 2011).

Left-to-Right Shunt

Atrial Septal Defect. Atrial septal defect often is first discovered in women of childbearing age because symptoms are absent or vague. This defect produces a left-to-right shunt because pressure in the left side of the heart is higher than that in the right side. Pregnancy is well tolerated by women with an uncomplicated atrial septal defect, and no specific treatment is recommended. Bacterial endocarditis is rare, and prophylactic antibiotics are not required. Pulmonary hypertension occasionally develops in uncorrected atrial septal defects because the additional blood that moves to the right side of the heart is transported to the lungs through the pulmonary artery (Cunningham et al., 2010; Easterling & Stout, 2012; Tomlinson, 2011).

Ventricular Septal Defect. Although ventricular septal defects are more common than atrial septal defects at birth, they usually are detected by auscultation and often close with no surgical closure needed. Most women with ventricular septal defects who become pregnant are asymptomatic, but fatigue or symptoms of pulmonary congestion may occur.

Pregnancy is well tolerated with small to moderate left-to-right shunts. However, pregnancy occasionally precipitates heart failure or a dysrhythmia, either of which is managed as in nonpregnant patients. Bacterial endocarditis is common with unrepaired defects, and antibacterial prophylaxis is recommended (Cunningham et al., 2010; Easterling & Stout, 2012; Tomlinson, 2011).

Patent Ductus Arteriosus. The communicating shunt between the pulmonary artery and aorta is usually discovered and treated in childhood. If the condition is untreated, the physiologic effects are related to size. If this lesion is small it may be well tolerated during pregnancy unless complicated by pulmonary hypertension. The patent ductus arteriosus tends to become infected, so antibiotic prophylaxis before labor is recommended (Cunningham et al., 2010; Easterling & Stout, 2012; Tomlinson, 2011).

EVIDENCE-BASED PRACTICE

Coronary Heart Disease is the Greatest Killer of American Women

Despite the many fears about breast cancer, coronary heart disease (CHD) remains the greatest killer of American women. Medical advances have improved survival in women age 25 to 64 years with better secondary prevention, revascularization, treatment of initial myocardial infarction (MI), treatment of heart failure, and risk factor (total cholesterol, systolic blood pressure, smoking, and physical inactivity) reduction. However, other risk factors, as a group, are increasing: obesity, prevalence of diabetes mellitus (DM), and greater rate of death due to CHD. Black women have a higher rate of mortality due to CHD. Cynthia Arslaneum-Engoren (2011) concluded that modification of lifestyle behaviors may have a favorable impact on reducing future CHD events in women.

Demographic variables include age, race, and low socioeconomic status. Women's risk of dying from CHD rises and is the number one risk for women 65 years and older. Although mortality has been higher for older women, it has also been rising for younger women 35 to 44 years old. Black women have been most affected overall with highest overall mortality rates, out of hospital death rates, and highest premature death rates when compared with White women, and they have a 28% higher age-adjusted death rate. Women of all races with a low socioeconomic status are at greater risk for MI, coronary insufficiency, and coronary death.

Comorbid risk factors include hypertension, DM, hypercholesterolemia and hyperlipidemia, and obesity, and all have a chance for improvement. Hypertension is defined as systolic blood pressure (SBP) 140 mm Hg or greater and diastolic blood pressure (DBP) 90 mm Hg or greater. Hypertension occurs in about 31% of non-Hispanic White women, 31% of Mexican American women, and 45% of Black women, with 75% of Black women older than 75 years having hypertension. Diabetes mellitus now affects 11.5 million women, who have the added risk of developing gestational diabetes and glucose intolerance during pregnancy. Glucose intolerance has a 40% to 60% chance of developing into DM during the next 5 to 10 years. In addition, about 55 million women have cholesterol levels 200 milligrams per deciliter (mg/dL) or greater despite treatment goals to bring it down.

Lifestyle behaviors may be modified. White women are more likely to smoke compared with Black or Hispanic women. Lowest rates are among women with graduate degrees and women age 65 years and above. Smoking causes two million years potential life lost and costs \$32.6 billion yearly. Two guidelines to modify physical activity in the article are to do 30 minutes of moderate intensity exercise 5 days a week, and another is to do 150 minutes per week of vigorous, high-intensity aerobic physical activity. Physical inactivity and high saturated fat diet are likely to increase obesity (≥ 30 kg/m²).

Sex hormones (estrogen and progesterone) fall with increasing age and have been associated with CHD as a woman ages. Although replacement of estrogen and progesterone was done in the Women's Health Initiative (WHI) to provide cardiac protection, further study revealed that these hormones increased CHD significantly, and that arm of the study was discontinued. A secondary analysis of data found that women who were started on hormone therapy had no increased risk for CHD.

Preeclampsia was identified as an independent risk factor for later CHD in women less than 66 years of age in one study (Bellamy, Casas et al. 2007; Haukkama et al., 2004). Another study found that women who had preeclampsia or eclampsia had a twofold higher risk of ischemic heart disease after 11.7 years and were 0.5 times more likely to die 14.5 years after preeclampsia or eclampsia (Harskamp & Zeeman, 2007).

Nontraditional risk factors will not be detailed here.

U.S. Preventive Services Task Force (USPSTF) CHD Screening Recommendations

Arslaneum-Engoren (2011) brought many facts together with the specific work for routine screening of CHD, citing the grading system for the best screening method among women. The USPSTF recommendations include the following:

- **Hypertension:** Screen all women age 18 and older to identify a SBP of 140 mm Hg or greater or DBP of 90 mm Hg or greater (grade A, high certainty of benefit). The Joint Commission also recommends BP screening every 2 years for women with SBP under 120 mm Hg and DBP under 80 mm Hg and annually for women with SBP of 120 to 139 mm Hg or DBP of 80 to 90 mm Hg.
- **Diabetes mellitus:** The USPSTF recommends (grade B, moderate net benefit) that women who have a sustained BP of 135/80 mm Hg be screened for DM, but the task force stated screening was insufficient for asymptomatic adults with BP under 135/80 mm Hg (inconclusive [I]).
- **Tobacco use:** The USPSTF recommends that all women be screened for tobacco use and that women who use tobacco be provided with tobacco cessation interventions, including pregnancy-tailored counseling (grade A, high certainty of benefit).

The USPSTF does not recommend that low-risk women have routine screening for coronary artery stenosis, electrocardiography, exercise treadmill test, or electron beam computer tomography. There is also insufficient evidence for the nontraditional risk factors reviewed in the article.

Implications for Nursing Practice

A nurse needs to use counseling skills that are based on trust and communication to help a woman alter her risks with protective behaviors such as exercising, eating a low-fat diet, and smoking cessation. The qualitative study by Arslaneum-Engoren (2011) found that women associated CHD risk with obese men who smoked and led a stressful life, which is a misperception of women's risk for CHD. Educational strategies must be used to alter women's perception of risk and to promote heart health. Lifestyle behavior change is a lifelong process, and the nurse must encourage and reinforce client behaviors so that the women progress toward their goals. Lifestyle changes with regard to customs, food patterns, and living space, as well as a woman's caregiver and family may also impact her cardiac health and how she incorporates health recommendations.

Arslaneum-Engoren concluded that preventive screening based on demographic characteristics, comorbid conditions, lifestyle behaviors, and risk factors be routinely performed taking into account the USPSTF recommendations to reduce women's risk for CHD.

Reference: Arslaneum-Engoren, C. (2011). Women's risk factors and screening for coronary heart disease. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 40(3), 337–347.

Right-to-Left Shunt

Tetralogy of Fallot. The primary cause of right-to-left shunting is tetralogy of Fallot, a combination of four defects (ventricular septal defect, pulmonary valve stenosis, right ventricular hypertrophy, and displacement of the aorta toward the right ventricle). Untreated patients with tetralogy of Fallot have obvious symptoms of heart disease, including (1) cyanosis; (2) clubbing of the fingers, indicating proliferation of capillaries to transport blood to the extremities; and (3) inability to tolerate activity.

Women who have undergone repair and in whom cyanosis did not reappear may do well during pregnancy. With uncorrected tetralogy of Fallot, maternal and fetal mortality are high (Cunningham et al., 2010; Easterling & Stout, 2012; Tomlinson, 2011).

Eisenmenger's Syndrome. Eisenmenger's syndrome is a cyanotic heart condition that develops when pulmonary resistance equals or exceeds systemic resistance to blood flow and a right-to-left shunt develops. Several congenital defects may underlie the equalization of pressures within the ventricles, such as a large ventricular septal defect

or a large patent ductus arteriosus (PDA). Operative closure of these defects must be done as soon as possible in defects that may cause Eisenmenger's syndrome. A late surgical correction often results in the woman's death. If she survives delayed surgery, pregnancy may carry a 50% maternal mortality risk, usually from right ventricular failure. Most newborns are preterm and small for gestational age (Cunningham et al., 2010; Easterling & Stout, 2012; Tomlinson, 2011).

Mitral Valve Prolapse. Mitral valve prolapse is one of the most common cardiac conditions among the general population. The incidence among otherwise normal young women is as high as 15%, but community-based studies have shown the incidence to be far lower, at 1% of the female population (Blanchard & Shabetai, 2009). Although the condition appears to be inherited, it may be associated with a variety of other cardiac disorders such as atrial septal defects and **Marfan syndrome**. In mitral valve prolapse, the leaflets of the mitral valve prolapse into the left atrium during ventricular contraction.

Mitral valve prolapse is considered a benign condition, and most women with mitral valve prolapse are asymptomatic and tolerate pregnancy well. Some women experience dysrhythmias or chest pain. Some physicians consider mitral valve prolapse to be a significant risk factor for bacterial endocarditis and administer prophylactic antibiotics before and during labor and delivery. Beta-blockers such as atenolol or metoprolol may be given for chest pain or dysrhythmias.

Peripartum and Postpartum Cardiomyopathy

Cardiomyopathy in the peripartum or postpartum period is a rare condition exclusively associated with pregnancy after exclusion of other causes. Women with the condition have no underlying heart disease, but symptoms of cardiac decompensation appear during the last weeks of pregnancy or from 2 to 20 weeks postpartum. The symptoms are those of CHF: dyspnea, edema, weakness, chest pain, and heart palpitations. Cardiomyopathy may suddenly appear in a woman who has been healthy. An abrupt downhill course in which the woman can be saved only with cardiac transplantation may occur in about 20% of women. About 50% of other women with cardiomyopathy may have a partial recovery with persistent CHF or other cardiac dysfunction. The rest may show recovery. Peripartum cardiomyopathy often recurs with subsequent pregnancies, particularly in women who did not have complete recovery of their left ventricular function. The woman should be informed of this risk (Blanchard & Shabetai, 2009; Cunningham et al., 2010; Easterling & Stout, 2012).

Anticoagulation with low-molecular-weight heparin (LMWH) is the usual therapy to prevent clot formation during pregnancy when coagulation factors are higher. Other medical therapy includes fluid restriction to reduce pulmonary edema and treatment of CHF and other pathologies associated with cardiomyopathy.

Diagnosis and Classification

Early recognition of underlying heart disease is essential, and careful assessment for specific signs and symptoms of heart disease is part of every initial prenatal visit. Signs and symptoms include dyspnea, syncope (fainting) with exertion, hemoptysis, paroxysmal nocturnal dyspnea, and chest pain with exertion. Additional signs that confirm the diagnosis are (1) cyanosis; (2) clubbing; (3) diastolic, presystolic, or continuous heart murmur; (4) cardiac enlargement; (5) a loud, harsh systolic murmur associated with a thrill; and (6) serious dysrhythmias (Blanchard & Shabetai, 2009).

Diagnosis of heart disease may be made from clinical signs and symptoms and from findings on physical examination. It usually is confirmed by heart imaging studies such as transesophageal echocardiography.

BOX 26-2 NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION OF HEART DISEASE

- Class I: Uncompromised. No limitation of physical activity. Asymptomatic with ordinary activity.
- Class II: Slightly compromised, requiring slight limitation of physical activity. Comfortable at rest, but ordinary physical activity causes fatigue, dyspnea, palpitations, or anginal pain.
- Class III: Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes excessive fatigue, palpitation, dyspnea, or anginal pain. Markedly compromised.
- Class IV: Inability to perform any physical activity without discomfort. Symptoms of cardiac insufficiency even at rest.

*In general, maternal and fetal risks with classes I and II are small but are greatly increased with classes III and IV.

Once the diagnosis is made, the severity of the disease can be determined by the client's ability to endure physical activity. A clinical classification based on the effect of exercise on the heart has been developed by the New York Heart Association (Box 26-2).

Therapeutic Management

Therapeutic management care of the pregnant woman who has a heart disorder is discussed in this segment. Management may include interventions, such as maintaining a low-sodium diet, which are not recommended in most pregnancies. The nurse should consult a medical-surgical nursing textbook for additional information that pertains to medical and nursing care of pregnant patients with cardiac conditions.

Class I or II Heart Disease

Because demands on the pregnant woman's heart are higher, a woman with heart disease should do the following (Cunningham et al., 2010; Easterling & Stout, 2012; Tomlinson, 2011):

- *Limit physical activity.* This is done so that demand does not exceed the functional capacity of the heart. In other words, the woman should remain free of symptoms of cardiac stress such as dyspnea, chest pain, and tachycardia.
- *Avoid excessive weight gain.* Excessive weight increases demands on the heart. A diet adequate in protein, calories, and sodium is necessary. A low-sodium diet may be advised to avoid CHF.
- *Prevent anemia.* Anemia decreases the oxygen-carrying capacity of the blood and results in a compensatory increase in heart rate that a diseased heart may be unable to tolerate. Most anemia is prevented by administration of iron and folic acid.
- *Prevent infection.* Immunizations for influenza, pertussis, and pneumonia are available. Prevention may include administration of prophylactic antibiotics. As with other people, a pregnant woman with cardiac disease should be advised to avoid contact with those who may be ill during times when upper respiratory tract infections are prevalent, such as winter months.
- *Undergo careful assessment for the development of CHF, pulmonary edema, and cardiac dysrhythmias.* Characteristics of heart failure may include persistent basilar rales, often accompanied by a cough during the night as the woman tries to sleep, sudden inability to carry out usual activities, dyspnea, cough, hemoptysis, increasing edema, and tachycardia.

Class III or IV Heart Disease

The primary goal of management is to prevent cardiac decompensation and development of CHF. Also, every effort is made to protect the fetus from hypoxia and IUGR, which can occur if placental perfusion is inadequate. In addition to the precautions listed for classes I and II heart disease, the woman may require bed rest, especially during the last trimester, because she has little reserve to tolerate rising metabolic demands. Reduced activity increases the maternal risk for thrombus formation and will require prophylaxis such as elastic compression stockings or a serial or boot compression device. Prophylactic anticoagulation may be needed.

Drug Therapy

Drug therapy for maternal cardiac disorders may extend from the prenatal period through the postpartum period. Drugs that were part of a woman's treatment before pregnancy may require a change during pregnancy. The medical team must consider risks and benefits when treating the pregnant woman with cardiac disease.

Anticoagulants. During pregnancy, clotting factors normally increase and thrombolytic activity decreases. These changes predispose the pregnant woman to thrombus formation. Superimposed cardiac problems such as mitral valve stenosis may require anticoagulant therapy during pregnancy. Warfarin (Coumadin) is associated with fetal malformations and should be restricted throughout pregnancy. Subcutaneous heparin, which does not cross the placental barrier, is an effective alternative anticoagulant for most women. Careful monitoring of the partial thromboplastin time (PTT), activated partial thromboplastin time (aPTT), and platelet count is essential to achieve effective, safe anticoagulation. Enoxaparin (Lovenox), a LMWH, may be used instead of standard heparin because it requires less-frequent monitoring for bleeding complications. Enoxaparin and heparin are not interchangeable. Both are given subcutaneously, but only heparin may be given intravenously. Heparin is withheld during labor and resumed 6 hours after vaginal birth and 18 to 24 hours after cesarean birth. Postpartum anticoagulation is continued with warfarin (Cunningham et al., 2010; Gaddipati & Troiano, 2013; Tomlinson, 2011).

Antidysrhythmics. Use of medications for heart disease during pregnancy must balance benefits to the mother against possible harm to the fetus. Another consideration is that maternal heart failure itself is harmful to the fetus. In addition to controlling the dysrhythmias, beta-blockers and calcium channel blockers may be used to control maternal hypertension. Digoxin, adenosine, and calcium channel blockers appear to be safe. Beta-blockers have been associated with neonatal respiratory depression, sustained bradycardia, and hypoglycemia when administered late in pregnancy or just before delivery but may be needed in selected cases. The beta-blockers atenolol and metoprolol may be preferred because they do not cause the uterine stimulation that other drugs of this class may cause (Cunningham et al., 2010; Easterling & Stout, 2012).

Antinfectives. In 2007, the American Heart Association (AHA) released a new set of guidelines for use of antibiotic prophylaxis to prevent infective endocarditis in persons at high risk (AHA, 2007). Some that may apply to pregnant women with cardiac disorders are as follows (AHA, 2007; Gaddipati & Troiano, 2013):

- Prosthetic heart valve or prosthetic material used for valve repair
- Previous infective endocarditis
- Congenital heart malformations, unrepaired or repaired using prosthetic material within 6 months of repair
- Residual heart defects at site of repair
- Surgically corrected systemic pulmonary shunts

- Dental procedures
- Cardiac transplantation recipients who develop disorders of heart valves

Antiinfective agents for endocarditis are chosen based on the infecting agent. Gram-positive *Staphylococcus* infections are common in IV drug users, and the mortality rate among them is high. Maternal gonorrhea infection may cause acute, rapidly developing endocarditis. A woman with an increased risk for bacterial endocarditis may receive prophylactic antibiotics such as amoxicillin, penicillin, ampicillin, and gentamicin at delivery. Ceftriaxone or vancomycin also may be given for acute endocarditis.

Drugs for Heart Failure. Diuretics may be needed when CHF remains uncontrolled in spite of restriction of activity and sodium intake. Careful monitoring of electrolytes and water balance is necessary to avoid excessively reducing maternal blood volume with resulting adverse effects on the fetus. Experience is greatest with furosemide and thiazide diuretics. IUGR has been associated with furosemide, and neonatal jaundice, thrombocytopenia, anemia, and hypoglycemia have been associated with thiazide diuretics (Cunningham et al., 2010; Easterling & Stout, 2012; Tomlinson, 2011). Beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, or angiotensin receptor blockers, and digoxin also may be used if beneficial for treatment of pregnancy-associated heart failure.

Intrapartum Management

Every effort is made to minimize the effects of labor on the cardiovascular system. For example, with every contraction, 300 to 500 mL of blood is shifted from the uterus and placenta into the central circulation. This extra fluid causes a sharp rise in cardiac workload. Therefore, careful management of IV fluid administration is essential to prevent fluid overload. The woman should be positioned on her side, with her head and shoulders elevated. Oxygen is administered to increase blood oxygen saturation and is monitored with pulse oximetry. Discomfort should be reduced to a minimum, but the use of an epidural block is sometimes controversial because of its potential hemodynamic effects (see Chapter 16). The environment is kept as quiet and calming as possible to decrease anxiety, which can cause tachycardia (Gaddipati & Troiano, 2013).

The fetus is monitored electronically, and signs of fetal compromise as well as maternal signs of cardiac decompensation (tachycardia, rapid respirations, moist rales, and exhaustion) should be reported immediately to the physician.

A vaginal birth is recommended for a woman with heart disease unless there are specific indications for a cesarean birth. Vacuum extraction or outlet forceps are often used to minimize maternal pushing and use of the Valsalva maneuver and to limit prolonged labor, which can add to the hemodynamic stress for the woman with cardiac disease. Cesarean birth may be chosen for obstetric indications. Although it is a common obstetric procedure, the woman and her physician must consider the added stress of major surgery on her heart. Expected blood loss is higher in cesarean birth than in vaginal birth. General anesthesia may be required if epidural anesthesia is not an option, leading to operative airway management by an anesthesiologist (Cunningham et al., 2010; Gaddipati & Troiano, 2013).

The fourth stage of labor is associated with special risks. After delivery of the placenta, about 500 mL of blood is returned to the intravascular volume. To minimize the risks of overloading the heart, abrupt positional changes should be avoided. Moreover, the uterus should not be massaged to expedite separation of the placenta. Careful assessment for signs of circulatory overload, such as a bounding pulse, distended neck and peripheral veins, and moist rales in the lungs, is performed throughout labor and the postpartum period.

Postpartum Management

Women who have shown no evidence of distress during pregnancy, labor, and childbirth may experience cardiac decompensation during the postpartum period. The relief of vena caval compression and auto-transfusion of blood from the uterus after placental delivery abruptly increases the blood returning to the right side of the heart.

The woman also must be observed closely for signs of infection, hemorrhage, and thromboembolism. These conditions can act together to precipitate postpartum heart failure in women with underlying heart disease. The woman is vulnerable in the postpartum period, as interstitial fluid is mobilized into the vascular space for elimination. Continue to observe for signs of CHF. Observe urine output because inadequate urine output may reflect the heart's inability to circulate blood adequately to the kidneys. If the mother cannot assume care of her infant, nurses should make every effort to promote contact between the mother, her significant others, and the infant.

Breastfeeding imposes extra demands on the mother's heart and is advised on an individualized basis. If no evidence of cardiac compromise during labor and the early postpartum period exists, breastfeeding usually is not contraindicated.

SAFETY ALERT

Signs and symptoms of CHF include the following:

- Cough (frequent, productive, hemoptysis)
- Progressive dyspnea with exertion
- Orthopnea
- Pitting edema of legs and feet or generalized edema of face, hands, or sacral area
- Heart palpitations
- Progressive fatigue or syncope with exertion
- Moist rales in lower lobes, indicating pulmonary edema

APPLICATION OF THE NURSING PROCESS

■ The Pregnant Woman with Heart Disease

Assessment

Begin with a review of the woman's medical record to determine the functional classification assigned (see [Box 26-2](#)). Assess the woman at each prenatal appointment to determine how pregnancy affects the functional capacity of the heart.

- Take vital signs and compare them with preconception levels. Note any changes such as tachycardia since the previous prenatal appointment.
- Assess the level of fatigue and any changes in fatigue since the previous prenatal appointment. This is especially important when fluid volume peaks and the chance of cardiac decompensation is greatest (18 to 32 weeks of gestation).
- Observe for signs or symptoms of CHF.
- Note additional factors that may increase the workload of the heart (anemia, infections, anxiety, lack of adequate support to manage the activities of daily living).
- Weigh the woman and compare the desired and actual patterns of weight gain to detect excessive weight gain or fluid retention.
- Assess the woman's knowledge of the prescribed regimen of care and her ability to comply with it.

Nursing Diagnosis

The pregnant woman with a cardiac defect may be unable to tolerate activity to the same degree as before pregnancy because of the stress imposed on her cardiovascular system. Arriving at the nursing diagnosis "Activity Intolerance related to insufficient knowledge of measures that reduce cardiac stress" is a priority.

Planning

Goals and outcomes are as follows:

- The woman (and her family) will identify factors that increase cardiac workload.
- The woman (and family) will describe measures that promote adaptation to activity restrictions.

Interventions

Prenatal nursing care focuses on teaching the woman and her family about the possible effects of the disease on their lives. This teaching may include specific instructions about factors that increase the workload of the heart and measures to promote adaptation to activity restrictions during pregnancy and birth. Teaching may also reinforce or clarify the physician's instructions.

Teaching about Increased Cardiac Workload

Excessive Weight Gain and Anemia. Excessive weight gain and anemia increase the workload of the heart just as they do in the non-pregnant state and should be avoided. A well-balanced diet that contains about 2200 calories is recommended, with adequate high-quality protein. Emphasize the importance of taking any prescribed iron supplements to prevent anemia and reduce the risk of tachycardia. Folic acid should be taken from before conception to avoid anemia and reduce the risk for neural tube defects in the fetus.

Exertion. Instruct the woman to modify her approaches to activities to regulate energy expenditures and reduce cardiac workload. For example, she might take rest periods during the day and for an hour after meals. If possible, she should sit rather than stand when performing activities. She should rest every few minutes when performing an activity that increases heart rate to allow the heart time to recover. Emphasize that she should stop an activity if she experiences dyspnea, chest pain, or tachycardia.

Exposure. Instruct the woman to avoid unnecessary exposure to environmental extremes. She should dress warmly during cold weather and create a barrier to cold temperatures by wearing layers of clothing. She must become aware that exertion in hot, humid weather or during extreme cold weather places additional demands on the heart and should be avoided.

Emotional Stress. Explain the effects of emotional stress on the cardiovascular system (increased blood pressure, heart rate, and respiratory rate). Help the woman to identify areas of stress in her life. Discuss various methods for stress management such as meditation, progressive relaxation of muscles, and biofeedback. Teach that cigarette smoking and use of illicit drugs such as cocaine and amphetamines greatly increase stress on the heart and are associated with hypertension that further adds to cardiac workload and fetal compromise.

Helping Family Accept Restrictions on Activity

Assist family members to accept the need for activity restriction. The amount of activity that can be tolerated depends on the severity of the disease. However, all women with heart disease need 8 to 10 hours of sleep each night, with periods of morning and afternoon rest. For some women, bed rest with bathroom privileges is necessary during the last half of pregnancy, and this may create special problems for the family.

Nurses often help family members plan ways to meet their needs while the mother continues bed rest. See the Case Study for Preterm Labor (Chapter 27) for additional interventions when a prolonged period of limited activity is required.

Providing Postpartum Care

The woman is vulnerable in the postpartum period, as interstitial fluid is mobilized into the vascular space for elimination. Continue to observe for signs of CHF. Observe urine output because inadequate urine output may reflect the heart's inability to circulate blood adequately to the kidneys.

After childbirth, the mother may be unable to assume care of the newborn, especially after a prolonged period of limited activity or bed rest. However, every effort should be made to promote contact between the mother and the baby. Many nurses assess the baby, perform the necessary newborn care at the bedside, and then allow the mother ample time to hold the infant. The father and other family members should be included in the care of the infant, whenever possible.

The decision about breastfeeding will be individualized according to the mother's condition and its demands on her energy. She should be encouraged to feed the infant whenever possible to promote maternal-infant attachment, even if she feeds formula. Consult with physicians, and make referrals as necessary for follow-up care, which may include home care by a nurse or nursing assistant. Be certain that the family understands the signs and symptoms of cardiac complications and when to notify the physician that problems have developed.

Evaluation

The ability to identify the factors increasing cardiac workload offers reassurance that the woman and her family will initiate measures promoting adaptation to restricted activity.

- Why is the fourth stage of labor particularly dangerous for the woman with heart disease?

ANEMIAS

Anemia is a condition in which a decline in circulating RBC mass reduces the capacity to carry oxygen to the vital organs of the mother or the fetus. Significant maternal anemia is associated with preterm birth and low birth weight. A pregnant woman is usually considered anemic if her hemoglobin level is less than 10.5 or 11 grams per deciliter (g/dL) (Blackburn, 2013; Cunningham et al., 2010; Kilpatrick, 2009; Samuels, 2012; Strong & Rutherford, 2011).

Anemia is one of the most common problems of pregnancy, affecting 15% to 25% of pregnant women. The incidence varies according to geographic location and socioeconomic group. Anemia may be caused by a variety of factors including nutritional deficits, hemolysis, and blood loss. The most common types of anemia observed during pregnancy is iron deficiency anemia; less common causes are folic acid deficiency, sickle cell disease, and thalassemia. The increase in bariatric

surgery has increased the number of women with vitamin B₁₂ deficiency (ACOG, 2010a; Samuels, 2012).

Iron Deficiency Anemia

The total iron requirement for a typical pregnancy with a single fetus is approximately 1000 mg. Unfortunately, most women of reproductive age do not have this amount of iron stores because of menstrual blood loss. Furthermore, meeting pregnancy needs by diet alone is difficult, although iron is present in many foods. The primary sources of iron are meat, fish, chicken, liver, and green, leafy vegetables.

Maternal Effects

Signs and symptoms of iron deficiency anemia include pallor, fatigue, lethargy, and headache. Clinical findings also may include inflammations of the lips and tongue. *Pica* (consuming nonfood substances such as clay, dirt, ice, and starch) also is a sign of iron deficiency anemia. Laboratory findings for iron deficiency anemia include RBCs that are microcytic (small) and hypochromic (pale). Plasma iron and serum ferritin levels are low, whereas the total iron-binding capacity is higher than normal. Women who have multifetal pregnancies or bleeding complications are more likely to be anemic during pregnancy (Kilpatrick, 2009).

Fetal and Neonatal Effects

All effects of maternal iron deficiency anemia on the fetus and neonate are unclear. In general, even with significant maternal iron deficiency, the fetus will receive adequate stores at a cost to the mother. If the mother is severely anemic, the fetus may have reduced RBC volume, hemoglobin, and iron stores. Profound maternal anemia can reduce fetal oxygen supply (Kilpatrick, 2009; Samuels, 2012).

Therapeutic Management

Routine supplemental iron therapy, rather than therapy based on an indication of anemia, is controversial. Ferrous sulfate, 325 mg, one to three times per day is commonly prescribed. Many women experience less gastrointestinal discomfort if iron supplementation is taken with meals, although absorption is less. Taking iron supplementation with 500 mg of vitamin C may enhance absorption. Therapy is often continued for about 6 months after the anemia has been corrected. Parenteral therapy may be necessary for the woman who cannot or will not take oral iron supplementation and is significantly anemic, with a hemoglobin level less than 8.5 g/dL (Samuels, 2012).

Folic Acid Deficiency (Megaloblastic) Anemia

Folic acid, which functions as a coenzyme in the synthesis of deoxyribonucleic acid (DNA), is essential for cell duplication and fetal and placental growth. It also is an essential nutrient for the formation of RBCs.

Maternal Effects

Maternal needs for folic acid double during pregnancy in response to the demand for greater production of erythrocytes and fetal and placental growth. A deficiency in folic acid results in a reduction in the rate of deoxyribonucleic acid (DNA) synthesis and mitotic activity of individual cells, resulting in the presence of large, immature erythrocytes (megaloblasts). Folate deficiency is the primary cause of megaloblastic anemia during pregnancy.

Nonfood factors that contribute to folic acid deficiency include hemolytic anemias with increased RBC turnover, multifetal pregnancies, some medications (such as anticonvulsants), and malabsorption entities. Folic acid deficiency often is present in association with iron deficiency anemia.

Fetal and Neonatal Effects

Folate deficiency is associated with increased risk of spontaneous abortion, abruptio placentae, and fetal anomalies. A known association exists between folic acid deficiency and an increase in neural tube defects.

Therapeutic Management

The recommended daily allowance for folic acid doubles during pregnancy, and some women have difficulty ingesting the amount needed, even though it does occur widely in foods. The best sources of folic acid are fortified greens; beans such as black beans and lentils; peanuts; and fresh, dark-green, leafy vegetables (see Table 9-4). Folic acid often is destroyed in cooking. As a result of the awareness of the association between folic acid deficiency and neural tube defects, it is now recommended that all women of childbearing age take 400 mcg (0.4 mg) of folic acid daily to reduce this risk. This supplementation should be increased to 600 mcg (0.6 mg) when pregnancy is confirmed. Women who have had a previous child with a neural tube defect should take 4 mg of folic acid for 1 month before and during the first trimester of pregnancy (AAP & ACOG, 2012; ACOG, 2010a; Samuels, 2012; Strong & Rutherford, 2011).

Most prenatal vitamins contain 1 mg of folate to ensure sufficient intake. Higher doses of folate may be prescribed according to individual needs.

Sickle Cell Disease

Sickle cell disease is an autosomal recessive genetic disorder. It occurs when the gene for the production of hemoglobin S is inherited from both parents. The defect in the hemoglobin causes erythrocytes to become shaped like a sickle, or crescent, under certain conditions. Low oxygen concentration usually causes the sickling, with acidosis and dehydration worsening the process. At first the erythrocytes regain their normal shape, but eventually they remain permanently sickled. Because of their distorted shape, the erythrocytes cannot pass through small arteries and capillaries and tend to clump together and occlude the blood vessel.

The disease is characterized by chronic anemia because of the short life span of erythrocytes affected with hemoglobin S, increased susceptibility to infection, and periodic episodes of obstruction of blood vessels by the abnormally shaped erythrocytes. Sickle cell disease occurs most often in people who have ancestors from sub-Saharan Africa, Spanish-speaking countries in the western hemisphere (South America, Caribbean, Central America), Saudi Arabia, India, and Mediterranean countries. In the United States, about 1 in 500 births in the Black or African-American population and 1 in 36,000 births in the Hispanic population will result in an infant with sickle cell anemia. Sickle cell anemia affects 90,000 to 100,000 people in the United States. One in 12 blacks or African-Americans are carriers of the sickle cell trait and may pass the gene on to their children, even though they are not affected (ACOG, 2008; National Institutes of Health [NIH]: National Heart, Lung, & Blood Institute [NHLBI], 2012; Samuels, 2012).

Maternal Effects

The physiologic anemia, increased coagulation factors, and venous stasis, which are normal in pregnancy may bring on *sickle cell crisis*,

sometimes for the first time. This broad term includes several different conditions, particularly temporary cessation of bone marrow function, hemolytic crisis with massive erythrocyte destruction resulting in jaundice, and severe pain caused by infarctions located in the joints and the major organs. In addition, expectant mothers with sickle cell anemia are prone to pyelonephritis, bone infection, and heart disease. Preeclampsia occurs in about 14% of these women. Preterm birth and IUGR are common. Mothers with higher hemoglobin F (fetal hemoglobin) levels may have a lower perinatal mortality rate, but fetal safety has not been established for hydroxyurea that increases its production (ACOG, 2008; NIH:NHLBI, 2012; Samuels, 2012; Strong & Rutherford, 2011).

Fetal and Neonatal Effects

In the absence of maternal sickle cell crisis, the fetus usually fares well, although complications such as prematurity and IUGR are more common. The incidence of fetal loss is high if sickle cell crisis occurs because of placental infarctions with loss of exchange surface on the placenta (ACOG, 2008; NIH:NHLBI, 2012; Samuels, 2012; Strong & Rutherford, 2011).

Therapeutic Management

Women with sickle cell disease should seek preconception care or early prenatal care and be informed of the maternal and fetal risks associated with the pregnancy. Folic acid supplementation of 4 mg (400 mcg) daily is prescribed, ideally before conception, because of frequent erythrocyte turnover. Frequent measurements of hemoglobin, complete blood cell count, serum iron, total iron-binding capacity, and serum folate are necessary to determine the degree of anemia and iron and folic acid stores. Testing is performed for infections such as hepatitis, human immunodeficiency virus (HIV) infection, tuberculosis (TB), and STDs. Hepatitis B and varicella vaccines may be given to the noninfected woman who is not immune to these infections. Urinalysis, with culture and sensitivity, if indicated, identifies both clinical and subclinical urinary tract infections that should be treated.

Fetal surveillance studies (ultrasonography, nonstress tests, and biophysical profiles) assess fetal growth and development and placental function. Exchange transfusions or prophylactic transfusions may be used to increase the amount of normal hemoglobin in the mother's circulation and to reduce severe anemia. Risks of prophylactic transfusions are comparable with risks in the woman without sickle cell disease. The woman with sickle cell disease may have a transfusion reaction and is likely to develop higher levels of antibodies to the cells in the transfused blood. Finding compatible blood for later transfusion might be more difficult. Prenatal supplementation of vitamins without iron may be prescribed for the woman who receives multiple transfusions but for whom additional folic acid is indicated (ACOG, 2010a; Cunningham et al., 2010; NIH:NHLBI, 2012; Samuels, 2012; Strong & Rutherford, 2011).

The goal of nursing management is to help the pregnant woman with sickle cell disease maintain a healthy state and avoid hospitalization. Women must be encouraged to keep all prenatal care appointments, usually every other week and more frequently, if needed. Topics in prenatal education include the need for (1) adequate hydration to prevent sickling, (2) adequate nutrition to meet metabolic needs, (3) folic acid supplementation for erythrocyte production, (4) rest periods throughout the day, (5) good hygiene practices and the avoidance of persons with infectious illnesses, and (6) prompt treatment for fever or other signs of infection.

Nurses must be alert for signs of a sickle cell crisis. The most common indications are pain in the abdomen, chest, vertebrae, joints, or extremities; pallor; and signs of cardiac failure. Nurses also must

provide comfort measures such as repositioning and good skin care, assisting with ambulation and movement in bed, and assisting the woman to splint the abdomen with a pillow when she must cough or breathe deeply.

Nurses must remember that pain is not always related to the sickling crisis but could be related to a complication of pregnancy. Women with sickle cell disease also can have ectopic pregnancy, abruptio placentae, appendicitis, and other painful complications not related to their blood disorder.

Intrapartum care focuses on preventing the development of sickle cell crisis. Oxygen is administered continuously, and fluids should be administered to prevent dehydration because hypoxemia and dehydration as well as exertion, infection, and acidosis stimulate the sickling process. Packed red blood cells (PRBCs) may be administered to women who have a hemoglobin level less than 8 g/dL or a hematocrit less than 20%. Prophylactic blood transfusions may be given in an attempt to reduce perinatal mortality (Samuels, 2012).

Thalassemia

Like sickle cell anemia, thalassemia is a genetic disorder that involves the abnormal synthesis of alpha or beta chains of hemoglobin. This abnormal synthesis leads to alterations in the RBC membrane and decreased life span of RBCs. Thalassemia is named and classified by the type of chain that is abnormal. Beta-thalassemia is most frequently encountered in the United States, often in those of Mediterranean, Middle Eastern, and Asian descent.

Beta-thalassemia minor refers to the heterozygous form that results from the inheritance of one abnormal gene from either parent. *Beta-thalassemia major* refers to inheritance of the gene from both parents (homozygous form). Females with beta-thalassemia major (Cooley's anemia) usually die in young adulthood. Those females who survive are often sterile (ACOG, 2008; Cunningham et al., 2010; Kilpatrick, 2009; Samuels, 2012).

Maternal Effects

Women with beta-thalassemia minor often are mildly anemic but otherwise healthy. Laboratory values normally associated with beta-thalassemia minor indicate a mild hypochromic and microcytic anemia. Large amounts of iron usually are not given despite the anemia because persons with beta-thalassemia absorb and store iron in their bodies excessively and must take a chelating agent to rid the excess. Chelation therapy to remove heavy metals such as iron is discontinued during pregnancy, if possible, because pregnancy safety has not been established (ACOG, 2008; Samuels, 2012; Strong, 2011).

Fetal and Neonatal Effects

Whether the disorders are associated with increased fetal or neonatal morbidity remains unresolved because of the many variants of thalassemia. There appears to be no increase in the rate of prematurity, low-birth-weight infants, or abnormal size for gestation. Fetal anemia may be serious if inadequate fetal hemoglobin is produced. The fetus may inherit the serious problem of beta-thalassemia major if both parents have beta-thalassemia minor.

Therapeutic Management

No specific therapy for beta-thalassemia minor during pregnancy exists. Generally, the outcomes for the mother and fetus are satisfactory (ACOG, 2012; Cunningham et al., 2010; Samuels, 2012). Infections that depress the production of RBCs and accelerate erythrocyte destruction should be identified and treated promptly.

MEDICAL CONDITIONS

Women with a preexisting medical condition should be aware of the effects that pregnancy will have on their conditions as well as the impact of their medical conditions on pregnancy outcome. Some conditions that complicate pregnancy are discussed in this section (Table 26-2).

Immune-Complex Diseases Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic, inflammatory, autoimmune disease that can affect any organ or system in the body. The body attacks its own tissues as it would foreign antigens that enter. Although the cause is unknown, an imbalance appears to exist between normal immune response to foreign antigens and an abnormal immune response of the body against its own cells. Signs and symptoms result from inflammation of multiple organ systems, especially the joints, skin, kidneys, and the CNS. The most common signs and symptoms of SLE are joint pain, photosensitivity, and a characteristic "butterfly rash" on the face, which may be less apparent because of the pigmentation changes of pregnancy. The disease is marked by episodes of *exacerbation* (flares), when the symptoms become worse, and *quiescence*, when the symptoms recede.

The disease tends to affect young women but may occur in any age group. Females are affected 6 to 10 times more often compared with males. There is sometimes a family aggregation, but it is usually sporadic. It is more common in women of African, Hispanic, Asian, and Native American descent (CDC, 2012f; Chin & Branch, 2012; Denney, Porter, & Branch, 2011; NIH:National Institute of Arthritis and Musculoskeletal and Skin Diseases [NIAMS], 2011).

Because pregnancy can worsen SLE (*flare*), the woman must be carefully observed for signs of disease progression. Renal complications, often evidenced by proteinuria or cellular casts in urine, pose a special risk. Women with a history of renal problems should be advised to seek the advice of a physician before becoming pregnant. Pregnancy is most likely to have a favorable outcome in the woman whose disease is well controlled at the beginning and who does not have renal involvement. However, flares of SLE or disorders such as preeclampsia are more likely to occur during pregnancy and early postpartum (Chin & Branch, 2012; Denney, Porter, & Branch, 2011).

SLE is associated with increased incidences of spontaneous abortion and fetal death during the first trimester. After the first trimester, the prognosis for a live birth is higher if no active disease exists. Newborn risks include preterm birth, often resulting from preterm rupture of the membranes, and growth restriction. The most serious potential complication for the neonate is a congenital heart block, which usually is permanent and will require a pacemaker (Chin & Branch, 2012).

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) is an autoimmune condition characterized by the production of antiphospholipid antibodies combined with certain clinical features. Specific clinical features include thrombosis confirmed by imaging or pathologic studies, abnormal and

TABLE 26-2 MEDICAL CONDITIONS AND THEIR EFFECTS ON PREGNANCY

CONDITION	MATERNAL-FETAL EFFECTS	NURSING CONSIDERATIONS
<p>Appendicitis</p> <p>Inflammation of appendix, often with fever. Most common nongynecologic surgical emergency during pregnancy.</p>	<p>Is difficult to diagnose during pregnancy. Early symptoms mimic common conditions of pregnancy. Ultrasonography may help rule out other diagnoses such as ectopic pregnancy.</p>	<p>When reasonable doubt exists that patient has appendicitis, appendix should be removed to prevent rupture and consequent complications. Location of appendix often is altered by growing uterus. Fetal hyperthermia may be caused by maternal fever.</p>
<p>Asthma</p> <p>Obstructive lung disease caused by airway inflammation. Characterized by dyspnea, cough, wheezing. Course in pregnancy is variable.</p>	<p>Effective therapy and avoidance of severe attacks are associated with good pregnancy outcome. Medications used are well tolerated in pregnancy and appear to be safe for fetus. Breastfeeding is safe for newborn and may reduce risk for allergies.</p>	<p>Early use of antiinflammatory agents such as inhaled corticosteroids may prevent severe attacks. Inhaled cromolyn sodium and nedocromil sodium are effective but require more time to become effective than inhaled corticosteroids. Bronchodilators such as theophylline and inhaled beta-agonists may be required.</p>
<p>Glucose-6-Phosphate Dehydrogenase Deficiency</p> <p>Female-linked genetic disorder that predisposes to lysis of red blood cells when exposed to oxidizing drugs (salicylates, acetaminophen, phenacetin, and some sulfa drugs) and ingestion of fava beans in some people.</p>	<p>Is not affected by pregnancy unless complicated by anemia. Iron and folic acid supplementation is recommended. Newborn males have a higher incidence of severe jaundice.</p>	<p>Advise client of risks and suggest she consult with her health care provider for recommended list of drugs for minor discomforts.</p>
<p>Hyperthyroidism</p> <p>An overactive, enlarged thyroid gland that is difficult to diagnose and manage during pregnancy because normal changes of pregnancy increase metabolic rate and mimic hyperthyroidism. Graves' disease is most common cause during pregnancy. Treatment ideally begins before pregnancy.</p>	<p>Increased incidence of hypertension such as preeclampsia and postpartum hemorrhage if not well controlled during pregnancy. Treatment is complicated by presence of fetus, which may be jeopardized by surgery or antithyroid medications. Propylthiouracil (PTU) has limited placental transfer and is widely used during pregnancy to control thyroid function. Additional drugs such as iodides and beta-blockers may be needed, particularly in a thyroid crisis.</p>	<p>Be aware of major signs that should be reported. These include resting pulse rate greater than 100 bpm, loss of weight or failure to gain weight in spite of normal intake of food, heat intolerance, and abnormal protrusion of eyes (exophthalmos).</p>
<p>Hypothyroidism</p> <p>Characterized by inadequate thyroid secretion; confirmed by an elevated level of thyroid-stimulating hormone and low levels of triiodothyronine and thyroxine.</p>	<p>Women with hypothyroidism have a higher incidence of preeclampsia, abruptio placentae, and low-birth-weight, preterm, or stillborn infants. If woman is untreated, there is an increased risk of neonatal goiter and congenital hypothyroidism; severity of symptoms depends on time of onset and severity of hormonal deprivation but may include neurologic deficits. Treatment is with levothyroxine.</p>	<p>State screening for congenital hypothyroidism is required. Signs of congenital hypothyroidism may include skin mottling, a large tongue, hypotonia, depressed reflexes, and abdominal distention.</p>
<p>Maternal Phenylketonuria (PKU)</p> <p>Inherited autosomal recessive defect leading to inability to metabolize essential amino acid phenylalanine, resulting in high serum levels of phenylalanine. Irreparable mental retardation occurs if pregnant woman is not treated early with a diet that provides adequate protein but restricts phenylalanine.</p>	<p>Woman must have low-phenylalanine diet before conception and pregnancy. If not, fetal risk for microcephaly, mental retardation, heart defects, and intrauterine growth restriction increases.</p>	<p>Child either will be a carrier of the gene or will inherit the disease, depending on the presence of the gene in the father of the child. Special low-phenylalanine foods are expensive, but they may be obtained through the state's Supplemental Nutrition Program for Women, Infants, and Children (WIC) or Medicaid or may be covered by private insurance.</p>

recurrent pregnancy outcomes, and elevated anticardiolipin antibody or presence of lupus anticoagulant. Pregnancy problems may include the following:

- One or more unexplained fetal deaths at or after 10 weeks of gestation
- One or more preterm births of a normal infant at or before 34 weeks of gestation that is related to severe preeclampsia or severe placental insufficiency
- Three or more unexplained recurrent spontaneous abortions before 10 weeks of gestation

Although the syndrome occurs most often in women with other underlying autoimmune diseases such as SLE, it also is diagnosed in women with no other recognizable autoimmune disease.

Women with APS should be informed about potential maternal and obstetric problems, including a possible risk of stroke. They should be assessed for evidence of anemia, thrombocytopenia, and underlying renal disease. Some physicians believe that treatment with heparin may be warranted on the basis of increased risk for thrombosis, even in women with no previous clotting problems. Combinations of low-dose aspirin and prophylactic heparin or enoxaparin are recommended for pregnant women with APS (Chin & Branch, 2012; Denney, Porter, & Branch, 2011).

Hashimoto's Thyroiditis

Hashimoto's thyroiditis, characterized by antithyroid antibodies, causes most cases of hypothyroidism in women. Hypothyroidism in pregnancy increases risk for miscarriage, preterm birth, and preeclampsia. Maternal hypothyroidism during pregnancy can adversely affect the child's mental development. Thyroid-stimulating hormone (TSH) level should be tested before or in early pregnancy and hypothyroidism corrected within the first trimester (Chin & Branch, 2012; Mestman, 2012).

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory disease that usually affects the synovial (hinged) joints. Although the cause is unknown, an autoimmune mechanism is suspected.

Marked improvement in symptoms of RA often occurs during pregnancy. The exact reason is unclear, but improvement is reported to parallel the rise in pregnancy-specific protein, which suppresses inflammatory reactions. Hormonal factors also have been suggested. For instance, increased levels of cortisol, estrogen, and progesterone may be beneficial in suppressing the immune response. Rheumatoid joints may become unstable in late pregnancy with the natural joint relaxation and changes in weight distribution. Unfortunately, a relapse (postpartum flare) occurs within 6 weeks to 6 months after birth (Chin & Branch, 2012; Denney, Porter, & Branch, 2011).

In contrast to SLE, the risk of abortion does not increase markedly in women with RA. Usually, obstetric problems do not occur at delivery unless the hips or cervical spine are significantly deteriorated (Chin & Branch, 2012; Denney, Porter, & Branch, 2011).

Neurologic Disorders

Seizure Disorders

Seizures are the most common form of epilepsy, which is a recurrent disorder of cerebral function. Epilepsy occurs in about 1% of the general population. Seizures may occur during pregnancy, even though the woman has been seizure free for many years. Seizures that occur only during pregnancy have also been reported (Carhuapoma, Tomlinson, & Levine, 2011; Samuels & Niebyl, 2012).

The effect of pregnancy on the course of epilepsy is variable and unpredictable. The frequency of seizures may increase, decrease, or

remain the same. In general, the longer the woman has been seizure free before pregnancy, the less likely is the occurrence of seizures during pregnancy. Those with partial (focal) seizures are more likely to experience increased frequency. Vomiting, reduced gastric motility, use of gastrointestinal medications, and weight gain affect the absorption and distribution of anticonvulsant drugs. Serum levels of anticonvulsants may rise, fall, or remain the same during pregnancy.

Women with epilepsy have a higher-than-normal incidence of stillbirth, and some studies have shown a higher incidence of preterm labor. Maternal bleeding may occur because of a deficiency of clotting factors associated with anticonvulsant drugs such as hydantoins (Dilantin) and phenobarbital. Anticonvulsant drugs also compete with folate for absorption, which may result in folate deficiency. Most anticonvulsants are classified as pregnancy category C or D. (See Appendix A for additional drugs and their possible adverse effects on the fetus.) Interactions between anticonvulsant drugs and other medications must be considered by the physician and pharmacist because dose changes or selection of valid alternative drugs may be needed. Effects of anticonvulsants and over-the-counter drugs must be considered as well.

A major concern is the teratogenic effects of anticonvulsant drugs. A specific syndrome known as *fetal hydantoin syndrome*, which includes craniofacial abnormalities, limb reduction defects, growth restriction, intellectual disability, and cardiac anomalies, has been described. Other anticonvulsants such as trimethadione, paramethadione, and carbamazepine also are associated with malformation syndromes. The teratogenic effects of phenobarbital are difficult to assess because it often is combined with other drugs. Newer anticonvulsants such as levetiracetam have fewer accumulated data related to fetal effects.

Health care professionals should recommend that the woman consult a neurologist before conception. The goal of treatment is to prevent generalized (formerly called *grand mal*) seizures and also reduce the adverse effects of anticonvulsant medications on the fetus. The family must be made aware of the risks involved when anticonvulsant drugs must be used. The woman and her family must also realize that treatment cannot be stopped during pregnancy unless the woman has been seizure free for a prolonged time and *stopped only at the directive of her physicians*. Generalized seizures result in fetal hypoxia and acidosis and therefore pose a serious problem for the fetus.

Bell's Palsy

Bell's palsy is a sudden unilateral neuropathy of the seventh cranial (facial) nerve that causes facial paralysis with weakness of the forehead and lower face. No cause for the neuropathy is often identified, although inflammation or viral infection of the facial nerve are possible causes. It is three times more common during pregnancy and generally occurs in the third trimester. Although the reason for the increase during pregnancy is unknown, one theory suggests that estrogen-induced edema causes pressure on the facial nerve, making the pregnant woman more vulnerable to the condition. Most women recover within 3 to 6 weeks after birth (Carhuapoma et al., 2011; Samuels & Niebyl, 2012).

The face feels stiff and pulled to one side. Closing the eye on the affected side may be difficult or impossible. Difficulty with eating or fine facial movements may occur. The ability to taste also may be disturbed.

Treatment is controversial. Some physicians prescribe steroids within the first few days. Supportive care includes applying a patch over the eye and applying ointment or eye drops to prevent dryness or injury to the exposed cornea. Facial massage may be helpful, and the woman should be cautioned to chew carefully, since she could easily

bite the inside of her mouth or her tongue. Psychological support is necessary to assist the woman and her family deal with the anxiety they naturally feel when sudden paralysis of the face occurs. They must be reassured that the condition is temporary in the majority of women who have Bell's palsy.

INFECTIONS DURING PREGNANCY

A number of different infections acquired during pregnancy can adversely affect the health of the fetus, the mother, or both. Some infections are mild or even subclinical in the mother and yet may cause severe birth defects or death of the fetus. Other infections may have adverse effects by increasing the risk for other pregnancy complications such as preterm labor. Some infections are transmitted primarily or exclusively by sexual means, whereas others may be transmitted not only in this way but also by other avenues.

The wide variety of infections affecting pregnancy care are divided into those caused by viruses and those caused by other organisms. [Table 26-3](#) presents nursing considerations related to major STDs and vaginal infections. Also, [Table 26-3](#) summarizes urinary tract infections and their effects on pregnancy. (See also [Chapter 34](#) for information about infection in the nonpregnant woman.)

Viral Infections

Pregnancy does not worsen the effects of most viral infections. Although viral infections may be mild or even asymptomatic in mothers, fetal and neonatal consequences can be catastrophic. Maternal infections with cytomegalovirus (CMV), rubella, varicella-zoster virus, herpes simplex, hepatitis B, and HIV have the greatest potential for causing harm to the fetus or newborn.

Cytomegalovirus

CMV, a member of the herpesvirus group, is widespread and eventually infects most humans. CMV has been isolated from urine, saliva, blood, cervical mucus, semen, breast milk, and stool. Transmission may occur from contamination with any of these fluids, although close personal contact is required. CMV infection during pregnancy may be primary or recurrent. Symptoms of CMV infection are so vague that a woman is often unaware that she has an infection.

Daycare centers are a common place for transmission of CMV among children, especially toddlers, because they often share objects contaminated with saliva. Mothers and caregivers of young children who attend a daycare center should be aware that a child might acquire an infection in the center and transmit it to those who are at risk for a primary infection. As puberty approaches, behaviors such as kissing, sexual intercourse, and other close bodily contacts again increase the possibility that CMV infection will be transmitted to a female who may be pregnant ([Bernstein, 2012](#); [Duff, 2012](#); [Duff, Sweet, & Edwards, 2009](#); [Roos & Baker, 2011](#)).

After primary infection, the virus becomes latent, but like other herpesvirus infections, periodic reactivation and shedding of the virus

may occur. Primary infection is more likely to cross the placenta, infecting the fetus, than is a reactivation infection. **Seroconversion** (change in blood test from negative to positive indicating development of antibodies in response to infection or immunization) and a rise in the specific IgM antibody titer can detect a primary infection that has occurred within the past 4 to 8 months. Isolation of the virus in amniotic fluid culture or **polymerase chain reaction (PCR)** (rapid analysis of gene sequence for in vitro diagnosis of infections) identifies infection but does not distinguish whether the infection is primary or recurrent ([Bernstein, 2012](#); [Roos & Baker, 2011](#)). Most infections are asymptomatic, so they may not be suspected during pregnancy, and testing may not be done. Diagnosis of neonatal infection is by urine culture.

Fetal and Neonatal Effects. About 90% of newborns are not affected, but about 10% are symptomatic at birth. About 10% of newborns showing signs of infection at birth will demonstrate full cytomegalic inclusion disease. Another 10% of the group showing CMV infection at birth will develop late-onset signs such as developmental delay, seizure activity, enlargement of the spleen and liver, chorioretinitis, dental defects, and hearing loss ([Bernstein, 2012](#); [Roos & Baker, 2011](#)).

Therapeutic Management. No effective therapy is currently available for the treatment of congenital CMV infection. Ultrasound scanning may identify manifestations of the infection, such as cranial abnormalities or growth restriction. Antiviral agents such as ganciclovir and foscarnet may be used for severe infections, but these drugs are toxic and only temporarily suppress the shedding of the virus. Primary prevention—by emphasizing handwashing (especially to women who care for small children), warning about the risks of having several sexual partners, and transfusing only CMV-free blood—is most effective ([Bernstein, 2012](#); [Roos & Baker, 2011](#)).

Rubella

Rubella is caused by a virus transmitted from person to person through droplets or through direct contact with articles contaminated by nasopharyngeal secretions. Rubella infection after birth is a mild disease, but congenital rubella could have severe consequences for the newborn. Common rubella signs and symptoms include fever, general malaise, and a characteristic maculopapular rash that begins on the face and migrates over the body. Fewer than 10% of pregnant women are not immune because infection confers permanent immunity. The overall incidence of rubella has declined since the vaccine became available in 1969, although many young adults remain at risk. The decline in adult rubella has virtually eliminated congenital rubella. Most U.S. cases of congenital rubella occur in foreign-born mothers, although there have been periodic rubella outbreaks in the United States ([Bernstein, 2012](#); [Riley, 2011](#)).

Fetal and Neonatal Effects. Rubella virus from the mother can cross the placental barrier and infect the fetus at any time during pregnancy. The greatest risk to the fetus is during the first trimester, when fetal organs are developing. If maternal infection occurs during this time, approximately one third of these cases will result in spontaneous abortions, and surviving fetuses may be seriously compromised. Deafness, developmental delay, cataracts, cardiac defects, IUGR, and microcephaly are the most common fetal complications. In addition, infants born to mothers who had rubella during pregnancy shed the virus for many months and therefore pose a threat to other infants and susceptible adults who come in contact with them. As pregnancy progresses, the risk of congenital rubella decreases ([Bernstein, 2012](#); [Duff, Sweet, & Edwards, 2009](#)).

Therapeutic Management. Prevention is the only effective protection for the fetus. Women who are immune do not become infected,

so determining the immune status of all women of childbearing age is critical.

A rubella titer of 1:8 or greater provides evidence of immunity. Women who are not immune should be vaccinated before they become pregnant, and they should be advised not to become pregnant for 28 days after vaccination because of the possible risk to the fetus from the live-virus vaccine, although the actual risk appears to be low. Many nonimmune women are vaccinated during the postpartum period so that they will be immune before becoming pregnant again. In most facilities, women of childbearing age must read and sign a document indicating that they understand the risks to the fetus if they become pregnant within 28 days. (See Chapter 17 for the drug guide for rubella vaccine.)

Varicella-Zoster Virus

Varicella infection (chickenpox) is caused by varicella-zoster virus (VZV), a herpesvirus that is transmitted by direct contact or through the respiratory tract. Over 90% of people will have varicella infection before reaching reproductive age. After the primary varicella infection, the virus can become latent in the nerve ganglia. If VZV is reactivated, herpes zoster (shingles) results. Maternal complications of acute varicella infection may include preterm labor, encephalitis, and varicella pneumonia, which is the most serious complication associated with VZV. Varicella immunization has resulted in a marked decrease in children's varicella, well before they reach the reproductive age.

Fetal and Neonatal Effects. Fetal and neonatal effects depend on the time of maternal infection. If the infection occurs during the first trimester, the fetus has a small risk for congenital varicella syndrome (0.4%). The greatest risk for development of congenital varicella syndrome occurs during 13 to 20 weeks of gestation (2% of births). Clinical findings include limb hypoplasia, cutaneous scars, chorioretinitis, cataracts, microcephaly, and IUGR. In later pregnancy, transplacental passage of maternal antibodies usually protects the fetus (Bernstein, 2012; Riley, 2011).

However, the infant who is infected during the perinatal period (5 days before through 2 days after birth) will not have the benefit of maternal antibodies. Four days before birth is not sufficient time for the mother to develop antibodies to VZV and pass them to the fetus. Varicella infection occurring in the fetus or infant just before or after birth would not be inactivated by antibodies, which leaves the infant at risk for life-threatening neonatal varicella infection. Varicella-zoster immune globulin (VZIG) is indicated for the infant infected perinatally. Infants born earlier than 28 weeks or who weigh 1000 g or less are given VZIG because maternal antibodies to VZV earlier in pregnancy have not yet crossed the placenta, reducing natural passive immunity (Bernstein, 2012; CDC, 2012a, c; Riley, 2011).

Therapeutic Management. Immune testing may be recommended for pregnant women who are presumed to be susceptible. VZIG should be administered to women who have been exposed and whose fetuses are at high risk for congenital rubella syndrome, although this may not prevent primary infection. Women infected with varicella during pregnancy should be instructed to report pulmonary symptoms immediately. Hospitalization, fetal surveillance, full respiratory support, and hemodynamic monitoring should be available for women diagnosed with varicella-zoster pneumonia because it may become severe in a short time. Acyclovir is the primary drug used to treat varicella quickly.

For infants born to mothers infected with varicella during the perinatal period, immunization with VZIG as soon as possible but within 96 hours of birth provides passive immunity against varicella. Women and infants with varicella are highly contagious and should be placed

in airborne and contact isolation. Only staff members known to be immune to varicella should come in contact with these clients.

Adult immunization with the live attenuated varicella vaccine (Varivax) is recommended for nonpregnant adults who have no evidence of having had varicella. A pregnant woman should not be immunized, but members of her household may be immunized because the vaccine is not transmissible from one person to another. A nonimmune woman should receive the vaccine before discharge and her second 4 to 8 weeks postpartum. She should be instructed to avoid pregnancy for 1 month after each of the two injections. Nonimmune health care workers should be immunized (Bernstein, 2012; CDC, 2012a; Riley, 2011).

Herpes Simplex Virus

Genital herpes is one of the most common sexually transmitted diseases in the herpes simplex virus (HSV) group. It may be caused by HSV type 1 or 2. Most infections of genital herpes are caused by type 2. Type 1, which is more common in the mouth and upper body, also may infect the genital area. HSV infection occurs as a result of direct contact of the skin or mucous membrane with an active lesion. Lesions form at the site of contact and begin as a group of painful papules that progress rapidly to become vesicles, shallow ulcers, pustules, and crusts. The infected person sheds the virus until the lesions are healed. The virus then migrates along the sensory nerves to reside in the sensory ganglion, and the disease enters a latent phase. It can be reactivated later as a recurrent infection. Many women infected with HSV do not have signs and symptoms of infection and thus may shed the virus unknowingly (Bernstein, 2012; Roos & Baker, 2011).

Vertical transmission (from mother to infant) generally occurs in one of two ways: (1) after rupture of membranes, when the virus ascends from active lesions; or (2) during birth, when the fetus comes in contact with infectious genital secretions or when the fetal skin is punctured such as with a fetal scalp electrode.

Diagnosis usually is based on clinical signs and symptoms. Definitive diagnosis requires culture of the virus from an active lesion, and results may take as long as 5 days. Newer tests based on genetic analysis (PCR) are becoming common for detection of HSV and other infections.

Fetal and Neonatal Effects. Complications of pregnancy from a recurrent infection are rare. However, if primary infection occurs during pregnancy, the rates of spontaneous abortions, IUGR, and preterm labor increase. Neonatal herpes infection is uncommon but potentially devastating. The neonate may have infection that is limited to skin lesions or systemic (disseminated). Symptoms usually appear within the first week, and the disease progresses rapidly. The likelihood of death or serious sequelae in infants who have systemic herpes infection is about 50%. The risk of neonatal infection is greatest if the mother has a primary (rather than recurrent) infection during the perinatal period. This is most likely because the amount of virus shed is higher during a primary infection than during subsequent ones (Bernstein, 2012; Roos & Baker, 2011).

Therapeutic Management. No known cure for herpes infection exists, although antiviral chemotherapy (acyclovir) is prescribed to reduce symptoms and shorten the duration of the lesions. Acyclovir may be given during late pregnancy to a woman with a recurrent outbreak to reduce the possibility of her having active lesions at the time of birth.

For women with a history of genital herpes, vaginal birth is allowed if there are no genital lesions at the time of labor. Cesarean birth is recommended for women with active lesions in the genital area, whether recurrent or primary, at the time of labor. Use of fetal scalp electrodes, which cause a break in the skin, is acceptable if there are no

TABLE 26-3 SEXUALLY TRANSMITTED DISEASES, URINARY TRACT AND VAGINAL INFECTIONS: IMPACT ON PREGNANCY

MATERNAL, FETAL, AND NEONATAL EFFECTS	NURSING CONSIDERATIONS
Sexually Transmitted Diseases	
Syphilis (Causative Organism: <i>Spirochete Treponema pallidum</i>)	
<p>If untreated, infection may cross placenta to fetus and result in spontaneous abortion, stillborn infant, premature labor and birth, or congenital syphilis. Major signs of congenital syphilis are enlarged liver and spleen, skin lesions, rashes, osteitis, pneumonia, and hepatitis.</p>	<p>Benzathine penicillin G is primary treatment to cure disease in both woman and fetus. Women who are allergic are desensitized and then treated.</p>
Gonorrhea (Causative Organism: <i>Bacterium Neisseria gonorrhoeae</i>)	
<p>Not transmitted via placenta; vertical transmission from mother to newborn during birth may cause ophthalmia neonatorum. Endocervicitis and weakness of fetal membranes increase risk for premature rupture of membranes and preterm labor. <i>Chlamydia</i> infection is likely to accompany gonorrhea infection.</p>	<p>Cephalosporins such as ceftriaxone (pregnancy category B) are recommended for gonorrhea during pregnancy. Because 20% to 50% of women with gonorrhea also have chlamydial infection, azithromycin or amoxicillin (pregnancy category B) is recommended to accompany gonorrhea treatment. Partner must also be treated to prevent reinfection. Infants are treated with an ophthalmic antibiotic such as ceftriaxone at birth to prevent ophthalmia neonatorum. Tetracycline should not be used in a pregnant woman for chlamydial infection that often accompanies gonorrhea.</p>
Chlamydial Infection (Causative Organism: <i>Bacterium Chlamydia trachomatis</i>)	
<p>Chlamydial infection is most common sexually transmitted disease in United States and often accompanies gonorrhea. Fetus may be infected during birth and suffer neonatal conjunctivitis or pneumonitis. Conjunctivitis is prevented by erythromycin ophthalmic ointment. <i>Chlamydia</i> may be responsible for premature rupture of membranes, premature labor, and chorioamnionitis.</p>	<p>Education is particularly important because infection is usually asymptomatic. Both partners should be treated to prevent recurrent infection. As with all sexually transmitted diseases, use of condoms decreases risk for infection. Azithromycin or amoxicillin is recommended treatment during pregnancy. Tetracycline should not be used during pregnancy.</p>
Trichomoniasis (Causative Organism: <i>Protozoan Trichomonas vaginalis</i>)	
<p>Common cause of vaginitis in 10% to 50% of pregnant women. Associated with premature rupture of membranes and postpartum endometritis.</p>	<p>Metronidazole (Flagyl), pregnancy category B, may be given to pregnant woman as 2-g single oral dose. Should withhold breastfeeding during treatment and 12 to 24 hours after last dose. Consistent association between fetal abnormalities or injury and metronidazole use has not been upheld.</p>
Condyloma Acuminatum (Causative Organism: <i>Human Papillomavirus [HPV]</i>)	
<p>Transmission of condyloma acuminatum, also called venereal or genital warts, may occur during vaginal birth and is associated with development of epithelial tumors of mucous membranes of larynx in children. Pregnancy can cause proliferation of lesions, which are associated with cervical dysplasia and cancer.</p>	<p>Common choices for nonpregnant therapy (podophyllin, podofilox, imiquimod) are not recommended during pregnancy. Excision of maternal lesions by cryotherapy or cautery may be done. HPV vaccine is available in a three-dose series to protect against four strains of virus that are major causes of cervical cancer and genital warts. Routine immunization of girls should start at 11 to 12 years but can start as young as 9 years. Catch-up immunization is recommended for girls and women 13 to 26 years to prevent infection with these four specific types of HPV. Immunization will not prevent disease if woman is already infected. Quadrivalent vaccine can also be used for males 9 to 26 years. See www.cdc.gov/vaccines for current information.</p>
Vaginal Infections	
Candidiasis (Causative Organism: <i>Yeast Candida albicans</i>)	
<p>Oral candidiasis (thrush) may develop in newborns if maternal vaginal infection is present at birth. Thrush is treated with application of nystatin (Mycostatin) over surfaces of oral cavity four times a day for several days. Characteristic "cottage cheese" vaginal discharge with vulvar pruritus, burning, and dyspareunia. Vulva may be red, tender, and edematous.</p>	<p><i>C. albicans</i> is part of the normal vaginal flora but may become pathogenic if the yeast becomes excessive. Candidiasis (sometimes called <i>Monilia vaginitis</i>) is a persistent problem for many women during pregnancy. Examples of maternal treatment choices include topical nystatin, miconazole, clotrimazole, butoconazole terconazole, and tioconazole.</p>

TABLE 26-3 SEXUALLY TRANSMITTED DISEASES AND URINARY TRACT AND VAGINAL INFECTIONS: IMPACT ON PREGNANCY—cont'd

MATERNAL, FETAL, AND NEONATAL EFFECTS	NURSING CONSIDERATIONS
<p>Bacterial Vaginosis (Causative Organism: <i>Gardnerella vaginalis</i>)</p> <p>Adverse pregnancy outcomes include preterm rupture of membranes, preterm labor and birth, intraamniotic infection, and postpartum endometritis. Marked by a major shift in vaginal flora from normal predominance of lactobacilli to predominance of anaerobic bacteria. Causes profuse, malodorous, “fishy” vaginal discharge, itching, and burning. “Clue cells” may be seen microscopically in a wet mount prep of vaginal secretions.</p>	<p>Metronidazole vaginal application or clindamycin oral therapy for 7 days is recommended during pregnancy. Clinical trials have shown that women at high risk for preterm birth may benefit from this medication regimen.</p>
<p>Urinary Tract Infections</p> <p>Asymptomatic Bacteriuria (Causative Organisms: <i>Escherichia coli</i>, <i>Klebsiella</i>, <i>Proteus</i>)</p> <p>Ascending bacterial infection can result in cystitis or pyelonephritis in later pregnancy if condition remains untreated.</p>	<p>Recovery of a urinary pathogen from a midstream, clean-catch urine specimen is defined as 100,000 colony-forming units (CFUs) per mL of urine. Rapid, less-expensive office tests to identify infection also may be used. Treatment for asymptomatic bacteriuria may include treatment for pathogens that also cause symptomatic cystitis.</p>
<p>Cystitis (Causative Organisms: <i>E. coli</i>, <i>Klebsiella</i>, <i>Proteus</i>)</p> <p>Signs and symptoms include dysuria, frequency, urgency, and suprapubic tenderness. Ascending infection may lead to pyelonephritis.</p>	<p>Antibiotics used for both asymptomatic bacteriuria and cystitis may include amoxicillin, ampicillin, trimethoprim-sulfamethoxazole, nitrofurantoin, or a 3rd-generation cephalosporin such as ceftriaxone. Emphasize importance of reporting signs of urinary tract infection. Stress importance of taking all medication prescribed in the 7-day course even if symptoms abate. Provide information about hygiene measures such as front-to-back perineal care after urination or bowel movements.</p>
<p>Acute Pyelonephritis (Causative Organisms: <i>E. coli</i>, <i>Klebsiella</i>, <i>Proteus</i>)</p> <p>Increased risk for preterm labor and premature delivery. Maternal complications include a high fever, flank pain, septic shock, and adult respiratory distress syndrome. Pregnant women often require hospitalization for acute care.</p>	<p>Inform women with asymptomatic bacteriuria or cystitis of signs and symptoms, such as sudden onset of fever (often higher than 102.2° F [39° C]), chills, flank pain or tenderness, nausea, and vomiting, so that treatment can begin promptly. Skin cooling equipment may be used to lower her temperature below 100.4° F (38° C), reducing possible compromise of fetal oxygen level. Woman may be hospitalized for intravenous administration of antibiotics. Common combinations include ampicillin or a cephalosporin plus an aminoglycoside. Serum levels of aminoglycosides are often measured to ensure an adequate dose without reaching a toxic level.</p>

Maternal and perinatal infection—Bacterial. In S.G. Gabbe, J.R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed., pp. 1140–1155). Philadelphia: Saunders.

active lesions in the mother (ACOG, 2012b; Bernstein, 2012; Roos & Baker, 2011).

Expectant mothers need information about effective ways to deal with the emotional and physical effects of herpes. Many women are concerned about privacy and do not want family members to know why cesarean birth is necessary. These women must be assured that their wishes will be respected. Women may need an opportunity to discuss their feelings of shame, anger, or anxiety about the possible effects of the virus on their infant.

After delivery, isolation of the mother from her infant is not necessary if direct contact with lesions is avoided and mothers use careful handwashing techniques. Mothers may breastfeed if there are no lesions on the breasts. The infant is observed for signs of infection,

including temperature instability, lethargy, poor sucking reflex, jaundice, seizures, and herpetic lesions. Acyclovir therapy is prescribed for neonatal infection (Bernstein, 2012; CDC, 2010b). (See Chapter 34 for care of nonpregnant women with herpes.)

THERAPEUTIC COMMUNICATIONS

Concern about Confidentiality

Mary, who had a cesarean birth the previous day because of two active herpes lesions in her vaginal and labial areas, appears anxious and uncomfortable during the morning assessment by nurse Eileen.

Mary: Why does everyone wear gloves when they come near me?

Eileen: You wonder why we wear gloves when we care for you? (*Reflecting content*)

Mary: Well, it bothers me that you think I am so contagious.

Eileen: You seem to think we wear gloves because you have a herpes outbreak. (*Clarifying content and feeling, since glove use is now standard for infection control in most settings*)

Mary: Yes, why else would it be necessary?

Eileen: We wear gloves when we care for all patients whenever we might come into contact with bodily fluids so we don't transmit infection from one person to another. I'm sorry you thought it was only because of your infection. (*Providing information and conveying empathy*)

Mary: I'm just so touchy about having my family find out I have herpes.

Eileen: You don't want your family to know why you had a cesarean? (*Clarifying and reflecting feelings*)

Mary: Yes, I'm so embarrassed. I wish they didn't have to know.

Eileen: They will know only if you tell them. We do everything possible to protect your privacy. I'd like to come back in a few minutes, and we can talk more about how you feel.

(*Offering reassurance about Mary's privacy and giving her the option to express her feelings more completely at a later time*)

Parvovirus B19

Erythema infectiosum (also called *fifth disease*), caused by human parvovirus B19, is an acute, communicable disease characterized by a highly distinctive rash. The rash starts on the face with a "slapped-cheeks" appearance, followed by a generalized maculopapular rash. Other symptoms include fever, malaise, and joint pain. Erythema infectiosum is most contagious before the rash is evident. The infection is more common among children and often occurs in community epidemics. The prognosis is usually excellent. However, if the disease occurs in pregnancy, potential fetal and neonatal effects exist. Parvovirus titers can be done if exposure during pregnancy is suspected to determine whether the mother is immune. PCR analysis of viral DNA is more sensitive than maternal antibodies, however (Bernstein, 2012; Riley, 2011).

Fetal and Neonatal Effects. When infection occurs during pregnancy, fetal death can result, usually from failure of fetal RBC production, followed by severe fetal anemia, hydrops (generalized edema), and heart failure. The level of maternal serum alpha-fetoprotein (MSAFP) is sometimes elevated when fetal hydrops is present. Serial ultrasonography can also be performed to detect hydrops. Intrauterine transfusion is an option to treat severe fetal anemia if it does not resolve spontaneously. The risk to the fetus is greatest when the mother is infected in the first 20 weeks of pregnancy. The affected infant is examined for any defect, and the child is assessed regularly for several years to identify delayed complications such as persistent infection because of low levels of viral replication.

Therapeutic Management. No specific treatment exists. Starch baths may help reduce pruritus, and analgesics may be necessary to relieve mild joint pain.

Hepatitis B

Multiple serotypes of hepatitis are recognized, but three are common in the United States: A, B, and C. Other serotypes such as D, E, and G require the presence of other hepatitis viruses to exist. Hepatitis A is transmitted primarily by fecal-oral contamination and can be limited by simple hygiene. Hepatitis A is rarely transmitted perinatally, and supportive care is usually sufficient.

Hepatitis B is transmitted via blood, saliva, vaginal secretions, semen, or breast milk and readily crosses the placenta. Mortality associated with acute hepatitis B is about 1%, but about 85% to 90% of adults recover. About 10% to 15% of adults develop chronic hepatitis B, increasing their risk for chronic liver disease, liver cirrhosis, and primary hepatocellular carcinoma. Hepatitis B is preventable with a vaccine, which is safe during pregnancy. Newborn vaccination against hepatitis B starts before discharge, with the second dose given 1 to 2 months later and the third dose given at 6 to 18 months.

Chronic hepatitis B develops in 10% of infected adults, who can continue to transmit the disease to others. Persons with chronic hepatitis B also are at greater risk for chronic liver disease, cirrhosis of the liver, and primary hepatocellular carcinoma (ACOG, 2012e; Andrews, 2011; Bernstein, 2012).

Hepatitis C is acquired through blood products. Those at higher risk include IV drug users, those with recurrent sexually transmitted diseases including HIV, and persons needing recurrent blood products (such as hemophiliacs). Hepatitis C may remain undiagnosed until the woman develops chronic liver disease that often requires liver transplantation. The incidence of hepatitis C in pregnant women is 1% to 5% (ACOG, 2012e; Andrews, 2011; Bernstein, 2012).

The incidence of hepatitis B virus (HBV) has fallen significantly with screening and immunization of at-risk people, including health care providers. Goals to eliminate HBV in the United States include the following:

- Universal newborn vaccination
- Routine screening of all pregnant women and provision of immunoprophylaxis to infants born to infected mothers or women with unknown infection status
- Routine vaccination to unvaccinated children and adolescents
- Vaccination of adults at increased risk of infection, including health care workers, those with STDs, household contacts or sexual partners with those having chronic HBV infection, multiple sex partners, recipients of certain blood products, or dialysis patients

Fetal and Neonatal Effects. The risk of prematurity, low birth weight, and neonatal death increases when the mother has hepatitis B infection during pregnancy. Infection of the newborn whose mother is known to be HBsAg-positive usually can be prevented by administration of hepatitis B immune globulin (HBIG, Hep-B-Gammagee), followed by hepatitis B vaccine (Recombivax HB, Engerix-B) within 12 hours of birth. The newborn must be carefully bathed before any injections are given to prevent infections from skin surface contamination by the virus. The infant's vaccination should be repeated at 1 to 2 months and 6 to 18 months. Breastfeeding is considered safe as long as the newborn has been vaccinated (AAP & ACOG, 2012; ACOG, 2012e; Andrews, 2011; Bernstein, 2012). (See Chapter 21 for the drug guide for hepatitis B vaccine in the newborn.)

Therapeutic Management. Hepatitis B is a preventable infection. Simple hygiene measures such as safe sex and the use of standard precautions with bodily fluids provide primary prevention. Hepatitis B vaccines are available as a series of three intramuscular injections into the deltoid for adults, with the second and third doses given 1 and 6 months after the first. Vaccination is recommended for any population at risk, including nurses and other health care workers who frequently come in contact with bodily fluids.

All pregnant women should be screened for HBsAg. Women at high risk for hepatitis should be rescreened in the third trimester if the initial screen is negative. Household members and sexual contacts should be tested and offered vaccination if they are not immune. No specific treatment exists for acute hepatitis B. Recommended supportive treatment includes bed rest and a high-protein, low-fat diet.

Human Immunodeficiency Virus

Acquired immunodeficiency syndrome (AIDS) is a failure in immune function caused by the retrovirus HIV. The infected person develops opportunistic infections or malignancies that ultimately are fatal. The time from infection with HIV to development of AIDS is approximately 11 years with current antiretroviral therapy, although the interval may be much longer for some individuals. Transmission of HIV infection is predominantly through three modes: (1) heterosexual exposure to genital secretions of an infected person, (2) parenteral exposure to infected blood or tissue, and (3) perinatal exposure of an infant to infected maternal secretions through birth (vertical transmission). The continuing occurrence of HIV infections of infants demonstrates the importance of identifying and treating maternal infections during pregnancy to reduce the risks of infant infections. Breast milk or prechewed food from an infected person can cause infant infection (AAP & ACOG, 2012; Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2013).

After rapid increase in the number of cases of HIV infections during the early years of the epidemic in the United States, deaths from AIDS have declined with improved antiretroviral therapies. Heterosexual spread is now a major mode of transmission, although HIV was largely confined to homosexual men in the early years of the epidemic. New cases of HIV in heterosexual women in the United States in 2012 were estimated to be 5300 among black women and 1200 among Hispanic and 1300 among white women. Black women were more affected by HIV compared with women of other races, accounting for 64%, or two-thirds, of all new HIV infections in 2010. The new HIV infection rate among black women was 15 times higher than that for white women, and most black women were infected through heterosexual sex. Although Hispanic women comprised about 16% of the U.S. population, they comprised 21% of new infections in 2010, four times higher than the rate for white women. Most Hispanic women were infected through heterosexual sex (CDC, 2012a).

CRITICAL TO REMEMBER

Facts about Human Immunodeficiency Virus

- After initial exposure to human immunodeficiency virus (HIV), there is a period of 3 to 12 months before seroconversion. The person is considered infectious during this time.
- There is a long period, averaging 11 years, from HIV infection to development of acquired immunodeficiency syndrome (AIDS), corresponding to the type of treatment received.
- A person infected by HIV can pass the virus to another person, even if he or she does not have symptoms.
- There is not yet a cure for the HIV infection or AIDS. Antiretroviral medications are available to slow the replication of the virus and delay the onset of opportunistic diseases.
- Zidovudine should be part of the medication regimen for a pregnant woman to reduce the risk of transmission to her fetus. The newborn also should receive zidovudine after birth.
- HIV is transmitted by sexual contact with an infected person, by contact with infected body fluids, and through the placenta from mother to fetus.

Pathophysiology. Like other retroviruses, HIV integrates its viral genetic makeup into the genetic makeup of the cell when infecting it. This results in an abnormal cell that cannot perform its functions properly. At the same time, this cell then replicates and produces more viruses that invade more cells. The disease worsens as more cells cease to function, and a greater number of viruses are produced. The principal mechanism whereby HIV leads to immunodeficiency is through its destructive effect on cells that provide and regulate immunity. CD4 T lymphocytes, or helper T cells, play a key role in organizing the body's immune response to help immune functions. CD8 lymphocytes are T suppressor cells that limit excessive immune responses that might attack the person's own body tissues. Helper CD4 T lymphocytes make up about 75% of these two types of lymphocytes in a healthy person.

When HIV infection invades body cells, the ratio of CD4 T lymphocytes to CD8 lymphocytes decreases. As the number of CD4 T lymphocytes declines, the immune response declines, and opportunistic infections can overwhelm the HIV-positive person. A CD4 T lymphocyte total count of less than 200 cells/mm³ confirms the diagnosis of progression to AIDS. Greater accuracy of testing includes the ratio of CD4 to CD8 T lymphocytes (>1 is normal) and determining specific antigens on the CD4 T lymphocytes. CD4 counts help determine how a person who develops infection should be treated. If the CD4 level is within normal values, the infection is less likely to be an opportunistic infection seen in AIDS and treatment can be routine (Bernstein, 2012; Pagana & Pagana, 2011; Petersen, 2010; Watts, 2011).

The clinical course of HIV infection follows fairly predictable stages:

- An early or acute stage occurs several weeks after HIV exposure (stage 1). Flulike symptoms may develop and last a few weeks. Antibodies to HIV (seroconversion) generally appear within a few months, but delays of more than a year have been reported occasionally.
- A middle or asymptomatic period of minor or no clinical problems follows (stage 2). This period is characterized by continuous low-level viral replication and CD4 cell loss.
- A transitional period of symptomatic disease follows (stage 3).
- A late or crisis period of symptomatic disease follows, which consists of opportunistic infections lasting months or years (stage 4).

During stages 1 and 2, the infected person is said to be HIV-positive. During stages 3 and 4, the immune system no longer offers adequate protection, and opportunistic diseases occur. The person is then said to have AIDS, regardless of the CD4 counts (Bernstein, 2012; Watts, 2011).

Fetal and Neonatal Effects. New antiretroviral drugs have improved the prognosis for HIV-infected women and their infants. Antiretroviral therapy during pregnancy should include three drugs, the primary antiretroviral being zidovudine (ZDV, also abbreviated AZT). Mothers who receive no or minimal HIV care during the prenatal period may have higher rates of infected infants. Infant infection may occur during pregnancy, during labor and birth, or after birth if the infant is breastfed (Bernstein, 2012; Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2013; Watts, 2011).

Infant tests to diagnose HIV may include PCR for viral DNA and viral culture in addition to standard antibody tests. However, infant HIV tests can remain positive for up to 18 months after birth because of passive maternal antibodies. An infected newborn is typically asymptomatic at birth, but signs and symptoms may become obvious during the first year of life. Early signs may include enlargement of the liver and spleen, lymphadenopathy, failure to thrive, persistent thrush, and extensive seborrheic dermatitis (cradle cap). Infected infants often have bacterial infections such as meningitis, pneumonia, osteomyelitis, septic arthritis, and septicemia.

Prompt treatment of the HIV-infected infant with appropriate antiretroviral medications and other prophylactic therapy may slow the infection's progress.

Prevention. Prevention remains the only way to control HIV infection. Sexual transmission can be avoided by several methods. Abstinence would render a person safe from all STDs, including HIV. However, for many people, sexual expression adds to the quality of life, and many are not willing to practice abstinence. Transmission of HIV also can be prevented if infected persons do not have vaginal intercourse with susceptible persons. If intercourse does occur, barrier methods such as latex condoms reduce contact with infectious secretions. A condom offers protection from transmission through oral sex.

Intravenous drug users who refuse rehabilitative treatment must be taught to wash the equipment with water, soap, and bleach before each use to reduce transmission of the virus through a soiled needle.

Therapeutic Management. Multiple antiretroviral drugs from different classes are beneficial in extending life after infection. ZDV is the most effective to reduce vertical transmission from mother to infant. Guidelines for the latest treatments from the National Institutes of Health for pregnant as well as nonpregnant patients may be found at www.aidsinfo.nih.gov/guidelines. Maternal ZDV therapy to reduce infant HIV infection must consider many situations such as the following:

- If the mother has had any antiretroviral therapy during pregnancy, including ZDV, and when it began
- If the mother had any prenatal care and when she started
- Fetal gestational age
- If the membranes have ruptured, how long they have been ruptured

See [Box 26-3](#) for measures to reduce infection in the infant.

Nursing Considerations. Learning of HIV infection during pregnancy can have a devastating and immobilizing effect on the entire

family. A nurse must also be careful not to allow personal attitudes to influence professional behavior or the care of the woman and family during pregnancy, birth, and the postpartum period. Care of the woman with HIV during pregnancy can present many challenges to the nurse (Tyer-Viola, 2007). Issues that arise during the postpartum period may include the following:

- Whether to continue or stop antiretroviral therapy
- Support services needed after discharge
- Contraceptive counseling, including the information that condoms can reduce the risk of acquiring or transmitting STDs and HIV transmission but have a low rate of effectiveness for contraception
- Comprehensive follow-up for infection indicators and associated medical conditions, counseling for a new diagnosis, and evaluation of the need for continued antiretroviral therapy

A nursing diagnosis of “Grieving or Possibly Complicated Grieving related to multiple losses that include the mother’s shortened life expectancy and possible death of the infant” should be considered. Initially, crisis intervention may be necessary to help the family cope.

Nurses frequently must determine what the family perceives as the most pressing needs and worries. Some of the most common fears are loss of control, loss of support and love, social isolation, and loss of privacy. The nurse’s response may involve finding ways for the woman to retain control while she is physically able and assisting her to select those in her family who will provide continued love and emotional support. Reassuring the woman that her right to privacy will not be violated is necessary.

Nurses should help the woman maintain the highest possible level of wellness. Adequate, high-quality nutrition decreases the risk of opportunistic infections and promotes vitality. A daily regimen should include sufficient rest and activity. Avoiding large crowds, travel to areas with poor sanitation, and exposure to infected individuals is important. Meticulous skin care is essential, especially during recurrent herpes infections.

The nurse should also provide information on routine ongoing health care for women. Examples are cervical cancer screening, adult immunizations, and mental health or substance abuse treatment. Instruction in signs and symptoms of postpartum depression and providing sources of assistance should be offered before discharge, just as for any woman in the postpartum period. See [Chapters 28](#) and [33](#) for additional information on these topics.

The mother almost certainly will experience a great deal of anxiety about whether her infant will be HIV-positive. Nurses need to respond honestly that testing will be required but that most infants do not contract the virus if the medication regimen is followed carefully. In addition, nurses must reinforce information about medications that slow the progression of the disease in the mother as well as decrease the incidence of vertical transmission to the infant.

BOX 26-3 RECOMMENDATIONS FOR THE PREVENTION OF PERINATAL HUMAN IMMUNODEFICIENCY VIRUS INFECTION OF THE INFANT

- **Pregnancy:** Zidovudine (ZDV), 100 mg orally five times per day initiated between 14 and 34 weeks of gestation. Alternative adult dose regimens for oral ZDV are 200 mg three times per day or 300 mg twice daily.
- **Labor:** Intravenous zidovudine with a 1-hour loading dose of 2 mg/kg, followed by continuous infusion of 1 mg/kg/hr until delivery.
- **Newborn:** Oral ZDV syrup, dose of 2 mg/kg every 6 hours for 6 weeks, beginning 8 to 12 hours after birth.

A cesarean birth at 38 weeks of pregnancy, before the onset of labor and rupture of membranes, is usual to reduce maternal transmission of human immunodeficiency virus (HIV) to the fetus. HIV-infected mothers are advised not to breastfeed because of the presence of the virus in their milk.

Nonviral Infections

Toxoplasmosis

Toxoplasmosis is a protozoan infection caused by *Toxoplasma gondii*. Infection is transmitted through organisms in raw and undercooked meat, through contact with infected cat feces or soil, and across the

placental barrier to the fetus if the expectant mother acquires the infection during pregnancy. Toxoplasmosis is more common in Europe because of greater consumption of meats that are rare or undercooked. Poor handwashing and sanitation of surfaces after food preparation increases the risk of toxoplasmosis in any country (Duff, 2012; Franco & Ernest, 2011).

Toxoplasmosis often is subclinical. The woman may experience a few days of fatigue, muscle pains, and swollen glands, but she may be unaware of the disease. If the infection is suspected, diagnosis can be confirmed by positive results of serologic tests, which include indirect fluorescent antibody tests for immunoglobulin G (IgG) and immunoglobulin M (IgM). Immune-compromised persons such as patients who received transplants or those infected with HIV are more likely to have severe toxoplasmosis infection.

Fetal and Neonatal Effects. Although toxoplasmosis may remain unnoticed in the pregnant woman, it may cause abortion or result in the birth of an infant with the disease. About 40% of infants born to mothers who had an acute primary infection during pregnancy have congenital toxoplasmosis. About 50% of affected infants may be asymptomatic at birth, but others have serious effects such as low birth weight, enlarged liver and spleen, jaundice, and anemia or coagulation disorders. Severe complications may develop several years after birth and include chorioretinitis that leads to blindness, deafness, seizures, hydrocephalus, and microcephaly (Duff, 2012; Franco & Ernest, 2011).

Therapeutic Management. All pregnant women should be advised to do the following:

- Cook meat, particularly pork, beef, and lamb, thoroughly until the juices run clear.
- Avoid touching the mucous membranes of your mouth and eyes while handling raw meat.
- Wash all surfaces that come in contact with uncooked meat.
- Wash your hands thoroughly after handling raw meat.
- Avoid uncooked eggs and unpasteurized milk.
- Wash fruits and vegetables before consumption.
- Avoid contact with materials that are possibly contaminated with cat feces (such as cat litter boxes, sandboxes, garden soil).

Maternal treatment of toxoplasmosis during pregnancy is essential to reduce the risk for congenital infection. Sulfonamides can be used alone but are less effective than combination therapy. Spiramycin is successfully used in Europe for maternal toxoplasmosis and may be used according to specific guidelines within the United States (Duff, 2012; Franco & Ernest, 2011).

Group B *Streptococcus* Infection

Group B *Streptococcus* (GBS) is a leading cause of life-threatening perinatal infections in the United States. The gram-positive bacterium colonizes the rectum, vagina, cervix, and urethra of pregnant as well as nonpregnant women. Approximately 15% to 40% of pregnant women are colonized by GBS in the vaginal or rectal area, but isolating the organism is often possible only intermittently. Often, these women are asymptomatic, although symptomatic maternal infections can occur. These infections include urinary tract infection, chorioamnionitis, and metritis. Most women respond quickly to antimicrobial therapy (AAP & ACOG, 2012; CDC, 2010a; Duff, 2012; Yudin, 2011).

Fetal and Neonatal Effects. Early-onset newborn GBS disease occurs during the first week after birth, often within 48 hours. Women who have GBS in the rectovaginal area at the time of birth have a 60% chance of transmitting the organism to the newborn, and about 1% to 2% of these infants will develop early-onset GBS disease. Sepsis, pneumonia, and meningitis are the primary infections in early-onset GBS disease. Late-onset GBS disease occurs after the first week of life, and meningitis is the most common clinical manifestation. Permanent

neurologic consequences are more likely in infants who survive meningitis infections (AAP & ACOG, 2007; Duff, 2012; Yudin, 2011). (See Chapter 30 for additional information about manifestations and recommended management of neonatal sepsis.)

Therapeutic Management. Health care providers have difficulty identifying pregnant women who are asymptomatic GBS carriers because the duration of carrier status is unpredictable. Revised guidelines to prevent perinatal GBS disease were released by CDC in 2010. Optimal identification of the GBS carrier status is obtained by vaginal and rectal culture between 35 and 37 weeks of gestation. Women who have had a previous infant with GBS or a GBS in their urine in any trimester will be considered GBS-positive at delivery. A woman who delivers at or before 37 weeks, has ruptured membranes for 18 hours or more, or has a temperature of 100.4°F (≥38°C) or higher is also considered positive for GBS and should receive antibiotic therapy. Cesarean birth before membrane rupture does not require GBS antibiotic therapy.

Penicillin is the first-line agent for antibiotic treatment of the infected woman during birth. Cephazolin is the alternative for the patient with non-life-threatening penicillin allergy. Clindamycin is used for the woman at high risk for anaphylaxis.

Tuberculosis

TB results from infection with *Mycobacterium tuberculosis*. It is transmitted by aerosolized droplets of liquid containing the bacterium, which are inhaled by a noninfected individual and taken into the lung. Initially, most individuals are asymptomatic. Women at risk should be screened for TB when obtaining prenatal care if they are not already known to be positive. This screening involves an intradermal injection of mycobacterial protein (purified protein derivative, or PPD). If the reaction is positive or the woman is already known to have a positive reaction, her abdomen should be protected by a lead shield while a chest radiograph is taken, preferably after the first trimester. Diagnosis is confirmed by isolating and identifying the bacterium in the sputum.

Signs and symptoms include general malaise, fatigue, loss of appetite, weight loss, and fever. Symptoms occur in the late afternoon and evening and are accompanied by night sweats. As the disease progresses, a chronic cough develops, and a mucopurulent sputum is produced.

TB increases with poverty, malnutrition, and HIV infection. Worldwide, it is responsible for more deaths than any other communicable disease. The incidence is increasing in inner-city areas and among homeless persons. It is also prevalent among immigrants from Southeast Asia and Central and South America.

Fetal and Neonatal Effects. Although perinatal infection is uncommon, it may be acquired as a result of the fetus swallowing or aspirating infected amniotic fluid. Diagnosis is made by finding the bacilli in the gastric aspirate of the neonate or in placental tissue. Signs of congenital TB include failure to thrive, lethargy, respiratory distress, fever, and enlargement of the spleen, liver, and lymph nodes. If the mother remains untreated, the newborn is at high risk for acquiring TB by inhalation of infectious respiratory droplets from the mother.

Therapeutic Management. Untreated TB poses a greater hazard to the fetus than its treatment (CDC, 2011c). Treatment of TB is based on two principles. First, more than one drug must be used to prevent the growth of resistant organisms. Second, treatment must continue for a prolonged period. The preferred treatment for pregnant women with active TB is isoniazid (INH), rifampin (RIF), and ethambutol (EMB) daily for 2 months, followed by INH and RIF daily or twice weekly for 7 months, for 9 months of total treatment duration. Pyridoxine (vitamin B₆) should be given with isoniazid to prevent fetal neurotoxicity and because pregnancy itself increases the demand for

this vitamin. Drug resistance in the TB organism may require addition of other drugs, although the following drugs are not recommended in pregnancy: streptomycin, kanamycin, capreomycin, and fluoroquinolones (CDC, 2011d; Gibson & Powrie, 2011; Whitty & Dombrowski, 2012).

Management of the infant born to a mother with TB involves preventing the disease and treating the infection early. If the mother's sputum is free of organisms, the infant does not need to be isolated from the mother. Breastfeeding is safe, and drugs may be secreted in breast milk. However, the maternal antituberculosis drugs in breast milk are not adequate for infant treatment. Drug serum levels in the infant can be measured to identify if levels are too high. Disease prevention focuses on teaching the mother and the family how the disease is transmitted so that they can protect the infant and other family members from airborne organisms. The infant should be skin-tested at birth and may be started on preventive isoniazid therapy immediately. Skin testing is repeated at 3 months. Isoniazid is usually continued for the infant until the mother's TB has been inactive for at least 3 months. Infant TB medication may be stopped if the mother and other family members have received full treatment and show no additional disease. If the skin test result shows conversion to positive, a full course of drug therapy should be given to the infant (AAP & ACOG, 2012; CDC, 2011d; Whitty & Dombrowski, 2012).

APPLICATION OF THE NURSING PROCESS

■ The Pregnant Woman with Tuberculosis

Assessment

Question each pregnant woman about signs or symptoms of TB such as fever, night sweats, fatigue, weight loss, and cough. Ask whether the cough is productive and the sputum is purulent (describe "purulent sputum"). Administer and read a PPD skin test, as directed. Identify factors that increase the risk of TB, such as poverty, homelessness, recent immigration from an area that has a high incidence of TB and HIV infection. Determine whether a family member or close friend has a history of TB.

If a woman has active TB infection, determine the extent of knowledge she has about the disease. For example, does she know the ways in which the disease is transmitted, the importance of completing the lengthy course of prescribed medications, and the major side effects of medications? Does she know about drug resistance in TB, particularly if she does not adhere to the drug regimen? Ask about stressors in her life that increase the risk of failure to adhere to therapy, such as lack of support from a significant other, substance abuse, unstable living conditions, and other factors.

Analysis

To achieve a cure, the woman with TB must adhere to a prolonged treatment regimen that has significant side effects. In addition, women with TB often have many other stressors in their lives, including

poverty, uncertain housing, and other infections such as HIV. The most relevant nursing diagnosis for this woman might be "Ineffective Individual or Family Management of Therapeutic Regimen related to lack of knowledge of disease process and expected course of treatment."

Planning

Expected outcomes for this nursing diagnosis are as follows:

- The woman and at least one other responsible person will verbalize information about the mode of transmission of TB, importance of medications, duration of treatment, and possible side effects of antituberculosis medications.
- The woman will adhere to the prescribed treatment plan until it is completed.

Interventions

Providing Information

1. Teach about the ways in which TB is transmitted to decrease the chance of transmission:
 - Isolating infants and other persons from persons who have infectious sputum is essential.
 - Covering the mouth when coughing, sneezing, and laughing helps prevent the organisms from entering the air.
 - Washing the hands carefully after any contact with bodily substances or soiled tissues decreases exposure to others.
2. Provide reassuring information about pregnancy and TB:
 - TB usually does not affect the course of pregnancy, the type of birth (vaginal or cesarean), or the birth weight of newborns.
 - Congenital TB infection of the newborn is rare.
 - Skin testing of the mother does not have adverse fetal effects.
 - Commonly used antituberculosis medications are in pregnancy risk category B or C (see [Appendix A](#)), making them reasonable to use in a serious infection.
 - TB may be cured or arrested if medication is taken as prescribed.
3. Teach the woman and another responsible person about correct administration of medications:
 - Take medications at the same time each day.
 - Follow instructions for specific drugs prescribed:
 - Rifampin and isoniazid (category C) are best taken on an empty stomach (1 hour before or 2 hours after a meal). Ethambutol (category B) may be taken with food.
 - Isoniazid can be taken with meals, but doing so will delay absorption.
 - Pyridoxine (vitamin B₆) should be taken because it reduces neurotoxicity to the fetus and there is greater demand for this vitamin during pregnancy.
 - Do not skip medications or double-up on missed doses.
 - Avoid the use of alcohol, which increases the risk of liver toxicity.
 - Avoid antacids containing aluminum because they impair absorption of isoniazid.
4. Educate the woman and another responsible person about expected or potential side effects:
 - Oral contraceptives are less effective when a woman is taking rifampin.
 - Bodily fluids such as urine, saliva, and tears may become a characteristic red-orange when taking rifampin. Soft contact lenses may be stained.
 - Nausea, heartburn, diarrhea, and flatulence are fairly common side effects. Rifampin may cause drowsiness.
 - Symptoms of hepatitis (jaundice, anorexia, excessive fatigue) should be reported to the physician.

- Teach the necessity of continuing medication after symptoms have disappeared to eradicate the organism and to avoid development of drug-resistant organisms. The total duration of therapy varies with medications that are prescribed.
- Emphasize the importance of keeping follow-up appointments.

Providing Support

Respiratory isolation may be necessary if the woman's sputum still contains organisms, and a new mother may be separated from her newborn. The nursing staff must provide emotional support and counseling so that the mother can deal with the anxiety and frustration she may feel because she is not allowed to care for the infant. Language barriers and cultural implications also should be addressed. Referral to social services may be necessary to arrange temporary care of the newborn outside the home until the infant and mother have received adequate treatment (Box 26-4).

Evaluation

Goals or outcomes are met if the following occur:

- The woman and another responsible person demonstrate knowledge of the mode of transmission, verbalize the importance of taking medications as prescribed, and describe the possible side effects of antituberculosis medications.
- The woman adheres to the treatment regimen as directed.

SUMMARY CONCEPTS

- The release of insulin accelerates during early pregnancy, which may result in episodes of maternal hypoglycemia. The availability of glucose and insulin favors the development and storage of fat that the mother will need later.
- Placental hormones, which reach their peak during the second and third trimesters, create resistance to insulin in maternal cells, resulting in increased insulin needs throughout the rest of pregnancy.
- Diabetes is classified according to onset (before or during pregnancy) and whether the woman requires the administration of insulin to prevent ketoacidosis. Type 1 diabetes requires insulin for control. Type 2 diabetes may be diet controlled (A_1) or may require both insulin and diet control (A_2).
- Type 1 diabetes adversely affects the mother in a variety of ways during pregnancy, including increasing her risk of hypertension, urinary tract infections, and ketosis.
- Because maternal hyperglycemia during the first trimester increases the risk for congenital anomalies in the fetus, a major goal of management is to establish normal blood glucose levels before conception.
- Fetal growth depends on the condition of maternal blood vessels. If no vascular impairment occurs, placental perfusion is adequate and the infant is likely to be large if maternal glucose levels remain too high (macrosomia). If vascular impairment does occur, placental perfusion may be reduced and the fetus may have intrauterine growth restriction.
- In addition to having an increased risk for congenital anomalies, the infant of a mother with preexisting diabetes has an increased risk for hypoglycemia, hypocalcemia, hyperbilirubinemia, and respiratory distress syndrome.
- Maternal adverse effects of gestational diabetes include increased urinary tract infections, hydramnios, premature rupture of membranes, and the development of preeclampsia.
- Gestational diabetes increases the risk for fetal macrosomia and neonatal hypoglycemia.
- Gestational diabetes usually can be treated by diet and exercise. However, insulin may be required if blood glucose levels remain high.
- Cardiovascular changes occurring in normal pregnancy impose an additional burden that may result in cardiac decompensation if the expectant mother has preexisting heart disease.
- The primary goal of management of the pregnant woman with heart disease is to prevent the development of congestive heart failure. This may be done by restricting activity, limiting weight gain, and preventing anemia and infection so that cardiac demand does not exceed cardiac reserves.
- Intrapartum and postpartum management of heart disease focuses on preventing fluid overload, which can cause a sharp rise in cardiac effort.
- Iron supplementation often is needed during pregnancy because most women do not have sufficient iron stores to meet the demands of pregnancy with diet alone.
- Folic acid deficiency is associated with increased risk of spontaneous abortion, abruptio placentae, and fetal anomalies such as neural tube defects. Folic acid supplementation of 400 mcg (0.4 mg) daily is recommended for all women of childbearing age to reduce the risk for neural tube defects.
- Sickle cell disease often is worsened by pregnancy, and a primary goal is to prevent sickle cell crisis during pregnancy.
- Laboratory values for thalassemia are similar to those of iron deficiency. However, administration of iron is risky because increased iron absorption and storage makes the woman susceptible to iron overload.
- Although the woman with systemic lupus erythematosus can have a normal pregnancy and give birth to a normal newborn, the

Continued

SUMMARY CONCEPTS—cont'd

- pregnancy must be treated as high risk because of the increased incidence of abortion, fetal death during the first trimester, and possible exacerbation of the disease.
- Antiphospholipid syndrome (APS) is a cluster of clinical entities and is associated with an increased risk for thrombosis, fetal loss, and decreased platelets. Preeclampsia is more common in the woman with APS.
- Marked improvement in rheumatoid arthritis often occurs during pregnancy, possibly as a result of pregnancy-specific hormone and hormonal factors. However, most women relapse soon after childbirth.
- Management of epilepsy is complex because of the teratogenic effects of anticonvulsant medications coupled with the importance of preventing seizures. Changes in anticonvulsant therapy that reduce the risks of adverse effects may be possible for the woman who wants to become pregnant.
- Although Bell's palsy usually is temporary, the woman may be anxious. Supportive care and emotional support are essential.
- Viral infections that occur during pregnancy can be transmitted to the fetus in two ways: across the placental barrier or by exposure to organisms during birth. Although they may be mild or even subclinical in the mother, viral infections can have serious effects on the fetus.
- The health care team is responsible for teaching how infectious diseases can be prevented and that early treatment also may reduce fetal and neonatal exposure to infections.
- Human immunodeficiency virus (HIV) is a retrovirus that gradually allows a decline in the effectiveness of the maternal immunity, often over many years in the treated woman. Maternal treatment with zidovudine, sometimes with other antiretroviral medications, can substantially reduce infection of the fetus with HIV.
- Pregnant women who are HIV-positive experience anxiety, fear, and grief as they contemplate potential losses resulting from the disease. Nurses must provide emotional support, information, and counseling, which will help the woman cope with her emotions and retain control of her care for as long as possible.
- Specific pregnancy and postbirth treatment of nonviral infections such as toxoplasmosis, group B streptococcus infection, and tuberculosis reduce long-term maternal and newborn complications.

CHAPTER 27

Intrapartum Complications

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain abnormalities that may result in dysfunctional labor.
2. Describe maternal and fetal risks associated with premature rupture of the membranes.
3. Analyze factors that increase a woman's risk for preterm labor.
4. Explain maternal and fetal problems that may occur if pregnancy persists beyond 42 weeks.
5. Describe the intrapartum emergencies discussed in this chapter.
6. Explain therapeutic management of each intrapartum complication.
7. Apply the nursing process to care of women with intrapartum complications and care of their families.

For most women, birth is a normal process that is free of major complications. However, complications sometimes make childbearing hazardous for the woman or her baby. The nurse's challenge is to identify the complications promptly and provide effective care for such mothers while nurturing the entire family at this significant time of life.

The complications addressed in this chapter are often interrelated. For example, a dysfunctional labor is likely to be prolonged, and the woman is more vulnerable to infection, psychological distress, and fetal compromise. Also, women who have complications are more likely to need interventions such as lengthy hospitalization before vaginal birth or cesarean birth. The nurse should provide nursing care that relates to all problems experienced by the woman.

DYSFUNCTIONAL LABOR

Normal labor is characterized by progress. Dysfunctional labor is one that does not result in normal progress of cervical effacement, dilation, and fetal descent. **Dystocia** is a general term that describes any difficult labor or birth. A dysfunctional labor may result from problems with the powers of labor, the passenger, the passage, the psyche, or a combination of these. Dysfunctional labor often is prolonged but may be unusually short and intense (*American College of Obstetricians and Gynecologists [ACOG], 2011b*).

An operative birth (assisted with a vacuum extractor or forceps, or cesarean birth) may be needed if dysfunctional labor does not resolve

or fetal or maternal compromise occurs. Signs of compromise include persistent nonreassuring fetal heart rate (FHR) patterns (see [Chapter 14](#)), fetal acidosis, and meconium passage. Maternal exhaustion or infection may occur, especially with long labors. Nursing measures that enhance progress and maternal comfort and promote fetal well-being also are discussed in this chapter.

Problems of the Powers

The powers of labor may not be adequate to expel the fetus because of ineffective contractions or ineffective maternal pushing efforts.

Ineffective Contractions

Effective uterine activity is characterized by coordinated contractions that are strong and numerous enough to propel the fetus past the resistance of the woman's bony pelvis and soft tissues. It is not possible to say how frequent, long, or strong labor contractions must be. One woman's labor may progress with contractions that would be inadequate for another woman. Possible causes of ineffective contractions include the following:

- Maternal fatigue
- Maternal inactivity
- Fluid and electrolyte imbalance
- Hypoglycemia
- Excessive analgesia or anesthesia
- Maternal catecholamines secreted in response to stress or pain

TABLE 27-1 PATTERNS OF LABOR DYSFUNCTION

HYPOTONIC DYSFUNCTION	HYPERTONIC DYSFUNCTION
<p>Contractions</p> <p>Coordinated but weak Become less frequent and shorter in duration Easily indented at peak Woman may have minimal discomfort because contractions are weak</p>	<p>Uncoordinated, irregular Short and poor intensity, but painful and cramplike</p>
<p>Uterine Resting Tone</p> <p>Not elevated</p>	<p>Higher than normal; important to distinguish from abruptio placentae, which has similar characteristics (see p. 515)</p>
<p>Phase of Labor</p> <p>Active; typically occurs after 4-cm dilation More common than hypertonic dysfunction</p>	<p>Latent; usually occurs before 4-cm dilation Less common than hypotonic dysfunction</p>
<p>Therapeutic Management</p> <p>Amniotomy (may increase risk of infection) Oxytocin augmentation Cesarean birth if no progress</p>	<p>Correct cause if it can be identified Light sedation to promote rest Hydration Tocolytics to reduce high uterine tone and promote placental perfusion</p>
<p>Nursing Care</p> <p>Interventions related to amniotomy and oxytocin augmentation</p> <p>Encourage position changes; abdominal binder may help direct fetus toward mother's pelvis if her abdominal wall is very lax Ambulation if no contraindication and if acceptable to woman Emotional support: allow her to vent her feelings of discouragement; explain measures taken to increase effectiveness of contractions; include her partner or family in emotional support measures because they may have anxiety that will heighten woman's anxiety</p>	<p>Promote uterine blood flow: side-lying position Promote rest, general comfort, and relaxation Pain relief</p> <p>Emotional support: accept reality of woman's pain and frustration; reassure her that she is not being childish; explain reason for measures to break abnormal labor patterns and their goal or expected results; allow her to vent her feelings during and after labor; include partner or family so that they also understand this variation in labor and what is being done to enhance normal process</p>

- Disproportion between the maternal pelvis and fetal presenting part
- Uterine overdistention such as with multiple gestation or **hydramnios** (excess volume of amniotic fluid)

Two patterns of ineffective uterine contractions are hypotonic dysfunction and hypertonic dysfunction. Hypotonic dysfunction is more common than hypertonic dysfunction. The characteristics and management of each are different, but either results in poor labor progress if it persists (Table 27-1).

Hypotonic Dysfunction. Hypotonic contractions are coordinated but too weak to be effective. They are infrequent and brief and can be indented easily with fingertip pressure at the peak.

Hypotonic labor dysfunction, or secondary arrest, usually occurs during the active phase of labor, when progress normally quickens. The active phase usually begins at about 4 cm of cervical dilation. Uterine overdistention is associated with hypotonic dysfunction because the stretched uterine muscle contracts poorly.

The woman may be fairly comfortable because her contractions are weak. However, she often is frustrated because labor slows at a time when she expects to be making faster progress. Hypotonic dysfunction is tiring simply because it adds to the duration of labor. Fetal hypoxia is not usually seen with hypotonic labor.

Management depends on the cause. Many women respond to simple measures. Administration of adequate intravenous (IV) or oral

fluids corrects maternal fluid and electrolyte imbalances or hypoglycemia. Maternal position changes, particularly different upright positions, favor fetal descent and promote effective contractions. The woman who actively changes positions typically has better labor progress and is more comfortable than the woman who remains in one position. Standing or sitting in a shower provides the comfort of warm water and an upright position. Pain management techniques such as epidural block may have outcomes that reduce the effectiveness of contractions, requiring interventions specific to that factor. Effective pain management may, however, improve the progress of labor.

The nurse should use therapeutic communication to help the woman identify anxieties or beliefs about labor and its progress. Identifying her anxieties is the first step to managing them effectively so that the stress response does not slow her labor. For example, the nurse might ask, "What do you think is making your labor slow?" or "How do you feel your labor is going?"

Many women need measures such as amniotomy and oxytocin infusion to promote labor progress. The birth attendant evaluates the woman's labor to confirm that she is having hypotonic active labor rather than a prolonged latent phase of labor or false labor. The latent phase of labor occurs within the first 3 cm of cervical dilation. The maternal pelvis and fetal presentation and position are evaluated to identify abnormalities. Reducing undesired maternal effects of a prolonged latent phase such as exhaustion or infection is a goal of the birth

attendant. However, the birth attendant must consider the possibility that a woman is in false labor rather than in a prolonged latent phase when choosing interventions to correct the labor progress.

Amniotomy or augmentation, usually with oxytocin, may be used to stimulate a labor that slows after it is established. The risks of amniotomy are umbilical cord prolapse, infection, and **abruptio placentae** (premature separation of placenta). Reduced placental perfusion caused by excessive uterine contractions is the most common risk of labor augmentation using oxytocin (Gee, 2011; Thorp, 2009; Wing & Farinelli, 2012). See Chapter 16 for additional information.

Hypertonic Dysfunction. **Hypertonic labor dysfunction** is less common than hypotonic dysfunction and more often affects women in early labor with their first baby. Contractions are uncoordinated and erratic in their frequency, duration, and intensity. The contractions are painful but ineffective. Hypertonic dysfunction usually occurs during the latent phase of labor. Basal intrauterine pressure is usually high (Gee, 2011; Thorp, 2009; Wing & Farinelli, 2012).

Although each contraction varies in its intensity, the **uterine resting tone** (uterine muscle tone when not having contraction) between contractions is higher than normal, reducing uterine blood flow. This uterine ischemia decreases fetal oxygen supply and causes the woman to have almost constant cramping pain. Because high uterine resting tone and constant pain also are seen in abruptio placentae, this complication should be considered as well.

The mother becomes very tired because of nearly constant discomfort. She may lose confidence in her ability to give birth and cope with labor. She often thinks, “If it hurts this much so early, I must be a real baby about pain.” Frustration and anxiety further reduce her pain tolerance and interfere with the normal processes of labor. The nurse should accept her frustration and discomfort. Cervical dilation should not be equated with the amount of pain a woman “should” experience.

Management of hypertonic labor depends on the cause. Relief of pain is the primary intervention to promote a normal labor pattern. Warm showers and baths promote relaxation and rest, often allowing a normal labor pattern to ensue. Systemic analgesics or, occasionally, low-dose epidural analgesia may be required to achieve this purpose.

Oxytocin is not usually given because it can intensify the already high uterine resting tone. However, very low doses of oxytocin sometimes are given to promote coordinated uterine contractions. **Tocolytic** drugs (drugs that inhibit uterine contractions) may be ordered to reduce uterine resting tone and improve placental blood flow. The decision to order uterine stimulant or relaxant drugs is very individualized, based on each woman’s labor pattern.

Ineffective Maternal Pushing

A reflexive urge to push with contractions usually occurs as the fetal presenting part reaches the pelvic floor during second-stage labor. However, ineffective pushing may result from the following:

- Use of nonphysiologic pushing techniques and positions
- Fear of injury because of pain and tearing sensations felt by the mother when she pushes
- Decreased or absent urge to push
- Maternal exhaustion
- Analgesia or anesthesia that suppresses the woman’s urge to push
- Psychological unreadiness to “let go” of her baby

Management focuses on correcting causes contributing to ineffective pushing. If maternal and fetal vital signs are normal, no maximum allowable duration for the second stage exists. Each woman is evaluated individually by her birth attendant to determine whether labor should be ended with an operative delivery or can continue safely (see Chapter 16).

Nursing care to promote effective pushing helps the mother make each effort more productive. Most women, even women who have had epidural analgesia, can detect the urge to push with today’s techniques. The practice of laboring down, or delayed pushing—encouraging the woman to wait until she feels the reflexive urge to push—has shown a lower incidence of adverse effects than pushing immediately on full cervical dilation. (See Chapter 13 for more information about the nursing practice of laboring down.)

Upright positions such as squatting add gravity to the woman’s pushing efforts. Semisitting, side-lying, and pushing while sitting on the toilet are other options. If she prefers to lie in bed on her side, she should pull her upper leg toward her chest with each push. Leaning forward while in the sitting or squatting position maintains the best alignment of the fetal head with the pelvis.

The woman who fears injury because of the sensations she feels when pushing may respond to accurate information about the process of fetal descent. If she understands that sensations of tearing often accompany fetal descent but her tissues can expand to accommodate the baby, she may be more willing to push with contractions.

Epidural analgesia for labor uses a mixture of a local anesthetic agent and an epidural opioid analgesic to provide pain control without the major loss of sensation that is likely if local anesthetic is used alone. However, if a woman cannot feel the urge to push at all or cannot feel it strongly after the fetus has descended, she can be coached to push with each contraction.

The woman who is exhausted may push more effectively if she is encouraged to rest and push only when she feels the urge, or she may push with every other contraction. Oral and IV fluids can provide energy for the strenuous work of second-stage labor. Reassuring her about fetal well-being and the fact that she has no absolute deadline to meet helps her work with her body’s efforts most effectively. This reassurance also helps the woman who may be emotionally readying herself to “let go” of her fetus in exchange for a newborn as she labors.

Problems with the Passenger

Fetal problems associated with dysfunctional labor are related to the following:

- Fetal size
- Fetal presentation or position
- Multifetal pregnancy
- Fetal anomalies

These variations may cause mechanical problems and contribute to ineffective contractions.

Fetal Size

Macrosomia. The **macrosomic** infant weighs more than 8 lb 13 oz (4000 g) at birth, although some authorities define it as a weight of 9 lb, 15 oz (4500 g) or greater. The head or shoulders may not be able to adapt to the pelvis if they are too large (**cephalopelvic disproportion**). In addition, distention of the uterus by the large fetus reduces the strength of contractions both during and after birth.

Size, however, is relative. The woman with a small or abnormally shaped pelvis may not be able to deliver an average-sized or small infant. The woman with a large pelvis may easily give birth to an infant heavier than 8 lb 13 oz (4000 g). Fetal position as the baby descends through the pelvis is another important factor in terms of fetal size and maternal pelvic size.

Shoulder Dystocia. Delayed or difficult birth of the shoulders may occur as they become impacted above the maternal symphysis pubis. After the head is born, it retracts against the perineum, much like a turtle’s head drawing into its shell (“turtle sign”). Shoulder dystocia is more likely to occur when the fetus is large or the mother has

FIG 27-1 Methods That May Be Used to Relieve Shoulder Dystocia. **A**, McRobert's maneuver. The woman flexes her thighs sharply against her abdomen, which straightens the pelvic curve somewhat. A supported squat has a similar effect and adds gravity to her pushing efforts. **B**, Suprapubic pressure by an assistant pushes the fetal anterior shoulder downward to displace it from above the mother's symphysis pubis. Fundal pressure should not be used because it will push the anterior shoulder even more firmly against the mother's symphysis.

diabetes, but many cases occur in pregnancies with no identifiable risk factors. Labor may be long, but shoulder dystocia may occur after a normal labor (ACOG, 2012d; Lanni & Seeds, 2012; Thorp, 2009).

Shoulder dystocia is an urgent situation because the umbilical cord can be compressed between the fetal body and the maternal pelvis. Preparations for surgical delivery must be anticipated while taking immediate steps to deliver the baby vaginally. Although the infant's head is out of the vaginal canal, the chest is inside, preventing respirations. Any of several methods may be used to quickly release the impacted fetal shoulders (Figure 27-1). Fundal pressure should be avoided so that the shoulders are not pushed even harder against the symphysis. The infant's clavicles should be checked for crepitus, deformity, and bruising, each of which suggests fracture (see Chapter 20). Documentation of all care is essential, including a clear description of suprapubic pressure, if it was used, to avoid confusion with fundal pressure in any subsequent legal action. One person is usually designated the "timekeeper" for accuracy of records (Lanni & Seeds, 2012; Simpson, 2008; Thorp, 2009).

Abnormal Fetal Presentation or Position

An unfavorable fetal presentation or position may interfere with cervical dilation or fetal descent.

Rotation Abnormalities. Persistence of the fetus in the occiput posterior (OP) or occiput transverse (OT) position can contribute to dysfunctional labor. These positions prevent the mechanisms of labor (cardinal movements) from occurring normally. Most fetuses that begin in the occiput posterior position rotate spontaneously to the occiput anterior (OA) position, promoting normal extension and expulsion of the head. The fetus may not rotate or may partly rotate

and remain in the OT position. Although many women cannot readily deliver a fetus in the OP position, the woman with a pelvis larger than the fetal size may be able to do so.

CRITICAL THINKING EXERCISE 27-1

A woman having her first baby has been in labor for several hours. Her nurse-midwife performs a vaginal examination and says that the cervix is 6 cm dilated and completely effaced, with the fetus in right occiput posterior position. The mother is having persistent back pain that worsens during contractions.

Questions

1. How should the nurse interpret this information? Should the nurse take any specific action based on the nurse-midwife's examination?
2. Should the nurse take any specific action based on this examination?

Labor usually is longer and more uncomfortable when the fetus remains in the OP or OT position. Intense back or leg pain that may be poorly relieved with analgesia makes coping with labor difficult for the woman. "Back labor" aptly describes the sensations a woman feels when her fetus is in the OP position. Some women who had a fetus in the OP position during labor continue to feel more pain in the back or coccyx during the postpartum period.

Maternal position changes promote fetal head rotation to the OA position and descent (see other examples in Chapter 13). Examples are as follows:

- Hands and knees—rocking the pelvis back and forth while on hands and knees promotes rotation. The woman's knees should be slightly behind her hips in this position.

- Side-lying (on the opposite side of the fetal occiput).
- Lunge—the mother places one foot on a chair with her foot and knee pointed to that side. She lunges sideways repeatedly for 5 seconds at a time during a contraction. The lunge also can be done in a kneeling position. The nurse or the woman's partner must secure the chair and help the woman balance.
- Squatting (for second-stage labor)—sitting on a slightly underinflated birth ball gives a similar effect.
- Sitting, kneeling, or standing while leaning forward.

Using a birthing ball—a large plastic ball capable of supporting an adult's weight—helps support the woman when in the hands-and-knees position. She can also sit on it and gain many of the benefits of squatting. In addition, the woman tends to move her hips back and forth, favoring fetal descent.

Upright maternal positions promote descent, which usually is accompanied by fetal head rotation. The hands-and-knees and side-lying positions promote rotation because the mother's abdomen is dependent in relation to her spine. In the hands-and-knees position, the convex surface of the fetal back tends to rotate toward the convex anterior uterus, similar to nesting of two spoons (Figure 27-2). The side-lying position has a similar effect, although not quite as pronounced. These positions decrease the mother's discomfort by reducing the pressure of the fetal head on her sacrum.

The lunge widens the side of the pelvis toward which the woman lunges. If the fetal position is known, she lunges toward the side where the occiput is located (Figure 27-3). If the fetal position is not known, the woman can lunge toward the side that gives her greater comfort.

All variations of the squatting position aid rotation and fetal descent by straightening the pelvic curve and enlarging the pelvic outlet. They add gravity to the force of maternal pushing.

If spontaneous rotation does not occur, the physician may assist with the rotation and descent of the head by using forceps. The vacuum extractor cannot always be applied to the fetal head when it remains in the OP position. However, some styles of vacuum extractors may be used to correct minor degrees of malrotation because the fetal head tends to rotate as it descends with downward traction. Cesarean birth may be needed if these methods are unsuccessful or cannot be used.

Deflexion Abnormalities. The poorly flexed fetal head presents a larger diameter to the pelvis than if flexed with the chin on the chest (see Figure 12-8). In vertex presentation, the head diameter is smallest. In military and brow presentations, the head diameter is larger. In face presentation, the head diameter is similar to that of vertex presentation but the maternal pelvis can be traversed only if the fetal chin (mentum) is anterior.

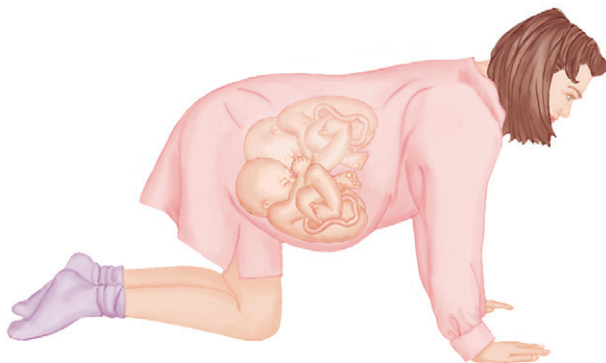

FIG 27-2 A hands-and-knees position helps this fetus rotate from a left occiput posterior (LOP) position to an occiput anterior position.

Breech Presentation. Cervical dilation and effacement often are slower when the fetus is in breech presentation because the buttocks or feet do not form a smooth, round dilating wedge like the head. The greatest fetal risk is that the head—the largest fetal part—is the last to be born. By the time the lower body is born, the umbilical cord is well into the pelvis and may be compressed. The shoulders, arms, and head must be delivered quickly so that the infant can breathe.

A breech presentation is common well before term, but only 3% to 4% of term fetuses remain in this presentation. Most breech births in North America are by cesarean section, but a surgical birth does not eliminate all problems associated with breech birth, which may include the following:

- Fetal injury, particularly with a difficult vaginal birth
- Prolapsed umbilical cord
- Low birth weight as a result of preterm gestation, multifetal pregnancy, or intrauterine growth restriction
- Fetal anomalies contributing to breech presentation, such as hydrocephalus
- Complications secondary to placenta previa or cesarean birth

External cephalic version (ECV) may be attempted to position the fetus in breech presentation or transverse lie to cephalic presentation (see Chapter 16). If the fetus remains in the abnormal presentation, cesarean section usually is performed to avoid complications of a difficult vaginal birth. Birth for the nulliparous woman with a fetus that remains in breech presentation is almost always by cesarean section. The fetus remaining in a transverse lie is delivered by cesarean section as well.

However, cesarean birth is not clearly beneficial for every woman with the fetus in breech presentation. The physician may offer a trial of labor when the fetus is in breech presentation in the following cases (Lanni & Seeds, 2012; Penn, 2011; Thorpe, 2009):

- The maternal pelvis is of normal size and shape.
- The estimated fetal weight is 4.4 to 8.4 lb (2000 to 3800 g).
- The fetus is in either frank or complete breech presentation (see Chapter 12).
- The fetal head is well flexed.

FIG 27-3 The “lunge” to one side promotes rotation of the fetal occiput from a posterior position to an anterior one.

FIG 27-4 Sequence for Vaginal Birth in a Frank Breech Presentation. **A**, Descent and internal rotation of the fetal body. **B**, Internal rotation complete; extension of the fetal back and neck as the trunk slips under the symphysis pubis. The birth attendant uses a towel for traction when grasping the fetal legs. **C**, After the birth of the shoulders, the attendant maintains flexion of the fetal head by using the fingers of the left hand to apply pressure to the lower face. The fetal body straddles the attendant's left arm. An assistant provides suprapubic pressure to help keep the fetal head well-flexed. **D**, After the fetal head is brought under the symphysis pubis, an assistant grasps the fetal legs with a towel for traction while the attendant delivers the face and head over the mother's perineum.

Some women are admitted in advanced labor with the fetus in breech presentation, so birth attendants and intrapartum nurses must be prepared to care for the woman having either a planned or an unexpected vaginal breech birth. (Figure 27-4 illustrates the mechanisms of vaginal birth for an infant in breech presentation.)

Multifetal Pregnancy

Multifetal pregnancy may result in dysfunctional labor because of uterine overdistention, which contributes to hypotonic dysfunction, and abnormal presentation of one or both fetuses (Figure 27-5). In addition, the potential for fetal hypoxia during labor is greater because the mother must supply oxygen and nutrients to more than one fetus. She also is at greater risk for postpartum hemorrhage resulting from uterine atony because of uterine overdistention.

Because of these problems, cesarean birth is more common for a woman with a multifetal pregnancy. If three or more fetuses are involved, the birth is almost always by cesarean section. The physician considers fetal viability, fetal presentations, maternal pelvic size, and presence of other complications such as preeclampsia or chronic hypertension.

Each twin's FHR is monitored during labor. When in bed, the woman should remain in the lateral position to promote adequate placental blood flow. After vaginal birth of the first twin, assessment of the second twin's FHR continues until birth, which usually occurs within about 30 minutes. Birth of the second twin is faster in cesarean birth than in vaginal birth (Dodd, Grivell, & Crowther, 2011; Newman & Unal, 2012).

FIG 27-5 Twins can present in any combination of presentations and positions.

The delivery staff must be prepared for the care and possible resuscitation of multiple infants. Radiant warmers, resuscitation equipment, medications, blankets, hats, and identification materials must be prepared for each infant. One or more neonatal nurses, a neonatal nurse practitioner, and a pediatrician or a neonatologist should be

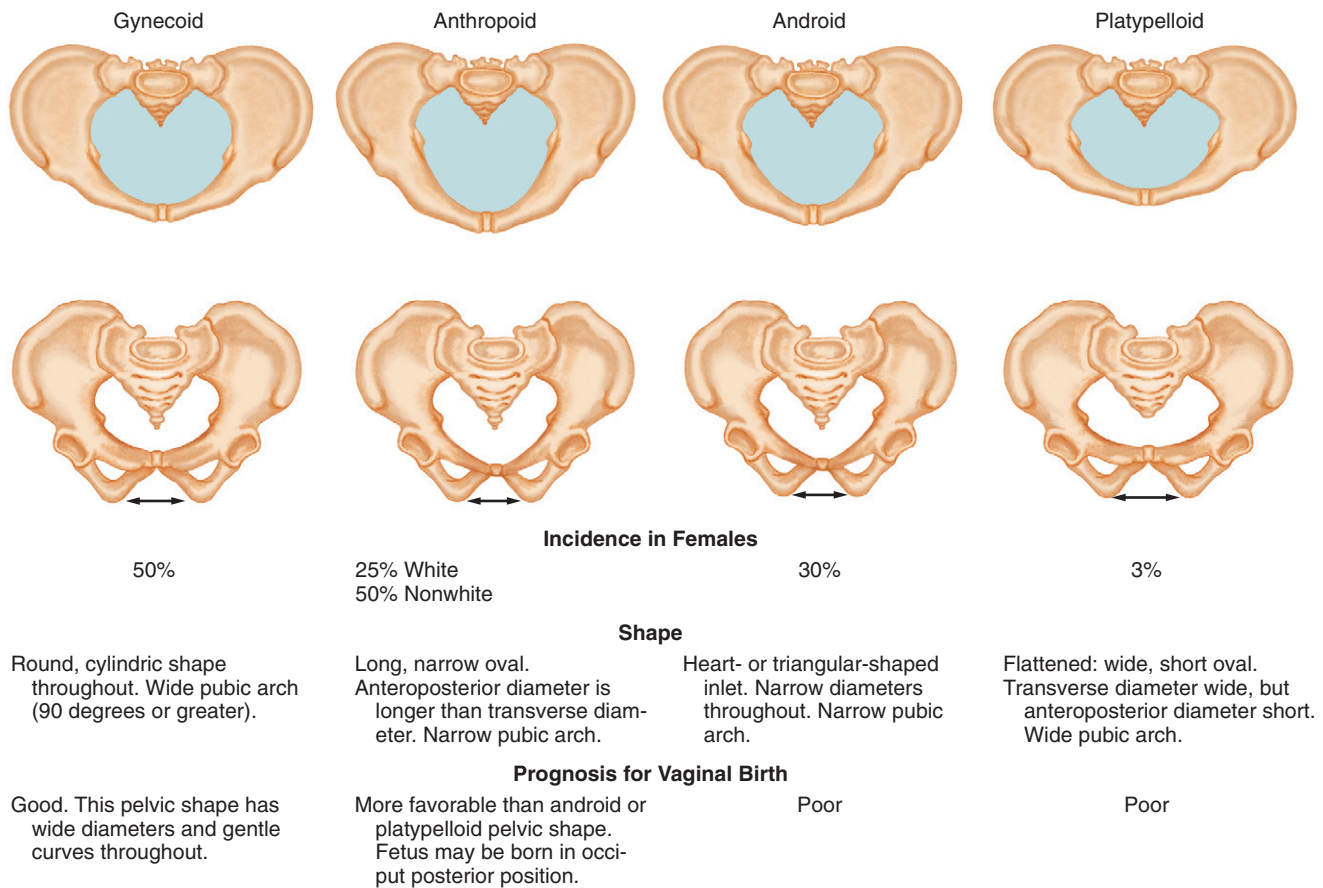

FIG 27-6 Pelvic shapes.

available to care for each infant. One nurse should be dedicated to caring for the mother.

Fetal Anomalies

Fetal anomalies such as hydrocephalus or a large fetal tumor may prevent normal descent of the fetus. Abnormal presentations such as breech or transverse lie also are associated with fetal anomalies. These abnormalities often are discovered by ultrasound examination before labor. Cesarean birth is scheduled if vaginal birth is not possible or is inadvisable.

1. How does hypotonic labor dysfunction differ from hypertonic labor dysfunction in terms of the most common labor phase when it becomes evident? Uterine contractions? Presence of pain? Therapeutic management?
2. How can maternal position changes favor rotation of the fetus from the OT or OP position to the OA position?
3. Why does cesarean birth not eliminate all adverse outcomes for infants in breech presentation?
4. How does preparation for the birth of multiple infants (vaginal or cesarean) differ from preparation for a single infant's birth?

Problems with the Passage

Dysfunctional labor may occur because of variations in the maternal bony pelvis or soft tissue problems that inhibit fetal descent.

Pelvis

A small (contracted) or abnormally shaped pelvis may retard labor and obstruct fetal passage. The woman may experience poor contractions,

slow dilation, slow fetal descent, and a long labor. The danger of **uterine rupture** (tear in uterine wall) is greater with thinning of the lower uterine segment, especially if contractions remain strong.

Four basic pelvic shapes exist, each with different implications for labor and birth (Figure 27-6). Most women do not have a pure pelvic shape but instead have mixed characteristics from two or more types. Different racial characteristics of the woman and her fetus may enhance labor and vaginal birth because they create a good fit between the two. Different racial characteristics of the woman and her fetus, however, may also result in a less-than-ideal fit between the pelvis and the passenger.

Maternal Soft Tissue Obstructions

During labor, a full bladder is a common soft tissue obstruction. Bladder distention reduces available space in the pelvis and intensifies maternal discomfort. The woman should be assessed for bladder distention regularly and encouraged to void every 1 to 2 hours. Catheterization may be needed if she cannot urinate or if epidural analgesia depresses her urge to void.

Problems of the Psyche

Labor is a stressful event for most women. However, a perceived threat caused by pain, fear, nonsupport, or personal situation can result in excessive maternal stress and interfere with normal labor progress. The woman's perception of stress more than the actual existence of a threat is what is most important.

Responses to excessive or prolonged stress interfere with labor in several ways:

- Increased glucose consumption reduces the energy supply available to the contracting uterus.

- Secretion of catecholamines (epinephrine and norepinephrine) by the adrenal glands stimulates uterine beta receptors, which inhibit uterine contractions (an action similar to that of tocolytic drugs such as terbutaline).
- Adrenal secretion of catecholamines diverts blood supply from the uterus and placenta to the woman's skeletal muscles.
- Labor contractions and maternal pushing efforts are less effective because these powers are working against the resistance of tense abdominal and pelvic muscles.
- Pain perception is increased and pain tolerance is decreased, and this further increases maternal anxiety and stress.

Assisting the woman to relax helps her body work more effectively with the forces of labor. General nursing measures involve the following:

- Establishing a trusting relationship with the woman and her significant other
- Making the environment comfortable by adjusting temperature and light
- Promoting physical comfort such as cleanliness
- Providing accurate information
- Implementing nonpharmacologic and pharmacologic pain management

Chapter 15 describes specific methods to encourage relaxation and promote comfort.

6. Why is psychological support during labor important for effective physiologic function?

Abnormal Labor Duration

An unusually long or short labor may result in maternal, fetal, or neonatal problems.

Prolonged Labor

Prolonged labor results from problems with any of the factors in the birth process. After the woman reaches the active phase of labor, cervical dilation should proceed at a minimum rate of 1.2 cm per hour in the nullipara and 1.5 cm per hour in the parous woman. The fetal presenting part is expected to descend at a minimal rate of 1 cm per hour in the nullipara and 2 cm per hour in the parous woman. Many factors are, however, part of labor progress. If a previous birth was by cesarean section before much cervical dilation occurred, the criteria that apply to a nullipara may be most appropriate. Effects of epidural analgesia on labor characteristics and the rate of progress and descent must also be considered by the birth attendant when deciding if interventions are needed to increase progress (Kilpatrick & Garrison, 2012; Thorp, 2009; Wing & Farinelli, 2012).

Possible maternal and fetal problems in prolonged labor include the following:

- Maternal infection, intrapartum or postpartum
- Neonatal infection, which may be severe or fatal
- Maternal exhaustion
- Higher levels of anxiety and fear during a subsequent labor

Maternal and neonatal infections are more likely if the membranes have been ruptured for a prolonged time because organisms ascend from the vagina. The mother is more likely to have an intrapartum infection, postpartum infection, or both.

Nursing measures for the woman who has prolonged labor include promotion of comfort, conservation of energy, emotional support,

position changes that favor normal progress, and assessments for infection. Nursing care for the fetus includes observation for signs of intrauterine infection and compromised fetal oxygenation (see Chapter 14).

Precipitate Labor

Precipitate labor is one in which birth occurs within 3 hours of its onset. Intense contractions often begin abruptly rather than gradually increasing in frequency, duration, and intensity, as is typical of most labors.

Precipitate labor is not the same as a precipitate birth. A **precipitate birth** occurs after a labor of any length, in or out of the hospital or birth center, when a trained attendant is not present to assist. However, a woman in precipitate labor also may have a precipitate birth. If the physician or nurse-midwife will not arrive in time for the baby's birth, the nurse should wear gloves and simply support the infant's body as it emerges. If the maternal pelvis is adequate and the soft tissues yield easily to fetal descent, little maternal injury is likely. However, if the soft tissues are firm and resist stretching, trauma (uterine rupture, cervical lacerations, and hematoma) of the vagina or vulva may occur.

The mother or her fetus or newborn may be affected by several conditions that can be associated with precipitate labor. These conditions may include abruptio placentae, fetal meconium, maternal cocaine use (also may be associated with abruptio placentae), postpartum hemorrhage, or low Apgar scores for the infant (Cunningham, Leveno, Bloom et al., 2010; Franco & Foley, 2012; Wing & Farinelli, 2012). The fetus may suffer direct trauma such as intracranial hemorrhage or nerve damage during a precipitate labor. The fetus may become hypoxic because intense contractions with a short relaxation period reduce the time available for gas exchange in the placenta. Nonreassuring electronic fetal monitoring patterns may include bradycardia and late decelerations.

Priority nursing care of the woman in precipitate labor includes promotion of fetal oxygenation and maternal comfort. The side-lying position enhances placental blood flow and reduces the effects of aortocaval compression. An added benefit of the side-lying position is to slow the rapid fetal descent and minimize perineal tears. Additional measures to enhance fetal oxygenation include administering oxygen to the mother and maintaining adequate blood volume with nonadditive IV fluids. If oxytocin is being used when rapid-fire contractions begin, it should be stopped. A tocolytic drug may be ordered.

Promoting comfort is difficult in a precipitate labor because intense contractions give the woman little time to prepare and use coping skills such as breathing techniques. Pharmacologic measures such as analgesics or epidural block may not be useful if rapid labor progress does not allow time for them to become effective. Also, possible newborn respiratory depression must be considered if opioid analgesia is given near birth. The nurse helps the woman focus on techniques to cope with pain, one contraction at a time. The nurse must remain with her to provide support and assist with an emergency birth if it occurs.

8. What is the priority nursing care for a woman in prolonged labor?
9. What are the maternal and fetal risks when labor is unusually short?

APPLICATION OF THE NURSING PROCESS

Dysfunctional Labor

Several nursing diagnoses and collaborative problems may be appropriate when caring for a woman having dysfunctional labor. The

potential complication of fetal compromise should be part of all intrapartum management (see [Chapter 14](#)). Pain management is especially important to women in dysfunctional labor because they may find that their coping skills are inadequate or difficult to use because of fatigue, possibly to the point of exhaustion. Anxiety or fear often is higher with abnormal labor, which limits the woman's ability to cope with labor. Anxiety or fear may reduce the effectiveness of pain medications or regional block analgesia. Maternal or newborn injury may become apparent after the birth.

In addition to these problems, nursing care is directed toward two other nursing diagnoses: "Possible Intrauterine Infection" and "Maternal Fatigue."

INTRAUTERINE INFECTION

Assessment

Infection can occur with both normal labors and dysfunctional labors. Assess the FHR and maternal vital signs for evidence of infection:

- Fetal tachycardia (>160 beats per minute [bpm] for a term fetus); a rising baseline FHR often is the first sign of intrauterine infection.
- Maternal temperature; assess every 2 to 4 hours in normal labor and every 2 hours after membranes rupture; assess hourly if elevated (100.4°F [38°C] or higher) or other signs of infection are present.
- Maternal pulse rate, respirations, and blood pressure; assess at least hourly to identify tachycardia or tachypnea, which often accompanies temperature elevation.

Assess amniotic fluid for normal clear color and mild odor. Small flecks of white vernix are normal in amniotic fluid. Yellow or cloudy fluid or fluid with a foul or strong odor suggests infection. The strong odor may be noted before birth or afterward on the infant's skin.

Nursing Diagnosis

For the woman without signs of infection but with risk factors, the nursing diagnosis selected is "Risk for Infection related to presence of favorable conditions for development." The nurse may specify the patient-specific conditions that may cause infection when choosing this nursing diagnosis.

Planning

Expected outcomes relate to detecting the onset of infection:

- Maternal temperature will remain below 100.4°F (38°C).
- The FHR will remain near the baseline with an average rate no higher than 160 bpm.
- The amniotic fluid will remain clear and without a foul or strong odor.

Interventions

Reducing the Risk for Infection

Nurses should wash their hands before and after each contact with all patients to reduce transmission of organisms. Limit vaginal examinations to reduce transmission of vaginal organisms into the uterine cavity, and maintain aseptic technique during essential vaginal examinations. The intrapartum nurse learns to estimate a woman's progress with few vaginal examinations. For example, increased bloody show and heightened anxiety may occur when the cervix is about 6 cm dilated. The woman may become irritable and lose control at about 8 cm dilation if she has chosen not to take epidural analgesia.

Keep underpads as dry as possible to reduce the moist, warm environment that favors bacterial growth. Periodically clean excess secretions from the vaginal area in a front-to-back direction to limit fecal contamination and promote the mother's comfort. Use personal protective equipment to avoid contact with body secretions.

SAFETY ALERT

Signs associated with intrapartum infection include the following:

- Fetal tachycardia (rising baseline or >160 bpm)
- Maternal fever (≥100.4°F [38°C])
- Foul-smelling or strong-smelling amniotic fluid
- Cloudy or yellow appearance to amniotic fluid

Identifying Infection

Assess the woman and fetus for signs of infection. Increase the frequency of assessments if labor is prolonged, if other risk factors are present, or if any signs of infection are found. If signs of infection are noted, report them to the birth attendant for further evaluation and treatment. Note the time at which the membranes ruptured to identify prolonged rupture, which adds to the risk for infection.

The birth attendant may collect specimens from the uterine cavity or placenta for culture to identify infectious organisms and determine antibiotic sensitivity. Aerobic and anaerobic culture specimens may be collected in containers specifically made for these two types of organisms. Follow directions on the container for proper handling and prevention of contamination with extraneous organisms, which would result in inaccurate results. Transport specimens to the laboratory promptly because living organisms are required for culture and sensitivity study. Antibiotic therapy is started promptly after collecting specimens.

Inform the newborn nursery staff if signs of infection are noted or increased maternal risk factors exist. Specimens of infant secretions also may be obtained for testing before administration of antibiotics.

The infant may receive prophylactic antibiotics to prevent neonatal sepsis (see [p. 661](#)). If results of maternal or infant cultures indicate that no infection is present, the antibiotic usually is discontinued. Culture and sensitivity testing may reveal an infection and indicate that a different antibiotic would be more effective.

Evaluation

The goals and expected outcomes are achieved if the following occur:

- The woman's temperature remains below 100.4°F (38°C).
- The amniotic fluid has no abnormal characteristics that are typical of infection (cloudiness, yellow color, foul or strong odor).
- The FHR remains within the expected range, not showing tachycardia, whether sudden or gradual in onset.

Even if the woman has no signs of intrapartum infection, she remains at higher risk for postpartum infection and should be observed for signs and symptoms of infection.

MATERNAL EXHAUSTION

Assessment

Many women begin labor with a sleep deficit because of fetal movement, frequent urination, and shortness of breath associated with advanced pregnancy. As labor drags on, the mother's reserves are further depleted. Even with epidural analgesia, a long labor drains the

mother's energy. Also, some women do not choose to or cannot take epidurals. Therefore, the labor nurse must be prepared to deal with this problem.

Assess the mother for the following signs of excessive fatigue:

- Verbal expression of tiredness, fatigue, or exhaustion
- Verbal expression of frustration with a prolonged, unproductive labor (“I can’t go on any longer. Why doesn’t the doctor just take the baby?”)
- Ineffectiveness of or inability to use coping techniques (such as patterned breathing) that she previously used effectively
- Changes in her pulse rate, respiration, and blood pressure (increased or decreased)

Nursing Diagnosis

The intense energy demands of a dysfunctional labor may exceed a woman's physical and psychological ability to meet them. For this reason, “Activity Intolerance related to depletion of maternal energy reserves” is an appropriate nursing diagnosis.

Planning

Contractions must continue for labor to progress. Two realistic goals or expected outcomes are that the woman will do the following:

- Rest between contractions with her muscles relaxed.
- Use coping skills such as breathing and relaxation techniques.

Interventions

Conserving Maternal Energy

Reduce the factors that interfere with the woman's ability to relax. Lower the light level, and turn off overhead lights. Reduce noise by closing the door or using soft music, water sounds, or other comforting sounds. Maintain a comfortable maternal temperature with blankets or a fan. If not contraindicated, a warm shower or bath is soothing.

Position the woman to encourage comfort, promote fetal descent, and enhance fetal oxygenation. Support her with pillows to reduce muscle strain and added fatigue. Help her change positions regularly (about every 30 minutes) to reduce muscle tension from constant pressure.

A soothing back rub reduces muscle tension and thus decreases fatigue. Firm sacral pressure and use of some maternal positions discussed in the section on fetal occiput posterior positions may reduce back pain. Using the birthing ball can relax and support her in some positions. Warmth to her back can reduce back pain. (See [Chapters 13 and 15](#) for added comfort measures.)

Maintain IV fluids at the rate ordered to provide fluid, electrolytes, and possibly glucose. Assess intake and output to identify dehydration, which may accompany prolonged labor. Dehydration also may cause maternal fever. If not contraindicated, provide juice, lollipops, frozen juice bars, or other clear liquids, as ordered by the physician or nurse-midwife, to moisten the woman's mouth and replenish her energy.

Promoting Coping Skills

When position changes or medical therapies are used to enhance labor, explain their purpose and expected benefits. Encourage the woman to visualize her baby passing downward smoothly through her pelvis as a result of her efforts. Provide mental images that allow her to “see” herself giving birth.

Generous praise and encouragement of the woman's use of skills such as breathing techniques motivate her to continue them even when she is discouraged. As with any laboring woman, tell her when she is making progress. Tell her that fetal heart rates and patterns are

reassuring if this is true. Knowing that her efforts are having the desired results and her fetus is doing well gives the woman courage to continue.

Evaluation

Goals are met if the woman does the following:

- Rests and relaxes between contractions. If she is unable to relax, discuss analgesia options with her. Inability to relax between contractions is associated with pain beyond the woman's tolerance.
- Continues to demonstrate adequate use of learned skills to cope with labor.

In addition, solicit the woman's perceptions of her ability to relax and cope with labor.

PREMATURE RUPTURE OF THE MEMBRANES

Rupture of the amniotic sac before onset of true labor is called *premature rupture of the membranes* (PROM) and is normal if it occurs at term. A precise term, *preterm premature rupture of the membranes* (PPROM, sometimes abbreviated as pPROM), refers to the rupture of membranes earlier than 37 weeks, with or without contractions. PPRM is associated with preterm labor and birth. The greatest newborn risks occur when birth occurs before completion of 34 weeks of gestation (ACOG, 2012d; Mercer, 2009b, 2012; Svignos, Dodd, & Robinson, 2011a).

Etiology

Several conditions are associated with PROM, but the exact cause often remains unclear. Conditions associated with preterm ruptured membranes include the following:

- **Chorioamnionitis** (intraamniotic infection), or inflammation of the membranes, which may be associated with group B streptococci, *Neisseria gonorrhoeae*, *Listeria monocytogenes*, or species from the general *Mycoplasma*, *Bacteroides*, and *Ureaplasma* in the amniotic fluid
- Infections, possibly asymptomatic, of the vagina or cervix, such as *N. gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, group B *Streptococcus* (GBS), or *Gardnerella vaginalis* (bacterial vaginosis) infection
- Amniotic sac with a weak structure
- Previous preterm birth, especially if preceded by PPRM
- Fetal abnormalities or malpresentation
- Incompetent cervix or a short cervical length (≤ 25 mm)
- Overdistention of the uterus
- Maternal hormonal changes
- Recent sexual intercourse
- Maternal stress or low socioeconomic status
- Maternal nutritional deficiencies

Complications

Both mother and newborn are at risk for infection during the intrapartum and postpartum periods. Chorioamnionitis can be both a cause and a result of PROM. Organisms that cause chorioamnionitis weaken the amniotic membrane, leading to the rupture. The mother is at higher risk for postpartum infection, and the newborn is vulnerable to neonatal sepsis. GBS is often associated with PPRM.

Chorioamnionitis, characterized by maternal fever and uterine tenderness, is most likely to precede preterm birth in the infant born before 34 weeks of gestation. Preterm infants with the lowest maturity

such as 24 weeks of gestation have higher risk for the infection than preterm infants who are even a few weeks more mature. The exact time at which infection occurs cannot be predicted for either term or preterm infants. Frequent performance of digital examination of the cervix increases the risk for all gestations. If chorioamnionitis does not precede PROM, it is more likely to occur if a long time elapses between membrane rupture and birth because vaginal organisms can readily enter the uterus. The risk for chorioamnionitis is known to increase after 24 hours.

Membranes that rupture before term may form a seal, stopping the fluid leak and allowing the amniotic fluid cushion to become reestablished. However, membranes may continue to leak, prolonging the loss of the amniotic fluid cushion (**oligohydramnios**) for the fetus. Umbilical cord compression, reduced lung volume, and deformities resulting from compression may occur, particularly if rupture occurs near the age of fetal viability, about 23 weeks of gestation, possibly extending the duration of amniotic fluid loss.

If preterm birth occurs, the infant is more likely to have respiratory distress syndrome (RDS) and complications related to prematurity. The hazards of prematurity are greatest before 34 weeks of gestation, especially if the woman did not receive steroids to accelerate fetal lung maturation before birth (see pp. 585-586).

Therapeutic Management

Management of PROM depends on the gestation and whether evidence of infection or other fetal or maternal compromise exists. For a woman at or near term (36 weeks or more of gestation), PROM may herald the imminent onset of true labor. Often the cervix is soft, with some dilation and effacement. If the fetus is less than 36 weeks or the woman's cervix is not soft and favorable for labor induction, therapeutic management is more complex. Risks for infection or preterm birth complications are weighed against risks of labor induction or cesarean birth.

Determining True Membrane Rupture

The first step is to determine whether the membranes are truly ruptured. Urinary incontinence, increased vaginal discharge, or loss of the mucous plug can make a woman think that her membranes have ruptured when they have not. A digital vaginal examination is avoided, particularly if the gestation is preterm and no evidence of labor exists. Instead, the physician or nurse-midwife performs a sterile speculum examination to look for a pool of fluid near the cervix and estimate cervical dilation and effacement. A pH swab or fern test may be done on the fluid to verify that the liquid is amniotic fluid (see [Chapter 13](#)). Tests to assess fetal lung maturity and identify infection are often performed. A transvaginal ultrasound examination may be performed to measure cervical length. A short (≤ 25 mm) cervix is more likely to continue effacement and dilation even if the gestation is far from term.

Gestation Near Term. If labor does not begin spontaneously, the woman's pregnancy is at or near term, her cervix is favorable, and fetal lungs are mature, labor is usually induced (see [Chapter 16](#)). If the cervix is not favorable and no infection is evident, induction may be delayed 24 hours or longer to allow cervical softening and administration of antibiotics, usually against GBS. Steroids to accelerate fetal lung maturity are not indicated if the fetus is 34 or more weeks of gestation ([ACOG, 2011c](#)). If induction is unsuccessful or if infection or other complications develop, a cesarean birth is most common. The nurse should remember, however, that cesarean birth also increases the risk for any mother's infection after birth.

Preterm Gestation. If the gestation is preterm, the physician weighs the risks of maternal-fetal infection against the newborn's

risk for complications of prematurity. Many variables must be considered by the physician and woman to determine the best course of management. Medical management changes as fetal maturation and conditions of the mother and fetus change with the continuation of pregnancy.

The cervix usually is not favorable for induction far from term. Factors such as gestational age, amount of amniotic fluid remaining, fetal lung maturity, and any signs of fetal compromise are considered. A **cerclage** (suture encircling the cervix) may have been placed earlier in the pregnancy to prevent premature cervical dilation. If infection is not already present, the physician must consider whether leaving the cerclage in place is likely to increase the risk for infection.

If no evidence of infection exists and the fetal lungs are immature, the woman usually is observed for infection or onset of labor in the hospital. Daily nonstress tests are performed to watch for FHR nonreactivity, which often occurs with intraamniotic infection. Biophysical profiles, in which sonographic evaluation is added to the nonstress test, may be done one or more times per week (see [Chapter 10](#)). Fetal lung maturity testing may be done as term approaches to identify the best time for delivery unless other complications require delivery before fetal lung maturity. Antibiotics are given during labor.

With very early gestations, management is more complex. Steroids given to the mother accelerate fetal lung maturity, and antibiotics reduce the risk of intrauterine infection, possibly extending pregnancy. Before 25 weeks of gestation, the likelihood of having a newborn who does well is lower. After initial inpatient evaluation the woman may be discharged for home management ([ACOG, 2012d](#); [Mercer, 2012](#); [Svigos, Dodd, & Robinson, 2011b](#)).

Maternal Antibiotics

Maternal antibiotics are usually prescribed for premature membrane rupture because of the increased likelihood that an infection caused or further complicated the rupture for both mother and fetus or newborn. Antibiotics may stop the infection that caused or will occur with the rupture, thereby delaying the onset of labor and allowing the fetus to mature. Drugs to stop infection if early membrane rupture occurs may include ampicillin, amoxicillin, and erythromycin. Drugs effective against GBS are common because the prenatal GBS culture has probably not been done with a prenatal visit if membranes rupture before 35 weeks of gestation. Guidelines for specific drugs to correct infection associated with early membrane rupture may vary with culture and sensitivity test results, other maternal laboratory results, or changes in the drugs most currently recommended for this purpose ([ACOG, 2012d](#); [Mercer, 2012](#)).

Nursing Considerations

The woman may remain hospitalized until birth, or she may return home after a few days of hospital observation. If she is hospitalized, the nurse observes for signs of infection. Preparation for home management includes teaching the woman the following:

- Avoid sexual intercourse, orgasm, or insertion of anything into the vagina, which increases the risk for infection caused by ascending organisms and can stimulate contractions.
- Avoid breast stimulation if the gestation is preterm because it may cause release of oxytocin from the posterior pituitary and thus stimulate contractions.
- Take your temperature at least four times a day, reporting any temperature of more than 100°F (37.8°C).
- Maintain any activity restrictions.
- Note and report uterine contractions or a foul odor to vaginal drainage.

PRETERM LABOR

Preterm labor begins after the 20th week but before the end of the 37th week of pregnancy. The physical risks to the mother are no greater than labor at term unless complications such as infection, hemorrhage, or the need for a cesarean delivery also exist. Preterm labor, however, may result in the birth of an infant who is ill equipped for extrauterine life, particularly if earlier than 32 weeks of gestation. Preterm birth affects 500,000 babies or 1 of 8 babies born in the United States. Adverse effects of prematurity may include cerebral palsy, developmental delay, and vision and hearing impairment. Families may suffer heavy emotional and economic burdens. Non-Hispanic black mothers are 1.5 times more likely to deliver preterm than non-Hispanic white women. In the 2007 birth data, the preterm-related infant mortality rates for non-Hispanic black women were 3.4 times higher than these rates for white women.

Many possible risk factors exist that might trigger preterm labor. A woman who has previously delivered a preterm infant is more likely to have others that she delivers early. Having a multifetal pregnancy or use of assisted reproductive technology carries higher risks for both mothers and their infants, such as cesarean birth, prematurity, and infant disability or death (Centers for Disease Control and Prevention [CDC], 2012).

The rate of preterm birth increased by 20% between 1990 and 2006, and most of the increase was in late preterm births, or infants born at 34 to 36½ weeks. Infant mortality for late preterm infants was three times the mortality for term infants (37 to 41 weeks) in 2005, numbers that demonstrate the maturational value of those few added weeks. Higher rates of induction and cesarean births are likely contributors to the higher late preterm birth rates. Inductions more than doubled, from 7.5% to 17.3% and cesarean births had a 46% rise from 23.5% to 34.3% during this period. Infants born at “early term” have an increased risk for poor outcomes in both the immediate and longer-term period (Craighead, 2012; Darcy, 2009; Martin, Kirmeyer, Osterman et al., 2009; Simhan, Iams, & Romero, 2012). The Association of Women’s Health, Obstetric and Neonatal Nurses (AWHONN) has launched an online campaign to promote the benefits of term pregnancy to women (www.gothefull40.com).

Associated Factors

Just as all causes of onset of labor at term are not known, the causes of preterm labor are not fully known. Over half of the women who have preterm labor and birth do not show known risk. Other women who have many risk factors deliver at term. Some of the possible causes of preterm labor are the following (Simhan, Iams, & Romero, 2012; Svigos, Dodd, & Robinson, 2011b):

- Maternal medical conditions, including infections of the urinary tract, reproductive organs, or systemic organs; dental disorders (periodontal disease); preexisting or gestational diabetes; connective tissue disorders; chronic hypertension; and drug abuse
- Conceptions enhanced by assisted reproductive technology, including conceptions resulting in a single fetal gestation rather than a multifetal gestation

EVIDENCE-BASED PRACTICE**Important Basic Nursing Actions for Care of Early Term (Late Preterm) Babies**

Normal, or spontaneous physiologic birth has been threatened by the rise in elective induction and cesarean births, often at early term, or 37 to 38 weeks of gestation. Craighead (2012) discussed the short-term health risks to infants and some of the possible long-term health outcomes when they arrive short of full term. Nurses need to be alert for poor outcomes in these near term (or late preterm) babies.

Data gathered by Craighead (2012) is presented here to improve the reader’s understanding of the problems. U.S. birth data show that the average age for spontaneous birth, births after premature rupture of the membrane (PROM), and births following medical intervention declined from 40 weeks to 39 weeks. Births from 37 to 39 weeks accounted for 17.5% of live births. At the same time, postterm births greater than 40 weeks decreased. Researchers have found that about half the women who were offered an elective induction would have it but that if it was not offered, over 90% did not have it. Researchers have also found that many women are confused about just when they reach full term.

Newborn morbidity has been shown to nearly double for each week before completing 39 weeks of gestation. The incidence of poor health and newborn complications decreased with each added week of gestation. Oshiro, Henry, Wilson et al. (2009) reported that the use of the neonatal intensive care unit (NICU) averaged 8.5% for newborns at 37 weeks but that only 3.34% of 39 week newborns needed it. Respiratory problems such as respiratory distress syndrome (RDS) and transient tachypnea of the newborn increase as gestational age fell below 38 weeks in another study. Feeding problems are more likely in the late preterm infants.

Craighead (2012) summarized some nursing actions to care for the early term and late preterm infants as (1) assessing frequently for respiratory difficulty; (2) observing for feeding difficulties; (3) monitoring frequently for temperature instability; and (4) educating parents. She encouraged nurses to use their professional opportunities to speak up and (1) discredit the myth that there is no risk to delivering a baby a few weeks early, (2) explain to other professionals that failure to communicate risks to a pregnant woman is likely to make her willing to deliver early as a matter of convenience or maternal fatigue, and (3) be sure that pregnant women and their families know the risks of early term birth and reduce their urge to deliver early. Nurses can help lower the incidence of early births that could have been prevented.

Reference: Craighead, D.V. (2012). Early term birth: Understanding health risks to infants. *Nursing for Women’s Health*, 16(2), 136-144.

- Present and past obstetric conditions such as short cervical length (≤ 25 mm), multifetal gestation, preterm membrane rupture, preeclampsia, and bleeding disorders that involve the woman, fetus, or placental implantation area
- Fetal conditions such as growth retardation, inadequate amniotic fluid volume, and chromosome abnormalities and other birth defects
- Social and environmental factors such as inadequate or absent prenatal or dental care, maternal domestic violence episodes, maternal smoking, and housing deficiency such as homelessness
- Demographic factors such as race and ages of the parents, financial stability, and the number and birth intervals of the woman’s other children

Signs and Symptoms

Signs and symptoms of early preterm labor are more subtle than those of labor at term and often occur in normal pregnancies as well. Prenatal visits and routine ultrasounds may reveal evidence of cervical

changes that have been occurring over several weeks during the second and third trimesters. The woman may be only vaguely aware that something seems different, or she may not detect that anything is amiss. Only when preterm labor reaches the active phase is it likely to have characteristics typical of term labor. Symptoms vary among women, but common ones are as follows:

- Uterine contractions that may or may not be painful (the woman may not feel contractions at all)
- A sensation that the baby is frequently “balling up”
- Cramps similar to menstrual cramps
- Constant low backache; irregular or intermittent low back pain
- Sensation of pelvic pressure or a feeling that the baby is pushing down
- Pain, discomfort, or pressure in the vagina or thighs
- Change or increase in vaginal discharge (increased, watery, “spotting,” bleeding)
- Abdominal cramps with or without diarrhea
- A sense of “just feeling bad” or “coming down with something”

Preventing Preterm Birth

Community Education

Preterm birth can impose substantial physical, emotional, and financial burdens on the child, family, and society. Ideally, nursing strategies to prevent preterm birth begin before conception, with community education. Topics may include the following:

- Role of early and regular prenatal care, including dental care, in preventing preterm birth
- Duration of normal pregnancy
- Consequences of preterm birth
- Conditions that increase risk for preterm birth
- Signs and symptoms of preterm labor
- Consequences of preterm birth for mother, baby, and family members

Women who are aware of the consequences of preterm birth may be more likely to take action to prevent it. If they recognize that they have risk factors, they may seek prenatal care earlier in pregnancy. Recognizing that onset of labor in early gestation has subtle signs and symptoms compared with labor near term makes the woman aware that she should seek care promptly rather than waiting for more definite signs of labor.

During Pregnancy

During pregnancy, measures to prevent preterm birth include the following:

- Reducing barriers and improving access to early prenatal care for all women
- Assessing for risk factors to permit changes, if possible
- Promoting adequate nutrition
- Promoting smoking cessation
- Teaching women and their partners about the subtle signs and symptoms of preterm labor and ways in which they differ from normal pregnancy changes
- Empowering women and their partners to take an active approach in seeking care if they have signs and symptoms of preterm labor

Improving Access to Care. Improving access to prenatal care must be customized for the community. What works in one area may be inappropriate for another. Difficult access is a serious problem for women who rely on public clinics for their care. Long waits, fragmented care, language barriers, and insensitivity of caregivers discourage women from obtaining care. Expanding the number of caregivers by using advanced practice nurses such as certified nurse-midwives and nurse practitioners, can reduce waits for care significantly. Nurses

CASE STUDY 27-1 NURSING CARE PLAN*

ASSESSMENT: Rhonda, a 28-year-old woman, is gravida 4, para 3. Her children were born at 40 weeks, 28 weeks, and 32 weeks of gestation, and are 7 years, 4 years, and 18 months old, respectively. She has mild cramping and pelvic pressure at 28 weeks and comes to the hospital immediately. Her cervix is dilated 1 to 2 cm and is beginning to efface. Her membranes are intact. Rhonda responds to intravenous (IV) magnesium sulfate to stop her contractions. The physician also orders betamethasone 12 mg intramuscular (IM) for two doses, 24 hours apart. After her contractions stop, she is prescribed oral terbutaline to maintain tocolysis and will be discharged home in 48 hours if no recurrent symptoms develop.

NURSING DIAGNOSIS: Impaired Home Maintenance related to activity restrictions and family demands

EXPECTED OUTCOME: By hospital discharge, Rhonda will:

1. Relate ways that she can maintain prescribed activity restrictions.

INTERVENTIONS AND RATIONALES

1. Assess what support systems are available and financially feasible to help Rhonda with child care and transportation, such as family and friends transporting children to elementary school, daycare, and “mother’s day out” programs at churches. *Responsibilities for other children may impede a woman’s ability to maintain activity limits. Coordination among several resources helps provide all-day coverage for child care.*
2. Encourage Rhonda to lower her standards for home management temporarily. *Many usual roles must be reallocated during this time. Having alternative arrangements increases the chance that Rhonda can maintain therapy. Considering the strengths and personal obligations of those who volunteer to help her is likely to increase the satisfaction of Rhonda and her family as well as the satisfaction of those who help.*
 - a. Have her eat nourishing take-out or fast food.
 - b. Have her set priorities regarding household tasks that must be done.
 - c. Let her children do tasks that are within their abilities.
 - d. Make lists of tasks for different people who ask to help her. Encourage her to consider the talents, resources, and obligations of volunteers.
3. Encourage Rhonda to accept help from others. Remind her that this situation is temporary and that she may be able to help someone else at another time. *If Rhonda feels that she can help others at another time, she may be more willing to accept help when she needs it.*

EVALUATION: Rhonda identifies three friends in addition to her mother-in-law who may be able to help with child care. She says she cannot afford to continue sending her children to their daycare center if she is not working. Rhonda feels that if her children are cared for, her husband can handle the other home management needs.

*Continues on p. 586.

can help coordinate various aspects of care to limit the number of different appointments a woman needs to obtain complete care.

Identifying Risk Factors. Identification of risk factors may allow reduction or elimination of these factors. Women should be rescreened regularly to identify new risks that emerge as pregnancy progresses. Women with high-risk factors benefit from care such as more frequent prenatal care appointments, reinforcement of the symptoms of preterm labor, telephone contacts, and added assessments of fetal growth and health.

Some risk factors can be reduced or eliminated if the woman changes her lifestyle. Many pregnant women stop smoking or using nontherapeutic drugs, changes that may be difficult for them, to

benefit their babies. A woman may need to rest more or stop working, which may be difficult or impossible for many. Nurses and social workers can help the woman reduce her risks as much as possible by helping her identify sources of support.

Infections of the urinary and reproductive tracts are associated with PPROM and preterm labor. Screening at the appropriate times for pathogenic organisms in the urine, vagina, and cervix identifies women who may benefit from antibiotic therapy.

Progesterone Supplementation. Progesterone (Delalutin) was used in the past to prevent spontaneous abortion. The drug proved to be ineffective for that purpose and was pulled from the market. However, progesterone in the form of 17-P alpha-hydroxyprogesterone caproate (Makena) continues to gather data to determine its effectiveness in reducing preterm birth to women who had had a previous preterm birth (Simhan, Iams, & Romero, 2012). A download of the clinical trials to release Makena may be found at www.fda.gov.

Promoting Adequate Nutrition. An adequate maternal diet contributes positively to the length of gestation and the infant's birth weight. The mother's height should be measured at the first prenatal visit, and her weight should be taken at each visit to evaluate adequacy of weight gain. Every pregnant woman should be offered culturally sensitive dietary counseling. The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) is available to supplement the diet of some women from low-income groups. Anemia can be corrected with appropriate supplements. Women carrying more than one fetus need additional food intake. (See Chapter 9 for additional information about nutrition and pregnancy, including nutrition related to cultural practices and vegetarianism.)

Educating Women and Their Partners about Preterm Labor.

All pregnant women and their partners should be taught about symptoms of preterm labor, because half of preterm births occur in women with no identified risk factors. Interpreters who are culturally acceptable to the woman and printed materials in her primary language should be used, if needed. Diagrams should supplement the words of any language for women of limited reading skills. Respecting cultural norms of the woman and her family is an essential part of prenatal care that encourages her to maintain care to identify possible problems early.

Information about the vague signs and symptoms of early preterm labor should be reinforced regularly as part of prenatal care. Women who often have uterine irritability may be given guidelines to observe at home before they must go to the hospital. Preterm labor often has vague sensations to the woman when her cervix has minimal dilation, so any home care guidelines are individualized according to the woman's risk for a preterm birth, the gestation and prenatal status, and the likelihood that specific interventions are beneficial to mother and baby. In addition, women are to enter the hospital for evaluation if they are not sure about the seriousness of their sensations. Examples of home care guidelines include the following:

- Drink an adequate amount of water to improve hydration or reduce bladder irritation that may accompany a urinary tract infection.
- Empty the bladder frequently because a full bladder may be associated with uterine irritability and contractions.
- Position yourself in the side-lying position to promote uterine blood flow. Limiting physical activity may increase diuresis. Prolonged limitation of physical activity is not usually beneficial or safe for prevention of premature labor, although it may be required for serious maternal disorders such as cardiac disease.
- Palpate contractions for 1 hour or as instructed because of the duration of any prior labor. However, notify the birth attendant or go directly to the labor unit for assessment if contractions increase in frequency, duration, or sensitivity.

The nurse should verify the woman's understanding by seeking feedback such as having her restate the signs and symptoms of preterm labor and the appropriate responses to them.

Empowering Women and Their Partners. Delaying birth depends critically on early identification of preterm labor. Women should be encouraged to seek treatment promptly if they suspect preterm labor. The woman must communicate her concerns clearly when she arrives at the clinic or hospital. She should tell the triage person that she should be checked for labor, regardless of the subtlety of the symptoms. Caregivers must not make the woman feel foolish if she reports signs and symptoms that could be preterm labor but turn out to be a false alarm. Otherwise she may not seek care for recurrent episodes when she truly is in labor, and the opportunity to delay preterm birth may be lost.

The nurse might suggest that a woman who is seeking care for possible preterm labor say, "I'm not due for 8 more weeks, but I think I may be in labor. I need to be seen right away, or I might have a premature baby."

Therapeutic Management

Management focuses on identifying those at risk for preterm birth, identifying preterm labor early, delaying birth, and accelerating fetal lung maturity if preterm birth is likely. Onset of changes that lead to preterm labor and birth may be subtle. The woman may not perceive any changes in her pregnancy.

Predicting Preterm Birth

Because treatment for preterm labor has been less than satisfactory at preventing preterm birth, research has focused on predicting which women will deliver early. Better identification of these women would allow more intensive treatment, ideally before preterm labor or rupture of membranes occurs. Also, many signs and symptoms of preterm labor occur in women who deliver at term, possibly exposing them to unneeded treatment. The key is to identify which women with the symptoms are really at risk for preterm birth and treat those women intensively while continuing regular prenatal care for women with these symptoms as a variant of normal pregnancy symptoms. A good screening test would provide quick results and would be inexpensive, usable for all pregnant women, noninvasive, and highly specific for the condition. No screening test meeting these criteria is available to screen for preterm labor yet. For this reason, many evaluations may be used in an attempt to determine the best medical management for a woman.

Cervical Length. A short cervix (≤ 25 mm), measured by transvaginal ultrasound, may allow vaginal organisms easier access to the uterus, where they weaken the membranes and cause premature rupture. Alternatively, the shortened cervix may reflect structural changes caused by an intrauterine infection or uterine contractions. The woman may have no symptoms of infection or pressure against the cervix (ACOG, 2012c; Iams, 2009; Mercer, 2009b; Simhan, Iams, & Romero, 2012).

PPROM in a Previous Birth. Some women may have a predisposition to weak amniotic membrane structure that predates the actual leaking of fluid. This predisposition seems to repeat in subsequent pregnancies (Mercer, 2009b; Mercer, 2012).

Fetal Fibronectin. Fetal fibronectin (fFN) is a protein present in fetal tissues. It is normally found in cervical and vaginal secretions until 16 to 20 weeks of gestation and again at or near term. If it appears too early, it suggests that labor may begin early, similar to the way elevated cardiac enzymes rise in the person experiencing a myocardial infarction. Maternal or fetal infections may be present if the fFN is positive during midpregnancy. To reduce false positives, the test specimen must be collected before significant vaginal manipulation from examination.

Cervical examination, recent sexual intercourse, and vaginal bleeding can result in a false-positive test when preterm labor is not truly present (Iams, Romero, & Creasy, 2009; Simhan, Iams, & Romero, 2012).

Infections. Infections often increase the risk for preterm membrane rupture or birth, even if the woman does not initially have clinical signs or symptoms with the preterm labor. A urinary tract infection is common with preterm labor, so catheterized or midstream urine is often obtained for urinalysis and for culture and sensitivity testing. Tests for other infections associated with preterm birth risk include those that often are found if membranes rupture prematurely (see discussion of premature rupture of the membranes on p. 577).

Measurement of blood peak and trough levels of indicated antibiotics such as gentamicin ensures that the woman is receiving a therapeutic level (peak) of the drug. Determining if the drug blood level is excessive just before the next dose (a high trough level) is important to prevent possible damage to mother or baby with some drugs. Testing for peak and trough drug levels allows the dose to be adjusted appropriately for the drug.

A woman with an infection that is not always related to pregnancy may seek care. Relevant testing may relate to acute gastrointestinal or respiratory tract infections that affect pregnant women as well as other people of both genders. More serious maternal infections may require cultures of maternal blood or respiratory tract or other secretions to determine the ideal treatment. Maternal pneumonia, although rare during pregnancy, increases the risk for fetal or maternal death as well as increasing the risk that a woman will give birth to a living preterm infant. Other poor health conditions during pregnancy (such as crowded living conditions) or a chronic medical condition (such as asthma) may increase a woman's risk for pneumonia as well.

Identifying Preterm Labor

The reason to predict risk for preterm birth or to identify preterm labor early is to delay birth, thereby promoting further fetal maturation.

Frequent Prenatal Visits. Women at risk for preterm labor should have more frequent prenatal visits, at which time they are checked for evidence of preterm labor and their ability to follow preventive therapy, in addition to their regular prenatal checkup. They should be assessed for development of new risk factors with each visit. Gentle cervical examinations, usually with sterile speculum, are done if indicated by other signs or symptoms. A transvaginal ultrasound examination may identify the shortened, thinned cervix that often precedes onset of labor in the asymptomatic woman. Infections can be identified and treated promptly before rupture of membranes or onset of labor occurs.

Stopping Preterm Labor

Once the diagnosis of preterm labor is made, management focuses on stopping uterine activity before the point of no return, usually after about 3-cm dilation. Preterm delivery may be inevitable, but steroid therapy promotes earlier fetal lung maturation. Particularly for very early gestations such as 25 weeks, treatment may add enough time for the steroids to be effective. Even one more day of fetal maturation may make a great difference in the outcome for the very premature infant.

Initial Measures. The physician initially determines whether any maternal or fetal problems exist that contraindicate continuing the pregnancy. Some examples are maternal complications such as hypertension or hypotension, hypovolemia, hypoxemia, cardiac disease, and pyelonephritis. Fetal problems needing prompt delivery may be demonstrated by persistent nonreassuring FHR.

Initial measures to stop preterm labor include identifying and treating infections, identifying other causes of preterm labor that may be treatable, and reducing activity.

Identifying and Treating Infections. Infection, both systemic and local, has a strong association with preterm birth and premature rupture of the membranes. However, it may be unclear whether various microorganisms found at diagnosis of preterm labor are significant if the membranes remain intact. Blood studies identify signs of infection and also conditions such as anemia that are associated with preterm labor or affect its management. Common studies include a complete blood cell count with differential white blood cell analysis and cultures for GBS infection, *Chlamydia* infection, gonorrhea, or other suspected infections. **Amniocentesis** (transabdominal puncture of amniotic sac) may be done to obtain amniotic fluid for culture if chorioamnionitis is suspected because this infection would contraindicate stopping preterm labor. Fetal lung maturity testing will likely be done on an amniotic fluid specimen as well. Urinalysis with culture and sensitivity testing may be performed to determine if treatment is indicated (Iams, Romero, & Creasy, 2009; Mercer, 2012).

Culture results require at least a minimum of 24 to 48 hours to complete, so antiinfectives that are usually effective against probable organisms are started as soon as the specimen is obtained. If cultures show that a different drug would be best, the medication is changed. Prompt treatment of acute infections such as pyelonephritis improves maternal and fetal outcomes. Broad-spectrum antibiotics (e.g., ampicillin, penicillin) and an aminoglycoside (e.g., gentamicin), which are effective against many organisms, may be chosen for possible chorioamnionitis. Anaerobic organisms may also cause infection for a woman who requires a cesarean birth, and medications such as clindamycin or metronidazole may be prescribed (American Academy of Pediatrics [AAP] & ACOG, 2012; Simhan, Iams, & Romero, 2012).

Identifying Other Causes for Preterm Contractions. The woman with polyhydramnios, identified by ultrasonography, may have more contractions because her uterus is stretched more than normal. Therapeutic amniocentesis to remove some amniotic fluid can reduce uterine irritability. Multifetal gestations also can be identified by ultrasonography if not previously diagnosed. These mothers may benefit from improved nutrition, stress reduction, assistance with household care, and other interventions.

Limiting Activity. Activity limits, usually by relaxing in the side-lying or semisitting position, increase placental blood flow and reduce fetal pressure on the cervix. However, lengthy and substantial activity restriction (e.g., complete bed rest) has not been shown to prolong pregnancy significantly (Simhan, Iams, & Romero, 2012; Svigos, Dodd, & Robinson, 2011a). As in other individuals, activity restriction is associated with serious maternal side effects, some of which develop within as few as 24 hours. Adverse effects of substantial activity restriction during pregnancy may include the following:

- Muscle weakness, including aching, muscle atrophy, and bone loss
- Diuresis as the body tries to reduce the normally higher fluid level of pregnancy
- Poor nutrition as a result of appetite loss, lower food intake, and increased indigestion; weight loss or inadequate weight gain
- Orthostatic hypotension caused by the change in blood pressure regulation by baroreceptors
- Psychological effects such as increased stress about separation from her family, anxiety about the pregnancy's outcome, depression, boredom from a decreased activity level and reduced contact with other people, and concerns about finances if her income is essential to her family
- Sleep changes as depression increases or usual activities that direct her sleep-wake cycles are not present

Because of problems and lack of benefits for most women, limited and individualized activity reductions are now prescribed if preterm birth risk is higher. Changes may be relatively simple, such as a change

in work hours or duties or finding ways to help the woman meet the needs for her other children, for example, transportation to school or other activities. Several rest periods may be prescribed for home care when the woman's risk status is lower. Positions for rest may include the semisitting position with the feet and legs elevated. If lying down for rest, a mother's frequent change of the side-lying position reduces discomfort from the pressure of remaining on one side for a prolonged time. Frequent position changes are also beneficial to women who require hospitalization for their preterm labor.

Women hospitalized for care of preterm labor may have a greater activity restriction. Because of IV hydration and drug therapy, bed rest is common during initial care. Ambulating to the bathroom may be limited because of maternal sedative effects from a drug such as magnesium sulfate to depress uterine activity (also given for preeclampsia; see Chapter 25). The woman usually has an indwelling catheter for precise urine output assessment needed with administration of magnesium. If preterm labor stops, the woman may usually walk to the restroom for showers, voiding, and bowel movements. If she remains hospitalized for longer-term care, she may sit in a chair periodically or take occasional short trips to another area in a wheelchair that her family or friends push.

Although preterm birth may occur, the severity of infant effects may be less if even a few days are gained in the duration of pregnancy. Whether the woman is expected to be hospitalized briefly or for a longer time, the following services may improve her adherence to care measures:

- Physical therapy to help maintain muscle strength and coordination, and to reduce muscle aching, fatigue, and bone loss
- Recreational therapy to identify appropriate activities to relieve boredom
- Occupational therapy to help the woman cope physically with lifestyle changes, particularly if discharge home is anticipated
- Complementary therapy to reduce stressors and enhance physical care measures
- Social work to identify how needs such as financial and child care can be met
- Consultation with a psychologist to help the woman and family cope with the added stressors

Hydrating the Woman. Hydration to stop preterm contractions has not been shown to be beneficial for all women. High-volume IV infusions may cause maternal respiratory distress if a drug such as magnesium sulfate to decrease uterine contractions is being administered because the drug may also reduce the respiratory rate, even if a woman has a normal blood pressure level.

However, dehydration may contribute to uterine irritability for some women. This is often the case in those who have had an infection such as an acute gastrointestinal infection, in which loss of fluid through diarrhea may exceed the nauseated woman's ability to drink water or other fluids. Infections with maternal fever (temperature of $\geq 100.4^{\circ}\text{F}$ [$\geq 38^{\circ}\text{C}$]) sometimes reduce the woman's fluid ingestion. IV fluids are ordered according to their expected benefit, for example, administration of magnesium sulfate drug therapy to stop preterm labor or initiation of an antibiotic to treat infection. Oral fluids are usually encouraged because they may reduce uterine irritability and the risk for urinary tract infections.

Tocolytics. The advantage of tocolytic drug therapy to reduce preterm birth is not clear. Tocolysis is most likely ordered if preterm labor occurs before the 34th week of gestation because the infant's risk for respiratory and other complications of prematurity is high if the infant is born during this time. Delay of preterm birth with tocolysis may provide time to give maternal corticosteroids to reduce respiratory distress in the newborn or time for transfer of the mother to a facility

with a neonatal intensive care unit that is appropriate for the gestation of her fetus at the time of birth. Tocolysis is most likely to be effective if the cervix is less than 3 cm dilated (ACOG, 2012c; Cunningham et al., 2010; Simhan, Iams, & Romero, 2012).

Because tocolytic drugs have significant side effects, the decision about whether to treat for preterm labor is individualized, based on risk factors, cervical dilation, and other signs and symptoms. If the cervix is between 2 and 3 cm dilated, the physician may recheck the cervix for further dilation or effacement after 1 or 2 hours. Electronic fetal monitoring helps identify uterine contractions or irritability and establish fetal status. A fFN test may be done to determine whether the woman is likely to be in preterm labor. Ultrasound imaging provides information that may be useful to determine fetal age, adequacy of placental supply, and status of the cervix. Tests for infection are done if indicated.

Current tocolytic drugs are used primarily for conditions other than preterm labor and therefore have effects on body systems other than the reproductive system. Risks and possible benefits of the drug chosen must be considered and communicated clearly to the woman. The lowest possible dose that inhibits contractions is used. Four types of drugs are used for tocolysis: (1) magnesium sulfate, (2) calcium antagonists, (3) prostaglandin synthesis inhibitors, and (4) beta-adrenergics. (Table 27-2 summarizes doses and routes of administration for each of these drugs.)

Magnesium Sulfate. Magnesium sulfate is used in management of pregnancy-associated hypertension to prevent seizures (see the Drug Guide on p. 525). Because of its added effect of quieting uterine activity, it often is used to inhibit preterm labor. Magnesium sulfate therapy has a well-established record of safety during pregnancy. When given to suppress preterm labor, magnesium sulfate has similar side effects (such as lethargy and sedation) as those seen in its use to prevent seizures related to hypertension. However, its efficacy for this purpose has not been supported by research.

Common hospital criteria for magnesium sulfate therapy include the following:

- Urine output of at least 30 mL per hour
- Presence of deep tendon reflexes
- At least 12 respirations per minute

In addition, the nurse should check heart and lung sounds with hourly vital signs because fluid overload and electrolyte imbalances can lead to pulmonary edema or cardiac dysrhythmias. Oxygen saturations are often included with the hourly vital signs and other assessments. Bowel sounds are checked when therapy begins and every 4 to 8 hours because the smooth muscle in the intestinal tract may be relaxed just as the uterus is relaxed. Serum magnesium level measurements guide maintenance of therapeutic levels. Electronic fetal monitoring identifies fetal drug effects such as reduced variability, which are common in preterm labor and with magnesium sulfate therapy.

Calcium gluconate (10%) should be available to reverse magnesium toxicity and prevent respiratory arrest if serum levels become high. Excess serum levels of magnesium are less likely when the drug is given for preterm labor because the woman's renal function is usually normal. However, the nurse must remain alert for this complication of magnesium sulfate therapy.

Calcium Antagonists. Nifedipine (Adalat, Procardia) is a calcium channel blocker usually given for problems such as hypertension. Calcium is essential for muscle contraction in smooth muscles such as the uterus, so blocking calcium reduces the muscular contraction. Flushing of the skin, headache, and a transient increase in the maternal and fetal heart rates are common side effects. Because nifedipine is a vasodilator, the woman may have postural hypotension.

TABLE 27-2 DRUGS USED IN PRETERM LABOR

DRUG AND PURPOSE	COMMON DOSE REGIMENS*	SIDE OR ADVERSE EFFECTS
Magnesium sulfate (use as tocolytic)	IV: Loading dose: 4–6 g over 30 min Maintenance dose for tocolysis: 1–4 g/hr When contraction frequency is no higher than 1 per 10 min (≤ 6 per hr), maintain infusion rate for 12 hr; then discontinue drug An oral tocolytic may be ordered to continue tocolysis after magnesium sulfate is stopped	Side and adverse effects are dose-related, occurring at higher maternal serum levels. Depression of deep tendon reflexes, which should be present, although less active Respiratory or cardiac depression if serum levels are high; greatest risk is in woman with poor urinary elimination of drug Less serious side effects: lethargy, weakness, visual blurring, headache, sensation of heat, nausea, vomiting, constipation Fetal-neonatal effects: reduced fetal heart rate (FHR) variability, hypotonia
Nifedipine (Procardia); nicardipine (Cardene) (calcium channel blockers for tocolysis)	Oral loading dose: 10–20 mg Continued oral therapy: 10–20 mg every 3–6 hr until contractions are rare followed by long-acting formulations of 30–60 mg every 8–12 hr until antepartum steroids have been administered	Maternal flushing, dizziness, headache, nausea Transient maternal tachycardia Mild hypotension Modest increases in blood glucose levels
Indomethacin (Indocin); sulindac (Clinoril) (prostaglandin synthesis inhibitors)	Limit use to preterm labor before 32 wk of gestation Use indomethacin for no longer than 48–72 consecutive hr Loading dose: 50 mg (oral) Maintenance dose: 25 mg orally every 6 hr for 48 hr Ultrasound examinations and fetal echocardiography help determine if maternal indomethacin has adverse effects on fetus	Epigastric pain, nausea, gastrointestinal bleeding Asthma in aspirin-sensitive woman Increased blood pressure in hypertensive woman Fetus: Adverse fetal effects may include constriction of ductus arteriosus, particularly if mother receives indomethacin for more than 48–72 hr and gestation is later than 32 wk; impairs fetal renal function, which may reduce volume of amniotic fluid and result in cord compression
Terbutaline (beta-adrenergic for tocolysis); should not be used beyond 48 to 72 hours for preterm labor	IV infusion: Begin at ordered rate of about 0.01 to 0.05 mg/min. Increase rate by 0.01 mg/min at 10- to 30-min intervals until contractions or the maximum dose of 0.08 mg/min is reached. Maintain this dose for 1 hr, then reduce the rate at 20-min intervals to reach the minimum maintenance dose when contractions stop. Continue maintenance dose for 12 hr or as ordered. Subcutaneous (most common parenteral route): Intermittent injections, 0.25 mg, every 4 hr. By subcutaneous infusion pump: low-dose continuous (baseline) drug infusion plus intermittent bolus doses. The subcutaneous pump is typically placed and its programming for continuous and bolus doses is verified before removing the IV infusion line for terbutaline or magnesium sulfate. Oral: Should not be used to either treat preterm labor or prevent recurrent preterm labor	Terbutaline is not approved by the U.S. Food and Drug Administration (FDA) for inhibiting uterine activity and now carries a <i>boxed warning and contraindications</i> (“black box”) against use as a tocolytic rather than its intended use as a bronchodilator. Infusion rate is not increased or may be decreased if maternal pulse rate exceeds 120 beats per minute (bpm) or systolic blood pressure (BP) falls below 80 to 90 mm Hg. Adverse reactions: 1. Cardiovascular: Maternal and fetal tachycardia, palpitations, cardiac dysrhythmias, chest pain, wide pulse pressure 2. Respiratory: Dyspnea, chest discomfort 3. Central nervous system: Tremors, restlessness, weakness, dizziness, headache 4. Metabolic: Hypokalemia, hyperglycemia 5. Gastrointestinal: Nausea, vomiting, reduced bowel motility 6. Skin: Flushing, diaphoresis
Corticosteroids (betamethasone and dexamethasone)	See Drug Guide: Betamethasone, Dexamethasone (p. 586)	
17-P alpha-hydroxyprogesterone caproate (Makena); in research now to evaluate effectiveness for prevention of preterm birth in women who had previous preterm birth(s). Side effects also being evaluated	IM: 250 mg (1 mL) every 7 days Begin treatment between 16 weeks, 0 days and 20 weeks, 6 days Continue until 37 weeks or delivery	Drug is a progestin indicated to reduce the risk of a preterm birth in a woman who had a previous preterm birth; not intended for women with multiple gestation or other risk factors for preterm birth

*Doses and frequency of administration are examples; actual protocols may vary.

TABLE 27-3 MATERNAL RISK FACTORS FOR PRETERM LABOR

MEDICAL HISTORY	OBSTETRIC HISTORY	PRESENT PREGNANCY	LIFESTYLE AND DEMOGRAPHICS
<ul style="list-style-type: none"> • Low weight for height • Obesity • Uterine or cervical anomalies, uterine fibroids • History of cone biopsy • Diethylstilbestrol (DES) exposure as a fetus • Chronic illness (e.g., cardiac, renal, diabetes, clotting disorders, anemia, hypertension) • Periodontal disease 	<ul style="list-style-type: none"> • Previous preterm labor • Previous preterm birth • Previous first-trimester spontaneous abortion (>2) • Previous second-trimester spontaneous abortion • History of previous pregnancy losses (2 or more) • Incompetent cervix • Cervical length ≤ 25 mm (2.5 cm [1 inch]) or less at midtrimester of pregnancy • Number of embryos implanted (assisted reproductive techniques) 	<ul style="list-style-type: none"> • Uterine distention (e.g., multifetal pregnancy, hydramnios) • Abdominal surgery during pregnancy • Uterine irritability • Uterine bleeding • Dehydration • Infection • Anemia • Incompetent cervix • Preeclampsia • Preterm premature rupture of membranes (PPROM) • Fetal or placental abnormalities 	<ul style="list-style-type: none"> • Little or no prenatal care • Poor nutrition • Age <18 yr or >40 yr • Low educational level • Low socioeconomic status • Smoking >10 cigarettes daily • Nonwhite • Employment with long hours and/or long standing • Chronic physical or psychological stress • Domestic violence • Substance abuse

The nurse should observe for side effects of nifedipine and report a maternal pulse rate greater than 120 bpm. The woman should be given information about possible dizziness or faintness with nifedipine's hypotensive effects. She should sit or stand slowly and call for assistance, if needed.

Prostaglandin Synthesis Inhibitors. Because prostaglandins stimulate uterine contractions, drugs can be used to inhibit their synthesis. Indomethacin (Indocin) is the drug in this class that is most often used for tocolysis.

Maternal side effects are minimal because of the brief duration of therapy. Gastrointestinal side effects are usually limited to nausea, vomiting, and heartburn.

Fetal adverse effects are more serious and may include constriction of the ductus arteriosus, pulmonary hypertension, and oligohydramnios. The ductus arteriosus should remain open before birth and close after birth. Fetal adverse effects are unlikely if treatment is no longer than 48 to 72 hours and the gestation is less than 32 weeks. The drug's effect in reducing the amount of amniotic fluid makes indomethacin useful for normalizing the volume if hydramnios is present. The amniotic fluid volume usually returns to its previous level when indomethacin treatment is discontinued. Regular ultrasound examinations and fetal echocardiography help determine if indomethacin is having adverse effects on the infant. After birth, assessment of the infant may be performed for other complications such as pulmonary hypertension or intracranial hemorrhage, depending on the duration of maternal indomethacin intake, the infant's gestation, and the probability that delivery occurs less than 24 hours after the drug is discontinued.

The nurse should observe the woman for gastrointestinal side effects. Because indomethacin can prolong bleeding time, the nurse observes for abnormal bleeding such as prolonged bleeding after injections and bruising with no apparent cause. The antiinflammatory effect of indomethacin can mask infection because fever may not be present. Checking the height of the fundus at the beginning of therapy and daily thereafter helps identify reduced amniotic fluid. Decreased fetal movements and absent FHR accelerations with fetal movement may occur if the fetal condition deteriorates.

Beta-Adrenergic Drugs. Although ritodrine (Yutopar) is the only beta-adrenergic medication approved by the U.S. Food and Drug Administration (FDA) for tocolysis, it is infrequently used because of significant side effects and minimal increase in the length of pregnancy. Terbutaline (Brethine), a bronchodilator, remains investigational for

treatment of preterm labor but has been the more widely used beta-adrenergic medication for tocolysis because of lower cost, longer duration of action between doses, and the ability to promptly administer a dose by the subcutaneous route if needed suddenly, as when tachysystole occurs in a woman in labor.

However, the main side effects for beta-adrenergic drugs, including terbutaline, involve the cardiorespiratory system. Maternal and fetal tachycardia are common (Table 27-3). Propranolol (Inderal), an agent that blocks beta-adrenergic drugs, should be available to reverse severe adverse effects.

Because of reported cardiovascular events, terbutaline now carries a *boxed warning and contraindications* ("black box") against prolonged parenteral use longer than 48 to 72 hours or treatment with oral terbutaline for treatment of preterm labor or to prevent recurrence of preterm labor (Wesley, 2011). See www.fda.gov for the FDA drug safety report.

The nurse should assess a woman's apical heart rate and lung sounds before administering each intermittent dose of terbutaline for preterm labor. A maternal heart rate over 120 bpm or respiratory findings such as "wet" lung sounds or a more rapid rate, possibly accompanied by shortness of breath, suggest drug toxicity that may be a reason to discontinue terbutaline. Nonreassuring maternal and fetal assessments should be promptly reported to the physician.

Accelerating Fetal Lung Maturity

The physician may order corticosteroids to speed fetal lung maturation if birth before 34 weeks seems inevitable. Steroid therapy may reduce the incidence and severity of RDS and intraventricular hemorrhage (IVH) in the preterm infant (ACOG, 2011a; Mercer, 2012; Svigos, Dodd, & Robinson, 2011a). Administering the steroid as late as 37 weeks of gestation may be chosen if fetal lung maturity studies demonstrate immature lungs later than 34 weeks. Betamethasone (Celestone) or dexamethasone (Decadron) may be used for this purpose (ACOG, 2011a).

Corticosteroids are indicated if the gestation period is between 24 and 34 weeks because of the high incidence of problems such as RDS that affect an infant born at this age. Delay of preterm birth for at least 24 hours after a woman begins corticosteroid therapy provides the greatest benefit in reducing critical neonatal problems associated with prematurity. Evidence shows that an infant born earlier than 24 hours after the mother begins taking the corticosteroid may have some fetal

CASE STUDY 27-1 NURSING CARE PLAN*

ASSESSMENT: At 31 weeks of gestation, Rhonda again experiences preterm labor and goes to the hospital. Her cervix is dilated 2 to 3 cm and is 75% effaced (about 0.5 cm long). Her contractions occur every 6 to 7 minutes, and last about 20 to 30 seconds each. The physician again orders a magnesium sulfate infusion. Rhonda's physician explains that preterm birth may be delayed but will probably occur within the next 24 to 48 hours. Rhonda begins crying and says, "I did what I was supposed to do, and now I'm still going to have another preemie! It will be weeks before I can be a real mother!"

NURSING DIAGNOSIS: Anticipatory Grieving related to loss of expected term birth experience

EXPECTED OUTCOME: Rhonda will:

1. Express her feelings about the loss of her expected birth at term.

INTERVENTIONS AND RATIONALES

1. Sit down and spend time with Rhonda. Use therapeutic communication to encourage her to express her feelings. *Unhurried time allows Rhonda to express her feelings, which is the first step in dealing with the anticipated loss of a term birth.*
2. When Rhonda has expressed her frustration about this development in her pregnancy, explain that much remains unknown about why labor begins, whether at term, preterm, or postterm. *If Rhonda knows that professionals do not have all the answers but must make recommendations based on what is known or appears to work for an individual woman, she may be more accepting of the inevitability of preterm birth.*
3. Explain to Rhonda that her efforts have been successful because she has gained 3 valuable weeks of gestation for her baby. *In addition, the drug betamethasone may reduce the chance that her preterm newborn will have the usual degree of common respiratory problems if born at that gestation. Knowing that her self-care has benefits, although not the desired term birth, reduces the sense of failure that Rhonda may feel.*

EVALUATION: Rhonda cries and expresses her frustration about the developments in her pregnancy. She says that she knew she was more likely to have another preterm infant but hoped that this time would be different. As the day goes by, she gradually begins expressing feelings that she did do something positive for this baby. Because contractions have not diminished but are becoming stronger and more regular, Rhonda plans to deal with the probable preterm birth within 24 hours.

ADDITIONAL NURSING DIAGNOSES TO CONSIDER

Health-Seeking Behaviors
 Interrupted Family Processes
 Ineffective Health Maintenance
 Ineffective Coping (Individual and/or Family)
 Readiness for Enhanced Family and/or Individual Coping

*Continued from p. 580.

lung maturation benefits. Thus, one benefit of tocolytic drugs to the woman at risk for preterm birth is to prolong labor enough that her fetus may receive the benefits of the corticosteroid drug given.

Vital signs should be assessed to identify fever and elevated pulse rate that may indicate infection associated with steroid administration. Lung sounds should be assessed with vital signs because corticosteroids can cause sodium retention with accompanying fluid retention and pulmonary edema. The nurse should observe for pulmonary edema and teach the woman about the signs of this complication. The woman is taught to report any chest pain or heaviness or any difficulty breathing because these symptoms could indicate pulmonary edema or

DRUG GUIDE

BETAMETHASONE, DEXAMETHASONE

Classification: Corticosteroids.

Indications: Acceleration of fetal lung maturity to reduce the incidence and severity of respiratory distress syndrome (RDS). Studies suggest that antenatal steroids can reduce the incidence of intraventricular hemorrhage (IVH) and neonatal death in the preterm infant. Greatest benefits accrue if at least 24 hours elapse between the initial dose and birth of the preterm infant, but the drug is indicated if birth is not imminent.

Dosage and Route

Betamethasone: 12 mg intramuscular (IM) for two doses, 24 hours apart.
 Dexamethasone: 6 mg IM every 12 hours for four doses.

Absorption: Rapid and complete after IM administration.

Excretion: Metabolized in the liver. Excreted in urine.

Contraindications: Active infection such as chorioamnionitis is a relative contraindication, although further study is needed. The National Institutes of Health (NIH) recommend use of corticosteroids for the woman who has preterm rupture of the membranes (24 to 34 weeks of gestation). The American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) agree with the NIH recommendation but recommend that the period for administration be 24 to 32 weeks and that 32 and 33 weeks might be beneficial; however, evidence supporting this is unclear (AAP & AC 2012).

Precautions: Possible infection. Pregnancies complicated by diabetes.

Adverse Reactions: Few, owing to the short-term use of the drug. Pulmonary edema is possible secondary to sodium and fluid retention.

Nursing Considerations: Explain to the woman the potential benefits of corticosteroid administration to the preterm neonate. Explain that the drug cannot prevent or lessen the severity of all complications of prematurity. If the woman has diabetes, explain that more frequent blood glucose determinations are common because these levels are often elevated while taking either of the corticosteroids. A temporary rise in platelet and white blood cell (WBC) levels may last 72 hours. WBC levels greater than 20,000/mm³ may indicate infection. Assess lung sounds. Report chest pain or heaviness or dyspnea.

possibly pneumonia. Pain and burning with urination are symptoms of urinary tract infection that is common in pregnancy even when steroids are not given.

17. What is the purpose of giving corticosteroids to a woman who is in preterm labor at 27 weeks of gestation? Why is it important that birth be delayed at least 24 hours?

APPLICATION OF THE NURSING PROCESS

■ Preterm Labor

Nursing care for the woman experiencing preterm labor often includes interventions related to tocolytic, corticosteroid, or antibiotic drug

therapy. If labor cannot be halted, care is similar to that for other laboring women, with additional care to prepare for a preterm infant's needs at birth. Support for anticipatory grieving may be needed if the infant is very immature and not expected to live.

Care for the family when an extremely preterm infant (about 20 through 24 weeks of gestation) is expected to be born can be heavily laden with ethical and legal issues. For example, what is the true accuracy of the gestational age? Has a corticosteroid to accelerate fetal lung maturity been administered, and when was the last dose given? If labor cannot be halted, is fetal monitoring beneficial? Nonreassuring fetal monitoring patterns in the very immature fetus can distress parents and caregivers alike. However, knowledge of the fetal response to labor helps the neonatologist make better decisions about how to treat the infant. In addition, ultrasound estimates of gestational age at this time have shown considerable variations. A fetus presumed to be 23 weeks of gestation before birth may be assessed to be 25 weeks or older after birth and suited to more intense treatment than planned, especially if the woman had no prenatal care before entering the hospital.

Much of the general nursing care for a woman having preterm labor also applies to women experiencing other types of high-risk pregnancies. Women may need multiple hospitalizations that occur in the middle of the night, disrupting sleep and family routines. Other women may have attended a routine prenatal visit and be shocked to discover that they may be in preterm labor. These women often have some activity restriction and may have to stop working if the best outcome for their pregnancy is to be achieved. Therefore, this section focuses on the family's psychosocial concerns, management of home care, and the woman's boredom.

PSYCHOSOCIAL CONCERNS

Assessment

The entire family is affected by stressors associated with a high-risk pregnancy. Assess how the woman and her family usually cope with crisis situations and how they are coping with this one. Identify their greatest concerns to prioritize care. For example, the nurse might say, "This development in your pregnancy must have been a shock." The following are other questions the nurse might ask: "How are you handling things?" "In what ways do you usually handle crisis situations in your family?" "What concerns you the most right now?" Rather than asking questions in a rapid-fire manner, the nurse must give the woman time to answer assessment questions because stress has narrowed her focus.

The woman or her family may have physical, emotional, and cognitive impairments because of the unexpected problems. Physical signs of emotional distress such as tremulousness, palpitations, and restlessness also are side effects of beta-adrenergic drugs and corticosteroids. The woman may express fear, helplessness, or disbelief. She may be irritable and tearful. Her ability to concentrate may be impaired at a time when she needs to absorb new information.

Her partner often feels at loose ends. He struggles to keep the household running if she must be inactive. Young children recognize their parents' anxiety and may misbehave or regress. They may feel abandoned if they must be temporarily placed with relatives or friends.

The woman often must curtail or stop working, straining family finances. If she does not have sick time or other benefits, the family sustains an abrupt drop in income at a time when medical expenses are mounting. The woman's career may not progress as expected if she must be off work for a prolonged time. A woman may be transferred to a distant hospital having a better capacity to care for her and her preterm baby. A distant transfer to a higher-level maternity care facility

makes it more difficult for the woman to receive support from friends, family, or support groups.

Overlaid on the sudden change in lifestyle is the family's concern for their baby's well-being. A woman may feel pulled in many directions by the needs of all her children—those already born and the fetus she is trying to mature. She may be concerned about the effects of drug therapy on the fetus and her own body.

Nursing Diagnosis

Unexpected development of complications during pregnancy can prevent a woman and her family from using their normal coping mechanisms. Therefore, the nursing diagnosis selected for the woman and family is "Anxiety related to uncertain outcome of the pregnancy, disruption of relationships with family and friends, and financial concerns."

Planning

The outcome of any pregnancy is never certain, especially when the pregnancy is a high-risk one. Goals and expected outcomes should focus on the family's ability to cope with the crisis of preterm labor. The appropriate goal is as follows:

- The woman and family will identify one or more constructive methods to cope with this temporary disruption in their lives.

Interventions

Providing Information

Knowledge decreases anxiety and fear related to the unknown. Include appropriate family members so that they are more likely to be supportive. Appropriate family members may include the woman's partner, mother or mother-in-law, adult siblings, and others, but this may vary according to culture. Determine the extent of the woman's knowledge about preterm birth and the specific therapy recommended. Determine what information the parents need about problems that a preterm infant may face. Use this opportunity to correct misinformation and reinforce accurate information.

Initially, the woman for whom activity restriction is prescribed may be highly motivated to maintain the restrictions. Because contractions often diminish, even if for only a short time, she may become restless. She may feel that there is now no need for any restriction such as how far she can ambulate. Explain what is currently known about the benefits of activity restriction for her pregnancy complication and assure her that recommendations to restrict her activity often lessen as her pregnancy progresses. Initiate consultations from caregivers such as physical, occupational, and recreational therapists; social workers; and other professionals whose services might benefit the woman.

The Sidelines National Support Network (www.sidelines.org) is an online network of local groups across the country for women experiencing high-risk pregnancy, including the risk for preterm birth. The site has information for women "sidelined" by pregnancy complications, including articles, information about reimbursement from insurance, and contact via e-mail with others who have been "sidelined."

Promoting Expression of Concerns

Encourage the woman and her family to express their concerns. Begin by exploring common concerns of women with problem pregnancies. For example, "Most women are worried when they must stop working. How has this affected your family?" An open-ended question gives the woman and her family a chance to express their feelings so that they can take the next step: identifying constructive methods to cope with the situation. Collaboration with a social worker may identify financial or other community resources available. Ask her if she would like a visit from a chaplain.

Teaching What May Occur during a Preterm Birth

Because preterm birth often occurs despite all interventions that gain some gestational time, a pregnant woman and her partner should be prepared for this possibility. If the hospital has a neonatal intensive care unit (NICU), a nurse often visits the parents to explain what might occur if their baby is born early. One or both parents may tour the unit to see the equipment and care given to preterm infants. Often, just seeing the infants in the NICU motivates a woman to maintain the recommended therapy, even though she is tired of doing so.

In hospitals with NICUs, one or more neonatal nurses, a neonatal nurse practitioner, a neonatologist, or a combination of these are present at birth to care for the infant. The woman who has planned to give birth in a hospital without a NICU may be transferred to a facility with this type of unit before the birth to allow immediate care and stabilization of her newborn. The infant also may be transferred after birth if there is no time to transfer the woman before birth or the infant has more problems than were anticipated. Hospitalization of the mother, infant, or both at a distant location adds to the stress on the family and can impair the attachment process.

Evaluation

The expected outcome for this nursing diagnosis is achieved if the woman and her family can identify one or more constructive methods to deal with their anxiety. If a high-risk pregnancy situation is prolonged or the family has difficulty adapting constructively to the situation, a nursing diagnosis of “Interrupted Family Processes” may be more appropriate.

MANAGEMENT OF HOME CARE

Assessment

Care of women with high-risk pregnancies, including a risk for preterm birth, often occurs in their homes if the gestation is sufficiently advanced and the signs and symptoms of preterm labor and birth have diminished significantly. Many daily household activities are managed by the woman, even if only by her directions to others. However, when preterm labor complication becomes greater, family roles are again disrupted because of the changed relationships among family members. Multiple professionals are likely to be involved in home care, including home care nurses and assistants, social workers, therapists (physical, occupational), and others.

Clarify the level of activity prescribed by the physician, and identify the role of each member of the household. A good way to do this is to have the woman describe a usual day before any limitations were recommended. Determine the number and ages of children in the home.

Evaluate the home itself, either by visual inspection or by questioning the family. Does the home or apartment have more than one level? Determine if a telephone is available for emergency contact. If the woman works, can she do her work online?

Evaluate the family’s resources and their willingness to use them. Ask whether family members and friends in the area are available to help. Explore local support groups such as churches or mother-to-mother networks, that the family might contact for assistance. Determine financial reimbursement that may be available through insurance coverage.

Nursing Diagnosis

The diagnosis chosen is “Impaired Home Maintenance related to change in usual roles and responsibilities.”

Planning

Two goals and expected outcomes are appropriate for this nursing diagnosis. The short-term goal may change over time if the woman remains pregnant.

- Short-term goal: The family will identify methods for management of daily household routines.
- Long-term goal: The woman will be able to maintain the prescribed levels of activity and drug therapy.

Interventions

The pregnancy threatened by preterm labor or other complications that require activity restriction is a self-limiting situation, making temporary adjustments somewhat easier. Needed changes in home routines may be brief but sometimes extend over several weeks. Even if the restriction consists only of added rest periods during the day, the woman still is unable to fulfill all her usual roles. For the woman who is prescribed more restricted activity, the disruptions are greater.

Caring for Children

The woman who has children has different concerns than the woman who does not. Toddlers and preschoolers rarely understand why their mother does not play with them as usual. If they already are in daycare, this can continue if the family can afford it. They may temporarily live with a relative or friend. Toddlers may feel that their parents have abandoned them if they are sent away, although this may be the only realistic solution if no one except the mother is available to supervise them.

School-age children can understand the situation better and often are quite helpful. They may assist with care of other children, but they should not be put into the role of an adult. They may resent responsibility that is excessive for their age. School-age children often enjoy learning new facts about their mother’s pregnancy and tests the baby may need.

Adolescents may welcome their parents’ trust but also resent the intrusion on independent activities with their peers. Teenagers who drive can be very helpful in taking younger siblings to school and other activities. They may be enlisted for grocery shopping and meal preparation. If resentment flares, a reminder that the situation is temporary and they are valuable contributors to the health of the new baby may defuse the situation.

Maintaining the Household

The first step to home maintenance during this time may be for the woman to lower her standards of housekeeping. Things may not be as clean or organized as she would like. The partner may take over some household tasks, but these may compete with responsibilities outside the home. Talk to the woman about ignoring chores that are not performed exactly as she wants and tell her to remember that it is temporary.

Advise the woman to have a list of tasks ready when friends and family ask, “Can I do anything to help?” If they offer to bring a meal or do laundry, encourage her to accept this help. Remind her that people who offer to help mean it and that she may be able to return the favor to someone else. Homemaker services may be an option to help the family deal with the woman’s temporary disability.

Transportation of school-aged children may be a concern. If no family or friends are available, the school nurse or the Parent-Teacher Association (PTA) may help find someone willing to take the children to school each day.

Evaluation

Identification of short-term goals and expected outcomes helps the nurse and patient, often including the family, identify resolution of immediate needs. Longer-term outcomes may be evaluated over a series of days or weeks as the prescribed therapy for the complicated pregnancy changes.

- The short-term goal is met if the family can identify realistic ways to manage minimal household care.
- The long-term goal is met if the woman can maintain the prescribed therapy until birth.

BOREDOM

Assessment

If activity is restricted, determine what skills the woman has for coping with boredom. Although bed rest to prolong gestation is often brief because of the questionable benefits and known problems, some reduction in activity is prescribed. The nurse should consider helping the woman choose appropriate activities, whether she is at home or hospitalized.

Ask about a usual day to identify activities that are still appropriate within the restrictions prescribed. Ask about hobbies, present and past. What type of leisure activities does the woman enjoy? Which activities are available or possible? Does she have more than one resting place to still give her a change of scenery and surrounding activity?

Assess her personality. Is she calm and composed, taking whatever comes with serenity? Or does she need to be busy most of the time? No matter how motivated, the woman who finds inactivity tiresome will find even limited activity restriction difficult to maintain.

Nursing Diagnosis

The nursing diagnosis is “Deficient Diversional Activity related to lack of knowledge about appropriate activities for her pregnancy restrictions.”

Planning

A possible expected outcome is that the woman will do the following:

- Pursue (with help of others) appropriate activities to relieve boredom while maintaining recommended activity limits.

Interventions

Identifying Appropriate Activities

Determine the woman’s understanding about needed activity restrictions to identify misunderstandings and reinforce correct information. Help her identify which usual activities are reasonable and which ones should not be done and why. If she understands the rationale, she may be more willing to maintain restrictions.

Some women continue work activities such as paperwork or phone calls that can be accomplished with minimal physical exertion. Work among colleagues and clients sometimes may be accomplished online. Workplace deadlines can increase stress, even at home. However, the feeling of usefulness gained by such activities may be beneficial because it reduces some financial concerns.

Computer connections can be used for work activities in some jobs and may also provide support from other women with similar problems or entertainment such as games played with other users. Internet sites, if carefully chosen, may provide health information about what she might expect with diagnostic tests and treatment for preterm labor, care of her baby in the special care nursery setting, providing breast

milk for her preterm newborn, and comfort measures that have been effective for others in her situation.

Help the woman identify appropriate activities to stay busy and productive. These may include household activities that can be done at rest, volunteer activities such as phone calls, and leisure activities such as puzzles, games, and hand needlework. Instructions for hobbies such as knitting are often available online. Help the woman identify someone who can obtain the necessary supplies for her. This might be a good time to reactivate an old (quiet) hobby or read books that she has previously delayed until “later.”

The woman can participate in many activities with her children while she rests. She can read to them and play board or card games. Encourage her to help the children with their homework and stimulate their development with thought-provoking discussions. Working with children on video games may help them learn during their playtime.

Changing the Physical Surroundings

Encourage the woman to identify at least two areas where she can maintain her prescribed rest periods. A change of location helps the woman be more willing to reduce her activities and still feel part of the family activities. Each area should include pillows, blankets, and a clipboard with writing materials. A laptop computer can be taken from place to place. Small rolling carts made of plastic help keep small things organized and together. The carts may be used after the baby is born for any kind of household need. Ideally, the telephone is within reach and is cordless or she has effective use of a cell phone. Either programming or writing important phone numbers such as those of family, friends, and physicians and emergency numbers helps assure the family that phone contacts are easily available for emergency as well as social needs.

Evaluation

The goal is met over time if the woman actually pursues only appropriate activities.

PROLONGED PREGNANCY

A prolonged pregnancy is one that lasts longer than 42 weeks. Most women who receive prenatal care today do not reach 42 weeks before their labor is induced if they have accurate due dates. Average gestational age at term birth is now 39 weeks rather than 40 weeks. Some apparent cases of prolonged pregnancy are actually miscalculations of the estimated date of delivery (EDD) because the woman has had irregular menstrual periods or forgotten the date of her last normal period. Late or no prenatal care limits the use of clinical methods such as ultrasound that are useful for pinpointing her EDD better and avoiding potential problems associated with prolonged gestation.

Complications

The main physical risk in prolonged pregnancy is to the fetus or newborn. Insufficiency of the placental function secondary to aging and infarction reduces transfer of oxygen and nutrients to the fetus and removal of waste. Because the fetus with placental insufficiency has less reserve to tolerate uterine contractions, signs of fetal compromise such as late decelerations and decreased variability may develop during labor. In addition, reduced amniotic fluid volume (oligohydramnios) that often accompanies placental insufficiency can result in umbilical cord compression. Meconium in the amniotic fluid may cause respiratory distress in the newborn if it is aspirated before or during birth. The infant may have late growth retardation and appear to have lost weight, with a normal-sized head and thin body.

Many postterm fetuses do not suffer from placental insufficiency and may continue growing. If the fetus becomes large, the woman and fetus then may have complications related to dysfunctional labor, inadequate postpartum uterine contraction to control bleeding, and injury if the birth is traumatic.

Psychologically, the woman often feels as though her pregnancy will never end. The added fatigue imposed by a pregnancy that extends significantly beyond her due date diminishes her resources for tolerating the added stress and anxiety about labor and birth.

Therapeutic Management

If the woman has no prenatal care or only receives care late in pregnancy, therapeutic management begins by determining her gestation as accurately as possible. Several markers used to pinpoint gestation, such as ultrasound examination, fundal height measurements, dates of quickening, and first identification of fetal heart tones with a nonamplified fetoscope or Doppler, may be lost if a woman begins prenatal care very late. Also, the woman may have forgotten the date of her last menstrual period or may have irregular menstrual cycles.

Another factor in management decisions is whether the fetus is thriving in the uterus. If antepartum tests such as a biophysical profile indicate that the fetus is doing well and that placental function is not diminished, the birth attendant can take a more conservative approach and can allow labor to begin naturally.

If the gestation appears to be truly postterm and no fetal urgency to deliver quickly exists, management depends on whether the cervix is favorable for induction of labor. If so, induction is usually begun. If the cervix is not favorable, the caregiver often uses a cervical ripening procedure (see [Chapter 16](#)) to soften the cervix. The cervical ripening also would be done if the fetal signs were nonreassuring and delivery was needed but the cervix was not favorable (unless the fetal situation was sufficiently nonreassuring that a cesarean birth was indicated).

Nursing Considerations

Nursing care for the woman with a prolonged pregnancy is tied to the medical management. The nurse's role may include the following:

- Teaching the woman about procedures such as antepartum testing or induction of labor
- Supporting the woman's psychological and physical fatigue

- Providing nursing care related to specific procedures such as induction of labor

INTRAPARTUM EMERGENCIES

Placental Abnormalities

Women with placental abnormalities may experience hemorrhage during the antepartum or intrapartum period. **Placenta previa** (abnormal implantation of the placenta in lower uterus) is sometimes associated with an abnormally adherent placenta (**placenta accreta**). The strongest risk for placenta accreta is prior uterine surgery, usually one or more cesarean births. Placenta accreta may cause immediate intrapartum hemorrhage, or hemorrhage may occur immediately after birth because the placenta does not separate cleanly, often leaving small fragments that prevent full uterine contraction. More extreme degrees of abnormal adherence occur when the placenta penetrates the uterine muscle itself (*placenta increta*) or even all the way through the uterus (*placenta percreta*). All or only part of the placenta may be involved. A hysterectomy may be required if a large portion of the placenta is abnormally adherent ([Francois & Foley, 2012](#); [Hull & Resnik, 2009](#)).

Prolapsed Umbilical Cord

A prolapsed umbilical cord slips downward after the membranes rupture, subjecting it to compression between the fetus and pelvis ([Figure 27-7](#)). It may slip down immediately with the fluid gush or long after the membranes rupture. Interruption in blood flow through the cord interferes with fetal oxygenation and is potentially fatal.

Causes

Prolapse of the umbilical cord is more likely when the fit is poor between the fetal presenting part and the maternal pelvis. When the fit is good, the fetus fills up the pelvis, leaving little room for the cord to slip down. Although prolapse of the cord is possible during any labor, it is more likely if the following conditions are present:

- A fetus that remains at a high station
- A very small fetus
- Breech presentations (the footling breech is more likely to be complicated by a prolapsed cord because the feet and legs are small and do not fill the pelvis well)

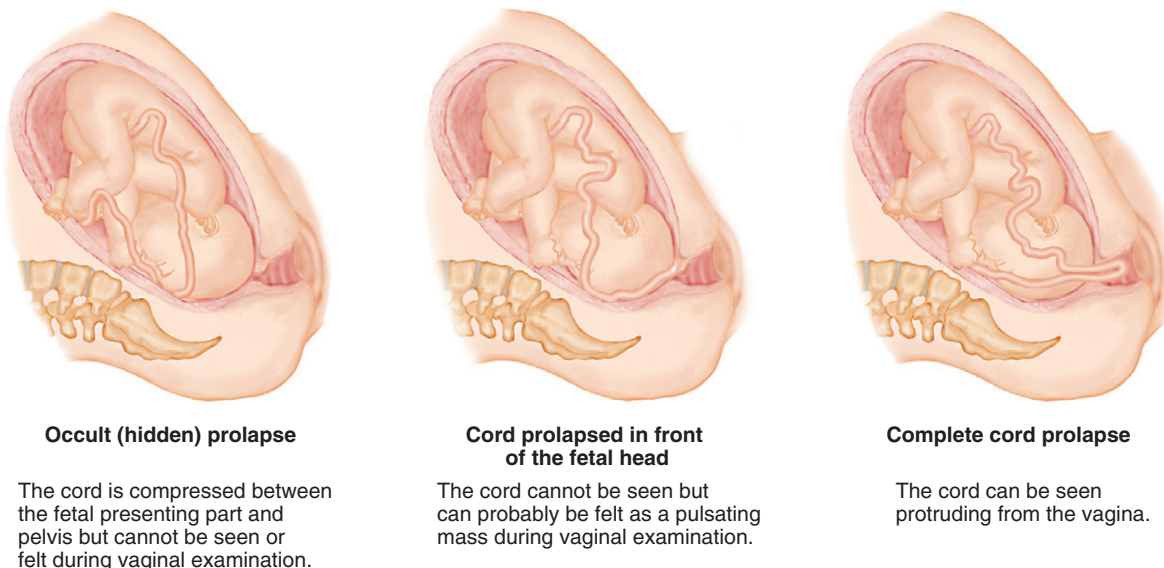

FIG 27-7 Variations of prolapsed umbilical cord.

- Transverse lie
- Hydramnios (often associated with abnormal presentations; also, the unusually large amount of fluid exerts more pressure to push the cord out)

Signs of Prolapse

Prolapse may be complete, with the cord visible at the vaginal opening. A **prolapsed cord** may not be visible but may be palpated on vaginal examination as it pulsates synchronously with the fetal heart. An **occult prolapse** of the cord is one in which the cord slips alongside the fetal head or shoulders. The prolapse cannot be palpated or seen but is suspected because of changes in the FHR, such as sustained bradycardia or variable decelerations.

⚡ SAFETY ALERT

Factors that increase a woman's risk for a prolapsed umbilical cord include the following:

- Ruptured membranes *and*
 - The fetal presenting part at a high station
 - A fetus that poorly fits the pelvic inlet because of small size or abnormal presentation
 - Excessive volume of amniotic fluid (hydramnios)

Therapeutic Management

Medical and nursing management often overlap, as they do in many emergency situations. Either the nurse or the birth attendant may be the first to discover umbilical cord prolapse. Birth is almost always cesarean unless vaginal delivery can be accomplished more quickly and

less traumatically. If fetal death has occurred, usually before patient arrival, management will focus on the best care for the mother based on other complications.

When cord prolapse occurs, the priority is to relieve pressure on the cord to improve blood flow through it until delivery. None of these interventions should delay the promptest possible delivery of a living fetus. Push the call light to summon help. Others should call the physician and prepare for birth while the nurse caring for the woman relieves pressure on the cord, if the physician or nurse-midwife is not doing so. Neonatal nurses and a pediatrician or neonatologist should be notified, and the staff should prepare for neonatal resuscitation.

Prompt actions reduce cord compression and increase fetal oxygenation:

1. Position the woman's hips higher than her head to shift the fetal presenting part toward her diaphragm. Any of these methods (Figure 27-8) may be used:
 - a. Knee-chest position
 - b. Trendelenburg position
 - c. Hips elevated with pillows, with side-lying position maintained
2. Maintain vaginal elevation of the presenting part using a gloved hand while the woman is transferred to the operating room (OR) until the physician orders cessation of vaginal elevation, usually just before cesarean birth. Minimize cord compression from the hand that is elevating the presenting part as much as possible during the woman's transport to the OR.
3. Avoid or minimize manual palpation or handling of the cord as much as possible to minimize cord vessel vasospasm.
4. Ultrasound examination may be used to confirm presence of fetal heart activity before cesarean delivery.

A gloved hand in the vagina pushes the fetus upward and off the cord.

Knee-chest position uses gravity to shift the fetus out of the pelvis. The woman's thighs should be at right angles to the bed and her chest flat on the bed.

The woman's hips are elevated with two pillows; this is often combined with the Trendelenburg (head down) position.

FIG 27-8 Measures that may be used to relieve pressure on a prolapsed umbilical cord until delivery can take place.

While preparing for surgery, give the woman oxygen at 8 to 10 liters per minute (L/min) by face mask to increase maternal blood oxygen saturation, making more available for the fetus.

Other actions may be used to enhance fetal oxygenation, but prompt delivery is the priority. A tocolytic drug such as terbutaline inhibits contractions, increasing placental blood flow and reducing intermittent pressure of the fetus against the pelvis and cord. Warm, saline-moistened towels retard cooling and drying of the cord. If the cord is protruding from the vagina, no attempt should be made to replace it because doing so could traumatize and further reduce blood flow through the cord. Manipulating the cord can induce umbilical artery spasm, which would reduce blood flow between the fetus and the placenta.

Prognosis for the woman is good because the only additional risks are those associated with cesarean birth. Prognosis for the infant depends on how long and how severely blood flow through the cord has been impaired. With prompt recognition and corrective actions, the infant usually does well.

Nursing Considerations

In addition to taking prompt corrective actions, the nurse must consider the woman's anxiety. The nurse must remain calm while working quickly during this time and acknowledge the woman's anxiety. Explanations must be simple because anxiety interferes with the woman's ability to comprehend them. Her partner and family should be included as much as possible.

Uterine Rupture

Sometimes a tear in the wall of the uterus occurs because the uterus cannot withstand the pressure against it (Figure 27-9). Uterine rupture may occur at home rather than in the hospital. Uterine rupture may precede labor's onset. Three variations of uterine rupture exist:

- *Complete rupture* is a direct communication between the uterine and peritoneal cavities.
- *Incomplete rupture* is a rupture into the peritoneum covering the uterus or into the broad ligament but not the peritoneal cavity.
- *Dehiscence* is a partial separation of an old uterine scar. Little or no bleeding may occur. No signs or symptoms may exist, and the rupture ("window") may be found incidentally during a subsequent cesarean birth or other abdominal surgery.

FIG 27-9 Uterine rupture in the lower uterine segment.

Causes

Although uterine rupture is rare, dehiscence is not unusual. Uterine rupture is associated with previous uterine surgery such as cesarean birth or surgery to remove fibroids. The risk for rupture in a woman who has had a prior cesarean birth depends on the type of uterine incision. The risk for rupture is greater in women with a classic incision (vertical into the upper uterine segment) than in women with a low transverse incision. For this reason, vaginal birth after cesarean (VBAC) is not recommended for women who have had a previous birth through a classic cesarean incision (see Figure 16-9 [types of uterine incisions]). The decision about choosing a VBAC is made by the woman and her physician because of the benefits as well as potential problems associated with vaginal birth that follows a previous cesarean (Francois & Foley, 2012; Thorp, 2009).

Rupture of the unscarred uterus is more likely for women of high parity with a thin uterine wall, women sustaining blunt abdominal trauma, and women having intense contractions, especially if fetopelvic disproportion is present. Excessively strong contractions (hypertonic) may cause the intrauterine pressure to exceed the tensile strength of the uterine wall. If the fetus cannot be expelled downward through the pelvis, contractions may push it through the lower uterine segment. Intense contractions are more likely to occur when uterine stimulants such as oxytocin and misoprostol are administered for induction or augmentation of labor, but they also may occur spontaneously.

Signs and Symptoms

Dehiscence does not have symptoms initially and may not interfere with labor or vaginal delivery if the area is small. However, labor progress may stop because the open area prevents efficient expulsion of the fetus. Intrauterine pressures may have little change during contractions. A larger area of dehiscence may cause abdominal pain that persists despite analgesia.

Manifestations of uterine rupture vary with the degree of rupture and may mimic other complications. Possible signs and symptoms of uterine rupture are as follows:

- Abdominal pain and tenderness: The pain may not be severe; it may occur suddenly at the peak of a contraction. The woman may describe a feeling that something "gave way" or "ripped."
- Chest pain, pain between the scapulae, or pain on inspiration: Pain occurs because of the irritation of blood below the woman's diaphragm.
- Hypovolemic shock caused by hemorrhage: Tachycardia, tachypnea, falling blood pressure, pallor, cool and clammy skin, and anxiety. Signs of shock may not occur until after birth. The fall in blood pressure is often a late sign of hemorrhage.
- Signs associated with impaired fetal oxygenation, such as late decelerations, reduced variability, tachycardia, and bradycardia.
- Absent fetal heart sounds with a large disruption of the placenta; absent fetal heart activity by ultrasound examination.
- Cessation of uterine contractions.
- Palpation of the fetus outside the uterus (usually occurs only with a large, complete rupture). The fetus is likely dead.

If the rupture is incomplete, blood loss is slower and signs of shock, chest pain, or intrascapular pain may be delayed. Complete rupture results in massive blood loss. Signs of shock and pain develop quickly. External bleeding may not be impressive, however, because most blood is lost into the peritoneal cavity. The fetus often dies in complete rupture because the placental blood supply is disrupted.

Therapeutic Management

Initial management is to stabilize the woman and the fetus for a cesarean birth. If the rupture is small and the woman wants other children,

it may be repaired. A woman with a large uterine rupture requires hysterectomy. Blood is replaced as needed.

Nursing Considerations

The nurse must be aware of women who are at increased risk for uterine rupture and must stay alert for the signs and symptoms. Administer uterine stimulant drugs cautiously to reduce the likelihood of excessive contractions. The nurse must keep in mind that hypertonic contractions also can occur spontaneously. Notify the birth attendant if hypertonic contractions occur. A tocolytic drug may be needed to reduce excessive contractions.

Uterine rupture may not be detected before birth. If postpartum bleeding is excessive and the fundus is firm, injury to the birth canal, including uterine rupture, is possible. Bleeding may be concealed if the ruptured area bleeds into the broad ligament. In this case, signs of hypovolemic shock are likely to develop quickly.

19. What is the immediate management of prolapse of the umbilical cord?
20. How can contractions stimulated with drugs such as oxytocin or misoprostol increase the risk for uterine rupture?

Uterine Inversion

An inversion occurs when the uterus completely or partly turns inside out, usually during the third stage of labor. Such an event is uncommon but potentially fatal.

Causes

Often, no single cause is identified. Predisposing factors are as follows:

- Pulling on the umbilical cord before the placenta detaches from the uterine wall spontaneously
- Fundal pressure during birth
- Fundal pressure on an incompletely contracted uterus after birth
- Increased intraabdominal pressure
- An abnormally adherent placenta
- Congenital weakness of the uterine wall
- Fundal placenta implantation

Signs and Symptoms

The birth attendant notes that either the uterus is absent from the abdomen or a depression in the fundal area is present. The interior of the uterus may be seen through the cervix or protruding into the vagina. Massive hemorrhage, shock, and pain quickly become evident. The woman has severe pelvic pain.

Management

Quick action by nursing and medical personnel is essential to reduce maternal morbidity and mortality rates. The physician tries to replace the uterus through the vagina into a normal position. If that is not possible, a laparotomy is used to replace the uterus. Hysterectomy may be required, and several units of blood are usually ordered immediately (Francois & Foley, 2012; Thorp, 2009).

Nursing Considerations

Nursing care during the emergency supplements that provided by other staff members. Postpartum nursing care is directed toward observing and maintaining maternal blood volume and correcting

shock. The woman may be transferred to the intensive care unit after delivery.

Assess the uterine fundus for firmness, height, and deviation from the midline. Assess vital signs every 15 minutes or more frequently until stable, and then according to recovery room routine. Observe for tachycardia and a falling blood pressure, which are associated with shock. Remember that the fall in blood pressure is often a late sign of hemorrhagic shock. A cardiac monitor identifies dysrhythmias, which may occur with shock, while a pulse oximeter indicates the woman's pulse rate and oxygen saturation. Invasive hemodynamic monitoring with central venous pressure and arterial lines is common to directly evaluate functions such as heart rate, venous and arterial pressures, blood gases, circulation to the lungs, venous functions, and other tests that may be needed.

An indwelling catheter usually is inserted to observe fluid balance and keep the bladder empty so that the uterus can contract well. Assess the catheter for patency, and record intake and output. Urine output should be at least 30 mL per hour. A fall in urine output may indicate hypovolemia or an obstructed catheter.

The woman is allowed nothing by mouth until her condition is stable. She usually can receive fluids and progress to solid foods quickly because **uterine inversion** does not usually recur in the current postpartum period. It may recur in a future pregnancy if conditions favor its development.

Anaphylactoid Syndrome

Pregnancy-related **anaphylactoid syndrome**, often called **amniotic fluid embolism** (AFE), occurs when amniotic fluid is drawn into the maternal circulation and carried to the woman's lungs. Fetal particulate matter (skin cells, vernix, hair, meconium) in the fluid obstructs pulmonary vessels. Failure of the right ventricle occurs early and can lead to hypoxemia. Left ventricular failure follows. Abrupt respiratory distress, depressed cardiac function, and circulatory collapse may occur rapidly. Disseminated intravascular coagulation (DIC) (see [Chapter 25](#)) is likely because thromboplastin-rich amniotic fluid interferes with normal blood clotting. This infrequent disorder is often fatal and survivors may have neurologic deficits (Cunningham et al., 2010; Martin & Foley, 2009; Wing & Farinelli, 2012).

Entry of amniotic fluid containing fetal cells and other matter such as vernix is more likely if labor is very strong. High intrauterine pressure forces amniotic fluid into open uterine or cervical veins. The meconium that often accompanies a stressed fetus in such a labor adds to the particulate matter forced into the woman's circulation.

Although this disorder has been called *amniotic fluid embolism*, the newer name *anaphylactoid syndrome* is preferred because of findings related to other complications. Other maternal conditions that are not characterized by leaking of amniotic fluids into the woman's circulation include septic shock, preeclampsia, and cardiac disease. Other complications may be associated with this disorder but are not fully known. Also, fetal cells are often found in blood samples of women who never develop this often fatal complication (Cunningham et al., 2010; Martin & Foley, 2009).

Rapid therapeutic management of a pregnancy-related anaphylactoid syndrome is primarily medical and includes the following (Cunningham et al., 2010; Martin & Foley, 2009):

- Cardiopulmonary resuscitation and support
- Oxygen with mechanical ventilation
- Correction of hypotension
- Blood component therapy (e.g., fibrinogen, packed red blood cells, platelets, fresh-frozen plasma) to correct coagulation defects

If the pregnant mother is in cardiac arrest, immediate cesarean birth is likely to improve survival odds for the baby.

TRAUMA

Most trauma during pregnancy occurs because of motor vehicle accidents (MVs), assault, or suicide. Battering, or interpersonal violence, is a significant cause of maternal-fetal trauma during pregnancy. (Social and emotional issues of battering are addressed in [Chapter 24](#).) Trauma may be blunt, such as that sustained in an automobile accident, or penetrating, such as gunshot and knife wounds. Burns and electrical injuries also may occur. Trauma is the leading cause of non-obstetric maternal death ([Bobrowski, 2011](#); [Cunningham et al., 2010](#); [Mozurkewich & Pearlman, 2012](#)).

Although injury may not be fatal, infant neurologic deficits may be found after birth. Direct fetal trauma such as skull fracture or intracranial hemorrhage may occur from maternal pelvic fracture, penetrating wounds, or blunt trauma. Indirect causes of fetal injury or death include abruptio placentae and disruption of the placental blood flow secondary to maternal hypovolemia or uterine rupture. The most common cause of fetal death is death of the mother.

The anatomic and physiologic changes of pregnancy make trauma care unique. During early pregnancy, the uterus is surrounded by the pelvis and is well protected from direct damage. As the uterus grows, it protrudes and becomes a large target for trauma. At the same time, it acts as a shield for other maternal organs such as the kidneys, often protecting them from direct trauma.

Normal alterations of pregnancy can affect the maternal and fetal outcomes after traumatic injury and can affect the interpretation of diagnostic studies that may be done. Pregnant women have a greater blood volume compared with nonpregnant women, which gives them a cushion against blood loss. However, the fetus may suffer if the woman hemorrhages because maternal blood is diverted from the placenta to increase her blood volume. Fetal hypoxia, acidosis, and death may then occur.

Maternal fibrinogen levels are higher during pregnancy (300 to 600 milligrams per deciliter [mg/dL]). A decrease to lower levels is associated with abruptio placentae and may indicate that disseminated intravascular coagulation is developing.

Management

Care of the pregnant trauma victim first focuses on injuries that threaten her life. Management of the fetus depends on whether the fetus is living and on the gestational age. Cesarean birth is opted for if the fetus is mature enough to survive and if the maternal or fetal condition is likely to be improved by prompt delivery. The fetus that is dead or too immature to survive is not usually delivered unless delivery will improve the mother's outcome. A Kleihauer-Betke (K-B) test may be ordered at intervals to identify placental disruptions that allow fetal blood to leak into the circulation.

Nursing Considerations

Motor vehicle accidents are the leading cause of blunt trauma during pregnancy. Non-use or incorrect use of automobile restraints such as seat belts or air bags may result in greater trauma or fatality in mother and fetus. Visit the website for the National Highway Traffic Safety Administration for information on correct use of seat belts and air bags during pregnancy (www.nhtsa.dot.gov).

Nursing care of the pregnant trauma victim also focuses first on maternal and then on fetal stabilization. A wedge is placed under one side of the mother to tip her uterus away from her major blood vessels. "Tipping" her to displace the uterus may prevent supine hypotension and further hemodynamic instability, also improving placental blood flow. Vital signs are taken as needed, based on the woman's condition. Vital signs and urine output (at least 30 milliliters per hour [mL/hr])

provide information about the adequacy of her blood volume. Bloody urine suggests bladder or renal damage. Other nursing care is directed toward specific injuries and implementation of medical care.

Signs suggesting abruptio placentae (vaginal bleeding with uterine pain and tenderness) should be reported because this complication may occur with abdominal trauma. Vaginal bleeding may not be apparent if the edges of the placenta remain attached but the center portion is detached. The uterine height may also increase as the uterus fills with blood. Tachycardia usually precedes a fall in blood pressure if hypovolemia is the cause. Fetal tachycardia or cessation of the FHR is likely to occur in more extensive uterine trauma or maternal hemorrhage. Fetal hemorrhage may occur with trauma to the placenta or the umbilical cord.

Once the woman's condition is stable, nursing care for the fetus is intensified. External monitoring is appropriate if the fetus has reached a viable gestational age. Preterm labor may occur but may not be recognized if the woman is unconscious or if pain from injuries overshadows discomfort from contractions. Recurrent restlessness or moaning may accompany contractions. The nurse should palpate the woman's uterus for contractions periodically because they may not be evident on the fetal monitoring strip, especially if the fetus is small.

21. What are the primary complications of a uterine inversion? How are they managed?
22. What are important nursing considerations for each kind of intrapartum emergency: Prolapsed umbilical cord? Uterine rupture? Uterine inversion? Amniotic fluid embolism?
23. What kinds of fetal injury may occur with maternal trauma during pregnancy?

APPLICATION OF THE NURSING PROCESS

Intrapartum Emergencies

Nursing care of the woman with an intrapartum emergency overlaps with care in other situations discussed elsewhere. Much of the nursing care is collaborative and supports medical management. Parents may suffer loss if the fetus dies or the mother loses her ability to bear future children, as may occur with uterine rupture. One problem expected in any emergency situation is the emotional distress of the woman and her family.

Assessment

When an emergency occurs, the woman and her family have little time to absorb what has happened, simply because of its suddenness. In umbilical cord prolapse, for example, labor often has been uneventful up to that point. Suddenly, nurses place the woman in a strange position, administer oxygen, and pull her toward the operating room. The staff is clearly excited as well.

Under such circumstances, the woman and her family have a very narrow focus. They are obviously apprehensive and feel out of control. The woman or her partner may be immobilized by fear.

Nursing Diagnosis

The nursing diagnosis is "Anxiety related to unexpected occurrences because of the sudden development of complications." This diagnosis is expected to differ from the anxiety associated with preterm labor because the onset is acute. The anxiety also may lessen more quickly because the emergency is sometimes resolved quickly. Grief may also occur because of ill effects of the emergency on mother and baby.

Planning

The focus of a goal is very narrow in an emergency situation. Two appropriate outcomes, during and after the emergency, are that the woman and her family will do the following:

- Indicate an understanding of emergency procedures.
- Express their feelings about the complication.

Interventions

Although little time for discussion exists, explain honestly and simply what is occurring. To reduce fear and anxiety of the unknown, tell the woman what is happening and why. Include her partner and family, if appropriate. Provide continued reassurance and support to the woman because her partner often must be excluded from the emergency or operating room when an emergency occurs.

The infant born in an emergency situation may need resuscitation or other supportive measures. Nurses and a neonatal nurse practitioner or pediatrician from the neonatal intensive care unit, if available, usually are present at the birth to attend the infant. A neonatologist also may be present. Explain to the family who the other professionals are and their roles. If possible, explain what is being done to care for the baby.

After the emergency, give the woman and her family a chance to ask questions. The ability to absorb new knowledge during periods of severe anxiety is very limited. Adequate explanations afterward help them understand and assimilate the experience (Box 27-1).

Although the nurse is usually anxious in an emergency situation, keeping a calm attitude is important. The woman and her family quickly pick up on the staff's anxiety, and consequently their anxiety escalates. Remain with the woman to reduce fears of abandonment. If possible, hold her hand. Speak in a low, calm voice. The nurses involved should also take time to talk out anxieties with their colleagues after the emergency situation is over.

BOX 27-1 NURSING DIAGNOSES TO CONSIDER WHEN CARING FOR WOMEN WITH INTRAPARTUM COMPLICATIONS

Activity Intolerance*
 Grieving, Anticipatory and/or Actual*
 Anxiety*
 Compromised or Disabled Individual and/or Family Coping
 Readiness for Enhanced Individual and/or Family Coping
 Deficient Diversional Activity*
 Health-Seeking Behaviors
 Impaired Home Maintenance*
 Ineffective Health Management
 Fatigue
 Powerlessness
 Risk for Infection*

*Nursing diagnoses explored in this chapter.

Evaluation

Evaluation of the goals is probably impossible until the emergency is over and the woman's physical condition stabilizes. Expected outcomes for this nursing diagnosis are achieved if the woman and her family do the following:

- Indicate that they understand the problem and the rationale for emergency procedures.
- Express, possibly over several days, their feelings about what has occurred.

SUMMARY CONCEPTS

- Dysfunctional labor may occur because of abnormalities in the powers, the passenger, the passage, or the psyche. Combinations of abnormalities are common.
- Nursing care in dysfunctional labor focuses on prevention or prompt identification and action to correct additional complications such as fetal hypoxia, infection, injury to the mother or fetus, and postpartum hemorrhage.
- Premature rupture of the membranes is associated with infection as both a cause and a complication.
- Early indications of preterm labor are often vague. Prompt identification of preterm labor enables the most effective therapy to delay preterm birth.
- Nursing care for the woman at risk for a preterm birth before 34 weeks of gestation focuses on helping her delay birth long enough to provide time for fetal lung maturation with corticosteroids, allow transfer to a facility that has neonatal intensive care, or reach a gestation at which the infant's problems with immaturity are less.
- The main risk in prolonged pregnancy is reduced placental function. This may compromise the fetus during labor and result in meconium aspiration in the neonate. Dysfunctional labor may occur if a fetus continues growing during the prolonged pregnancy.
- The key intervention for umbilical cord prolapse is to relieve pressure on the umbilical cord and to expedite delivery.
- Be aware of women at risk for uterine rupture, and observe for signs and symptoms such as signs of shock, abdominal pain, a sense of tearing, chest pain, pain between the scapulae, abnormal fetal heart rate patterns, cessation of contractions, and palpation of the fetus outside the uterus. However, lesser degrees of uterine rupture or dehiscence may have minimal symptoms.
- Uterine inversion can be accompanied by massive blood loss and shock. Recovery care promotes uterine contraction and maintenance of adequate circulating volume.
- Anaphylactoid syndrome (formerly amniotic fluid embolism) is more likely to occur when labor is intense and the membranes have ruptured. The true causes of anaphylactoid syndrome are not known because it is uncommon.
- The uterus is protected by the maternal pelvis during early pregnancy. As the uterus enlarges and ascends out of the pelvis, it is more vulnerable to trauma from direct impact. The fetus may be injured by disruption of the placenta, direct trauma, or either fetal or maternal hemorrhage.
- Medical and nursing care of the pregnant trauma victim focuses on stabilization of the mother first. Management of the fetus depends on gestational age and whether the fetus is alive. Abruptio placentae and uterine rupture are obstetric complications that may occur with direct abdominal trauma.

Continued

SUMMARY CONCEPTS—cont'd

- Motor vehicle accidents are a major cause of blunt force trauma that may cause premature separation of the placenta, hemorrhage, fractures, and internal injuries. Penetrating injuries caused by knife or gunshot wounds are particularly dangerous for the fetus.
- Treatment of trauma in the pregnant woman is similar to that in a nonpregnant woman. Cardiopulmonary resuscitation and controlling bleeding are the priorities. Careful evaluation of the uterus and fetus also is essential after even minor trauma.

Postpartum Maternal Complications

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe postpartum hemorrhage: predisposing factors, causes, signs, and therapeutic management.
2. Explain major causes, signs, and therapeutic management of subinvolution.
3. Describe three major thromboembolic disorders (superficial venous thrombosis, deep vein thrombosis, pulmonary embolism) and their predisposing factors, causes, signs, and therapeutic management.
4. Discuss puerperal infection in terms of location, predisposing factors, causes, signs and symptoms, and therapeutic management.
5. Describe the major mood disorders (postpartum depression, postpartum psychosis, and bipolar II disorder) and anxiety disorders (panic disorder, postpartum obsessive-compulsive disorder, and post-traumatic stress disorder).
6. Describe the role of the nurse in the management of women who have a postpartum complication.

Pregnancy and childbirth are natural functions from which most women recover without complication. However, nurses must be aware of problems that may occur and their effect on the family. The most common complications are hemorrhage, thromboembolic disorders, infection, and postpartum mood and anxiety disorders.

POSTPARTUM HEMORRHAGE

Postpartum hemorrhage is a major cause of maternal death and morbidity in the United States and the world. (Berg, Callaghan, Syverson et al., 2010). In the United States, it complicates 1% to 5% of births (Francois & Foley, 2012). Current literature provides multiple working definitions of postpartum hemorrhage, but no single definition is agreed upon and used consistently. Current definitions include blood loss of more than 500 mL after vaginal birth or 1000 mL after cesarean birth, a decrease in hematocrit of 10% or more since admission or the need for a blood transfusion (Cunningham, Leveno, Bloom et al., 2010), and continued bleeding even with the “usual treatment” (Belfort & Dildy, 2011). Estimates of blood loss are frequently only about half the actual amount (Cunningham et al., 2010). Hemorrhage in the first

24 hours after childbirth is called *early postpartum hemorrhage*. Hemorrhage after 24 hours or up to 6 to 12 weeks after birth is called *late postpartum hemorrhage*.

Early Postpartum Hemorrhage

Early postpartum hemorrhage usually occurs during the first hour after delivery and is most often caused by uterine atony (Cunningham et al., 2010). Trauma to the birth canal during labor and birth, **hematomas** (localized collections of blood in a space or tissue), retention of placental fragments, and abnormalities of coagulation are other causes. Hemorrhage from disseminated intravascular coagulation and placenta previa are discussed in Chapter 25. Other causes of hemorrhage include **placenta accreta** (abnormal adherence of the placenta to the uterine wall) and inversion of the uterus, which are described in Chapter 27.

Uterine Atony

Atony refers to lack of muscle tone that results in failure of the uterine muscle fibers to contract firmly around blood vessels when the placenta separates. With uterine atony, the relaxed muscles allow rapid

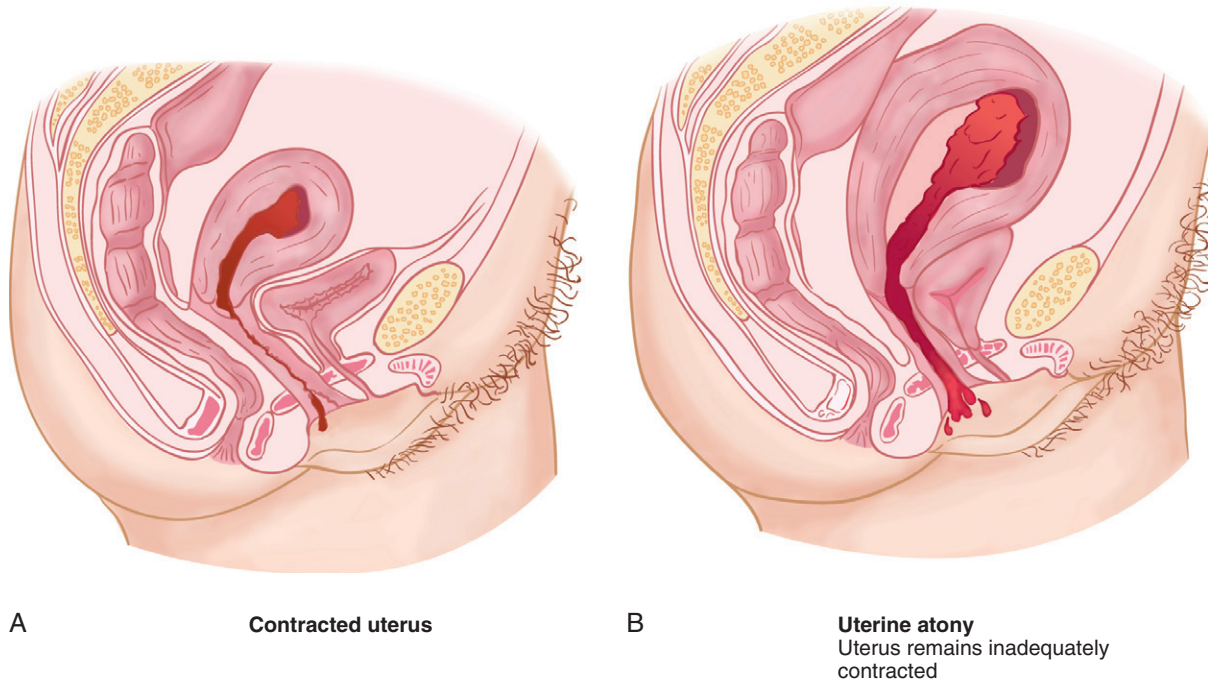

FIG 28-1 **A**, When the uterus remains contracted, the placental site is smaller, so bleeding is minimal. **B**, If uterine muscles fail to contract around the endometrial arteries at the placental site, hemorrhage occurs.

bleeding from the endometrial arteries at the placental site. Bleeding continues until the uterine muscle fibers contract to stop the flow of blood. Figure 28-1 illustrates the effect of uterine contraction on the size of the placental site and the amount of bleeding that occurs.

Predisposing Factors. Knowledge of factors that increase the risk of uterine atony helps the nurse anticipate and therefore reduce excessive bleeding. Overdistention of the uterus from any cause such as multiple gestation, a large infant, or **hydramnios** (excessive volume of amniotic fluid) makes it more difficult for the uterus to contract with enough firmness to prevent excessive bleeding. Multiparity results in muscle fibers that have been stretched repeatedly and these flaccid muscle fibers may not remain contracted after birth. **Blomberg (2011)** identified an increase in the incidence of postpartum hemorrhage due to uterine atony in obese women, with the significance of the increase corresponding to increasing body mass index.

Intrapartum factors include contractions that were barely effective, resulting in prolonged labor; contractions that were excessively vigorous, resulting in precipitate labor; and labor that was induced or augmented with oxytocin. Retention of a large segment of the placenta does not allow the uterus to contract firmly and therefore can result in uterine atony. **Box 28-1** summarizes predisposing factors for postpartum hemorrhage.

Clinical Manifestations. Major signs of uterine atony include:

- A uterine fundus that is difficult to locate
- A soft or “boggy” feel when the fundus is located
- A uterus that becomes firm as it is massaged but loses its tone when massage is stopped
- A fundus that is located above the expected level
- Excessive lochia, especially if it is bright red
- Excessive clots expelled, either with or without uterine massage

For the first 24 hours after childbirth the uterus should feel like a firmly contracted ball roughly the size of a large grapefruit. It should be easily located at about the level of the umbilicus. Lochia should be dark red

BOX 28-1 COMMON PREDISPOSING FACTORS FOR POSTPARTUM HEMORRHAGE

- Overdistention of the uterus (multiple gestation, large infant, hydramnios)
- Multiparity (five or more)
- Precipitate labor or delivery
- Prolonged labor
- Use of forceps or vacuum extractor
- Cesarean birth
- Manual removal of the placenta
- Uterine inversion
- Placenta previa, placenta accreta, or low implantation
- Drugs: oxytocin, prostaglandins, tocolytics, or magnesium sulfate
- General anesthesia
- Chorioamnionitis
- Clotting disorders
- Previous postpartum hemorrhage or uterine surgery
- Disseminated intravascular coagulation
- Uterine leiomyomas (fibroids)

and scant to moderate in amount. Saturation of one peripad in 15 minutes represents an excessive blood loss (**Whitmer, 2011**). The nurse must realize that although bleeding may be profuse and dramatic, a constant steady trickle, dribble, or slow seeping is just as dangerous (see **Chapter 17** for assessment of the uterus and lochia).

Therapeutic Management. Nurses are responsible for assessments and initial management of uterine atony. If the uterus is not firmly contracted, the first intervention is to massage the fundus until it is firm and to express clots that may have accumulated in the uterus.

FIG 28-2 Technique for fundal massage.

One hand is placed just above the symphysis pubis to support the lower uterine segment while the other hand gently but firmly massages the fundus in a circular motion (Figure 28-2).

Clots that may have accumulated in the uterine cavity interfere with the ability of the uterus to contract effectively. They are expressed by applying firm but gentle pressure on the fundus in the direction of the vagina. It is critical that the uterus is contracted firmly before attempting to express clots. *Pushing on a uterus that is not contracted could invert the uterus and cause massive hemorrhage and rapid shock* (see Chapter 27).

If the uterus does not remain contracted as a result of uterine massage or if the fundus is displaced, the bladder may be distended. A full bladder lifts the uterus, moving it up and to the side, preventing effective contraction of the uterine muscles. Assist the mother to urinate or catheterize her to correct uterine atony caused by bladder distention. Note urine output.

Pharmacologic measures also may be necessary to maintain firm contraction of the uterus. A rapid intravenous (IV) infusion of dilute oxytocin (Pitocin) often increases uterine tone and controls bleeding (see Drug Guide: Oxytocin on p. 309). Methylergonovine (Methergine) may be given intramuscularly, but it elevates blood pressure and should not be given to a woman who is hypertensive. Analogs of prostaglandin $F_{2\alpha}$ (PGF_{2 α} , carboprost tromethamine, Hemabate, Prostin) are very effective when given intramuscularly or into the uterine muscle if oxytocin is ineffective in controlling uterine atony (Kim, Hayashi, & Gambone, 2010). Prostin E2 (Dinoprostone) or misoprostol (Cytotec) given rectally may also be used to control bleeding.

If uterine massage and pharmacologic measures are ineffective in stopping uterine bleeding, the physician or nurse-midwife may use bimanual compression of the uterus. In this procedure, one hand is inserted into the vagina and the other compresses the uterus through the abdominal wall (Figure 28-3). A balloon may be inserted into the uterus to apply pressure against the uterine surface to stop bleeding

DRUG GUIDE

METHYLERGONOVINE (METHERGINE)

Classification: Ergot alkaloid, uterine stimulant

Action: Stimulates sustained contraction of the uterus and causes arterial vasoconstriction.

Indications: Used for the prevention and treatment of postpartum or postabortion hemorrhage caused by uterine atony or subinvolution.

Dosage and Route: Usual dosage is 0.2 mg intramuscularly (IM) every 2 to 4 hours for a maximum of five doses. Change to the oral route 0.2 mg every 6 to 8 hours for a maximum of 7 days. Intravenous use not recommended; use in life-threatening emergency only and give over at least 60 seconds with close monitoring of BP and pulse; may cause severe hypertension.

Absorption: Well absorbed after oral or IM route.

Excretion: Metabolized by the liver; excreted in the feces and urine.

Contraindications and Precautions: Methylergonovine should never be used during pregnancy or to induce labor. Do not use IM if the mother is hypersensitive to ergot. Contraindicated for women with hypertension, severe hepatic or renal disease, thrombophlebitis, coronary artery disease, peripheral vascular disease, hypocalcemia, sepsis, or before the fourth stage of labor.

Adverse Reactions: Nausea, vomiting, uterine cramping, hypertension, dizziness, headache, dyspnea, chest pain, palpitations, peripheral ischemia, seizure, and uterine and gastrointestinal cramping.

Nursing Considerations: Before administering the medication, assess the blood pressure. Follow facility protocol to determine at what BP level medication must be withheld. Caution the mother to avoid smoking because nicotine constricts blood vessels. Remind her to report any adverse reactions.

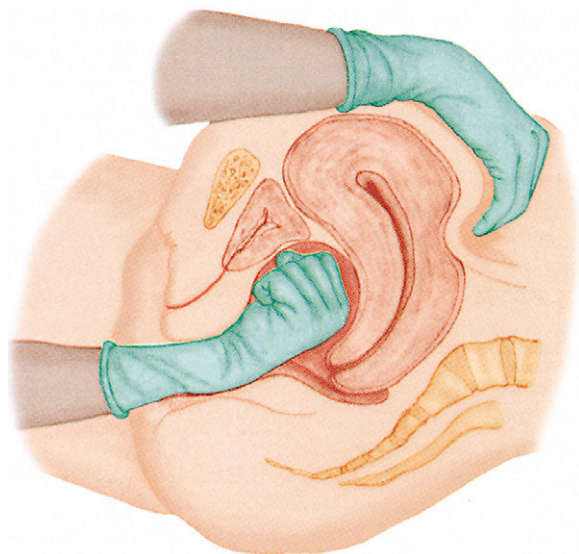

FIG 28-3 Bimanual compression. One hand is inserted in the vagina, and the other compresses the uterus through the abdominal wall.

DRUG GUIDE

CARBOPROST TROMETHAMINE (HEMABATE, PROSTIN/15M)

Classification: Prostaglandin, oxytocic.

Action: Stimulates contraction of the uterus.

Indications: Used for the treatment of postpartum hemorrhage caused by uterine atony. Also used for abortion.

Dosage and Route: Postpartum hemorrhage: 250 micrograms intramuscularly. May repeat at 15- to 90-minute intervals. Maximum total dose 2 mg.

Absorption: Metabolized by the liver and by enzymes in the lungs.

Excretion: Primarily excreted in urine.

Contraindications and Precautions: Contraindicated for women with hypersensitivity to carboprost or other prostaglandins; acute pelvic inflammatory disease; cardiac, pulmonary, renal, or hepatic disease. Use caution if the woman has a history of asthma, hypotension or hypertension, anemia, jaundice, diabetes, epilepsy, previous uterine surgery.

Adverse Reactions and Side Effects: Excessive dose may cause tetanic contraction and laceration or uterine rupture. May cause uterine hyper-tonus if used with oxytocin. Nausea, vomiting, diarrhea (frequent), fever, chills, facial flushing, headache, hypertension or hypotension, tachycardia, pulmonary edema.

Nursing Considerations: Should be refrigerated. Give via deep intramuscular injection and aspirate carefully to avoid intravenous injection. Rotate sites if repeated. Monitor vital signs. Administer antiemetics and antidiarrheals as ordered.

(Belfort & Dildy, 2011). Uterine packing may also be used. It may be necessary to return the woman to the delivery area for exploration of the uterine cavity and removal of placental fragments that interfere with uterine contraction.

A laparotomy may be necessary to identify the source of the bleeding. Uterine compression sutures may be placed to stop severe bleeding. Ligation of the uterine or hypogastric artery or embolization

FIG 28-4 A vulvar hematoma is caused by rapid bleeding into soft tissue, and it causes severe pain and feelings of pressure.

(occlusion) of pelvic arteries may be required if other measures are not effective. Hysterectomy is a last resort to save the life of a woman with uncontrollable postpartum hemorrhage.

Hemorrhage requires prompt replacement of intravascular fluid volume. Lactated Ringer's solution, whole blood, packed red blood cells, normal saline, or other plasma extenders are used. Enough fluid should be given to maintain a urine flow of at least 30 mL/hr and preferably 60 mL/hr (Cunningham et al., 2010). Typically, the nurse is responsible for obtaining properly typed and crossmatched blood and inserting large-bore IV lines that are capable of carrying whole blood.

Trauma

Trauma to the birth canal is the second most common cause of early postpartum hemorrhage. Trauma includes vaginal, cervical, or perineal lacerations and hematomas.

Predisposing Factors. Many of the same factors that increase the risk of uterine atony increase the risk of soft tissue trauma during childbirth. For example, trauma to the birth canal is more likely to occur if the infant is large or if labor and delivery occur rapidly. Induction and augmentation of labor and use of assistive devices, such as a vacuum extractor, increase the risk of tissue trauma.

Lacerations. The perineum, vagina, cervix, and the area around the urethral meatus are the most common sites for lacerations. Small cervical lacerations occur frequently and generally do not require repairs. Lacerations of the vagina, perineum, and periurethral area usually occur during the second stage of labor, when the fetal head descends rapidly or when assistive devices such as a vacuum extractor or forceps are used to assist in delivery of the fetal head.

Lacerations of the birth canal should always be suspected if excessive uterine bleeding continues when the fundus is contracted firmly and is at the expected location. Bleeding from lacerations of the genital tract often is bright red, in contrast to the darker red color of lochia. Bleeding may be heavy or may appear to be minor with a steady trickle (dribble or oozing) of blood that continues.

Hematomas. Hematomas occur when bleeding into loose connective tissue occurs while overlying tissue remains intact. Hematomas develop as a result of blood vessel injury in spontaneous deliveries and deliveries in which vacuum extractors or forceps are used.

The rapid bleeding into soft tissue may cause a visible vulvar hematoma, a discolored bulging mass that is sensitive to touch (Figure 28-4).

Hematomas in the vagina or retroperitoneal areas cannot be seen. Hematomas produce deep, severe, unrelieved pain and feelings of pressure that are not relieved by usual pain-relief measures. Formation of a hematoma should be suspected if the mother demonstrates systemic signs of concealed blood loss, such as tachycardia or decreasing blood pressure, when the fundus is firm and lochia is within normal limits.

Therapeutic Management. When postpartum hemorrhage is caused by trauma of the birth canal, surgical repair is often necessary. Visualizing lacerations of the vagina or cervix is difficult, and it is necessary to return the mother to the delivery area, where surgical lights are available. She is placed in a lithotomy position and carefully draped. Surgical asepsis is required while the laceration is being visualized and repaired.

Small hematomas usually reabsorb naturally. Large hematomas may require incision, evacuation of the clots, and location of the bleeding vessel so that it can be ligated.

5. How are hematomas treated?

Late Postpartum Hemorrhage

The most common causes of late postpartum hemorrhage are **subinvolution** (delayed return of the uterus to its nonpregnant size and consistency) and fragments of placenta that remain attached to the myometrium when the placenta is delivered. Clots form around the retained fragments, and excessive bleeding can occur when the clots slough away several days after delivery. Infection of the uterus may also be a cause.

Late postpartum hemorrhage caused by retained placental fragments is generally preventable. When the placenta is delivered, the health care provider carefully inspects it to determine whether it is intact. If a portion of the placenta is missing, the provider manually explores the uterus, locates the missing fragments, and removes them.

Late postpartum hemorrhage, also called *secondary postpartum hemorrhage*, is defined as hemorrhage occurring between 24 hours and 6 weeks after birth (Ambrose & Repke, 2011). It usually happens after discharge and can be dangerous for the unsuspecting mother. Women should be taught how to assess the fundus and normal characteristics and duration of lochia flow. They should be instructed to notify their health care provider if bleeding persists or becomes unusually heavy.

Predisposing Factors

Attempts to deliver the placenta before it separates from the uterine wall, manual removal of the placenta, placenta accreta (see Chapter 27), previous cesarean birth, and uterine leiomyomas are primary predisposing factors for retention of placental fragments.

Therapeutic Management

Initial treatment for late postpartum hemorrhage is directed toward control of the excessive bleeding. Oxytocin, methylergonovine, and prostaglandins are the most commonly used pharmacologic measures. Placental fragments may be dislodged and swept out of the uterus by the bleeding, and if the bleeding subsides when oxytocin is

administered, no other treatment is necessary. Sonography can identify placental fragments that remain in the uterus. If bleeding continues or recurs, **dilation and curettage** (stretching of the cervical os to permit suctioning or scraping of the walls of the uterus) may be necessary to remove fragments. Broad-spectrum antibiotics may be given if postpartum infection is suspected because of uterine tenderness, foul-smelling lochia, or fever.

HYPOVOLEMIC SHOCK

During and after giving birth, the woman can tolerate blood loss that approaches the volume of blood added during pregnancy (approximately 1500 to 2000 mL). A woman who was anemic before birth has less reserve than a mother with normal blood values. The amount of blood lost can be estimated by comparing the hematocrit before labor and delivery with one measured after delivery. If the hematocrit is lower after delivery, the woman lost the amount of blood added during pregnancy and an additional 500 mL for each 3% drop in the hematocrit value (Cunningham et al., 2010).

When blood loss is excessive, **hypovolemic shock** (acute peripheral circulatory failure resulting from loss of circulating blood volume) can ensue. **Hypovolemia** (abnormally decreased volume of circulating fluid in the body) endangers vital organs by depriving them of oxygen. The brain, heart, and kidneys are especially vulnerable to hypoxia and may suffer damage in a brief period.

Pathophysiology

Recognition of hypovolemic shock may be delayed because the body activates compensatory mechanisms that mask the severity of the problem. Carotid and aortic baroreceptors are stimulated to constrict peripheral blood vessels. This shunts blood to the central circulation and away from less essential organs, such as the skin and extremities. The skin becomes pale and cold, but cardiac output and perfusion of vital organs are maintained.

In addition, the adrenal glands release catecholamines, which promote vasoconstriction in nonessential organs, increasing the heart rate and raising the blood pressure. As a result, blood pressure remains normal initially, although a decrease in **pulse pressure** (difference between systolic and diastolic blood pressures) may be noted. The tachycardia that develops is an early sign of compensation for excessive blood loss.

As shock worsens, the compensatory mechanisms fail and physiologic insults spiral. Inadequate organ perfusion and decreased cellular oxygen for metabolism result in a buildup of lactic acid and the development of metabolic acidosis. Acidosis results in vasodilation, which further increases bleeding. Eventually, circulating volume becomes insufficient to perfuse cardiac and brain tissue. Cellular death occurs as a result of anoxia, and the mother dies.

Clinical Manifestation

Early signs of blood loss such as mild tachycardia or hypotension may not appear until 20% to 25% of the woman's blood volume has been lost (Francois & Foley, 2012). Tachycardia is one of the earliest signs of hypovolemic shock; even gradual increases in the pulse rate should be noted. A decrease in blood pressure and narrowing of pulse pressure occur when the circulating volume of blood is sufficiently decreased. The respiratory rate increases as the woman becomes more anxious and attempts to take in more oxygen to overcome the need that is created when hemoglobin is inadequate to transport oxygen adequately.

Skin changes also provide early clues. Vasoconstriction in the skin causes it to become pale and cool to the touch. As hemorrhage worsens,

the skin changes become more obvious as pallor increases and the skin becomes cold and clammy.

As shock progresses, changes also occur in the central nervous system. The mother becomes anxious, then confused, and finally lethargic as blood loss increases. Urine output decreases and eventually stops.

Therapeutic Management

The goals of therapy are to control bleeding and prevent hypovolemic shock from becoming irreversible. A second IV line should be inserted with a large-bore (14- to 18-gauge) catheter capable of carrying whole blood. Central intravenous catheters may be placed. Sufficient fluid volume is infused to produce a urinary output of at least 30 mL/hr. Vasopressors may be needed for low blood pressure. The health care team makes every effort to locate the source of bleeding and to stop the loss of blood. Interventions may include uterine packing; ligation of the uterine, ovarian, or hypogastric artery; or hysterectomy.

Nursing Considerations

Immediate Care

One person should be assigned to evaluate and record vital signs. Blood pressure and pulse should be assessed every 3 to 5 minutes. The location and consistency of the fundus, amount of lochia, skin temperature and color, and capillary return also are assessed. Oxygen may be administered by tight face mask at 8 to 10 L/min to increase the saturation of fewer red blood cells. Oxygen saturation levels are carefully monitored. Nurses often follow facility protocols that allow them to draw blood for hemoglobin, hematocrit, clotting studies, and type and crossmatch. Nurses administer fluids, whole blood, and medications as directed and report their effectiveness. A urinary catheter is inserted to measure hourly urinary output. The catheter is also necessary if a surgical procedure to control the hemorrhage is required. In addition, nurses must make every effort to provide information and emotional support to the woman and her family.

SAFETY ALERT

Signs of postpartum hemorrhage include:

- A uterus that does not contract or does not remain contracted
- Large gush or slow, steady trickle, ooze, or dribble of blood from the vagina
- Saturation of one peripad per 15 minutes
- Severe, unrelieved perineal or rectal pain
- Tachycardia

APPLICATION OF THE NURSING PROCESS

■ The Woman with Excessive Bleeding

Assessment

The initial postpartum assessment includes a chart review to determine if risk factors for hemorrhage are present. This alerts the nurse to a woman at increased risk for hemorrhage.

Uterine Atony

Priority assessments for uterine atony include the fundus, bladder, lochia, vital signs, skin temperature, and color. Assess the consistency and the location of the uterine fundus. The fundus should be firmly contracted at or near the level of the umbilicus and midline. If the fundus feels soft (boggy), the uterus is not firmly contracted and bleeding from the placental site is rapid and continuous. If the fundus is above the level of the umbilicus and displaced, a full bladder may be

the cause of excessive bleeding. (See Procedure 17-1, for assessing the fundus.)

When inspecting for blood loss, remember to check under the woman's legs, buttocks and back for lochia drainage by asking the woman to turn on her side. This allows visibility of any blood that may not be obvious from the front. Obese women have an increased risk for uterine atony with subsequent postpartum hemorrhage (Blomberg, 2011); however, assessment of the fundus is difficult in this population. Monitor these women frequently for other signs of uterine atony and attempt to assess the uterine fundus while watching for increased lochia flow or clots to be expelled.

It is difficult to estimate the volume of lochia by visual examination of peripads. More accurate information is obtained by weighing peripads, linen savers, and, if necessary, bed linens before and after use and subtracting the difference. One gram (weight) equals approximately 1 mL (volume).

Measure vital signs at least every 15 minutes or more often if necessary. Apply a pulse oximeter to determine oxygen saturation levels. This helps to detect trends, such as tachycardia or a decrease in pulse pressure that may reveal a deteriorating status in a woman with significant blood loss. Because the body initially compensates for excessive bleeding, the vital signs may remain normal even when the woman is becoming hypovolemic. The skin should be warm and dry, mucous membranes of the lips and mouth should be pink, and capillary return should occur within 3 seconds when the nails are blanched. These signs confirm adequate circulating volume to perfuse the peripheral tissue.

SAFETY ALERT

To determine the amount of blood loss:

Weigh all blood-soaked items (e.g., peripads, linens).

Weigh similar clean items.

Subtract the weight of the dry items from that of the wet items.

1 g weight = 1 mL of blood.

Trauma

If the fundus is firm but bleeding is excessive, the cause may be lacerations of the cervix or birth canal.

If the mother complains of deep, severe pelvic or rectal pain or if vital signs or skin changes suggest hemorrhage but excessive bleeding is not obvious, the cause may be concealed bleeding and the formation of a hematoma. Examine the vulva for bulging masses or discoloration of the skin. However, a hematoma developing in the vagina or in the retroperitoneal area will not be obvious when the vulva is examined. This sign warrants examination of the vaginal walls and the cervix by the health care provider. Table 28-1 summarizes assessments, abnormal signs and symptoms, and nursing implications.

Nursing Diagnosis

Postpartum hemorrhage is a complication that requires the efforts of all members of the health care team to control the hemorrhage and prevent further complications such as hypovolemic shock.

Planning

Client-centered goals are inappropriate for this potential complication because the nurse cannot manage postpartum hemorrhage independently but must use orders from the physician or nurse-midwife to treat the condition. Planning should reflect the nurse's responsibility to:

- Monitor for signs of postpartum hemorrhage.
- Perform actions that minimize postpartum hemorrhage and prevent hypovolemic shock.

TABLE 28-1 NURSING ASSESSMENTS FOR POSTPARTUM HEMORRHAGE

ASSESSMENTS	ABNORMAL SIGNS AND SYMPTOMS	NURSING IMPLICATIONS
Chart review Fundus	Presence of predisposing factors Soft, boggy, displaced	Perform more frequent evaluations. Massage, express clots, and assist to void or catheterize; notify primary health care provider if measures are ineffective.
Lochia	Bleeding (steady trickle, dribble, oozing, seeping, or profuse flow); heavy: saturation of 1 pad/hr; excessive: 1 pad/15 min	Assess for trauma; save and weigh pads, linen savers, and bed linens so estimation of blood loss will be more accurate. Notify health care provider.
Vital signs	Tachycardia, decreasing pulse pressure, falling blood pressure, decreasing oxygen saturation level	Report signs of excessive blood loss.
Urine output Comfort level	Decreased urine output; should be at least 30 mL/hr Severe pelvic or rectal pain	Report decrease in output. Assess for signs of hematoma, usually perineal or vaginal; examine vulva for masses or discoloration; report findings.
Skin	Cool, damp, pale	Look for signs of hypovolemia; vigilant assessment and management by entire health care team is necessary.

- Notify the provider if signs of excessive blood loss are observed or if the woman does not respond as desired.

Interventions

Preventing Hemorrhage

The key to successful management of early postpartum hemorrhage is early recognition and response. All postpartum women are at risk for hemorrhage. However, be aware of factors that increase this risk further and be particularly vigilant in monitoring these women so that excessive bleeding can be anticipated and minimized.

When predisposing factors are present, initiate frequent assessments. Many hospitals and birth centers have a standard of care that calls for assessments every 15 minutes during the first hour after birth, every 30 minutes for the next 2 hours, and hourly for the next 4 hours. This plan may not be adequate for the woman at known risk for postpartum hemorrhage because bleeding occurs rapidly.

Collaborating with the Health Care Provider

When excessive bleeding is suspected and the fundus is boggy, begin uterine massage. Check the woman's bladder for distention and have her empty it if necessary. If she is not able to void and the bladder is distended, catheterize the woman. Weigh blood-soaked pads, linen savers, and linens to accurately determine the amount of blood lost. If massage is not effective in controlling bleeding promptly, notify the physician or nurse-midwife. Save any tissue or clots passed.

Most facilities also have protocols which permit nurses to catheterize patients and initiate specific laboratory studies, such as hemoglobin and hematocrit levels and type and crossmatch of blood, so that blood is available if transfusions become necessary. Coagulation studies that may be ordered include fibrinogen, prothrombin time, partial thromboplastin time, fibrin split products, fibrin degradation products, platelets, D-dimer, and blood chemistry. Many protocols also allow the nurse to increase the flow rate of an existing IV or insert a large-bore catheter to start IV fluids while the health care provider is being informed of the mother's condition. These actions do not substitute for notifying the provider, but they do allow nurses to make initial interventions quickly.

Keep the woman on bed rest to increase venous return and maintain cardiac output. The full Trendelenburg's position may interfere with cardiac and pulmonary function and is not advised. A modified Trendelenburg's position may be used with the legs elevated 10 to 30 degrees to increase blood return from the legs, the trunk horizontal, and the head slightly elevated. Continue assessments, call for

assistance, and save all blood-soaked materials so that an accurate estimation of blood loss can be made. Assistance is necessary because one nurse must continue to massage the uterus and perform and record assessments while another notifies the health care provider of the mother's condition and gathers medications and supplies needed.

When notifying the provider, document the time and content of each communication. For example, "1300: Dr. X notified of implementation of postpartum hemorrhage protocol due to difficulty maintaining uterine contraction and continued excessive bleeding. Requested Dr. X to see client."

Administer medications, fluids, and treatments as ordered by the health care provider or as stated in the facility's protocol. Note the effects and relay the information to the health care provider. Physicians and nurse-midwives base medical management on information relayed by the nurse. The nurse should be familiar with the standing orders and protocols for his or her patient population.

Because of oxytocin's antidiuretic effect, listen to breath sounds to identify signs of pulmonary edema from fluid overload if large amounts of oxytocin are given. Document blood pressure if Methergine is given. If measures fail to control bleeding, notify the health care provider so that additional procedures can be initiated. These may include preparation for operative intervention (surgical preparation, consent signed for operative procedure, or confirmation that blood replacement is available).

Providing Support for the Family

The unusual activity of the hospital staff may make the mother and her family anxious. Be alert to their nonverbal cues, and when they appear frightened, acknowledge their feelings. Keeping the family informed is one of the most effective ways of reducing anxiety.

Acknowledge the anxiety and provide simple appropriate explanations of the activity. "I know all this activity must be frightening. She is bleeding a little more than we would like and we are doing several things at once."

Posthemorrhage Care

After the hemorrhage is controlled, continue to assess the woman frequently for a resumption of bleeding. The woman may be anemic and fatigued. Allow rest periods and organize work to help her conserve energy. Because the woman may experience orthostatic hypotension, assist her in getting out of bed after dangling her legs and assess for dizziness and low blood pressure. Encourage intake of fluids and foods high in iron. She may need assistance feeding her newborn.

Home Care

Nurses who work in home care or nurse-managed postpartum clinics must be aware that women who have had postpartum hemorrhage are subject to a variety of complications. In general, they are exhausted, and it may take weeks for them to feel well again. Anemia often results, and a course of iron therapy may be prescribed to restore an adequate hemoglobin level. Activity may be restricted until strength returns. Some women need extra assistance with housework and care of the new infant. Fatigue may interfere with bonding and attachment. Because extensive blood loss increases the risk of postpartum infection, the woman must be taught to observe for specific signs and symptoms.

Evaluation

Although client-centered goals are not developed for potential complications (collaborative problems), the nurse collects and compares data with established norms and judges whether the data are within normal limits. If problems arise, the nurse acts to minimize hemorrhage and notifies the health care provider.

CRITICAL THINKING EXERCISE 28-1

Dawn, a 26-year-old gravida 5, para 4, is admitted to the hospital. She has a rapid labor and delivers a baby boy weighing 4000 g (8 lb, 13 oz). Two hours later, she is transferred to the postpartum unit. At the initial postpartum assessment, Dawn's fundus is firm, at the level of the umbilicus. Lochia is heavy, with occasional small clots expressed. Vital signs are unchanged from prenatal norms.

Questions

1. Do any "red flags" suggest a potential problem or complication? What actions should the nurse take?
2. At the next assessment, the nurse observes that the fundus is soft and lochia is excessive. What are the priority interventions? Why?
3. Within an hour the fundus becomes "boggy" again and is located 3 cm above the umbilicus and displaced to the right. What is the priority nursing action? Why?
4. Dawn voids 500 mL. The fundus is difficult to locate, however, and lochia is excessive. What is the next nursing action? Why?

SUBINVOLUTION OF THE UTERUS

Subinvolution refers to a slower-than-expected return of the uterus to its nonpregnant size after childbirth. Normally the uterus descends at the rate of about 1 cm or one fingerbreadth per day. By 14 days, it is no longer palpable above the symphysis pubis. The endometrial lining has sloughed off as part of the lochia, and the site of placental attachment is well healed by 6 weeks after childbirth if involution progresses as expected.

The most common causes of subinvolution are retained placental fragments and pelvic infection. Signs of subinvolution include prolonged discharge of lochia, irregular or excessive uterine bleeding, and sometimes profuse hemorrhage. Pelvic pain or feelings of pelvic heaviness, backache, fatigue, and persistent malaise are reported by many women. On bimanual examination the uterus feels larger and softer than normal for that time of the puerperium.

Therapeutic Management

Treatment is tailored to correct the cause of subinvolution. Methylergonovine maleate (Methergine) given orally provides long, sustained contraction of the uterus. Infection responds to antimicrobial therapy.

Nursing Considerations

In most cases subinvolution is not obvious until the mother has returned home after childbirth. Therefore nurses must teach the mother and her family how to recognize its occurrence.

Demonstrate how to locate and palpate the fundus and how to estimate fundal height in relation to the umbilicus. The uterus should become smaller each day (by approximately one fingerbreadth). Also explain the progressive changes from lochia rubra to lochia serosa and then to lochia alba (see Chapter 17).

Instruct the mother to report any deviation from the expected pattern or duration of lochia. A foul odor often indicates uterine infection for which treatment is necessary. Additional signs include pelvic or fundal pain, backache, and feelings of pelvic pressure or fullness. The mother should be able to verbalize the warning signs prior to leaving the facility.

8. What is the nurse's primary responsibility in the management of subinvolution?

THROMBOEMBOLIC DISORDERS

A **thrombus** is a collection of blood factors, primarily platelets and fibrin, on a vessel wall. **Thrombophlebitis** occurs when the vessel wall develops an inflammatory response to the thrombus. This further occludes the vessel. An **embolus** is a mass that may be composed of a thrombus or amniotic fluid released into the bloodstream that may cause obstruction of capillary beds in another part of the body, frequently the lungs. **Pulmonary embolus** is a potentially fatal complication that occurs when the pulmonary artery is obstructed by a blood clot that was swept into circulation from a vein or by amniotic fluid. The three most common thromboembolic disorders encountered during pregnancy and the postpartum period are superficial venous thrombophlebitis (SVT), deep vein thrombosis (DVT), and occasionally pulmonary embolism (PE). SVT generally involves the saphenous venous system and is confined to the lower leg. DVT can involve veins from the foot to the iliofemoral region. It is a major concern because it predisposes to PE. Figure 28-5 illustrates the venous system of the leg.

Incidence and Etiology

The incidence of venous thromboembolism is about 1 in 1500 pregnancies; however, it is a leading cause of maternal mortality (Pettker & Lockwood, 2012). Thrombi can form whenever the flow of blood is impeded. Once started, the thrombus can enlarge with successive layering of platelets, fibrin, and blood cells as the blood flows past the clot. Thrombus formation is often associated with thrombophlebitis.

The three major causes of thrombosis are venous stasis, hypercoagulable blood, and injury to the endothelial surface (the innermost layer) of the blood vessel. Two of these conditions—venous stasis and hypercoagulable blood—are present in all pregnancies; the third, blood vessel injury, is likely to occur during birth.

Venous Stasis

During pregnancy, compression of the large vessels of the legs and pelvis by the enlarging uterus causes venous stasis. Stasis is most

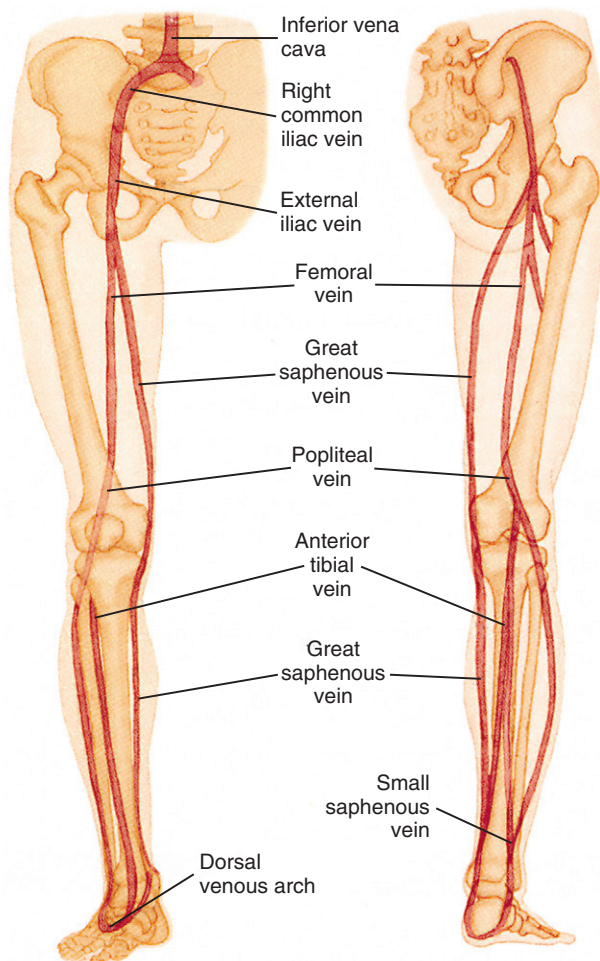

FIG 28-5 The venous system of the leg is affected when deep venous thrombosis occurs.

pronounced when the pregnant woman stands for prolonged periods of time. It results in dilated vessels that increase the potential for continued pooling of blood postpartum. Relative inactivity during pregnancy and activity restriction due to complications during pregnancy lead to venous pooling and stasis of blood in the lower extremities. Prolonged time in stirrups for delivery and repair of the episiotomy also may promote venous stasis and increase the risk of thrombus formation.

Hypercoagulation

Pregnancy is characterized by changes in the coagulation and fibrinolytic systems that persist into the postpartum period. During pregnancy the levels of many coagulation factors are elevated. In addition, the fibrinolytic system, which causes clots to disintegrate (lyse), is suppressed. The result is that factors that promote clot formation are increased and factors that prevent clot formation are decreased to prevent maternal hemorrhage, resulting in a higher risk for thrombus formation during pregnancy and the postpartum period.

Blood Vessel Injury

Injury to the endothelium of the blood vessels may occur during pregnancy, especially at birth. Lower extremity trauma, operative delivery,

BOX 28-2 FACTORS THAT INCREASE THE RISK OF THROMBOSIS

- Inactivity
- Prolonged bed rest
- Obesity
- Cesarean birth
- Sepsis
- Smoking
- History of previous thrombosis
- Varicose veins
- Diabetes mellitus
- Trauma
- Prolonged labor
- Prolonged time in stirrups in second stage of labor
- Maternal age older than 35
- Increased parity
- Dehydration
- First-degree relative with thrombosis
- Use of forceps
- Antiphospholipid antibody syndrome
- Inherited thrombophilias
- Air travel

and prolonged labor can cause vascular damage (Rhode, 2011). Cesarean birth significantly increases the risk for thromboembolic disease (Dizon-Townson, 2010). See Box 28-2 for additional risk factors for thromboembolic disease.

Superficial Venous Thrombosis

Clinical Manifestations

Superficial thrombophlebitis is most often associated with varicose veins and limited to the calf area. It can also occur in the arms as a result of IV therapy. Signs and symptoms include swelling of the involved extremity and redness, tenderness, and warmth. It may be possible to palpate an enlarged, hardened, cordlike vein. The woman may experience pain when she walks, but some women have no signs at all.

Therapeutic Management

Treatment includes analgesics, rest, and elastic support. Elevation of the lower extremity improves venous return. Warm packs may be applied to the affected area. Anticoagulants are not needed but anti-inflammatory medications may be used. After a period of bed rest with the leg elevated, the woman may ambulate gradually if symptoms have disappeared. She should avoid standing for long periods and should continue to wear support hose to help prevent venous stasis and a subsequent episode of superficial thrombosis. Little chance of pulmonary embolism exists if the thrombosis remains in the superficial veins of the lower leg.

Deep Venous Thrombosis

Signs and symptoms of DVT or PE may be vague and attributed to normal changes of pregnancy (Farquharson & Greaves, 2011). Those that occur are caused by an inflammatory process and obstruction of venous return. The woman may report pain in the leg, groin, lower back or right lower quadrant (Rhode, 2011). Swelling of the leg (more than 2 cm larger than the other leg), erythema, heat, and tenderness

over the affected area are the most common signs. A positive Homans' sign (presence of leg pain when the foot is dorsiflexed) has been thought to be an indicator of DVT. However, it is not a reliable or valid test. Reflex arterial spasms may cause the leg to become pale and cool to the touch with decreased peripheral pulses. Additional symptoms may include pain on ambulation, chills, general malaise, and stiffness of the affected leg.

Diagnosis

Venous ultrasonography with vein compression and Doppler flow analysis of the deep veins of the upper legs are most commonly used to detect alterations in blood flow that are diagnostic of DVT. Magnetic resonance imaging (MRI) may be sensitive and accurate in diagnosing pelvic and leg thrombosis; venography is seldom used (Pettker & Lockwood, 2012). D-dimer tests may be performed but the results are normally higher during pregnancy and postpartum, and the test may not be as accurate as at other times. A negative result has a very high predictive value; therefore a D-dimer test may be used to rule out a thrombus in low-risk women. If the test is positive, it is followed by venous ultrasound (Pettker & Lockwood, 2012).

Therapeutic Management

Preventing Thrombus Formation. Women who have had a previous DVT or PE are at risk for another. These women and others at high risk may receive prophylactic heparin, which does not cross the placenta. Either standard unfractionated heparin (UH) or a low-molecular-weight heparin (LMWH) such as enoxaparin (Lovenox) or tinzaparin (Innohep) may be used. LMWH is longer acting and can be given less frequently and with less laboratory testing. It has fewer side effects and is less likely to cause bleeding. However, it is more expensive than UH and must be given subcutaneously. UH is given intravenously or subcutaneously.

Women receiving LMWH during pregnancy are changed to UH at approximately 36 weeks of gestation. The change is necessary because UH has a shorter half-life and epidural anesthesia, which may be needed in labor, is contraindicated within 24 hours of the last dose of LMWH. Heparin is discontinued during labor and birth and resumed approximately 6 to 12 hours after uncomplicated birth and 12 hours after the epidural catheter is removed (ACOG, 2011).

If stirrups must be used during the birth, risks of thrombus development can be reduced by placing the woman's legs in stirrups that are padded to prevent prolonged pressure against the popliteal angle during the second stage of labor. If possible, the time in stirrups should be no more than 1 hour.

All new mothers are encouraged to ambulate frequently and as early as possible. Ambulation prevents stasis of blood in the legs and decreases the likelihood of thrombus formation. If the woman is unable to ambulate, range-of-motion and gentle leg exercises, such as flexing and straightening the knee and raising one leg at a time, should begin within 8 hours after childbirth. In addition, a new mother should not use pillows under her knees or the knee gatch on the bed. These devices may cause sharp flexion at the knees and pressure against the popliteal space, leading to pooling of blood in the lower extremities.

Graduated compression stockings or sequential compression devices are used for mothers with varicose veins, a history of thrombosis, or a cesarean birth. Sequential compression devices should be applied preoperatively for a woman undergoing a cesarean birth who is not on anticoagulant therapy and should be continued until she begins to ambulate postpartum (ACOG, 2011). Compression stockings should be applied before the mother gets out of bed to prevent

venous congestion, which begins as soon as she stands. It is important that she understands the correct way to put on the stockings. Improperly applied stockings can roll or bunch and slow venous return from the legs.

Initial Treatment. Initial treatment when a DVT has occurred includes:

- Bed rest, with the affected leg elevated to decrease interstitial swelling and to promote venous return from the leg. Ambulation is permitted when symptoms have disappeared.
- Anticoagulant therapy to prevent extension of the thrombus. Therapy may begin with a continuous infusion of IV UH that is later changed to subcutaneous UH. The drug does not dissolve clots but prevents enlargement.
- Laboratory testing to determine response to medications. The activated partial thromboplastin time (aPTT) and the platelet count should be monitored when UH is given. The dose should be adjusted to maintain a therapeutic level shown by an aPTT of 1.5 to 2.5 times control (Castro & Ogunyemi, 2010). If subcutaneous LMWH is used instead of UH, less frequent laboratory monitoring is necessary. Antifactor Xa and platelets may be monitored if LMWH is used.
- Analgesics, as necessary, to control pain.
- Antibiotic therapy, if necessary, to prevent or control infection.
- Continuous, moist heat for relief of pain and to increase circulation.
- Gradual ambulation, which is allowed when symptoms have disappeared. Sitting with the legs dependent should be avoided.

Subsequent Treatment. The long-term management of DVT depends on whether the woman is pregnant or in the postpartum period. The pregnant woman with a DVT receives anticoagulation therapy until labor begins. It is resumed 6–12 hours after birth and continued for 6 weeks to 6 months after birth (ACOG, 2011). Warfarin (Coumadin) is contraindicated during pregnancy because of teratogenic effects and the risk of fetal hemorrhage. Therefore pregnant women are given UH or LMWH, neither of which cross the placenta.

During the postpartum period, warfarin is started before heparin is stopped to provide continuous anticoagulation. Heparin is discontinued when the international normalized ratio (INR) has been at therapeutic levels for 2 days. Warfarin therapy is continued for at least 6 weeks postpartum (Ambrose & Repke, 2011). Warfarin is safe for use during lactation. Longer use of warfarin is necessary in some women with continuing risk factors. The INR is used to monitor coagulation time when warfarin is used.

Before discharge from the birth facility, the mother should be taught about lifestyle changes that can improve peripheral circulation. This includes avoiding clothing that is constricting around the legs and prolonged sitting. If sitting for long periods is necessary, walking for a short time hourly or moving her feet and legs frequently will help prevent circulatory stasis.

WOMEN WANT TO KNOW

How Do I Prevent Thrombosis (Blood Clots)?

Methods to improve peripheral circulation will help prevent the occurrence of thrombophlebitis:

- Improve your circulation with a regular schedule of activity, preferably walking.
- Avoid prolonged standing or sitting in one position.
- When sitting, elevate your legs and avoid crossing them. This will increase the return of venous blood from the legs.
- Maintain a daily fluid intake of 12 or more 8-oz glasses to prevent dehydration and consequent sluggish circulation.
- Stop smoking. Smoking is a risk factor for thrombosis and can cause respiratory problems in you and your newborn.

APPLICATION OF THE NURSING PROCESS

■ The Mother with Deep Venous Thrombosis

Assessment

Assessment focuses on determining the status of the venous thrombosis. Inspect both legs at the same time so that the affected leg can be compared with the unaffected leg. DVT is most often unilateral, usually affecting the woman's left side (Farquharson & Greaves, 2011). Warmth or redness indicates inflammation; coolness or cyanosis indicates venous obstruction. Palpate the pedal pulses, comparing the strength of the right and left. Measure the affected and unaffected legs, comparing the circumferences to obtain an estimation of the edema that may be present in the affected leg. Record the measurements for ongoing assessment. It may be helpful to mark the woman's legs at the location of the measurement for consistency in assessments. Assess for pain. Pain is caused by tissue hypoxia, and increasing pain indicates progressive obstruction.

Evaluate the laboratory reports of clotting studies. In addition to activated partial thromboplastin time, platelets may be evaluated when UH is used. Thrombocytopenia is a concern when heparin is administered for a prolonged time. The INR is evaluated when the anticoagulant for the postpartum woman is changed to warfarin.

Nursing Diagnosis

The treatment of DVT includes the administration of anticoagulants for a prolonged time. An appropriate nursing diagnosis for this situation is "Risk for Bleeding related to lack of understanding of anticoagulant therapy precautions."

Planning

Expected Outcomes

The woman will:

- Remain free of bleeding from anticoagulant therapy.
- Verbalize precautions necessary when taking anticoagulants.
- Plan for changes necessary as a result of anticoagulant therapy.

Interventions

Monitoring for Signs of Bleeding

At least twice a day, inspect the mother for the appearance of bruising or petechiae. Instruct her to report any signs of bleeding: bruises, bloody nose, blood in urine or stools, bleeding gums, or increased vaginal bleeding. Be alert for signs of hemorrhage, such as tachycardia, falling blood pressure, or other signs of shock that may indicate internal bleeding.

Observe for excessive or bright red lochia. If the uterus is boggy, the cause is uterine atony. Massage the uterus and express clots. If the fundus is firm, bleeding may be from trauma or anticoagulant therapy. In either case the physician should be notified.

Unless frank hemorrhage is present, the usual treatment for excessive anticoagulation is temporary discontinuation of the anticoagulant. Protamine sulfate, which is the antidote for UH and is partially effective against LMWH, should be available. The antidote for warfarin is vitamin K.

Explaining Continued Therapy

Teach the woman how to prevent excessive anticoagulation. Carefully explain the treatment regimen, including the schedule of medication. Help her develop a method for remembering to take the medication as directed. Caution her not to "double up" if a dose is missed. If necessary, teach her and another family member how to inject heparin or enoxaparin. Explain the need for repeated laboratory testing to regulate the dose of the anticoagulant. Emphasize the importance of careful attention to dosage changes to keep the medication at the appropriate blood levels.

Oral anticoagulants are associated with many clinically significant drug interactions; emphasize the importance of keeping the health care provider informed about any medications she takes. Caution the woman that common over-the-counter medications, such as aspirin and other nonsteroidal anti-inflammatory drugs, increase the risk of hemorrhage. Explain that many herbs and dietary supplements may affect the potency of anticoagulants, and the woman should check with her health care provider before using them.

Instruct the woman taking warfarin that eating large amounts of vitamin K-containing foods may interfere with anticoagulation. These foods include broccoli, cabbage, lettuce, spinach, and lentils. Caution her against drinking alcohol, which inhibits the metabolism of oral anticoagulants. The woman should use effective contraception as long as she is taking warfarin because the drug can cause fetal defects.

Suggest that the mother use a soft toothbrush and floss her teeth gently to prevent bleeding from the gums. An electric toothbrush may be too vigorous and may cause bleeding. She should postpone dental appointments until the therapy is completed. Using a depilatory or waxing product or shaving with an electric razor to remove unwanted hair is safer than using a blade razor during anticoagulant therapy. Remind the mother not to go barefoot and to avoid activities that could cause injury. Emphasize the importance of reporting unusual bleeding.

Helping the Family Adapt to Home Care

Nurses often assist the family to adapt to home care. Assess the family structure and function to determine how prepared the family is to cope with the mother's illness. Determine the ages of any children and availability of family members or friends to help while the mother is confined to bed or on limited activity. Help the family develop a plan of care that includes the temporary assistance needed.

Note interactions between the mother and the newborn and between the father and the newborn. Although the health of the mother is of primary importance, care must be taken that the attachment process between her and the infant progresses normally.

Evaluation

- The mother demonstrates no signs of unusual bleeding or other side effects of the medication.
- The woman discusses precautions she has taken to prevent hemorrhage.
- Necessary changes have been made in the home.

Pulmonary Embolism

Pathophysiology

Pulmonary embolism (PE) is a serious complication of DVT and a leading cause of maternal mortality. Approximately 70% of patients with PE also have symptoms of DVT (Cunningham et al., 2010). PE occurs when fragments of a blood clot dislodge and are carried to the lungs. An embolus can also consist of amniotic fluid and its debris, a condition called *anaphylactoid syndrome* (Chapter 27). The embolus lodges in a vessel and partially or completely obstructs the flow of blood into the lungs. If pulmonary circulation is severely compromised, death may occur within a few minutes. If the embolus is small, adequate pulmonary circulation may be maintained until treatment can be initiated.

Clinical Manifestations

Clinical signs and symptoms depend on how much the flow of blood is obstructed. Dyspnea, chest pain, tachycardia, and tachypnea are the most common signs (Cunningham et al., 2010). Syncope (fainting) is uncommon and may indicate massive emboli (Pettker & Lockwood, 2012). Pulmonary rales, cough, hemoptysis (expectoration of blood or bloody sputum), abdominal pain, and low-grade fever may also occur. Pulse oximetry shows decreased oxygen saturation. Arterial blood gas determinations show decreased partial pressure of oxygen, and chest radiography reveals areas of atelectasis and pleural effusion (Castro & Ogunyemi, 2010).

The woman with symptoms of a PE should also be assessed for a DVT. If she has symptoms of a DVT, a venous sonogram (VUS) may be performed. If there is evidence of a DVT, anticoagulation therapy will be initiated as discussed earlier. If the VUS is negative, a chest x-ray may be done to rule out other causes such as pneumothorax or pneumonia. In the presence of a normal chest x-ray, a ventilation-perfusion scan and possibly a spiral CT scan may be ordered. The D-dimer assay is no longer considered appropriate in the evaluation of a pregnant patient with suspected PE (Pettker & Lockwood, 2012). If the patient is critically ill or unstable, anticoagulation therapy may be initiated prior to the chest x-ray.

Therapeutic Management

Treatment of PE is aimed at dissolving the clot and maintaining pulmonary circulation. Oxygen is used to decrease hypoxia, and narcotic analgesics are given to reduce pain and apprehension. Bed rest with the head of the bed elevated is used to help reduce dyspnea. The level of care, including support of ventilation, depends on her pulmonary status. Pulse oximetry and arterial blood gases are evaluated. Heparin therapy is initiated and is continued throughout pregnancy if the embolism occurs prior to birth. Therapy may be continued with warfarin for months after birth to prevent further emboli.

Emergency medications, such as dopamine, may be used to support falling blood pressure. Thrombolytic drugs, such as streptokinase, urokinase, or tissue-type plasminogen activator, may be used for life-threatening pulmonary emboli but are associated with bleeding. Embolectomy (surgical removal of the embolus) is rare; limited evidence exists regarding its use in the obstetric population (Cunningham et al., 2010).

Nursing Considerations

Monitoring for Signs. When caring for a woman with DVT, nurses must be aware of the danger of pulmonary embolism and focus the assessment for early signs and symptoms. This includes frequent assessment of respiratory rate and thorough and frequent auscultation of breath sounds. Abnormalities, such as diminished or unequal breath

sounds, or coughing should be reported immediately to the health care provider. Additional signs that require immediate attention include air hunger, dyspnea, tachycardia, pallor, and cyanosis.

Facilitating Oxygenation. Oxygen should be administered at 8 to 10 L/min by tight face mask. The nurse should remain with the mother to allay fear and apprehension. The head of the bed should be raised to facilitate breathing. Narcotic analgesics, such as morphine, may be used to relieve pain. Sedatives may be given to help control anxiety.

Seeking Assistance. The woman's condition is precarious until the clot is lysed or until it adheres to the pulmonary artery wall and is reabsorbed. The primary nurse should call for assistance to initiate interventions. These include continuous assessment of vital signs and administration of IV heparin and emergency drugs that may be needed. The woman who has pulmonary embolism requires critical care nursing skills and is usually transferred to an intensive care unit.

PUERPERAL INFECTION

Puerperal infection is a term used to describe bacterial infections after childbirth. Until the advent of antibiotics, puerperal infection often resulted in death. Even today, it is a cause of maternal death, especially in Third World countries. The most common postpartum infections are **endometritis** (an infection of the inner lining of the uterus), wound infections, urinary tract infections, **mastitis** (infection of the breast), and septic pelvic thrombophlebitis. **Endomyometritis** is an infection of the muscle and inner lining of the uterus. If the surrounding tissues are also involved, **endoparametritis** is present. **Metritis** is the infection of the decidua, myometrium, and parametrial tissues of the uterus.

Definition

The definition of **puerperal infection** is a temperature of 38°C (100.4°F) or higher after the first 24 hours and occurring on at least 2 of the first 10 days following childbirth. Although a slight elevation of temperature may occur during the first 24 hours because of dehydration or the exertion of labor, any mother with fever should be assessed for other signs of infection.

Effect of Normal Anatomy and Physiology on Infection

Every part of the reproductive tract is connected to every other part, and organisms can move from the vagina, through the cervix, into the uterus, and through the fallopian tubes to infect the ovaries and the peritoneal cavity. The entire reproductive tract is particularly well supplied with blood vessels during pregnancy and after childbirth. Bacteria that invade or are picked up by the blood vessels or lymphatics can carry the infection to the rest of the body, which can result in life-threatening septicemia.

The normal physiologic changes of childbirth increase the risk of infection. During labor and birth the acidity of the vagina is reduced by the amniotic fluid, blood, and lochia, which are alkaline. An alkaline environment encourages growth of bacteria.

Necrosis of the endometrial lining and the presence of lochia provide a favorable environment for the growth of anaerobic bacteria. Many small lacerations, some microscopic in size, occur in the endometrium, the cervix, and the vagina during birth and allow bacteria to

TABLE 28-2 RISK FACTORS FOR PUERPERAL INFECTION

RISK FACTOR	REASON
History of previous infections (urinary tract infection, mastitis, thrombophlebitis)	May be more vulnerable to infectious process.
Colonization of lower genital tract by pathogenic organisms	Infections usually caused by several microbes that have ascended to the uterus from the lower genital tract.
Cesarean birth	Provides increased portals of entry for bacteria.
Trauma	Provides entrance for bacteria and makes tissues more susceptible.
Prolonged rupture of membranes	Removes barrier of amniotic membranes and allows access by organisms to interior of uterus.
Prolonged labor	Increases number of vaginal examinations; allows time for bacteria to multiply.
Catheterization	Could introduce organisms into bladder.
Excessive number of vaginal examinations	Increases chance that organisms from the vagina or outside source are carried into the uterus.
Retained placental fragments	Provide growth medium for bacteria and may interfere with flow of lochia.
Hemorrhage	Results in loss of infection-fighting components of blood.
Poor general health (excessive fatigue, anemia, frequent minor illnesses)	Increases vulnerability to infections and complications of labor.
Poor nutrition (decreased protein, vitamin C)	Less able to repair tissue and defend against infection.
Poor hygiene	Increases exposure to pathogens.
Medical conditions such as diabetes mellitus	Decreases ability to defend against infections of any kind; diabetes increases glucose level in urine.
Low socioeconomic status	More likely to have poor nutrition and inadequate prenatal care.

enter the tissue. Although the uterine interior is not sterile until 3 to 4 weeks after childbirth, infection does not develop in most women, partly because granulocytes in the lochia and endometrium help prevent infection. Scrupulous aseptic technique during labor and birth and careful handwashing during the postpartum period are also major preventive factors.

Other Risk Factors

Other factors may predispose a woman to infection (Table 28-2). Cesarean birth is a major predisposing factor due to the tissue trauma that occurs in surgery, the incision that provides an entrance for bacteria, the possibility of contamination during surgery, and foreign bodies such as sutures that can promote infection. In addition, women who must have a surgical birth because of a problem that develops during labor may have other risk factors, such as prolonged labor, which raise the chances of infection. Colonization of the vagina with organisms, such as group B *Streptococcus*, *Chlamydia trachomatis*,

Mycoplasma hominis, and *Gardnerella vaginalis*, also predisposes the woman to the development of infection after childbirth.

Any trauma to maternal tissues increases the hazard of infection. Trauma during vaginal birth may occur with rapid delivery, birth of a large infant, use of a vacuum extractor or forceps, manual delivery of the placenta, or lacerations and episiotomies. Catheterization during labor increases the chance of introduction of organisms into the bladder and adds to the trauma to the urinary tract that occurs during normal childbirth.

When prolonged rupture of membranes occurs during labor, organisms from the vagina are more likely to ascend into the uterine cavity. A long labor or many vaginal examinations during labor increases the danger of infection. Each vaginal examination increases the possibility of contamination from organisms in the vagina that are carried through the open cervix. Use of a fetal scalp electrode or intra-uterine pressure catheter has the same effect. If part of the placenta remains inside the uterus after delivery, the tissue becomes necrotic and provides a good place for bacteria to grow.

Additional factors include postpartum hemorrhage, which causes loss of infection-fighting components of the blood, such as leukocytes, and leaves the mother in a weakened condition. Prenatal conditions (poor nutrition, anemia) interfere with the mother's ability to resist infection. Lack of knowledge of hygiene or lack of access to facilities that permit adequate hygiene increases the risk of postpartum infection.

CHECK YOUR READING

- Why is the woman who had an assisted birth or cesarean birth at increased risk for postpartum infection?
- Why do the normal physiologic changes of childbearing make a mother especially susceptible to infection of the reproductive system?
- Why is infection more likely to develop in a mother who had prolonged labor?

Specific Infections

Endometritis

Incidence and Etiology. Endometritis occurs in 1% to 3% of women following vaginal birth and 5% to 15% of women after scheduled cesarean birth. If extended labor and rupture of membranes precede cesarean birth, infection occurs in 30% to 35% of women who have no prophylactic antibiotics and 15% to 20% of those who receive prophylactic antibiotics (Duff, 2012). Endometritis is usually caused by organisms that are normal inhabitants of the vagina and cervix. Most infections are polymicrobial with both aerobic and anaerobic organisms involved. Organisms most often found include aerobic and anaerobic streptococci, *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus*, *Bacteroides*, and *Gardnerella*. (Dickinson, 2011). *Chlamydia trachomatis* is not a cause of early infection but is associated with late-onset infections (Duff, 2012).

Clinical Manifestations. The mother with severe endometritis looks sick. She presents a different picture from the typical happy new mother. The major signs and symptoms are temperature of 38°C (100.4°F) or higher within 36 hours of birth, chills, malaise, anorexia, abdominal pain and cramping, uterine tenderness, and purulent, foul-smelling lochia. Additional signs include tachycardia and subinvolution. In most cases, the signs and symptoms of endometritis occur within the 36 hours after birth (Duff, 2012).

Laboratory data may confirm the diagnosis. The results of a complete blood count may show an elevation in the number of leukocytes (15,000/mm³ to 30,000/mm³). Leukocyte levels are normally elevated to as high as 30,000/mm³ during labor and early postpartum (Gordan,

2012); however, leukocytosis that is not decreasing should prompt further evaluation. A blood culture may be obtained. Cultures of the vagina or endometrium are not usually helpful. A catheterized urine specimen may be obtained.

Therapeutic Management. Administration of IV antibiotics is the initial treatment for endometritis. The goal is to confine the infectious process to the uterus and to prevent spread of the infection throughout the body. Broad-spectrum antibiotics, such as the cephalosporins, clindamycin plus gentamicin, or ampicillin plus an aminoglycoside, are often used. Metronidazole with penicillin may also be given. Antibiotics are continued until the woman has been afebrile and asymptomatic for about 24 hours (Duff, 2012).

To decrease the incidence of endometritis and wound infections, many physicians give a single prophylactic IV dose of an antibiotic to any woman who is having a cesarean birth or who is at an increased risk for infection. For many years, the antibiotic was given during surgery or birth, after clamping of the umbilical cord to avoid exposure of the infant to the drug. A current recommendation based on more recent studies is for the antibiotic to be administered before skin incision (Duff, 2012). Other medications include antipyretics for fever and oxytocics such as methylergonovine to increase drainage of lochia and promote involution.

Complications. If the infection spreads outside the uterine cavity, it may affect the fallopian tubes (salpingitis) or the ovaries (oophoritis), which could result in sterility. Peritonitis (inflammation of the membrane lining the walls of the abdominal and pelvic cavities) may occur and lead to formation of a pelvic abscess. In addition, the risk of pelvic thrombophlebitis is increased when pathogenic bacteria enter the bloodstream during episodes of endometritis. Figure 28-6 illustrates complications of metritis.

Salpingitis: Infection in fallopian tubes causes them to become enlarged, hyperemic, and tender.

Peritonitis: Infection spreads through the lymphatics to the peritoneum; a pelvic abscess may form.

FIG 28-6 Areas of spread of uterine infection.

Signs and symptoms that the infection is spreading may be similar to those of endometritis but more severe. Fever and abdominal pain will be particularly pronounced. Peritonitis may result in paralytic ileus and abdominal distention with absent bowel sounds.

Nursing Considerations. The woman with endometritis should be placed in a Fowler's position to promote drainage of lochia. She should be medicated as needed for abdominal pain or cramping, which may be severe. Monitor the woman's response to treatment, and note signs of improvement or of continued infection (nausea and vomiting, abdominal distention, absent bowel sounds, and severe abdominal pain). Assess vital signs every 2 hours while fever is present and every 4 hours afterward. Comfort measures include warm blankets, cool compresses, cold or warm drinks, or use of a heating pad. Foods high in vitamin C and protein to aid healing are encouraged along with oral fluids to maintain hydration.

Teaching should include signs and symptoms of worsening condition, side effects of therapy, and the importance of adhering to the treatment plan and follow-up care. If the woman is so sick that she must be separated from her infant or her infant is discharged before the mother, a nursing diagnosis of "Risk for Impaired Attachment related to separation from infant" should be considered. If the mother is breastfeeding, she will need help to pump her breasts to establish and maintain lactation.

Wound Infection

Wound infections are common types of puerperal infection because any break in the skin or mucous membrane provides a portal of entry for organisms. The most common sites are cesarean surgical incisions, episiotomies, and lacerations. Approximately 3% to 5% of cesarean incision sites become infected (Duff, 2012). Risk factors include obesity, diabetes, hemorrhage, anemia, chorioamnionitis, corticosteroid therapy, and multiple vaginal examinations.

Clinical Manifestations. Signs of wound infection are edema, warmth, redness, tenderness, and pain. The edges of the wound may pull apart, and seropurulent drainage may be present. If the wound remains untreated, generalized signs of infection, such as fever and malaise, also may develop. As with other puerperal infections, cultures may reveal mixed aerobic and anaerobic bacteria. Necrotizing fasciitis is a rare infection that may occur at any incision site. The necrosis may spread and the condition may be fatal.

Therapeutic Management. An incision and drainage of the affected area may be necessary. The wound exudate is cultured, and broad-spectrum antibiotics are ordered until a report of the organism is returned. Analgesics are often necessary, and warm compresses or sitz baths may be used to provide comfort and to promote healing by increasing circulation to the area. Surgical debridement is performed for necrotizing fasciitis.

Nursing Considerations. Despite their small size, wound infections are painful and annoying to the mother. Perineal infections cause discomfort during many activities, such as walking, sitting, or defecating, and are particularly troublesome because they are not expected by the new mother.

Wound infections may require readmission to the hospital or home health care visits. The woman requires reassurance and supportive care. Comfort measures include sitz baths, warm compresses, and frequent perineal care. She should be taught to wipe from front to back and to change perineal pads frequently. Good handwashing techniques are emphasized. Adequate fluid intake and a healthy diet are important. Activity may be modified depending on the site, severity, and treatment of the wound infection.

The infant is not routinely isolated from the mother with a wound infection, but she must be advised how to protect her infant from

contact with contaminated articles such as dressings. Anticipatory guidance should include teaching side effects of medications, signs of worsening condition, self-care measures, and the importance of handwashing.

CHECK YOUR READING

18. What are the signs and symptoms of endometritis? How is it usually treated?
19. What are the most common sites for wound infections?
20. How does the nurse assess for wound infection?

Urinary Tract Infections

Etiology. During childbirth, the bladder and urethra are traumatized by pressure from the descending fetus. Insertion of a catheter, with its risk of infection, may also occur during labor. After childbirth the bladder and urethra are hypotonic, with urinary stasis and retention common problems. Residual urine and reflux of urine may occur during voiding.

Women who had bacteria in the urine during pregnancy, often without symptoms, are at increased risk for cystitis and pyelonephritis, which may result in preterm labor. Asymptomatic bacteriuria occurs in 5% to 10% of pregnancies. Urinary tract infections are most often caused by coliform bacteria, such as *E. coli*. Other organisms include *Klebsiella pneumoniae* and *Proteus* species (Duff, 2012).

Clinical Manifestations. Symptoms typically begin on the first or second postpartum day. They include dysuria, urgency, frequency, and suprapubic pain. Hematuria may also occur. A low-grade fever is sometimes the only sign. On the third or fourth day, some women may develop an upper urinary tract infection, such as pyelonephritis, with chills, spiking fever, costovertebral angle tenderness, flank pain, and nausea and vomiting. This infection of the renal pelvis may result in permanent damage to the kidney if not promptly treated.

Therapeutic Management. Most urinary tract infections can be treated with antibiotics on an outpatient basis. Without effective treatment, about one third of pregnant women with asymptomatic bacteria will develop acute pyelonephritis (Duff, 2012). Pyelonephritis during pregnancy may require hydration and IV administration of broad-spectrum antibiotics. In addition, the woman should be observed for signs of preterm labor. If the postpartum woman is only mildly ill, she can be treated with oral antibiotics at home. Urinary analgesics such as phenazopyridine (Pyridium) may also be ordered. Antibiotics that are safe for use during lactation are given if the mother is breastfeeding.

Nursing Considerations. The woman with a urinary tract infection must be instructed to take the medication for the entire time it is prescribed and not to stop when symptoms abate. In addition, she must drink at least 2500 to 3000 mL of fluid each day to help dilute the bacterial count and flush the infection from the bladder. Acidification of the urine inhibits multiplication of bacteria, and drinks that acidify urine, such as apricot, plum, prune, and cranberry juices, are frequently recommended. Grapefruit and carbonated drinks should be avoided because they increase urine alkalinity. Teaching should also include measures to prevent urinary tract infections, such as using proper perineal care, increasing fluid intake, and urinating frequently.

Mastitis

Incidence and Etiology. Mastitis, an infection of the breast, occurs most often 2 to 4 weeks after childbirth, although it may develop at any time during breastfeeding. Approximately 2% to 10% of lactating women are affected (Newton, 2012). It usually affects only one breast. Mastitis is often caused by *Staphylococcus aureus*, *E. coli*, or

streptococci (Ambrose & Repke, 2011). The bacteria are most often carried on the skin of the mother or in the mouth or the nose of the newborn. The organism may enter through an injured area of the nipple, such as a crack or blister, although no obvious signs of injury may be apparent. Soreness and pain of a nipple may result in insufficient emptying of the breast during breastfeeding.

Engorgement and stasis of milk may precede mastitis. This may occur when a feeding is skipped, when the infant begins to sleep through the night, or when breastfeeding is suddenly stopped. Constriction of the breasts by a bra that is too tight may interfere with emptying of all the ducts and may lead to infection. The mother who is fatigued or stressed or who has other health problems that might lower her immune system is also at increased risk for mastitis.

Clinical Manifestations. Initial symptoms may be flu-like with fatigue and aching muscles. Symptoms progress to include a temperature of 39°C (102.2°F) or higher, chills, malaise, and headache. Mastitis is characterized by a localized lump or wedge-shaped area of pain, redness, heat, inflammation, and enlarged axillary lymph nodes. A hard, tender area may be palpated (Figure 28-7). Untreated mastitis may progress to breast abscess.

Therapeutic Management. Antibiotic therapy and continued emptying of the breast by breastfeeding or breast pump constitute the first line of treatment. With early antibiotic treatment, mastitis usually resolves within 24 to 48 hours. Antibiotics should be continued for a full 7 days (Newton, 2012). Women who develop a breast abscess are treated with surgical drainage and antibiotics. Approximately 10% of women with mastitis develop a breast abscess (Ambrose & Repke, 2011).

Supportive measures include application of moist heat or ice packs, breast support, bed rest, fluids, and analgesics. The mother should continue to breastfeed from both breasts. Regular and thorough emptying of the breast is important in preventing abscess formation. If an abscess forms and is surgically drained, breastfeeding can be continued as long as the incision is not near the areola and the mother is comfortable. If an abscess ruptures into the milk ducts, breastfeeding on that side should be discontinued temporarily and a breast pump used to empty the breast (Lawrence & Lawrence, 2011).

Nursing Considerations. Because mastitis rarely occurs before discharge from the birth facility, the nurse must provide adequate information for prevention. Measures to prevent mastitis include positioning the infant correctly and avoiding nipple trauma and milk stasis. The mother should breastfeed every 2 to 3 hours and should avoid formula supplements. Nursing pads should not have a plastic layer and should be changed as soon as they are wet. The mother should also avoid continuous pressure on the breasts from tight bras or infant carriers.

Once mastitis occurs, nursing measures are aimed at increasing comfort and helping the mother maintain lactation. Moist heat promotes comfort and increases circulation. A disposable diaper, wet with warm water and placed over the breast, is an easy way to apply heat. The thickness helps to maintain the temperature, and the plastic cover prevents dripping. A shower or hot packs should be used before feeding or pumping the breasts. The woman should complete the entire course of antibiotics to prevent recurrence or a breast abscess.

The breast should be completely emptied at each feeding to prevent stasis of milk. If the mother is too sore to breastfeed on the affected side, she should be shown how to express the milk or use a pump to empty the breasts.

Breastfeeding or pumping every 1.5 to 2 hours makes the mother more comfortable and prevents stasis. Starting the feeding on the unaffected side causes the milk-ejection reflex to occur in both breasts, making milk available in the painful breast as soon as the infant begins to nurse on that side. Massage over the affected area before and during

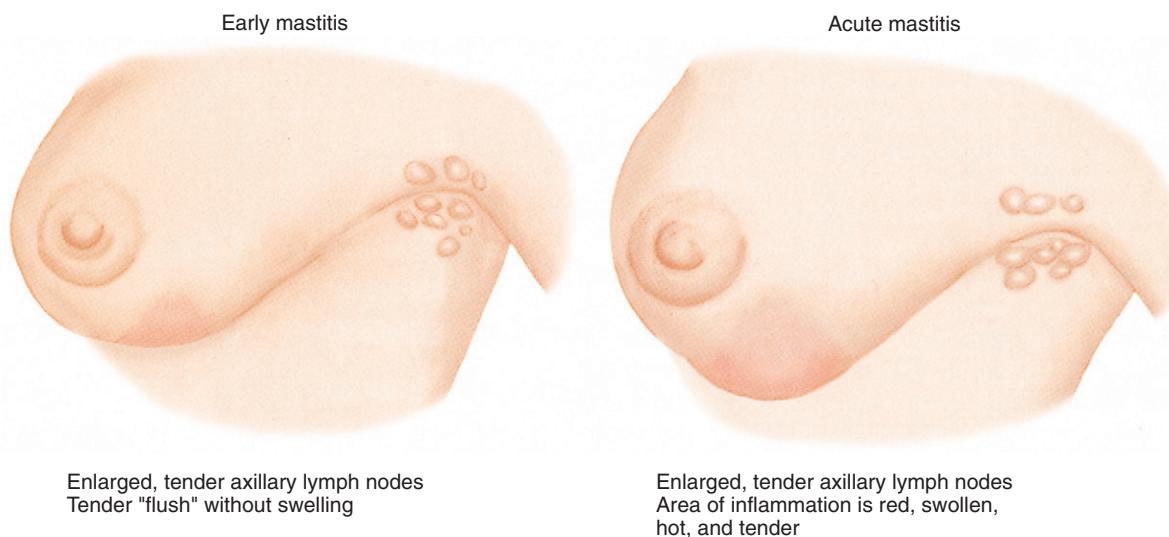

FIG 28-7 Mastitis typically occurs after 2 to 3 weeks following birth in the breast of a woman who breastfeeds.

the feeding helps to ensure complete emptying. The mother should stay in bed during the acute phase of her illness. Her fluid intake should be 2500 to 3000 mL per day. Analgesics may be required to relieve discomfort.

The mother with mastitis is likely to be very discouraged. Some mothers decide to stop breastfeeding because of the discomfort involved. Weaning during an episode of mastitis may increase engorgement and stasis, leading to abscess formation or recurrent infection. The mother may need much encouragement, and she will need help in arranging care for other children or with other responsibilities so that she can rest. The nurse should tell the mother to expect lower milk production from the affected breast for a short time after the infection and that milk supply will return to normal in a few weeks (Riordan & Wambach, 2010). The nursing diagnosis "Interrupted Breastfeeding related to discomfort, infectious process, or effects of therapy" may be appropriate.

Septic Pelvic Thrombophlebitis

Incidence and Etiology. Septic pelvic thrombophlebitis is the least common of the puerperal infections, occurring in 1 of 3000 pregnancies (Ambrose & Repke, 2011). It usually is not seen until 2 to 4 days after childbirth. It occurs when infection spreads along the venous system and thrombophlebitis develops. It develops more often in women with wound infection and usually involves one or both ovarian veins, called *ovarian vein syndrome*. A less frequent form is enigmatic fever, in which the only manifestation is fever.

Clinical Manifestations. In ovarian vein syndrome, the primary symptom is pain in the groin, abdomen, or flank. Also present may be fever, tachycardia, nausea, vomiting, bloating, gastrointestinal distress, and decreased bowel sounds. In enigmatic fever, spiking fever that does not respond to antibiotics and tachycardia may be the only signs in a woman who is originally treated for endometritis. After initial improvement, the woman appears well except for the fever (Duff, 2012).

Laboratory data may be used to exclude other diagnoses and usually include complete blood count with differential, blood chemistries, coagulation studies, and cultures. Computed tomography, magnetic resonance imaging (MRI), or pelvic ultrasound may be performed to confirm the diagnosis.

Therapeutic Management. Readmission to the hospital is usually necessary. Primary treatment includes anticoagulation therapy with IV heparin and IV antibiotics. Warfarin may be given when heparin is discontinued. Improvement usually occurs within 2 to 3 days of anticoagulation therapy (Duff, 2012). Supportive care is similar to that for DVT and includes monitoring for safe levels of anticoagulation therapy and for signs and symptoms of pulmonary embolism.

APPLICATION OF THE NURSING PROCESS

■ Infection Assessment

Although all women are observed for indications of infection as part of routine nursing assessments, the nurse must practice increased vigilance for mothers who are at increased risk of infection.

Pay particular attention to signs that may be expected in infection, such as fever, tachycardia, pain, or unusual amount, color, or odor of lochia. Generalized symptoms of malaise and muscle aching may also be significant. Examine all wounds each shift for signs of localized infection, such as redness, edema, tenderness, discharge, or pulling apart of incisions or sutured lacerations. Ask the mother if she has difficulty emptying her bladder or discomfort related to urination.

Assess the mother's knowledge of hygiene practices that prevent infections, such as proper handwashing, perineal care, and handling of perineal pads. Evaluate her knowledge of breastfeeding and any problems that might result in breast engorgement and stasis of milk in the ducts. Examine the nipples for signs of injury that might provide a portal of entry for organisms.

Nursing Diagnosis

Because all women are at risk for infection after childbirth, most facilities have developed standards of practice that protect postpartum women from infection. When predisposing factors increase the likelihood of infection, however, routine assessments and care must be modified and preventive measures intensified. In this case the most relevant nursing diagnosis is "Risk for Infection related to the presence of significant risk factors."

Planning

The expected outcomes for this nursing diagnosis are that the mother will:

- Remain free of signs of infection during the postpartum period.
- Describe methods to prevent infection.
- List signs of infection that should be reported immediately.

SAFETY ALERT

Signs and symptoms of postpartum infection include:

- Fever, chills
- Pain or redness of wounds
- Purulent wound drainage or wound edges not approximated
- Tachycardia
- Uterine subinvolution
- Abnormal duration of lochia, foul odor
- Elevated white blood cell count
- Frequency or urgency of urination, dysuria, or hematuria
- Suprapubic pain
- Localized area of warmth, redness, or tenderness in the breasts
- Body aches, general malaise

Interventions

Preventing Infection

Promoting Hygiene. Nursing responsibilities for the woman at risk for puerperal infection focus on prevention of initial infection. Preventive measures include using aseptic technique for all invasive procedures and paying attention to meticulous handwashing. Handwashing is important for the nursing staff and the mother. She should wash her hands before and after changing pads or touching the perineum. Instruct her on care of the perineum and episiotomy site (see [Chapter 17](#)). Make sure that she can demonstrate cleansing methods before she is discharged.

Preventing Urinary Stasis. An adequate intake of fluids (at least 2500 to 3000 mL/day) is important for preventing stasis of urine. Encourage the woman to empty her bladder at least every 2 to 3 hours during the day. Measure the first two voidings after childbirth or removal of a urinary catheter, and assess the bladder and fundus to be certain the bladder is empty. Instruct her to report any signs of urinary tract infection immediately so that early treatment can be initiated.

Use appropriate measures to promote bladder emptying if she has difficulty. Drinking hot fluids, such as tea, helps some mothers void. Running water or having the mother blow bubbles in a glass of water uses the sound of water to stimulate the urge to urinate. Pouring warm water over the perineum or having the mother void in a sitz bath or shower may help relax the urinary sphincter. Administration of analgesics may help her relax enough to urinate.

Teaching Breastfeeding Techniques. Mothers often need assistance in establishing an effective pattern of breastfeeding that results in complete emptying of the breasts at each feeding and that reduces the risk of nipple trauma (see [Chapter 22](#)).

Providing Information. Advise mothers to obtain adequate rest and sufficient food of high nutritive value to replenish their energy and prevent infection. Identify foods high in protein and vitamin C, necessary for repair of damaged tissue. Red meat, poultry, fish, cheese, eggs, whole-grain breads, cereals, and pasta are some of the best sources of protein. This is particularly important if the mother is breastfeeding.

Obtaining adequate rest is a problem for many mothers. Nursing interventions focus on helping them plan a schedule that allows them to rest while the infant sleeps and to identify family members or friends who are available to provide support and assistance.

Teaching Signs and Symptoms That Should Be Reported

Before discharge, teach the woman signs and symptoms of infection that should be reported to her health care provider. These include fever, chills, dysuria, and redness and tenderness of a wound. Malodorous lochia, discharge from a wound, and prolonged lochial discharge also should be reported.

Evaluation

The interventions can be judged to be successful if the mother:

- Shows no signs of infection.
- Explains methods she will use to prevent infection.
- Lists signs and symptoms that she should report to her health care provider.

If infection occurs, the problem is no longer amenable to independent nursing actions but becomes a collaborative problem requiring medical and nursing interventions.

22. How can mastitis be prevented?

AFFECTIVE DISORDERS

The postpartum period is a time of change and adjustment for the mother and the family. Postpartum women have an increased risk for mood disorders (blues, depression and psychoses, and rarely, bipolar disorders) and for anxiety disorders (obsessive-compulsive disorder, generalized anxiety disorder, panic disorder). The American Psychiatric Association considers an onset of a mental disorder during the peripartum or postpartum period a subset of the disorder, not a separate condition ([Stuart, 2013](#)).

Postpartum Mood Disorders

Mood disorders are disturbances in function, affect, or thought processes that can affect the family after childbirth as severely as physiologic problems. Postpartum blues (*baby blues*) is a transient, self-limiting mood disorder (discussed in [Chapter 18](#)). Postpartum depression (PPD), postpartum psychosis, and bipolar disorder are more serious disorders that disrupt the family and require intervention.

Postpartum Depression

The American Psychiatric Association (2013) defines “peripartum depression” as a period of depression with onset during pregnancy or within 4 weeks after childbirth that lasts at least 2 weeks. It includes depressed mood or loss of interest in almost all activities. It also includes at least four of the following: changes in appetite or weight, sleep, and psychomotor activity; decreased energy; feelings of worthlessness or guilt; difficulty thinking, concentrating, or making decisions; recurrent thoughts of death or suicide; or death or suicide plans or attempts.

Incidence. PPD is the most common complication of childbirth, affecting 10% to 15% of postpartum women ([Stuart, 2013](#)). Women of all ethnic groups and educational levels are affected. Postpartum depression is underdiagnosed and underreported ([Goodman & Tyer-Viola, 2010](#)). It usually develops during the first 3 months but may occur at any time during the first year postpartum.

Predictors of Postpartum Depression. PPD is more likely to occur in primigravidas but can develop after any pregnancy. Factors

NURSING CARE PLAN 28-1

Postpartum Infection

ASSESSMENT: Lisa, a thin, pale, 16-year-old primipara, is admitted to the postpartum unit after a cesarean birth because of fetal distress. She was in labor for 16 hours and her membranes were ruptured for 14 hours before the birth. She was catheterized twice during labor, with insertion of an indwelling catheter shortly before her surgery. She plans to breastfeed her infant.

Critical Thinking: *What data indicate that Lisa is at increased risk for infection? What additional data should be obtained?*

Answer: *Factors that increase the risk for endometritis include a cesarean birth and rupture of membranes 14 hours before the surgery was performed. Catheterization increases the risk for urinary tract infection. Additional necessary data to better evaluate the risks for infection include estimated blood loss and prenatal conditions such as anemia or other infections.*

NURSING DIAGNOSIS: Risk for Infection related to presence of favorable conditions for infections

EXPECTED OUTCOMES: Before discharge Lisa will:

1. Demonstrate no signs of infection.
2. Discuss methods she will use to prevent infections.
3. List signs of infection she will report to her health care provider.

INTERVENTIONS AND RATIONALES

1. Assess vital signs every 4 hours. *Temperature above 38°C (100.4°F) or tachycardia suggests an infectious process and should be reported.*
2. Observe the surgical incision for redness, tenderness, edema, drainage, and approximation, and note the odor of lochia every 4 hours. Determine character of urine and whether Lisa experiences frequency, urgency, or pain with urination after the catheter is removed. *Redness, pain, or edema of the incision suggests wound infection. Drainage could be bleeding or a sign of infection. Separation also can indicate infection. Foul odor of lochia suggests endometrial infection. Frequency, urgency, or painful urination may indicate urinary tract infection.*
3. Instruct Lisa in hygienic practices to prevent infection:
 - a. Careful handwashing before and after perineal care. *Hand washing is the most important defense against infection and its spread.*
 - b. Perineal cleansing after elimination. *Perineal cleansing helps prevent growth of bacteria.*

- c. Changing peripads frequently. *Frequent pad changes remove accumulated lochia, an excellent culture medium for bacteria.*
 - d. Wiping the perineum from front to back. *Wiping from front to back prevents fecal contamination of the vagina.*
4. Initiate measures to reduce the risk of urinary tract infection.
 - a. Provide fluids of Lisa's choice when she is able to take them, and emphasize the importance of drinking 2500 to 3000 mL/day. *Adequate hydration helps prevent stasis of urine, which increases the risk of urinary tract infection.*
 - b. Monitor bladder distention to prevent overfilling. Teach Lisa the importance of emptying her bladder every 2 to 3 hours during the first days after childbirth. *Frequent emptying of the bladder helps prevent stasis of urine.*
 - c. Use methods to promote bladder emptying, such as running water in the shower or sink, pouring warm water over the perineum, and providing pain medication as needed. *The sound of running water may stimulate the urge to void. Relief of pain may allow the mother to relax enough to void.*
 5. Assist Lisa with breastfeeding. Explain the reasons for proper positioning and frequent, adequate feedings. *Poor positioning and short, infrequent feedings may cause nipple trauma, engorgement, and incomplete emptying of the breasts, leading to mastitis.*
 6. Offer and encourage Lisa to eat well-balanced meals when she progresses to a regular diet. Emphasize the importance of a diet high in protein and vitamin C. *Adequate protein and vitamin C is necessary for healing damaged tissues.*
 7. Organize nursing care to allow periods of rest. *Rest is important to help the body heal and fight infection.*
 8. Teach Lisa signs of infection that she should report to her health care provider. Include fever, chills, dysuria, increased incisional tenderness or drainage, lochia with a foul odor, or pain and redness of the breast. *Prompt recognition and reporting of signs of infection ensures early treatment and reduces further complications.*

EVALUATION: Lisa is free of signs and symptoms of infection throughout her hospital stay and at her postpartum checkup. She verbalizes measures she will take to reduce her risk of infection when she is discharged from the hospital. She is able to list signs of infection that require treatment.

that are believed to increase the risk are listed in [Box 28-3](#). The cause of PPD is unknown. Theories include interactions between biochemical, genetic, and psychosocial factors, and life stress.

Clinical Manifestations. Postpartum depression may resemble postpartum blues at first. However, PPD is differentiated from the normal labile emotions of pregnancy and the postpartum period by the number, intensity, and persistence of symptoms. Most of the symptoms are intensely and consistently present for at least a 2-week period and tend to become worse over time. The woman experiencing PPD shows a depressed mood with loss of interest in her usual activities and a loss of her usual emotional response toward her family. These are not mood swings but a persistent depressed state. Even though she cares for her infant, she is unable to feel pleasure or love. She sees the infant as demanding and herself as inept at mothering.

The woman may have intense feelings of anxiety, unworthiness, guilt, agitation, and shame, and she often expresses a sense of loss of self. Generalized fatigue, irritability, complaints of ill health, and

difficulty in concentrating and making decisions are also present. She often has little interest in food, may have weight changes, and experience sleep disturbances (insomnia or excessive sleeping).

Impact on the Family. PPD creates strain on the family's usual methods of coping and often causes difficulties in relationships. Stressors tend to be magnified, and, as a result, family members may decrease their interactions with the depressed mother at a time when she needs support the most. Communication is impaired because she gradually withdraws from contact with others. The decreased libido commonly associated with depression may also affect her relationship with her significant other.

Partners of depressed women report a sense of loss of the partner and the relationship they had known previously. They express feelings of loss of control, anger, frustration, and embarrassment. Fathers may take on household chores and child care duties that the depressed mother is unable to manage. The father may also suffer from depression.

BOX 28-3 RISK FACTORS FOR POSTPARTUM DEPRESSION

Depression during pregnancy or previous PPD (strong predictors)

- First pregnancy
- Hormonal fluctuations that follow childbirth
- Medical problems during pregnancy or after birth, such as preeclampsia, preexisting diabetes mellitus, anemia, or postpartum thyroid dysfunction
- Personal or family history of depression, mental illness, or alcoholism
- Personality characteristics, such as immaturity and low self-esteem
- Marital dysfunction or difficult relationship with the significant other, resulting in lack of support
- Anger or ambivalence about the pregnancy
- Single status
- Young maternal age
- Feelings of isolation, lack of social support, or support that does not meet the mother's needs
- Fatigue, lack of sleep
- Financial worries
- Child care stress (infant who is ill, has anomalies, or has a difficult temperament)
- Multifetal pregnancy
- Chronic stressors
- Unwanted or unplanned pregnancy

⚡ SAFETY ALERT

Signs and symptoms of postpartum depression include:

- Anxiety
- Feelings of guilt
- Agitation
- Fatigue, sleeplessness
- Feeling unwell
- Irritability
- Difficulty concentrating or making decisions, confusion
- Appetite changes
- Loss of pleasure in normal activities
- Lack of energy
- Crying
- Sadness
- Depression (may not be present at first)
- Suicidal thoughts
- Less responsive to infant

Depressed mothers interact differently with their infants than do women who are not depressed. They appear tense, are more irritable, and feel less competent as mothers. They may not notice the infant's cues or smiles and may therefore fail to meet the infant's needs and to enjoy the positive feedback. They are less likely to provide healthy feeding and sleep practices or positive enrichment activities with their infants. Maternal PPD creates a home environment that may have a negative effect on the development of the infant's physical and psychosocial development (Earls, 2010).

Therapeutic Management. Depression responds best to a combination of psychotherapy, social support, and medication. Psychotherapy may be helpful to assist the woman to cope with changes in her life. The woman's partner and immediate family must be included in counseling sessions so they can develop an understanding of what the

woman feels and needs. Although Letourneau, Stewart, Dennis et al., (2011) did not find peer support an effective treatment for PPD, Dennis (2010) demonstrated positive results when peer support was used as a preventative strategy.

If psychotherapy alone is not effective, it should be combined with medication. Selective serotonin reuptake inhibitors and tricyclic antidepressants are the most commonly prescribed medications. It may take up to 4 weeks for the medications to be fully effective, and they may be continued for 9 to 12 months after remission of symptoms. Whether the woman is still pregnant or is breastfeeding must be considered when any drugs are prescribed because some are safer than others for use in pregnancy and lactation. Women who discontinue medications for depression during pregnancy are more likely to have a relapse during pregnancy or postpartum (Haskett, 2011).

Postpartum Psychosis

Psychosis is a mental state in which a person's ability to recognize reality, communicate, and relate to others is impaired. Postpartum psychosis can be classified as a depressed or a manic type of psychosis (Stuart, 2013). It is a rare condition that affects 1 or 2 women per 1000 births. It can occur as early as 2 days after delivery and is a psychiatric emergency which usually requires hospitalization. Manifestations include agitation, irritability, rapidly shifting moods, disorientation, and disorganized behavior. Some mothers also have delusions about the baby and may experience hallucinations (Miller, 2011). Women who have had one episode of postpartum psychosis are at increased risk for having another episode. Management requires hospitalization, pharmacologic treatment, and psychiatric care (Cunningham et al., 2010).

Assessment and management of postpartum psychosis are beyond the scope of maternity nurses, and mothers who experience this condition must be referred to specialists for comprehensive therapy.

Bipolar II Disorder

Women with bipolar disorder suffer from periods of irritability, hyperactivity, euphoria, and grandiosity. They exhibit little need for sleep and are seldom aware they have a problem. The poor judgment and confusion they experience make self-care and infant care impossible and can be life-threatening for the mother and infant.

The depressions of the bipolar disorder and major depression are similar and are characterized by tearfulness, preoccupations of guilt, feelings of worthlessness, sleep and appetite disturbances, and an inordinate concern with the baby's health. Delusions about the infant being dead or defective are common. Hallucinations may also be present. Women who have depressive symptoms must be assessed for risk of suicide or harming the infant and treated according to the severity of the threat.

Postpartum Anxiety Disorders

Postpartum anxiety disorders include panic disorder, postpartum obsessive-compulsive disorder (OCD), and post-traumatic stress disorder. Panic disorder manifests as episodes of tachycardia, palpitations, shortness of breath, chest pain, and fear of dying or of "going crazy." Episodes are repetitive and interfere with the woman's daily life. Anti-anxiety and antidepressant medications and counseling are the treatment for this condition.

Postpartum OCD is a condition in which the woman has consuming thoughts that she might harm the baby and fears being alone with the baby. Anxiety and depression occur, and the woman may perform compulsive behaviors to avoid acting on her thoughts (Hudak & Wisner, 2012). Treatment includes antianxiety and antidepressant medications and counseling.

In post-traumatic stress disorder (PTSD), women perceive childbirth as a traumatic event. Beck, Gable, Sakala et al. (2011) found that 9% of the new mothers they sampled screened positive for meeting the criteria for post-traumatic stress disorder and another 18% had scores which indicated that they were experiencing elevated levels of post-traumatic stress symptoms. Women with PTSD have nightmares and flashbacks about the event, anxiety, and avoidance of reminders of the traumatic event; many have depression after giving birth. Feeling a lack of caring or communication or having a birth very different from what they expected may contribute to this disorder. Women need to talk about their experiences and how they perceived them and often search for answers about their experiences. They may feel isolated from their infants and have prolonged difficulty feeling close to them.

EVIDENCE-BASED PRACTICE

Post-traumatic stress disorder (PTSD) is an anxiety disorder that develops after a traumatic event. Symptoms include reliving the traumatic event (flashbacks or nightmares), avoiding feelings, people and places associated with the event and having increased anxiety that can result in irritability, outbursts, and insomnia. Perinatal PTSD occurs when the woman perceives the pregnancy or birth as a traumatic event. Beck, Gabel, Sakala & Declercq (2011) examined data from a two-stage United States national survey conducted by Childbirth Connections: Listening to Mothers II (LTMII) and Listening to Mothers II Postpartum Survey (LTMIIIPP). The surveys were completed online or over the telephone.

The researchers found that 9% of the new mothers screened positive for meeting the diagnostic criteria for PTSD; 18% demonstrated elevated levels of post-traumatic stress symptoms. They found a strong relationship between increased posttraumatic stress symptoms and the number of depressive and physical symptoms experienced by the new mothers. They also found that the following factors were associated with increased incidence of post-traumatic stress symptoms: no private health insurance, unplanned pregnancy, pressure to have an induction or epidural analgesia, planned cesarean birth, not breastfeeding as long as the mother wanted, not exclusively breastfeeding at 1 month, and consulting with a clinician about mental well-being since birth.

Questions

1. Why do you think so many women perceive birth as a traumatic event?
2. What can nurses do to decrease this rate?
3. How should nurses intervene with a woman whose birth experience was not what she expected?

Beck, C.T., Gable, R.K., Sakala, C., & Declercq, E.R. (2011). Posttraumatic stress disorder in new mothers: Results from a two-stage U.S. national survey. *Birth* 38(3), 216-227.

Cultural Aspects

Postpartum depression has been shown to occur in many cultures, and the risk factors are frequently similar to those found in Western cultures. Risk is also increased in cultures with gender-based factors (preference for male babies, role restrictions for women, excessive unpaid workload, and in multigenerational households where the daughter-in-law has little autonomy (Fisher, de Mello, Patel et al., 2012).

APPLICATION OF THE NURSING PROCESS

Postpartum Affective Disorders

Assessment

Early identification and treatment of postpartum mood and anxiety disorders is a significant factor in the duration of the conditions

CRITICAL THINKING EXERCISE 28-2

Aricella, a 23-year-old multipara, gave birth 5 days ago to her second baby. It is obvious to the nurse making a telephone follow-up call after discharge that Aricella is crying. She says, "I don't know what's wrong with me! I can barely get out of bed in the morning and I'm worn out just trying to take care of the kids." The nurse responds, "Oh, that's just the 'baby blues'. Just look at that beautiful baby and you'll feel better."

Questions

1. What assumptions has the nurse made?
2. Is the nurse's response helpful for Aricella? Why or why not?
3. What would be a more therapeutic response?
4. What additional action should the nurse take?

(Association of Women's Health, Obstetric & Neonatal Nurses, 2008). Assess all women for depression during pregnancy, at the birth facility, and during follow-up visits after birth. The woman should be reassessed at each contact with health care providers (including follow-up telephone calls). Women whose infants are in a neonatal intensive care unit should be assessed for PPD during visits to their infants. New mothers take their infants to the pediatrician's office frequently during the early months after childbirth. These are ideal settings in which to include assessment of the new mother's emotional state and provide referrals if necessary (Earls, 2010).

Assessment tools such as the Postpartum Depression Predictors Inventory-Revised may be helpful. This inventory identifies prenatal depression, life stress, social support, prenatal anxiety, satisfaction with marital relationship, history of depression, self-esteem, unwanted or unplanned pregnancy, marital status, socioeconomic status, child care stress, infant temperament, and maternity blues as factors that may predict the likelihood of a woman developing PPD (Beck, Records, & Rice, 2006). In addition, screening for excessive fatigue in the first 2 weeks after childbirth may help identify women who will later develop PPD and enable them to get early treatment.

Other screening tools include the Edinburgh Postnatal Depression Scale and the Postpartum Depression Screening Scale. Ask the woman if she is often sad or depressed, or if she has felt a loss of pleasure or interest in things she once enjoyed. These questions may enable early identification and treatment of depression and may reduce the duration and severity (Earls, 2010). Asking shows interest and acceptance of expressions of feelings and opens the door for further discussion. Inform the mother that many women feel depressed after childbirth and that help is available.

Observe for subjective symptoms, such as apathy, lack of interest or energy, anorexia, or sleeplessness. The mother's verbalizations of failure, sadness, loneliness, anxiety, or vague confusion are important cues. Focus on the frequency, duration, and intensity of the woman's feelings to determine their severity.

Assess for objective data, such as crying, sleeplessness, poor personal hygiene, or inability to follow directions or to concentrate. Determine what, if any, support is available. Mothers with an absent or unavailable support system may feel increasingly isolated, leading to stress and a feeling that they are unable to manage. Inappropriate expressions of blame or anger toward the partner and unmet expectations of the baby or the parenting role are sometimes present.

Nursing Diagnosis

A likely nursing diagnosis is Risk for Ineffective Coping related to depression secondary to stressors associated with childbirth and parenting (Box 28-4).

BOX 28-4 COMMON NURSING DIAGNOSES FOR THE WOMAN WITH A POSTPARTUM COMPLICATION

Activity Intolerance
 Fatigue
 Interrupted Breastfeeding
 Pain
 Risk for Impaired Attachment
 Risk for Ineffective Coping*
 Risk for Bleeding*
 Risk for Infection*

*Nursing diagnoses discussed in this chapter.

Planning

To achieve the expected outcomes for this nursing diagnosis, the new mother will:

- Verbalize feelings with the health care provider and significant other throughout the postpartum period.
- Discuss her own strengths.
- Identify available resources for the postpartum period.

Interventions

Providing Anticipatory Guidance

Because of short hospital stays for new mothers, and timing of the usual onset of affective disorders, most incidences of postpartum depression (and postpartum psychosis) occur after the woman has gone home. Anticipatory guidance of the mother and her family is the most critical nursing intervention. Success of treatment is largely affected by early diagnosis. During the prenatal period, initiate a discussion with all pregnant women and their partners to provide anticipatory guidance about the early weeks at home. Explain the signs of PPD and the importance of seeking early help to decrease the length of time the condition lasts.

Discuss the need for frequent contact with other adults so that the mother does not become isolated. Emphasize the importance of continued communication with the partner or a close friend who can provide support when loneliness or anxiety becomes a problem.

Explain that adequate rest and nutrition can help the mother maintain energy and a feeling of health and well-being. Teach mothers and their support persons the signs of PPD and other postpartum psychological disorders, including when they should seek help.

Demonstrating Caring

Conveying a caring attitude is an important nursing strategy to help mothers decrease their emotional distress and to guide them in regaining their well-being during the postpartum period. Acknowledge that something is wrong and that the woman seems depressed. Spend time with her and reassure her that the condition is not her fault.

Explain to the woman that what she is feeling is a common experience after childbirth. Encourage her to talk about her feelings and reassure her that help is available for her.

Helping the Mother Verbalize Feelings

Because women are expected to be happy after giving birth, many women do not discuss their negative feelings with others. They may feel ashamed and believe a social stigma is attached to admitting to depression at any time and especially after giving birth. They may fear

that their infants may be taken away from them if they disclose their problem. If they do discuss their feelings, their friends or even health care workers may trivialize the problem by making comments such as, “You’ll get over it. After all, you have a beautiful baby.” Women and their families minimize depression because they cannot find the exact cause.

Recommend that although some of her feelings may seem “unreasonable” (anger, guilt, shame), the woman should acknowledge negative feelings to herself and insist that others recognize them too. Discuss the realities of parenting and the fact that it is often exhausting. It may be helpful to rehearse some of the situations that may occur, such as a fussy baby or being home alone and feeling lonely.

Enhancing Sensitivity to Infant Cues

Point out infant cues and explain their meaning. Model behavior to show the mother how to respond to the infant’s cues. Suggest measures that may enhance her sensitivity to cues. Kangaroo care (skin-to-skin contact) has demonstrated some success in reducing symptoms of postpartum depression (Bigelow, Power, MacLellan-Peters et al., 2012). Measures to help the mother relax may help improve her mood and her response to her infant.

Assess the infant’s growth and development. Depressed mothers may not give the care and nurturing needed. Determine the infant’s weight gain or loss, and observe the mother’s response to the infant’s crying. If the mother is breastfeeding, make suggestions to help her continue because it may increase her feelings of closeness to the infant. If she is taking medication, be sure that it is recommended for use during lactation.

Helping Family Members

Include the father in discussions about depression, before and after the birth. Acknowledge his feelings and those of the mother. Stress his role in helping his partner and other family members. Offer practical suggestions of ways he can help manage the changes in their lives. Discuss ways to help, such as arranging for the mother to get more sleep and to eat better, which may help decrease her irritability and anxiety. Determine the father’s need for additional support. Fathers may be reluctant to seek help from professionals and from their informal support group. They may need information and instrumental support (Doucet, Letourneau & Blackmore, 2012). Explain the impact of PPD on each family member. Emphasize the importance of the mother taking medications as ordered. Discuss signs that the mother is getting worse and when to call the health care provider.

Providing Help

Explore practical suggestions with the family on how to help the mother. Explain the importance of sleep and suggest that another family member care for the infant at night, if possible, to allow the mother to sleep. Because depressed mothers do not interact with their infants well, emphasize the importance of other family members holding and interacting with the infant.

Discussing Options and Resources

Ask the mother about stressors in her life that may be contributing to her depression. Help her plan ways to reduce common areas of stress. Assist the mother and her partner to identify people who are available to provide support. In addition, provide telephone numbers for local PPD support groups. Internet sources are another place to find help. Examples are Postpartum Support International (www.postpartum.net), Depression After Delivery (ww2.depression-afterdelivery.com), and the National Women’s Health Information Center (www.womenshealth.gov).

Evaluation

The interventions have been successful if the mother:

- Talks about her feelings to staff and family members.
- Identifies her personal strengths.
- Discusses community and family resources and makes plans to use them.

SUMMARY CONCEPTS

- Postpartum hemorrhage can sometimes be prevented by careful examination of factors that predispose to excessive bleeding.
- Overstretching of the muscle fibers during pregnancy and repeated stretching during past pregnancies predispose to uterine atony and excessive uterine bleeding.
- Initial management of uterine atony focuses on measures to contract the uterus and provide fluid replacement.
- Soft tissue trauma (lacerations, hematomas) can cause rapid loss of blood even when the uterus is firmly contracted. Management involves repairing the trauma before excessive blood loss occurs.
- Compensatory mechanisms maintain the blood pressure so that vital organs receive adequate oxygen. When these mechanisms fail, hypovolemic shock follows.
- The process of uterine involution may be delayed (subinvolution) when placental fragments are retained or when the uterus is infected.
- Subinvolution of the uterus develops after the mother goes home. The nurse teaches the family the process of normal involution and the signs and symptoms that should be reported to the health care provider.
- Venous stasis that occurs during pregnancy, increased levels of coagulation factors, and decreased levels of thrombolytic factors that persist into the postpartum period increase the risk of thrombus formation during the puerperium.
- Treatment for deep venous thrombosis includes anticoagulants, analgesics, and bed rest with the affected leg elevated.
- Nurses who administer anticoagulant therapy monitor the mother's laboratory test results for therapeutic medication dosage so that

23. What are the symptoms of PPD, and how does PPD differ from postpartum blues?
24. How can nurses intervene for PPD?
25. What is the therapeutic management for postpartum psychosis?

overmedication with anticoagulants does not result in unexpected bleeding.

- Pulmonary embolism occurs when a clot is dislodged from the vein, or amniotic fluid debris is carried by the blood to a pulmonary vessel, which may be completely or partially occluded.
- The risk of infection is increased with childbearing because bacteria has open access from the vagina through the fallopian tubes and into the peritoneal cavity. Increased blood supply to the pelvis and the alkalization of the vagina by the amniotic fluid further increase the risk of infection.
- Any break in the skin or mucous membranes during childbirth provides a portal of entry for pathogenic organisms and increases the risk of puerperal infection. Nurses must assess women with an incision or laceration for signs of localized wound infections.
- Urinary stasis and trauma to the urinary tract increase the risk of urinary tract infection. Nurses must initiate measures to prevent urinary stasis.
- Nurses must provide information about the importance of completely emptying the breasts at each feeding and about measures to avoid nipple trauma to prevent mastitis.
- Mood disorders include postpartum blues, postpartum depression, and postpartum psychosis.
- Postpartum depression is a disabling affective disorder that affects the entire family. Nurses help the woman acknowledge her feelings and assist her in identifying measures that will help her cope with the condition.
- Anxiety disorders include panic disorder, postpartum obsessive-compulsive disorder, and post-traumatic stress disorder.

High-Risk Newborn: Complications Associated with Gestational Age and Development

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the implications of late preterm birth.
2. Explain the special problems of the preterm infant.
3. Identify common nursing diagnoses for preterm infants and explain the nursing care for each.
4. Explain the complications that may result from premature birth.
5. Describe the characteristics and problems of the infant with postmaturity syndrome.
6. Explain the effects of fetal growth restriction.
7. Compare the problems of the large-for-gestational-age infant with those of the small-for-gestational-age infant.

Maternity nurses identify and begin care for the immediate needs of neonates with complications until nurses from the neonatal intensive care unit (NICU) can assume care. Neonatal intensive care nursing is a specialty that requires additional education and experience to prepare for this role. NICU nurses often attend births when complications of the newborn are expected.

CARE OF HIGH-RISK NEWBORNS

Nurses care for minor illness in the mother-baby unit or the normal newborn nursery, but more serious problems require intensive care in NICUs, specialized nurseries designed for that purpose (Figure 29-1). Approximately 9% of all newborns are sick enough at birth to require intensive care (Carlo, 2011c).

Multidisciplinary Approach

The care of infants with problems at birth often involves collaboration among many different professionals. In the hospital setting, such professionals may include nurses, nurse practitioners, physicians with different specialties, respiratory therapists, laboratory personnel, and pharmacists. Care from social workers, physical therapists, feeding specialists, occupational therapists, and infant development experts may begin during the hospital stay and continue after the infant is discharged. Nurses often must coordinate this care and explain or clarify it for parents.

LATE PRETERM INFANTS

Infants born between 34% and 36% weeks of gestation are called **late preterm infants** (LPIs) because they have many needs that are similar to those of preterm infants. They are more stable than preterm infants but are physiologically and metabolically immature and have higher mortality and morbidity rates compared with full-term infants. In 2005, the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) launched a multiyear Late Preterm Infant Initiative to develop evidence-based practice guidelines for care of the late preterm infant. Results of the study showed 46% of late preterm infants spent some time in a special care nursery. Hypothermia, hypoglycemia, feeding difficulties, hyperbilirubinemia, respiratory distress, and/or a need for a septic workup occurred in half of the infants studied (Cooper, Holditch-Davis, Verklan et al., 2012). More information is available at www.AWHONN.org.

Incidence and Etiology

Late preterm births comprised 8.28% of births in 2011 (Hamilton, Hoyert, Martin et al., 2013). Contributing factors in late preterm birth include elective and medically indicated inductions and cesarean births, preterm labor, premature rupture of membranes, preeclampsia, multifetal pregnancies, obesity, assisted reproductive technology, advanced maternal age, and inaccurate estimate of gestational age before delivery (Ramachandrapa & Jain, 2011).

FIG 29-1 The infant in a neonatal intensive care unit is cared for by nurses with highly specialized skills.

Characteristics of Late Preterm Infants

Because late preterm infants often look like full-term infants, they may not be recognized as being preterm. However, they are physiologically immature. They are at risk for respiratory disorders, problems with temperature maintenance, hypoglycemia, hyperbilirubinemia, feeding difficulties, acidosis, and infection (such as respiratory syncytial virus) because of their immaturity (Coffman, 2009; Pappas & Walker, 2010; Ramachandrappa & Jain, 2011). They are also at risk for long-term neurodevelopmental disorders as well as cognitive and behavioral problems (Talge, Holzman, Wang et al., 2010). They are more likely to be admitted to the NICU after birth and are at increased risk for rehospitalization after discharge.

Therapeutic Management

Therapeutic management varies according to the problems presented. Many interventions are similar to those for preterm infants discussed in this chapter.

Nursing Considerations

Assessment and Care of Common Problems

LPIs may receive care similar to full-term infants, but, compared with full-term infants, these infants need closer monitoring for complications during the hospital stay. Nursing care is similar to that given to preterm infants in many aspects.

Thermoregulation. Once stable, normal newborns usually have their temperature checked only once a shift. A late preterm infant may develop cold stress that is not noticed until signs appear or it is time for the next vital sign assessment. Therefore, nurses should be more vigilant in watching for thermal instability in these infants. The temperature, as well as other vital signs, should be checked every 3 to 4 hours for the first 24 hours and then every shift, depending on need and agency policy (AWHONN, 2010; Ramachandrappa & Jain, 2011). **Kangaroo care (KC)**, a method of providing skin-to-skin contact between infants and their parents, is often used to keep infants warm. A radiant warmer or an incubator may also be used if the infant cannot maintain normal temperature.

Feedings. Late preterm infants may have immature suck and swallow reflexes, have shorter awake periods, and may fall asleep during feedings before they have fed adequately (Cleveland, 2010). They may have difficulty with latch when breastfeeding. Their low tone and weak suck may decrease the amount of milk they obtain with each suck (Walker, 2008). They have an increased caloric need and should be fed every 2 to 3 hours.

Feeding problems are common and nurses should assess feeding sessions to ensure swallowing is occurring. Breastfeeding mothers need special help to see that infants are feeding well. The football and cross-cradle holds are helpful in positioning these infants at the breast. Urine and stool output are monitored as indications of adequate intake. Breastfeeding should be evaluated at least twice daily (Ramachandrappa & Jain, 2011). LPIs are at risk for hypoglycemia, and blood glucose measurements should be performed according to hospital protocol, especially during the first 24 hours.

Documentation that breastfeeding has been evaluated at least twice daily is important. Supplemental feedings by bottle, gavage, or use of a supplemental nursing system may be necessary if the infant's weight loss is greater than 10% total or more than 3% per day (Dave & Campbell, 2009). Because LPIs are at greater risk for breastfeeding-associated rehospitalization compared with term infants, lactation consultants should be involved in their care (Radtke, 2011).

Discharge. Late preterm infants can often be discharged at the same time as full-term infants. They should not be discharged earlier than 48 hours after birth. Before discharge, nurses should ensure that infants are feeding adequately and have had normal vital signs for at least 24 hours. Bilirubin levels should be assessed before discharge (AWHONN, 2010; Ramachandrappa & Jain, 2011).

Teaching should include the need for keeping the infant warm. The infant should be kept away from drafts and dressed with one more layer than an adult would wear. LPIs are subject to overstimulation (see p. 622). This may occur when parents take the baby home to an environment of many different stimuli. The nurse should teach signs of overstimulation and how to minimize them.

A car seat challenge should be conducted before discharge to ensure the infant can tolerate sitting in a car seat without bradycardia, apnea, or decreased oxygen saturation. The parents bring their own car seat for the test. The infant is monitored while remaining in the car seat for a minimum of 30 minutes or as long as it will take the family to get home (Rivers, 2010). Preterm and low-birth-weight infants should be observed in the car seat for 90 to 120 minutes (or more, if travel time to go home is longer) (AAP & ACOG, 2012).

Parents should be taught signs of common complications such as jaundice or dehydration and what to do if they occur. Because some problems may not be noticeable at discharge, late preterm infants should have a follow-up visit with the health care provider 24 to 72 hours after discharge (AWHONN, 2010; Dave & Campbell, 2009; Ramachandrappa & Jain, 2011).

PRETERM INFANTS

Preterm infants (also called *premature infants*) are born before the beginning of the 38th week of gestation. The word *preterm* is sometimes confused with the term **low birth weight (LBW)**, which refers to infants weighing 5 lb, 8 oz (2500 g) or less at birth and of any gestational age. **Very-low-birth-weight (VLBW)** infants weigh 3 lb, 5 oz (1500 g) or less at birth. **Extremely-low-birth-weight (ELBW)** infants weigh 2 lb, 3 oz (1000 g) or less at birth. Although most of these infants are preterm, others are full term and have failed to grow normally while in the uterus, a condition called **fetal growth restriction (FGR)**.

Incidence and Etiology

Scope of Problem

Advances in technology have resulted in infant survival at much lower birth weights than ever before. The preterm birth rate for 2011 declined for the fifth year in a row to 11.72% of births (Hamilton et al., 2013). A *Healthy People 2020* goal is a preterm birth rate not exceeding 7.6% (U.S. Department of Health & Human Services, 2010). Much progress is yet to be made in reaching this goal.

Disorders related to short gestation and low birth weight are the second leading cause of infant mortality, surpassed only by those from congenital anomalies and chromosomal abnormalities (Hoyert & Xu, 2012). In terms of the suffering of infants and their parents, lost potential, and medical expense, preterm birth is extremely costly. Infant mortality and morbidity rates increase as gestational age decreases.

Causes

The exact causes of preterm birth are not known, but all risk factors in pregnancy are potential causes. See Maternal Risk Factors for Preterm Labor (p. 585).

Prevention

Prevention of preterm birth is best accomplished by provision of adequate prenatal care for every pregnant woman to identify and treat risk factors as early as possible. Teaching women signs of preterm labor will help them seek care when stopping labor is still a possibility (see Chapter 27).

Characteristics of Preterm Infants

Characteristics of preterm infants vary, depending on gestational age. For example, the appearance and problems of infants born at 34 weeks of gestation are different from those of infants born at 26 weeks of gestation. Some characteristics, however, are common to all preterm infants.

Appearance

Preterm infants often appear frail and weak, and they have less developed flexor muscles and muscle tone compared with full-term infants. Their extremities are limp and offer little or no resistance when moved. Premature newborns typically lie in an extended position (see Figure 20-20). The infant's head is large in comparison with the rest of the body.

Preterm infants lack subcutaneous or white fat, which makes their thin skin appear red and translucent, with blood vessels being clearly visible. The nipples and areola may be barely perceptible, but vernix caseosa and lanugo may be abundant. Plantar creases are absent in infants of less than 32 weeks of gestation (see Figure 20-26).

The pinnae of the ears are flat and soft and contain little cartilage (see Figure 20-28). They lack the rolled-over appearance of the pinnae of a full-term infant. In the female infant, the clitoris and labia minora appear large and are not covered by the small, separated labia majora. The male infant may have undescended testes, with a small, smooth scrotal sac (see Figures 20-29 and 20-30).

Behavior

The behavior of preterm infants varies, depending on gestational age. It often differs from that of full-term infants because of the stress of having to adjust to extrauterine life before they are ready. Premature newborns may have poor development of flexion and little excess energy for maintaining muscle tone. They are easily exhausted by noise and routine activities. Their responses are varied, including lowered oxygenation levels and stress-related behavior changes. The cry may be feeble.

Assessment and Care of Common Problems

Because preterm infants are “unfinished” in their growth and development, they are prone to problems affecting all systems and body processes.

Problems with Respiration

Problems of the respiratory system are a major concern because preterm newborns have immature lungs but must go through the same processes as the full-term infant to begin breathing. The presence of surfactant in adequate amounts is of primary importance. Surfactant reduces surface tension in the alveoli and prevents their collapse with expiration. It allows the lungs to inflate with lower negative pressure, decreasing the work of breathing. Infants born before surfactant production is adequate develop respiratory distress syndrome (RDS) (p. 643). In addition, preterm infants have a poorly developed cough reflex and narrow respiratory passages, which increase the risk for respiratory difficulty.

Assessment. The infant's respiratory status must be observed constantly. The lungs are assessed for adventitious breath sounds or areas of absent breath sounds.

The nurse differentiates periodic breathing from apneic spells. **Periodic breathing** is the cessation of breathing for 5 to 10 seconds without other changes followed by 10 to 15 seconds of rapid respirations (Goodwin, 2010). Changes in color or heart rate do not occur. Although periodic breathing sometimes occurs in term infants, preterm infants experience it more often.

Apneic spells involve absence of breathing lasting more than 20 seconds or less if accompanied by cyanosis, pallor, bradycardia, or hypotonia (Goodwin, 2010). Apneic spells are common in preterm infants, increasing in incidence with lower gestational age. Apnea without an identified cause in a preterm infant is called *idiopathic apnea* or *apnea of prematurity* and generally improves as the infant matures. Spells may occur along with periodic breathing, and the infant may require gentle tactile stimulation, bag and mask ventilation, medications, or continuous positive airway pressure. Apnea should be investigated because it may be related to other conditions.

The nurse observes the effort required for breathing and the location and severity of retractions. Retractions are particularly noticeable in preterm infants, whose weak chest wall is drawn in with each inspiration. The excessive **compliance** (elasticity) of the chest cage during retractions occurs because the bones of the chest wall are very pliable. This may interfere with full expansion of the lungs.

Grunting may be an early sign of RDS. It closes the glottis and increases the pressure within the alveoli. This keeps the alveoli partially open during expiration and increases the amount of oxygen absorbed.

Nursing Interventions. Interventions focus on collaborating with other team members such as the respiratory therapist to manage technical equipment and facilitate removal of secretions.

Working with Respiratory Equipment. An oxygen hood is often used for infants who can breathe independently but need extra oxygen. The hood is a plastic dome that fits over the infant's head or over the head and upper body. The infant breathes the higher levels of oxygen within the hood, and the device does not interfere with access to the rest of the infant's body for care (Figure 29-2).

Oxygen also may be given by nasal cannula to the infant who breathes well independently. After discharge, many preterm infants continue to receive oxygen via nasal cannula at home. Oxygen must be warmed to maintain body temperature and humidified to prevent insensible water loss and drying of the delicate mucous membranes.

Continuous positive airway pressure (CPAP) may be necessary to keep the alveoli open and improve expansion of the lungs. CPAP can be delivered via nasal prongs, a mask, or an endotracheal tube. The

FIG 29-2 The oxygen hood is one way of delivering oxygen to an infant who can breathe unassisted. (Courtesy of Cheryl Briggs, RN.)

infant may need conventional mechanical ventilation when respiratory failure, severe apnea, bradycardia, or other conditions are present. High-frequency ventilation may be used to provide very fast respirations with less pressure and volume. This helps decrease lung injury from pressure (barotrauma) and volume (volutrauma).

When oxygen is administered, the level of oxygen in the infant's blood must be monitored. Arterial blood may be drawn for testing oxygen levels. **Pulse oximetry** may also be used. This method is less invasive and provides continuous information about oxygen partial pressure (P_{O_2}) levels through sensors attached to the skin. Nurses and respiratory therapists titrate oxygen, depending on the pulse oximetry or arterial oxygen levels, according to agency policy.

The nurse must observe the infant's increasing or decreasing dependence on breathing assistance and need for oxygen during activity such as handling, feeding, and linen changes. Handling, feeding, and linen changes may increase oxygen need. Changes in settings on equipment may be necessary during such activity.

Positioning the Infant. The side-lying and prone positions facilitate drainage of respiratory secretions and regurgitated feedings. The prone and side-lying positions are not recommended for normal newborn infants because they are associated with an increased incidence of sudden infant death syndrome (SIDS). In the preterm infant, however, the prone position increases oxygenation, enhances respiratory control, improves lung mechanics and volume, and reduces energy expenditure (Gardner & Goldson, 2011).

The reason for prone positioning should be explained to parents. Supine positioning for sleep is begun as soon as the infant can tolerate it and before discharge so that the infant can become accustomed to sleeping on the back before going home. The supine position can often be used at approximately 32 weeks' gestational age (AAP & ACOG, 2012). Before discharge parents should be taught the importance of supine positioning in preventing SIDS. It is important for nurses to model SIDS prevention by placing infants in the supine position as soon as infants are able because parents are more likely to position infants as they saw them positioned in the hospital (Carrier, 2010; McMullen, Lipke, & LeMura, 2009).

Suctioning Secretions. The weak or absent cough reflex and very small air passages make the preterm infant's airways susceptible to obstruction by mucus. The nurse checks the suction equipment at the beginning of each shift to ensure that it is available and functioning properly at all times.

The infant is suctioned only as necessary. Suction should be gentle to avoid traumatizing the delicate mucous membranes. Trauma could

cause edema, decreasing the size of the air passages further and leading to more respiratory difficulty.

Suctioning also provides an entry for organisms and decreases oxygenation. The procedure causes changes in heart rate, blood pressure, and cerebral blood flow. Suction should be applied for only 5 to 10 seconds at a time and increased oxygen should be provided before and after each suction attempt. The mouth is suctioned before the nose because stimulation of the nares causes reflex inspiration that could cause aspiration of fluids in the infant's mouth (Gardner, Enzman-Hines, & Dickey, 2011b). A rest period should be provided after suctioning.

Maintaining Hydration. Adequate hydration is essential to keep secretions thin so that they can be removed by drainage or suction. If infants become dehydrated, secretions will become thick and viscous and could obstruct tiny air passages. Fluid intake should be increased, as ordered by the physician, if secretions seem to indicate even minimal dehydration.

1. How does the appearance of a preterm infant differ from that of a full-term infant?
2. What factors contribute to respiratory problems in preterm infants?
3. What nursing responsibilities relate to care of preterm respiratory problems?

Problems with Thermoregulation

Although heat loss can be a thermoregulation problem for full-term infants, it is even more significant in preterm infants. Their skin is thin with blood vessels near the surface, and little subcutaneous white fat for insulation. As a result, heat loss is rapid. The preterm infant's shorter time in the uterus allows less brown fat to accumulate before birth, impairing the infant's ability to produce heat.

Preterm infants have a larger head in proportion to body size compared with full-term infants. The preterm infant's extended extremities increase exposure to air and thus heat loss. Their body surface area in proportion to their body mass is five or more times that of adults (Blackburn, 2013). The temperature control center of the brain of preterm infants is less mature and may be further impaired by asphyxia. These conditions all contribute to heat loss.

Complications from heat loss are more likely to develop in preterm infants. These include hypoglycemia, respiratory problems, metabolic acidosis, pulmonary vasoconstriction, impaired surfactant production, and more respiratory difficulty. In addition, calories used for heat production are unavailable for growth and weight gain.

Assessment. The infant's temperature is monitored continuously by a skin probe on the infant's abdomen, which is attached to the heat control mechanism of the radiant warmer or incubator. The abdominal skin temperature is usually maintained at 96.8°F to 97.7°F (36°C to 36.5°C) (Brown & Landers, 2011). The infant's temperature as shown on the monitor should be recorded every 30 to 60 minutes initially and every 1 to 3 hours when the infant is stable. The axillary temperature should be compared with the heat control reading to ensure that the equipment is functioning properly.

The axillary temperature for a preterm infant should remain between 97.3°F and 98.4°F (36.3°C and 36.9°C), slightly lower than the temperature for full-term infants (Brown & Landers, 2011). If the infant has accumulated brown fat, a normal axillary temperature when the monitor shows a decreased skin temperature may indicate that heat from brown fat in the axillary space is being used to maintain the infant's core temperature.

FIG 29-3 This preterm infant has mildly mottled skin and slight abdominal distention and retractions.

Indications of inadequate thermoregulation include poor feeding or intolerance to feedings in an infant who previously had little difficulty, irritability, lethargy, poor muscle tone, cool skin temperature, and mottled skin (Figure 29-3). Hypoglycemia and respiratory distress may be the first signs that the infant's temperature is low. A decrease in weight gain or weight loss may occur over time. Because temperature instability may be an early sign of infection, the nurse should assess for other evidence that infection may be present.

CRITICAL TO REMEMBER

Signs of Inadequate Thermoregulation

- Axillary temperature <97.3°F or >98.4°F (<36.3°C or >36.9°C)
- Abdominal skin temperature <96.8°F or >97.7°F (<36°C or >36.5°C)
- Poor feeding or feeding intolerance
- Irritability followed by lethargy
- Weak cry or suck
- Decreased muscle tone
- Cool skin temperature
- Mottled, pale, or acrocyanotic skin
- Signs of hypoglycemia
- Signs of respiratory difficulty
- Poor weight gain, if chronic

Nursing Interventions. Maintenance of heat in preterm infants involves the same basic nursing care principles as for the full-term infant (see Chapter 21). These principles, however, must be adapted to meet the needs of the preterm infant.

Maintaining a Neutral Thermal Environment. A neutral thermal environment is especially important to prevent the need for increased oxygen to maintain the infant's body temperature. The temperature necessary to maintain a neutral thermal environment varies according to gestational age. Charts are available that indicate the appropriate temperature setting to maintain a neutral thermal environment according to the infant's size and maturity.

The delivery room should be warm to decrease heat loss at birth. Immediately after birth, the infant is dried and placed on the mother's abdomen or a prewarmed radiant warmer for care. Before infants are dried, place those who are less than 29 weeks of gestation in a polyethylene bag or wrap that covers the body from the shoulders down. This prevents heat loss by evaporation during initial care and transfer to the NICU and is used until the infant's condition is stabilized (Kattwinkel, 2011). It also decreases insensible water loss.

Because they produce heat less effectively and lose more heat than larger or older preterm infants, smaller, less-mature infants need more warmth to maintain body heat. Radiant warmers or incubators are used until infants can maintain normal body temperature alone. Some devices convert from a radiant warmer to an incubator and back again to eliminate the need to move the infant from one device to another.

Infants needing many procedures are usually placed under an open radiant warmer to make it easier to see them and work with equipment. However, air currents around an unclothed infant can cause heat loss by convection despite the heat generated by the warmer. Doors near the warmer should be closed and traffic kept to a minimum to decrease convective heat loss. The infant should receive only warmed oxygen because thermal receptors in the face are very sensitive to cold. Cold oxygen could quickly lead to cold stress.

Equipment and caregivers should not come between the infant and the heat source, preventing heat from reaching the infant. A transparent plastic blanket over the infant allows heat from the warmer to pass across to the infant. The blanket decreases convective heat loss from exposure to drafts and insensible water loss while maintaining visibility of the infant's body.

Incubators are used for infants who do not need to be under radiant warmers. They have double walls to minimize radiant heat loss to the cooler outer walls. Warmed air circulating inside the incubator provides heat. Humidity may be added to decrease evaporative heat loss and insensible water loss, especially in very preterm infants. Incubators should be placed away from air-conditioning ducts or windows that may affect the incubator temperature.

When infants are in incubators, the nurse should keep portholes and doors closed as much as possible. A significant amount of heat is lost each time the incubator is opened, and it takes time to build up the heat again. When removed from the incubator for procedures or holding, infants should be wrapped in heated blankets and a hat applied. Incubator doors should be closed while the infant is outside to retain the heat inside. Infants should be placed under a radiant warmer or on a surface padded with warm blankets for procedures that cannot be performed inside the incubator. A heat lamp provides an alternative source of heat.

Although temperature loss is the most common concern, overheating also is a problem for preterm infants. Overheating may occur when heating devices such as radiant warmers are set too high or a skin probe comes loose. Overheating leads to an increase in the metabolic rate, with increased oxygen and glucose needs, and insensible water losses. Alarms to detect high or low temperature should be turned on at all times.

Although temperature regulation in preterm infants is usually provided in incubators until infants can maintain their own temperature, warmth is also provided when parents hold them. Adequate temperature is maintained in stable infants during KC (p. 640).

Weaning to an Open Crib. Preparation of infants for moving to an open crib should begin early. When stable, infants can be dressed in a shirt, diaper, and hat while in the incubator. Clothing conserves heat and helps infants adjust to a different temperature on the face than the rest of the body. Infants who weigh about 3 lb, 5 oz (1500 g), have a consistent weight gain for 5 days, have no medical complications, and are tolerating feedings can begin gradual weaning from external heat (Brown & Landers, 2011).

Each NICU has its own protocol for the weaning process. The incubator temperature is usually decreased gradually. It is raised if the infant's temperature falls below the normal range. If the temperature remains stable, the process can continue the next day.

When the infant is ready for transfer to an open crib, double-wrapping with warm blankets helps insulate body heat. Sleep sacks (sleepers made of blanket material and closed at the bottom) are often

used when infants are dressed. The temperature is assessed at gradually increasing intervals until the infant is on a routine schedule. A blanket is added for a low temperature, but if the temperature does not rise to normal, the infant is returned to the incubator.

Nurses should observe infants carefully during the first few days after transfer to an open crib. Signs that may indicate inadequate thermoregulation include decreased weight gain, poor feeding, or increased requirement for oxygen.

Problems with Fluid and Electrolyte Balance

Preterm infants lose fluid very easily, and the loss increases with the degree of prematurity. The rapid respiratory rate and the use of oxygen increase fluid losses from the lungs. Their thin skin has little protective subcutaneous white fat and is more permeable than the skin of term infants. The large surface area in proportion to body weight and lack of flexion further increase transepidermal water losses. Radiant warmers raise insensible water losses by 40% to 50% compared with loss in an incubator (Brown & Landers, 2011). Heat from phototherapy lights causes even more fluid to be lost through the skin.

The ability of the kidneys to concentrate or dilute urine is poor, causing a fragile balance between dehydration and overhydration. Great differences in fluid needs occur, depending on variables such as the infant's size, gestational age, insensible water losses, and medical needs. Normal urinary output is 1 to 3 mL/kg/hr for preterm infants for the first few days. After 24 hours of life, output less than 0.5 mL/kg/hr is considered oliguria (Blackburn, 2013).

Regulation of electrolytes by the kidneys is also a problem. Preterm infants need higher intakes of sodium because the kidneys do not reabsorb it well. If they receive too much sodium, however, they may be unable to increase sodium excretion adequately and are susceptible to sodium and water overload.

Assessment. The nurse must be alert for fluid overload or deficit. Monitoring intake and output of fluids helps determine fluid balance. The infant's intake and output by all routes are carefully calculated. Parenteral, feeding tube, medication, and oral fluids are included when measuring intake. Output from regurgitation, drainage tubes, stools, and urine should be measured. The nurse must also keep track of the amount of blood taken for laboratory tests because the loss can be substantial and the infant cannot make new blood fast enough.

Urine Output. There are several methods of measuring urine output. Plastic bags that adhere to the perineum are not suitable for the preterm infant because they may damage the fragile skin. Weighing diapers is less harmful to the infant. The weight of dry diapers is subtracted from the weight of wet diapers to determine the amount of urine excreted. One gram (1 g) is equivalent to one milliliter (1 mL) of urine. However, humidification may add moisture to the diaper, and a radiant warmer may cause evaporation of urine on the diaper. When precise measurement is essential, diapers can be fastened instead of being placed open under the infant.

Specific gravity should be checked to determine if urine is more concentrated or dilute than expected. Urine is collected by placing gauze at the perineum. The specific gravity should range between 1.002 and 1.01 (Jones, Hayes, Starbuck et al., 2011).

Weight. Changes in the infant's weight can give an indication of fluid gain or loss, especially if the changes are sudden or greater than would be expected. The undressed infant should be weighed at the same time each day with the same scale. Very small infants are often placed in a bed with a scale so that they are not disturbed for daily weighing. They may be weighed two to three times a day to monitor their fluid status more closely.

Signs of Dehydration or Overhydration. The nurse should observe for signs that indicate the infant has received too little or too much fluid. See the Critical to Remember box for a list of these signs.

CRITICAL TO REMEMBER

Signs of Fluid Imbalance in the Newborn

Dehydration

- Urine output <1 mL/kg/hr
- Urine specific gravity >1.01
- Weight loss greater than expected
- Dry skin and mucous membranes
- Sunken anterior fontanel
- Poor tissue turgor
- Blood: elevated sodium, protein, and hematocrit levels
- Hypotension

Overhydration

- Urine output >3 mL/kg/hr
- Urine specific gravity <1.002
- Edema
- Weight gain greater than expected
- Bulging fontanels
- Blood: decreased sodium, protein, and hematocrit levels
- Moist breath sounds
- Difficulty breathing

Nursing Interventions. The nurse must carefully regulate intravenous (IV) fluids using infusion control devices that administer fluid with a precision of 0.1 mL/hr to help prevent fluid volume overload (Jones et al., 2011). IV medications should be diluted in as little fluid as is consistent with safe administration of the drug and should be included when intake is measured. Starting IV lines on infants with poor veins is a lengthy, difficult procedure. Infants must be restrained, as necessary, to prevent infiltration. If they infiltrate, some solutions cause extensive damage as a result of tissue sloughing.

IV sites should be assessed at least every hour for signs of infiltration. Many infants have central venous catheters or umbilical lines that must be assessed for infection and position changes. Small blood transfusions may be necessary to replace blood drawn for frequent laboratory tests.

Problems with the Skin

Preterm infants have fragile, permeable, easily damaged skin. They often have endotracheal tubes, IV lines, electrodes, and other equipment that must be maintained in place, but standard adhesive tape should not be used because it can be very damaging to the skin. Removal of adhesive tape may strip the epidermal layer of the skin, causing pain and increasing transepidermal water loss and the risk of infection. Preparations used to disinfect the skin before invasive procedures can injure fragile skin and may be absorbed.

Assessment. The nurse should frequently assess the condition of the infant's skin and record any changes. The infant's response to products used for cleansing and disinfection should be noted.

Nursing Interventions. Guidelines for evidence-based practice in care of the neonate's skin have been developed by the AWHONN (2013). Medical adhesives that effectively secure devices and monitoring equipment but cause the least injury to tissues should be used. Skin can be protected from adhesives by using silicone-based protective films.

Adhesives should be removed slowly and gently by pulling horizontally parallel to the skin. The interface between the adhesive and the skin should be wet with gauze or saline pledgets. Mineral oil, petrolatum, or silicone-based adhesive removers can also be used to wet the area. (AWHONN, 2013).

All disinfectants have potential risks when used on neonates. Aqueous chlorhexidine gluconate solutions are commonly used at this time. Povidone-iodine may injure the skin and may have toxic effects on the thyroid gland in premature infants. All disinfectants should be removed with sterile water or saline. Alcohol should not be used (AWHONN, 2013; Lund & Durand, 2011).

Cleansers with a pH of 5.5 to 7 may be used for bathing infants. Preterm infants should usually not be bathed every day. Warm water without soap should be used for infants less than 32 weeks of gestational age for the first week after birth. Sterile water is not necessary unless there are concerns about the safety of tap water or there is a break in skin integrity (AWHONN, 2013). Stable preterm infants without umbilical IV lines may be immersed in water that covers the shoulders for bathing if there are no contraindications. Swaddled bathing, where the infant is wrapped in a blanket and then immersed in water for bathing, may also be used. Tubs should be used by only one infant for the duration of hospital stay, or cleaned well if used between infants.

Humidity in incubators should be regulated to reduce the drying effects of heat. Emollients can help reduce fissures in dry skin and transepidermal water loss. They are safe to use under radiant warmers and during phototherapy (AWHONN, 2013). The infant's skin should be observed for signs of infection.

Infants and their equipment should be positioned to avoid undue pressure on the skin. Skin breakdown may occur over any bony prominence but especially on the head, which has the largest body surface area. Frequent position changes are important but should be based on the infant's ability to tolerate changes.

Problems with Infection

The incidence of infection in preterm infants is 3 to 10 times greater than that in full-term newborns (Stoll, 2011). Many preterm infants have one or more episodes of sepsis during their hospital stay. Factors that contribute to the high rate of infection include exposure to maternal infection, lack of adequate passive immunity from the transfer of immunoglobulin G (IgG) from the mother during the third trimester, and immature response to infection.

Preterm infants are often exposed to situations that may cause infection. A prolonged stay in the hospital increases the likelihood of acquiring an infection from multiple exposures to organisms.

Infants are subject to invasive procedures such as insertion of IV lines and drawing of blood specimens. Peripherally inserted central catheters (PICCs) are commonly used for intravenous therapy. However, catheter-related bloodstream infections may occur and special care is necessary when they are used. Infants often have central intravenous catheters that require sterile dressings. All dressing changes should be done under strict sterile technique.

Assessment. The nurse should be alert for signs of sepsis at all times (see Chapter 30, p. 663).

Nursing Interventions. Handwashing is one of the most important aspects of preventing hospital-acquired infections. Nursing care involves scrupulous cleanliness and maintenance of the infant's skin integrity. Even normal flora on the hands of caregivers may cause sepsis. Therefore, parents and staff members should thoroughly wash their hands and arms before handling infants. No jewelry is worn in many units because of the possibility of it carrying organisms. Exposure to family and staff members who have contagious diseases should be prevented.

Early signs of infections should be identified and reported so that treatment may begin immediately. The nurse carefully notes the infant's response to treatment as some organisms become resistant to antibiotics. Other nursing care for infection is discussed in Chapter 30.

Problems with Pain

Infants in the NICU undergo many painful procedures and treatments such as intubation, heel sticks, chest tube placement, venipuncture, and suctioning each day. Younger and sicker infants tend to need more interventions and suffer more pain-producing procedures compared with older, less-ill infants. It was once thought that newborns, particularly preterm infants, were neurologically too immature to feel pain. It is now recognized that preterm infants do feel pain and that pain stimuli cause physiologic and behavioral changes in infants.

Pain can have numerous untoward effects. For example, increases in intracranial pressure resulting from pain elevate the risk for intraventricular hemorrhage. Other risks include hypoxia, changes in metabolic rate, and adverse effects on growth and wound healing. Stress and pain in the newborn may alter pain thresholds and cause permanent changes in neural pathways (Blackburn, 2013). Tissue injury occurring early in development may lead to higher sensitivity to pain at the involved site and the surrounding areas (Gardner, Enzman-Hines, & Dickey, 2011a).

The long-term effects of pain in the neonate are not yet fully understood. It is possible that repeated painful events may cause emotional, behavioral, and learning disabilities. The American Academy of Pediatrics (AAP), the American College of Obstetricians and Gynecologists (ACOG), and the National Association of Neonatal Nurses (NANN) recommend that pain be routinely assessed, painful procedures be minimized, and nonpharmacologic and pharmacologic therapies be used to prevent pain from minor procedures and to eliminate pain from surgeries and major procedures in neonates (AAP & ACOG, 2012; NANN, 2012).

Assessment. Because pain is the fifth vital sign, pain assessment is performed whenever vital signs are taken. In addition, the nurse must assess the infant's response to potentially painful stimuli and to pharmacologic and nonpharmacologic interventions.

Assessment tools are available to evaluate physiologic and behavioral responses to pain in term and preterm infants. Some such as the Premature Infant Pain Profile (PIPP) are designed for term or preterm infants. This tool assesses gestational age and behavior states, heart rate, oxygen saturation, brow bulge, eye squeeze, and nasolabial furrow (lines from the edge of the nostrils to beyond the corners of the mouth) to assign a pain score (Gardner, Enzman-Hines, & Dickey, 2011a).

Both physiologic and behavioral responses to pain occur. However, physiologic changes may be unpredictable and cannot be used alone to assess pain.

CRITICAL TO REMEMBER

Common Signs of Pain in Infants

- Increased or decreased heart and respiratory rates, apnea
- Increased blood pressure
- Decreased oxygen saturation
- Color changes: red, dusky, pale
- High-pitched, intense, harsh cry
- Whimpering, moaning
- "Cry face"
- Eyes squeezed shut
- Mouth open
- Grimacing
- Furrowing or bulging of the brow
- Tense, rigid muscles or flaccid muscle tone
- Rigidity or flailing of extremities
- Sleep-wake pattern changes

Infants who are intubated or too weak to cry have a “cry face,” a facial expression of crying without the sound of a cry. Less than half of preterm infants experiencing painful stimuli respond with crying (Gardner, Enzman-Hines, & Dickey, 2011a). Infants who have been exposed to prolonged or repeated pain may no longer be able to show behavioral changes even though they are experiencing pain. Critically ill or very immature infants may also not show pain responses in the same way that older, less sick infants do. Therefore, lack of response to a painful situation should not be perceived as absence of pain.

Parents often spend many hours with their preterm infants in the NICU setting. The nurse should involve them in assessing the infant’s pain and encourage them to share their evaluation of the infant’s response to relief measures. They may have questions the nurse can answer about the effects of pain and the measures used to treat it.

Nursing Interventions. Nurses should prepare infants for potentially painful procedures by waking them slowly and gently and using containment. **Containment** simulates the enclosed space of the uterus, prevents excessive and disorganized motor activity, and is comforting to infants. It involves keeping the extremities in a flexed position with swaddling, positioning devices, or with the nurse’s hands. The infant is in the supine or side-lying position with at least one of the infant’s hands near the mouth for sucking. Containment is also called *facilitated tucking* (Fernandes, Campbell-Yeo, & Johnston, 2011).

KC and breastfeeding also are used to reduce pain. They are a way for mothers to be involved in helping relieve infant pain. The mother’s voice and smell, which are familiar to the infant, are added to skin-to-skin contact to increase pain relief (Campbell-Yeo, Fernandes, & Johnston, 2011).

Handling before a painful procedure should be minimized, if possible. Even positioning for procedures can be uncomfortable and upsetting. Therefore, other care should be performed at another time to allow the infant to rest before and after the procedure. If several things must be done together, the least traumatic should be performed first. The infant is often hypersensitive after a painful stimulus and may perceive other activities as painful (NANN, 2012).

Comfort measures help the infant cope with short-term, mild pain and reduce agitation. Nonnutritive sucking with a pacifier or the infant’s hands is helpful but is effective only as long as the infant continues to suck. Sucrose placed on a pacifier or in the infant’s mouth 2 to 3 minutes before a painful stimulus increases pain relief. Combining sucrose with nonnutritive sucking has been found to reduce pain in neonates when used before and during painful procedures (Naughton, 2013). Sucrose may not be appropriate, however, for very young preterm infants.

Talking softly, holding, rocking, and restraining the extremities to prevent flailing are other common methods of pain relief that may be used alone or with sucrose. Measures should be adapted according to the infant’s responses. A combination of measures, such as skin-to-skin contact and a sucrose-dipped pacifier may increase effectiveness (Academy of Breastfeeding Medicine, 2010).

Comfort measures alone are not enough for moderate to severe pain. The nurse should discuss the infant’s pain with the primary care provider to ensure that medications are available for long-term and more severe pain. Opioids such as morphine and fentanyl can be tolerated by preterm infants. Nonnarcotic analgesics such as acetaminophen may also be used. Topical anesthesia can be used to reduce pain during some procedures.

Sedatives may be used for agitation in sick newborns but are not effective for pain and should not be used in place of analgesics. Regional or general anesthesia is given during surgery.

The nurse gives ordered medications before painful procedures and when the infant demonstrates signs of pain. The infant’s response is

carefully noted to determine the need to increase or decrease the dosage. Analgesics may be given continuously or on an as-needed basis.

APPLICATION OF THE NURSING PROCESS

■ The Preterm Infant

Preterm infants commonly have difficulty with stress from the NICU environment and in obtaining adequate nutrition. Their parents may have difficulty with bonding.

ENVIRONMENTALLY CAUSED STRESS

The effects of environmental factors on the preterm infant have led to developmentally supportive care. Developmental care keeps stressors in the environment to a minimum based on the infant’s physiologic and behavioral responses.

In the past, the effects of exposing preterm infants to bright lights and a noisy environment were not well understood. Improvements have occurred but noise continues to be a problem. Although the recommended noise level in NICUs is below 45 decibels, levels may range between 38 and 90 decibels or higher (Gardner & Goldson, 2011). Noise tends to be loudest during report and caregiver rounds and in areas where staff congregate such as at entrances, sinks, and computer areas.

The sounds of ventilators, incubators, doors, people, and alarms from pumps and oxygen monitors can create a noise level that increases the risk of hearing loss and other complications. In addition, stimulation of any kind can cause increased energy expenditure by the preterm infant. Noise and even routine handling and nursing interventions are often accompanied by changes in heart rate, oxygen saturation levels, and behavior states.

Preterm infants undergo multiple assessments, procedures, and treatments that may cause frequent interruptions of sleep and may interfere with the development of normal sleep-wake cycles. Sleep disruption alters neuronal maturation and secretion of growth hormone and interferes with growth and development (Gardner & Goldson, 2011). Energy that must be directed toward coping with an overstimulating and stressful environment may be unavailable for normal growth and development.

Although touch is generally thought to be comforting to infants, it is often associated with painful events for preterm infants. This can cause them to develop touch aversion, a negative response to touch of any kind. They may cry, squirm, and recoil when touched, expecting that touch will lead to pain.

CASE STUDY 29-1 INTRODUCTION

Katherine had a cesarean birth 3 days ago. She had experienced two spontaneous abortions before this pregnancy. This was a difficult pregnancy with frequent episodes of preterm labor. She delivered her son, Giovanni, at 30 weeks of gestation. He is being cared for in the neonatal intensive care unit.

*Continues on p. 631.

Assessment

Assess the amount of noise to which the infant is exposed. Determine how often interruptions occur and how the infant responds to different types of care.

Assess the infant's ability to tolerate activity and noise. Overstimulation results in changes in oxygenation and behavior. Behavioral indications of stress, also called *avoidance cues* or *avoidance behavior*, show the infant is seeking to escape the noxious stimuli. Observe for these signs and determine what situations cause them to occur or increase.

CRITICAL TO REMEMBER

Signs of Overstimulation in Preterm Infants

Oxygenation Changes

Blood pressure, pulse, and respiratory instability
Cyanosis, pallor, or mottling
Flaring nares
Decreased oxygen saturation levels
Sneezing, coughing

Behavior Changes

Stiff, extended arms and legs
Fisting of the hands or splaying (spreading wide apart) of the fingers
Arching
Alert, worried expression
Turning away from eye contact (gaze aversion)
Regurgitation, gagging, hiccupping
Yawning
Fatigue signs

Nursing Diagnosis

A nursing diagnosis appropriate for preterm infants having difficulty enduring the multiple stimuli in their environment is "Risk for Disorganized Infant Behavior related to stress from an overstimulating environment." Use of this nursing diagnosis can help the nurse plan ways to increase the infant's ability to tolerate interventions.

Expected Outcomes

The expected outcomes for this nursing diagnosis are that the infant will:

1. Show decreasing signs of overstimulation during routine activity as evidenced by fewer respiratory and behavioral changes during handling and increased periods of relaxed behavior or sleep.
2. Gradually show an ability to withstand more activity before signs of overstimulation occur.

Interventions

Interventions are focused on providing developmentally supportive nursing care that meets the preterm infant's ability to tolerate stimulation. Developmental care keeps stressors in the environment to a minimum based on the infant's physiologic and behavioral responses.

Scheduling Care

Schedule periods of undisturbed rest throughout the day to allow the infant to recover from treatments. Avoid waking the infant during the short quiet sleep phase. If the infant must be awakened for care, try to do it during an active period of sleep when the infant can be more easily aroused using quiet talking and gentle touch.

Arrange routine care to correspond with the infant's awake periods, and avoid disturbing rest. Decrease the frequency of taking vital signs

and performing other routine care as soon as possible. Even the handling involved in routine sponge bathing may cause stress in small infants.

Routine daily baths are unnecessary and should be avoided. Bathing every fourth day does not increase skin flora or pathogen counts. Bathing should be postponed until infants are physiologically stable (Gardner & Goldson, 2011).

Cluster or group care so that several tasks are performed at once to allow for more rest between interruptions. However, keep clustered care short and be alert to the infant's signs of stress. Too many activities may be more than the infant can tolerate without rest. Clustered care may not be appropriate for preterm infants less than 28 weeks of gestational age (Gardner & Goldson, 2011).

Provide short rest periods or "time out" periods for recovery within grouped activities or during long or painful procedures. Do not include painful procedures in a cluster of other care. Rest is needed before and after painful procedures.

An important nursing responsibility is managing the infant's care by coordinating activities of different health care workers. For example, many different tests often are needed, and the nurse must see that they are done properly while protecting the infant from overstimulation.

Reducing Stimuli

Keep noise around the infant as low as possible. Place incubators away from traffic and congestion areas, and avoid talking near the incubator. Use incubator covers to help lower sound inside the incubator. Set alarms on low volume and respond quickly when they sound. Open and close portholes and doors on incubators and cupboards quietly.

Do not place objects on top of the incubator or use it as a writing surface because it increases the noise inside. Teach parents and others to avoid tapping on the incubator. Soft classical music is sometimes used to help promote rest.

Lights that are on 24 hours a day in the nursery may interfere with the development of sleep cycles. Position the incubator so the infant is not facing bright lights, and drape a blanket or incubator cover over the back and end to decrease light and noise further. Use a dimmer switch to vary the intensity of lights, as needed. Reduce lighting at night to as low as possible to help promote rest and conserve energy for growth.

Some NICUs have single rooms for each infant. This reduces noise and allows environmental stimuli to be adapted to each infant's individual needs. It also provides more privacy for visiting family members and may reduce hospital-acquired infections.

Promoting Rest

When possible, schedule "quiet periods" when lights and noise in the unit are kept to a minimum to promote rest. Rest periods should be at least an hour long to allow preterm infants to complete a sleep cycle (Gardner & Goldson, 2011). Only emergency procedures should take place during rest times.

Scheduled naps when infants are disturbed as little as possible may lead to longer uninterrupted sleep. A daytime and evening nap and two naps during the night will help the infant begin to differentiate between day and night sleeping patterns. Lights should be lowered at night to help development of circadian rhythms.

Contain the infant's arms and legs to promote flexion and reduce energy loss from flailing extremities. Containment also promotes quieting, improves physiologic stability, and reduces stress (Gardner & Goldson, 2011). Provide boundaries with rolled blankets or commercial positioning devices placed around the infant. For the side-lying and supine positions, arrange the infant's arms and legs in a flexed

position, with the hands near midline to allow hand-to-mouth activity and sucking.

Stroking and gentle massage may be calming for stable preterm infants. It may help increase weight gain and improve development. It can also help involve parents in care of the infant. However, it may not be appropriate for smaller, more fragile infants (Carrier, 2010).

Promoting Motor Development

Preterm infants may have musculoskeletal and developmental problems from prolonged immobilization and the effects of gravity on their immature neuromuscular system. Because the extensor muscles mature before the flexor muscles, the infant tends to remain in an extended, “frog-leg” position. Shoulder retraction, abduction and external rotation of the lower extremities, lateral flexion of the arms, neck hyperextension, and flattening of the sides of the head may be prevented by using correct positioning.

Reposition the infant every 2 to 3 hours or when other care is given. Change the position slowly, as position changes may be stressful. When possible, position the infant with the extremities flexed and the hands placed in the midline and near the mouth to allow the infant to suck them for comfort. Use swaddling, blanket rolls, and commercial positioning devices to maintain flexion.

Individualizing Care

Although all NICU nurses are competent in caring for preterm infants, they have slightly different styles in approaching infants. When possible, the same nurse or nurses should be assigned to care for the infant. This allows the nurse to learn the infant’s unique behavior and response to stress and allows the infant to get accustomed to the nurse’s individual caregiving pattern. It is also very helpful to parents to relate with a small number of nurses who know their infant well.

The ability to tolerate stress varies with each infant. Adapt general care according to the infant’s ability to tolerate it. Determine the infant’s response to various stimuli, particularly those that cause adverse responses. Even positive stimuli such as soft music or talking quietly can cause overstimulation at times.

Infants often require extra energy to adjust to changes in care. Observe how well they tolerate changes such as moving from assisted to more independent breathing or introduction of new feeding methods. Increase rest periods during these times.

Communicating Infants’ Needs

Use the nursing care plan, Kardex, and shift reports to inform other caregivers of techniques that are especially effective for certain infants. Tape notes at the bedside as reminders of needs unique to each infant. Doing so also alerts the parents to the methods that nurses use to care for the infant. Explain all techniques to the parents, and solicit their suggestions so they can participate in care appropriately.

Evaluation

As a result of interventions, the infant displays signs of overstimulation less often and shows an increasing tolerance to stimuli before signs appear.

NUTRITION

Preterm infants are born before full accumulation of nutrient stores has occurred or digestive capacity is achieved. The problem increases with decreasing gestational age.

Full-term newborns have reservoirs of calcium, iron, and other nutrients, but these are lacking in preterm infants. Fat stores are minimal or absent, and glucose reserves are used soon after birth.

Hypoglycemia develops very quickly and must be prevented or treated promptly.

Preterm infants receiving enteral feedings need approximately 105 to 130 kcal/kg/day (Kleinman, 2009). This amount varies according to activity, illness, and other factors that may affect caloric need. These infants need more protein, iron, calcium, and phosphorus. The average healthy preterm infant should gain approximately 15 to 20 g/kg/day (Anderson, Wood, Keller et al., 2011).

The gastrointestinal tract of preterm infants does not absorb nutrients as well as that of full-term infants. Although they digest protein well, preterm infants have insufficient bile acids and pancreatic lipase to absorb fat adequately. They have some lactase deficiency but rarely have lactose intolerance (Anderson et al., 2011). Their smaller stomach capacity limits the volume preterm infants can tolerate at each feeding. They need more of many nutrients per kilogram than do full-term infants and supplementation is necessary.

Assessment

Changes in feedings are often made according to the nurse’s assessment of an infant’s adjustment to feedings, readiness for change, and signs indicating complications.

Feeding Tolerance

Assess how well the infant tolerates enteral feedings, whether by gavage or nipple. Aspirate the stomach contents to measure the residual amount of feeding in the stomach before intermittent gavage feedings or every 2 to 4 hours for continuous feedings or according to hospital policy. This procedure helps determine whether the stomach is emptying and prevents overdistention. Report residuals to the physician if they are more than half the previous feeding for intermittent feedings or more than 2 to 4 mL/kg or a 1-hour volume for continuous feeding (Anderson et al., 2011). An excessive residual indicates the amount, type, or flow rate of formula may need to be changed. It also may be an early sign of a complication such as necrotizing enterocolitis (NEC).

Unless they are bloody, have large amounts of mucus, or are otherwise abnormal, gastric residuals are often replaced to prevent loss of electrolytes. Abnormal residuals are also reported to the physician and the feeding is held. The next feeding may be reduced by the amount of the residual. If residuals are not replaced, observe carefully for signs of electrolyte imbalance.

Vomiting or frequent regurgitation may indicate that the feedings are too large. Vomitus or residuals containing bile may be a sign of intestinal obstruction and may require surgery. Diarrhea may be caused by too rapid advancement of the feeding or intolerance to the type of formula.

Observe for signs of intestinal complications such as visible loops of bowel. Obtain objective data about abdominal distention by using a tape to measure abdominal girth every 4 to 8 hours. Place the tape at the level of the umbilicus, and record the placement on the nursing care plan to ensure consistency. Stools may be tested for reducing substances (which indicate malabsorption of carbohydrates) or occult blood if feeding intolerance is suspected. Report signs to the health care provider because they may be early indications of complications such as ileus, sepsis, obstruction, or NEC.

Readiness for Nipple Feeding

Preterm infants often are fed parenterally or by gavage (feeding tube) initially to conserve energy for growth and basic functioning. The ability to feed orally and the ability to gain weight are important milestones, as they are often among the criteria for discharge from the hospital. Coordination of sucking, swallowing, and breathing is a complex task for infants.

CASE STUDY 29-1 NURSING CARE PLAN*

ASSESSMENT: Giovanni now weighs 4 lb (1800 g) and breathes on his own with oxygen by hood. He needs many treatments throughout the day. He demonstrates pallor and an increased respiratory rate when tired. Noises often cause a drop in oxygen saturation. When held or disturbed for care, Giovanni may stiffen and extend his arms with the fingers splayed. He sleeps most of the time when he is undisturbed.

NURSING DIAGNOSIS: Activity Intolerance related to weakness, fatigue, and possible overstimulation

EXPECTED OUTCOMES: Giovanni will:

1. Show fewer signs of overstimulation (increased respirations, pallor, decreased oxygen saturation level, stiffening of arms and legs, or splaying of fingers) as a result of normal activity.
2. Increase tolerance to activity gradually as demonstrated by fewer signs of fatigue or stress.

INTERVENTIONS AND RATIONALES

1. Arrange to provide routine care during Giovanni's natural awake periods, whenever possible. *Preterm infants need undisturbed sleep to promote growth.*
2. Schedule periods of uninterrupted rest, especially before and after energy-draining activities. *Infants tolerate activities best when they begin in a rested state and are allowed to recover before other activities are necessary.*
3. Experiment with clustering care to determine the number and combination of activities that Giovanni tolerates best. *Clustering accomplishes more tasks at once so longer rest periods are possible. However, too many activities are too fatiguing.*
4. Determine Giovanni's stress level before beginning care activities. Reassess again during each activity and again after care is completed. *Careful assessment allows the nurse to give flexible, individualized nursing care to meet the changing needs of the infant.*
5. Determine which activities cause signs of overstimulation and fatigue. Stop and allow Giovanni rest periods, if possible. *Careful assessment allows the nurse to be sensitive to the infant's ability to tolerate care.*
6. Reduce the noise level around Giovanni. Avoid unnecessary talking, open and close doors softly, and keep alarm volumes low. *Noise may be overstimulating and may cause increased oxygen need.*
7. Reduce nonessential lighting. Turn Giovanni to face away from bright lights. Partially cover the incubator over his head to keep out light but allow him to be seen. Schedule regular nap times when lights are turned down. *Continuous lighting interferes with the infant's sleep. Reducing light in the infant's face and providing scheduled nap times increase rest.*
8. Use positioning devices to form "boundaries" around Giovanni and keep his extremities flexed. *Enclosed space promotes rest and comfort. Positioning devices prevent the infant from bumping against the hard walls of the bed.*
9. Explain Giovanni's needs for rest and low stimulation to his mother Katherine. Suggest ways she can interact appropriately to meet his needs, and point out signs that he is receiving too much stimulation. For example, splayed fingers are a "stop" sign. Ask for her input. *Informed parents can care for their infant appropriately and feel that they are members of the team and parenting their child by learning his needs.*
10. Collaborate with Katherine and other nurses to determine what works best in decreasing overstimulation and fatigue for Giovanni. Use shift report, the nursing care plan, the Kardex, and signs taped on the bed to provide this information to parents and others. *All caregivers should have information available to help meet the infant's needs consistently.*

Critical Thinking: Who else besides the primary nurse needs to know about methods to maintain appropriate stimuli in Giovanni's environment?

Answer: Everyone involved in caring for Giovanni—other nurses, physicians, respiratory therapists, and other members of the health care team, as well as parents—needs to know about the plan for appropriate stimuli so that everyone will follow the same methods for developmental care.

EVALUATION: Giovanni gradually shows increased ability to tolerate progressive activity with fewer episodes of overstimulation. His respirations and oxygen saturation levels remain stable, and he rarely stiffens his arms and legs during activity.

*Continued from p. 628; continues on p. 632.

Preterm infants do not have the well-developed buccal sucking pads in the cheeks that term infants use to form a seal around the nipple for efficient sucking. The jaw is less stable and the infant tires easily during oral feedings. The gag reflex may function poorly. The infant's respiratory status, other problems, and distractions in the environment can greatly affect feeding ability.

During gavage feedings, watch for signs that nipple feeding may soon be possible. These include rooting, respiratory rate below 60 breaths per minute, and increasing ability to tolerate holding and handling. Although sucking on the gavage tube, a finger, or a pacifier may be a sign of readiness, it is not enough. Infants must also have an intact gag reflex, or they are more likely to aspirate feedings. Note whether the infant gags on the catheter or a gloved finger inserted into the mouth.

Most infants are ready to begin oral feedings when they reach 34 to 35 weeks of **corrected age** and some are ready by 30 to 34 weeks (Gardner & Goldson, 2011). (Corrected or developmental age is the chronological age minus the number of weeks the infant was born early.) At this time, many healthy preterm infants are able to coordinate sucking with swallowing and breathing and have a functional gag reflex. In addition, infants must have enough energy to feed orally without compromising oxygenation. Very weak infants expend too

much oxygen, glucose, and energy when sucking and must continue to receive gavage feedings.

When the infant begins to feed by nipple, assess coordination of suck, swallow, and breathing and observe for aspiration. Frequent choking, gagging, or cyanosis during feedings may indicate that the infant cannot coordinate all feeding movements well enough for nipple feeding. Some infants are so weak that the usual signs of aspiration are minimal or absent.

Assess the respiratory rate before and during feedings. When the respiratory rate is more than 60 breaths per minute before feedings, gavage feed to prevent aspiration. During feedings observe for signs that the effort of nipple feeding requires too much energy and oxygen for the infant.

Nursing Diagnosis

When the infant's nutritional needs are met by parenteral methods, the nursing care is mainly collaborative. However, once the infant is able to breastfeed or take formula by bottle, many nursing interventions are involved. They address the nursing diagnosis "Risk for Imbalanced Nutrition: Less Than Body Requirements related to uncoordinated suck and swallow and fatigue during feedings."

CASE STUDY 29-1 CRITICAL THINKING EXERCISE*

When Giovanni is able to take enteral feedings, Katherine asks the nurse if there are any differences between how to give her baby a bottle and feeding her sister's baby who wasn't premature. How should the nurse answer her?

*Continued from p. 631; continues on p. 636.

Expected Outcomes

The expected outcomes are that the infant will:

1. Consume adequate amounts of breast milk or formula to meet nutrient needs for age and weight.
2. Gain weight as appropriate for age, generally 15 to 20 g/kg/day.

The actual amount of feedings and weight gain will vary according to the infant's gestational age and other conditions. Discuss what is appropriate for a particular infant with the physician or nurse practitioner.

Interventions

Administering Parenteral Nutrition

The nurse manages the administration of **total parenteral nutrition**, the IV infusion of solutions containing major nutrients needed for metabolism and growth. It may be necessary for very immature infants because of respiratory problems, limited gastric capacity, surgery, or reduced peristalsis. It provides calories, amino acids, fatty acids, vitamins, and minerals in amounts adapted to the specific needs of infants. It is continued, in decreasing amounts, until the infant is able to tolerate full enteral feedings.

Administering Enteral Feedings

Enteral feedings (feeding into the gastrointestinal tract, orally or by feeding tube) are usually begun within the first few days with minimal enteral feedings, also called *trophic feedings*. These feedings are given by gavage with only a few milliliters of breast milk or formula at a time. They stimulate development of the gastrointestinal tract, enhance gut motility, decrease need for parenteral nutrition, and shorten hospital stay (Carlo, 2011b). Bowel sounds should be present, there should be no significant abdominal distention, and infants should be in relatively stable condition. Human milk is preferred if it is available. Colostrum is especially high in immune agents to help prevent infection. Feedings are gradually increased according to the infant's tolerance.

Colostrum or breast milk can also be used for oral care of infants. It is applied to the infant's lips and inside of the mouth every 3 hours with a sterile swab. It provides the immunologic benefits of breast milk before the infant can take feedings (Spatz, 2011).

Preterm infants need special formulas or fortified breast milk. These formulas are adapted to meet the need for easily digestible, concentrated nutrients in a smaller volume of fluid. Preterm infants may need formulas that have 24 kcal/oz (instead of 20 kcal/oz used for the full-term infant) to meet their requirements. Preterm formulas may contain added calories, protein, vitamins, minerals, and complex fatty acids. Other components may be added to meet individual needs. Breast milk fortifiers add needed nutrients to breast milk.

Administering Gavage Feedings

Gavage feedings are usually started before oral feedings for preterm infants (see Procedure 29-1). A small, soft catheter is inserted through the nose or mouth every 2 to 3 hours for intermittent (bolus) feedings. An indwelling catheter may also be used to provide for intermittent or continuous feedings.

Inserting the catheter at each feeding may be more traumatic than leaving it in place. Frequent oral placement may cause vomiting or increase infant aversion to oral stimuli, which may lead to difficulty with oral feedings later. Vagal stimulation during insertion may cause apnea and bradycardia. Nasal placement avoids aversive oral stimulation but may increase airway resistance by interfering with air flow through the infant's small nasal passages.

Intermittent bolus feedings provide a more normal feeding pattern with periodic stimulation of gastric hormones and enzymes. They should be given slowly over 30 to 60 minutes.

Continuous feedings may be better for infants with short-bowel syndrome, congenital heart disease, intolerance to bolus feedings, or those recovering from NEC (Anderson et al., 2011). However, continuous feedings carry a higher risk of aspiration because the infant is not observed at all times during the feeding. In addition, bacteria counts in the milk or formula may become too high, and fats tend to adhere to the tubing during continuous feeding.

Feedings are gradually increased according to the infant's tolerance. Carefully observe the infant's response at each feeding to determine when the feeding type or amount can be changed. Parenteral nutrition continues until the infant is able to take adequate enteral feedings.

Pacifiers are often used during gavage feedings. Preterm infants have been exposed to noxious oral stimulation, such as intubation and suctioning. As a result, they may react negatively to any additional oral stimulation, which interferes with feedings. Providing a pacifier during gavage feedings gives positive oral stimulation and helps associate the comfortable feeling of fullness with sucking. Nonnutritive sucking increases later success in oral feedings and decreases behavior changes during feedings.

Nonnutritive sucking can also be provided by having an infant who is not ready for oral feeding suck on the mother's emptied breasts as a way to prepare for feeding from the breast. Gavage feeding can be done at the same time to help infants associate the breast with the feeling of being fed. This may improve breastfeeding ability when the infant is ready to be fed at the breast (Black, 2012).

Administering Oral Feedings

The first nipple feedings may consist of only a few milliliters once a day and may be completed by gavage. Feedings are based on infant cues showing readiness for oral feeding. They are gradually increased in amount and frequency until the infant feeds by breast or bottle once every 8 hours, then every second or third feeding, and eventually every feeding (Figure 29-4).

Oral feedings should be cue based (begun when the infant shows signs of physiologic and behavioral readiness to feed) rather than on a time schedule (Morris, 2011). Crying is a late hunger sign and may cause the infant to be too tired to eat. Cue-based feedings may help infants develop sleep-wake cycles and begin to self-regulate better.

Preparing for Feedings. Provide for maintenance of heat during feedings. When infants have stable temperature maintenance, wrap them in warm blankets and hold them for feedings. If thermoregulation is a problem, feed the infant in the radiant warmer or incubator.

Nipple feedings involve a greater expenditure of energy by the infant than gavage feedings. Allow for a period of rest before and after feedings. Use of a pacifier before feedings helps bring preterm infants to an alert state that enhances oral feeding success. Infants take feedings better if they are awake. Assess for signs of overstimulation and stress during feedings. If they occur, stop the feeding and let the infant rest. If the infant continues to show signs of stress, the feeding should be completed by gavage.

Infants may be fed according to a schedule such as every 3 hours or when they demonstrate hunger cues such as sucking on fingers.

PROCEDURE 29-1 ADMINISTERING GAVAGE FEEDING

PURPOSE: To feed infants who are unable to take the full feedings by nipple; may be used alone or along with nipple feedings

1. Wash hands. Gather equipment, including gavage catheter of proper size (4 to 8 French, depending on the size of the infant), measured container, 20-mL syringe, stethoscope, syringe pump, extension tubing, if needed. Warm the breast milk or formula to room or body temperature. Check the chart to determine how previous feedings were tolerated. Add fortifier to breast milk, if necessary. *Having all materials ready helps the procedure go smoothly and avoids disturbing the infant or delaying feedings. Cold milk could interfere with thermoregulation. Information about previous feedings will help meet the infant's needs.*
2. Don gloves. If the parents are present, they may hold the infant in their arms or in kangaroo care once the catheter is inserted. If the infant cannot be held, they may hold the infant's hands. *Feeding is important to the parents, and helping increases their sense of involvement.*
3. Determine the length of catheter to insert. Measure from the tip of the nose to the base of the ear to halfway between the xiphoid process and the umbilicus. Mark the catheter at the proper point with a piece of tape or indelible ink. If the tube is to be indwelling, check every 4 to 8 hours to see that the mark or tape remains in the same place. *The measured distance is equal to the distance from the mouth or nose to the stomach. The mark on the catheter shows whether the tube has moved out of place.*
4. For oral placement, insert the tube gently into the mouth until the mark on the tube is reached. For nasal placement, lubricate the tip with sterile water or lubricant. Gently insert into one nostril until premeasured mark is reached. Remove the catheter immediately if persistent coughing, choking, cyanosis, apnea, or bradycardia occurs. *Moistening or lubricating the tip allows easier passage. Gentle insertion prevents trauma. Signs may indicate that the catheter is entering the trachea instead of the esophagus. Stimulation of the vagus nerve may cause bradycardia or apnea.*
5. Check for placement. Attach a syringe to the catheter and gently aspirate stomach contents. Move or rotate the catheter slightly if the plunger does not withdraw easily. Check the pH of the aspirate or follow hospital protocol for method of checking for placement. Check that the mark on the tube is in the same place whenever care is given and before feeds. *The pH shows if the aspirate is stomach contents. Radiography may also be used to verify placement (usually only if done for another reason). Use of force could traumatize the stomach lining if the end of the catheter is resting against it. Moving the catheter may draw it away from the stomach lining. Checking the tube marking ensures the tube is still in the correct place.*
6. Secure the catheter to the cheek with an adhesive dressing. *Securing ensures the catheter will remain inserted to the proper point during the procedure.*

Continued

PROCEDURE 29-1 ADMINISTERING GAVAGE FEEDING—cont'd

7. Withdraw the stomach contents to check the gastric residual. Observe the amount, color, and consistency of the aspirate. During continuous feedings, check the gastric residual every 2 to 4 hours or according to hospital policy. Do not feed the infant if the aspirate is abnormal. The residual should not be more than half the previous feeding or happen more than once or twice. Report abnormal appearance or amount of stomach contents. *Stomach contents that are red or dark brown may indicate blood. If the aspirate is green with bile or brown with feces, intestinal obstruction may have occurred. An excessive residual may mean that the infant is receiving too*

much or that stomach emptying is delayed. Abnormal amount of residual may show the feedings are too large.

8. Replace the aspirate before beginning the feeding unless it is abnormal. If it is replaced, subtract the amount of gastric residual from the amount of milk to be given. *Replacement of aspirate prevents loss of electrolytes. Overdistention of the stomach is avoided by subtracting the residual from the feeding to be given.*
9. Remove the plunger, and attach the syringe to the feeding tube. Pour the correct amount of milk into the syringe. Attach to a feeding pump that will regulate the amount of flow. *A gravity flow or regulation of the flow by a pump causes less trauma and prevents filling the stomach too fast.*
10. If using gravity flow, raise or lower the syringe to increase or decrease the rate of flow so that the feeding moves slowly into the stomach over 30 minutes. *The higher the syringe, the faster the flow of solution and the greater the pressure. Feedings should be given slowly to prevent sudden distention or trauma from pressure.*
11. For continuous feedings, place no more than a 2- to 4-hour supply of milk in a syringe. Set the pump to deliver the correct rate of flow. Change the equipment according to hospital policy. *Limiting the amount of feeding and changing equipment prevent excessive growth of bacteria in the milk or tubing. Infusion pumps deliver the feeding at a constant, measured rate.*
12. Give the infant a pacifier during the feeding. *The pacifier stimulates the sucking reflex, helps prepare the infant for nipping, is comforting, and helps the infant associate sucking with feeding.*
13. For intermittent feedings with a catheter that remains in place, clear the catheter with 1 to 2 mL of sterile water and close off the end when the feeding is completed. *This prevents clogging of the tubing. Closing the end prevents formula from coming back through the catheter.*
14. When the catheter is to be withdrawn, pinch it and remove quickly. *Pinching prevents drops of fluid from entering the trachea as the catheter is removed, and quick removal decreases irritation.*
15. Burp the infant after feeding. *Air may be swallowed around the catheter and can cause the infant to regurgitate and aspirate.*
16. Record time, amount, and characteristics of gastric residual, type and amount of feeding given, and how the infant tolerated it. *Documentation allows monitoring of the infant's ability to tolerate feedings and meet nutritional needs.*

CRITICAL TO REMEMBER

Nipple Feedings**Signs of Readiness for Nipple Feedings**

Rooting
Sucking on gavage tube, finger, or pacifier
Ability to tolerate holding
Respiratory rate <60 breaths per minute
Presence of gag reflex

Signs of Nonreadiness for Nipple Feedings

Respiratory rate >60 breaths per minute
No rooting or sucking
Absence of gag reflex
Excessive gastric residuals

Adverse Signs during Nipple Feedings

Tachycardia
Bradycardia
Increased or decreased respiratory rate
Nasal flaring
Markedly decreased oxygen saturation level
Cyanosis, pallor
Apnea
Choking, coughing
Gagging, regurgitation
Drooling, gulping
Falling asleep early in the feeding
Feeding time longer than 20 to 30 minutes

FIG 29-4 The nurse feeds a preterm infant.

Crying is a late hunger sign and infants who cry excessively may be too tired to eat.

Choosing a Nipple. A variety of nipples for neonates are available. Soft, high-flow nipples (“preemie” nipples) are more pliable than regular nipples and require less energy for sucking. However, they may deliver milk too rapidly, cause choking, and interfere with breathing between sucking bursts. Standard nipples are firmer and deliver the milk more slowly so the infant can control it more easily. Nipples are available in several sizes, including those for infants with a very small mouth.

Nursing interventions for bottle feeding the preterm infant are presented in [Case Study 29-1](#). Common nursing diagnoses used for infants at risk are listed in [Box 29-1](#).

Facilitating Breastfeeding

Breast milk is best for almost all infants and especially for preterm infants. The [National Association of Neonatal Nurses’ Position Statement \(NANN, 2009\)](#) states human milk and breastfeeding are essential components in care of critically ill newborns. The American Academy of Pediatrics recommends that all preterm infants receive human milk ([AAP, 2012](#)).

Explain to parents that the immunologic benefits of breast milk are particularly important to the preterm infant who did not receive passive immunity during fetal life. Human milk provides protection against infections and decreases the incidence of NEC ([Carlo, 2011b](#)). Breast milk may stimulate the immune system and gastrointestinal maturation. It is well tolerated, and the nutrients in it are more available than those in cow’s-milk formulas. Nutrients in breast milk are more easily digested and it provides antimicrobial components, enzymes, hormones, and growth factors important for the preterm infant.

In addition, breastfeeding may be less stressful than bottle feeding for preterm infants. Oxygenation levels are often higher during breastfeeding because the infant can regulate breathing and suckling better than with bottle feeding ([Hurst & Meier, 2010](#)).

Offer support and encouragement to mothers who want to breastfeed. Contributing her milk helps the mother realize she has something important to offer at a time when she may believe she can do little to help her baby. Many mothers find this particularly rewarding and worth the effort involved. They may develop a sense of increased control when they are able to breastfeed and may take on more responsibility in infant care ([Black, 2012](#)).

BOX 29-1 COMMON NURSING DIAGNOSES FOR PRETERM INFANTS

- Activity Intolerance*
- Acute Pain
- Ineffective Airway Clearance
- Ineffective Infant Feeding Pattern*
- Ineffective Thermoregulation
- Interrupted Family Processes
- Pain
- Risk for Caregiver Role Strain
- Risk for Delayed Growth and Development
- Risk for Disorganized Infant Behavior*
- Risk for Imbalanced Fluid Volume
- Risk for Imbalanced Nutrition: Less Than Body Requirements*
- Risk for Impaired Parent–Infant Attachment*
- Risk for Impaired Parenting
- Risk for Impaired Skin Integrity
- Risk for Infection

*Nursing diagnoses explored in this chapter.

The mother who plans to breastfeed needs help with maintaining lactation until the infant is mature enough to nurse. Help her to begin to use a breast pump as soon as possible after birth and instruct her to pump at least eight times daily for 10 to 15 minutes ([Hurst & Meier, 2010](#)). [AWHONN \(2013\)](#) considers providing a breast pump and instruction to mothers of preterms within 6 hours of birth a nursing care quality measure.

Give the mother sterile containers to store her milk. Show her how to label her milk and where to take it when she brings it to the NICU. When she goes home, tell her to place her milk in a refrigerator if the infant will receive it within 24 hours or in a freezer if it will be more than 24 hours. If fortifiers will be added to the milk, explain the higher needs of the preterm infant so that the mother does not think something is wrong with her milk or that it is inadequate.

In some facilities, healthy preterm infants progress to breastfeeding from gavage feedings without using the bottle at all. This should be encouraged with eligible infants and mothers who desire breastfeeding.

Ongoing support for the mother is important. Encourage her efforts in feeding, which may be difficult at first. Remind her that even full-term infants must learn how to breastfeed. Mothers who have not breastfed previously have to learn the basic techniques and also how to adapt them for the preterm infant.

Relaxation needed for feeding is difficult in the busy NICU. Provide as much privacy as possible, using a separate room or screens. Help the mother feel comfortable holding the tiny infant and any attached equipment. The presence of a lactation consultant during initial breastfeeding sessions is very helpful.

Adapt breastfeeding teaching to the needs of a very small infant. Show the mother how to use the football and cross-cradle holds, which allow her to see the infant’s face well during latching on and throughout the feeding (see [Figures 22-4](#) and [22-5](#)). A supplemental nursing system, a device that holds expressed breast milk in a bag with a small tube attached to the mother’s nipple, may be used to help infants receive more milk with less effort during early feedings. Feedings should begin gradually and progress similar to initial bottle feedings.

Make the same observations of the infant during breastfeeding as during bottle feeding. Signs of fatigue, bradycardia, tachypnea, or apnea may show lack of readiness for breastfeeding. Be sure the infant

CASE STUDY 29-1 NURSING CARE PLAN*

ASSESSMENT: Two or three times a day Giovanni receives feedings by nipple supplemented by gavage when he becomes too tired. The feeding plan is for him to receive 120 kcal/kg/day to meet his needs. He has occasional episodes of increased respirations or short cyanotic spells when fed. He sometimes takes only half the feeding before falling asleep and must receive the rest by gavage. Katherine has decided to give him formula.

NURSING DIAGNOSIS: Ineffective Infant Feeding Pattern related to muscle weakness and fatigue during feedings

EXPECTED OUTCOMES: Giovanni will:

1. Take approximately 216 kcal/day to meet his needs at a weight of 1800 g.
2. Gain approximately 27 to 36 g (15 to 20 g/kg) daily.
3. Complete nipple feedings without signs of excessive fatigue (such as increased respiratory rate or falling asleep during feeding).

INTERVENTIONS AND RATIONALES

1. Schedule rest periods before and after nipple feedings. Feed Giovanni when he begins to show hunger cues but before he begins to cry with hunger. *Nippling consumes a great deal of energy. Rest helps prevent excessive fatigue that might prevent the infant from completing the feeding. Crying increases energy use.*
2. Use a pacifier before feedings. *Nonnutritive sucking helps alert the infant to prepare him for feeding.*
3. Gather equipment. Use a feeding container on which each milliliter is marked. Place the container in warm water to heat the milk to room or body temperature. *Having all equipment ready prevents wasted motion and allows the infant to be fed without interruption. Exact measurement of the amount taken is important to ensure infants receive required nutrients. Some infants will take slightly warmed milk better.*
4. Determine the type of nipple that works best for Giovanni. *The correct nipple will deliver milk at a rate the infant can manage without choking or expending more energy than necessary.*
5. Wrap Giovanni in warmed blankets with his extremities flexed and at the midline. Place a hat on his head. Choose a quiet area and avoid distractions and interruptions. *A hat and blankets help maintain temperature. The position is calming and decreases disorganized behavior. Too many stimuli may exhaust the infant and prevent optimal feeding behaviors.*
6. Position him at a 45- to 60-degree angle. Support his head and neck in a neutral position. *A flexed, upright position helps the infant control the flow of formula.*
7. Allow the infant to set the pace of the feeding. Feed slowly, and allow him to rest when he stops sucking. Remove the nipple from his mouth if he has

signs of stress or long sucking bursts without pausing to breathe. *Slow feeding is necessary because of Giovanni's decreased energy. Preterm infants have difficulty regulating their breathing while feeding. Removing the nipple allows the infant to rest and breathe.*

8. Do not move the nipple around in his mouth to force Giovanni to resume feeding before he is ready. Burp the infant frequently. *Moving the nipple interferes with the infant's ability to pace the feeding and need to rest periodically. Preterm infants may swallow more air than full-term infants do because sucking is less efficient.*
9. Observe for coughing, gagging, cyanosis, apnea, and changes in heart rate, respirations, and oxygen saturation. Stop feeding and evaluate the infant's ability to continue. Provide or increase oxygen, if needed. *These signs show difficulty coordinating sucking, swallowing, and breathing, and possible aspiration. Feeding requires more oxygen intake.*
10. Tip the bottle down to stop the flow if the infant is drinking too fast or having difficulty with pacing or coordination. *Allows the infant to rest yet avoids removing the nipple from the mouth if the infant has difficulty latching again.*
11. Assess for signs of overfatigue: falling asleep during feedings, feedings lasting more than 20 to 30 minutes, increased respirations, decreased oxygen saturation. *Feedings may require more energy than the infant has available. Infants who are overfatigued are more likely to aspirate. Calories may be used for energy for feeding instead of for growth.*
12. Finish the feeding by gavage, if necessary. *Completing the feeding by gavage conserves energy, prevents aspiration, and ensures the infant receives the desired nutrient intake.*
13. Teach Katherine how to feed Giovanni when she is ready to participate in his care. Teach her to assess feeding cues and Giovanni's response to feedings. Help her learn the infant's usual pattern of sucking, swallowing, and breathing and to watch for changes such as milk dribbling out of the infant's mouth or breathing irregularities that indicate a need to stop the feeding temporarily. *Feeding allows parents to participate in the infant's care. Their comfort with feedings and learning about the infant's responses will help them prepare for discharge.*

EVALUATION: Giovanni consumes an average of 220 calories a day and gains an average of 33 g daily. He gradually takes more of his feeding by nipple and rarely needs gavage feeding to finish it. His respiratory rate remains under 60 breaths per minute, and he stays awake for the entire feeding. Katherine becomes more comfortable when she sees him gaining weight and begins to participate in his care wholeheartedly.

*Continued from p. 632; continues on p. 643.

stays warm. The mother's body heat will help maintain the infant's temperature during feedings. KC is often started before the infant is able to breastfeed. As the infant becomes ready to breastfeed, KC can be continued during the feeding.

Thin nipple shields may be used in the first few days of breastfeeding to help the infant latch on to the breast and remain latched. Instruct the mother to pump her breasts at the end of each feeding because preterm infants may not suckle well enough to extract all milk from the breasts at first (AWHONN, 2007).

Making Ongoing Assessments

Continually assess the infant's responses to all feeding methods. Watch for signs of distress, especially when feedings are first initiated. Record the amount of breast milk or the amount of formula that the infant takes by gavage or bottle and compare it with the amount needed to meet nutrient needs for the infant's age and weight.

Because accurate estimation of milk intake is difficult during breastfeeding, infants may be weighed on an electronic scale before and after feedings to determine intake. Both weights should be taken with the infant wearing the same clothing and before the diaper is changed after the feeding. The difference in the weights in grams equals the milliliters taken. This allows supplementary gavage feeding amounts to be calculated on the basis of the infant's oral intake of breast milk.

Note the infant's response to other stimuli during feedings. Some infants respond well to being talked to and rocked during feedings. Others become distracted by any noise, motion, or nearby activities.

Weigh the infant daily at the same time with the same scale. Record the length and head circumference each week. Plot measurements on a growth chart for preterm infants and compare results with expected ranges. Weight increase not accompanied by increased length may be caused by edema and may be a sign of a complication such as congestive heart failure.

Observe changes in the infant's ability to take feedings. The suck and swallow coordination should gradually improve with maturity and practice. As the infant becomes more mature, less energy should be expended during the feeding sessions. The infant will take the feedings more quickly and show fewer signs of fatigue such as falling asleep during feedings.

Explain to the mother that she may need to continue to pump her breasts after feedings several times a day after the infant goes home. The infant's suck may still be too weak to adequately stimulate milk production. Pumping helps maintain the milk supply. The need to pump will lessen gradually as the infant nurses more vigorously.

Evaluation

If the expected outcomes have been met, the infant will consume adequate amounts of breast milk or formula to meet nutrient needs for age and weight and will gain weight as appropriate for age.

CHECK YOUR READING

8. What can the nurse do for the infant at risk for stress from overstimulation?
9. How does the nurse assess feeding tolerance?
10. Why should the nurse allow the infant to set the pace of feedings instead of urging continuous sucking?
11. How can the nurse help the mother who wants to breastfeed her preterm infant?

PARENTING

The birth of a preterm infant is generally unexpected and always emotionally traumatic to parents. Infants are often hurried to the NICU shortly after birth. Later, when parents go to the NICU, the infant is attached to an array of machines.

Parents cannot hold or feed the infant, at first, or offer any of the usual care that parents expect to give their infants. The infant may not be capable of common newborn behaviors such as making eye contact and grasping the parent's finger. When the infant's appearance and behavior are different from the parents' expectations, attachment may be delayed.

The extended hospitalization of the preterm infant causes separation of the parents from their newborn, produces emotional trauma, and disrupts family life. Parents must relinquish the role of primary caregiver during their infant's hospitalization. They may feel they are in the nurse's way and may state they do not feel like parents at all. Loss of the parental role is a major stressor for these parents.

Being unable to participate fully in the infant's care for a prolonged period hampers the parents' ability to learn their baby's unique characteristics such as the way the infant responds to stress and the methods of consolation that work best. Separation delays the development of the parent–infant relationship and may impair the parents' bonding.

In addition, parents worry about the infant's condition and outcome. They need help in understanding the infant's condition and what can be expected to occur throughout the hospital stay. Nurses must evaluate the progress of attachment to assist parents to feel important in caring for their infant.

Assessment

Assess for signs of parental attachment on the first and subsequent visits to the NICU nursery. Expect parents to be fearful at first but more able to focus on the infant as they recover from the initial shock of preterm birth. Assess for common behaviors that show normal progression of attachment. These include talking about the infant in

positive terms, making eye contact, pointing out physical characteristics, naming the infant, and calling the infant by name.

Parents should ask questions about the infant. When they are able to hold and participate in the care of the infant, observe for gradual increase in comfort and skill. The parents should smile and talk to the infant and verbalize increasing confidence in their caregiving abilities.

Watch for signs that bonding is not occurring as expected. These include failure to show usual attachment behaviors or a decrease in behaviors that were previously present. Parents who seem as interested in other infants in the NICU as in their own infant or talk about the infant in an impersonal way may be having difficulty. Note how often the parents make visits or calls to the NICU and changes that may indicate their need for support.

Determine if there are other stressors in the parents' lives that may interfere with their ability to visit and form attachment to the infant. The financial need to return to work, lack of transportation, long distances, or the need to care for other children may prevent parents from visiting as often as they would like.

After the critical period in the early days after birth, healthy preterm infants become more stable. They still require specialized nursing care and hospitalization but gradually need fewer technologic interventions. They are sometimes called "growers" at this time. This is a time when parental participation in the infant's care should increase in preparation for discharge.

CRITICAL TO REMEMBER

Signs That Bonding May Be Delayed

- Using negative terms to describe the infant
- Discussing the infant in impersonal or technical terms
- Failing to give the infant a name or to use the name
- Visiting or calling infrequently or not at all
- Decreasing the number and length of visits
- Showing interest in other infants equal to that in their own infant
- Refusing offers to hold and learn to care for the infant
- Showing a decrease in or lack of eye contact
- Spending less time talking to or smiling at the infant

Nursing Diagnosis

For most parents of preterm infants, an important nursing diagnosis is "Risk for Impaired Attachment related to separation of parents from infant and lack of understanding about the preterm infant's condition and characteristics."

Expected Outcomes

The expected outcomes for this nursing diagnosis are that the parents will:

- Demonstrate bonding behaviors, including visiting or calling frequently and interacting as appropriate for the infant's condition throughout the hospital stay.
- Verbalize understanding of the preterm infant's condition and characteristics within 2 days.
- Express gradually increasing comfort in participating in infant care throughout the hospital stay.

Interventions

Making Advance Preparations

Preparing for stressful situations such as preterm birth helps parents cope with the actual event. Parents at higher risk for a preterm birth should visit the NICU before delivery. If the mother is confined to bed,

arrange for a nurse from the NICU to visit her so that she feels a link with the nursery. The father or another support person should tour the nursery so that he can discuss the nursery environment with the mother. Encourage the parents to ask questions.

EVIDENCE-BASED PRACTICE

A Nurse-led Intervention for Maternal Stress

Maternal stress associated with the neonatal intensive care unit (NICU) experience is a common and unfortunate occurrence. [Morey and Gregory \(2012\)](#) conducted a study of women to determine the effect of a nurse-led intervention on maternal stress.

Forty-two women who were being cared for in a high-risk antenatal unit of a large academic medical center in the northeastern United States were recruited for the study. The women were admitted for preterm labor, preterm premature rupture of membranes, cervical changes, and other maternal or fetal complications. They completed surveys before the intervention, immediately following the intervention, and up to 72 hours after admission of their infant to the NICU.

The intervention was an educational class held on the high-risk antenatal unit. The class consisted of (1) a video to show the NICU, interviews with NICU parents, and NICU infants; (2) a teaching segment by a NICU nurse with information about prematurity, care of preterm infants, and family involvement in the NICU; and (3) a tour of the NICU and observation of a preterm baby.

The surveys were given to the 42 women before and after the NICU class. Only 32 infants were admitted to the NICU, and their mothers completed the third survey. The mothers' knowledge was assessed at each time point. Following the class, they were significantly more knowledgeable about their infant's body, physical needs, NICU equipment, the persons who would be taking care of their infant, and the importance of breastfeeding. The surveys showed them to be more knowledgeable right after the class than when their infants were admitted to the NICU. The reasons were thought to be anxiety about the actual birth and NICU admission and the time span between the class and the admission.

Stress was measured by the Parental Stressor Scale: NICU. There was significantly less stress related to the sights and sounds of the NICU and infant behavior and appearance between the first and third survey points. Although there was less change in stress in the area of parental role alteration, the authors attributed this to the separation that occurs when the infant is admitted to the NICU. Overall, the intervention increased the mothers' knowledge and decreased their stress and is being continued in the hospital that was the study setting.

What is done in your unit to increase parents' knowledge about preterm infants and to decrease their stress? Why do you think the mothers in this study did not have a significant decrease in their feelings about parental role alteration?

Reference: Morey, J.A. & Gregory, K. (2012). Nurse-led education mitigates maternal stress and enhances knowledge in the NICU. *MCN: The American Journal of Maternal/Child Nursing*, 37(3), 182-191.

Assisting Parents after Birth

After the birth, allow the parents to see and touch the newborn in the delivery room, even if only for a few moments, so they have a realistic idea of the infant's appearance and condition. This helps the bonding process that began in pregnancy to continue.

If possible, allow the father or primary support person to watch the initial care in the NICU. Explain what is happening and why. This attention allows him to see the intense efforts made on behalf of his infant, increases his confidence in the staff, and enables him to give the

FIG 29-5 An infant in the neonatal intensive care unit is surrounded by highly technologic equipment. This can be very frightening to parents at first. Preparation of parents before they visit is an important nursing responsibility.

mother a full description later. Support the father as well as the mother by using therapeutic communication during this difficult time.

If the infant must be transported to another facility, ask the transport team to visit the parents before leaving, if possible. The visit helps parents feel connected to their infant and to the staff providing care. Leaving photographs with the mother is another way of helping her bond even though the infant is not with her.

Supporting Parents during Early Visits

Take the parents to the NICU as soon as possible. If the mother is too ill to be with her infant, bring her photographs. Before parents first visit the infant, prepare them for what they will see. Describe the equipment, the various attachments to the infant, and the purposes ([Figure 29-5](#)). Explain how the infant will look and behave. [Box 29-2](#) provides specific steps that the nurse can follow to help parents become familiar with the NICU setting.

At first, stay with the parents during visits. When they are comfortable, allow them time alone with the infant so that they can interact in private. Answer questions and explain changes in the infant's condition and treatment. Expect to repeat explanations because stressed parents may not understand or remember what was said. Parents often do not know what questions to ask at first or are too overwhelmed to ask questions. In this situation, discuss questions that are common when parents first visit the NICU. Use therapeutic communication as the parents cope with their grief, guilt, and emotional turmoil.

Parents should touch the infant as soon as possible because touching helps promote attachment. They may be hesitant initially because of fear they will interfere with equipment. The smaller the infant, the more reluctant the parents may be. Some parents may hesitate to touch because they are afraid of becoming attached to an infant who may not live. They need sensitive support from the nurse until they are ready to progress in their relationship with the infant.

Show parents how to touch in ways appropriate for the infant, such as holding the infant's hand through the portholes of the incubator or touching the small areas of skin not encumbered by equipment. Explain that handling is kept to a minimum for physiologically unstable infants because it is too stressful to them. As the infant becomes more stable and mature, show parents which forms of touch work best

BOX 29-2 INTRODUCING PARENTS TO THE NICU SETTING**Before Parents Visit the NICU**

If possible, provide the parents with a tour of the NICU before the birth. If a tour is not possible, describe the NICU environment. Include the noise of alarms, the busyness of the staff, and the number of people and sick infants.

Describe the equipment. Include ventilators, IV lines, feeding tubes, and monitors. Explain how they look and how they are attached to the infant. Keep the explanations simple, without technical details.

Show the parents photographs of their infant. This helps prepare them but seeing photographs is not as overwhelming as seeing the infant in person.

Describe the infant. Include the size, lack of fat, breathing problems, and weak cry. Explain that no sound of crying can be heard if the infant is intubated. Include some personal aspects: "He's a real fighter" or "She makes the funniest faces during her feedings."

When Parents Visit the NICU

Help the parents perform thorough handwashing, and explain the importance.

Stay with the parents during their visit. Having a familiar person nearby will help them feel more comfortable while they adjust to this unfamiliar environment.

Introduce them to their infant's nurse. Ask the NICU nurse to explain some of the care being provided for the infant.

Give parents printed information about the NICU so that they can take it home to read later. This includes visiting hours, telephone updates, availability of classes on preterm infant care, and support groups.

Tell the parents they will receive instruction on how to care for their infant in time. Encourage them to visit the infant as much as they can. Emphasize how important they are to their infant.

Offer realistic encouragement based on the infant's condition.

Provide an opportunity for the parents to express their concerns and feelings and ask questions.

with their infant. This helps parents feel more a part of the infant's plan of care.

Help the parents hold the baby as soon as possible. Parents often look forward to the opportunity to hold the baby as a positive sign of the infant's condition. Yet it is frightening, too, especially if the infant is attached to various kinds of equipment. Help the parents find a comfortable position for themselves and the infant and point out positive responses from the infant.

Supporting the Father

Nurses often concentrate on the mother in providing support. However, fathers also must deal with the shock of having a preterm infant in the NICU. They need support in learning about their infant and how to parent. One study showed fathers of NICU infants had elevated levels of stress and symptoms of depression throughout the 7 weeks of the study (Mackley, Locke, Spear et al., 2010).

In addition, fathers have work responsibilities, are expected to provide emotional support for the mother and explain the condition of the mother and infant to friends and family, and may take on other family responsibilities as the mother focuses on care of the newborn. Fathers may spend less time in the NICU because they are at work but may have many questions and concerns. If their time for visiting is limited, fathers may be less comfortable than the mother with caregiving activities. Encourage them to participate in hands-on care

THERAPEUTIC COMMUNICATIONS**Reassuring Parents during Visits to the NICU**

Shareen gave birth to a preterm infant, Valerie, at 28 weeks of gestation. Shareen is visiting the NICU for the first time the day after the birth. Andy, the nurse, has talked to her about what to expect and stays with her during the visit.

Shareen: Oh, she looks so tiny! I saw her for only a minute after she was born, and I didn't really get a good look. How can she ever survive when she's so small and covered with tubes?

Andy: So far, Valerie's doing very well. Her vital signs are stable, and she's holding her own. But it's frightening when she looks so small and vulnerable, isn't it? (*Offering realistic reassurance and reflecting Shareen's fearful feelings. Using infant's name to promote bonding.*)

Shareen: I stayed in bed like they told me to do to help my blood pressure. I thought she wouldn't be born so soon if I stayed in bed.

Andy: It must have been a shock, especially when you tried so hard to prevent it. (*Reflecting feelings and acknowledging that Shareen did what she could to prevent early birth.*)

Shareen: Now she's so tiny and so sick! She looks very different from what I expected.

Andy: Valerie's small, but babies her size grow very quickly. Would you like to touch her? (*Offering realistic reassurance and attempting to bring Shareen closer to her infant.*)

Shareen: Oh, I might hurt her. Maybe I should wait until she's bigger.

Andy: Even tiny babies like to have their mothers touch them and talk to them. She listened to your voice all through your pregnancy, so it's familiar to her. Why don't you talk softly to her while I work with her? And I can tell you about all this equipment and what we are doing for Valerie. (*Emphasizing the mother's importance, involving her in care being given, and offering information about the infant's equipment and care.*)

whenever possible. Compliment each parent as they care for the infant so they are encouraged to participate even more.

Providing Information

An important role of the nurse is providing accurate information to parents. Allow parents to express their concerns before beginning to teach. Encourage them to ask questions about all aspects of their infant's condition and care. Although some mothers are not hesitant to ask questions, others may avoid asking for explanations or advocating for their need to care for their infants because they are afraid that they might be seen as difficult or "demanding parents" (Siegel, Gardner, & Dickey, 2011). Let the parents know that their questions are welcome, and do everything possible to give them the answers when they do ask questions. Give information about common concerns if the parents do not ask questions.

Explain the equipment used to care for the infant. Interpret the information obtained from monitors and the meanings of alarms. Clarify all nursing care, its purpose, and the expected response. Point out how preterm infants are similar to and different from full-term infants to help parents develop an accurate understanding of the infant's capabilities.

Offer realistic reassurance about the infant's condition, emphasizing positive aspects while being truthful. If the parents have misconceptions or did not understand a physician's explanations, clarify or ask the physician to go over specific information again. Translate medical terms into words the parents can understand. Repeat explanations, especially at first. Because of their emotional distress, parents are often unable to fully comprehend or remember what is said to them.

Use an interpreter if the parents do not understand English. Offer written information about NICU policies and procedures in the parents' language. Explanations about visiting hours, who can visit, routines for handwashing, and the role of parents can be reinforced in writing so they are available for later reading by overwhelmed parents.

CRITICAL THINKING EXERCISE 29-1

A woman delivered a 29-week preterm infant 3 days ago. She comes to see her baby infant each day, but refuses to touch the infant, in spite of frequent offers from the nurses.

Questions

1. What might explain her behavior?
2. How might the nurse help her?

Instituting Kangaroo Care

Parents need to feel that they can contribute to the care their infants receive. One way to do this is KC. Begin KC as soon as possible, if the parents are interested. KC is a method of providing skin-to-skin contact between stable preterm infants and their parents.

During KC, the infant, wearing only a diaper and hat, is placed upright under the mother's clothes between her breasts. A blanket is placed over them both (Figure 29-6). Mothers may breastfeed if they wish and if the infant is able. Fathers are encouraged to participate in KC also (Figure 29-7). The infant is monitored for changes in vital signs and behavior.

Explain the advantages of KC to parents, and elicit their participation. This method of care has been found safe for stable infants, even if intubated. It provides an opportunity for parents to participate in the infant's care and increases parental attachment. KC provides developmental care so important for the preterm infant. It is associated with stability of vital signs, increased weight gain, shorter length of stay, more quiet sleep, and less crying (Carrier, 2010). It also promotes thermoregulation, bonding, and helps relieve pain (Hardy, 2011b).

The upright position of the infant against the parent's chest makes breathing easier. The containment of the extremities decreases purposeless movements that use valuable oxygen and calories.

FIG 29-6 This mother has her 27-week-gestation preterm infant tucked under her clothes against her skin as she gives kangaroo care. Such care enhances bonding and has many other benefits for infants and parents.

Breastfeeding is facilitated, and the infant has more alert periods and increased deep sleep. The contact with the parent's skin maintains the infant's body temperature. In addition, KC enhances early and long term maternal-infant interaction and maternal confidence and competence (Gardner & Goldson, 2011).

KC also provides gentle stimulation. This includes tactile stimulation against the parent's skin, auditory stimulation as the infant listens to the parent's heartbeat and voice, and the vestibular stimulation of moving with the parent's breathing or rocking.

Provide privacy for parents interested in KC. Assist them in transferring the infant from the bed, managing the attachments, and making the infant comfortable. Also, check to see that they are comfortable. Explain that alarms are often set off because of changes in the infant's vital signs or oxygenation during the transfer process but that the infant becomes stable again once settled. KC should last at least an hour to improve the infant's sleep (Hardy, 2011b).

Facilitating Interaction

Preterm infants often have little facial expression and seldom make eye contact. Parents may feel rejected by the infant's lack of response or by negative responses during interactions. Explain that the interaction that is so effective with full-term infants may be too stimulating for very young or sick preterm infants. Suggest forms of touch and interaction based on the individual infant's capacity. Quiet holding may be better until the infant is able to tolerate more stimulation.

Help parents understand the infant's behavior and cues. Teach them signs of overstimulation to help them adapt their interaction to meet the infant's needs. Explain that these signs help protect the infant from overstimulation and show that the infant needs a quiet rest period without added stimulation. Discuss methods to avoid too much stimulation and to calm the infant. If several types of simultaneous

FIG 29-7 Even though he is intubated, this 1 lb, 8 oz preterm infant goes to sleep against his father's chest.

stimulation (such as rocking, eye contact, and talking) cause signs of distress, suggest they stop one or more activities until the infant has had a rest period.

In learning to provide comfort care, parents may go through stages. At first they are afraid to touch the infant. They spend time just observing the infant before they feel comfortable enough to touch the infant. When they begin to participate in caregiving such as changing a diaper, their confidence grows. Parents become more confident in their ability to recognize when the infant is uncomfortable and their skill in comforting their infant (Skene, Franck, Curtis et al., 2012).

Teach parents how to soothe infants when they show signs of stress. Explain containment and demonstrate how to do it. Placing the palm of the hand over the infant's chest or holding the infant's arms on the chest may help quiet the infant (Gardner & Goldson, 2011). Show the parents how to position the infant with the hands near the mouth so that the infant can suck on them as a self-comforting measure. As the infant is ready for more interaction, suggest appropriate types of stimulation.

Point out small signs of improvement and even minor strengths. Talk about normal preterm characteristics and emphasize individual traits that make this infant different from all others. The way the infant eats, reacts to sounds, or seems to get tangled in the monitor leads may help parents feel closer to their newborn.

Involve the parents in care of the infant as soon as possible to help them gain a sense of control (Figure 29-8). Plan to change the linens in the incubator or radiant warmer when the parents are there so that they can hold their infant, even if for only a few moments. Save baths and other routine caregiving for times when parents can be present and can participate. As the infant's condition improves, parents can develop skill in caring for the tiny infant by changing diapers, feeding, and bathing.

In some NICUs, infants who are stable, who weigh more than 1000 g, and who do not need phototherapy, an umbilical catheter, or chest tubes are dressed in normal baby clothes. This helps them appear more normal to parents and assists in attachment. Parents use hospital-supplied clothing or bring their own and enjoy the opportunity to dress their infants (Bosque & Haverman, 2009).

Include other family members by allowing them to visit with the parents (Figure 29-9). Being able to see the infant in the hospital setting allows family members to provide the parents with more realistic

emotional support. Involve family members in learning how to feed and care for the infant if they will be helping the parents after discharge.

In some facilities, parents and, in some cases, grandparents are allowed to visit at any time of the day or night. They might be asked to leave during reporting or be invited to stay and participate to help them feel more a part of the infant's care.

Web-cameras are used in some NICUs to allow parents to see their infants from their homes or from the hospital room. A web-camera is placed over the infant's bed, and parents use a computer to access a secure website to see their infant. The camera may be on continuously or only on at certain times. Parents can share the website with family and friends so that they can see the infant as well. Families report being very satisfied with this opportunity (Rhoads, Green, Lewis et al., 2012).

Increasing Parental Decision Making

Parents should be considered an essential part of the health care team, rather than visitors (Klaus, Kennell, & Edwards, 2011). Give them the information they need to take an active part in decisions made about the infant's treatment plan. This is true even for decisions that seem insignificant to the staff (Baker, 2009). This knowledge will increase their feelings of control over a situation in which many parents feel they have little power.

As parents get to know the infant better, they become experts on the infant's response to various situations and caregiving activities. Their expertise should be recognized and respectfully considered in planning infant care. Although parents often feel like outsiders when first visiting the NICU, they can, in time, move into the role of partners with the NICU staff in caring for the infant.

Look for opportunities to praise parenting abilities. Point out positive ways the infant responds to the parents' touch and caregiving. Model methods to respond to behavioral cues and acknowledge parents when they respond to the infant's signals appropriately. Listen to their ideas about what works best for the infant, and incorporate them if at all possible.

Alleviating Concerns

Invite parents to call the NICU at any time for information about their infant. This helps allay worry when parents wake up at night and wonder how the infant is doing. Phone calls are especially beneficial for parents unable to visit the infant because of distance or other reasons.

Parents also need support from others besides nursing staff. Put them in touch with parents of other preterm infants, and refer them

FIG 29-8 To promote family bonding with the infant, parents are involved as much as possible in the care of their infant. This father bottle feeds his infant who is in a radiant warmer.

FIG 29-9 The parents look on while the grandmother holds the infant in the neonatal intensive care unit.

to support groups, parent-to-parent groups with veteran NICU parents, telephone support, educational offerings, or counseling sessions. Tell them about Internet sources such as www.premiecare.org.

Talking with others who have faced the same problems can be very comforting as parents compare notes and get practical suggestions from an experienced parent's point of view. Some agencies pair parents with a "buddy," who has had a similar experience and is from the same culture. Special programs may be available after discharge to provide parents with ongoing support and education. It is important to consider language and culture during this process.

Cultural practices should be incorporated into the care of the infant. Determine who in the family will make the decisions and who will be managing the infant's care. In some cultures, the father makes decisions, and the grandmother, rather than the mother, is the major caregiver. In these cases, it is essential that the right persons be included in appropriate teaching. In many cultures, the mother is expected to stay at home to recover after giving birth. This interferes with her ability to spend time in the NICU. Another family member may be enlisted to be with the infant in these cases (Moore, Moos, & Callister, 2010).

Helping with Ongoing Problems

Parents may be unprepared for the inconsistent progress infants often make after surviving the risks of the early days. They expect steady progress once the infant can breathe independently and take feedings. However, complications such as NEC or sepsis can cause major setbacks at this time. To cope with a new crisis, parents need extensive support from the nurse. Use therapeutic communication techniques such as reflecting feelings to help them express and cope with their extreme disappointment. Give information about the infant's changing condition and what to expect in the days ahead.

Having a hospitalized child can be exhausting for the parents. Remind them to take breaks away from the infant, whether to go to the cafeteria for a meal or to go home and rest. As the infant's condition improves, parents may take more time away as they begin to prepare for discharge. Encourage them to do this, while making sure that they feel welcome to stay with the infant as much as they desire (Discenza, 2009b).

Mothers with infants in a NICU may have problems with sleep disturbances and depressive symptoms (Lee & Kimble, 2009). Be alert for signs of postpartum depression because fatigue and having an ill infant are factors that may lead to this condition. One study found a 20% rate of depression in mothers during the 18 months following their high-risk infants' discharge from a NICU (Northrup, Evans, & Stotts, 2013). (See Chapter 28.)

Preparing for Discharge

In the past, preterm infants often were discharged about the time of their expected birth. However, many infants now go home before 40 weeks' **corrected age**. It is important that the parents understand the expected hospital course.

Begin early to teach parents and other caregivers any special procedures, treatments, and medications that the infant will need after discharge. Observe the parents as they perform care until they are comfortable and can do it safely. Praise their efforts, and provide hints to make the care easier. Provide written information about home care of the preterm infant.

Help the parents learn what is normal for their infant and how to recognize and respond to abnormal signs. Some hospitals have the parents spend a night or two in a special "parent room," where they assume full 24-hour care of the infant and still have help when they need it. This helps increase parents' confidence that they can care for

the infant by themselves. It also allows staff to evaluate the parents' abilities to care for the infant.

In one study, the parents reported that they felt more confident in activities such as recognizing changes in the infant's condition, giving medications, and working with cardiorespiratory monitoring when they were in the NICU than when they were home with the infant (Raines & Brustad, 2012). Help them practice more with these "medical" care activities so that they know how to handle problems that might occur at home.

Help the parents determine what adaptations they will need to make at home before discharge. Utility companies should be notified if the infant is considered medically fragile to ensure that the family receives priority service in case of a power failure. Provision for emergency electricity such as batteries should also be arranged. Arrange home nursing services, purchase of supplies, and delivery of special equipment before discharge.

Discuss what to expect with regard to care of the infant after discharge. Infants may require oxygen, cardiorespiratory monitoring, suctioning, gavage or gastrostomy (tube) feedings, or other treatments that parents will have to learn to perform. Many infants need feedings every 3 hours, day and night, to help them gain weight adequately. Feedings may be time consuming, and parental fatigue resulting from sleep interruptions may be more than they expected.

Infants are used to the noises of a nursery 24 hours a day and may not sleep well at first in a quiet home environment. Suggest parents play soft music and use a night light for the first week. They should gradually eliminate these aids to avoid conditioning the infant to their use. Visitors and noise or activity may be too much for the infant at first and should be limited.

Explore with parents what kind of help they might need to meet the everyday requirements of the infant and the rest of the family. Help them identify where they might find assistance from family and friends. Reassure them that friends and family often welcome opportunities to help.

The AAP and ACOG (2012) recommend the following in determining the time of discharge:

- Signs of readiness for discharge include a sustained pattern of weight gain, adequate maintenance of body temperature in an open bed, feeding without cardiorespiratory compromise, and stable cardiorespiratory function.
- Appropriate immunizations should have been given; car seat evaluation completed; metabolic screening performed; assessment of hearing, the eyes, hematologic status, and nutritional risks performed; and appropriate treatment plans completed before discharge.
- The family and home should have been evaluated. The family must have at least two members who demonstrate the ability to feed and provide all needed care, perform cardiopulmonary resuscitation, give medications, operate equipment, and show understanding of signs of problems and what to do about them.
- A primary care physician and other appropriate follow-up care have been arranged.

Help parents form realistic expectations about the infant. For example, they should know that the infant will accomplish developmental tasks such as crawling and walking later compared with full-term infants. Parents should base their expectations on the infant's corrected or developmental age rather than on chronologic age.

Assist the parents in planning how to integrate the new infant into the family. Meeting the needs of their other children, in addition to the new responsibilities of caring for the preterm infant, is a major source of worry. Listen to their concerns about their other children, and encourage siblings who do not have infections to visit, if possible.

Help parents prepare siblings for what they will see and do when visiting. Siblings should touch or hold the infant, if possible, to help them bond. Taking photographs of the siblings with the infant will help them remember the visit.

Before discharge, a car seat challenge is often performed (see p. 622). Proper positioning with blanket rolls may be necessary because the infants may slump over, interfering with chest expansion. Some infants need car beds to allow them to ride in the recumbent position.

Evaluation

Expected outcomes are met if parents visit often and interact appropriately with the infant, express their understanding of and comfort with the infant's needs, and take an increasingly active role in the care of the infant.

CASE STUDY 29-1 CRITICAL THINKING EXERCISE*

Giovanni was discharged from the hospital at 8 weeks of age. He was seen by the pediatrician at 48 hours after discharge and again at 2 weeks. At a well-baby checkup 6 weeks after discharge, Katherine asks many questions about infant development. One question is when Giovanni will begin to roll over from the abdomen to the back. The nurse knows that most full-term infants reach this developmental milestone at 4 to 5 months of age.

Question:

1. How should the nurse answer this mother?

*Continued from p. 636.

CHECK YOUR READING

12. How can the nurse help parents be comfortable with their preterm infant?
13. How should the nurse prepare parents for the discharge of their preterm infant?

COMMON COMPLICATIONS OF PRETERM INFANTS

Complications of prematurity increase as the infant's gestational age and birth weight decrease. Some complications that occur in full-term and preterm infants, such as hyperbilirubinemia, are discussed in [Chapter 30](#). Complications most often associated with preterm birth are discussed here. Further information about each condition can be found in pediatric texts.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) is a condition caused by insufficient production of surfactant in the lungs. It occurs most often in preterm infants under 28 weeks of gestation and increases as the gestational age decreases. It also occurs in birth asphyxia, cesarean birth, multiple births, male gender, cold stress, and maternal diabetes because these conditions interfere with surfactant production. It is less frequent, however, when antenatal corticosteroids or chronic fetal stress, such as in heroin addiction, maternal hypertension, or prolonged rupture of membranes, causes the lungs to mature more quickly ([Carlo & Ambalavanan, 2011](#)).

Pathophysiology

Surfactant is a phospholipid that lines the alveoli. Surfactant decreases surface tension to allow the alveoli to remain open when air is exhaled. It must be continuously produced as it is used. Enough surfactant is usually produced beginning at 34 to 36 weeks of gestation to prevent respiratory distress syndrome ([Gardner, Enzman-Hines, & Dickey, 2011b](#)).

When too little surfactant is present, the alveoli collapse each time the infant exhales. The lungs become **noncompliant** or "stiff" and resist expansion. Noncompliant lungs require a much higher negative pressure for the alveoli to open with each inhalation. This results in severe retractions with each breath because the chest wall is very compliant. The weak muscles of the chest are drawn inward, placing pressure on the lungs that further interferes with expansion. Seesaw respirations may also occur.

As fewer alveoli expand, atelectasis, hypoxia, and hypercapnea (increased carbon dioxide) occur. This causes pulmonary vasoconstriction and decreased blood flow to the lungs because of the high resistance within the pulmonary blood vessels. Persistent pulmonary hypertension can result in a return to fetal circulation patterns, with opening of the ductus arteriosus (see [Chapter 30](#)). Acidosis and alveolar ischemic injury further complicate the condition by interfering with surfactant synthesis.

Tests of amniotic fluid can detect lecithin, sphingomyelin, phosphatidylglycerol, and phosphatidylinositol, which are components of surfactant. These tests can predict whether the fetal lungs are mature enough for survival outside of the uterus. They are performed before an induction or cesarean birth is performed on an infant younger than 38 weeks of gestation (see [p. 172](#)). The incidence and severity of RDS may be reduced by giving the mother corticosteroids before birth.

Manifestations

Signs of RDS begin during the first hours after birth. They include tachypnea, tachycardia, nasal flaring, xiphoid and intercostal retractions, and cyanosis. Audible grunting on expiration is characteristic. It results from air moving past a partially closed glottis, which helps maintain lung expansion, gas exchange during exhalation, and functional residual capacity. Breath sounds may be decreased, and rales may be present.

Acidosis develops as a result of hypoxemia. Blood gases show increased carbon dioxide levels and decreased oxygen levels. Chest radiographs show the "ground glass" reticulogranular appearance of the lungs that is characteristic of RDS. Areas of atelectasis are present. Signs become worse and peak within 3 days and then begin to improve gradually ([Carlo & Ambalavanan, 2011](#)).

Therapeutic Management

Surfactant is instilled into the infant's trachea shortly after birth or as soon as signs of RDS become apparent. Doses are repeated, if necessary. Infants treated with surfactant have higher survival rates, although the incidence of other complications of prematurity such as bronchopulmonary dysplasia (BPD) is unchanged ([Carlo & Ambalavanan, 2011](#); [Gardner, Enzman-Hines, & Dickey, 2011b](#)).

Other treatment is supportive, including oxygen, continuous CPAP or mechanical ventilation, inhaled nitric oxide, correction of acidosis, IV fluids, and care of other complications. Antibiotics may be given because signs of neonatal pneumonia are similar to RDS ([Hamvas, 2011](#)). Low temperature and low glucose level may occur and should be treated promptly.

Nursing Considerations

The nurse observes for signs of developing RDS at birth and during the early hours after birth. Changes in the infant's condition are constantly assessed. Changes in ventilator settings may be necessary as the infant's ability to oxygenate increases. Observation for signs of common complications such as patent ductus arteriosus and BPD is important. The nurse must monitor the results of laboratory tests for abnormalities in blood gases and acid-base balance. Early signs of sepsis must be

identified and reported. Other care is similar to general care for the preterm infant.

Bronchopulmonary Dysplasia (Chronic Lung Disease)

Bronchopulmonary dysplasia (BPD), also known as *chronic lung disease*, is a chronic condition in which damage to the infant's lungs requires prolonged dependence on supplemental oxygen. It occurs most often in infants less than 32 weeks' gestational age and in one third of VLBW infants. Infants generally continue to require oxygen at 36 weeks postmenstrual age or at 28 days after birth (Campbell, 2009).

Pathophysiology

BPD results from a combination of factors such as high levels of oxygen, oxygen free radicals, and pressure of mechanical ventilation that injure bronchial epithelium and interfere with alveolar development. The result is inflammation, atelectasis, edema, and airway hyper-reactivity with loss of cilia, thickening of the walls of the alveoli, and fibrotic changes.

Manifestations

The major sign of BPD is an increased need for or an inability to be weaned from respiratory support and oxygen. Other signs include tachycardia, tachypnea, retractions, crackles, wheezing, respiratory acidosis, cyanosis, increased secretions, bronchospasm, and characteristic changes in the lungs on chest radiographs. Pulmonary edema may occur.

Therapeutic Management

Prevention includes use of maternal steroids to reduce prematurity and RDS, minimizing exposure to oxygen and pressure with ventilation as much as possible, avoidance of fluid overload, and increased nutrition. Treatment is supportive, with antibiotics and bronchodilators as necessary, and gradual decreases in the amount of oxygen. Diuretics are given and fluids are restricted as infants are prone to fluid overload. Increased calories and protein are important. The infant may be discharged home with long-term oxygen therapy, and some need frequent rehospitalization during the first 2 years of life because of respiratory tract infections.

Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) is also called *germinal matrix hemorrhage* and *periventricular-intraventricular hemorrhage*. It is bleeding into and around the ventricles of the brain. Approximately 30% of preterm infants weighing less than 1500 g develop intraventricular hemorrhage (Carlo, 2011d). The first few days of life are the most common times for hemorrhage to occur. It may also occur in term infants from asphyxia or trauma (Verklan & Lopez, 2011).

Pathophysiology

IVH results from rupture of the fragile blood vessels in the germinal matrix, located around the ventricles of the brain. It is associated with increased or decreased blood pressure, asphyxia or respiratory distress requiring mechanical ventilation, and increased or fluctuating cerebral blood flow. Rapid blood volume expansion, hypercarbia, anemia, and hypoglycemia are other causes.

Hemorrhage is graded 1 through 4, according to the amount of bleeding. Grade 1 is a very small bleed at the germinal matrix, producing few if any clinical changes. Grade 2 hemorrhage extends into the lateral ventricles, and grade 3 causes distention of ventricles. Grade 4 hemorrhage causes ventricular dilation and extends into surrounding brain tissue. The condition is diagnosed by cranial ultrasound through the anterior fontanel.

Manifestations

Signs of IVH are determined by the severity of the hemorrhage. They may have no signs or lethargy, poor muscle tone, deterioration of respiratory status with cyanosis or apnea, drop in hematocrit, acidosis, hyperglycemia, decreased reflexes, tense fontanel, and seizures. Mild aberrations of eye position or movement may occur. Signs may be few and subtle.

Therapeutic Management

Most hemorrhages take place in the first week. Ultrasonography performed at 7 days of age for preterm infants at risk for IVH shows 90% of hemorrhages (de Vries, 2011). If bleeding is found, serial ultrasonography may be performed to determine progression of the problem.

Treatment is supportive and focuses on maintaining respiratory function and dealing with other complications. Hydrocephalus may develop from blockage of cerebrospinal fluid flow. A ventriculoperitoneal shunt (catheter leading from the ventricles of the brain to the peritoneal cavity) may be necessary to drain the fluid.

Nursing Considerations

Many aspects of care may increase cerebral blood flow and blood pressure. These include mechanical ventilation, suctioning, and excessive handling. Even crying may produce changes in cerebral blood flow. Therefore, the nurse must avoid situations that may increase the risk of IVH as much as possible. Handling is kept to a minimum, and pain and environmental stressors are reduced as much as possible. Developmental care has been found helpful. Nurses are alert for early signs of IVH. Nursing care includes daily measurement of the head circumference and observation for changes in neurologic status, which may be subtle.

Parents need assistance to cope with the diagnosis and their concerns regarding long-term implications. They should learn how to assess for signs of increasing intracranial pressure from hydrocephalus and understand that follow-up care may include periodic ultrasound examinations.

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is a condition where injury to the blood vessels in the eye may result in visual impairment or blindness in preterm infants. It occurs more often in preterm infants weighing less than 1000 g and less than 29 weeks of gestational age (Gardner, Enzman-Hines, & Dickey, 2011a).

Pathophysiology

The exact cause of ROP is unknown, but high levels of oxygen are a risk factor. However, ROP develops in some infants who have never received supplementary oxygen. Prolonged ventilation, acidosis, sepsis, shock, IVH, and fluctuating blood oxygen levels have all been associated with ROP (AAP & ACOG, 2012; Pollan, 2009).

In ROP, immature blood vessels in the eye are injured. After a period, new vessels proliferate, extending throughout the retina and into the vitreous humor of the eye in some infants. Fluid leakage and hemorrhages from the fragile vessels may cause scarring, traction on the retina, and retinal detachment. However, the progress of pathology stops in more than 90% of infants and there is little visual loss (Olitsky, Hug, Plummer et al., 2011).

Therapeutic Management

Infants with a birth weight of 1500 g or less or gestational age of 30 weeks or less and selected infants with a birth weight of 1500 to 2000 g or gestational age of more than 30 weeks with an unstable clinical

course should be screened to detect changes of the eye. The frequency of repeat examinations is determined by the results of screenings (AAP Section on Ophthalmology, 2013).

Laser surgery to destroy abnormal blood vessels is the current treatment of choice. Intravitreal bevacizumab has been used in some cases and will have more study to determine its use in the future. (AAP Section on Ophthalmology, 2013). Cryosurgery or reattachment of the retina also may be necessary.

Nursing Considerations

The nurse should check the pulse oximetry readings frequently for any infant receiving oxygen. Parents should be informed about ophthalmologic tests and receive an explanation of the results. Eye examinations can be very stressful to the infant, and swaddling and rest periods should be provided as appropriate. Mydriatic eye drops given to dilate the eyes may cause hypertension, bradycardia, and apnea (Askin & Diehl-Jones, 2010). If surgery is performed, the eye is assessed for drainage. Ice packs may be used for edema, and pain medication should be given. Support for parents is essential throughout the examinations and especially if damage to the eye is found.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a serious inflammatory condition of the intestinal tract that may lead to cellular death of areas of intestinal mucosa. It occurs in 1% to 5% of infants admitted to NICUs (Greenberg, Narendran, Schibler et al., 2009). The mortality rate ranges from 10% to 30% and survivors may have long-term gastrointestinal problems (Caplan, 2011). The ileum and proximal colon are the areas most often affected.

Pathophysiology

Although the exact causes are unknown, immaturity of the intestines is a major factor in preterm infants. The rate of NEC increases with decreasing gestational age. Previous hypoxia of the intestines may be a causative factor. The incidence of NEC is much higher after infants have received feedings.

Although minimal enteric feedings are thought to increase maturation of the intestines, feedings that are too early or increased too fast may cause NEC. When infants are fed, bacteria proliferate, and gas-forming organisms may invade the intestinal wall in some infants. Eventually, necrosis, perforation, and peritonitis may occur. Breast milk, which contains immunoglobulins, leukocytes, and antibacterial agents, may have a preventive effect on the development of NEC. Studies about using prenatal steroids to prevent NEC are mixed with some showing less and others showing greater incidence (Gephart, McGrath, Efken et al., 2012).

Manifestations

Signs include increased abdominal girth caused by distention, increased gastric residuals, decreased or absent bowel sounds, loops of bowel seen through the abdominal wall, vomiting, bile-stained residuals or emesis, abdominal tenderness, signs of infection, and occult blood in the stools. Respiratory difficulty may occur because of pressure from the distended abdomen on the diaphragm. Apnea, bradycardia, temperature instability, lethargy, hypotension, and shock also may be present. On radiographs, there may be loops of bowel dilated with air. The presence of air within the intestinal wall is characteristic of the condition. Free air in the peritoneum indicates that perforation has occurred, although perforation may occur without this sign.

Therapeutic Management

Supplementation of formula with probiotics is under study as a means of establishing normal intestinal flora and preventing NEC (Zupancic,

2008). Mothers should be encouraged to breastfeed, especially if the infant has risk factors for NEC. If maternal breast milk is not available, donor milk can be used.

Treatment of NEC includes antibiotics, discontinuation of oral feedings, continuous or intermittent gastric suction, and use of parenteral nutrition to rest the intestines. Surgery may be necessary if perforation or continued lack of improvement occurs. The necrotic area is removed, and an ostomy may be performed. Infants who have had large areas of bowel removed may develop short-bowel syndrome with malabsorption and malnutrition.

Nursing Considerations

Nurses should encourage interested mothers to provide breast milk for their infants because NEC is less likely to occur in breastfed infants. Early recognition of signs of NEC is essential to decrease mortality. Because nurses are constantly observing the infant, they often are able to detect the early, subtle signs that lead to prompt diagnosis. If one or more signs are noted, the nurse withholds the next feeding and notifies the physician.

Abdominal girth is measured, and IV fluids and parenteral nutrition must be managed. Intake and output are important, as third-space fluid loss occurs when fluid moves from the intravascular spaces to the extracellular spaces. The infant should be positioned on the side to minimize the effects of pressure on the diaphragm from the distended intestines. During recovery, the nurse must observe for signs of feeding intolerance when feedings are resumed. Scar tissue may cause partial or complete bowel obstruction.

Short Bowel Syndrome

Short bowel syndrome (SBS) is a condition caused by a bowel that is shorter than normal. It is caused by congenital malformations of the GI tract or surgical resection that decreases the length of the small intestines.

Pathophysiology

When the bowel is too short, decreased mucosal surface area causes inadequate absorption of fluids, electrolytes, and nutrients. A loss of greater than 50% of the small bowel may result in symptoms of generalized malabsorption or deficiencies of certain nutrients related to the region of bowel that has been removed (Vanderhoof & Branski, 2011).

Manifestations

The most common symptoms of SBS are malabsorption, diarrhea, and failure to thrive. If the small bowel is 40 cm or more, the malabsorption may improve in time because the remaining bowel continues to grow and adapt in function.

Therapeutic Management

During surgery, every effort is made to preserve as much of the small bowel length as possible. After surgery, the child's fluid and electrolyte balance must be restored and stabilized. The mainstay of treatment for infants and children is nutritional support.

Total parenteral nutrition (TPN) is begun as the primary source of nutrition. It is formulated to meet the child's nutritional needs as well as promote weight gain and growth. Enteral nutrition is begun as soon as possible following surgery to allow the intestines to adapt to food.

Nursing Considerations

The nurse manages the infant's TPN and enteral feedings. TPN is generally infused through a central venous access device. Strict asepsis must be used when performing insertion site dressing changes and when administering TPN to prevent central line-associated bloodstream infections. Enteral nutrition is advanced slowly while

corresponding adjustments are made to the composition of the TPN. The nurse carefully assesses and documents tolerance of enteral feedings noting any signs of dehydration, electrolyte imbalances, and nutritional deficits. Nonnutritive sucking is provided as well.

POSTTERM INFANTS

Postterm infants are those who are born after the 42nd week of gestation. Their longer-than-normal gestation places them at risk for a number of complications.

Scope of the Problem

Approximately 3% to 14% of all pregnancies are considered postterm (V. C. Smith, 2012). In some cases, the fetus continues to be well supported by the placenta and is of normal size or is large for gestational age. Some grow to more than 8 lb, 13 oz (4000 g), placing them at risk for birth injuries or cesarean birth.

In other cases, placental functioning decreases when pregnancy is prolonged (see Chapter 27). If placental insufficiency is present, decreased amniotic fluid volume (oligohydramnios) and compression of the umbilical cord may occur. The fetus may not receive the appropriate amount of oxygen and nutrients and may be small for gestational age. This condition results in hypoxia and malnourishment in the fetus and is called **postmaturity syndrome** or *dysmaturity syndrome*. Postmaturity syndrome occurs in about 20% of postterm pregnancies (Blickstein & Flidel-Rimon, 2011).

When labor begins, poor oxygen reserves may cause fetal compromise. The fetus may pass meconium as a result of hypoxia before or during labor, increasing the risk of meconium aspiration at delivery (see Chapter 30). These infants are also at higher risk for asphyxia than are other infants. Postterm infants have a higher perinatal mortality rate than infants born at term.

Assessment

Most infants will be normal at birth. If the infant is large, the nurse should observe for injury and hypoglycemia. The infant with postmaturity syndrome may have an apprehensive look associated with hypoxia (McGrath & Hardy, 2011). The infant may be thin with loose skin and little subcutaneous fat. There is little or no vernix caseosa, but the infant generally has abundant hair on the head and long nails. The skin is wrinkled, cracked, and peeling (Figure 29-10). If meconium was present in the amniotic fluid, the cord, skin, and nails may be stained yellow green, indicating that meconium was present for some time. The umbilical cord is thin with little Wharton's jelly.

FIG 29-10 The postmature infant has no vernix and dry, cracked, peeling skin.

Postterm infants should be assessed for hypoglycemia because of rapid use of glycogen stores. If loss of subcutaneous fat has occurred, the infant is at risk for low temperature.

Therapeutic Management

Therapeutic management focuses on prevention and symptomatic treatment. Expectant mothers who are “overdue” are scheduled for tests of placental functioning, and labor is induced if signs of placental deterioration are discovered during fetal diagnostic testing. If the fetus cannot tolerate labor, a cesarean birth is necessary. Apgar scores less than 7 are more likely in postterm infants. In cases of asphyxia or meconium aspiration, respiratory support is needed at birth (see Chapter 30, pp. 651 and 653).

Nursing Considerations

The nurse's role is primarily one of prevention of complications, where possible, and monitoring of changes in status. During labor and delivery, the nurse responds appropriately to fetal heart rate decelerations, prepares for and assists in emergency delivery, and cares for respiratory problems at birth.

Signs of postmaturity syndrome in infants are noted during the initial assessment. Respiratory problems may necessitate continued assessment and care. Infants with any indications of postmaturity should be tested for hypoglycemia soon after birth and again an hour later or according to hospital policy. They need early and more frequent feedings to help compensate for the period of poor nutrition before birth.

Temperature regulation may be poor because fat stores were used for nourishment in utero. Providing extra blankets, assessing temperature frequently, and teaching parents about prevention of cold stress are important throughout the hospital stay. Polycythemia, resulting from hypoxia before birth, increases the risk of hyperbilirubinemia.

SMALL-FOR-GESTATIONAL-AGE INFANTS

Small-for-gestational-age (SGA) infants are those who fall below the tenth percentile in size on growth charts. They have failed to grow in the uterus as expected and have FGR. Some infants who do not meet the definition for SGA may have FGR and fail to grow to full potential before birth for a variety of reasons. However, the terms SGA and FGR often are used interchangeably.

SGA infants may be preterm, full-term, or postterm. Infant mortality and morbidity increase steadily as growth restriction increases. Approximately one third of all low-birth-weight (LBW) infants are SGA (V. C. Smith, 2012).

Causes

Many risk factors may cause an infant to be SGA. Congenital malformations, chromosomal anomalies, genetic factors, multiple gestations, and fetal infections such as rubella or cytomegalovirus may cause FGR. Poor placental function resulting from aging of the placenta, small size, separation, or malformation may interfere with fetal growth. Illness in the expectant mother, such as preeclampsia or severe diabetes, restricts uteroplacental blood flow and decreases fetal growth. Smoking, drug or alcohol abuse, and severe maternal malnutrition also impair fetal growth.

Scope of the Problem

Infants affected with FGR have higher perinatal morbidity and a mortality rate that is 10 to 20 times that of infants who are not growth restricted (Kliegman, 2011). Death may occur from asphyxia before or

during labor because of poor placental functioning or from complications of congenital anomalies or prematurity.

Full-term SGA infants are subject to many of the same complications as those who are preterm or postterm. Problems tend to be greatest in infants who are preterm in addition to being SGA.

Low Apgar scores, meconium aspiration, and polycythemia are increased in the SGA infant. Hypoglycemia is common because of inadequate storage of glycogen in the liver. Although mature muscle tone enables the SGA infant to maintain better flexion than the preterm infant, SGA infants are prone to inadequate thermoregulation because subcutaneous white fat and brown fat stores have been used to survive in utero. If hypoglycemia develops, inadequate glucose is available for increased metabolism to produce heat, increasing the problem.

Characteristics of Small-for-Gestational-Age Infants

The appearance of the SGA infant varies, depending on whether the cause of growth restriction began early or late in the pregnancy. Variation occurs because growth restriction affects the weight first. If it continues, the length and then the head size eventually will be affected.

Symmetric growth restriction involves the entire body. It may be caused by congenital anomalies, genetic disorders, exposure to infections or drugs early in pregnancy, or normal genetic predisposition. Although the infant's weight, length, and head circumference are all below the 10th percentile, the body is proportionate and appears normally developed for size. The total number of cells as well as the cell size is decreased and the infant may have long-term complications. These infants are often small throughout their lives. They have a higher rate of neonatal mortality. Approximately 20% of SGA infants have symmetric growth restriction (Kliegman, 2011).

Asymmetric growth restriction is caused by complications such as preeclampsia that begin in the third trimester and interfere with uteroplacental function. In asymmetric restriction, the head is normal in size but seems large for the rest of the body. Brain growth and heart size are normal. The length is normal, but the weight is below the 10th percentile for gestational age. The abdominal circumference is decreased because the liver, spleen, and adrenals are smaller than normal (Kliegman, 2011).

The infant appears long, thin, and wasted. The dry, loose skin has longitudinal thigh creases from loss of subcutaneous fat. The infant has a sunken abdomen, sparse hair, a thin cord, and the facial appearance of being elderly. The anterior fontanel may be large with wide or overlapping cranial sutures (Furdon & Benjamin, 2010). These infants generally "catch up" in growth, particularly in the first 2 years, if they are adequately nourished after birth.

Therapeutic Management

Therapeutic management is focused on prevention with good prenatal care to identify and treat problems early. When growth restriction cannot be prevented, ultrasound examination may permit early discovery of the condition. Serial nonstress tests and biophysical profiles help determine if the infant should be delivered early, and preparation can be made for the expected complications at birth. Problems during and after birth are treated as they occur. They may include asphyxia, meconium aspiration, hypoglycemia, and polycythemia (Kliegman, 2011). SGA infants have a greater surface area and higher metabolic rate than infants who are appropriate for gestational age. This increases their risk for problems with temperature stability (Brown & Landers, 2011).

Nursing Considerations

Because the causes of growth restriction are so varied, care of the SGA infant must be adapted to meet the specific problems presented. When signs of growth restriction are present, the nurse must observe for

complications that commonly accompany it. The general appearance and measurements give an indication of the type of growth restriction that has occurred. Measurements of the head, chest, length, and weight are below normal in the infant with symmetric growth restriction. If the restriction is asymmetric, the head circumference and length are normal, but the abdominal circumference and weight are low.

The nurse should assess for hypoglycemia, especially in asymmetric, growth-restricted infants. The brain of the infant is normal and needs large amounts of glucose, but the liver is small and has inadequate stores of glycogen. Caloric needs are greater than for a normal infant, making early and more frequent feedings important. Temperature regulation and respiratory support are additional nursing concerns. Observation for jaundice is important in infants with polycythemia because a large amount of bilirubin may be released when the red blood cells break down.

LARGE-FOR-GESTATIONAL-AGE INFANTS

Large-for-gestational-age (LGA) infants are those who are above the 90th percentile for gestational age on intrauterine growth charts. They may have **macrosomia** (weigh more than 8 lb, 13 oz to 9 lb, 15 oz [4000 to 4500 g]) and are usually born at term, although they may be preterm or postterm. The preterm LGA infant may be mistaken for full-term but has the same problems as other preterm infants.

Causes

Infants who are LGA may be born to multiparas, large parents, mothers who are obese, and members of certain ethnic groups known to have large infants. Diabetes in the mother may also cause increased size, as may erythroblastosis fetalis (see Chapter 30).

Scope of the Problem

The LGA infant is more likely to go through a longer labor, suffer injury during birth, or need a cesarean birth. Shoulder dystocia may occur because the shoulders are too large to fit through the pelvis. Fractures of the clavicle or skull, injury to the brachial plexus or the facial nerve, cephalhematoma, subdural hematoma, and bruising occur more often in these infants than those of normal size. Congenital heart defects and a higher mortality rate also are more common (Carlo, 2011a).

Therapeutic Management

Therapeutic management is based on identification of increased size during pregnancy by measurements of fundal height and ultrasound examination. Delivery problems may lead to use of vacuum extraction, forceps, or cesarean birth. Birth injuries and complications are treated as they arise.

Nursing Considerations

The nurse assists in a difficult delivery or cesarean birth resulting from dystocia when the infant is LGA. After birth the infant is carefully assessed for injuries or other complications such as hypoglycemia (p. 396) or polycythemia (p. 665). Nursing care is geared to the problems presented.

16. How are symmetric and asymmetric FGR different?
17. What problems may occur in infants who are LGA?

SUMMARY CONCEPTS

- Late preterm infants, born between 34% and 36% weeks, are at risk for respiratory, thermoregulation, and feeding problems as well as hypoglycemia, hyperbilirubinemia, acidosis, and sepsis.
- Preterm infants differ in appearance from full-term infants. Some differences include small size, limp posture, red skin, abundant vernix and lanugo, and immature ears and genitals.
- The lungs of preterm infants may lack adequate surfactant, which interferes with expansion of the lungs, increasing the amount of energy necessary for breathing and leading to atelectasis.
- Other factors that may increase respiratory problems are poor cough reflex, narrow respiratory passages, and weak muscles.
- The prone position is used for preterm infants because it decreases breathing effort and increases oxygenation.
- Preterm infants are subject to cold stress because they have thin skin with blood vessels near the surface, little subcutaneous white fat or brown fat, a large surface area, a limp position, and an immature temperature control center.
- Maintaining a neutral thermal environment at all times for infants is important. The nurse should prevent drafts, use warmed oxygen, and keep incubator doors and portholes closed. When taken out of heating devices, the infant should be wrapped in warmed blankets and should wear a hat.
- Preterm infants are subject to increased insensible water losses and have difficulty maintaining fluid balance. Their kidneys do not concentrate or dilute urine as well as those of full-term infants. Intake and output must be carefully measured.
- The fragile skin of a preterm infant is easily damaged. Adhesives or chemicals that could injure the skin should be avoided. Special products designed to prevent injury to the skin should be used.
- Preterm infants are subject to infections because they lack passive antibodies from the mother, have an immature immune system, have fragile skin, and are subjected to many invasive procedures.
- The nurse must watch carefully for signs of pain and use comfort measures, containment, pacifiers, sucrose, breastfeeding, kangaroo care, and medications to alleviate it.
- Infants demonstrate they are receiving too much stimulation by changes in oxygenation and behavior. The nurse should schedule care to allow rest periods, keep noise to a minimum, and teach parents how to interact with the infant appropriately.
- Preterm infants lack nutrient stores and need more nutrients but do not absorb them well. They lack coordination in sucking and swallowing and fatigue easily.
- Signs indicating an infant may be ready for nipple feeding include rooting, sucking on a gavage catheter or pacifier, presence of gag reflex, and respiratory rate less than 60 breaths per minute.
- The nurse should teach mothers who wish to breastfeed their preterm infants how to use a breast pump and store breast milk. Nurses provide privacy, give support and encouragement, explain the infant's behavior, and answer questions about breastfeeding.
- Nurses can increase parents' comfort with their preterm infant by providing information about the infant's condition and characteristics, the neonatal intensive care unit, equipment, and infant care. Spending time with parents during visits, offering therapeutic communication and realistic encouragement, and involving parents in care of the infant also help with bonding.
- Preparation for discharge should be started early in the infant's hospital stay. This allows parents to learn gradually and assume increasing responsibility in the care of the infant until they are comfortable with complete care.
- Common complications of preterm birth are respiratory distress syndrome, bronchopulmonary dysplasia, intraventricular hemorrhage, retinopathy of prematurity, necrotizing enterocolitis, and short bowel syndrome.
- Infants with postmaturity syndrome may appear thin with loose skin folds, cracked and peeling skin, and meconium staining. They may have respiratory difficulties at birth and suffer from hypoglycemia and inadequate temperature regulation.
- Infants with fetal growth restriction may be small for gestational age at birth. In symmetric growth restriction, the infant is proportionately small; in asymmetric growth restriction, the head and length are normal and the body is thin.
- Large-for-gestational-age infants may have birth injuries such as fractures, nerve damage, or bruising as a result of their size. They may have hypoglycemia or polycythemia.

High-Risk Newborn: Acquired and Congenital Conditions

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the steps involved in neonatal resuscitation.
2. Explain common respiratory problems in the newborn.
3. Explain the causes and significance of nonphysiologic jaundice.
4. Describe the nursing care of the infant with nonphysiologic jaundice.
5. Describe causes of neonatal infections and nursing care for infants with infections.
6. Explain the effect of maternal diabetes on the newborn and the implications for nursing care.
7. Explain polycythemia, hypocalcemia, and phenylketonuria and the nursing considerations of each.
8. Describe the effect of maternal substance abuse on the newborn and the nursing care needed.
9. Describe common congenital anomalies.

In addition to the high-risk conditions related to gestational age discussed in [Chapter 29](#), the newborn at risk may have acquired or congenital complications. Acquired conditions may be associated with prenatal complications or may occur at birth or shortly thereafter. Common nursing diagnoses for infants with acquired or congenital complications are listed in ([Box 30-1](#)).

RESPIRATORY COMPLICATIONS

Respiratory distress is one of the most common problems of the neonate. It may be caused by asphyxia before or during birth, disease of the respiratory system, and other conditions that affect the infant's ability to breathe. The nurse is responsible for identification and evaluation of respiratory status at birth and throughout the hospital stay.

Asphyxia

Asphyxia is insufficient oxygen and excess carbon dioxide in the blood and tissues. It may occur in utero, at birth, or later and results in ischemia to major organs. When asphyxia occurs at birth, it may be a continuation of asphyxia that began before birth or the result of other factors such as preterm lungs with insufficient surfactant to function adequately. Maternal, placental, or fetal factors may be involved.

Maternal factors include complications such as hypertension, infection, and drug use. Asphyxia in utero may be caused by placental conditions such as placenta previa, abruption placentae, or postmaturity. Cord problems, infection, premature birth, and multifetal gestation are among the fetal causes of asphyxia.

Lack of oxygen transported to the cells leads to anaerobic metabolism and the production of lactic acid. Metabolic acidosis develops when inadequate bicarbonate is available to buffer the accumulating acids. Respiratory acidosis occurs as carbon dioxide accumulates. A high partial pressure of carbon dioxide occurs in arterial blood (P_{aCO_2}), and the partial pressure of oxygen (P_{O_2}), the pH, and bicarbonate are low.

Vasoconstriction caused by low oxygen decreases blood flow to all organs except the brain, myocardium, and adrenal glands. The ductus arteriosus and foramen ovale may remain open because of the low oxygen in the blood, high resistance to blood flow through constricted pulmonary vessels, and elevated pressure on the right side of the heart. Therefore, even circulating blood remains low in oxygen concentration. Progression toward brain injury and death is rapid unless intervention is prompt.

Problems may continue even if the infant survives. Pulmonary ischemia interferes with the ability to produce surfactant, increasing the risk of respiratory distress syndrome (RDS). Intrauterine stress

may lead to passage of meconium and meconium aspiration syndrome (MAS).

Manifestations

When asphyxia occurs after birth, rapid respirations are followed by cessation of respirations (primary apnea) and a rapid fall in heart rate. Stimulation, alone or with oxygen, may restart respirations. If asphyxia continues without intervention, gasping respirations may resume weakly until the infant enters a period of secondary apnea. In secondary apnea, the oxygen levels in blood continue to decrease, the infant loses consciousness, and stimulation is ineffective. Resuscitative measures must be initiated immediately to prevent permanent injury to the brain or death. Asphyxia seen at birth may be a continuation of asphyxia that began before or during birth. Therefore, it is essential to begin resuscitation without delay.

Infants at Risk

Complications that occur during pregnancy, labor, or birth increase the infant's risk for asphyxia. In addition, if the expectant mother receives narcotics for analgesia shortly before birth, the infant's central nervous system (CNS) may be too depressed at birth to allow adequate spontaneous breathing. If infants have a normal color and heart rate but depressed respirations and the mother received opiates within 4 hours of the birth, naloxone (Narcan) may be given.

Neonatal Resuscitation

Although 90% of newborns have no difficulty with breathing at birth, approximately 10% require some help to begin respirations and 1% require extensive resuscitative measures (Kattwinkel, 2011). Therefore, all personnel involved in deliveries should know how to perform resuscitative measures. Courses in neonatal resuscitation are usually required of all staff members working with newborns, and many agencies expect these skills to be updated every 1 to 2 years (see Procedure 30-1).

Nurses must be prepared for situations in which asphyxia may develop. Equipment should be readily available and functioning properly at all times so that there is no delay in starting resuscitation. Nurses begin resuscitation measures as necessary and assist the physician or

DRUG GUIDE

NALOXONE HYDROCHLORIDE (NARCAN)

Classification: Opiate antagonist.

Action: Reverses central nervous system and respiratory depression caused by narcotics (opiates). Competes with narcotics at receptor sites.

Indications: Severe respiratory depression in the newborn when the mother has received narcotics within 4 hours of delivery.

Dosage and Route: Available in 0.02 mg/mL, 0.4 mg/mL, and 1 mg/mL. Dose for neonates is 0.1 mg/kg (Kattwinkel, 2011). Given intravenously (IV), intramuscularly (IM), subcutaneously (SQ), or into an endotracheal tube. IV route is preferred during resuscitation. IM is acceptable, but action may be delayed. There are no studies on the efficacy of endotracheal tube administration (Kattwinkel, 2011).

Absorption: Well absorbed by all routes. Onset of action is 1 to 2 minutes if given IV.

Excretion: Metabolized by the liver and excreted by the kidneys.

Contraindications and Precautions: Duration of effect is 20 to 60 minutes. The dose may need to be repeated because the opiate may have a longer half-life than naloxone. It should never be given to an infant of a mother addicted to opiates because it will cause withdrawal and may cause seizures. It is not recommended as part of initial resuscitative measures after birth. Ventilation support alone may be adequate (American Academy of Pediatrics & American College of Obstetricians & Gynecologists [AAP & ACOG], 2012).

Nursing Considerations: Note the strength of the medication available when calculating the dose. When depression from opiates is expected, prepare the syringe before birth by drawing up more than is needed. After birth, the amount to be given is calculated according to the estimate of the infant's weight. The excess is removed from the syringe and the correct dose given. Monitor for response, and be prepared to give repeated doses, if necessary.

nurse practitioner with intubation, insertion of umbilical vein catheters, and administration of medications.

Maintenance of thermoregulation is very important throughout care. A warming pad may be placed under linens in the radiant warmer to provide extra heat. Infants less than 29 weeks of gestation may be placed in a polyethylene bag up to the neck before they are dried to reduce heat loss from evaporation. The bag also reduces stress from handling during drying. It is important to prevent hyperthermia when the bag is used with a chemical warming pad (Kattwinkel, 2011).

Some infants develop hypoxic-ischemic encephalopathy after asphyxia. Therapeutic hypothermia has been used to improve neurologic outcomes for these infants. Infants must be 36 or more weeks of gestation, have evidence of an acute perinatal hypoxic-ischemic event, and be in a facility where the treatment can be initiated within 6 hours of birth (Kattwinkel, 2011).

Once the infant is stabilized, the nurse continues to assess for changes. Infants with asphyxia often have other complications such as hypoglycemia, feeding and thermoregulation problems, seizures, hypotension, pulmonary hypertension, metabolic acidosis, renal problems, and fluid and electrolyte imbalances. They need close monitoring and often need intensive nursing care.

Communication with the parents is a vital nursing function. They will be confused and frightened and will need explanation and realistic reassurance. Parents often need continued support after the crisis to talk about their fears and concerns.

Transient Tachypnea of the Newborn (Retained Lung Fluid)

Infants who experience **transient tachypnea of the newborn** (TTN) develop rapid respirations soon after birth from inadequate absorption of fetal lung fluid. Although the condition usually resolves within 24 to 48 hours, it is the most common respiratory cause of admission to a neonatal intensive care nursery (NICU) (Greenberg, Narendran, Schibler et al., 2009).

Risk factors include cesarean birth with or without labor, macrosomia, multiple gestation, excessive maternal sedation, prolonged or precipitous labor, male gender, and maternal diabetes or asthma. Mild immaturity of surfactant production also may be a factor. Infants are usually term or late preterm, although some may be preterm (Greenberg et al., 2009; Kienstra, 2012).

Cause

Although the exact cause of TTN is unknown, it is thought to result from a delay in absorption of fetal lung fluid by the pulmonary capillaries and lymph vessels. This leads to decreased lung compliance and air trapping and produces signs similar to those of RDS.

Manifestations

In TTN, tachypnea develops within 6 hours of birth. Grunting, retractions, nasal flaring, and mild cyanosis also are present. Chest radiography demonstrates hyperinflation, perihilar streaking that shows engorged lymphatics, and the presence of fluid in the fissures between the lobes and in the pleural space.

Therapeutic Management

Treatment is supportive and may include oxygen for cyanosis. Gavage feeding may be given when the respiratory rate is high to prevent aspiration and conserve energy. Because the signs are similar to those of RDS and sepsis, the infant is observed for those complications. Antibiotics may be given until sepsis is ruled out. Continuous positive airway pressure is rarely needed.

Nursing Considerations

The nurse may be the first person to see signs of TTN, especially if they are not apparent at birth. After identifying these signs, the nurse notifies the provider and carries out treatment. General nursing care is similar to that of the respiratory care of the preterm infant (see Chapter 29).

Meconium Aspiration Syndrome

Meconium staining of amniotic fluid occurs in 10% to 15% of births. **Meconium aspiration syndrome** (MAS) is a condition in which there is obstruction, chemical pneumonitis, and air trapping caused by meconium in the lungs. It develops in 5% of those infants (Ambalavanan & Carlo, 2011a) (Figure 30-1). The condition occurs most often in infants who are postterm, small for gestational age, and are compromised before birth by placental insufficiency with decreased amniotic fluid and cord compression (Abu-Shaweesh, 2011).

Causes

Although the normal fetus may pass meconium, MAS occurs most often when hypoxia causes increased peristalsis of the intestines and relaxation of the anal sphincter before or during labor. MAS develops when meconium in the amniotic fluid enters the lungs during fetal life or at birth. It may be drawn into the lungs if gasping movements occur in utero as a result of asphyxia and acidosis, or the meconium in the upper airways may be pulled deep into the respiratory passages when the infant takes the first breaths after birth.

Obstruction of the airways may be complete or partial. Atelectasis may result if small airways are completely obstructed. In partial obstruction, air can enter but not escape from the alveoli. During inhalation, the bronchioles expand slightly as air flows into them past the meconium. During exhalation, the passages constrict and meconium blocks the movement of air out of the lungs.

This ball-valve mechanism results in air trapping. The overdistended alveoli may develop an air leak, with escape of air into the pleural cavity (pneumothorax) or mediastinum (pneumomediastinum). Surfactant production may be inhibited, increasing respiratory distress. In addition, meconium is irritating to lung tissue and causes an inflammatory reaction and chemical pneumonitis.

Severe MAS develops in only a small number of newborns with meconium below the vocal cords. The addition of meconium to lungs injured by asphyxia may increase the severity of the condition. Injury from asphyxia interferes with clearing of lung fluid and production of surfactant and causes pulmonary vasoconstriction that can result in return to fetal circulation patterns. Persistent pulmonary hypertension may occur in one third of infants with MAS (Burris, 2012).

Manifestations

If meconium in the amniotic fluid is minimal, respiratory problems usually do not develop. However, more meconium may cause serious respiratory pathology. Signs of mild to severe respiratory distress are present at birth, with tachypnea, cyanosis, retractions, nasal flaring, grunting, rales, and, in severe cases, a barrel-shaped chest from hyperinflation. Radiography shows patchy infiltrates, atelectasis, consolidation, and hyperexpansion from air trapping. The infant's nails, skin, and umbilical cord may be stained a yellow-green color.

Therapeutic Management

Suctioning the infant's secretions as soon as the head is born has not been found to reduce the incidence of MAS. At birth, the vigorous infant (who has a heart rate more than 100 beats per minute [bpm], spontaneous respirations, and good muscle tone) does not need special suctioning and receives routine care. In infants with depressed respirations and muscle tone or a heart rate below 100 bpm, an endotracheal tube is used to remove as much meconium as possible (Kattwinkel, 2011).

Infants may need only warmed, humidified oxygen, or extensive respiratory support with mechanical ventilation may be required. High-frequency ventilation may be used. Surfactant lavage has been used in severe cases but is controversial (Abu-Shaweesh, 2011).

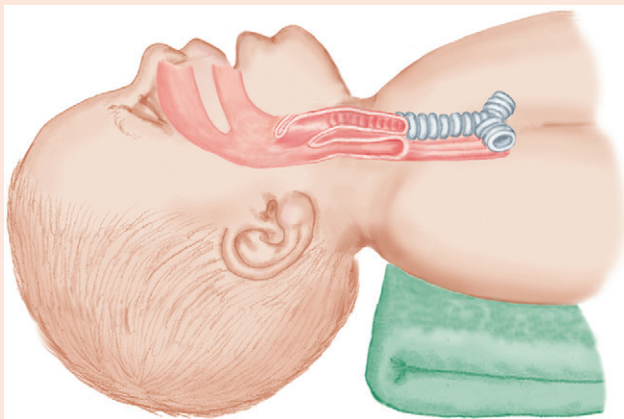

Ongoing management consists of supportive care to meet the problems presented. Infants with severe MAS who do not respond to conventional treatment may benefit from extracorporeal membrane oxygenation (ECMO). ECMO, which is available in some hospitals, oxygenates blood while bypassing the lungs, much like heart-lung machines used during heart surgery. It allows the infant's lungs to rest temporarily and recover.

PROCEDURE 30-1 PERFORMING RESUSCITATION IN THE NEWBORN

PURPOSE: To ensure adequate oxygenation of the neonate with asphyxia

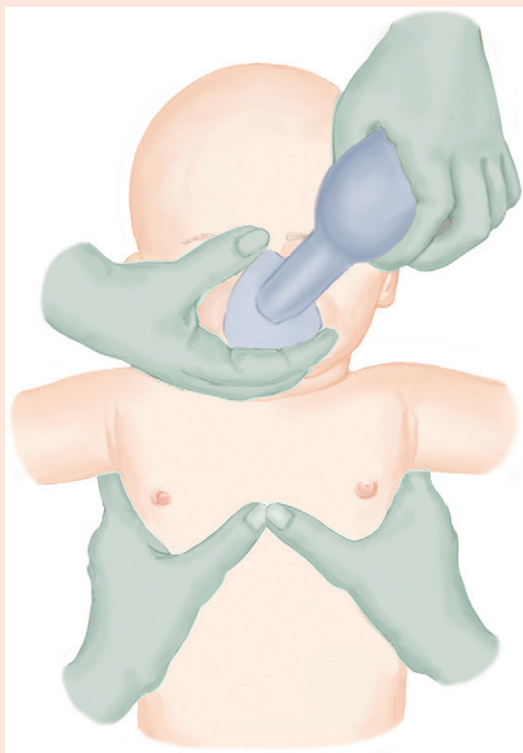

NOTE: Although this procedure is described in steps, resuscitation is performed as an integrated process rather than in individual steps. Because two or more people often are working together, several steps can be performed at the same time.

1. Place the infant under a preheated radiant warmer immediately. *Prevention of cold stress is important to prevent increased oxygen need.*
2. Position the infant with the neck in a slightly extended ("sniffing") position. Place a small, rolled blanket under the shoulders. Avoid hyperextension or flexion of the neck. *Proper positioning will help maintain an open airway. Hyperextension or flexion may obstruct the airway.*

3. Suction the mouth and then the nose. If meconium is present and the infant is vigorous (showing strong respiratory effort, good muscle tone, and heart rate above 100 beats per minute [bpm]), suction and continue with usual care. If the infant is not vigorous, an endotracheal tube may be used for suction. After suctioning, an endotracheal tube may be inserted at this time or later, if necessary, to provide an open airway. *Infants often gasp when the nose is suctioned and may aspirate secretions from the mouth into the lungs. Tracheal suctioning removes more meconium in the infant who is not vigorous.*
4. Dry the infant. Remove wet linens and replace with dry linens. Stimulate the infant, if necessary, by gently rubbing the back, body, or extremities, or flicking or slapping the soles of the feet. If two people are present, one can dry the infant while the other positions and suctions. Reposition the head, as necessary. Positioning, clearing the airway, drying, and stimulation should take no more than 30 seconds. *Drying helps prevent cold stress and increased oxygen need. Removal of wet linens prevents heat loss. The tactile stimulation of drying and suctioning may cause spontaneous respirations. Stimulation should be gentle to avoid injury. Repositioning may be necessary because the infant has been moved.*
5. If no response occurs after stimulating once or twice, stop and evaluate need for immediate resuscitation. Do not delay resuscitation to continue stimulating or until the Apgar scores are given. *Resuscitation becomes more difficult the longer it is delayed. Apgar scores at 1 and 5 minutes can be determined without interrupting the resuscitation process. Also assess scores at 10, 15, and 20 minutes for a score under 7 at 5 minutes.*
6. Evaluate the respirations, heart rate, and color. Use a stethoscope or feel the pulsations at the base of the cord. Count for 6 seconds and multiply by 10 for a quick estimate of the heart rate. *Evaluation helps determine the next steps. Immediate resuscitation may be needed to prevent hypoxic brain damage.*
7. If central cyanosis is present, the infant is breathing, and the heart rate is more than 100 bpm, give supplemental oxygen. Hold the oxygen mask or tubing close to the infant's nose (called "blow-by" or "free-flow" oxygen) to provide oxygen mixed with room air. Attach a pulse oximeter probe to the infant's right palm or wrist. Then connect the probe to the pulse oximeter. If the infant becomes pink with oxygen and oximeter readings are 85% to 90%, the oxygen can be gradually removed. *Oxygen will help relieve cyanosis and prevent damage to vital tissues. An oximeter measures oxygen saturation in blood and helps determine if the infant is receiving the right amount of oxygen. It is more accurate than assessment of color.*
8. If the term infant fails to breathe spontaneously with initial stimulation, has gasping respirations, a heart rate less than 100 bpm when respirations have begun, or remains cyanotic and has low oxygen saturation with supplemental oxygen, begin positive-pressure ventilation (PPV). Use an appropriately sized bag and mask and 21% oxygen (room air). If the infant is preterm, a higher oxygen content may be necessary. The amount of oxygen used is varied as necessary according to the oximeter reading. The mask should rest on the chin and cover the mouth and nose but not the eyes. *PPV ensures oxygen entry into the lungs. An oxygen blender is used to vary the percent of oxygen used. An appropriately sized mask allows a seal to prevent oxygen from escaping around the sides.*
9. Place the mask snugly over the infant's nose and mouth. Squeeze the bag gently to force air into the infant's lungs. Use a bag with a pressure gauge and a pressure release valve. Start with a pressure of 20 cm H₂O. *A pressure gauge shows the amount of pressure being used. A pressure release valve opens if the pressure is high enough to cause lung injury.*
10. Ventilate the infant at a rate of 40 to 60 breaths per minute until the infant is breathing spontaneously and the heart rate is above 100 bpm. At that point, PPV may be gradually discontinued and free-flow oxygen given. *PPV is adjusted according to the infant's response.*
11. If heart rate and oxygen saturation do not improve, breath sounds are not heard, and the chest does not move, reposition the mask and the head and suction secretions. If necessary, gradually increase the pressure until chest movement and bilateral breath sounds are present. If chest expansion is not adequate, an endotracheal tube should be inserted. *The airway must not be occluded by positioning or secretions. Pressure must be high enough to inflate the lungs without causing injury from overinflation. More pressure is needed for the first breaths and diseased lungs.*
12. If PPV is necessary for more than a few minutes, insert an 8-French feeding tube through the mouth to the stomach. Suction the stomach contents, and leave the tube in place and open. *The feeding tube allows air that may enter the stomach to escape through the tube.*
13. Assess heart rate, color, muscle tone, and presence of spontaneous breathing. If the heart rate is above 60 bpm after 30 seconds, continue PPV, and assess as above every 30 seconds. If the heart rate is less than 60 bpm after 30 seconds of effective assisted ventilation, a second person should begin chest compressions while the first continues to ventilate the infant. An endotracheal tube may be inserted if it has not been placed previously. Increase oxygen to 100%. *Adequate ventilation causes improvement of bradycardia in most infants. Evaluation of the infant's status determines whether ventilation can be discontinued or chest compressions must be added for the infant to survive. The oximeter may not be accurate if the heart rate is below 60 bpm.*

PROCEDURE 30-1 PERFORMING RESUSCITATION IN THE NEWBORN—cont'd

14. Compress the chest by placing the hands around the infant's chest with the fingers under the back to provide support and the thumbs over the lower third of the sternum (below an imaginary line drawn between the nipples and above the xiphoid process). This is the preferred method because it gives more consistent pressure and depth control. An alternate method is to use two fingers of one hand to compress the chest, with the other hand under the back to provide support. *Correct hand position compresses the heart but avoids or minimizes injury to the liver, fractures of the ribs, and pneumothorax. The alternative method may be necessary to allow access to umbilical vessels or for people with small hands.*
15. Compress the sternum to a depth of approximately one third of the antero-posterior diameter of the chest. Release the pressure between compressions, but do not remove the fingers from the chest. *The size of the infant determines the depth of compressions. The fingers should remain in contact with the chest at all times to prevent the need to repeatedly reposition them.*
16. Use 3 compressions followed by 1 ventilation for a combined rate of 120 compressions and ventilations each minute. This provides 90 compressions and 30 ventilations each minute. Counting "one-and-two-and-three-and-breathe-and-one ..." may be helpful. Pause after every third compression (during "breathe-and") for ventilation. *Simultaneous compression and ventilation may interfere with adequate ventilation. The short pause allows air to enter the lungs.*
17. Check heart rate after at least 45 to 60 seconds. If it is 60 bpm or more, discontinue compressions but increase PPV at a faster rate of 40 to 60 bpm until the heart rate is more than 100 bpm and spontaneous breathing begins. Then discontinue PPV slowly. *Periodic evaluation is necessary to ensure that treatment is appropriate to the infant's status.*
18. If the heart rate is less than 60 bpm, an endotracheal tube should be inserted if not done previously. Recheck to see that ventilation and compressions are being given correctly and 100% oxygen is being used for PPV. *Endotracheal intubation may be necessary to ensure an adequate airway.*
19. An umbilical catheter should be inserted, and epinephrine should be given if heart rate remains below 60 bpm. If necessary, epinephrine may be given through an endotracheal tube until intravenous (IV) access is established. IV volume expanders such as normal saline, Ringer's lactate, or type O Rh-negative packed red blood cells (if severe fetal anemia is expected) may be given. *Epinephrine stimulates the heart. The endotracheal route results in less predictable levels of epinephrine. Volume expanders are given for hypovolemic shock from fluid or blood loss.*
20. Naloxone is not recommended for initial resuscitation after birth because ventilation support may be adequate (AAP & ACOG, 2012). However, it may be given IV to infants who have normal heart rate and color but continued depressed respirations. It is used only if the mother received opiates within 4 hours of delivery. The intramuscular route is acceptable if necessary but has a delayed onset. *Naloxone counteracts effects of opiates given to the mother.*

Data from: Kattwinkel, J. (Ed.). (2011). *Textbook of neonatal resuscitation* (5th ed.) Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association.

Nursing Considerations

When meconium is noted in the amniotic fluid during labor, the nurse notifies the primary caregiver so that delivery care can be adapted as necessary. Nurses from the NICU and a neonatologist may be present for the delivery. The nurse ensures that equipment such as oxygen and suction is functioning properly and assists with care at delivery. After the infant's birth, nursing care is adapted to the problems presented. Although meconium is sterile, lung injury promotes the growth of bacteria. Infants should be closely observed for infection, which may further complicate the condition. Nursing attention to thermoregulation and decreased stimulation is important.

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN) is a condition in which pulmonary vasoconstriction occurs after birth and elevates vascular resistance of the lungs. Normal changes to neonatal circulation are impaired as a result. For this reason, the condition also is called *persistent fetal circulation*.

Causes

PPHN occurs most often in infants who are term or postterm. The cause may be abnormal lung development or maternal use of non-steroidal antiinflammatory drugs or selective serotonin reuptake inhibitors, or it may be unknown. It is often associated with hypoxemia and acidosis from conditions such as asphyxia, MAS, sepsis, polycythemia, diaphragmatic hernia, and RDS (Ambalavanan & Carlo, 2011b).

Inadequate oxygenation results in vasoconstriction, instead of the normal dilation, of the pulmonary artery and small pulmonary vessels, which causes increased resistance in the lungs. The elevated pulmonary vascular resistance causes a rise in pressure on the right side of the heart. This results in a right-to-left shunt of unoxygenated blood that flows through the foramen ovale. In addition, unoxygenated blood from the pulmonary artery flows through the ductus arteriosus to the aorta. Thus, blood bypasses the lungs, as occurs during fetal circulation. Metabolic acidosis causes more pulmonary vasoconstriction, making the condition even worse.

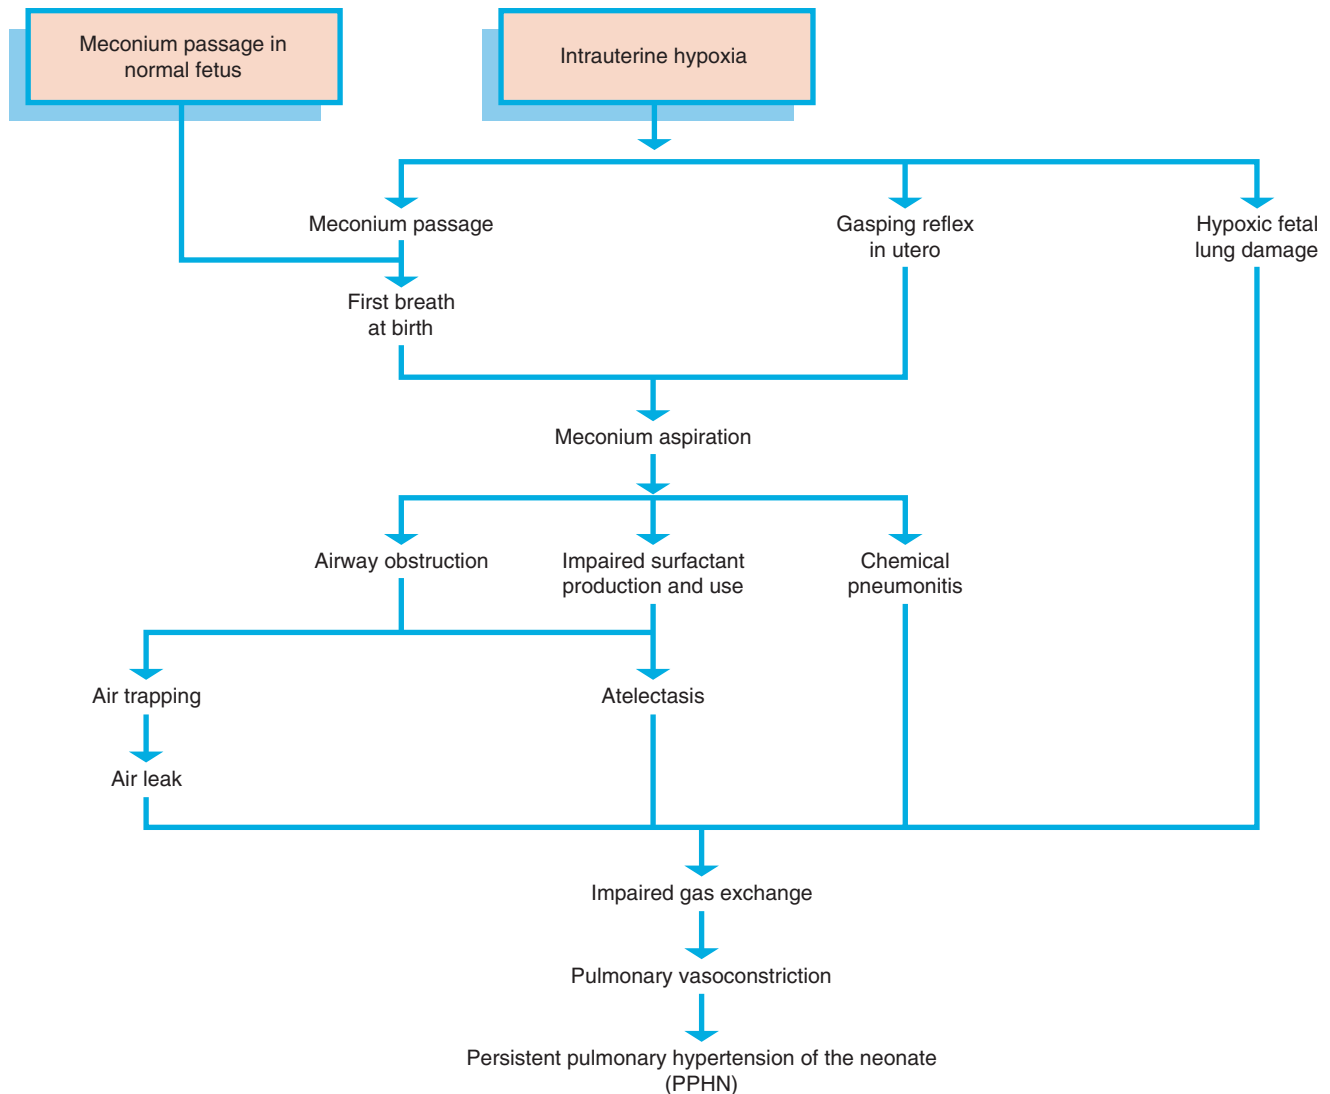

FIG 30-1 Flow chart showing the effects of meconium aspiration syndrome.

Manifestations

Infants with PPHN develop signs within the first 12 hours after birth. Tachypnea, respiratory distress, and progressive cyanosis often become worse with handling. Oxygen saturation and partial pressure of oxygen in arterial blood (P_{aO_2}) are decreased, P_{aCO_2} is increased, and acidosis is present. Other signs may result from associated conditions. An echocardiogram demonstrates right to left shunting through the foramen ovale and ductus arteriosus.

Therapeutic Management

Management involves treating the underlying cause of poor oxygenation and relieving pulmonary vasoconstriction. Arterial pH may be increased with respiratory therapy and drug therapy to cause pulmonary vasodilation. Sedation, high-frequency ventilation, and surfactant therapy may be necessary. Inhaled nitric oxide may be given to dilate pulmonary vessels. ECMO therapy may be lifesaving if conventional therapies are unsuccessful.

Nursing Considerations

Nursing care is similar to care of other infants with severe respiratory disease. Because infants become hypoxic with activity and other

stimuli, handling and noise are kept to a minimum. Cold stress increases the metabolic rate and need for oxygen and causes additional pulmonary vasoconstriction. Therefore, the nurse should pay particular attention to maintaining the infant's temperature in the normal range. Assessment for hypoglycemia, hypocalcemia, anemia, and metabolic acidosis is important.

HYPERBILIRUBINEMIA (PATHOLOGIC JAUNDICE)

Jaundice is a common concern in the care for neonates. Conjugation of bilirubin and physiologic jaundice are discussed in [Chapter 19, p. 376](#), and [Chapter 20, p. 396](#). This discussion focuses on nonphysiologic or pathologic jaundice.

When the total serum bilirubin (TSB) level is greater than 5 to 6 milligrams per deciliter (mg/dL), jaundice appears (Blackburn, 2013). Jaundice is considered abnormal or nonphysiologic when the TSB rises more rapidly and to a higher level than is expected or stays elevated for longer than normal. Charts showing the expected rise and fall of bilirubin according to the age of the infant in hours are used to determine the degree of risk and which infants need treatment for rising TSB level.

Nonphysiologic jaundice may be seen in the first 24 hours of life. It is a concern because it may lead to **bilirubin encephalopathy**, the acute manifestation of bilirubin toxicity. This may lead to **kernicterus**, the chronic and permanent result of bilirubin toxicity. In this condition, bilirubin deposits cause yellowish staining of the brain, especially the basal ganglia, cerebellum, brainstem, and hippocampus. It is more likely to occur in infants who have suffered hypoxemia, respiratory acidosis, infection, dehydration, or other injury that impairs the blood–brain barrier and allows unconjugated bilirubin to enter the brain (Blackburn, 2013).

Although bilirubin encephalopathy and kernicterus are rare today because of improved treatment measures, the mortality and morbidity rates among affected infants are high. Those who survive may suffer from cerebral palsy, cognitive impairment, hearing loss, or more subtle long-term neurologic and developmental problems. The exact level at which bilirubin encephalopathy develops is not known. The toxic level may not be the same for all infants. It occurs at lower TSB levels and is more severe in infants who have complications or are preterm, late preterm, or low-birth-weight than in full-term healthy infants.

Causes

The most common cause of pathologic jaundice is hemolytic disease of the newborn from incompatibility between the blood of the mother and that of the fetus. The best known cause is Rh incompatibility, in which the Rh-negative mother forms antibodies when blood from an Rh-positive fetus enters her circulation (see Chapter 25). Antibodies may have developed during a previous pregnancy or after injury, abortion, amniocentesis, or a transfusion of Rh-positive blood. The antibodies cross the placenta, attach to fetal red blood cells (RBCs), and destroy them. The result is **erythroblastosis fetalis**, agglutination and hemolysis of fetal erythrocytes from maternal-fetal blood incompatibility.

Infants with erythroblastosis fetalis are anemic from destruction of RBCs. Severely affected infants may develop **hydrops fetalis**, a severe anemia that results in heart failure and generalized edema. Intrauterine fetal transfusions may be given. After birth, phototherapy and exchange transfusions are used to prevent kernicterus (Gruslin & Moore, 2011). Use of Rho(D) immune globulin (RhoGAM) to prevent the mother from forming antibodies against Rh-positive blood has greatly decreased the incidence of erythroblastosis fetalis.

ABO incompatibility also causes pathologic jaundice. Mothers with type O blood have natural antibodies to type A and B blood. The antibodies cross the placenta and cause hemolysis of fetal RBCs. However, the destruction is much less severe than with Rh incompatibility and causes milder signs. This is because most of the antibodies are immunoglobulin M (IgM), which does not cross the placenta. Some of the antibodies are immunoglobulin G (IgG), which does cross the placenta and can cause RBC destruction, but usually at a lower rate (Blackburn, 2013).

Other causes of nonphysiologic jaundice include infection, hypothyroidism, glucuronyl transferase deficiency, polycythemia, glucose-6-phosphate dehydrogenase deficiency, and biliary atresia. Infants of diabetic mothers are more likely to develop nonphysiologic jaundice, especially if they have macrosomia. Any condition that causes

destruction of erythrocytes or impairment of the liver may result in elevated bilirubin levels.

Therapeutic Management

The focus of therapeutic management is prevention of bilirubin encephalopathy and kernicterus. The cause is determined by history and diagnostic tests to identify infections or blood abnormalities. During pregnancy, an Rh-negative mother will have blood drawn for an indirect Coombs' test to identify the presence of antibodies against fetal blood. If the test is positive, amniocentesis may be performed to determine the fetal Rh factor and the degree of hyperbilirubinemia (see Chapter 25).

When an infant is jaundiced, the infant's blood type and a direct Coombs' test are performed using cord blood. A positive Coombs' test indicates that antibodies from the mother have attached to the infant's RBCs. TSB levels are monitored closely to detect changes that indicate treatment should be initiated or changed. The health care provider considers the bilirubin level as well as other factors such as gestational age and presence of other risk factors to determine if therapy is appropriate for an individual infant.

Nurses assess infants for changes in jaundice. However, visual inspection for jaundice is not an accurate way of determining actual bilirubin levels. Because taking blood samples for TSB measurement is painful and expensive, other noninvasive tests may be used. Transcutaneous bilirubinometers are hand-held devices that allow screening of transcutaneous bilirubin (TcB) level. When the sensor on the device is placed against the infant's skin, the amount of bilirubin in the tissues is measured. This noninvasive test allows frequent estimates of the TSB level without discomfort to the infant. However, it may not be accurate in preterm infants, in infants receiving phototherapy, or if TSB levels are above 15 mg/dL (Bradshaw, 2010).

Phototherapy

Phototherapy is the most common treatment for jaundice and involves placing the infant under special fluorescent lights. During phototherapy, bilirubin in the skin absorbs the light and changes into water-soluble products, the most important of which is lumirubin. These products do not require conjugation by the liver and can be excreted in bile and urine. Because preterm infants are more vulnerable to bilirubin toxicity, phototherapy is begun at lower TSB levels than for full-term infants.

Phototherapy can be delivered in several ways. A bank of fluorescent lamps or "bili" lights can be placed over the infant who is in an incubator or under a radiant warmer to maintain heat or in an open crib. The infant wears only a diaper to ensure maximal exposure of the skin to the lights. The diaper is removed if the TSB is becoming dangerously high. The eyes are closed and patches placed over them to protect them from injury (Figure 30-2). The lights are placed above the infant at a distance determined by the type of bulb used. More than one bank of lights may be used if the bilirubin level is very high. Bilirubin levels are checked frequently to determine the effectiveness of treatment and when it can be discontinued.

Other options for phototherapy include light emitting diodes (LEDs), halogen lamps, and fiberoptic phototherapy blankets. As with fluorescent lights, the LED device is placed over the infant. It is long lasting and does not generate excessive heat, and it decreases insensible water loss. The halogen spotlight is used alone or with other lamps. The infant can be swaddled with the fiberoptic phototherapy blanket against the skin and does not require patches over the eyes. With the blanket, the mother may hold the infant without interfering with therapy. However, the blanket is not as effective alone as the other methods. To increase its effectiveness, the blanket may be placed under

FIG 30-2 An infant receiving phototherapy is wearing eye patches to protect the eyes.

the infant when phototherapy lights are used. A “bilibed” is also available with the phototherapy device built into the part of the bed that lies under the infant.

The side effects of phototherapy include frequent, loose, green stools that result from increased bile flow and peristalsis. This causes more rapid excretion of the bilirubin but may be damaging to the skin and result in fluid loss. A 25% increase in fluid intake is needed during phototherapy (Kaplan, Wong, Sibley et al., 2011). A macular skin rash may occur in some infants. *Bronze baby syndrome*, a grayish brown discoloration of the skin and urine, occurs in some infants with cholestatic jaundice. The rash and color changes disappear gradually when phototherapy is completed.

When phototherapy is discontinued, a rebound TSB level increase of 1 to 2 mg/dL is normal. Therefore, the TSB should be monitored for at least 24 hours to see that it does not become excessively high. Explain the expected elevation to parents and that the health care provider may order additional blood tests after discharge.

Exchange Transfusions

Exchange transfusions are seldom necessary but are performed when phototherapy cannot reduce dangerously high bilirubin levels quickly enough. This treatment removes maternal antibodies, unconjugated bilirubin, and antibody-coated (sensitized) RBCs. It provides fresh albumin with binding sites for bilirubin and helps correct severe

anemia. When an immediate transfusion is needed for Rh incompatibility, type O, Rh-negative blood cross-matched against the mother and infant are used. In ABO incompatibility, packed RBCs with type AB plasma are used so that there are no anti-A or anti-B antibodies present to destroy the erythrocytes (Gregory, Martin, & Cloherty, 2012).

Procedure. During the exchange transfusion, small portions of blood are removed from the infant and replaced with an equal amount of donor blood. Because the donor blood mixes with the infant’s blood, approximately twice the infant’s blood volume is administered. At the end of the transfusion, approximately 85% to 90% of the infant’s RBCs will have been replaced and the bilirubin level reduced by 50% (Kaplan et al., 2011).

When the bilirubin level in blood decreases, bilirubin from tissues moves into plasma. This may increase the blood level to 60% of the preexchange level (Blackburn, 2013). This rebound elevation of bilirubin level may necessitate repeat transfusions, but phototherapy is generally adequate to resolve it.

Complications. Complications that may occur from exchange transfusions include electrolyte and acid-base imbalance, hypocalcemia, hypomagnesemia, hypoglycemia, hyperkalemia, infection, cardiac dysrhythmias, necrotizing enterocolitis, bleeding, thrombosis, thrombocytopenia, and air embolism. Samples of blood are analyzed for a complete blood cell (CBC) count, bilirubin and calcium levels, and other tests as needed before and after the exchange.

Role of the Nurse. The nurse’s role during exchange transfusion is to prepare equipment, assess the infant during and after the procedure, and keep accurate records. A cardiac monitor is attached to the infant, and warmth is provided by a radiant heater. The nurse also must clarify any misunderstandings that the parents may have about the treatment and help allay their anxiety.

APPLICATION OF THE NURSING PROCESS

■ Hyperbilirubinemia

Although collaborative care of the infant with jaundice is an important part of the nurse’s role, several nursing diagnoses are appropriate. “Risk for Injury” is discussed in this section. The diagnoses “Risk for Deficient Fluid Volume” and “Impaired Skin Integrity” are discussed in *Nursing Care Plan: The Infant with Jaundice*.

Assessment

Assess the level of jaundice at least every 8 hours by blanching the skin (pressing the skin over a bony prominence) to see the color in the area before blood returns. Evaluate the skin color in good light with phototherapy lights turned off because they distort the skin color. In infants with dark skin, assess the color of the palate and mucous membranes of the mouth and the conjunctivae. Determine the areas of the body affected by jaundice, and document carefully to use for comparison during future assessments. Jaundice begins at the head and moves down the body as the bilirubin level rises. Monitor the TSB and TcB levels for change because visualization of jaundice is a subjective assessment and the color in the skin may be affected by phototherapy.

Assess for risk factors that might further increase bilirubin levels. Note temperature fluctuations, hypoglycemia, and infection. Determine the infant’s oral intake and number of stools.

Nursing Diagnosis

Nurses can do many things to prevent situations that might cause further rises in bilirubin. They must also protect the infant from injury

NURSING CARE PLAN

The Infant with Jaundice

ASSESSMENT: Holly, a 2-day-old, full-term infant born by cesarean, is jaundiced secondary to ABO incompatibility and is receiving phototherapy. She weighs 7 lb, 1 oz (3.2 kg), and her mucous membranes appear slightly dry. Skin turgor is good with quick recoil, and the anterior fontanel is flat. Urine appears slightly dark in color. Holly had three loose green stools with no water ring on this shift. She is a sleepy infant, who takes formula poorly. Valerie, her mother, appears tired and frustrated with her infant's slow eating behavior.

NURSING DIAGNOSIS: Risk for Deficient Fluid Volume related to inadequate oral intake to meet needs of increased insensible water loss and frequent loose stools.

EXPECTED OUTCOMES: Holly will:

1. Take at least 127 to 192 mL of fluid per day (27 to 45 mL/lb/day or 60 to 100 mL/kg/day) to meet normal needs within 24 hours.
2. Show adequate hydration (moist mucous membranes, elastic skin turgor, flat fontanels, pale yellow urine, and at least 3 to 4 wet diapers by the third day).

INTERVENTIONS AND RATIONALES

1. Instruct Valerie to feed Holly every 3 hours. Offer to feed Holly in the nursery at night or when Valerie needs rest, if she prefers. *Adequate intake of breast milk or formula is necessary to meet the infant's nutrient and fluid needs and ensure excretion of bilirubin in the stools. The mother's need for rest must be met without interfering with the infant's needs.*
2. Explain to Valerie that Holly needs frequent feedings to help her pass stools that contain the bilirubin causing her jaundice. *The mother's understanding of the reasons will increase her willingness to work with the infant.*
3. Observe Valerie feeding Holly and offer suggestions, as needed. Show her how to waken the infant by unwrapping and gentle stimulation. Use a pacifier or insert a gloved finger into the infant's mouth to elicit the suck reflex before feedings. Try warming the formula slightly. *Observation of feedings may identify problems and interventions that work for this situation. A wide-awake infant is more likely to feed well. Nonnutritive sucking may help the infant suck effectively during feedings. Some infants prefer warm milk.*
4. Tell the parents about the need for frequent feeding to provide added fluid, protein, and other nutrients. *Infants receiving phototherapy have a greater than normal insensible water loss. Albumin (protein) is necessary to carry bilirubin to the liver for conjugation. Heightened intestinal motility decreases absorption of nutrients.*
5. Avoid offering water or dextrose-water. Use breast milk or formula instead. *Water supplements may decrease the intake of milk and necessary nutrients. Milk increases motility of intestines and expedites excretion of bilirubin in stools, but water does not have the same effect.*
6. If water loss appears excessive, weigh all diapers, and check the specific gravity of the urine. Urine output should be 2 to 5 mL/kg/hr, which for Holly is a total of 154 to 384 mL daily. Specific gravity should be 1.002 to 1.01 for full-term infants. *Weighing the diapers and checking specific gravity will*

identify inadequate output and dehydration early. The wet diaper weight in grams minus the weight of the dry diaper equals the milliliters of urine.

7. Use therapeutic communication techniques to help Valerie vent her frustrations. Offer praise for her attempts to feed Holly. *Assisting the mother to cope with her feelings helps her meet the infant's needs. Feeding difficulties often interfere with the mother's view of herself as a "good" mother. Praise increases her sense of adequacy.*
8. Before discharge, teach the parents to call the physician if the infant has increasing jaundice, fewer wet diapers than expected, is feeding poorly, is lethargic or irritable, or has other changes in behavior. *Increases in bilirubin level may occur after discharge and the parents should know when to call the health care provider.*

EVALUATION: Holly drinks a total of 7.5 oz (224 mL) of formula during 24 hours. Valerie is able to wake Holly, who begins to suck more vigorously. Holly's mucous membranes are moist, and she has 6 wet diapers with pale yellow urine by the third day of life.

ASSESSMENT: Holly's diaper area is slightly red and irritated from her frequent loose stools.

NURSING DIAGNOSIS: Impaired Skin Integrity related to frequent loose stools.

EXPECTED OUTCOME: Holly's skin will return to normal within 2 days without further signs of irritation or breakdown.

INTERVENTIONS AND RATIONALES

1. Check diapers every hour. Gently cleanse the diaper area with mild soap and water after each stool. *Extended exposure of the skin to stool and urine may cause skin breakdown. Thorough cleansing removes irritating substances from the skin.*
2. Expose the entire diaper area to air for short periods. Place a diaper under Holly to catch urine and stools. *Exposure to air dries the area and aids healing.*
3. Avoid lotions or wipes containing alcohol and powders. Apply ointments, if prescribed, and cover with the diaper. *Alcohol changes the pH of the skin and may irritate. Powder may promote bacterial and Candida albicans growth. If ointments are used, the area should be covered to prevent the risk of burns from the phototherapy lights.*
4. Explain the reason for loose stools and methods of treatment of the skin irritation to Valerie. *The mother may need help to understand that the condition is not the result of poor care. She should learn how to care for diaper rash at home.*

EVALUATION: Holly's diaper area returns to normal with no redness or irritation within 1.5 days.

caused by the light during phototherapy. Therefore, an appropriate nursing diagnosis is "Risk for Injury related to preventable causes of further elevation of bilirubin or injury to the skin or eyes secondary to phototherapy."

Expected Outcomes

The expected outcome for this nursing diagnosis is that the infant will have no injury resulting from increased bilirubin levels or from exposure of the skin or eyes to phototherapy lights.

Interventions

Interventions are designed to prevent situations that might cause injury to the infant from rising bilirubin levels or effects of treatment.

Maintaining a Neutral Thermal Environment

Prevent situations such as cold stress or hypoglycemia, which could result in increased fatty acids in blood caused by acidosis. Acidosis would decrease the availability of albumin-binding sites for

unconjugated bilirubin. Prevent cold stress at birth and during all care by maintaining the infant in a neutral thermal environment. Check the infant's axillary temperature every 2 to 4 hours to identify an early decrease before it becomes a problem. Dress the infant in warmed clothes and blankets on removal from phototherapy lights.

Prevent elevation of the infant's temperature from exposure to the heat of the "bili" lights. Position the lights according to the manufacturer's guidelines to prevent overheating the infant. Use a skin probe when the infant is in an incubator or radiant warmer to maintain the appropriate environmental temperature, and monitor the settings to be sure they are correct for the infant's needs.

Providing Optimal Nutrition

Ensure that the infant receives feedings every 2 to 3 hours, whether by breast or bottle. Breastfeeding should not be stopped because the infant is receiving phototherapy. Provide extra support and teaching to breastfeeding mothers having difficulty. Frequent feedings prevent hypoglycemia, provide protein to maintain the albumin level in the blood, and promote gastrointestinal motility and prompt removal of bilirubin from the intestines.

Avoid offering water because the infant may take less milk, which is more effective in promoting stooling and removal of bilirubin from the intestines. If breastfeeding must be supplemented, use formula instead of water. Weigh the infant twice a day, and monitor intake and output to identify dehydration early and intervene appropriately.

Protecting the Eyes

Provide patches to protect the eyes from retinal damage from the phototherapy lights. Close the infant's eyes before placing the patches to avoid abrasions to the cornea. Check the position of the patches at least every hour. Infants often wiggle enough to push the patches above or below the eyes, leaving them exposed. The edges of the patches can press too hard on the eyes or compress the nose and interfere with breathing. Turn off the lights, and observe for skin irritation around or under the patches at least every 4 hours. Explain to the parents that it is normal for the yellow color under the patches to be deeper than in areas that have been exposed to the lights.

CRITICAL THINKING EXERCISE 30-1

Why is it important to remove the patches from the eyes each time the infant is taken from phototherapy for feeding or when parents visit?

Enhancing Response to Therapy

Position the lights the proper distance away from the infant. Lights that are too close may burn the skin. Lights too far away from the infant will not be effective in reducing jaundice. Halogen lights must be placed farther away from the infant than other lights to prevent burning. Follow the manufacturer's instructions about light placement. Although phototherapy increases insensible water loss from the skin, avoid the use of creams or lotions on the infant's skin that might cause burning.

Use a light meter to check the level of irradiance (energy output) to be sure the apparatus is functioning appropriately and to determine if the bulbs need to be replaced. Check laboratory reports of TSB levels to determine the effectiveness of treatment and when it can be discontinued.

Expose as much skin as possible to the light. Remove all of the infant's clothing except a diaper. Turn the infant every 2 hours to expose all areas evenly and prevent irritation of the skin from lack of

position change. If a fiberoptic blanket is used, check the position of the blanket frequently. Infants sometimes need to be repositioned so that the blanket remains in contact with the skin.

Detecting Complications

Observe for other complications. Although bilirubin encephalopathy is rare today, monitor for signs that indicate its presence. These include lethargy, increased or decreased muscle tone, poor feeding, decreased or absent Moro reflex, high-pitched cry, opisthotonos, and seizures (Kamath, Thilo, & Hernandez, 2010). Note the presence of rashes or changes in the color of the skin. Inform parents that they are not harmful and will disappear when phototherapy is discontinued.

Teaching Parents

Explain care to parents, who may be frightened to see their infant in an incubator with the infant's eyes covered. Explaining the causes of jaundice and the purpose of phototherapy will decrease their worry. Removing the infant from phototherapy for feeding and interaction with the parents for periods up to an hour at a time does not significantly decrease the effectiveness of phototherapy (Kaplan et al., 2011). In addition, allowing the parents to hold their baby increases their opportunity for attachment. Explain the importance of minimizing further interruptions to phototherapy.

When the infant is discharged, give the parents written and verbal information about jaundice. Teach them how to assess for further jaundice, signs of complications, and when to call the health care provider. Emphasize the need to keep follow-up laboratory work and visits to the health care provider so that any increases in jaundice or other problems can be identified and treated early. Explain that most infants have no further problem with jaundice.

Although sunlight is known to reduce bilirubin level, caution the parents against putting the infant in direct sunlight. The infant might be sunburned or have temperature instability and is exposed to unnecessary ultraviolet light from the sun.

Evaluation

No signs of injury should be present. The infant's eyes will not have been exposed to the phototherapy lights, and the skin should not be harmed. Laboratory reports should show a steady decrease of serum bilirubin level.

- How can the nurse help reduce bilirubin levels in infants receiving phototherapy?

INFECTION

Nurses must be constantly alert for signs of infection in newborns. As many as 10% of infants develop infections during the first month of life (Stoll, 2011).

Transmission of Infection

Newborns can acquire infections before, during, or after birth. Vertical infection is acquired before or during birth from the mother. Organisms such as those causing rubella, cytomegalovirus infection, syphilis, human immunodeficiency virus (HIV) infection, and toxoplasmosis may pass across the placenta and cause infection during pregnancy. During labor and birth, organisms in the vagina such as group B *Streptococcus* (GBS), herpes, and hepatitis may enter the uterus after

rupture of membranes or infect the infant during passage through the birth canal.

Horizontal infection occurs after birth, acquired from hospital staff members or from contaminated equipment (health care–associated infections), or from family members or visitors. An example is staphylococcal infections associated with central venous catheters. Some of the most common infections and their effects on the neonate are listed in Table 30-1. Other infections are discussed in Chapter 26, p. 556.

Sepsis Neonatorum

Infection that occurs during or after birth may result in sepsis neonatorum, a systemic infection from bacteria in the bloodstream.

Newborns are particularly susceptible to sepsis because their immune systems are immature and they react more slowly to invasion by organisms. Newborns and especially preterm infants have fewer antibodies and are unable to localize infection as well as older children. This inability allows the infection to spread easily from one organ to another. In addition, the blood–brain barrier is less effective in preventing the entrance of organisms, and CNS infection may result.

Causes

Common causative agents of neonatal sepsis include bacteria such as GBS, *Escherichia coli*, coagulase-negative *Staphylococcus*, *Staphylococcus*

TABLE 30-1 COMMON INFECTIONS IN THE NEWBORN

TRANSMISSION	EFFECT ON NEWBORN	NURSING CONSIDERATIONS
Viral Infections		
Cytomegalovirus		
Transplacental, during birth, in breast milk	Most asymptomatic at birth. SGA, FGR, enlarged liver, CNS abnormalities, jaundice, learning impairment, hearing loss, purpura, chorioretinitis, microcephaly, seizures. May have no signs for months or years.	Diagnosed by urine or pharyngeal culture. May shed virus in saliva and urine for months or years. Antiviral drug therapy may be used but has toxic effects and is not recommended routinely. Treatment supportive.
Hepatitis B		
Usually during birth through contact with maternal blood Also transplacental and from breast milk	Asymptomatic at birth. LBW, prematurity. Most become chronic carriers. Risk of later liver cancer.	Wash well to remove all blood before skin is punctured for any reason. After cleaning, administer HBIG and hepatitis B vaccine to prevent infection. May breastfeed if infant receives vaccine and HBIG.
Herpes		
Usually during birth through infected vagina or ascending infection after rupture of membranes Transplacental rarely Transmission highest with primary infection	Clusters of vesicles, temperature instability, lethargy; poor suck, seizures, encephalitis, jaundice, purpura. Death or severe neurologic impairment is high with disseminated infection. High mortality rate if untreated.	Contact precautions. Obtain specimens of lesions for culture. Antiviral drugs given to mother during pregnancy and to infant after birth. May breastfeed if no lesions on the breasts.
Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome		
Transplacental, during birth from infected blood and secretions, or from breast milk Transmission rate much lower if mother receives antiretroviral drugs during pregnancy and labor, and birth is by cesarean before rupture of membranes	Asymptomatic at birth; signs usually apparent at 12 to 24 months. Enlarged liver and spleen, lymphadenopathy, failure to thrive, pneumonia, persistent <i>Candida</i> and bacterial infections, diarrhea, meningitis, septic joints.	Diagnosis may be delayed because of maternal antibodies. Some early tests available. Wash early to remove blood before skin is punctured. Treat with antiretroviral drugs and prophylaxis against other infections. Advise against breastfeeding.
Rubella		
Transplacental	Spontaneous abortion, asymptomatic or FGR, cataracts, cardiac defects, deafness, microcephaly, cognitive impairment. Injury greatest if infected in first trimester.	Contact precautions. Infant may shed virus for 1 year after birth. Diagnosed by presence of antibody and virus. Treatment supportive.
Varicella-Zoster virus (Chickenpox)		
Transplacental	Congenital varicella syndrome (skin scarring, limb hypoplasia, CNS and eye abnormalities, death), rash. Highest incidence between 13 and 20 weeks of gestation. Severe effects with maternal infection between 5 days before and 2 days after birth.	Varicella immune globulin for pregnant woman exposed in pregnancy or for infants of mothers infected just before or after delivery. It modifies but does not prevent infection. Acyclovir to treat. Strict isolation precautions for mothers and infants with lesions.

Continued

TABLE 30-1 COMMON INFECTIONS IN THE NEWBORN—cont'd

TRANSMISSION	EFFECT ON NEWBORN	NURSING CONSIDERATIONS
Other Infections		
Group B Streptococcal Infection		
During birth or ascending after rupture of membranes	Sudden onset of respiratory distress in infant usually well at birth, temperature instability, pneumonia, shock, meningitis. May have early or late onset.	Early identification essential to prevent death. Antibiotic treatment of infected mothers during labor has decreased neonatal infection. IV antibiotics given to infected infants.
Gonorrhea		
Usually during birth	Conjunctivitis (ophthalmia neonatorum), with red, edematous lids and purulent eye drainage. May result in blindness if untreated.	All infants receive prophylactic treatment. Erythromycin eye ointment is most common. Infected infants are treated with IV antibiotics.
Chlamydial Infection		
During birth	Conjunctivitis 1-2 weeks after birth, pneumonia at 4-11 weeks, otitis media, bronchiolitis.	Treated with oral azithromycin or erythromycin. Topical treatment of conjunctivitis is not effective.
Candidiasis		
During birth	White patches in mouth (thrush) that bleed if removed. Rash on perineum. May be systemic in preterm or LBW.	Administer nystatin drops or cream and teach parents how to administer them. Assess mother for vaginal or breast infection. IV antibiotics for systemic infection.
Toxoplasmosis		
Transplacental	Asymptomatic, or FGR, LBW, preterm, thrombocytopenia, enlarged liver and spleen, jaundice, cerebral calcifications, encephalitis, seizures, microcephaly, hydrocephalus, chorioretinitis. Signs may not develop for years.	Consider in infants with FGR. Confirmed by serum tests. Treatment: spiramycin during pregnancy, pyrimethamine, sulfadiazine, and folic acid for 1 year for infant.
Syphilis		
Transplacental	Asymptomatic or spontaneous abortion, stillbirth, enlarged liver and spleen, jaundice, hepatitis, anemia, rhinitis, pink or copper-colored peeling rash, pneumonitis, osteochondritis, CNS involvement.	Diagnosed by blood and cerebrospinal fluid testing. Treated with penicillin.

*Standard precautions for infection control apply to all patients and are not listed in this table. Also see [Table 26-3](#).

CNS, Central nervous system; FGR, fetal growth restriction; HBIG, hepatitis B immune globulin; IV, intravenous; LBW, low birth weight; SGA, small-for-gestational-age.

aureus, *Haemophilus influenzae*, and fungi such as *Candida albicans* (Edwards, 2011; Lott, 2010). Sepsis may be divided into early-onset and late-onset sepsis, according to when signs of disease begin. Early-onset sepsis is acquired during birth, often from complications of labor such as prolonged rupture of membranes, prolonged labor, or chorioamnionitis. Infants often show signs during the first hours after birth, and 90% show signs within 24 hours (Puopolo, 2012). It is a rapidly progressive multisystem illness with high mortality and morbidity rates. Pneumonia and meningitis are commonly present.

Late-onset sepsis occurs from 8 to 90 days after birth in healthy term infants or after 72 hours of life in very-low-birth-weight infants (Puopolo, 2012). It is acquired during or after birth, before or after hospital discharge. It usually is a localized infection such as meningitis, and serious long-term effects are common.

Therapeutic Management

Diagnostic Testing. Neonatal sepsis may be confused with other illnesses. For example, GBS pneumonia has the same initial symptoms

as RDS. Diagnostic testing helps identify sepsis and the organisms responsible.

A CBC count with differential may show decreased total neutrophils, increased bands (a form of immature neutrophils), an increased ratio of immature neutrophils to total neutrophils, and decreased platelets. Elevated levels of leukocytes are normal in newborns. However, a sudden rise or fall in leukocyte levels compared with previous results is abnormal. A leukocyte count below 4000 to 5000/mm³ or above 24,000 to 30,000/mm³ suggests infection but is not diagnostic (Blackburn, 2013). The presence of elevated IgM levels in cord blood or shortly after birth indicates that infection was acquired in utero because this immunoglobulin does not cross the placenta. It often indicates transplacental infection.

The cross-reactive protein (CRP) level, a sign of an inflammatory process, may be elevated. Serial tests of CRP are often performed to check for rise and then fall as infection improves. Cultures of blood, urine, any skin lesions, and cerebrospinal fluid may be obtained. Cultures of the nasopharynx, umbilical cord, and gastric aspirate usually

show colonization with organisms but not infection. Chest radiography helps differentiate between RDS and sepsis. Blood glucose levels should be checked because they may be unstable (high or low) in sepsis.

Treatment. Women who are GBS positive receive antibiotics during labor. Their infants who appear well, are at least 37 weeks of gestation, and had amniotic membranes ruptured less than 18 hours are observed for 48 hours or more after birth. If the mothers did not receive antibiotics during labor and delivered at less than 37 weeks of gestation or with membranes ruptured over 18 hours, infants who appear well receive a blood culture and CBC with differential and platelets, and observation for 48 hours or more (Verani, McGee, & Schrag, 2010).

Those who develop signs of infection are then treated. Broad-spectrum antibiotics are given intravenously until culture and sensitivity results are available. Continued antibiotic therapy is based on culture results. Commonly used antibiotics include ampicillin, aminoglycoside, and cephalosporins. Vancomycin may also be used (Venkatesh, Adams, & Weisman, 2011).

Other care is supportive to meet the infant's specific needs. The infant may require oxygen or mechanical ventilation. Fluid balance maintenance and monitoring of the blood pressure and hourly urine output are important. Shock, hypoglycemia or hyperglycemia, electrolyte imbalances, and problems in temperature regulation are potential complications.

Nursing Considerations

Assessment

Risk Factors. The nurse should identify infants at risk for infection. Prematurity and low birth weight are the most important risk factors. Preterm infants less than 32 weeks of gestation have a 4- to 25-times greater risk of infection compared with term infants (Lott, 2010). Infants of mothers who have rupture of membranes longer than 18 hours also have an increased risk for infection (Venkatesh, Adams, & Weisman, 2011). Other risk factors for sepsis include prolonged or precipitous labor, signs of maternal infection before or during labor, chorioamnionitis, and foul-smelling amniotic fluid. The nurse needs to identify women known to be GBS positive and those who show signs of infection so they can be treated with antibiotics during labor to reduce risk to the infant.

Every infant in the NICU is at risk for healthcare-associated infections. These infants have complications or conditions such as prematurity that make them more susceptible to infection. The risk of infection increases as gestational age and birth weight decrease. Preterm infants have not received maternal antibodies that help protect them from infection. In addition, they sometimes spend prolonged periods in the NICU, where they are exposed to many invasive procedures such as use of IV catheters and endotracheal tubes, which increase their risk of infection. NICU patients may develop abnormal flora that may be carried by personnel from one infant to another and may be resistant to usual drug therapy. Catheter-related bloodstream infections are a significant problem in NICUs (Semelsberger, 2009).

Signs of Infection. In the newborn, early signs of infection are not as specific or obvious as those in the older infant or child. Instead, they tend to be subtle and could indicate other conditions. Temperature instability may occur. Only 50% of infected newborns have an axillary temperature above 100°F (37.8°C) (Stoll, 2011).

Respiratory problems are common, and changes may occur in feeding habits or behavior. Other than the parents, the nurse is the only person who spends a significant amount of time with the infant and is in a position to identify the early, subtle changes in behavior that may indicate sepsis. Experienced nurses may have a feeling that the

infant is not doing well even before specific signs of infection are present. When this occurs, the nurse expands the assessment and watches carefully for the development of other signs. Early identification and treatment are important because infants can develop septic shock with little warning.

CRITICAL TO REMEMBER

Signs of Sepsis in the Newborn

General Signs

- Temperature instability (usually low)
- Nurse's or parents' feeling that the infant is not doing well
- Rash

Respiratory Signs

- Tachypnea
- Respiratory distress (nasal flaring, retractions, grunting)
- Apnea

Cardiovascular Signs

- Color changes (cyanosis, pallor, mottling)
- Tachycardia
- Hypotension
- Decreased peripheral perfusion
- Edema

Gastrointestinal Signs

- Decreased oral intake
- Vomiting
- Excessive gastric residuals
- Diarrhea
- Abdominal distention
- Hypoglycemia or hyperglycemia

Neurologic Signs

- Decreased or increased muscle tone
- Lethargy
- Jitteriness
- Irritability
- Full fontanel
- High-pitched cry

Signs That May Indicate Advanced Infection

- Jaundice
- Evidence of hemorrhage (petechiae, purpura, pulmonary bleeding)
- Anemia
- Enlarged liver and spleen
- Respiratory failure
- Shock
- Seizures

Nursing Interventions

Preventing Infection. Although it is not always possible to prevent infection, every effort should be made. Careful and frequent handwashing is the most important aspect of infection prevention. The nurse should practice and teach parents to perform good handwashing or to use hospital-provided hand disinfectants before and after touching any infant. Equipment must be disinfected according to hospital protocols. Meticulous sterile technique must be used during invasive procedures. Invasive procedures should be kept to the lowest number possible.

The skin is delicate in the newborn, particularly so in preterm infants. Handling and trauma to the skin should be minimized as much as possible to prevent skin breakdown and infection.

Transmission of infection to other infants must be prevented. This is accomplished with handwashing, separation of each infant's supplies, and standard precautions for infection control. These techniques must be conscientiously performed by all who come in contact with the infant. Parents should be taught about all infection control measures so that they can help protect their infants.

Placing the infant in an incubator provides a physical separation between infected and well infants, similar to placing adults in isolation in private rooms. In addition, the nurse can observe the infant in an incubator more easily.

Providing Antibiotics. The nurse is responsible for obtaining or helping obtain specimens for laboratory analysis and checking that other tests ordered by the physician are completed. Laboratory tests will help determine the type and duration of antibiotics prescribed.

Because the signs of infection are nonspecific and the disease can be fatal, physicians may order antibiotics before an actual diagnosis is made for infants who are at high risk or show early signs. Broad-spectrum IV antibiotics are given after samples for culture and sensitivity are taken and before the results are available. Continued antibiotic therapy is based on organisms found on culture. The nurse must be knowledgeable about the specific antibiotics used and possible side effects.

The nurse starts IV fluids and ensures that medications are administered on time. If more than one antibiotic is ordered, the timing of administration must be coordinated to increase effectiveness. Antibiotics usually are continued for 7 to 14 days for sepsis and 14 to 21 days for meningitis (Lott, 2010).

Providing Other Supportive Care. Infants may be critically ill and need intensive nursing care. Care includes giving oxygen or other respiratory support, as needed. Fluid balance maintenance, monitoring of vital signs, and hourly urine output measurements are important. IV or gavage feeding may be necessary if the infant is unable to take oral feedings.

Infants with sepsis may have additional problems. They may be premature or have other transplacentally acquired infections. In addition, the nurse must be alert for signs of other complications such as disseminated intravascular coagulopathy.

Supporting Parents. Nurses provide support to parents of newborns with sepsis and help them understand their infant's illness and treatment. The infant with sepsis often appears healthy at birth but suddenly becomes critically ill. Parents experience feelings of shock, fear, and disappointment when their apparently healthy newborn is suddenly moved to the NICU. Or the preterm infant they thought was making good progress may suddenly develop a life-threatening illness. Parents benefit from a chance to talk about their feelings with an understanding nurse who can explain the infant's treatment and care. Keeping the parents informed and involving them in care are essential.

INFANT OF A DIABETIC MOTHER

Scope of the Problem

The infant of a diabetic mother (IDM) faces many risks that depend on the type of diabetes the mother has and how well it is controlled. The neonatal mortality rate is five times that of infants born to mothers without diabetes, and congenital anomalies are three times more likely in IDMs (Carlo, 2011a). Cardiac, urinary tract, and gastrointestinal anomalies, neural tube anomalies, and sacral agenesis are most frequent. Cardiomegaly is common and may lead to heart failure. The

FIG 30-3 Macrosomia is common in infants of mothers with diabetes.

incidence of anomalies is less with good control of diabetes before conception and in the early weeks of gestation when fetal organs are being formed. It is not increased in women with gestational diabetes (Kalhan & Devaskar, 2011).

Insulin acts as a growth hormone. The accelerated protein synthesis and the deposit of fat and glycogen in fetal tissues result in macrosomia (Figure 30-3). It occurs in as many of 20% of infants of mothers with gestational diabetes and 35% of women with other types of diabetes. Strict control of the mother's blood glucose level, especially during the third trimester, reduces the risk of macrosomia (Blackburn, 2013). Infants with macrosomia are at risk for trauma during birth, including fracture of the clavicles from shoulder dystocia, cephalhematoma, and facial nerve and brachial plexus injury.

When the mother is hyperglycemic, large amounts of amino acids, free fatty acids, and glucose are transferred to the fetus. Insulin does not cross the placenta because the molecules are too large. The excessive glucose received by the fetus causes the fetal pancreas to secrete large amounts of insulin and leads to hypertrophy of the islet cells. Hypoglycemia may occur after birth when the supply of glucose from the mother is no longer available but the infant's high insulin production continues.

Infants of mothers with long-term diabetes and vascular changes may have fetal growth restriction instead of macrosomia because of decreased placental blood flow. Hypertension occurs more often in women with diabetes and further compromises uteroplacental blood flow.

The IDM has a higher risk of asphyxia and RDS. RDS occurs because increased levels of insulin block the effect of cortisol on stimulation of lung maturation (Lee-Parritz & Cloherty, 2012.) Other complications for which the IDM is at risk include hypocalcemia (p. 665) as a result of decreased parathyroid hormone production. Magnesium levels may also be low.

Polycythemia (p. 665) may occur as a response to chronic hypoxia in utero. It may cause hyperbilirubinemia when the large number of RBCs break down after birth. In addition, IDMs are more likely to be born prematurely.

Characteristics of Infants of Diabetic Mothers

The IDM with macrosomia is different from other large-for-gestational-age (LGA) infants. The infant's size results from fat deposits and hypertrophy of the liver, spleen, and heart. The brain and kidneys are normal in size (Kalhan & Devaskar, 2011). The length and head circumference are also generally within the normal range for gestational age. Other LGA infants do not have enlargement of the organs and tend to be long, with large heads to match the rest of their bodies. IDMs have a characteristic appearance. The face is round, the skin is often red (plethoric), and the body is obese. The infant has poor muscle tone at rest but becomes irritable and may have tremors when disturbed. The small-for gestational-age (SGA) IDM is similar to infants who are SGA from other causes but is more likely to have congenital anomalies.

Therapeutic Management

Therapeutic management includes controlling the mother's diabetes throughout pregnancy to decrease complications in the fetus and newborn (see Chapter 26). If the infant is large, there may be shoulder dystocia or cephalopelvic disproportion, and a cesarean birth may be required. Immediate care of respiratory problems and continued observation for complications determine treatment.

Nursing Considerations

Assessment

The IDM is assessed for signs of complications, trauma, and congenital anomalies at delivery and during the early hours after birth. Respiratory problems may be apparent at birth or may develop later. The initial assessment may reveal injuries. For example, an infant who cries when an arm is moved or fails to move an arm may have a fractured clavicle or nerve injury.

Hypoglycemia occurs in 25% to 50% of infants of mothers with pregestational diabetes and 15% to 25% of those with gestational diabetes (Carlo, 2011a). It may be present without observable signs. The most frequent sign of low blood glucose is jitteriness or tremors. Diaphoresis is uncommon in newborns but may occur with hypoglycemia. Rapid respirations, low temperature, and poor muscle tone are also common (see Chapter 20, p. 396). Because these signs are not specific for hypoglycemia, the nurse must be alert for other complications, particularly if signs continue after feeding.

Nursing Interventions

The nurse assesses glucose levels according to hospital policy. An example is screening every hour for 4 hours after birth and then every 4 hours twice or until the results are normal. Glucose levels of less than 40 to 45 mg/dL measured with a bedside glucometer should be reported and verified by laboratory analysis. Glucose levels reach the lowest point at 1 to 3 hours after birth and begin to improve by 4 to 6 hours (Carlo, 2011a). Infants should be fed early to prevent hypoglycemia and immediately if low blood glucose occurs to prevent further decreases. Gavage feeding may be used if the infant does not suck well or if respirations are rapid. The glucose level is rechecked in 30 to 45 minutes. Infants whose glucose levels are not maintained with feedings or whose condition does not allow enteral feedings need IV glucose to maintain glucose balance and prevent injury to the brain.

The nurse must be alert for signs of other complications that occur in IDMs. RDS or other respiratory complications may develop. Cold stress, which increases the need for oxygen and glucose, could increase respiratory problems and exacerbate hypoglycemia. Infants with polycythemia need adequate hydration to prevent sluggish blood flow to vital organs and ischemia. Hypocalcemia may be suspected if tremors continue and the blood glucose concentration is normal.

Providing support to parents is important. Approximately one third of IDMs are poor feeders (Nafday, 2009). The nurse must work with the infant and the parents to ensure feedings are adequate. Parents may have many questions for the nurse. They may not understand why their infant, who appears fat and healthy to them, needs close observation and frequent blood tests. The mother may have had a difficult pregnancy and may feel guilty, even if she followed a program of good diabetic control. Ample opportunity for discussion of feelings as well as information about the care of the infant is important.

9. Why are IDMs more likely to develop macrosomia?
10. Why are IDMs at risk for hypoglycemia after birth?

POLYCYTHEMIA

In polycythemia, infants have a hemoglobin level greater than 22 grams per deciliter (g/dL) and a hematocrit greater than 65% (Luchtman-Jones & Wilson, 2011). The increased viscosity of the blood causes resistance in the blood vessels and decreases blood flow. Blood flow to all organs is impaired. Organ damage from ischemia and microthrombi, elevated pulmonary vascular resistance, stroke, renal vein thrombosis, necrotizing enterocolitis, and congestive heart failure may result (O'Reilly, 2012). Polycythemia also may result in hyperbilirubinemia as the excessive RBCs break down after birth.

Causes

Polycythemia may occur when poor intrauterine oxygenation causes the fetus to compensate by producing more erythrocytes than normal. It is more common in infants who are postterm, LGA, or SGA or have fetal growth restriction (FGR). It also occurs in infants of mothers who smoke or have hypertension or diabetes. Delayed cord clamping or a transfusion from one twin to another may also cause the condition.

Manifestations

Most infants have minimal or no signs of polycythemia. Symptomatic infants may have a plethoric color, lethargy, irritability, poor tone, and tremors. Abdominal distention, decreased bowel sounds, poor feeding, hypoglycemia, and respiratory distress may also be present. Hyperbilirubinemia occurs as RBCs are broken down.

Therapeutic Management

Treatment is primarily supportive. Infants who are asymptomatic are observed and receive increased hydration. Partial exchange transfusions may be performed if the hematocrit is above 70% (Luchtman-Jones & Wilson, 2011). Blood is replaced with normal saline to decrease the total number of RBCs. Phototherapy is used to treat the jaundice.

Nursing Considerations

Monitoring of bilirubin levels is important to determine if phototherapy is necessary. Infants must be hydrated adequately to prevent dehydration that would slow already sluggish blood flow and increase ischemia to vital organs. If an exchange transfusion is performed, the nurse assists and watches for complications.

HYPOCALCEMIA

Hypocalcemia is a total serum calcium concentration of less than 7 mg/dL. It is divided into early-onset (in the first 72 hours of age) and late-onset (1 week of age) forms (Jones, Hayes, Starbuck et al., 2011).

Causes

Early-onset hypocalcemia occurs most often in IDMs, and infants with asphyxia, prematurity, maternal anticonvulsant therapy, and delayed nutrition. Late-onset hypocalcemia is caused by hyperparathyroidism, malabsorption, low magnesium levels, diuretic therapy, and rickets (Jones et al., 2011).

Manifestations

Signs of hypocalcemia include irritability, jitteriness, poor feeding, high-pitched cry, muscle twitching, apnea, seizures, and electrocardiographic changes. It is often asymptomatic.

Therapeutic Management

Laboratory testing of serum calcium level determines the presence of the problem. IV calcium gluconate is given if feeding alone does not raise the calcium level. A cardiac monitor is necessary when IV calcium is given because bradycardia can occur.

Nursing Considerations

The nurse must be alert for signs of hypocalcemia. IV calcium should be administered slowly and stopped immediately if bradycardia or dysrhythmia develops. The IV site should be assessed frequently because infiltration can cause necrosis and ulceration.

PRENATAL DRUG EXPOSURE

Substance abuse affects the fetus at any time during pregnancy. Most drugs readily cross the placenta and cause a variety of problems. The effects of substance abuse on pregnancy, the fetus, and the neonate are discussed in Chapter 24. This section includes nursing care for infants with **neonatal abstinence syndrome** (NAS), a disorder in which infants exposed to maternal drugs before birth demonstrate signs of drug withdrawal.

Identification of Drug-Exposed Infants

Maternal substance abuse may be identified before an infant is born, but some infants are born to women whose substance use is not known to the health care professionals caring for them. A history of minimal or no prenatal care or the mother's behavior during labor may cause nurses to suspect substance abuse. When there is any reason to suspect drug use, the infant is observed closely for signs of prenatal drug exposure.

NAS occurs in infants who have suffered prenatal opiate exposure sufficient to cause withdrawal signs after birth. Women who use heroin are generally switched to methadone during pregnancy to decrease the incidence of wide variations in the drug dosage, which is harmful to the fetus. These women usually receive better prenatal care and their infants have a higher birth weight compared with those exposed to heroin. However, infants must undergo withdrawal after birth.

NAS is also seen in some infants exposed to other drugs such as codeine, hydroxyzine, amphetamines, and antidepressants (Carlo, 2011b). Methamphetamine exposure results in lethargy, irritability, high-pitched cry, and hypertonicity in infants (Altshul, 2012). Neonates exposed to cocaine may exhibit CNS signs such as irritability followed by lethargy, tremors, and increased tone. They respond poorly to comforting and become distressed easily. These effects are thought to be caused by the drug rather than the withdrawal (Pitts, 2010).

Selective serotonin reuptake inhibitors and other antidepressants taken during pregnancy may result in some behaviors that are similar to NAS but the effects are usually milder (Carlo, 2011b). Signs of drug exposure usually begin during the first 24 to 72 hours after birth but

may not occur for up to 4 weeks depending on the specific drug, the dose, and the time of the mother's last use (Bandstra & Accornero, 2011). Use near the time of delivery causes a later onset but more severe signs of withdrawal.

Polydrug use along with use of alcohol and cigarettes is common. This makes it difficult to determine which substance led to individual effects. Signs differ according to the drug or combination of drugs used but often include neurologic and gastrointestinal abnormalities. Some infants with prenatal drug exposure show no abnormal signs at all.

Infants with NAS may be irritable and have hyperactive muscle tone and a high-pitched cry. Although they have tremors, the blood glucose level is normal. Infants appear hungry and suck vigorously on their fists but have poor coordination of suck and swallow. Frequent regurgitation, vomiting, and diarrhea are common. Infants are restless, and their excessive activity coupled with poor feeding ability results in failure to gain weight. Seizures may occur.

Various scoring systems are available to determine the number, frequency, and severity of behaviors that indicate NAS. The score is used when considering whether drug therapy to alleviate withdrawal signs is needed and to determine dosage. Behaviors are generally scored every 2 to 4 hours until low scores are obtained consistently. It is important that all nurses are able to use the scoring tool consistently to provide for optimal treatment of the infant.

Congenital anomalies and other effects of prenatal drug exposure may be apparent at birth. Fetal growth restriction and prematurity are common. Infants are more likely to have respiratory problems at birth, jaundice, or sudden infant death syndrome. Infants with fetal alcohol syndrome have a characteristic appearance.

When drug exposure is suspected, a urine specimen is collected for analysis. Drugs or their metabolites are present in the newborn's urine for various lengths of time after the mother has used them. Some drugs last several days because the infant's immature liver and kidneys delay excreting them, whereas others disappear very soon. Therefore, it is important to obtain the first urine output from the infant, if possible (Procedure 30-2). Meconium analysis is sensitive for drug exposure from the 24th week of gestation (Stewart, 2012). A hair sample or a segment of umbilical cord is tested in some facilities.

Therapeutic Management

Because many signs of drug exposure are similar to those for other conditions, testing may be performed to rule out other causes. Sepsis, hypoglycemia, hypocalcemia, and neurologic disorders are possible causes for the infant's problems. In addition, the infant may have been exposed to infections from the mother, such as hepatitis or sexually transmitted diseases.

Therapeutic management includes dealing with the complications common to drug-exposed infants during and after birth. Respiratory problems and those related to prematurity are treated as for other infants. Drug therapy may be necessary for approximately 50% to 60% of infants because of high scores on abstinence scales (Weiner & Finnegan, 2011). Medications commonly used include oral morphine and methadone. Phenobarbital may be used with opiates for polydrug exposure (Weiner & Finnegan, 2011). Buprenorphine and clonidine have also been used, but further studies are needed (Bell, 2012; Hudak, Tan, & The Committee on Drugs and the Committee on the Fetus and Newborn, 2012). Medication dosage is gradually tapered until the infant no longer needs it. Although these drugs help relieve the signs of withdrawal, all have side effects that may be undesirable.

Because the infant's suck and swallow are uncoordinated, gavage or IV feeding may be required. Some infants need more than the normal caloric requirements because of their excessive activity. The specific

CRITICAL TO REMEMBER**Signs of Intrauterine Drug Exposure*****Behavioral Signs**

 Fever
 Diaphoresis
 Excoriation
 Mottling

*Some infants with prenatal drug exposure have no abnormal signs at all, or signs may be delayed.

PROCEDURE 30-2 APPLYING A PEDIATRIC URINE COLLECTION BAG

PURPOSE: To collect a nonsterile urine specimen from an infant

1. Wash hands, and obtain needed equipment. Include pediatric urine collector, washcloth and towel, diaper, sterile specimen cup, and clean gloves. *Gathering equipment allows the procedure to be completed efficiently.*
2. Apply gloves. Wash and dry the genitalia. Dry the skin completely. *Removal of gross contaminants prevents contamination of the specimen. The bag adheres to a clean, dry surface best.*
3. Remove the paper covering on the posterior adhesive tabs of the bag first. To apply to female infants, gently hold the skin taut at the perineum (skin between the rectum and the vagina). Fold the bag in half and apply smoothly over the perineum, extending the tabs to the side. For male infants, place the penis and scrotum (if small enough) inside the bag and apply the posterior adhesive tabs to the perineum. If the scrotum will not fit in the bag easily, apply the tabs smoothly over the scrotum. *Covering the perineum with the posterior tabs first helps ensure a smooth fit at this area, where leakage of urine may occur in the female infant especially, and prevents contamination with feces. Care in application prevents losing the specimen.*
4. Remove the paper covering on the anterior adhesive tabs, and apply to cover the genitalia. Be sure that there are no wrinkles in the tabs. *Wrinkles allow openings for urine to leak out of the bag.*
5. Cut a slit in the diaper, and gently pull the bag through the slit. Apply the diaper loosely. *Cutting a slit in the diaper allows visualization of the bag. Placing the diaper too tightly over the bag might pull against the adhesive, causing trauma to the skin and providing an opening through which the specimen is lost.*
6. Check the bag for urine frequently and gently remove it as soon as urine is present. Transfer the urine to a specimen cup by removing the tab over the hole in the bottom and pouring. The specimen also can be aspirated with a syringe after cleaning the puncture site with alcohol. *This step ensures removal of the bag before urine loosens the adhesive and prepares the specimen to be sent to the laboratory for analysis.*
7. Clean the genitalia, and observe for irritation. *This removes urine and adhesive from the skin.*
8. Place the specimen in a biohazard bag, and label it. Transport the specimen to the laboratory, or refrigerate it, if necessary. Record the date and time of urine collection, and the amount, color, and appearance of urine in the infant's chart. *This ensures proper disposition of the specimen.*

calories needed for each infant will be prescribed by the health care provider.

Involvement by social services in and out of the hospital is important to deal with the long-term effects of the drugs, placement of the infant after hospitalization, and follow-up of the mother or other caregiver to help provide for the infant's needs.

Nursing Considerations

The infant who has been exposed to drugs prenatally needs special care to cope with drug withdrawal. Care is focused on encouraging feeding, promoting rest, and, if possible, enhancing parental attachment.

Feeding

Feeding can be difficult and time consuming. The poor suck and swallow coordination of drug-exposed infants interferes with caloric intake, yet their excessive activity increases their caloric needs.

Assessment. Infants often suck frantically on their fists or a nipple but are unable to coordinate feeding behaviors well. The nurse should assess the infant's ability to suck and swallow with breathing. Changes in the frequency and amount of regurgitation, vomiting, or the length of time it takes infants to finish feedings should be noted.

Nursing Interventions. Gavage feedings may be necessary to conserve the infant's energy and prevent aspiration if the infant is excessively agitated, is unable to suck and swallow adequately, or has rapid respirations. The infant's excessive activity, poor sleeping, vomiting, and diarrhea increase the caloric need. The infant may need as many as 150 to 250 calories per kilogram (cal/kg) each day (Ostrea, Alviedo, Banadera et al., 2009). Formula with 24 calories or more per ounce instead of the usual 20 calories per ounce may be used. More frequent feedings may be needed, as well.

Distractions during feedings can be prevented by choosing a quiet, low-activity area of the nursery for feedings. Infants should be swaddled to prevent the startling that occurs when drug-exposed infants are handled. Stimuli such as rocking and talking should be kept to a minimum during feedings. After feedings, infants should be positioned on the right side with the head of the bed elevated 30 to 45 degrees. Some infants respond better to the prone position. If possible, the infant should be positioned in the supine position for sleep.

Rest

The excessive activity and poor sleep patterns of drug-exposed neonates interfere with their ability to rest.

Assessment. The infant's muscle tone, tremors, and tendency for excessive activity with and without being disturbed should be assessed. The degree of tremors and stimuli that increase or decrease irritability are important. The nurse also keeps track of the number of hours the infant sleeps after each feeding.

Nursing Interventions. Keep stimulation of the drug-exposed infant to a minimum, especially at first when the infant is excessively irritable. Position the crib in the quietest corner of the nursery. Place a sign nearby to remind others of the need for quiet near the infant. The number of different types of stimulation should be kept to a minimum and adapted to each infant's needs. Reduce noise and bright lights as much as possible. If the infant shows signs of overstimulation, stop all activity briefly to allow a rest.

Swaddling the infant in a flexed position helps prevent startling and agitation. Placing the excessively agitated infant in a dark, quiet room may be necessary. As the infant shows the ability to withstand stimulation, add new types of stimuli gradually, one at a time. Some infants respond well to soft music, which has the added advantage of masking other environmental sounds.

Organize nursing care to reduce handling and disturbances. Cluster care activities to avoid unnecessary interruptions, yet provide rest periods if signs of stress occur. A calm approach and slow, smooth movements during care help avoid startling the infant. A pacifier for nonnutritive sucking also helps quiet the infant.

Skin abrasions from excessive activity and rubbing of the face, elbows, and knees may increase discomfort and agitation. Cover the infant's hands with mittens or the end of the shirtsleeves to help prevent facial scratching. Diaper rash from frequent diarrhea also may occur. Skin breakdown should be prevented, if possible, and treated promptly if it occurs. Placing the infant in the prone position promotes better sleep for some infants but supine positioning should be used as soon as possible.

Bonding

When an infant tests positive for drugs, child protective services become involved. The infant may not be released to the mother until her ability to care for her infant safely has been assessed by social services or a court. She may be required to enter a drug rehabilitation program before she can obtain custody of the infant. After hospital discharge, the infant may be cared for by family members approved by the court, in a foster home, or in an institution. The mother will most likely gain custody of the infant eventually if she complies with court-ordered treatment, and attachment to the infant should be encouraged.

Assessment. The frequency of the mother's visits and her response to the infant may give an indication of her apparent interest in the infant. Although some substance-abusing mothers are uninterested in their infants, for others the infant provides a reason to attempt to overcome their addiction. Bonding behaviors such as calling the infant by name and smiling at the infant should be noted.

Nursing Interventions. Child neglect, abuse, and failure to respond appropriately to infant signals and cues are associated with alcohol and drug abuse. Because the mother may become the infant's primary caregiver, it is essential that nurses do whatever they can to enhance mother-infant bonding. Helping the mother feel welcome when she visits the infant poses a challenge. It is sometimes easy to be judgmental and difficult to be accepting of the mother whose behavior has been harmful to her infant. Yet a friendly approach will make the mother more likely to visit the infant and accept teaching from the nurse.

Promote bonding by encouraging mothers to participate actively in infant care during visits. If the mother feels that the nurses trust her to care for the infant, her confidence may increase. This may encourage her efforts to go through rehabilitation to regain custody of her newborn.

The mother's participation also provides a chance to assess her infant care skills and areas in which further discussion of the newborn's needs will be helpful. In addition, it gives the nurse an opportunity to demonstrate parenting skills. Many mothers who use drugs have not had good parenting role models and do not know how to care for an infant. Frequent positive feedback about the mother's participation is also important.

Provide the mother the same teaching given to all new parents, as well as special techniques necessary to meet the needs of drug-exposed infants. Teach her about her newborn's unique characteristics and help her assume more of the infant's care as she demonstrates readiness.

Teach the mother that infants are easily overstimulated. These infants cannot tolerate simultaneous visual and tactile stimulation. Signs of overstimulation in drug-exposed infants have some similarities with those for the preterm infant. In addition, some infants cannot tolerate more than brief periods of interaction. They may not make

eye contact, or they may avert their eyes after 30 to 60 seconds of social interaction. Cuddling and soothing to console the infant may not elicit the same response in these infants as in other infants. Teach the mother that the infant responds poorly to everyone so that she does not think that only she is being rejected.

Parents of a drug-exposed infant may experience feelings of rejection, frustration, and even hostility when the infant stiffens while being held, cries after being fed, or looks away. Explain that drug-exposed infants are easily stressed because of the decreased stability of their CNS. Emphasize that the infant needs gentle handling. Also explain that crying indicates a need, not a spoiled infant.

Show the mother comfort measures that work best for her infant. These infants are often comforted when they are snugly swaddled in a flexed position with their hands brought to midline. Holding the swaddled infant close to the mother's body may increase comfort. Some infants are consoled with slow, rhythmic, vertical or horizontal rocking movements. Placing them in a front pack as the nurse or mother moves around may also be comforting.

When the infant is nearing discharge explain that sleep problems will probably continue at home. The infant should sleep in a quiet room because normal household noises will disturb the drug-exposed infant more than other infants (Weiner & Finnegan, 2011).

Cocaine, amphetamines, heroin, and other drugs pass into breast milk. Trying to breastfeed an infant with poorly developed feeding skills may be too much stress for the mother who is trying to recover from addiction. Therefore, mothers who are likely to continue drug use after delivery should be discouraged from breastfeeding.

Women taking methadone may be allowed to breastfeed if they are not taking other drugs that are contraindicated (Altshul, 2012; Pitts, 2010). Methadone and buprenorphine have been found to be at very low levels in breast milk (Hudak et al., 2012). Breastfeeding assistance should be given to women who are interested because of the advantages of breast milk over formula and because it may help the mother with bonding. The mother should begin breastfeeding within an hour of birth, and a lactation consultant should be involved (Hilton, 2012).

Provide information and referral to any special programs available to help parents learn special stimulation techniques appropriate for drug-exposed infants. Some withdrawal signs may continue for 4 to 6 months, and the mother needs to know how to cope with them (Weiner & Finnegan, 2011). If the mother is unable or not allowed to care for the newborn after discharge, the same interventions can be used to help the person who will take over care of the infant.

PARENTS WANT TO KNOW

Measures to Prevent Frantic Crying in a Drug-Exposed Infant

Swaddle the infant with the hands brought to the midline.
Provide a pacifier.
Slowly and smoothly rock in a vertical or horizontal motion with the infant held upright.
Coo softly and gently.
Place the infant over your shoulder, and gently stroke the back.
Keep the room fairly dark because some infants are particularly sensitive to light.
Avoid simultaneous auditory and visual stimuli.
Curtail stimulation if the infant shows signs of stress (yawning, sneezing, jerky movements, or spitting up).

- How can the nurse deal with the inability to rest in infants with prenatal exposure to drugs?
- How can the nurse promote bonding when there has been prenatal drug abuse?

PHENYLKETONURIA

Phenylketonuria (PKU) is a genetic disorder that causes CNS injury from toxic levels of the amino acid phenylalanine in blood. The incidence is 1 in 15,000 (Trahms & Ogata, 2012). Severe cognitive impairment occurs in untreated infants and children. In the United States, all newborns are screened for this condition before or shortly after discharge from the birth facility. Positive screening tests are followed by other testing to confirm the diagnosis.

Causes

PKU is caused by a deficiency of the liver enzyme phenylalanine hydroxylase, which is necessary to convert phenylalanine to tyrosine for use. It is an autosomal recessive disorder (see Chapter 5).

Manifestations

Signs of untreated disease may begin with digestive problems and vomiting and later progress to seizures, musty odor of the urine, and severe cognitive impairment. Older children have eczema, hypertonia, hyperactive behavior, cognitive impairment, and hypopigmentation of the hair, skin, and irises.

Therapeutic Management

Treatment is a low-phenylalanine diet that should start no later than 3 weeks after birth and continue throughout life to avoid irreversible neurologic damage (Braverman & Hamosh, 2009). Women who are not following the diet closely need to return to it before they conceive and throughout pregnancy to prevent abnormalities in the fetus. These infants receive a special formula low in phenylalanine, and low-protein foods are introduced when solids are started. Small amounts of phenylalanine are allowed because it is a necessary amino acid. Early and continued treatment is necessary to prevent or minimize cognitive impairment.

Nursing Considerations

The nurse should be sure that all newborns are screened for PKU at the appropriate time in the birth facility. Screening performed before 24 hours of age should be repeated because the infant may not yet have consumed enough protein for the test to be accurate.

The nurse assists parents in regulating the diet to meet the infant's changing phenylalanine needs. Parents may need to talk about their feelings regarding the difficulty of following the diet for their children. They can be reassured that good control helps avoid long-term neurologic problems. However, mild decrease in intelligence and behavioral difficulties may occur (Zinn, 2011).

CONGENITAL ANOMALIES

Approximately 2.5% or 1 in 40 neonates have a malformation at birth (Wynshaw-Boris & Biesecker, 2011). Congenital anomalies are the leading cause of deaths in the first year of life. Some infants have more than one anomaly, which may be part of a syndrome or result from unrelated causes. Although congenital anomalies generally are treated in the pediatric setting, they usually are identified soon after birth. Common congenital anomalies are noted in Box 30-2. Congenital

🎯 NURSING CARE PLAN

The Drug-Exposed Infant

Beth was born at 39 weeks of gestation to Gloria, who was in a methadone maintenance program. However, during labor, Gloria admitted using heroin several times in the last weeks of her pregnancy.

ASSESSMENT: Beth weighs 4 lb, 15 oz (2240 g) and is small for gestational age. She is jittery, becomes agitated easily, and has a poor suck and swallow. Beth sleeps less than an hour after feedings. When she awakens, her high-pitched cry and agitation begin immediately. Her activity elicits the Moro reflex, which leads to more agitation. She is irritable and does not respond to caregiving activities as quickly as other infants.

NURSING DIAGNOSIS: Disturbed Sleep Pattern related to agitation from own activity and irritability.

EXPECTED OUTCOMES: The infant will:

1. Sleep for periods of 2 hours or more after feedings within 3 days.
2. Decrease crying by at least 1 hour a day within the 1st week.

INTERVENTIONS AND RATIONALES

1. Place Beth's crib in the quietest corner of the nursery. Place a sign nearby to remind others of the need for quiet in that area. *Drug-exposed infants are easily overstimulated by noise and activity.*
2. Keep lights turned down as much as possible. Partially cover the crib with a blanket to decrease light. *Lowered lighting provides a more restful environment.*
3. Keep Beth swaddled in a flexed position during sleep and feedings. *The drug-exposed infant's own movements can cause startling, awakening, and agitation.*
4. Use a pacifier, and position her hands near her mouth when she is awake. *Nonnutritive sucking may have a calming effect on the infant. Positioning the hands near the mouth allows the infant to self-comfort by sucking.*
5. Organize nursing care so that Beth is not disturbed unnecessarily, especially when sleeping. *Drug-exposed infants may have difficulty going back to sleep if awakened.*
6. Stop all activity if she shows signs of increased stress. *Providing a time-out in response to stress allows the infant to rest.*

EVALUATION: The infant gradually lengthens her sleep periods to 2 hours and decreases crying episodes within the 1st week.

ASSESSMENT: Gloria visits Beth sporadically. She seems hesitant when she comes into the nursery and afraid to touch or care for Beth. She asks, "Why does she cry so much?" When the nurse helps her hold Beth, Gloria states, "I don't think she likes me."

NURSING DIAGNOSIS: Impaired Parenting related to lack of understanding of the infant's characteristics and how to relate to an irritable infant.

EXPECTED OUTCOMES: Within 1 week Gloria will:

1. Visit at least every other day.
2. Participate in Beth's care by holding and feeding her.
3. Make positive statements about her daughter.

INTERVENTIONS AND RATIONALES

1. Show acceptance of Gloria when she comes to visit Beth. Greet her, and provide her with an update on Beth's progress. *A mother is more likely to*

visit her infant if she feels accepted by staff. The more she visits, the more she is likely to learn about parenting her infant.

2. Assist Gloria to hold and feed Beth. Explain nursing actions such as placing the crib in a secluded corner and covering the top. Offer help with kangaroo care. *Participating in care of the infant helps the mother get to know her infant and gain comfort in providing infant care. Kangaroo care can help the mother feel closer to her infant.*
3. Demonstrate and explain comfort measures such as swaddling. Show her how to place positioning devices around the infant to provide a feeling of security and help promote sleep. *When the mother learns ways to comfort her infant, the positive response from the infant may increase bonding.*
4. Discuss the behavioral characteristics of infants who are drug exposed. Explain that Beth's stiff body posture, failure to "mold" to the mother's body, and excessive activity are normal at this time for her. Point out signs such as gaze aversion and increase in irritability that show Beth is overstimulated. *Understanding that the infant's behavior is part of the infant's problem and is not caused by the mother's handling of her is reassuring to the mother.*
5. Model ways of interacting with Beth and calming her when she becomes agitated. Point out signs that Beth is ready to interact. Suggest only one stimulus at a time, such as talking softly without rocking. *The mother learns appropriate interaction when she sees it performed by the nurse. Infants may need short time-outs before they are ready for more stimulation. Decreasing multiple stimuli may be effective in calming the infant.*
6. Point out positive points about Beth—for example, her long eyelashes or delicate fingers. Discuss signs that show that Beth is making progress. *Gloria needs help to focus on positive aspects of the infant as well as the problems.*
7. Explain the routine care of a newborn. Spread teaching out over Gloria's visits. *The mother needs to learn the usual care of any newborn as well as the infant's special needs.*
8. Give praise and encouragement frequently as Gloria works with Beth. *The mother needs positive reinforcement and help to feel that she is capable of mothering her infant.*
9. Use therapeutic communication techniques to help Gloria discuss her feelings as she cares for Beth. *Mothers often find it frustrating to care for the drug-exposed infant. Helping them vent their feelings may increase their ability to cope with the infant's needs.*
10. Discuss sources of support from family members or friends. Refer Gloria to support groups in the community. *Ongoing support is necessary for the woman with addiction problems. Support for the mother will help her care more effectively for her infant.*
11. If Gloria will have custody of Beth, help her make plans for discharge. Discuss ongoing problems and concerns such as continued withdrawal signs and sudden infant death syndrome (SIDS). Explain that some withdrawal behaviors may last as long as 6 months. *Preparation for discharge must be made well in advance. Infants will have ongoing problems that will continue in the home setting. Infants exposed to heroin have an increased incidence of SIDS.*

EVALUATION: Gloria begins to visit more often, coming three or four times a week. She participates in care, begins to talk about her "pretty little girl," and discusses her plans for taking Beth home with her.

BOX 30-2 COMMON CONGENITAL ANOMALIES

Gastrointestinal Tract**Cleft Lip and Palate**

These are among the most common congenital anomalies. They occur together or separately on one or both sides.

Lip: minor notching of the lip or complete separation through the lip and into floor of nose.

Palate: only the soft palate or division of the entire hard and soft palate. Both genetic and environmental factors are included in the causes.

**Assessment**

Severe clefts are obvious at birth.

Palpate the hard and soft palate of all neonates during initial assessment.

Therapeutic Management

Lip surgery is usually performed by 3 months to enhance appearance and parental bonding. Further surgery may be needed at 4 to 5 years.

Palate surgery is usually done by 1 year to minimize speech problems.

Long-term follow-up is necessary for orthodontia, speech therapy, and treatment of possible hearing problems.

Nursing Considerations

The degree of the cleft determines the approach to feeding.

Experiment to find methods that work best for individual infants. Try:

1. Breastfeeding (soft breast tissue fills in a small cleft of the lip or palate)
2. Nipples with enlarged hole
3. Compressible bottles
4. Special longer nipples
5. Special assistive devices

Feed the infant in the upright position because milk enters nasal passages through the palate, causing an increased tendency to aspirate.

Feed slowly with frequent stops to burp because infants tend to swallow excessive air.

Wash away milk curds with water after feeding.

Help the parents deal with their disappointment over the infant with an obvious anomaly. Show them before and after pictures of plastic surgery.

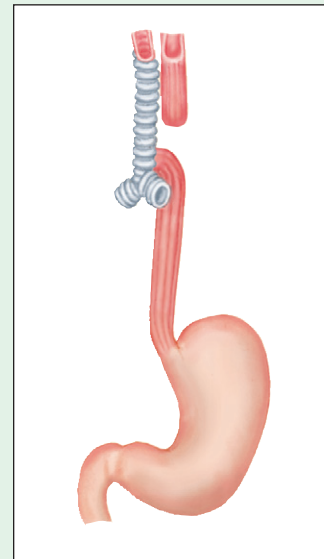

Reinforce the physician's explanation of plans for surgery.

Teach parents feeding techniques. Let them observe at first, then take over gradually.

Prevent infections. Infants are especially susceptible to respiratory tract and ear infections, which can delay surgery. Ear infections may lead to hearing loss. Emphasize the need for long-term follow-up. Refer to agencies that help with the expense of long-term care and to support groups for help and emotional support from other parents.

Esophageal Atresia and Tracheoesophageal Fistula

In **esophageal atresia** (EA) the esophagus is most commonly divided into two unconnected segments (atresia) with a blind pouch at the proximal end. If the distal end is connected to the trachea, it causes **tracheoesophageal fistula** (TEF). The cause is a failure of normal development during the fourth week of pregnancy.

**Assessment**

Watch for EA when polyhydramnios occurs because the excessive fluid may be caused by fetal inability to swallow amniotic fluid.

Observe for other defects that may also occur.

Signs vary by the type of defect.

Suspect EA in infants with excessive frothy drooling and needing suction more often than usual, when regurgitation occurs from secretions that pool in a blind pouch, and when a catheter will not pass into the stomach.

If a fistula connects the distal esophagus and the trachea, the stomach becomes distended with air from the trachea. Gastric secretions may be aspirated into the lungs, causing a severe inflammatory reaction.

Therapeutic Management

Diagnosis is confirmed by symptoms and radiography.

Esophageal suctioning should be used for the upper pouch, and a gastrostomy tube is placed.

Surgery involves ligation of the fistula and anastomosis of the esophageal segments. If the separation is large, surgery may be done in stages to allow growth.

Long-term follow-up is needed for esophageal reflux and dilation of strictures that may form at the surgical site.

Nursing Considerations

Observe all infants carefully during the first feeding for respiratory difficulty or other signs.

Prevent aspiration by maintaining the infant in a semi-upright position to prevent reflux of gastric fluids.

Continued

BOX 30-2 COMMON CONGENITAL ANOMALIES—cont'd

Maintain suction equipment.

Care after surgery involves low-pressure ventilation, chest tubes, parenteral nutrition, and gastrostomy feedings.

Omphalocele and Gastroschisis

Both of these anomalies are caused by congenital defects in the abdominal wall. In **omphalocele**, the intestines protrude into the base of the umbilical cord. Other anomalies often occur with omphalocele.

Gastroschisis is a defect to the side of the abdomen, through which the intestines protrude. They are not covered by peritoneum or skin and float freely in the amniotic fluid.

Assessment

Diagnosis is made by prenatal measurement of elevated alpha-fetoprotein level and by prenatal ultrasound and is obvious at birth.

Therapeutic Management

A gastric tube is placed to decrease air in the stomach. Gastric suction, parenteral nutrition, and antibiotics are necessary.

Surgery is performed as soon as the infant is stable. A Silastic silo (pouch) may be used to replace the intestines gradually over a period of days to prevent pressure on the other organs. The abdomen is closed when the contents have been replaced in the abdominal cavity.

Nursing Considerations

Place the infant's torso into a sterile plastic bag or cover the intestines with Silastic or warm sterile saline dressings wrapped with plastic immediately after birth to reduce heat and water loss.

Observe for respiratory distress from increased intraabdominal pressure.

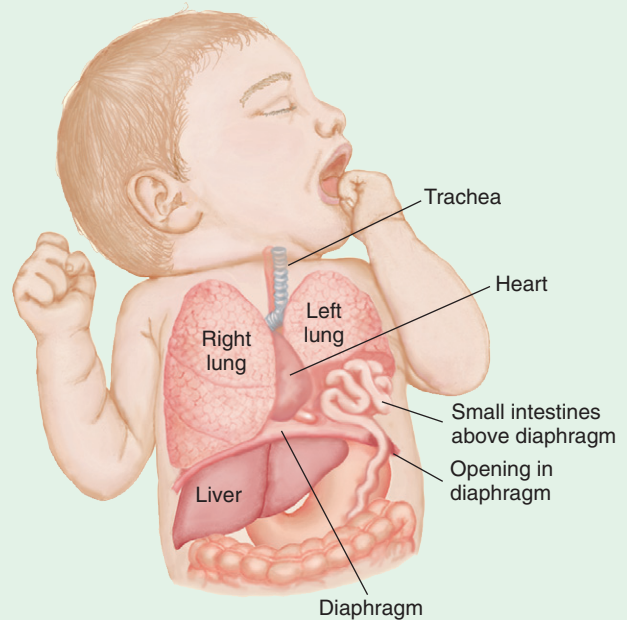

Prevent infection and trauma.

Position to avoid pressure on the intestines.

Diaphragmatic Hernia

The diaphragm fails to fuse during gestation. A large or small part of the abdominal contents moves into the chest cavity, usually on the left side.

If the herniation is large enough, the lungs may fail to develop (hypoplastic lungs). When gas fills the bowel, further pressure on the heart and lungs results.

Assessment

Mild to severe respiratory distress may occur at birth, with breath sounds diminished or absent over the affected area, and barrel chest. The heartbeat may be displaced to the right. Bowel sounds are heard in the chest.

The abdomen may be scaphoid (concave).

The condition may be diagnosed prenatally by ultrasound or by radiography after birth.

Therapeutic Management

Fetal surgery may be performed.

An endotracheal tube is placed for mechanical ventilation and a gastric tube for decompression of the stomach.

Surgery to replace the intestines and repair the defect is performed when the infant is stable.

Extracorporeal membrane oxygenation (ECMO) or inhaled nitric oxide may be used.

Nursing Considerations

Position the infant on the affected side to allow the unaffected lung to expand.

Elevate the head to decrease pressure on the heart and lungs. Assist with ventilation, and monitor respiratory status.

Continue to monitor respiratory status after surgery to determine whether lung function will be adequate.

Central Nervous System

Neural Tube Defects

Folic acid supplements in pregnancy help prevent neural tube defects, especially if they are taken before conception and in early pregnancy.

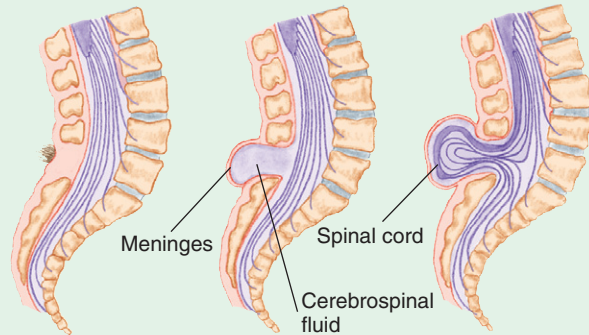

Spina bifida is failure of the vertebral arch to close. *Spina bifida occulta* is failure of the vertebra to close, usually without other anomalies. It is seen by a dimple on the back, which may have a tuft of hair over it.

BOX 30-2 COMMON CONGENITAL ANOMALIES—cont'd

Meningocele is protrusion of meninges and spinal fluid through the spina bifida, covered by skin or a thin membrane. Because the spinal cord is not involved, paralysis does not occur.

Myelomeningocele is protrusion of a membrane-covered sac through the spina bifida. The sac contains meninges, nerve roots, the spinal cord, and spinal fluid. The degree of paralysis depends on the location of the defect. The infant may also have hydrocephalus, or it may develop after surgery.

Spina bifida occulta Meningocele Myelomeningocele

**Assessment**

Prenatal diagnosis by elevated alpha-fetoprotein level or ultrasound.
Note the position and covering of the defect at birth.
Observe movement below the defect to determine the degree of paralysis.
Examine for a relaxed anus and dribbling of stool and urine.
Check for other anomalies.

Therapeutic Management

Fetal surgery may be performed.
Surgery is performed for meningocele and myelomeningocele as soon as possible to prevent infection.
A shunt is placed to divert cerebrospinal fluid if hydrocephalus develops.
Antibiotics are given to prevent infection.
Long-term follow-up is necessary, with physical therapy and other care as needed.

Nursing Considerations

Place the infant's torso in a sterile plastic bag or cover the defect with a sterile saline dressing and plastic to prevent drying.
Handle the infant carefully, and position prone or to the side to prevent trauma to the sac.

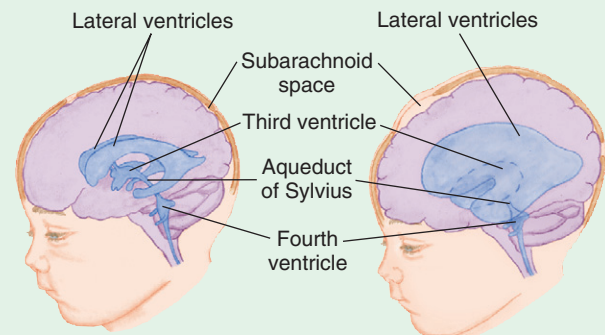

Observe for signs of infection. Keep free of contamination from urine and feces. Inspect the sac for intactness before surgery.

Every shift, check for increasing head circumference, bulging fontanel, separation of sutures, intermittent apnea, and other signs of increased intracranial pressure to identify early hydrocephalus.

The mother should take increased folic acid before and during future pregnancies to reduce the risk of a recurrence.

Congenital Hydrocephalus

This is a problem with absorption or obstruction to the flow of cerebrospinal fluid in the ventricles of the brain, causing compression of the brain and enlargement of the head.

**Assessment**

The fontanel is full or bulging, and sutures may be separated.
The head is enlarged, especially in the frontal area.
Irritability and poor feeding occur.
The setting-sun sign is apparent (sclera visible above the pupils of the eyes).

Therapeutic Management

Surgery, most often with a ventriculoperitoneal shunt to drain fluid into the peritoneal cavity. Will need revision as the child grows.

Nursing Considerations

Measure head circumference daily.
Prevent pressure areas.
Observe for signs of infection and intracranial pressure.
Teach parents how to care for the shunt and to observe for signs of increased intracranial pressure.

cardiac conditions are discussed in this section. (See a pediatric nursing textbook for more detailed information.)

CONGENITAL CARDIAC DEFECTS

Approximately 0.8% of newborns have congenital heart defects. The defects are discovered by 1 week of age in 40% to 50% of infants and by 1 month of age in 50% to 60% of infants. Congenital heart defects are the leading cause of death from congenital anomalies (Bernstein, 2011). Genetics, teratogens, maternal diabetes, and rubella are known to be possible factors.

Classification of Cardiac Defects

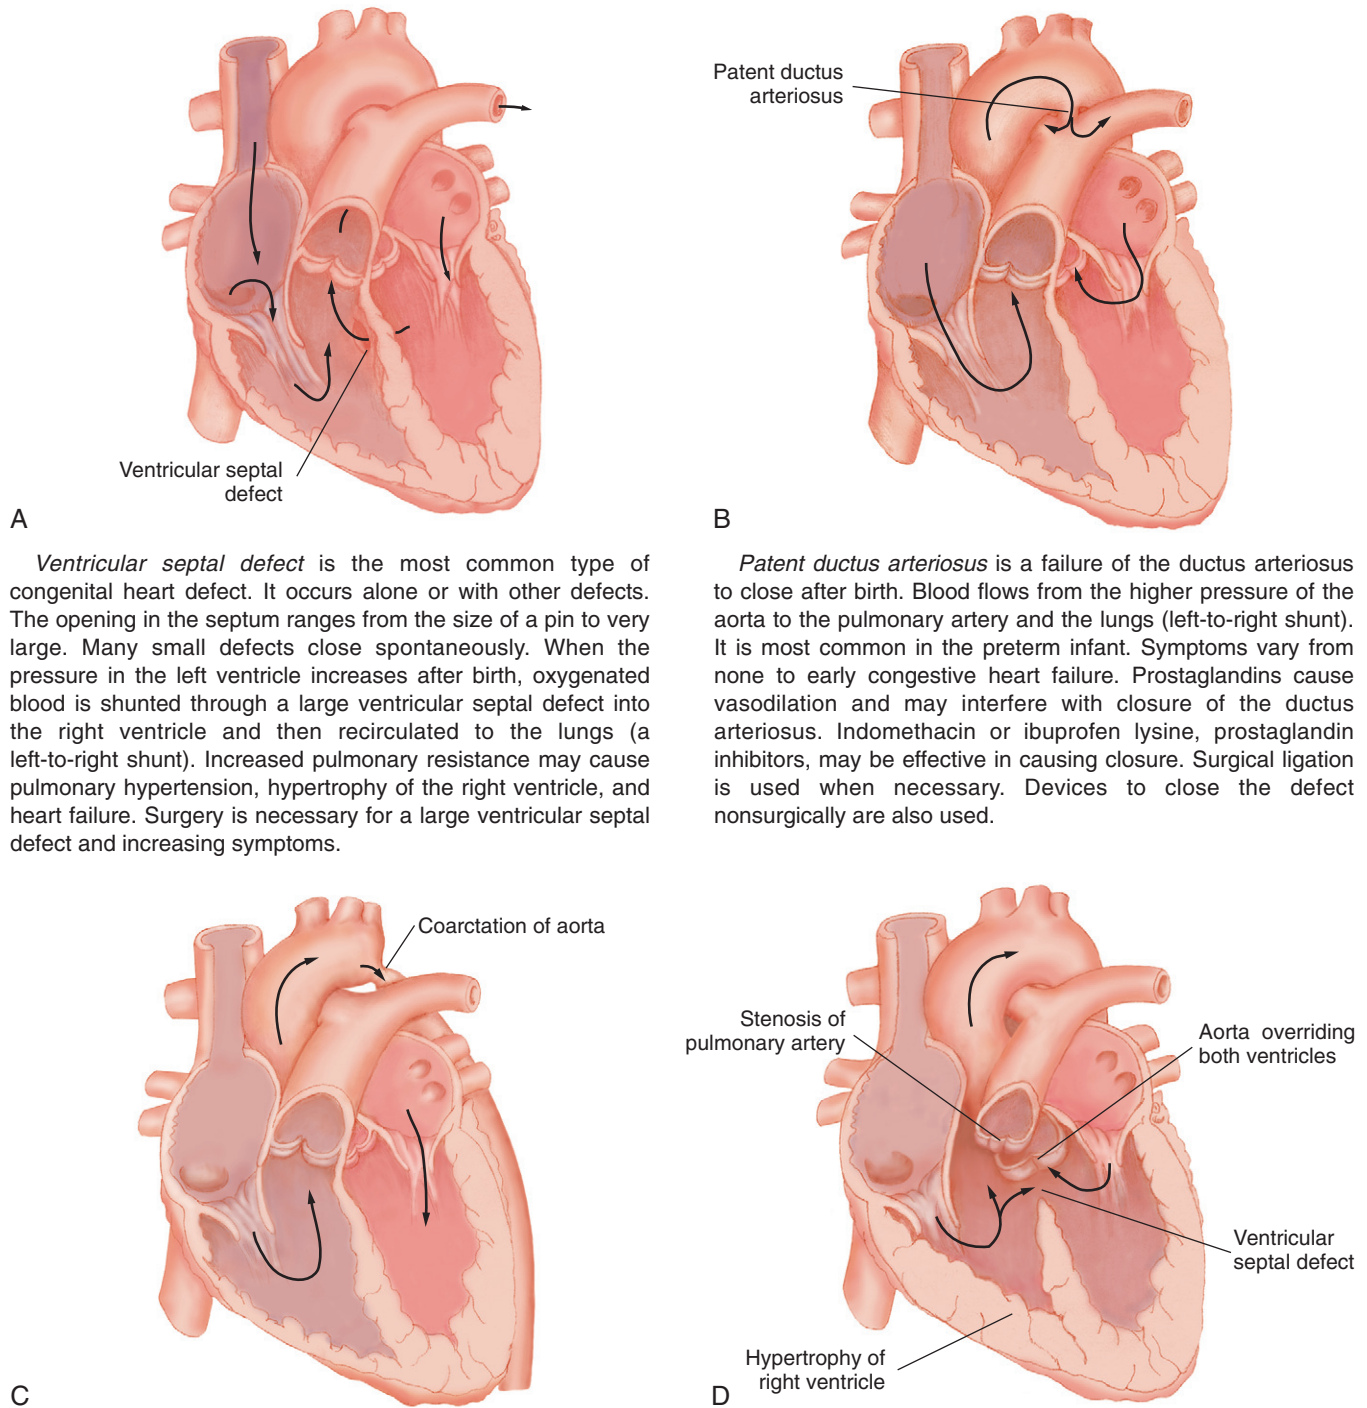

Cardiac defects are generally categorized according to whether cyanosis results from the defect and by the pattern of blood flow. Some of the most common defects are illustrated in Figure 30-4.

Acyanotic Defects

In acyanotic conditions, an obstruction of blood flow from the ventricles or a defect that causes increased flow of blood to the lungs occurs. Both increase the work of the heart. In addition, congestion in the lungs may eventually cause increased resistance of the pulmonary vessels and pulmonary hypertension. Infants are prone to respiratory tract infections because of the pulmonary congestion and increased work of the heart and lungs. Growth is slowed, and the infant fatigues easily. The heart may fail from overwork. Patent ductus arteriosus is an example of this group.

Cyanotic Defects

In cyanotic defects, blood flow to the lungs decreases, or venous blood and oxygenated blood are mixed in the systemic circulation, or both, decreasing the oxygen carried to the tissues and resulting in cyanosis. When venous blood from the right side of the heart flows through an

Ventricular septal defect is the most common type of congenital heart defect. It occurs alone or with other defects. The opening in the septum ranges from the size of a pin to very large. Many small defects close spontaneously. When the pressure in the left ventricle increases after birth, oxygenated blood is shunted through a large ventricular septal defect into the right ventricle and then recirculated to the lungs (a left-to-right shunt). Increased pulmonary resistance may cause pulmonary hypertension, hypertrophy of the right ventricle, and heart failure. Surgery is necessary for a large ventricular septal defect and increasing symptoms.

Patent ductus arteriosus is a failure of the ductus arteriosus to close after birth. Blood flows from the higher pressure of the aorta to the pulmonary artery and the lungs (left-to-right shunt). It is most common in the preterm infant. Symptoms vary from none to early congestive heart failure. Prostaglandins cause vasodilation and may interfere with closure of the ductus arteriosus. Indomethacin or ibuprofen lysine, prostaglandin inhibitors, may be effective in causing closure. Surgical ligation is used when necessary. Devices to close the defect nonsurgically are also used.

In *coarctation of the aorta*, blood flow is impeded through a constricted area of the aorta near the ductus arteriosus, increasing pressure behind the defect. The blood pressure is higher in the upper extremities than in the lower extremities. Carotid, brachial, and radial pulses are bounding, but pulses in the legs are weak or absent. The increased pressure in the left ventricle causes hypertrophy from the added workload. Congestive heart failure may result.

Tetralogy of Fallot has four characteristics: a ventricular septal defect, aorta positioned over the ventricular defect, pulmonary stenosis, and hypertrophy of the right ventricle. Cyanosis occurs if venous blood from the right ventricle flows through the septal defect and into the overriding aorta and blood flow to the lungs is diminished because of the narrowed pulmonary valve. The amount of right-to-left shunting and cyanosis varies according to the degree and position of each defect.

FIG 30-4 Common Congenital Heart Defects. **A**, Ventricular septal defect. **B**, Patent ductus arteriosus. **C**, Coarctation of the aorta. **D**, Tetralogy of Fallot.

E

In *transposition of the great arteries*, the positions of the aorta and the pulmonary artery are reversed. The aorta carries venous blood from the right ventricle back to the general circulation. The pulmonary artery returns oxygenated blood from the left ventricle to the lungs. Unless there is another source for mixing oxygenated and venous blood, the infant cannot survive. A septal defect, open foramen ovale, or patent ductus arteriosus may be present. Prostaglandins may be given to keep the ductus open, and surgical correction is performed.

FIG 30-4, cont'd E, Transposition of the great arteries.

abnormal opening to the left side of the heart, it is called a *right-to-left shunt*. Although the heart and lungs work harder, adequate oxygenation may be impossible, resulting in hypoxia of the major organs. Infants usually have serious problems from birth. They grow poorly, have frequent infections, and are easily fatigued. Heart failure may be an early complication. Transposition of the great vessels is an example of a cyanotic heart defect.

The presence of cyanosis depends on the severity and combination of defects and the child's ability to compensate. Some infants with cyanotic heart disease may be pink, and some with acyanotic heart defects may develop cyanosis. Because of this potential change in classification, further classification by blood flow is helpful.

Left-to-Right Shunting Defects

These heart defects allow blood to flow from the higher pressure of the left side of the heart to the right side or from the aorta to the pulmonary artery. This increases blood flow to the lungs and is called a *left-to-right shunt*. It causes some oxygenated blood to be sent to the lungs instead of to the rest of the body, increasing the work of the right side of the heart and the lungs. Congestive heart failure and pulmonary hypertension may result. Examples are ventricular septal defects and patent foramen ovale.

Defects with Obstruction of Blood Outflow

In defects with obstruction of blood flow, a decrease in the blood flow through a vessel or valve occurs because of stenosis (narrowing). This adds to the work of the heart, causes hypertrophy of the heart or major blood vessels, and may lead to heart failure. Coarctation of the aorta and stenosis of the pulmonary or aortic valves fit into this classification.

Defects with Decreased Pulmonary Blood Flow

An impairment in the flow of blood from the right side of the heart to the lungs, combined with abnormal openings between pulmonary and systemic circulations, occurs in defects with decreased pulmonary blood flow. Systemic hypoxemia causes cyanosis. An example is tetralogy of Fallot.

Cyanotic Defects with Increased Pulmonary Blood Flow

These defects allow survival only if a mixing of venous and oxygenated blood in the heart occurs. There is increased blood flow to the lungs and mixing of venous and oxygenated blood in the systemic circulation. Transposition of the great vessels is an example of this type of defect.

Manifestations

Congenital heart defects may present obvious signs at birth or may not become apparent until later, when changes from fetal to neonatal circulation are completed. Some infants have no difficulty for months or years, but others experience early heart failure. The most common indications of cardiac problems are cyanosis, heart murmurs, tachycardia, and tachypnea.

Cyanosis

Cyanosis is a major sign of cardiac anomaly when it is not a result of respiratory disease. If the cyanosis is caused by mixing of oxygenated and unoxygenated blood, giving oxygen will not improve the infant's color. Cyanosis increases with crying, feeding, or other activity. Pallor, mottling, or a gray color may be present in infants who do not have cyanosis.

Heart Murmurs

Murmurs may sound like clicks, machinery, rumbling, swishing, or other muffled noises. It takes much practice to detect heart murmurs accurately. Although many infants have a temporary murmur until the fetal structures are closed, all abnormal sounds must be referred to the physician.

Tachycardia and Tachypnea

Tachycardia and tachypnea may occur anytime the heart and lungs must work harder to provide sufficient oxygen to the body. Therefore, they are present in both respiratory conditions and cardiac conditions. They increase in congestive heart failure.

Other Signs

Fatigue and tachypnea may interfere with the infant's ability to eat. Infants may feed slowly and take small amounts. They may fall asleep before the feeding is finished because of the effort required for sucking. As a result, weight gain may be slow. Although diaphoresis is uncommon in the newborn, it may appear during feedings in the infant with a heart defect.

CRITICAL TO REMEMBER

Common Signs of Cardiac Anomalies

Cyanosis increasing with crying
 Pallor
 Murmurs
 Tachycardia
 Tachypnea
 Dyspnea
 Choking spells
 Poor intake, falling asleep during feedings
 Diaphoresis

Therapeutic Management

Therapeutic management involves diagnosis of the specific defect and supportive and surgical treatment, as indicated. Various tests such as echocardiograms and cardiac catheterizations confirm the diagnosis. The decision for surgery depends on the status of the infant and whether surgery can be delayed safely. Palliative surgery may be performed to partially correct a defect or make another defect to allow greater amounts of oxygenated blood to get to the systemic circulation.

Oxygen and drugs such as digitalis, diuretics, potassium supplements, and sedatives may be prescribed for the infant. Prostaglandins may be given to prevent the ductus arteriosus from closing in those cases in which keeping it open will increase the flow of oxygenated blood in the infant's body.

Nursing Considerations

Nursing care is focused on assessing for changes in condition and reducing the infant's need for oxygen. The need for rest is especially important, and the infant's response to all activity is assessed. Infants with rapid respirations are at risk for aspiration and may need feeding by gavage. Oxygen may be increased during feedings or other exertion, but only enough oxygen to maintain saturation levels adequately should be used. Frequent rest periods are provided by clustering small amounts of nursing care.

Feedings with increased calories may be used to promote nutrition and weight gain. Accurate intake and output measurement is necessary. Maintaining a neutral thermal environment is important to avoid increasing oxygen need.

Support of the parents and education about the infant's condition and expected treatment are essential. The physician may use drawings to help parents understand the defect and plans for surgery. The nurse verifies the parents' understanding and provides additional teaching, as necessary. The parents are taught techniques for accurate administration of medications because the range between the therapeutic and toxic dosage of the drugs is narrow. Parents may be referred to support groups for families of children with heart anomalies.

SUMMARY CONCEPTS

- Asphyxia before or during birth may cause apnea, acidosis, pulmonary hypertension, and possible death. Neonatal resuscitation must be initiated immediately.
- Nurses must identify conditions that increase the risk of asphyxia, begin resuscitation promptly, and assist other members of the team during treatment. Continued follow-up of the infant and parental support are important.
- In transient tachypnea of the newborn, respiratory difficulty in infants is caused by failure of fetal lung fluid to be absorbed completely. It usually resolves spontaneously with supportive care.
- In meconium aspiration syndrome, meconium in amniotic fluid enters the lungs before birth during gasping movements or is drawn in during the first breaths after birth, causing obstruction, air trapping, and inflammation.
- The nurse's role in meconium aspiration is to notify caregivers when meconium is discovered in amniotic fluid, prepare equipment, assist with intubation if necessary, and observe for further respiratory difficulty, infection, and other problems.
- Persistent pulmonary hypertension is a condition in which pulmonary vascular resistance remains high after birth and right-to-left shunting of blood occurs, causing severe respiratory difficulty.
- Nonphysiologic jaundice appears in the first 24 hours of life. Bilirubin levels rise faster and to higher levels than in physiologic jaundice. If untreated it may result in injury to the brain.
- The nurse's role in phototherapy is to decrease situations such as cold stress or hypoglycemia that might further elevate bilirubin levels, ensure that lights are used properly, protect the eyes, observe for excessive fluid loss or skin impairment, ensure adequate oral intake, and teach parents.
- Infection can be transmitted to the neonate from the mother during pregnancy or birth or from the mother, family members, visitors, or agency staff after birth.
- Infection in neonates is a problem because their immune system is immature, infection spreads easily, and the blood-brain barrier is less effective.
- The infant of a diabetic mother (IDM) may have congenital anomalies, may be large or small for gestational age, and may suffer from respiratory distress syndrome, hypoglycemia, hypocalcemia, and polycythemia.
- Nursing responsibilities in caring for the IDM include early identification and follow-up of complications, monitoring of blood glucose levels, ensuring early and adequate feedings, and support of the parents.

Continued

SUMMARY CONCEPTS—cont'd

- Infants with polycythemia have increased viscosity of blood that may cause thromboemboli, stroke, hyperbilirubinemia, and other complications.
- Infants with prenatal exposure to drugs may have behavioral and feeding abnormalities. They may have difficulty relating to others and fail to gain weight.
- Nursing care for infants with neonatal abstinence syndrome includes decreasing stimuli from lights, noise, and handling; increasing feeding abilities; and fostering the mother's attachment to and ability to care for her infant.
- Infants with phenylketonuria must be on a low phenylalanine diet to prevent severe intellectual disability.
- Congenital heart defects include left-to-right shunting defects, defects with obstruction of blood outflow, defects with decreased pulmonary blood flow, and cyanotic defects with increased pulmonary blood flow.

Family Planning

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the role of the nurse in helping couples choose contraceptive methods.
2. Explain why informed consent is important for contraception.
3. Compare and contrast contraceptive needs of adolescent and perimenopausal women.
4. Explain the mechanism of action, advantages, disadvantages, side effects, and teaching needed for methods of family planning.
5. Discuss the nurse's role in contraceptive counseling and education.

Family planning involves choosing if and when to have children. It includes **contraception**—the prevention of pregnancy—as well as methods to achieve pregnancy. It should be part of a reproductive life plan that determines goals about having children and how to achieve those goals (Sanders, 2009). Chapter 32 describes methods used by couples having difficulty attaining pregnancy. This chapter focuses on techniques used to avoid pregnancy.

If both partners are fertile, approximately 90% of women will conceive within 1 year if they do not use contraception (Cunningham, Leveno, Bloom et al., 2010). Therefore, those who wish to control the timing of pregnancies cannot leave contraception to chance.

Approximately 43 million women in the United States are fertile, sexually active, and do not want a pregnancy at this time. Of those women, 89% are practicing contraception (Alan Guttmacher Institute [AGI], 2012a). However, they may not be using contraception consistently. A national survey of unmarried adults age 18 to 29 years found that although 86% of the men and 88% of the women did not want a pregnancy at the present time, 19% did not use contraception at all and 24% used contraception inconsistently (Kaye, Suellentrop, & Sloup, 2009).

Unintended pregnancies are those that are unwanted or mistimed, occurring in women who want to become pregnant at some time in the future but not at the time their pregnancies occur. These pregnancies may result in economic hardship, health problems, interference

with educational or career plans, and other disruptions in the lives of women and their families. Pregnancies that are spaced less than 6 months apart result in a higher risk for maternal mortality and morbidity, preterm birth, and low-birth-weight infants (Reinold, Dalenius, Smith et al., 2009).

In the United States, 3.2 million unintended pregnancies occur each year (AGI, 2012b). A *Healthy People 2020* goal is to increase the number of intended pregnancies to 56% from a baseline of 51% (U.S. Department of Health and Human Services [USDHHS], 2010.)

Because most contraceptive methods available must be practiced by women, they often choose the type of contraception used. During a woman's reproductive lifetime, her needs for contraception change. Most women use a variety of methods before they reach menopause. Because the average woman in the United States bears only two children, she must make contraceptive decisions for more than 30 years. Many of those years occur after she has borne the number of children she would like to have, and the desire to avoid further pregnancies is high.

INFORMATION ABOUT CONTRACEPTION

Common Sources

Women often obtain information about contraception from friends, relatives, television, newspapers, magazines, and the Internet. They

seek answers to practical questions about comfort, partners' responses, and problems encountered. The information they receive, however, may be incomplete or incorrect when their source is not a qualified health care professional.

Women frequently turn to nurses in clinics, physicians' offices, birth settings, and even social settings for accurate information about family planning. Some women are more comfortable asking a nurse, rather than a physician, about contraception, particularly when they are unsure about what technique would be best for them.

Role of the Nurse

The nurse's role in family planning is that of counselor and educator. To fulfill this role, nurses need current, correct information about contraceptive methods and should share this information with women in their practice.

Some women who do not plan to become pregnant have gaps in contraceptive use when there are changes in relationships or when they are planning to change their method. Slightly more than half (52%) of unintended pregnancies occur in women who were not using any contraceptive method in the month they became pregnant. Approximately 43% of unintended pregnancies occur in women who used their contraceptive method incorrectly or inconsistently (AGI, 2012b).

This might occur less often if women had adequate ongoing education about their chosen method. The initial teaching that accompanies selection of the contraceptive technique may be insufficient to meet the woman's needs. Reinforcing teaching and providing an opportunity to ask questions after initial use can help ensure that the woman is using her method correctly. The likelihood of a woman using contraception correctly is increased if she receives counseling directed to her specific needs.

Women are more likely to use contraception if they have received counseling that is directed to their own needs instead of general information about contraception. Therefore, the nurse must provide individualized family planning information to women in every situation in which it would be appropriate. For example, nurses working in maternity settings should discuss family planning with women after birth to provide an opportunity to clarify misinformation and answer questions. Then the woman will be ready to discuss contraception further with her primary caregiver, if necessary.

Nurses must feel comfortable discussing contraception and be sensitive to the woman's concerns and feelings. In discussing family planning, the woman's preferences take precedence. Care must be taken that nurses do not introduce their own biases toward or against specific methods. The nurse's personal experiences and choices regarding contraception are not pertinent. The focus of counseling must be the needs and feelings of the woman and her partner (Figure 31-1).

Counseling about contraception should include:

- Types of contraception available
- Risks and benefits of each
- How to ensure proper use of each method
- What to do if an error is made
- Emergency contraception (EC)
- Backup methods and when they should be used
- What to do if the woman wants to change methods
- Questions and concerns

CONSIDERATIONS WHEN CHOOSING A CONTRACEPTIVE METHOD

The perfect contraceptive method does not exist. Each has advantages and disadvantages (Table 31-1). Women change contraceptive methods

FIG 31-1 Success of contraception is more likely when both the woman and her partner are involved in discussions. The nurse demonstrates filling a foam applicator.

as circumstances in their lives change and in response to dissatisfaction with side effects or other traits of their contraceptive (Table 31-2). Women often try several methods before finding one that is satisfactory. Some women have an interval of using no contraception before beginning a new method, even though they do not wish to become pregnant.

The most popular methods of contraception in the United States are oral contraception, tubal sterilization, male condoms, and vasectomy (AGI, 2011b; Centers for Disease Control and Prevention [CDC], 2012). However, the most popular methods may not be right for every woman. Nurses can help women weigh the factors involved in choosing a family planning method. Careful consideration of all factors can help a woman choose the method that best meets her needs and that she will continue to use.

Safety

The safety of the method is a primary consideration. Medical conditions may make some methods unsafe for certain women. For example, oral contraceptives (OCs) should not be used by women who have had thrombophlebitis or stroke because the hormones in the contraceptives increase the risk for these conditions to recur. The diaphragm and cervical cap are unsafe for women with a history of toxic shock syndrome, a possible complication of these methods (see Chapter 34). However, use of contraceptives is generally safer than pregnancy (Trussell & Guthrie, 2011).

Protection from Sexually Transmitted Diseases

No contraceptive (other than abstinence practiced perfectly) is 100% effective in preventing sexually transmitted diseases (STDs). The risk for exposure to STDs should be discussed when counseling women about contraceptive choices. The male condom is inexpensive and offers the best protection available. It should be used whenever there is a risk that one partner may have an STD, even when another form of contraception is practiced or the woman is pregnant.

Effectiveness

The importance of avoiding pregnancy must be considered when choosing a contraceptive method. A woman may wish to delay pregnancy for a time but may not mind if pregnancy occurs earlier. Other women may be extremely upset about an accidental pregnancy because it would affect their health or education or have a major impact on their financial stability.

TABLE 31-1 ADVANTAGES AND DISADVANTAGES OF THE MOST COMMON CONTRACEPTIVE METHODS

METHOD	ADVANTAGES	DISADVANTAGES
Sterilization	<ul style="list-style-type: none"> Ends concern about contraception. Tubal sterilization performed during or right after childbirth or between pregnancies. Vasectomy performed in physician's office with local anesthesia. Low long-term cost. 	<ul style="list-style-type: none"> No protection against STDs.* Reversal is difficult, expensive, and may be unsuccessful. Potential complications as in any surgery. Vasectomy requires another contraceptive method until semen is free of sperm. Expensive initially.
Intrauterine device or intrauterine system	<ul style="list-style-type: none"> Unrelated to coitus. In place at all times. Low long-term cost. Effective for 5 to 10 years. Decreases dysmenorrhea and menstrual blood loss. Some women become amenorrheic. Copper IUD may also be used for EC. 	<ul style="list-style-type: none"> No protection against STDs. High initial cost. Can be expelled without woman's knowledge; must check for threads. Potential side effects or complications: menorrhagia, infection near time of insertion, ectopic pregnancy, spontaneous abortion if pregnancy occurs, perforation.
Progestin implant	<ul style="list-style-type: none"> Unrelated to coitus. Provides 3-year protection. Safe during lactation. Body weight has no effect. 	<ul style="list-style-type: none"> No protection against STDs. Major side effect is irregular bleeding.
Progestin injections (Depo-Provera)	<ul style="list-style-type: none"> Unrelated to coitus. Avoids need for daily use. May cause amenorrhea with continued use. Requires use only every 12 weeks. 	<ul style="list-style-type: none"> No protection against STDs. Must remember to repeat every 12 weeks. Causes temporary decrease in bone density. Effect on peak bone mass and osteoporosis unknown. Side effects similar to those of other progestin contraceptives.
Oral contraceptives	<ul style="list-style-type: none"> Taken at a time unrelated to coitus. See Table 31-4. 	<ul style="list-style-type: none"> No protection against STDs. Must be taken daily at or near same time. May cause side effects and complications. See Table 31-4.
Emergency contraception	<ul style="list-style-type: none"> Helps prevent pregnancy after unprotected coitus. Some available without prescription 	<ul style="list-style-type: none"> No protection against STDs. Must be taken within 120 hours of unprotected intercourse. May cause nausea.
Transdermal contraceptive patch	<ul style="list-style-type: none"> Unrelated to coitus. Requires only weekly application. Regulates menstrual cycles. 	<ul style="list-style-type: none"> No protection against STDs. Must apply on the right day. Less effective for women over 198 lb (90 kg). May cause skin irritation. Other side effects similar to those of OCs. Higher risk of clot formation.
Vaginal contraceptive ring	<ul style="list-style-type: none"> Unrelated to coitus. In place for 3 weeks at a time. No fitting required. 	<ul style="list-style-type: none"> No protection against STDs. Must remember when to remove and when to insert. Side effects include headache, expulsion, vaginitis, vaginal discomfort or discharge, and others similar to those of OCs.
Barrier		
All methods	<ul style="list-style-type: none"> Avoid use of systemic hormones. Offer some protection against STDs. 	<ul style="list-style-type: none"> Most coitus-related (must be used just before coitus). May interfere with sensation. Contraindicated for allergies to components of spermicide or latex.
Chemical (spermicide)	<ul style="list-style-type: none"> Quick and easy. No prescription needed. Inexpensive per single use. Provides lubrication. 	<ul style="list-style-type: none"> Films and suppositories must melt to be effective. Effective time less than 1 hour. No douching for 6 hours. May be messy. May cause irritation. New application needed for repeated intercourse.
Condom	<ul style="list-style-type: none"> Quick and easy. No prescription needed. Best protection available for STDs. Low cost per single use. Can be carried discreetly. Vaginal condoms increase women's control over contraceptive use and protection from STDs. 	<ul style="list-style-type: none"> Interferes with spontaneity. Must be checked for expiration date and holes. Can break or slip off. Can be used only once. Female condoms may seem unattractive.

Continued

TABLE 31-1 ADVANTAGES AND DISADVANTAGES OF THE MOST COMMON CONTRACEPTIVE METHODS—cont'd

METHOD	ADVANTAGES	DISADVANTAGES
Sponge	<ul style="list-style-type: none"> • Available over the counter. • Can be inserted several hours before coitus. • Effective for repeated intercourse. • No prescription needed. 	<ul style="list-style-type: none"> • No protection against STDs. • Must remain in place for 6 hours but no more than 30 hours total. • May cause irritation. • Risk of toxic shock syndrome if used too long or during menstruation.
Diaphragm	<ul style="list-style-type: none"> • Can be inserted several hours before coitus. • Provides some protection from STDs. • Can remain in place up to 24 hours. 	<ul style="list-style-type: none"> • Initially expensive. • Requires health care provider to fit. • Requires education on proper use. • Difficult to insert or remove for some women. • Added spermicide necessary for repeat coitus. • Possibility of toxic shock syndrome with prolonged use or use during menses. • Bladder infection may occur. • Must remain in place at least 6 hours after coitus. • Should be checked for fit annually and after pregnancy or weight change of more than 10 lb (4.5 kg).
Cervical cap	<ul style="list-style-type: none"> • Smaller than diaphragm and may fit women who cannot use a diaphragm. • No pressure against bladder. • Less noticeable and requires less spermicide than diaphragm. • Provides some protection from STDs. • Can remain in place 48 hours. 	<ul style="list-style-type: none"> • Initially expensive. • Requires health care provider to fit. • Requires education on proper use. • Added spermicide needed for repeat coitus. • Possibility of toxic shock syndrome. • Must remain in place at least 6 hours after coitus.
Natural Family Planning		
All methods	<ul style="list-style-type: none"> • Inexpensive. • No drugs or hormones. • Help woman learn about her body. • Can be combined with barrier methods to increase effectiveness. • Acceptable in most religions. • May be used to help achieve pregnancy. 	<ul style="list-style-type: none"> • No protection from STDs. • Requires high motivation and extensive education. • Abstinence necessary for large part of each cycle. • High risk of pregnancy from error. • Many factors may change ovulation time.

*EC, Emergency contraception; IUD, intrauterine device; OCs, oral contraceptives; STD, sexually transmitted disease.

Effectiveness is determined by how often the method prevents pregnancy (Table 31-3). Effectiveness rates reflect two types of contraceptive failure:

1. The ideal, perfect, or theoretic effectiveness rate refers to perfect use of the method with every act of intercourse. Failures are caused by a problem with the method itself rather than with the use of the method.
2. The typical, actual, or user effectiveness rate is most useful because it refers to the occurrence of pregnancy under typical use of the method. Failure is presumably the result of incorrect or inconsistent use of the technique.

The difference between the two rates of effectiveness shows how forgiving a method is—that is, how likely pregnancy is to occur if the use is occasionally imperfect. For example, in 100 women using OCs in 1 year, perfect use results in 0.3 pregnancies but typical use results in 9 pregnancies. The typical failure rate is more meaningful when counseling women and their partners. When comparing different methods, the same method of analysis must be used.

Effectiveness varies according to accuracy of use. It drops greatly when the user does not understand how to use the method. The failure rate commonly decreases after the first year of use because experience with the method leads to more accurate use. Combining two less

reliable methods, for example, a condom and a spermicide, increases effectiveness. The most effective long-acting reversible contraceptives are the intrauterine device and contraceptive implants (AAP & ACOG, 2012).

Other factors that affect the number of unintended pregnancies that occur with contraceptive use include frequency of intercourse and age of the woman. Women who have more frequent intercourse have more opportunities for failing to use the contraceptive correctly. Both frequency of intercourse and fertility tend to decline with age.

Acceptability

The effectiveness of a method must be balanced against its acceptability to the couple. Surgical sterilization is an extremely effective method but is unacceptable to couples planning to have children at a later time. Side effects or religious objections may cause some women to choose less effective methods. A woman or her partner may be concerned about certain contraceptives because of perceived effects such as weight gain.

A contraceptive such as spermicide that seems “messy” may be considered unacceptable because it is unattractive. Spermicide may drip from the vagina and decrease satisfaction for both partners. Less

Data from: Trussell, J. & Guthrie, K. A. (2011). Choosing a contraceptive: Efficacy, safety, and personal considerations. In R. A. Hatcher, J. Trussell, A. L. Nelson, et al. (Eds), *Contraceptive technology* (20th ed., pp. 45-74). New York: Ardent Media.

spermicide may decrease dripping but increase the risk for pregnancy. Teenagers or older women who are not comfortable with their bodies may be unlikely to be accepting of methods that involve inserting a device into the vagina or assessing the cervical mucus.

Convenience

Convenience is another important factor in choosing a contraceptive method. If the woman perceives her contraceptive as difficult to use, time consuming, or too much “bother,” she is less likely to use it consistently unless her level of motivation is very high. The education she receives about the method may affect her perception of its difficulty. Women who are knowledgeable about their family planning method are less likely to feel that the contraceptive is difficult to use.

Methods that can be used monthly or weekly instead of daily or with intercourse are more convenient and likely to lead to better compliance. Spotting between periods, common with some methods, may be viewed as very inconvenient by many women.

The desire to avoid monthly menstruation should also be considered. Some women prefer extended cycles with several months between menses and others desire to avoid menstrual periods altogether. Extended or continuous use of OCs, the patch, and the ring may be used. Hormone implants or injections and intrauterine devices (IUDs) may also lead to *amenorrhea* (absence of menstruation) in some women.

Education Needed

Women may fail to use contraception because they do not understand their risk for pregnancy. They may not be familiar with the variety of methods available or the risks and benefits of the different types. Some

Data from: Trussell, J. & Guthrie, K. A. (2011). Choosing a contraceptive: Efficacy, safety, and personal considerations. In R.A. Hatcher, J. Trussell, A. L. Nelson, et al. (Eds.), *Contraceptive technology* (20th ed., pp. 45-74). New York: Ardent Media; Speroff, L., & Darney, P. D. (2011). *A clinical guide for contraception* (5th ed.). Philadelphia: Lippincott Williams & Wilkins.

methods such as condoms involve very little education, whereas others are more complicated. Women using natural family planning methods need extensive education about body changes that indicate ovulation to practice these methods successfully.

Benefits

Some methods have special benefits that should be discussed with the woman. OCs have many beneficial side effects such as reduction in acne, decreased bleeding during periods, or prolonged amenorrhea. Natural family planning methods offer freedom from exposure to hormones. Condoms provide better protection from human immunodeficiency virus (HIV) compared with other contraceptives.

Side Effects

Many methods of contraception have bothersome side effects that should be explained clearly when discussing the advantages and disadvantages of each method. When women know what to expect, they often are more willing to tolerate the side effects, especially if they know that they do not pose a health risk. This may help them continue an effective contraceptive method instead of discontinuing it and using no method or a less effective one.

Effect on Spontaneity

Contraceptive methods related to **coitus** (sexual intercourse) must be used just before sexual intercourse. They include barrier methods, withdrawal, and periodic abstinence that require skill and motivation near the time of intercourse and are more likely to be used inconsistently or incorrectly. The fact that these methods must be readily available and interrupt lovemaking increases the chance that they will not be used. Some couples remedy this problem by including application of the contraceptive device such as a condom as a part of foreplay. Others prefer methods such as OCs or IUDs that do not interrupt sexual activity.

Availability

Condoms and spermicides are readily available without prescriptions. They can be purchased anonymously at any time without a trip to a health care provider. This may be important to an adolescent who wants to hide her sexual activity or to women who are embarrassed to discuss contraception with a health care provider.

Expense

The cost of family planning methods is important. Less effective contraceptives are often chosen by some couples to save money. These methods may be less expensive but more likely to result in pregnancy, which costs more than the yearly expense of any contraceptive method.

The “per use” cost of methods can be compared with long-term expense. The price of condoms or spermicides is relatively low, but frequent use makes them expensive over a period of years. Couples may find them economical for occasional sexual intercourse or until they can afford a more expensive method. Methods that depend on periodic visits to a health care provider are more costly than over-the-counter methods. However, the visits provide an opportunity for teaching that may enhance contraceptive effectiveness. They also provide an opportunity for health screening and discussion of other health concerns. Long-term contraceptives such as IUDs are very cost effective over a 5- to 10-year period because they prevent pregnancy so well.

Publicly funded family planning clinics may provide free or low-cost contraceptives as well as counseling about all contraceptive methods and follow-up services. However, women who attend these clinics may have a long wait and may see a different health care provider at each visit. Family planning is covered by Medicaid and most insurance companies. The Affordable Care Act includes contraception coverage without co-payments or deductibles for insured women.

Preference

The woman usually makes the final decision about her contraceptive method, and her satisfaction with her choice is crucial. Consistent use of any method depends on whether it meets the needs of the woman and her partner. If the woman feels pressured to choose a certain method or if the chosen method fails to live up to her expectations, use is more likely to be inconsistent. The opinion of the woman's partner and her friends may also influence what method she chooses.

Religious and Personal Beliefs

Religious or other personal beliefs affect the choice of contraceptives. Roman Catholics may not believe in the use of any contraceptives other than natural family planning.

Culture

Culture may influence the method chosen. Some cultures place a high value on large families and especially on male children. A woman may

have more pregnancies than she might otherwise desire in an effort to have sons. Asian and Hispanic women are often very modest and do not talk about sexuality with others. They need to feel very comfortable with the nurse before talking about sexual matters. Taking time to establish rapport before discussing intimate subjects is important.

Some cultures restrict a woman's activities during menses. Methods that cause increased bleeding or breakthrough bleeding as a side effect may not be acceptable to these couples. If there is a cultural taboo against a woman touching the genital area, sponges, cervical caps, diaphragms, and spermicides would not be acceptable.

Other Considerations

Women also consider factors other than those discussed previously when choosing a contraceptive. The length of time before a pregnancy is desired will determine if a long-acting contraceptive is appropriate. The breastfeeding woman must choose a method that will not harm the baby or reduce milk production. The woman at risk for acquiring or transmitting an STD should use condoms either alone or with another more effective method of preventing pregnancy.

Women who have inconsistent use or problems with their contraceptive method may be in a situation of intimate partner violence. These women are often at risk for unintended pregnancy because of their partner's interference with their use of contraceptives (Fontenot & Fantasia, 2011). (See Chapter 24.)

Informed Consent

Because some methods have potentially dangerous side effects, it is necessary for the woman to sign an informed consent form to show that she received and understands information about risks and benefits. These methods include surgical sterilization, OCs, hormone injections, implants, and IUDs. Of course, regardless of whether a consent form is used, every woman should receive information about the chosen contraceptive method and its proper use, its risks and benefits, and alternative methods available.

ADOLESCENTS AND CONTRACEPTION

In 2011, 47% of high school students reported that they had had sexual intercourse, 34% that they were currently sexually active, and 40% that they did not use a condom the last time they had sex (CDC, 2012). Although the rate of adolescent pregnancies has decreased in recent years, adolescent pregnancy is still a major problem (see Chapter 24). Because of the serious impact of pregnancy on adolescents, the U.S. *Healthy People 2020* goals include:

- Increasing condom use at first intercourse to 73.6% of adolescent females and 88.6% of males
- Increasing the number of sexually active adolescents ages 15 to 17 years who used a condom and hormonal or intrauterine contraception at first and last intercourse (USDHHS, 2010)

Adolescent Knowledge

Many adolescents have little knowledge about their own anatomy and physiology, including how and when conception occurs. They are likely to learn about contraception from other teenagers, who often pass on incorrect information. Adolescents have higher failure rates with all methods of contraception. Contraceptive failure is almost twice as likely in teenagers as in women age 30 years or more (Ochalski & Sanfilippo, 2011).

Misinformation

Misinformation and erroneous beliefs about contraception are common among teens. Some teenagers assume they cannot become pregnant the first time they have intercourse. Others believe they must have an orgasm or must have been menstruating a certain length of time to become pregnant. Even adolescent mothers are more likely to be inconsistent in contraceptive use or to use ineffective methods (Speroff & Darney, 2011). However, pregnancy can result from any intercourse near ovulation. Although many adolescents have anovulatory menstrual cycles during the early months after menarche, they cannot depend on absence of ovulation to avoid pregnancy because some will ovulate before their first menses.

Teenagers and older women may *douche* (insert a solution into the vagina) after intercourse to prevent pregnancy. However, douching is ineffective because sperm may enter the cervix very soon after ejaculation. **Coitus interruptus** (withdrawal) is used by some teenagers, but it is unreliable. It requires more control over timing of ejaculation than most adolescent boys have. Semen spilled near the vagina can enter and cause pregnancy, even without penetration by the penis.

Risk-Taking Behavior

Adolescents often have a feeling of invincibility. They are more likely than adults to take risks in sexual activity because they believe their chances of becoming pregnant are low. They often do not plan intercourse and therefore are not prepared with contraceptives. This behavior may lead to STDs and pregnancy. Most teenagers wait at least 6 months after becoming sexually active to begin using contraception (Ochalski & Sanfilippo, 2011).

Some adolescents have ambivalent feelings about becoming pregnant. Although they do not plan to become pregnant, they do not have a firm commitment to avoid pregnancy during their teenage years. Discussing how pregnancy may affect them will help determine their true feelings about it.

Counseling Adolescents

Nurses who counsel adolescents about sexuality must be sensitive to their feelings, concerns, and needs (Figure 31-2). They must be accepting of the teenagers regardless of personal feelings about adolescent sexuality.

For an adolescent to seek information about contraception, she must admit that she is, and plans to continue to be, sexually active. The teenager may be afraid to ask about contraception because she does not want anyone to know she is sexually active or she fears she will be lectured about her behavior. Her need for secrecy may cause her to miss appointments for family planning. The nurse must be adept at determining the adolescent's needs and reassure her that her visits are confidential and what is discussed will not be shared with others.

Each contact with the health care system provides an opportunity for counseling that should not be missed. Visits to a health care provider for well-woman checkups, minor illnesses, or pregnancy testing provide such opportunities. If an adolescent thinks that she might be pregnant but the pregnancy test result is negative, she can be asked

FIG 31-2 Although many adolescents choose oral contraceptives, the nurse emphasizes the need to use condoms for protection against sexually transmitted diseases. Demonstrating with actual contraceptives increases understanding.

about her desire to become pregnant. She may be particularly interested in pregnancy prevention at that time. The nurse can assess the adolescent's use of contraception and the adequacy of her knowledge and can provide information as appropriate.

Although nurses should encourage adolescents to discuss contraception with their parents, many teenagers will forgo contraception rather than talk to their parents about it. Therefore, they need other reliable sources of information. Schools have helped increase birth control use among adolescents by offering information about family planning and prevention of STDs.

Contraceptive services also are available on some school campuses. School nurses and classroom discussions supply information about abstinence as well as contraception. Encouragement to delay becoming sexually active and discussion of the effect pregnancy might have and ways to remain abstinent are included. Some family planning clinics are open after school, during evenings, and on weekends and have staff who are especially skilled in working with adolescents.

The pelvic examination, greatly dreaded by many women, is not necessary for a prescription for OCs in healthy women and may be postponed until a later time (Nelson & Cwiak, 2011). Current recommendations from the American Cancer Society (ACS) are that Papanicolaou (Pap) tests should occur every 3 years beginning at age 21 years and every 5 years beginning at age 30 years for healthy women. Women with abnormalities should have the test more often (ACS, 2012).

During the first visit, the teenager receives information about contraceptive methods. Taking this extra time to explain different methods helps dispel misinformation and allays the common concerns of adolescents about potential adverse health effects of contraceptives. It also helps the teenager to feel comfortable in the clinic setting.

Because of her youth and possible lack of knowledge about anatomy and physiology, the adolescent often needs more extensive teaching than does the older woman. Liberal use of audiovisual materials such as pictures, anatomic models, and samples of various methods helps the teenage girl understand the information more easily. Giving her a patch, a vaginal ring, and a condom to manipulate or showing her the packet of pills she will be using are important aids.

Using understandable terminology is especially important when teaching adolescents. The nurse must know street terms for body parts and sexual intercourse because they may be the only words that are familiar to the teenager.

Adolescents are most successful when they choose contraceptive methods that are easy to use and seem unrelated to coitus. The most popular contraceptives for adolescents are OCs and condoms (Speroff & Darney, 2011). Teenagers choose OCs because they are safe, have few contraindications for adolescents, seem unrelated to sex, and are not difficult or messy. In addition, they increase bone density, regulate menses, reduce menstrual flow and cramping, and may decrease acne (Cunningham et al., 2010; Speroff & Darney, 2011).

Adolescent girls may, however, be inconsistent in taking pills every day. A method like a patch used once a month may be more useful. Use of long-acting reversible contraception (implants and IUDs) are particularly effective in adolescents and are recommended by the American College of Obstetricians and Gynecologists (2012).

Teens are more likely than older women to discontinue any method for side effects such as spotting. Their concerns should be taken seriously, and attempts should be made to alleviate side effects. Otherwise, they are likely to stop using the method, with pregnancy a possible result. They should understand all aspects of management of their contraceptive method and when a backup method is necessary.

Adolescents may use condoms alone to prevent pregnancy and STDs, especially at the beginning of a relationship or with casual partners. With long-term partners, they may use hormonal methods. Increased use of hormonal methods is associated with decreased use of condoms by many adolescents. Some may use condoms, with or without hormonal methods, only if they have casual partners or if they are very concerned about both pregnancy and STDs.

Condom use should be encouraged to help prevent STDs, even when another contraceptive method is used (see Figure 31-2). Discussing perceived barriers to using condoms helps dispel misconceptions about pregnancy and STDs. Many young women are uneasy about asking their partners to use condoms. Discussing how to negotiate condom use with a partner can be particularly helpful. Teaching should include signs of STDs and what to do if they should occur. Using a condom and an OC provides highly effective contraception along with protection from STDs and should be encouraged.

CRITICAL THINKING EXERCISE 31-1

A 15-year-old girl approaches the nurse with questions about contraception. She says she does not want to become pregnant, but her boyfriend does not want to use condoms. She says she is too embarrassed to go to a physician for other methods because she is afraid of the examination.

Questions

1. How should the nurse begin the discussion?
2. What should the nurse tell her about visiting a health care provider for contraception?
3. What should the nurse discuss about condom use?

CONTRACEPTION USE IN PERIMENOPAUSAL WOMEN

Pregnancy is uncommon after age 50 years. However, perimenopausal women may continue to ovulate as long as they have regular menstrual periods, and some ovulate even when indications of menopause are present. Therefore, contraceptive counseling is important for these women.

Fertility begins to decline when women reach 35 to 40 years, but they are still at risk for an unintended pregnancy (Nelson, 2011b). In

fact, more than 30% of pregnancies in women over age 35 years are unintended (Godfrey, Chin, Fielding et al., 2011).

One study found that 14% of women ages 35 to 44 years did not use a contraceptive at last intercourse and women ages 40 to 44 years failed to use contraception at last intercourse twice as often. The study also found that women who received contraceptive counseling in the past year were 80% more likely to use contraception (Upson, Reed, Prager et al., 2010). Therefore the nurse must offer these women contraceptive counseling whenever possible. To avoid pregnancy, effective contraception should be used until 1 year after a woman's last menses (Barry, 2011).

Sterilization is a very common method used by women who are older than 30 years. Healthy, nonobese, nonsmoking women in their 40s can use combined hormonal contraceptives (COCs; ring, patch) to provide contraception and help regulate the irregular bleeding that often occurs during perimenopause. Women who smoke and are over the age of 35 years should not use estrogen-containing contraceptives (CDC, 2010). Barrier methods or progestin-only contraception such as the progestin IUD (Mirena), Depo-Provera, or progestin-only OCs are also good choices for the older woman.

Perimenopausal women should have regular physical examinations to identify any conditions that would necessitate a change of contraceptive method.

8. What considerations are necessary in contraception for perimenopausal women?

METHODS OF CONTRACEPTION

Sterilization

Sterilization (male and female combined) is the most widely used contraception in the United States with approximately one in three married couples using this method of contraception (Beckmann, Ling, Barzansky et al., 2010). Although it is expensive at the time of surgery, sterilization ends all further contraceptive costs. It should always be considered a permanent end to fertility because reversal surgery is difficult, expensive, not always successful, and often not covered by insurance.

Couples considering sterilization need counseling to ensure that they understand all aspects of the procedure. When surgery is planned for immediately after childbirth, the decision should be made well before labor begins. Future marriage, divorce, or death of a child may cause couples to regret their decision. The greatest risk for later regret occurs in women less than 30 years of age at the time of sterilization, when there is pressure from a spouse, when there is a medical indication, or the couple did not receive enough information (Beckmann et al., 2010).

Complications of sterilization are the same as those of any surgery, such as hemorrhage, infection, and anesthesia complications. Although pregnancy is rare after sterilization, the risk of failure should be discussed. Pregnancies occurring after tubal sterilization are more likely to be ectopic. Failures may occur because a pregnancy was already present before the sterilization was performed.

Tubal Sterilization

Tubal sterilization (also called *tubal ligation*) is widely used throughout the world. The surgery involves cutting or occluding the fallopian tubes to prevent fertilization. It can be performed at any time but is easiest during abdominal surgery or cesarean birth. The first 48 hours after vaginal birth is also a good time for the surgery because the fundus is located near the umbilicus and the fallopian tubes are directly below the abdominal wall. Interval sterilization, not associated with childbirth, is generally performed as outpatient surgery under general anesthesia.

The surgery is usually performed in one of three ways. A minilaparotomy incision may be made near the umbilicus in the postpartum period or just above the symphysis pubis at other times. Surgery can also be performed through a laparoscope inserted through a small incision. The third method is performed during other surgery, generally along with cesarean birth, when a woman is sure that she wants the procedure regardless of the outcome of the birth. In each method, the surgeon blocks the tubes with clips, bands, or rings, removes a piece of the tubes and ties the ends, or uses electrocoagulation to destroy a portion of the tubes. If portions of the tubes are removed, they are sent to pathology to ensure that the tissues are actually fallopian tubes.

After sterilization, the woman avoids intercourse, strenuous exercise, or lifting heavy objects for 1 week. Mild analgesics may be needed for pain. The woman should call the health care provider if she has a fever over 100.4°F, fainting, severe pain, or bleeding or discharge from the incision (Roncari & Hou, 2011).

Two nonsurgical methods of sterilization are also possible. *Essure* involves the insertion of a small coil through the vagina and uterus into each fallopian tube. *Adiana* involves use of radiofrequency energy to remove a thin layer of tissue and insertion of a silicone implant in each tube. The procedures can be performed in the physician's office. The tubes become permanently blocked during the next 3 months as tissue grows in and around the inserts. During this time, another contraceptive method is necessary. A hysterosalpingogram is performed at the end of 3 months. The [American College of Obstetricians and Gynecologists \(ACOG, 2010\)](#) emphasizes the importance of the hysterosalpingogram at 3 months to ensure the tubes are completely blocked.

Vasectomy

Vasectomy, the male sterilization procedure, involves making a small incision or puncture in the scrotum to cut, tie, cauterize, or remove a section of the vas deferens, which carries sperm from the testes to the penis. After vasectomy, sperm no longer pass into the semen.

Although performed less frequently than female sterilization, vasectomy is a very popular method of contraception. It involves a lower morbidity rate and has a lower failure rate compared with tubal sterilization. Because it can be performed in a physician's office using a local anesthetic, it is less expensive as well.

After surgery the man rests and then wears a scrotal support for 48 hours. He applies ice to the area for 4 hours and takes a mild analgesic, if needed. He should avoid bathing for 24 hours. Strenuous activity should be avoided for 1 week. The health care provider should be notified of fever, severe pain, bleeding or discharge at the site, swelling greater than twice the normal size, or a painful nodule (Roncari & Hou, 2011).

Intercourse may be resumed in one week, but the man is not sterile at that time (CDC, 2013). Sperm may be present in the ductal system, distal to the ligation of the vas deferens, and the man may be able to impregnate a woman until sperm are no longer present in the semen. The couple should understand that complete sterilization may not occur for 3 months or more. The man should submit a semen specimen for analysis at 8 to 16 weeks to be sure that sperm are no longer present.

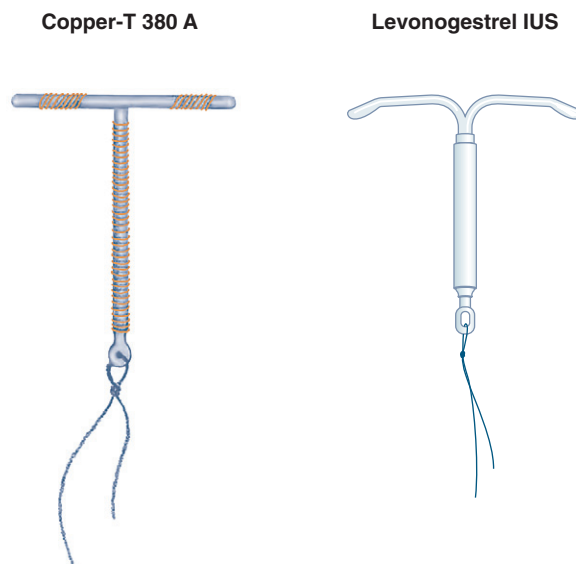

FIG 31-3 The Copper T 380A (ParaGard) intrauterine device (IUD) and the levonorgestrel intrauterine system (LNG-IUS or Mirena). Currently, IUDs are considered a very safe method for preventing pregnancy.

Intrauterine Devices

Intrauterine devices (IUDs) are inserted into the uterus to provide continuous pregnancy prevention. The Copper T 380A (ParaGard) and the levonorgestrel intrauterine system (LNG-IUS, or Mirena) are both shaped like the letter “T” (Figure 31-3). ParaGard is effective for 10 years, and Mirena is effective for 5 years. Mirena is more effective than any other contraceptive method except Implanon and male sterilization.

IUDs can be inserted at any time the woman is not pregnant and does not currently have an STD or pelvic infection. Insertion immediately after delivery of the placenta and during lactation are safe (Jensen & Mishell, 2012). ParaGard is effective immediately, and no backup is required. If Mirena is inserted within 5 days of the start of the last menses, no backup contraceptive is needed. If it is inserted later, a backup contraceptive should be used for 7 days (ACOG, 2011).

Fertility returns promptly when the device is removed. ACOG recommends increased usage of IUDs because they are a long-term, cost-effective means of lowering the risk of unintended pregnancy (ACOG, 2009 & 2011). IUDs are expensive at the time of insertion but have a low long-term cost.

Many women have misperceptions regarding the safety and effectiveness of IUDs (Hladky, Allsworth, Madden et al., 2011). Although safety was a concern with early models, IUDs are considered very safe at this time. IUDs provide long-term, continuous contraception without the need to take pills, have injections, or perform other tasks just before intercourse.

IUDs can be used by some women who cannot use other hormonal contraception. They are generally considered safe for adolescents, nulliparas, and, if they use condoms, for women at risk for STDs (Dean & Schwarz, 2011).

Action

IUDs cause a sterile inflammatory response, which results in a spermicidal intrauterine environment. They do not cause abortion (Speroff & Darney, 2011). Progestin is continuously released from the LNG-IUS (Mirena), which must be replaced in 5 years. The progestin thickens cervical mucus and prevents transport of sperm into the endometrial

cavity and fallopian tubes. Only a small amount of progestin is absorbed systemically, leading to lower blood levels than those in users of other progestin-containing contraceptives.

The copper-covered ParaGard produces a spermicidal intrauterine environment. Progestin is continuously released from the LNG-IUS (Mirena). The progestin causes decreased sperm and ova viability, thickening of cervical mucus barring sperm penetration, inhibits sperm motility, prevents ovulation some of the time, and makes the endometrium hostile to implantation.

Side Effects

Side effects include cramping and bleeding following insertion. *Menorrhagia* (increased bleeding during menstruation) and *dysmenorrhea* (painful menstruation) are common reasons for removal of the copper-containing device ParaGard. Irregular bleeding or spotting may occur with either method in the early months, but is less with the LNG-IUS and may be followed by amenorrhea. The LNG-IUS may be used in women who had menorrhagia before using an IUD. Ibuprofen or another nonsteroidal antiinflammatory drug may reduce bleeding and cramping, and some women need iron supplementation to treat anemia.

Complications include perforation of the uterus at the time of insertion, and expulsion, which occurs in 1% to 5% of users (Beckmann et al., 2010). Although the rate of ectopic pregnancies in IUD users is much less than that in women not using contraceptives, pregnancies that do occur are more likely to be ectopic or result in spontaneous abortion or preterm birth. Women with recent or recurrent pelvic infections, a history of ectopic pregnancy, bleeding disorders, or abnormalities of the uterus should choose another contraceptive method.

There is a small risk for infection from contamination at the time of insertion. Subsequently, the risk for infection is low. The IUD should not be inserted if the woman has had a recent STD.

Teaching

Teaching the woman about side effects and to check for the presence of the plastic threads or strings extending from the IUD into the vagina is important. Expulsion, though uncommon, may occur during menses. Therefore, the woman should feel for the threads weekly for the first 4 weeks, then monthly after menses, and if she has signs of expulsion (cramping or unexpected bleeding). If the threads are longer or shorter than they were previously, she should see her health care provider.

Signs and symptoms of infection such as unusual vaginal pain, discharge, or itching; low pelvic pain; and fever should prompt a call to the health care provider. Any signs of pregnancy should be reported to rule out ectopic pregnancy or spontaneous abortion. The IUD should be removed promptly if pregnancy is confirmed. The woman is advised to watch for influenza-like signs and symptoms which may indicate a septic spontaneous abortion (Dean & Schwarz, 2011).

CHECK YOUR READING

9. What factors should a couple consider in deciding which method of sterilization to use?
10. What education is important for women choosing an IUD?

Hormonal Contraceptives

Hormonal contraceptives alter the normal hormone fluctuations of the menstrual cycle. Hormones may be delivered via implant, injection, patch, or vaginal ring or can be taken orally.

Hormone Implant

The progestin implant (Inplanon), a single rod implant, is inserted subcutaneously into the upper inner arm with the use of a local anesthetic. It is 2 mm thick and 4 cm (1.6 in) long and releases progestin continuously to provide 3 years of contraception. It acts to inhibit ovulation, thicken cervical mucus to prevent sperm penetrability, and makes the endometrium unfavorable for implantation. Increased usage of hormone implants is recommended by ACOG as a means of offering effective, long-acting, reversible contraception (ACOG, 2009, 2011).

Implants can be inserted immediately postpartum in women who are not breastfeeding. They are considered a category 2 (advantages generally outweigh the theoretical or proven risks) for women who are breastfeeding after 30 days because there is a theoretic concern about the effect of implants on milk production (CDC, 2011).

Nexplanon is a newer version of Implanon from the same company that has been approved by the U.S. Food and Drug Administration (FDA). It can be seen on a radiograph or ultrasound if it is necessary to verify placement. It is also easier to insert (Bowers, 2012).

Side effects include irregular menstrual bleeding as with other progestin-only contraceptives. Bleeding is expected and not a sign of abnormality. Amenorrhea may occur with longer use. Fertility returns promptly and pregnancy can occur at normal rates when the implant is removed (Speroff & Darney, 2011).

Hormone Injections

Depo-Provera (medroxyprogesterone acetate, or DMPA) is an injectable progestin available in an intramuscular (IM) and a subcutaneous (Sub Q) form. It prevents ovulation for 15 weeks, although injections should be scheduled every 13 weeks (CDC, 2013). It is convenient and contains no estrogen. The action and side effects are similar to those of other progestin contraceptives.

The IM form of Depo-Provera is given by deep intramuscular injection. The Sub Q form is given in the anterior thigh or abdomen. The site should not be massaged after injection because massage accelerates absorption and decreases the period of effectiveness. No backup method of contraception is necessary after the first injection if it is given within 7 days of the beginning of a menstrual period. A backup method of contraception is used for 7 days if the first injection is given at other times or if the woman is more than 2 weeks late returning for a subsequent injection (CDC, 2013). It can also be given on the day it is prescribed if it is certain the woman is not pregnant and that she will use backup for the first week.

Menstrual irregularities are the major reason for discontinuation and women should be informed about this before beginning the method. Although spotting and breakthrough bleeding are common, amenorrhea occurs in 80% of women using the IM form at 5 years and in 55% of women using the SubQ form after 1 year (Speroff & Darney, 2011). Other side effects include weight gain, headaches, depression, hair loss, nervousness, decreased **libido** (sexual desire), breast discomfort, and depression.

A decrease in bone density occurs with Depo-Provera. Although there is an increase in bone density after the drug is discontinued, the effect on peak bone mass and risk of osteoporosis is not known. Therefore, current prescribing information states that Depo-Provera should not be used for longer than 2 years unless other methods of contraception are not suitable. It may be more of a problem for women who begin the drug during adolescence or in the perimenopausal period. However, the World Health Organization considers the advantages of use of Depo-Provera in adolescents under age 18 years to generally outweigh the theoretical or proven risks (CDC, 2010). Women using

this method should obtain adequate amounts of calcium and vitamin D and should increase weight-bearing exercises.

Depo-Provera can be started in the immediate postpartum period, and it increases the quantity of milk in lactating women. The effectiveness is not changed by a woman's weight. There is a delay in return to fertility after the drug is discontinued. Approximately 59% of women resume menses in 6 months, and 25% do not resume menses for a year or more (Beckmann et al., 2010).

Oral Contraceptives

Oral contraceptives (OCs) are drugs that inhibit ovulation. They are the leading reversible contraceptive method in the United States (AGI, 2012a). They are available as combination OCs, which contain both estrogen and **progestin** (a natural or synthetic form of progesterone), and "minipills," which contain only progestin. Both types have much lower hormone levels than the original OCs, and therefore the risk for long-term side effects is decreased. If OCs are used perfectly, 3 women in 1000 become pregnant in the first year.

Combination OCs. Estrogen and progestin combinations (COCs) are the most common OCs. COCs cause thickening of cervical mucus, which prevents sperm from entering the upper genital tract. They also suppress production of luteinizing hormone and follicle-stimulating hormone, thus inhibiting maturation of the follicle and ovulation. In addition tubal motility is slowed interfering with sperm and ova transport (See Chapter 4 regarding the menstrual cycle.)

Monophasic or multiphasic dosages are available. Monophasic pills have an estrogen-and-progestin content, which remains constant throughout the cycle. With multiphasic pills, the estrogen dose and progestin levels may vary at different times of the cycle. Because the dosage changes throughout the phases, women must take the pills in the proper order to maintain effectiveness.

Patterns of pill use vary. Most COCs are available in packets of 21 or 28 tablets. With 21-tablet packets, the woman takes 1 pill daily for 3 weeks and then stops for 1 week, during which time menstruation occurs. Packets of 28 tablets include 21 active tablets and 7 tablets made of an inert substance that the woman takes during the fourth week. In some types, the "placebo" pills have estrogen or iron in them. The extra pills avoid disrupting the everyday routine of taking pills. Some formulations contain 24 active tablets with 4 inactive tablets. Women using them have shorter, lighter withdrawal bleeding.

Some women prefer extended cycles in which menses is delayed for a few days for special occasions or for a longer time. These women take two or more pill packs without taking the placebo pills for several packs or indefinitely. A COC designed to provide 84 days of active pills and 7 placebo pills or 7 pills with a small amount of estrogen allows women to have menses only four times a year. The added estrogen is given to decrease breakthrough bleeding and give a shorter withdrawal bleed. Another formulation taken every day without stopping suspends menstrual periods indefinitely. Breakthrough bleeding and spotting are a common problem with extended or continuous use, but they usually lessen with time. A disadvantage is that a woman might not recognize an early pregnancy if it occurred.

Progestin Only. Progestin-only pills (POPs) are taken daily with no hormone-free days. POPs are less effective at inhibiting ovulation but cause thickening of cervical mucus to prevent penetration by sperm. They also make the endometrial lining unfavorable for implantation. These pills avoid the side effects and risk factors associated with estrogen and are useful for women who cannot take estrogen.

If a woman misses any pills or does not take them at the same time each day, the chances of pregnancy increase. Another method of contraception should be used for the first 2 days of the first cycle unless the woman starts the method during the first 5 days of her cycle or

immediately after stopping another hormonal method. Backup contraception should also be used for 2 days if the woman is more than 3 hours late in taking a pill or has vomiting or diarrhea (Raymond, 2011).

Breakthrough bleeding and higher risk for pregnancy have made POPs less popular than the COCs. Amenorrhea occurs in some women.

Benefits, Risks, and Cautions. When OCs are chosen, the balance between benefits and risks must be weighed for each individual (Table 31-4). Women often believe that the risks are higher than they actually are, yet OCs are safer for most women than pregnancy (Beckmann et al., 2010). The method has many benefits in addition to safe, reliable contraception. OCs result in regular menses and decreased flow, premenstrual syndrome, and dysmenorrhea, reduced acne, and improved bone density.

OCs should not be used by women who have certain medical complications (see **Critical to Remember: Cautions in Using Combined Oral Contraceptives**). Smoking significantly increases complications for women of all ages. Women who smoke and are over the age of 35 years should not use estrogen-containing contraceptives (CDC, 2010). Women who have previously smoked must abstain from all sources of nicotine for at least 6 to 12 months to be considered a nonsmoker (Speroff & Darney, 2011). Taking any COCs increases the chance of venous thromboembolism (VTE) and therefore their use should be avoided in women with risk factors for that condition.

CRITICAL TO REMEMBER

Cautions in Using Combined Oral Contraceptives

Combined oral contraceptives should not be used by women with a history of any of the following:

- Thrombophlebitis and thromboembolic disorders
- Cerebrovascular or cardiovascular diseases
- Any estrogen-dependent cancer or breast cancer
- Benign or malignant liver tumors
- Hypertension (unless well controlled by medication)
- Migraines with aura or migraines in women over 35 years of age
- Diabetes longer than 20 years or with vascular or other organ involvement

Combined oral contraceptives should not be used by women who currently have any of the following:

- Any of the previously listed conditions
- Impaired liver function
- Suspected or known pregnancy
- Undiagnosed vaginal bleeding
- Cigarette smoking in women older than 35 years
- Major surgery requiring prolonged immobilization

Data from Nelson, A. L. & Cwiak, C. (2011). Combined oral contraceptives. In R. A. Hatcher, J. Trussell, A. L. Nelson, et al., (Eds.), *Contraceptive technology* (20th ed., pp 249-341). New York: Ardent Media.

Many risks were associated with the higher doses of hormones used in the original OCs, but the current significantly lower-dose OCs pose less of a problem. Hazards are decreased by careful screening for risk factors in each woman. Obese women have a higher risk of thromboembolic problems, but this is not considered a contraindication to OC use. Evidence is inconsistent about whether body weight affects OC effectiveness (CDC, 2010). Women with diabetes of less than 20 years' duration, who do not smoke, and are in good health may use OCs with adequate supervision of their condition (CDC, 2010).

TABLE 31-4 POTENTIAL BENEFITS, DISADVANTAGES, AND RISKS OF ORAL CONTRACEPTIVES

BENEFITS	DISADVANTAGES	RISKS*
<ul style="list-style-type: none"> • Unrelated to coitus • Highly effective • Regulates menstrual cycles and reduces dysmenorrhea, menstrual blood loss, and associated anemia • Amenorrhea (may be seen as a disadvantage) • Fertility usually returns within 3 months • Decreased incidence of: <ul style="list-style-type: none"> • Premenstrual dysphoric disorder symptoms • Benign breast disease • Pelvic inflammatory disease • Salpingitis • Ectopic pregnancy • Ovarian, endometrial, and colorectal cancer • Improves: <ul style="list-style-type: none"> • Acne • Endometriosis • Many premenstrual symptoms • Dysmenorrhea • Bleeding from fibroids (leiomyomas) • Bone mass (COCs only) • Hirsutism (excessive hair growth) • Rheumatoid arthritis 	<ul style="list-style-type: none"> • Must be taken every day near same time, especially POPs • Side effects may include: <ul style="list-style-type: none"> • Breakthrough bleeding • Nausea • Headache • Breast tenderness • Amenorrhea (may be seen as an advantage) • Chloasma 	<ul style="list-style-type: none"> • No protection against STDs • May increase risk of cervical cancer • Increased incidence of: <ul style="list-style-type: none"> • Deep and superficial vein thrombosis • Pulmonary embolism • Myocardial infarction • Stroke (in smokers) • Hypertension • Migraines • Chlamydial infection • Gallbladder disease

*Incidence of many risks is significantly reduced with low-dose OCs presently used. Avoiding OC use in women who smoke or have other risk factors lowers risk for cardiovascular disease significantly.

COC, Combined oral contraceptive; POP, progestin-only contraceptive pills; STD, sexually transmitted disease.

OCs provide no protection against STDs and may increase susceptibility to *Chlamydia* infection. A woman should be advised to have her partner use a condom and spermicide if he may be infected or the relationship is not monogamous.

Side Effects. Approximately 33% of women who do not wish to become pregnant discontinue COCs within the first year, usually because of side effects (Trussell, 2011). Most side effects are minor and include signs and symptoms often seen in pregnancy. Using a different formulation of hormones may reduce some side effects. For example, decreasing the amount of estrogen helps relieve nausea and breast tenderness. Breakthrough bleeding occurs most often in the first 3 months and then usually subsides. If it is a problem, a COC with a different level of hormones can be used to decrease bleeding. Some women complain of weight gain while taking OCs, but studies have not shown it to be caused by the pills (Beckmann et al., 2010). Other side effects include fluid retention, amenorrhea, and melasma. Side effects often decrease after the first few months of use and are less frequent in low-dose OCs.

Teaching. Many unintended pregnancies result from failure to carefully follow instructions for the use of OCs. However, education about proper use greatly increases effectiveness. Teaching should be extensive when the woman begins to use the hormones. Follow-up is necessary to ensure that her questions are answered and unanticipated problems resolved. Because the instructions can be complex, they should be written clearly and simply in her own language, if she can read.

Teaching about when to start taking OCs is especially important. Methods of beginning OC use include:

- **Quick start:** The woman takes the first pill on the day the pills are prescribed (if it is reasonably certain that she is not pregnant). A backup method is needed for the first 7 days of the first cycle unless her period started 5 days ago or less. This method is preferred because it provides immediate protection and may improve continuation. It avoids a delay during which a pregnancy might occur.
- **First-day start:** The first pill is taken on the first day of the next menstrual period. No backup method is needed.
- **Sunday start:** The pills are begun on the first Sunday after menses begins. With this method, the woman avoids having a period on the weekend. A backup method is used for the first 7 days of the first cycle.

The nurse should listen carefully to women's concerns about side effects and help them find methods of relief. One study showed that women who did not fully understand the advantages of OCs and had low confidence in their ability to use them were less likely to continue use at 6 months (Dempsey, Johnson, & Westhoff, 2011).

When women discontinue OCs because of the side effects, they may not use another contraceptive or may use one that is less effective and become pregnant as a result. Women should be instructed to keep a backup contraceptive method readily available in case they decide to stop taking their OCs.

It is essential that nurses be honest about the side effects that should be expected with all contraceptives. Teaching about temporary side effects may help the woman endure them until they are no longer present. Women should know that spotting is a common side effect of many hormonal contraceptive methods, particularly at the beginning. Over time, spotting may diminish, or amenorrhea may develop. If

changes in bleeding patterns or irregularity are unacceptable to the woman, she should choose another contraceptive method.

Blood Hormone Levels. Maintaining a constant blood hormone level is important for effectiveness, especially with POPs. Therefore, the woman must take the pills near the same time each day. Many women make them a part of their bedtime routine, others take their OCs with a meal to avoid nausea, and some take their OCs when they brush their teeth in the morning. Breakthrough bleeding is more likely when a significant time variation occurs between doses.

Women should understand that some pills must be taken in a certain order and that changing the order will decrease the effectiveness of the method. Illness may affect the blood hormone levels. A woman who experiences vomiting or diarrhea should use a backup method of contraception for 7 days as the hormones may not have been properly absorbed.

Missed Doses. Instructions for the woman who misses one or more doses should be provided. Women who frequently miss OCs should be counseled about other contraceptive methods that might be more effective for them.

The woman should follow instructions from her provider if she misses doses of her OC. Instructions may vary according to the type of OC used, the number of doses missed, and the time in the cycle the OC is missed. The woman who misses pills early in the cycle is at higher risk for ovulating. Different health care providers may use different regimens. See “Women Want to Know: What to Do if an Oral Contraceptive Dose Is Missed,” for an example of instructions.

WOMEN WANT TO KNOW

What to Do If an Oral Contraceptive Dose Is Missed

Instructions for missed OCs include: (CDC, 2013):

General

Missing inactive tablets at any time will not increase the risk of pregnancy. Discard the missed pills.

Combined Oral Contraceptives One Missed Pill

- Take 1 active pill as soon as possible. Take the next dose at the usual time.
- Continue the pack as usual.
- No backup contraceptive is necessary.

Two or More Missed Pills in the First 2 Weeks

- Take 2 pills as soon as possible, then one tablet daily.
- Use backup contraception for the next 7 days.

Two Missed Pills in the Last Week of Active Pills

- Take 1 active pill each day until they are finished.
- Discard the inactive pills.
- Start a new package the next day.
- Use backup contraception for 7 days if unable to start a new pack of pills.

If a woman misses a period and thinks she may be pregnant because she missed one or more doses, she should stop taking the pills and get a sensitive pregnancy test immediately. Using another contraceptive method during this time is essential. However, there is no association between inadvertently taking OCs when pregnant and fetal complications.

Postpartum and Lactation. COCs increase the risk for VTE and reduce milk production in lactating women, and very small amounts may be transferred to the milk. All postpartum women should avoid COCs for 3 weeks after giving birth and lactating women should avoid COCs for 4 weeks. Those with risk factors for VTE should avoid COCs for 6 weeks. Progestin-only OCs may be a better choice if a woman wishes to use a hormonal contraceptive because these OCs do not affect milk quantity or quality. There is no evidence of adverse effects on the infant, and no waiting period is required (CDC, 2013).

Other Medications. OCs may interact with other medications, and the effectiveness of each may be changed. Some may increase or decrease estrogen or progesterone levels. OCs may interact with some anticonvulsants, antiretroviral drugs, and rifampicin or rifabutin. Over-the-counter drugs should also be considered. For example, St. John's wort, which some women take for depression, interferes with OC effectiveness (Renner & Jensen, 2012). Because of these various interactions, the woman should always tell her health care providers and her pharmacist about other drugs she is taking.

Follow-Up. The only essential follow-up for women who take OCs is yearly blood pressure measurement. It is not necessary for women to have yearly pelvic examinations, Pap tests, or breast examinations to receive prescriptions for OCs. Women using OCs should follow the same recommendations as those for women who do not take OCs.

During the follow-up visit, the woman's ability to remember to take a pill every day should be evaluated. Some women set an alarm on a cell phone as a reminder every day. Other methods should be discussed if remembering is a problem or if she wants to change methods.

Return of fertility is rapid after the pills are discontinued (Nelson & Cwiak, 2011). A woman may wish to wait until her menstrual cycle is reestablished before conceiving so that she can date the beginning of her pregnancy more accurately. She should be advised to take folic acid for several months before becoming pregnant to help prevent neural tube defects in the fetus.

The woman should report any signs of adverse reactions immediately. Use of the acronym *ACHES* may help the woman remember signs that may indicate complications (Table 31-5).

Emergency Contraception

Emergency contraception (EC), often called the “morning-after pill,” is a method to prevent pregnancy after unprotected intercourse. EC may be used after contraceptive failure such as a condom breaking during intercourse or when a woman misses too many OCs. It also may be used after rape or in other situations in which contraceptives were used incorrectly or not at all.

Three forms of EC (Plan B One-Step, Next Choice, Next Choice One Dose) contain the progestin levonorgestrel. In the past EC was available at pharmacies without a prescription for women age 17 years and older but those younger than 17 years needed a prescription (FDA, 2009). In 2013, a federal court decision declared Plan B One-Step should be available to women of all ages.

The progestin-only ECs work by delaying or inhibiting ovulation, thickening cervical mucus and interfering with the function of the corpus luteum. The treatment is ineffective if implantation has already occurred, and it does not harm a developing fetus (Trussell & Schwarz, 2011).

Another form of EC is ulipristal acetate (Ella), which requires a prescription for all ages. Ella acts to delay or block the surge of luteinizing hormone and ovulation. It may also inhibit implantation and requires a pregnancy test before use, as it may disrupt an early pregnancy (American Academy of Pediatrics, 2012; Nichols, 2010).

TABLE 31-5 ACHES: WARNING SIGNS OF ORAL CONTRACEPTIVE COMPLICATIONS

	WARNING SIGN	POSSIBLE COMPLICATION
A	Abdominal pain (severe)	Mesenteric or pelvic vein thrombosis Benign liver tumor, gallbladder disease
C	Chest pain, dyspnea, hemoptysis, cough	Pulmonary emboli or myocardial infarction
H	Severe headache, weakness or numbness of extremities, hypertension	Stroke, migraine
E	Eye problems (complete or partial loss of vision), headache	Retinal vein thrombosis, stroke, migraine
S	Severe leg pain or swelling (calf or thigh), swelling, heat, redness	Deep vein thrombosis

*The acronym *ACHES* can be used to help women remember warning signs that may indicate complications when using oral contraceptives. Other signs include jaundice, a breast lump, and depression. The woman should contact her health care provider if any of these signs develops.

Data from: Nelson, A. L. & Cwiak, C. (2011). Combined oral contraceptives. In R. A. Hatcher, J. Trussell, A. L. Nelson, et al. (Eds.), *Contraceptive technology* (20th ed., pp 249-341). New York: Ardent Media.

The most common method of EC involves taking one (Plan B One-Step, Next Choice One Dose) or two (Next Choice) tablets (taken together) that contain a high dose of progestin. The pills should be taken as soon as possible or up to 120 hours after unprotected intercourse (Trussell & Schwarz, 2011). EC will not prevent pregnancy if unprotected intercourse occurs after EC is used.

Combined OCs may also be used in larger-than-usual doses to prevent pregnancy. The number of tablets varies according to the specific COC used. They may cause nausea, so women are often advised to take an antiemetic before taking the pills.

Insertion of the Copper T 380A IUD within 5 days of intercourse also may be used and provides 99% effectiveness (Trussell & Schwartz, 2011). It has the added advantage of providing long-term (10 years) protection from pregnancy for those who choose this method.

Although EC is available, use is suboptimal. Many women are unaware of the availability of EC, and those who are do not always use it to prevent unintended pregnancies. Women may not know how or where to get it. Information about EC and how to obtain it should be included whenever education about contraception is offered to women in case they might later wish to use it. The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) states that nurses should ensure that women receive information about all types of contraception, including how to obtain emergency contraception (AWHONN, 2012).

Women who need EC should receive counseling about their regular contraceptive method. They may not understand how to use their method correctly or may wish information about other, more effective options. Because of the short time frame during which EC is effective, some health care providers give women prescriptions to use at a later date if they should need it. Information about where EC can be obtained is available on the Internet at www.NOT-2-LATE.com, or the

woman can call 1-888-NOT-2-LATE (1-888-665-2528). Women who use EC have not been shown to be more likely to have risky sex, future unplanned pregnancies, or STDs (Jurrow, 2011).

Transdermal Contraceptive Patch

The **transdermal contraceptive patch** (Ortho Evra) releases small amounts of estrogen (ethinyl estradiol) and progestin (norelgestromin), which are absorbed through the skin to suppress ovulation and thicken cervical mucus. It also regulates menstrual cycles.

The contraceptive patch is as effective as OCs, or it even may be more effective because it is used once a week instead of daily. A non-hormonal contraceptive should be used during the first week of use, unless the patch is started within the first 5 days of the menstrual period (CDC, 2013). For most users, fertility returns quickly, with hormone levels back to normal within 1 month of discontinuing the patch (Nanda, 2011).

The patch is applied to clean, dry, nonirritated skin on the abdomen; buttock; upper outer arm; or upper torso, excluding the breasts. Areas where clothing such as straps or waistbands may rub the patch should not be used. The woman should avoid using oils or lotions in the area because the patch may not stick. Adherence to the skin is good even in the shower or when exercising or swimming. The patch should not be cut or altered, and no more than one patch should be worn at a time.

A new patch is applied to a different site weekly on the same day of the week for 3 weeks and worn continuously for 7 days. Then the patch is removed for 1 week. During the patch-free week, the woman has a period. After 7 patch-free days, she applies a new patch and begins the cycle again. Women can have extended cycles without menses by using patches for several cycles or continuously.

Side effects include spotting, breast tenderness, headaches, and skin reactions. Other side effects and risks are similar to those for combination OCs. The patch has been found to be less effective in women who weigh more than 198 lb (90 kg) (Nanda, 2011).

The risk of VTE is higher with patch use than with OC use because total exposure to estrogen is greater. However, studies have had conflicting results (Cunningham et al., 2010). The risk of VTE is less than that of pregnancy, but women with risk factors for VTE should discuss the risks and benefits of patch use with their health care provider (Nanda, 2011).

Because the patch must be applied only once a week, it may be easier than OCs for women who have difficulty remembering to take a pill every day. However, it is visible on the skin, which may be a problem for adolescents who do not want their contraceptive use known by others.

If a patch detaches, the woman should try to reattach it. If it will not adhere again, she should replace it with a new patch. She should not use tape to keep it on as the contraceptive is in the glue of the patch. No backup contraception is necessary. If the patch is off 2 or more days or she is 2 or more days late in changing the first or second patch, the woman should apply a new one and use backup for 7 days. If the woman is 2 or more days late in changing the patch in the 3rd patch week, a new one should be applied, she should omit the patch-free week, and start a new patch cycle (CDC, 2013).

Contraceptive Vaginal Ring

Women using the **vaginal contraceptive ring** (NuvaRing) insert a soft, flexible vinyl ring into the vagina and leave it in place for 3 weeks. The ring, which measures 2 inches (5 cm) in diameter and is 4 mm thick, releases small amounts of progestin and estrogen continuously to prevent ovulation (Figure 31-4). The woman removes the ring at the end of the third week, and withdrawal bleeding occurs. A new

FIG 31-4 The vaginal contraceptive ring (NuvaRing) is 5 cm (2 inches) across and 4 mm thick.

ring is inserted to begin the next cycle 1 week after the old ring was removed.

Although a prescription is required, no fitting or particular placement in the vagina is necessary. There is no need to think about contraception except twice a month when the ring is being placed or removed.

Women must be comfortable inserting the device into the vagina. Placement and removal are quick and easy. Allowing a woman to try placing the ring in the provider's office where help is available often increases confidence. For the woman who does not want her contraceptive use known by others, the fact that the ring is not visible to others is appealing.

Use can begin during the first 5 days of the menstrual cycle, even if the woman is still bleeding, or on any other day. A backup contraceptive is necessary for the first 7 days of the first cycle if the ring is inserted on any day but the first 5 days of menses.

The most common side effect is headache. Other side effects include vaginitis, expulsion, or vaginal discharge or discomfort. Although some women or their partners can feel the ring during intercourse, it is generally not a problem. Breakthrough bleeding is less common than with OCs. Women who should not use hormonal contraceptives should also not use the vaginal ring.

The ring may be removed for up to 3 hours without loss of effectiveness. If 48 or more hours without the ring occurs in the first 2 weeks, the ring should be reinserted and a backup method used for 7 days. If the ring is out of the vagina for 48 or more hours in the third week, the woman can leave it out and have a withdrawal bleed or insert a new ring, omit the ring-free week, and start a new cycle of ring use (Nanda, 2011; CDC, 2013). If the woman desires extended cycles, she can insert a new ring when she removes the old one and avoid the withdrawal bleeding.

11. What is the mechanism of action of hormonal contraceptives?
12. What side effect is most likely to cause some women to discontinue use of some hormonal contraceptives?
13. What do women taking OCs need to know about this contraceptive method?
14. How soon after unprotected intercourse should EC be used?

Barrier Methods

Barrier methods of contraception involve chemicals or devices that prevent sperm from entering the cervix. The method may kill the sperm or place a temporary partition between the penis and the cervix. All barrier methods are coitus related and may interfere with spontaneity. They avoid the use of systemic hormones, however, and provide some protection from STDs.

Chemical Barriers

Chemicals that kill sperm are called **spermicides** and are available in many forms. Creams and gels are generally used with mechanical barriers such as the diaphragm or the cervical cap. Foams, foaming tablets, suppositories, and vaginal film may be used alone or with another contraceptive. They are inserted deep into the vagina about 15 minutes before sexual intercourse so that they are in contact with the cervix. Vaginal films and suppositories must melt before they become effective, which takes approximately 15 minutes. Spermicides are generally effective for less than 1 hour. They should be reapplied if intercourse is repeated. Women should not douche for at least 6 hours after intercourse (Taylor, 2011; Cates & Harwood, 2011).

Spermicides are readily available without a prescription, inexpensive, and easy to use. Using spermicides increases lubrication, which decreases the risk for condom breakage. This is an advantage, especially during lactation or in menopause when vaginal secretions are decreased. Effectiveness is increased when spermicides are used with a mechanical barrier method.

Some women and their partners think that spermicides are messy and interfere with sensation during intercourse. Spermicides do not protect against STDs and should not be used for that purpose. Frequent use (two or more times a day) or sensitivity to the products may cause genital irritation, which could increase susceptibility to infections, including HIV infection.

Mechanical Barriers

Mechanical barriers are devices placed over the penis or the cervix to prevent passage of sperm into the uterus. They include the condom, sponge, diaphragm, and cervical cap.

Male Condom. Condoms, the only male contraceptive device currently available, are the third most popular method of contraception in the United States and are used by almost 9 million couples (Warner & Steiner, 2011). They cover the penis to prevent sperm from entering the vagina.

Condoms are most often made of latex and may be coated with a lubricant. Latex condoms provide the best protection available (other than abstinence) against STDs, including HIV infection. For this reason, condoms should be used during any possible exposure to an STD, even if another contraceptive technique is practiced or the woman is pregnant.

People who are allergic to latex should avoid the use of latex condoms because severe reactions are possible. They may use polyurethane or natural membrane condoms instead. Polyurethane condoms are thinner than latex but may require lubrication to avoid breakage and are more likely to slip off. Natural membrane condoms do not prevent passage of organisms that may cause STDs.

Condoms are readily available, are inexpensive, and can be carried inconspicuously by the man or the woman. The typical failure rate can be decreased by combining condom use with another method such as a vaginal spermicide. Reservoir tips and water-based lubricants help prevent breakage. The slippage and breakage rate is approximately 5% to 8% (Beckmann et al., 2010).

Because condoms must be applied just before intercourse, some couples object to the interference with spontaneity. Others feel that

condoms interfere with sensation. Men with erectile dysfunction may have problems with condom slippage (Nelson, 2011a). Condoms may be affected by vaginal medications, and they should not be used concurrently. Only water-based lubricants should be used for latex condoms because oil-based lubricants will cause deterioration of the latex.

COUPLES WANT TO KNOW

What Is the Proper Way to Use Male Condoms?

Although condoms are easy to use, proper use increases their effectiveness.

- Condoms are available in a variety of colors, textures, and materials, but those made of latex or polyurethane are most effective. Natural membrane condoms may help protect against pregnancy but not against STDs.
- Check the expiration dates on packages because condoms may deteriorate after 5 years. Open the package carefully, and check the condom to see that it is not torn or damaged before using it.
- Lubrication may increase comfort for the woman and reduce the risk of breakage. Use a water-soluble lubricant or a spermicide because oil-based products (such as petroleum jelly or baby oil) cause deterioration of latex condoms.
- Always apply the condom before there is any contact of the penis with the vagina.
- Squeeze the air out of the end of the condom, and leave half an inch of space at the tip as the condom is unrolled to the base of the erect penis. This space allows a place for sperm to collect and helps prevent breakage.
- Withdraw the erect penis from the vagina while holding the condom at the base so it does not slip off and no semen spills into the vagina.
- Use a new condom each time intercourse is repeated.

Female Condom. The female condom (also called a *vaginal pouch*) is a polyurethane sheath inserted into the vagina. A flexible ring inside the closed end of the condom fits over the cervix like a diaphragm. Another ring extends outside the vagina to partially cover the perineum (Figure 31-5). The female condom is the first contraceptive device that allows a woman some protection from STDs without relying on the male condom. Male and female condoms should not be used together as they may adhere to each other.

Sponge. The contraceptive sponge (Today) is made of soft polyurethane that traps and absorbs semen and contains the spermicide nonoxynol-9. The sponge is approximately 2 inches (5 cm) in diameter

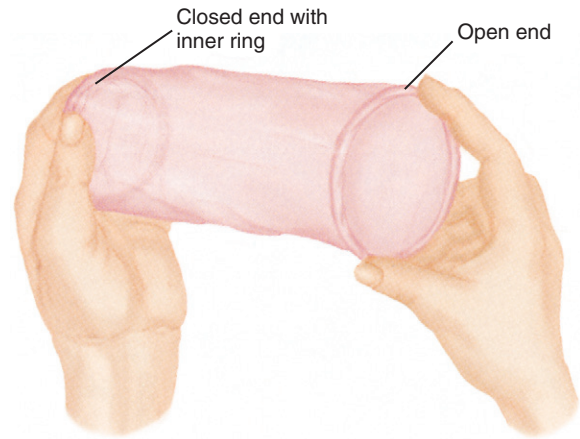

FIG 31-5 The Female Condom. A woman can protect herself from sexually transmitted diseases without relying on use of the male condom.

and provides contraception for 24 hours without the need to add spermicide for repeated intercourse. It does not require a prescription, contains no hormones, is easy to use, and can be inserted just before intercourse or hours ahead of time.

To use the sponge, the woman washes her hands and wets the sponge with about two tablespoons of water, squeezing the sponge until it becomes sudsy. She then folds the sponge, with the concave (“dimple”) area inside and the loop on the outside of the fold, and inserts it into the vagina. When the sponge is released, the “dimple” covers the cervix and helps keep the sponge in place during intercourse. To eliminate interference with spontaneity, some women insert the sponge hours in advance when intercourse is anticipated.

Repeated intercourse does not require added spermicide or a new sponge. It should remain in place for at least 6 hours after the last intercourse. It is removed by inserting a finger into the loop and pulling slowly. The sponge should not be used during menstruation or left in the vagina for more than 24 to 30 hours because of an increased risk of toxic shock syndrome (Cates & Harwood, 2011). It should not be used by women with a history of toxic shock syndrome, and it does not protect against STDs. The sponge may cause irritation or be difficult to remove for some women.

Diaphragm. The **diaphragm** is a latex dome surrounded by a spring or coil. The woman places spermicidal cream or gel into the dome and around the rim and then inserts the diaphragm over the cervix. Because it covers the cervix, the diaphragm prevents passage of sperm while holding spermicide in place for additional protection.

Diaphragms must be fitted by a health care provider. The correct size may not be available for all women. The woman should be checked for size changes yearly, after a weight gain or loss of 10 lb (4.5 kg) or more, and after each pregnancy (Cates & Harwood, 2011). It should not be used for the first 6 weeks after delivery (AAP & ACOG, 2012).

Pressure on the urethra may cause irritation and urinary tract infections. Voiding after intercourse may help prevent infections. An allergy to latex or a history of toxic shock syndrome precludes use. The diaphragm may be damaged by oil-based lubricants and some medications used for vaginal infections.

Cervical Cap. The **cervical cap** (FemCap) is a cuplike device placed over the cervix to prevent sperm from entering. It is similar to the diaphragm but smaller. It is fitted by a health care provider. The flexible silicone cap is inserted over the cervix after placing spermicide on both sides. It stays in place by suction. The cap does not cause

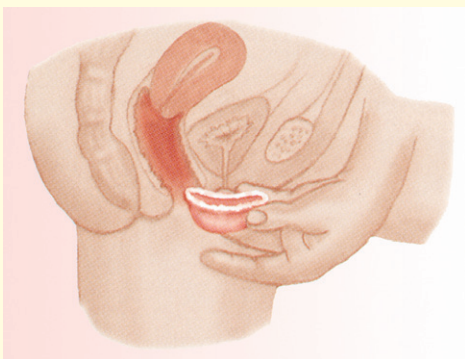

WOMEN WANT TO KNOW

How to Use a Diaphragm

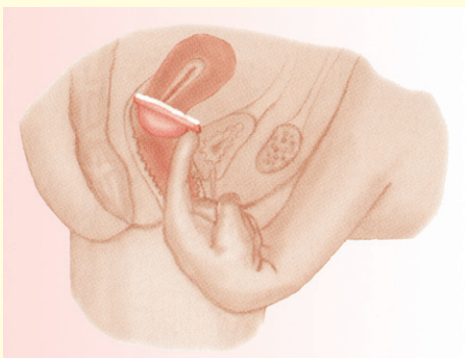

- Follow instructions carefully when using your diaphragm. Skill at insertion and removal increases with practice.
- Plan to insert the diaphragm up to 6 hours before intercourse. Empty your bladder before insertion.
- Spread about a tablespoon of spermicidal cream or gel inside the dome and around the rim.

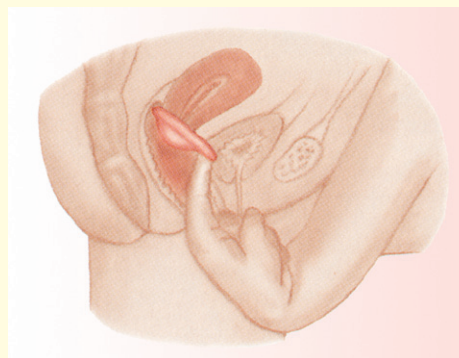

- Insert the diaphragm into the vagina with the spermicide toward the cervix. A squatting position or placing one foot on the tub or toilet seat makes insertion and removal easier.

- Be sure that the front rim fits behind your pubic bone and that you can feel the cervix through the center of the diaphragm.

- If more than 6 hours pass between insertion and intercourse or if you have intercourse again, insert more spermicide into the vagina without removing the diaphragm.
- Leave the diaphragm in place for at least 6 hours after the last intercourse. Leaving it in place for more than 24 hours increases the risk of toxic shock syndrome.
- Using the diaphragm during menstrual periods increases the risk of toxic shock syndrome.
- Douching with the diaphragm in place is unnecessary and lessens the effectiveness.
- To remove the diaphragm, assume a squatting position and bear down. Hook a finger around the front rim to break the suction, and pull down.

- Wash the diaphragm with mild soap and dry well after each use. Inspect it for holes by holding it up to a light or filling it with water. If you find a hole, use another contraceptive method and go to your health care provider for a new diaphragm.

pressure on the bladder and can remain in place for 48 hours. More spermicide is inserted into the vagina without removing the cap if intercourse is repeated. The nurse should teach the woman to feel her cervix to check placement before and after intercourse because the cap can become dislodged.

Cervical caps should not be removed for 8 hours after the last intercourse (Speroff & Darney, 2011). There is a loop to assist in removal. Caps should not be used during menses or in women with a history of toxic shock syndrome. Cap sizes are based on whether the woman has had past pregnancies and births.

Natural Family Planning Methods

Natural family planning methods, also called *fertility awareness* or *periodic abstinence methods*, use physiologic cues to predict ovulation so that women can determine when conditions are favorable for fertilization (Table 31-6). These methods can help women who wish to become pregnant (see Chapter 32) or avoid it.

Natural family planning helps women learn about how their bodies change throughout the menstrual cycle. It is acceptable to most religious groups and avoids the use of drugs, chemicals, and devices.

TABLE 31-6 NATURAL FAMILY PLANNING METHODS

METHOD	APPLICATION	COMMENTS
Calendar method	Subtract 18 days from shortest cycle and 11 days from longest cycle to determine fertile period.	Example: 28- to 32-day cycle = fertile between days 10 and 21.
Standard days method	Intercourse is safe only on days 1 through 7 and day 20 to the end of the cycle. Use a barrier method or abstain on days 8 through 19.	Ineffective if cycle length is shorter than 26 days or longer than 32 days.
Basal body temperature method	See "Women Want to Know: How to Assess Cervical Mucus and Basal Body Temperature."	Avoid intercourse until night of third day after temperature rise. Unreliable if used alone. Affected by illness, lack of sleep, stress.
Cervical mucus (ovulation or Billings) method	Assess mucus at vaginal orifice daily. Avoid intercourse during menses and from time mucus appears until 4 days after clear, slippery, stretchy mucus ends.	Intercourse is safe only every other day, as semen interferes with assessment of mucus.
Two-day method	Check for mucus each day. Fertility is determined by presence of cervical mucus on current or previous day.	Intercourse is avoided if woman notices any secretions at all.
Symptothermal method	Combine all above methods and assess weight gain, libido, bloating, and mittelschmerz.	Requires much education and motivation.

Couples must be highly motivated to use these methods because they must abstain from intercourse during as much as half the menstrual cycle. The method is very unforgiving, and errors in predicting ovulation may lead to pregnancy from intercourse during the fertile time. Some women use the method to determine when they are fertile and use a barrier contraceptive at that time.

Calendar

The calendar method is based on the timing of ovulation approximately 14 days before the onset of menses. The couple must abstain or use another method during the days calculated to be fertile. The method is unreliable because many factors such as illness or stress can affect the time of ovulation.

Standard Days Method

This method uses a string of color-coded beads to help keep track of the fertile and infertile days of each cycle. The woman begins with the first bead on the first day of menses. The method is designed for women with cycles that vary from 26 to 32 days in length but is ineffective for other women. Days 8 through 19 are considered fertile days.

Cervical Mucus

Also called the *ovulation* or *Billings method*, the cervical mucus technique is based on changes in cervical secretions caused by rising estrogen levels during the follicular phase of the menstrual cycle. The woman assesses cervical mucus by wiping it from the vaginal orifice with tissue each day. To prevent pregnancy, couples must avoid intercourse from the time the mucus is first present after menses until 4 days after the end of the slippery mucus.

Two-Day Method

The two-day method is a simpler form of the cervical mucus method. The woman checks for cervical secretions of any kind each day. If she notices any secretions on a given day or the day before, she considers herself fertile. If there were no secretions on either day, she can consider herself infertile (Jennings & Burke, 2011).

Symptothermal Method

The symptothermal method combines assessment of **basal body temperature** (BBT) (body temperature at rest) and cervical mucus daily. In addition, symptoms that occur near ovulation, such as weight gain, abdominal bloating, **mittelschmerz** (pain on ovulation), and increased libido are noted. This increases awareness of when ovulation occurs and increases effectiveness. Some women also use an electronic hormonal fertility monitor. It is designed for women trying to become pregnant but can also be used by women to avoid pregnancy by identifying fertile times.

- How do barrier methods of contraception work?
- What are the advantages and disadvantages of natural family planning methods?

Abstinence

Abstinence is avoidance of sexual intercourse and any activity that may allow sperm to enter the vagina. Although it is the only completely effective method of preventing pregnancy and STDs, abstinence requires perfect use to be effective. Depending on the time within the menstrual cycle it occurs, intercourse without the use of a contraceptive has up to an 85% chance of resulting in pregnancy. Most women are not abstinent all of their reproductive lives, but many practice abstinence at various intervals. Some women practice abstinence part of the time but have other methods available to use if they decide to become sexually active. Periodic abstinence is also practiced by women using the natural family planning methods.

Nurses should support women who choose to be abstinent. Sexual education programs in schools often include information on ways to maintain abstinence. Abstinence-only education programs have not been successful in reducing teen pregnancy (Speroff & Darney, 2011). Adolescents who choose abstinence need assistance to define their values and learn practical methods of reaching their goal. They need to consider just what this entails and when it might

WOMEN WANT TO KNOW

How to Assess Cervical Mucus and Basal Body Temperature

Cervical Mucus Assessment

Your cervical mucus normally changes throughout your menstrual cycle. If you check the mucus each day, you can estimate when ovulation occurs. Before and after ovulation, the mucus is scant, thick, sticky, and whitish. It stretches less than 2.3 inches (6 cm). Just before and for 2 to 3 days after ovulation, cervical mucus is thin, slippery, and clear and is similar to raw egg white. It stretches 2.3 inches (6 cm) or more, a quality called *spinnbarkeit*. When this mucus is present, you have probably ovulated and could become pregnant.

Use a tissue to obtain a small sample of mucus each day from just inside your vagina. Note the following:

- The general sensation of wetness (around ovulation) or dryness (not near ovulation) on your labia.
- The appearance and consistency of the mucus: thick, sticky, and whitish; or thin, slippery, and clear or watery.
- The distance the mucus will stretch between your fingers.

Your cervical mucus may be thicker if you take antihistamines. Vaginal infections, contraceptive foams or jellies, sexual arousal, and semen can make the

mucus thinner even if ovulation has not occurred. Keep a record of the type of mucus present each day and anything that might affect it.

To use cervical mucus assessment as a method of contraception, avoid intercourse from the time secretions first occur until 4 days after the slippery mucus ends. Intercourse is safe only every other day when there is no mucus because semen interferes with mucus assessment.

As a method to enhance conception, you should have intercourse every 2 days during the period of ovulatory mucus. Ovulation predictors available over the counter provide added information that may be helpful if you are trying to conceive.

Basal Body Temperature

Basal body temperature (BBT) is the lowest, or resting, temperature of the body. It is assessed to detect the slight elevation in temperature that occurs near the time of ovulation. During the first half of your menstrual cycle, your temperature is lower than it is during the second half of the cycle. The BBT may drop slightly just before ovulation. Not all women experience this fall in temperature.

Progesterone is secreted during the second half of the cycle, its level rising just after ovulation. This causes an increase in BBT. The BBT rises near ovulation and remains higher during the second half of the cycle. However, some women do not have a temperature rise even when they ovulate. BBT remains higher if conception occurs and falls about 2 to 4 days before menstruation if conception does not occur.

An electronic thermometer digitally displays temperature in tenths of a degree. You should place the thermometer under your tongue as soon as you awaken each morning and before any activity. It should remain in place until the electronic signal sounds. Record your BBT on a chart.

Also note events that may alter your BBT, such as menstrual periods, intercourse, illness, or other occurrences. BBT may be altered by illness, restless or inadequate sleep (fewer than 6 hours), waking later than usual, traveling across time zones (jet lag), alcohol intake the evening before, sleeping under an electric blanket, or performing any activity before taking the temperature.

As a method to avoid pregnancy, you should not have intercourse from the onset of your menstrual period until the night of the third day of elevated temperature. However, relying on cervical mucus is a better indicator of when intercourse is safe.

To enhance the chances of conception, this method has limited value because the rise in temperature indicates that ovulation has already occurred. It is helpful as a screening method to identify whether the woman is likely to be ovulating and if progesterone is secreted to prepare the endometrium for implantation.

be difficult to maintain abstinence. Role playing often is used to help them work through what to do and say before it becomes necessary.

Abstinence has no cost, avoids the use of hormones, and has no side effects or medical risks. It is important that users understand that abstinence must include all forms of sexual contact, including oral and anal intercourse, to avoid exposure to STDs. Women using abstinence should know where to get information and contraception if they decide to become sexually active at a later time.

Least Reliable Methods of Contraception

The following methods of contraception are not considered reliable but are used by women who lack information about their risks and other options or who do not wish to use other methods for medical or personal reasons. The nurse needs to be familiar with these methods to help women understand the risks involved.

Breastfeeding

Breastfeeding inhibits ovulation because suckling and prolactin interfere with secretion of gonadotropin-releasing hormone and luteinizing hormone. During lactation the ovarian response to follicle-stimulating hormone and luteinizing hormone may be altered. The frequency, intensity, and duration of suckling are very important in inhibiting ovulation.

Women who breastfeed fully with no supplementary feedings may avoid ovulation and resumption of menstrual cycles. However, use of formula or solid foods decreases the frequency and duration of breastfeeding, increases the length of time between feedings, and reduces night feedings. This may lead to ovulation and a return of menses. The menstrual cycle generally resumes by 6 months, even in women who breastfeed fully. Another method of contraception should be used by that time or earlier if menses has resumed or supplementary feedings are used.

Coitus Interruptus

Also called *withdrawal*, coitus interruptus is the removal of the penis from the vagina before ejaculation. The method requires great control by the man and may be unsatisfying to both partners. Even a man who wishes to use the method may misjudge the timing and withdraw too late. Sperm spilled on the vulva may enter the vagina and cause pregnancy.

APPLICATION OF THE NURSING PROCESS

■ Choosing a Contraceptive Method

Contraceptive failure often occurs because women lack knowledge about how to use their contraceptive methods correctly or choose methods unsuited to their needs. When contraception fails, the woman is exposed to the physical, psychological, and social consequences of unintended pregnancy. Lack of understanding also may expose her to unnecessary side effects, possible complications, or STDs.

Assessment

Because contraception is a very private matter, approach it in a sensitive manner. Perform the assessment in a quiet area where interruptions are unlikely, and keep voices low to increase the woman's comfort. Assure the woman that her confidentiality will be maintained.

Introducing the Subject

In the postpartum setting, introduce the subject by asking the woman if she plans to have more children. Most women indicate a desire to wait a certain period before the next pregnancy. Ask the woman, "What method of family planning are you thinking about using now?" or "How did you feel about the method you used before pregnancy?" These questions may identify problems that the woman has had with contraception in the past.

Introduce the topic during well-woman checkups by asking about the woman's current contraceptive method. In other settings, a woman may make some reference to her contraceptive method. The nurse can respond by asking her, "How do you like using (name method)?" This shows the nurse is interested if the woman wishes to pursue the topic.

Determining the Woman's Understanding

Determine the woman's understanding of her contraceptive technique. For example, ask where she places her patch or if it is hard for her to remember to take her OC each day. The woman should know how to use her technique effectively and what to do in special circumstances such as when she misses an OC pill. Explore any misinformation, concerns, or problems that she may have with regard to effectiveness, technique, or common side effects of the method.

Assessing the Woman's Satisfaction

Assess the woman's satisfaction with her contraceptive. Women may be unsure about their method in the early months until they gain comfort from repetitive use. Satisfaction and effectiveness increase with greater familiarity with the method. Side effects also affect satisfaction. They may be severe enough to cause the woman to consider another method, or they may be relieved by simple techniques. Talking about side effects helps differentiate serious complications from minor effects and leads to a discussion of relief methods.

Assessing Appropriate Choices

If the woman is considering a change in contraceptive method, assess factors that would help determine the best method for her. Include a history of medical conditions that might eliminate certain methods,

childbearing history, cultural and religious beliefs, and intensity of her desire to prevent pregnancy. The woman's ability to understand and follow complex directions is important as well.

The couple's relationship is important in terms of contraceptive choice and protection against STDs. If the relationship is mutually monogamous and neither partner is infected, STDs are not a risk. If there is a possibility that either member of the couple is infected or has more than one partner, condom use is essential, even if the woman uses another type of contraceptive.

Frequency of coitus may help determine the best choice of contraception. For occasional sexual intercourse, a barrier method may be most satisfactory. If intercourse is frequent, the woman may desire a method that is always in place, such as an IUD or a hormone implant. Explore her past experience with other methods, what she considers important, and her individual preferences.

Nursing Diagnosis

Lack of knowledge about family planning is common. A nursing diagnosis that addresses this problem is "Risk for Ineffective Health Maintenance related to lack of understanding about contraceptive methods chosen and available."

Expected Outcomes

Expected outcomes for this diagnosis are that the woman will:

- Correctly describe how to use her contraceptive method, including solving common problems.
- Describe common side effects, signs of complications, and correct follow-up.
- Report that she and her partner are satisfied with their contraceptive method or explore choosing another method.

Interventions

Interventions involve teaching about contraceptive techniques and follow-up of problems that may interfere with the woman's ability to maintain health.

Increasing Understanding of the Chosen Method

Fill in gaps in the woman's knowledge about how her contraceptive method works, its effectiveness, advantages and disadvantages, common side effects and complications, and when to seek help. Use demonstrations (such as applying a patch or inserting a vaginal ring) and return demonstrations for using the method. Give suggestions for managing side effects and common problems. Understanding common side effects and how to manage them often helps women continue to use a method.

Teaching about Other Methods

Provide information about other forms of contraceptives, if the woman wishes. Discuss characteristics of methods that are most important to the woman and her lifestyle. Compare other methods with the one she is currently using. Talk about benefits, disadvantages, and risks so that she can make an informed choice. If a prescription or fitting is needed for a new method, discuss what may happen during the visit. Provide written information she can take home to discuss with her partner, if she wishes, before making a final decision.

Protecting against Sexually Transmitted Diseases

Address defense against STDs, particularly if the woman is using a method that does not provide protection. This is a delicate subject. A way to approach it might be to say, "The method you are using is very effective against pregnancy but does not protect you against diseases such as HIV infection that you might catch from a partner. If there is

any chance that you or your partner might have sex with someone other than each other or that your partner might have an infection, you should protect yourself by using condoms along with your regular contraceptive.”

Including the Woman's Partner

Invite the woman to include her partner in the discussions, if possible. He may influence the woman's choice of contraception and whether she actually uses it and uses it correctly. If the partner understands the proper method of use, he may be more cooperative and willing to help ensure contraceptive success.

Providing Ongoing Teaching

Instruct the woman to call if she has any questions or difficulties. If she chooses a new contraceptive, suggest that she visit again in 1 to 2

months to discuss her satisfaction with it. Make a note in the chart to discuss contraception at her next visit, even if the visit is for another reason.

Evaluation

The woman should explain her contraceptive method, including ways to solve common problems and when to seek help for side effects or complications. At later visits, evaluate continued understanding, compliance with proper use, and satisfaction with the method. The woman who wishes to change her contraceptive method should describe other contraceptives available and how they should be used. She should choose a new method and, if necessary, visit a health care provider for further discussion, examination, fitting, or prescription.

SUMMARY CONCEPTS

- The average woman must consider use of contraception for more than 30 years.
- The nurse helps women with family planning by providing current, accurate information about contraception and assisting them to find methods that best meet their needs.
- Important issues in choosing contraceptives include safety, protection from STDs, effectiveness, acceptability, convenience, education needed, benefits, side effects, effect on spontaneity, availability, expense, preference, and religious and cultural beliefs.
- Because some methods have potentially serious complications, a written informed consent form may be necessary.
- Adolescents may lack knowledge about their own bodies, conception, and methods of contraception. Risk-taking behaviors are common.
- Adolescents feel more comfortable talking about contraception with nurses who have an accepting attitude, provide extra time to teach, and use understandable terms and visual aids.
- The most successful methods of contraception for adolescents are those unrelated to coitus.
- Women over 35 years who smoke and women who have other risk factors should not use combined oral contraceptives.
- Sterilization offers permanent contraception. A tubal ligation can be performed soon after childbirth or at any time. Vasectomy is less expensive and can be performed in the physician's office using local anesthesia. Surgery to reverse sterilization is possible but expensive and not always successful.
- Intrauterine devices are very effective and safe. Women must check for the device's threads each month and know when to seek medical treatment.
- Hormonal contraceptives include implants, injections, oral contraceptives, emergency contraception, patches, and vaginal rings. Side effects and complications make these unsuitable for some women.
- Oral contraceptives, the patch, and the ring may be used on a monthly basis, for extended cycles, or indefinitely to decrease menstrual periods.
- Emergency contraception helps protect against pregnancy if taken within 5 days after unprotected intercourse.
- Barrier methods may be chemical or mechanical. They kill or prevent sperm from entering the cervix and provide some protection against sexually transmitted diseases.
- Natural family planning methods involve avoidance of coitus when physiologic cues suggest that ovulation is likely. Women need high motivation and extensive education about their bodies to be successful with these methods.

Infertility

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe settings in which the nurse may encounter couples with infertility problems.
2. Explain factors that can impair a couple's ability to conceive.
3. Explain factors that may cause repeated pregnancy losses.
4. Specify evaluations that may be done when a couple seeks help for infertility.
5. Explain procedures and treatments that may aid a couple's ability to conceive and carry the fetus to viability.
6. Analyze ways in which infertility can affect a couple and other family members.
7. Summarize the nurse's role in caring for couples experiencing problems with fertility.

Infertility nursing is a specialty, but general practice nurses also meet couples who are seeking help or have had treatment for infertility in varied settings. The nurse's own friends and family members often turn to the nurse as a source of information when they have problems conceiving. Nurses working in the perioperative area may care for these couples during diagnostic or therapeutic surgery. Nurses in urology settings often see men who are being evaluated or treated for infertility. In the emergency department, nurses may care for women who are having a spontaneous loss of a hard-won pregnancy.

Nurses in antepartum, intrapartum, and postpartum settings often encounter women with high-risk pregnancies or couples who have a new baby after infertility therapy. In addition, parenthood after infertility is not always easy, and nurses in pediatric and psychosocial settings may counsel families about parenting and changes in their personal relationships.

EXTENT OF INFERTILITY

The extent of infertility depends on its definition. Infertility is not an absolute condition but is a reduced ability to conceive. **Infertility** is strictly defined as the inability to conceive after 1 year of unprotected, regular sexual intercourse. A more workable definition does not specify a time limit but recognizes that infertility is any involuntary inability to conceive when desired. The definition is commonly expanded to include couples who conceive but repeatedly lose a

pregnancy (pregnancy wastage) before the fetus is old enough to survive. Couples with primary infertility have never conceived. Couples with secondary infertility may have conceived before but are unable to conceive again.

About one in six couples of reproductive age cannot have a baby when they desire, and the number is increasing with the intentional delay in childbearing. *The National Survey of Family Growth (2012)* reported that about 36% of married women and 9% of cohabiting women were involuntarily childless. Couples who delay childbearing until their mid to late 30s or later may feel pressured by the approaching end of the woman's reproductive years. A woman with no male partner may seek infertility help before she runs out of time. To older couples, delay in achieving pregnancy or having a living baby is more significant than for young couples, who have more time to pursue pregnancy and make treatment decisions. As new methods of diagnosis and treatment emerge, couples who once accepted childlessness may enter infertility therapy or resume therapy they abandoned (Martinez, Daniels, & Chandra, 2012; Mahomed, 2011; Morgan, Merrell, Rentschler et al., 2012).

FACTORS CONTRIBUTING TO INFERTILITY

Conception depends not only on normal reproductive function in each partner but also on a sensitive interaction between the partners. For some couples, identification and treatment of infertility are

simple, but others require complex evaluation and treatment. Some couples delay childbearing until their mid to late 30s, when a natural decline in fertility begins. As improved diagnostic and treatment options become available, couples who might have accepted childlessness may enter infertility therapy or resume therapy they had abandoned. Women who want to have a child without a male partner may be served by infertility services. About one third of infertility cases are male factor, one third are female factor, and one third are a combination of the two (American Society for Reproductive Medicine [ASRM], 2012).

Because some factors contributing to infertility remain unknown, treatment of an identified problem does not always lead to a successful pregnancy. For example, it may be likely that a couple will be infertile because of problems in either or both partners, yet the couple nevertheless has several children. About 20% of infertile couples have no identified problem, yet some never conceive despite having undergone all available treatments.

Factors in the Man

The test of a man's fertility is his ability to initiate pregnancy in a fertile woman. Few absolute criteria exist to distinguish normal from abnormal male fertility, although an adequate number of sperm having normal structure and function must be deposited near the woman's cervix. Problems may exist with the sperm, erection, or ejaculation of **semen** or the seminal fluid that carries the sperm into the woman's reproductive tract.

Abnormalities of the Sperm

Other conditions are permanent, such as a genetic disorder. One or more findings may be abnormal. Further complicating evaluation of a man's fertility are the normal daily variations in semen.

Evaluation of the semen may reveal that the man has **azoospermia** (sperm absent in semen) or **oligospermia** (decreased sperm in semen). The average number of sperm released at ejaculation is 35 million to 200 million but varies between 150 million and 600 million in a typical ejaculate. Twenty million sperm per milliliter of semen is considered the minimum number adequate for unassisted fertilization (Hall, 2011; Jones, 2009b). Liquefaction of the semen occurs within approximately 30 minutes, allowing motile sperm to move into the uterus without the seminal fluid. A sufficient number of normal sperm must move in a purposeful direction to reach the ovum in the fallopian tube. Semen analysis (Table 32-1) is used to evaluate whether the quantities and qualities of sperm and the seminal fluid are likely to result in successful conception, assuming that the woman's studies are normal. Abnormal sperm structure or movement may reduce fertility, regardless of the actual number of sperm (Figure 32-1). Inflammatory processes in the man's reproductive organs may cause the sperm to clump, inhibiting their motility and fertilizing ability. Other sperm may have a normal appearance but may not be able to penetrate the ovum.

Factors that can impair the number and function of the sperm include the following:

- Abnormal hormonal stimulation of sperm production
- Acute or chronic illness such as mumps, cirrhosis, or renal failure
- Infections of the genital tract
- Anatomic abnormalities such as a varicocele or obstruction of the ducts that carry sperm to the penis
- Exposure to toxins such as lead, pesticides, or other chemicals
- Therapeutic treatments such as antineoplastic drugs or radiation for cancer
- Excessive alcohol intake
- Use of illicit drugs such as marijuana or cocaine

FIG 32-1 Abnormal infertile sperm compared with a normal sperm on the left. (From Hall, J.E. [2011]. *Textbook of medical physiology* [12th ed., p. 1001]. Philadelphia: Saunders.)

- An elevated scrotal temperature resulting from febrile illness, repeated use of saunas or hot tubs, or sitting for prolonged periods of time
- Immunologic factors, produced by the man against his own sperm (autoantibodies) or by the woman, causing the sperm to clump or be unable to penetrate the ovum

Abnormal Erections

Abnormal erections reduce the man's ability to deposit sperm-bearing seminal fluid in the woman's upper vagina. Erections are influenced by physical and psychological factors. Central nervous system dysfunction, which may be caused by drugs, psychiatric disturbance, or chronic illness, can interfere with erections. Surgery and disorders affecting the spinal cord or the autonomic nervous system also may disrupt normal erections. Peripheral vascular disease reduces the amount of blood entering the penis and thereby reduces the ability to maintain an erection. Drugs such as antihypertensives or antidepressants may reduce the erection or shorten its duration.

Abnormal Ejaculation

Abnormal ejaculation prevents deposition of the sperm in the ideal place to achieve pregnancy. **Retrograde** ejaculation is the release of semen backward into the bladder rather than forward through the tip of the penis. Conditions that may cause retrograde ejaculation are diabetes, neurologic disorders, surgery that impairs function of the sympathetic nerves, and drugs such as antihypertensives and psychotropics. Men who have suffered spinal cord injury may retain the ability to ejaculate, depending on the level of cord damage.

Anatomic abnormalities such as hypospadias (urethral opening on the underside of the penis) may cause deposition of semen near the vaginal outlet rather than near the cervix.

Excessive alcohol intake or use of some therapeutic or illicit drugs can adversely affect ejaculation as well as sperm number and function. Ejaculation may be slow, absent, or retrograde when a man takes drugs that affect neurologic coordination of this event. Premature ejaculation is usually related to psychological disorders such as performance anxiety or unresolved conflicts.

Abnormalities of Seminal Fluid

The seminal fluid nourishes, protects, and carries sperm into the vagina until they enter the cervix. Only sperm enter the cervix; the

TABLE 32-1 SELECTED DIAGNOSTIC TESTS ON INFERTILITY

TEST AND PURPOSE	NURSING IMPLICATIONS
<p>Male</p> <p>Semen Analysis</p> <p>Evaluates structure and function of sperm and composition of seminal fluid. Semen volume: 2 mL or more. pH: 7.2-7.8. Sperm concentration: 20 million/mL or more. Motility: 50% or more with normal forms. Morphology: 30% or more with normal forms. Viability: 50% or more live. Liquefaction: within 30 min. Leukocytes (white blood cells): fewer than 1 million/mL.</p> <p>Endocrine Tests</p> <p>Evaluate function of hypothalamus, pituitary gland, and response of testicles. Assays are made to determine testosterone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) levels. Additional tests may be done based on history, physical findings, and results of other tests.</p> <p>Ultrasonography</p> <p>Evaluates structure of prostate gland, seminal vesicles, and ejaculatory ducts by use of a transrectal probe.</p> <p>Testicular Biopsy</p> <p>An invasive test for obtaining a sample of testicular tissue; identifies pathology and obstructions.</p> <p>Sperm Penetration Assay</p> <p>Evaluates fertilizing ability of sperm; assesses ability of sperm to undergo changes that allow penetration of a hamster ovum from which the zona pellucida has been removed. Infrequent use.</p>	<p>Explain purpose of semen analysis: three or more specimens are usually collected over several weeks for improved accuracy.</p> <p>Explain to the man that he should collect the specimen by masturbation after a 3-day abstinence; semen may be collected in a condom if masturbation is unacceptable.</p> <p>Teach him to note the time the specimen was obtained so the laboratory can evaluate liquefaction of the semen. To maintain warmth, the specimen should be transported near the body and should arrive in the laboratory within 30 min.</p> <p>Teach the man about the relationship between hypothalamic and pituitary function and sperm formation; LH stimulates testosterone production by Leydig cells of the testes, and FSH stimulates Sertoli cells of the testes to produce sperm.</p> <p>Teach the man that ultrasonography uses sound waves to evaluate these structures; no radiation is involved.</p> <p>Explain the purpose of the test; a local anesthetic is used, and there should be little discomfort. Ask the man questions to confirm that he understands the test.</p> <p>Explain the purpose of the test and that abnormal penetration of the hamster ovum does not necessarily mean that the sperm cannot fertilize a human ovum.</p>
<p>Female</p> <p>Ovulation Prediction</p> <p>Identifies the surge of LH, which precedes ovulation by 24 to 36 hr; improves ability to time intercourse to coincide with ovulation, and identifies the absence of ovulation. Common prediction methods include commercial ovulation predictor kits and cervical mucous assessment (see Women Want to Know, p. 697). Basal body temperature (BBT), or temperature at rest, may be used to identify if ovulation has occurred and the timing of intercourse in relation to probable ovulation.</p> <p>Ultrasonography</p> <p>Evaluates structure of pelvic organs. Evaluates cyclic endometrial changes. Identifies ovarian follicles and release of ova at ovulation. Evaluates for presence of ectopic or multifetal pregnancy.</p> <p>Hysterosalpingogram (HSG)</p> <p>Gentle injection of contrast medium into the cervix while imaging the pelvis to visualize passage of the dye through the uterus and fallopian tubes.</p> <p>Postcoital Test</p> <p>Evaluates characteristics of cervical mucus and sperm function within that mucus at time of ovulation. Ultrasonography ensures proper timing for test.</p>	<p>Explain the purpose of the assessments.</p> <p>Teach the woman to follow the instructions on commercial ovulation predictor.</p> <p>Teach her how to do the basal body temperature and cervical mucous assessment if that is used. Teach her to indicate days on which she and her partner had intercourse to identify frequency during the menstrual cycle and intercourse near ovulation.</p> <p>Teach the woman that ultrasonography uses sound waves to evaluate these structures; no radiation is involved. Explain preparations needed for specific evaluations.</p> <p>Review purposes of the imaging test to determine if the woman understands the procedure.</p> <p>Ultrasound imaging will use different contrast medium than radiographic.</p> <p>Explain that the test is performed 6 to 12 hr after intercourse; the woman may have to rearrange her personal or work commitments each time this test is done. Use is infrequent because of stress on the woman and her partner.</p>

Data from Lobo, R.A. (2012). Infertility: Etiology, diagnostic evaluation, management, prognosis. In G.M. Lentz, R.A. Lobo, D.M. Gershenson & V.L. Katz (Eds.), *Comprehensive gynecology* (6th ed., pp. 869-895). St. Louis: Elsevier; and Pagana, K.D., & Pagana, T.J. (2011). *Diagnostic and laboratory test reference* (10th ed.). St. Louis: Elsevier Mosby.

seminal fluid remains in the vagina. Semen coagulates immediately after ejaculation but liquefies within 60 minutes, permitting forward movement of sperm. Seminal fluid that remains thick traps the sperm, impeding their movement into the cervix. The pH of seminal fluid is slightly alkaline to protect the sperm from the acidic secretions of the vagina. Adequate fructose, citric acid, and other nutrients must be present to provide energy for the sperm.

The specific abnormality found in the seminal fluid suggests the cause of the abnormality, such as obstruction or infection in a specific area of the genital tract. Seminal fluid that is abnormal in amount, consistency, or chemical composition suggests obstruction, inflammation, or infection. The presence of large numbers of leukocytes suggests infection.

CHECK YOUR READING

1. How is infertility defined? What is the difference between primary and secondary infertility?
2. What are normal characteristics of sperm and the seminal fluid that carries sperm into the woman's vagina?
3. What problems in the man can occur with erection? With ejaculation of semen?
4. What can cause abnormalities in the sperm, ejaculation, and seminal fluid?

Factors in the Woman

A woman's fertility depends on the following:

- Regular production of normal ova
- An open path from her cervix through the fallopian tube to permit fertilization and movement of the embryo into the uterus for implantation
- A uterine endometrium that supports the pregnancy after implantation

See [Chapter 4](#) for a complete discussion of the interrelated factors that contribute to normal female fertility.

Disorders of Ovulation

Normal ovulation depends on delicately timed and balanced secretions from the hypothalamus and pituitary gland and on an ovarian response to cause maturation and release of an ovum. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) beginning even before the obvious changes of puberty. GnRH stimulates the pituitary to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH stimulates maturation of several follicles in the ovary. As the follicles mature, the ovary secretes estrogen to thicken the endometrium. About 24 to 36 hours before ovulation, a marked increase of LH level occurs, which stimulates final maturation and release of one ovum from its follicle. The other follicles regress permanently. The collapsed follicle from which the ovum was released, now called a *corpus luteum*, produces progesterone and estrogen, which further prepare the endometrium for implantation and nourishment of the fertilized ovum.

Ovulation can be disrupted by many factors, including the following:

- A dysfunction in the hypothalamus or pituitary gland that alters the secretion of GnRH, FSH, and LH
- Failure of the ovaries to respond to FSH and LH stimulation, preventing maturation and release of the ovum

Disruption of hormone secretion or of the ovarian or endometrial responses to hormone secretion can be caused by many factors, such as cranial tumors, stress, obesity, anorexia, systemic disease, and

abnormalities in the ovaries or other endocrine glands. Women with polycystic ovarian syndrome (PCO or PCOS) often have infertility in addition to other problems with abnormal hormone effects and ovarian function. A few women have premature ovarian failure, also known as *early menopause*.

As a woman approaches the end of her reproductive life, also known as the **climacteric**, she ovulates and menstruates more erratically as her pool of ova diminishes and fewer are available for fertilization. Oocytes are produced only during prenatal life and are vulnerable to cumulative toxic effects of therapeutic drugs, abused substances, and environmental agents. In addition to normal aging of oocytes and menstrual cycles, factors that may impair normal ovulation include cancer chemotherapeutic agents, excessive alcohol intake, and cigarette smoking.

Women with ovulation disorders often have abnormal menses because hormone levels do not permit normal development and shedding of the endometrium. The woman may have absent, scant, or heavy menstrual periods. However, other women may have no menstrual disorders, and the inability to conceive may be their only complaint.

Abnormalities of the Fallopian Tubes

At least one open fallopian tube is needed for natural conception and implantation to occur ([Figure 32-2](#)). Tubal obstruction may occur because of scarring and adhesions after reproductive tract infections. Infections such as chlamydia, gonorrhea, and other sexually transmissible diseases (STDs) are responsible for many cases of infertility from tubal obstruction. Prevention or prompt treatment and eradication of pelvic infections can reduce the incidence of fallopian tube damage.

Endometriosis (uterine lining tissue outside the uterine cavity) may cause tubal adhesions, painful menstrual periods, and painful intercourse. Small lesions are unlikely to affect tubal function, but large lesions can distort tubal anatomy and lead to infertility. See [Chapter 34](#), [p. 737](#), for more information about endometriosis.

Tubal obstruction may occur if adhesions develop after pelvic surgery, ruptured appendix, peritonitis, or ovarian cysts. In addition,

FIG 32-2 A radiographic hysterosalpingogram (HSG) evaluates patency of fallopian tubes. Contrast medium that was injected through the cervix spills out of the fallopian tubes into the peritoneal cavity if tubes are open. Sonohysterographic technique with ultrasound is becoming more common and uses contrast medium with hypoechoic effects. (From Meldrum, D.R. [2010]. *Infertility and assisted reproductive technologies*. In N.F. Hacker, J.C. Gambone, & C.J. Hobel [Eds.], *Hacker & Moore's essentials of obstetrics and gynecology* [5th ed., pp. 371-378]. Philadelphia: Saunders.)

the fallopian tubes and other reproductive organs may have congenital anomalies that disrupt normal function.

The conditions that cause obstruction may interfere with normal motility within the fallopian tube. Poor movement of the fimbriated (distal) end of the tube may prevent the ovum from being picked up at the ovarian surface after ovulation. Abnormal action of the cilia within the tube prevents normal transport of the ovum toward the uterine cavity.

Depending on the extent and location of the blockage, fallopian tube obstructions can prevent fertilization of the ovum or lead to an ectopic pregnancy. Complete tubal occlusion prevents fertilizing sperm from reaching the ovum, and the woman will be **sterile**, or have a total inability to conceive, without the use of advanced techniques such as in vitro fertilization (IVF). Partial obstruction may result in a tubal ectopic pregnancy because sperm can reach the ovum to fertilize it but the embryo cannot reach the uterine cavity to implant.

Abnormalities of the Cervix

Estrogen levels from the ovary peak twice during the menstrual cycle, once before ovulation and again about 1 week after ovulation. The first peak occurs about 2 days before ovulation and causes the woman's cervix to dilate slightly and produce a clear, thin, slippery mucus that is similar to egg white in consistency (**spinnbarkeit**). This mucus facilitates passage of sperm into the uterus and capacitation to prepare one sperm for fertilization. Low estrogen levels prevent development of this mucus and are usually associated with **anovulation** (menstrual cycles that occur without ovulation). See also p. 697 and pp. 735–736.

Polyps or scarring from past surgical procedures such as cauterization or conization may obstruct the woman's cervix. Abnormal cervical mucus caused by estrogen deficiency, surgical destruction of the mucus-secreting glands, and cervical damage secondary to infection or other factors prevent normal capacitation and movement of the sperm into the uterus and fallopian tubes for fertilization.

7. What are some causes of fallopian tube obstruction?
8. How do abnormalities of cervical mucus contribute to infertility?

Repeated Pregnancy Loss

Couples who repeatedly lose pregnancies have the same result as those unable to conceive: no living child after conception. Repeated losses may result from abnormalities in the fetus or placenta or from maternal factors.

Abnormalities of the Fetal Chromosomes

Errors in the fetal chromosomes may result in spontaneous abortion, usually in the first trimester. Chromosome abnormalities often severely disrupt development, and the embryo or fetus cannot survive to live birth. Maternal age–associated chromosome abnormalities in the ova increase spontaneous abortions and decrease live births in women who conceive.

Most chromosome abnormalities are sporadic, occurring randomly. Others occur because one parent has a balanced chromosome translocation that is passed on to the offspring. The parent with the balanced translocation has a normal total amount of chromosome material, but the chromosome material is rearranged. When the chromosomes are divided during **gametogenesis** (development and

FIG 32-3 Types of uterine malformations that may cause infertility or repeated pregnancy loss.

maturation of sperm and ova), the resulting sperm or ovum may receive too much or too little chromosome material, or it may receive a balanced translocation like the parent. The sperm or ovum also may receive a normal chromosome complement with no translocation. (See [Chapter 5](#) for more information about chromosome abnormalities that may affect fertility.)

Abnormalities of the Cervix or Uterus

Stenosis or congenital malformations of the cervix or uterine cavity may cause repeated loss of a normal embryo or fetus ([Figure 32-3](#)). These malformations may prevent normal implantation of the fertilized ovum or normal prenatal growth of the placenta or fetus. Others may increase the risk for miscarriage or birth before the fetus is viable.

Women who were exposed prenatally to diethylstilbestrol (DES), prescribed to pregnant women as recently as the early 1970s to prevent several pregnancy complications, are more likely to have uterine malformations or an **incompetent cervix** (will not remain closed). Cervical or uterine abnormalities and possibly hysterectomy also may occur after surgery or trauma from a previous birth. Painless and premature cervical dilation, often early in the second trimester, is characteristic in women with an incompetent cervix. Although the woman may conceive, she may be unable to carry the pregnancy long enough to survive if born. DES effects may be seen in a woman with gynecologic problems past childbearing years.

Uterine myomas (benign tumors of the uterine muscle) and adhesions inside the uterine cavity may cause repeated fetal losses. These problems can alter the blood supply to the developing fetus or cause uterine irritability that results in preterm labor and birth. Myomas on the outer surface of the uterus are often obvious but may not cause the complications that inner myomas may cause.

Endocrine Abnormalities

Inadequate progesterone secretion by the corpus luteum (luteal phase defect) prevents normal thickening of the endometrium for

implantation and establishment of the placenta. The embryo may not implant, or it may implant poorly. In other cases, the corpus luteum may develop and function properly but the woman's endometrium may not respond to its progesterone secretion.

Hypothyroidism and hyperthyroidism may be associated with the inability to conceive and with recurrent pregnancy loss. Poorly controlled diabetes can result in repeated pregnancy loss and many other complications of pregnancy because of its effects on maternal blood glucose levels and the vascular system (see [Chapter 26](#)).

Immunologic Factors

Immunologic factors are implicated in some cases of recurrent pregnancy loss, although not all are established conclusively. The embryo has antigens different from those of the mother and ordinarily would be rejected like any other foreign tissue. However, the mother's body normally blocks this rejection response and tolerates the developing baby. Some women's bodies respond inappropriately to the embryo, rejecting it as any other foreign tissue. These women often have recurrent spontaneous abortions.

Women with autoimmune disease such as systemic lupus erythematosus (SLE) are more likely to experience fetal loss. Pregnancy loss in these women appears related to thrombosis or other damage in placental blood vessels. Women with SLE often have other complications during pregnancy, such as exacerbation of their symptoms, fetal heart block, nonreassuring fetal status on antepartum tests or labor monitoring, and fetal death (see also [Chapter 26](#)).

Environmental Agents

Some environmental agents have a well-established relationship to impairment of fertility and pregnancy loss. Others are believed to be damaging but do not show a conclusive link to pregnancy loss. In addition, the amount of exposure (dose) relates to the pregnancy outcome in most cases. For example, radiation exposure in the form of a chest radiograph is unlikely to have an adverse effect on pregnancy, whereas the larger doses used for cancer therapy might be toxic.

Examples of established toxins are ionizing radiation, alcohol, and isotretinoin (Accutane). Suspected or known toxins are numerous—for example, cigarette smoke, anesthetic gas, chemicals such as organic solvents or pesticides, and lead and mercury in occupational settings. These agents may be directly toxic to the embryo or fetus, causing its death, or they may interfere with the normal placental function necessary to sustain the pregnancy.

Infections

Infections of the reproductive tract are associated with general complications of pregnancy, and they also may be related to early pregnancy losses. These infections often are asymptomatic, making their diagnosis and link to pregnancy loss difficult to establish. [Chapter 26](#) provides greater details about significant infections affecting pregnancy.

10. What endocrine factors can cause repeated pregnancy loss?
11. What known immunologic factors may cause loss of a normal fetus?

EVALUATION OF INFERTILITY

[Devine \(2003\)](#) has likened the infertility evaluation to reading a mystery novel, moving from the simpler evaluations to the more

complex ones. Couples are often in a hurry for definitive therapy, but a thorough assessment of their problem is essential for effective and financially sound treatment. Some tests, such as semen evaluation, must be repeated sequentially for an accurate picture. Even a targeted, or focused, evaluation is frustrating to many couples, especially those who are anxious for a child before the end of the woman's reproductive years. In addition, the usefulness and well-accepted normal values are not yet established for some tests, and other diagnostic tests are investigational. Despite many examinations and tests, infertility may remain unexplained in couples who seek care ([Lobo, 2012](#)).

Infertility specialists use histories, physical examinations, and diagnostic testing to identify the best course of treatment. The proposed treatments will consider the couple's ages, especially the woman's, and the results of their histories, physical examinations, and diagnostic testing. Therapy often requires a series of steps rather than a single treatment.

The evaluation and care of infertile couples may involve numerous professionals: nurses, physicians specializing in reproductive medicine, gynecologists, genetic counselors, urologists, microsurgons, embryologists, and ultrasonographers. In addition, general and specialized laboratory facilities may provide diagnostic services. Nutrition counseling may be needed to support other therapy. Psychological counseling may be offered to help the couple deal with personal issues such as the probability of success with therapy or their anticipated ages when their child reaches adulthood. Nurses working in infertility clinics often coordinate communication among the many providers and help the couple negotiate the maze of evaluation and treatment.

Preconception Counseling

Couples may be offered preconception counseling to help them evaluate their risk for birth defects and perhaps reduce their risk for bearing a child with a serious birth defect. Many women seeking infertility care are older than 35, an age at which having an infant with a chromosome defect increases (see [Chapter 5](#)). A thorough history and physical examination of both members of the couple, including their family histories, may identify increased risk for having a child with a single-gene defect. Counseling can help the woman understand *before conception* the importance of an adequate diet and avoidance of teratogens that can harm the developing fetus before she knows she is pregnant.

History and Physical Examination

A thorough history and physical examination of each partner can help identify the appropriate diagnostic tests and therapy and identify risks for birth defects in the couple's offspring.

HISTORY

A reproductive history including the following is taken for the partners:

- The woman's menstrual pattern, including age at onset, and menstrual characteristics (frequency, regularity, duration, amount of flow, presence of pain)
- Any pregnancies, complications, and their outcomes
- Contraceptive methods, past and present
- Previous fertility of the man or woman with other partners
- Pattern of intercourse in relation to the woman's cycles
- Length of time the couple has had intercourse without using contraception
- Exposure to potential toxins; prescribed and over-the-counter medications

- Family history of multiple pregnancy losses, birth defects, or mental retardation
- Home tests the couple has used, such as over-the-counter ovulation predictor kits
- Past surgeries, pelvic inflammatory disease, STDs, abnormal Pap tests and treatment

The past medical history, including childhood illnesses and surgery, and a history of exposure to toxins may give clues about the cause of infertility. The couple's past and present occupations may identify toxin exposure, stresses, or other adverse influences on reproduction. Investigation of their usual frequency and timing of intercourse may identify the need for a change to promote conception at the time of ovulation.

Physical Examination

Couples who seek help for infertility are usually healthy. However, a thorough physical examination of each partner may identify endocrine disturbances, cranial tumors, or undiagnosed chronic disease. Examination of the reproductive organs may reveal structural defects, infection, cysts, or other abnormalities. Chromosomal analysis or maternal blood clotting studies may be done for couples experiencing repeated pregnancy loss.

Diagnostic Tests

Each couple's evaluation is individualized, but, based on the history and physical examinations, testing generally proceeds from the tests that are simple, least invasive, and less expensive to the more complex and expensive diagnostics expected to pinpoint the problem. Simple evaluations are done simultaneously, but more complex tests are delayed until their need is established.

Early evaluation for both partners may include the following:

- Ovulation monitoring kit to identify if ovulation has occurred
- Evaluation of the cervical mucus to identify changes that occur with ovulation
- Hormone evaluations such as estrogen, progesterone, LH, FSH, thyroid function
- Ultrasound imaging of internal reproductive organs
- Radiographic imaging to visualize the uterine cavity and fallopian tubes
- Semen analysis
- Testicular biopsy

Table 32-1 (p. 704) describes diagnostic tests that may be offered to an infertile couple and the nursing care associated with each.

Therapies to Facilitate Pregnancy

Evaluation of the couple identifies whether therapy might improve their chances to conceive and complete a pregnancy. A variety of procedures may be used, depending on the couple's initial and ongoing evaluations and their personal choices. Some therapy is simple, such as timing intercourse to better coincide with ovulation. Other procedures may involve considerable expense, discomfort, or unpleasant side effects. Many infertile couples need a combination of treatments to improve their chances of conception.

Identification of appropriate infertility therapy is not always straightforward. Many factors must be considered, including the couple's history, medical evaluations, financial resources, ages and other time constraints, and religious and cultural values. Simple treatments are indicated before more complex ones, but the needs of each couple are considered individually. More aggressive diagnostic testing and therapy may be appropriate if the woman is approaching the end of her reproductive years.

INFERTILE COUPLES WANT TO KNOW

What Is Infertility Treatment Like?

General

Both members of the couple are evaluated systematically to identify the most time- and cost-effective therapy.

Simpler evaluations and therapies are done before more complex efforts are undertaken.

A complete medical history is taken and physical examination performed for each partner.

The ages of the partners, particularly the woman's, are considered. Evaluations and therapy proceed more quickly if the woman is in her mid 30s or older.

Costs may be partially covered by insurance; check to see what your insurance covers.

Difficult decisions may be required at different times during evaluation and treatment. Decisions might include whether to proceed to more complex and expensive tests and therapies, whether to take a break from treatment, or whether to abandon treatment altogether.

Infertility treatment can be stressful, can occupy many hours per week, and requires a substantial commitment to self-care.

Infertility remains unexplained in as many as 20% of couples.

Internet resources for infertility include the Centers for Disease Control and Prevention (www.cdc.gov), American Society for Reproductive Medicine (www.asrm.org), and Society for Assisted Reproductive Technology (www.sart.org).

Men

Semen analysis is usually the first test. Several semen specimens are obtained over several weeks for the best evaluation.

Depending on the man's medical history, physical examination findings, and semen analysis, other diagnostic tests may be done (hormone assay, an ultrasound of the reproductive organs, a biopsy of the testicles, and specialized tests of sperm function).

Corrective measures may include medications, surgery, and methods to reduce the scrotal temperature.

Women

The first evaluation is usually to determine whether the woman is ovulating each month. An ovulation predictor kit is most often used for this purpose. Self-assessment of basal body temperature and cervical mucus may also be taught. These assessments are often done at the same time as other tests.

Other common evaluations include ultrasound or x-ray imaging of the uterus and the fallopian tubes to determine their patency. Contrast media specific to the imaging technique help identify patency or obstructions to the reproductive tract.

For some tests and therapies, an operative procedure is required (e.g., hysteroscopy, laparoscopy, laser surgery, and microsurgery).

Typically, infertility evaluations and treatments require more of the woman's time, energy, physical discomfort, and risk than the man's.

Corrective measures depend on the problem identified. Examples include medications, surgery, and advanced reproductive techniques, such as in vitro fertilization.

Statistical success rates for various procedures often are difficult for couples to evaluate and vary widely among facilities. Factors that affect a center's success rate for a procedure are numerous. For example, a referral center that is willing to help couples with long-standing infertility may have lower success rates than one that accepts only couples with less severe problems.

TABLE 32-2 SELECTED MEDICATIONS USED IN INFERTILITY THERAPY

DRUG	PRIMARY USE
Bromocriptine (Parlodel); cabergoline (Dostinex)	Corrects excess prolactin secretion by anterior pituitary, improving gonadotropin-releasing hormone (GnRH) secretion, in turn, normalizing release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). These drug actions increase ovulation and support early pregnancy by stimulating progesterone secretion by the corpus luteum.
Chorionic gonadotropin, human (hCG; [Novarel, Pregnyl]); recombinant deoxyribonucleic acid (DNA) origin (r-hCG; [Ovidrel])	Used in conjunction with gonadotropins to stimulate ovulation in the female or sperm formation in the male. Stimulates progesterone production by corpus luteum.
Clomiphene citrate (Clomid) Letrozole (Femara)	Induction of ovulation in women who have specific types of ovulatory dysfunction. Drug increases frequency of GnRH secretion from the hypothalamus, thus increasing FSH and LH release, maturing the ovarian follicle, and causing release of the ovum.
FSH, recombinant DNA origin (follitropin [Gonal-F])	Stimulation of ovarian follicle growth; ovulation-induction gonadotropin.
GnRH antagonists (e.g., cetrorelix [Cetrotide], ganirelix [Antagon])	Reduces endometriosis; adjunct to drugs given to stimulate ovulation by suppressing LH and FSH, reducing ovarian hyperstimulation.
GnRH agonists (goserelin [Zoladex], leuprolide [Lupron], nafarelin [Synarel])	Stimulates release of FSH and LH from the pituitary gland in men and women who have deficient GnRH secretion by their hypothalamus. FSH and LH, in turn, stimulate ovulation in the female and stimulate testosterone production and spermatogenesis in the male.
Gonadotropins (Bravelle, Humegon, Pergonal, Repronex)	Induction of ovulation with human-derived FSH and LH; brands may differ in the proportions of FSH to LH; recombinant DNA preparations are becoming more common because of their greater purity.
LH, recombinant DNA origin	Replacement of LH via subcutaneous pump; promotes ability of mature ovarian follicle to rupture and luteinize when hCG is secreted.
Progesterone (parenteral or vaginal preparations)	Luteal phase support; prepares uterine lining and promotes implantation of embryo.
Metformin (Glucophage)	Adjunctive treatment for ovulation induction in women with polycystic ovary syndrome.
Erectile agents (sildenafil [Viagra], tadalafil [Cialis], vardenafil [Levitra])	Increase blood flow to the penis, improving erectile function.

Data from Lobo, R.A. (2012). Infertility: Etiology, diagnostic evaluation, management, prognosis. In G.M. Lentz, R.A. Lobo, & D.M. Gershenson, V.L. Katz (Eds.), *Comprehensive gynecology* (6th ed., pp. 869-895). St. Louis: Elsevier Mosby.

Medications

Hormones and other medications may be given to either the man or the woman. A medication may be given to improve semen quality, induce ovulation, prepare the uterine endometrium, or support the pregnancy once it is established. Medications may be given to correct infections or endometriosis. Others may help men for whom **erectile dysfunction** (also known as **impotence** or the consistent inability to achieve or maintain a sufficiently rigid penis) is the primary problem. [Table 32-2](#) summarizes many of the medications used in infertility therapy.

Medications to induce ovulation may be prescribed for the woman who does not ovulate or who ovulates erratically. Medications may also be given to provide multiple ova if a woman plans to have intrauterine insemination, in vitro fertilization, gamete intrafallopian transfer, or tubal embryo transfer. Progesterone vaginal suppositories or clomiphene citrate (Clomid) is often used to stimulate follicle development. Human chorionic gonadotropin (hCG) can then be given to induce release of several ova. Human menopausal gonadotropin (hMG) may be injected in small regular pulses for pituitary insufficiency of LH and FSH, similar to use of an insulin pump.

Ovulation induction, also known as *superovulation*, increases the risk of multiple births because several ova may be released and fertilized. Another serious complication is *ovarian hyperstimulation syndrome*, which involves marked ovarian enlargement with exudation of fluid and protein into the woman's peritoneal and pleural cavities. Adjustment of medication dosage and serial ultrasound examinations to determine the number of mature follicles reduce the occurrence of high-order multifetal pregnancy (triplets or more) and ovarian hyperstimulation syndrome.

Surgical Procedures

Endoscopic procedures may be used to correct obstructions with minimal invasiveness in either the man or the woman. The woman may need a laparotomy to relieve pelvic adhesions and obstructions caused by endometriosis, infection, or previous surgical procedures if these cannot be corrected via laparoscopy. Laser surgical techniques may be used to reduce adhesions because they are minimally invasive, precise, and less likely to cause new adhesions. Correction of a **varicocele**, an abnormal dilation or varicosity, by ligating or embolizing the dilated vein may improve sperm quality and quantity, although there is not a consensus on its usefulness. Microsurgical techniques may be attempted for correction of obstructions in the fallopian tubes or male tubal structures.

Transcervical balloon tuboplasty is a minimally invasive method to unblock the fallopian tubes. A thin catheter is threaded through the cervix and uterus into the fallopian tube. The balloon is then inflated to clear the blockage.

Therapeutic Insemination

Therapeutic insemination may use either the partner's semen or that of a donor to overcome a low sperm count. Donor insemination also may be used if the woman's partner carries a genetic defect or if a woman wants a biologic child without having a relationship with a male partner. Intrauterine insemination (IUI) is a variation of therapeutic insemination that allows sperm to be placed directly into the uterus, thus bypassing the cervical mucus and reducing some immunologic incompatibilities. This process also removes many of the antibodies that interfere with sperm motility and ability to penetrate the ovum.

DRUG GUIDE

CLOMIPHENE CITRATE (CLOMID, SEROPHENE)

Classification: Ovarian stimulant.

Action: Stimulates pituitary gland to increase secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH stimulate maturation of the ovarian follicle, ovulation, and development of the corpus luteum.

Indications: Female infertility in which estrogen levels are normal.

Dosage and Route: Female sterility: First course: 25 to 50 mg PO daily for 5 days. Second course: Same dose if ovulation occurred with first course. If ovulation did not occur, increase dose to 100 mg daily for 5 days. Some women require up to 250 mg daily. A higher dose is not beneficial if ovulation is triggered with a lower dose.

Absorption: Readily absorbed from the gastrointestinal tract. Time to peak effect is 4 to 10 days after last day of treatment.

Excretion: Excreted in the feces.

Contraindications and Precautions: Pregnancy, liver disease, abnormal bleeding of undetermined origin, ovarian cysts, neoplastic disease. Therapy is ineffective in women with ovarian or pituitary failure.

Adverse Reactions: Ovarian enlargement; symptoms similar to premenstrual syndrome. Ovarian hyperstimulation syndrome. Multiple gestation, if more than one ovum is released. Visual disturbances. Abdominal distention, discomfort, nausea, vomiting. Abnormal uterine bleeding. Breast tenderness. Insomnia, nervousness, headache, depression, fatigue, lightheadedness, dizziness. Hot flashes, increased urination, allergic symptoms, weight gain, reversible alopecia. Dry cervical mucus.

Nursing Considerations: Take the history to determine whether the woman has a history of liver dysfunction or abnormal uterine bleeding. Rule out the possibility of pregnancy. Teach the woman to report abdominal distention, pain in the pelvis or abdomen, and visual disturbances. Teach her to avoid tasks requiring mental alertness or coordination because the drug can cause lightheadedness, dizziness, and visual disturbances. Instruct her to stop taking clomiphene and report to the physician if she suspects she might be pregnant. Teach the woman and her partner that she may notice irritability, mood swings, and other symptoms similar to those in premenstrual syndrome but that these are temporary.

Sperm for therapeutic insemination or IUI are obtained from semen collected by masturbation. The sperm are washed in laboratory solutions to remove prostaglandins that cause uterine cramping and then concentrated before insemination. Washing also removes many of the antibodies that interfere with sperm motility and ability to penetrate the ovum. If the man has retrograde ejaculation, he may take sodium bicarbonate 2 hours before obtaining the semen to render the urine alkaline. The urine is collected in a sterile container and washed with a medium to separate sperm from urine.

Men who donate semen for insemination are screened to reduce the risk of transmitting diseases or genetic defects. They are questioned about their personal and family health history, including genetic disorders or birth defects. Questions about their social habits and personality can disclose high-risk behaviors and give recipient parents information about potential traits of their child. Physical and laboratory examinations are performed to evaluate the man's general health, determine his blood type and Rh factor, and screen for infections such as STDs or human immunodeficiency virus (HIV). Carrier testing for specific genetic defects, such as sickle cell and Tay-Sachs diseases,

reduces the risk of passing on these disorders. To reduce the risk of transmitting diseases that may not be apparent at the initial screening, donor semen is frozen and held for 6 months before use. The man is retested for diseases such as HIV several times during the 6 months.

Inadvertent **consanguinity** (blood relationship) can occur because half-siblings from two families may not know they were conceived with donor gametes. They may later conceive a child who shares a larger number of genes, both normal and abnormal, than the general population. For this reason, the number of sperm donations may be limited.

Egg Donation

Use of donor oocytes may be an option for some women who do not produce ova because of premature ovarian failure, who do not respond to ovarian stimulation, or whose ova are not successfully fertilized despite apparently normal sperm. It is less successful if used for women who have a birth defect such as Turner's syndrome, in which the ova regress early in life, or for women who have had radiation therapy to the pelvis (Lobo, 2012).

As in use of donor semen, egg donation carries with it the risk for infecting the recipient, the fetus, and possibly the male partner of the recipient. The egg donor is routinely screened for genetic problems that are more prevalent in her race and for hereditary problems that may exist in the donor or her first-degree relatives (parent, sibling, child). Other tests may be available before conception such as chromosome analysis that may show fragile-X carrier status or an abnormal arrangement of her chromosomes. Chromosome analysis may not indicate a problem in the woman who donates the egg, but it might increase the possibility of an abnormality in the conceptus. Decisions about whether to pursue available testing of the fetus must be made by the recipient, however.

Surrogate Parenting

A **surrogate mother** may enter the picture if the woman is infertile or cannot carry a fetus to live birth. The surrogate mother may supply her uterus only (**gestational surrogate**), with the infertile couple supplying the sperm and ovum. Or she may be inseminated with the male partner's sperm and carry the fetus to birth, thus supplying both the genetic component and the gestational component. Surrogacy is different from therapeutic insemination with donor sperm because it is not anonymous. In addition, the woman who carries the child inevitably forms bonds with the fetus during the months of pregnancy. For these reasons, extensive interviews and counseling of both the infertile couple and the surrogate mother are required.

Money paid to the surrogate mother can raise ethical issues. Could a poor but fertile woman feel compelled to provide her body for a more well-to-do couple? However, not compensating a woman for the real physical and emotional risks of this undertaking can be construed as coercive as well.

Custody of the resulting child has been the issue in several court cases involving surrogate mothers. In the *Baby M* case, a woman who was inseminated with the man's sperm refused to relinquish the baby as stated in the contract between the birth mother and the infertile couple. Ultimately, custody was awarded to the man providing the sperm and his spouse, but visitation rights were granted to the surrogate mother.

Custody issues when the birth mother is a gestational surrogate are clearer than when she also donates her ovum to the child. Courts have more often recognized the genetic parents as the legal parents and upheld the contracts between them and the gestational surrogate.

Assisted Reproductive Technologies

More than 1% of births in the United States each year are brought about by **assisted reproductive technologies (ART)**. The definition used by Centers for Disease Control and Prevention (CDC) is specific: surgically removing eggs from a woman's ovaries, combining them with sperm in a laboratory, and returning them to the woman's body or donating them to another woman. ART involves medical, surgical, laboratory, and micromanipulation techniques used with ova and sperm to improve the chance of conception. Simpler evaluations and other treatments often precede or accompany ART therapy. Annual National Summary and Fertility Clinic Success Rates are available in ART Reports and Resources at the www.cdc.gov website.

In Vitro Fertilization

In vitro fertilization (IVF) may be done to bypass blocked or absent fallopian tubes, for male factor infertility, or for unexplained infertility in either the man or the woman. The physician removes the ova by ultrasound-guided transvaginal retrieval or occasionally laparoscopy and mixes them with prepared sperm from the woman's partner or a donor. The ova are examined to determine if fertilization has occurred about 18 hours after addition of the sperm. The fertilized oocytes are then returned to the uterus or may be cultured for 48 to 96 more hours, allowing cell division for a total of 5 days (Figure 32-4). The number of fertilized ova returned is individualized but is approximately two or three based on the prognosis for success. Older women may have more ova transferred than younger women to improve their chances of pregnancy without greatly increasing the risk of having a triplet or higher pregnancy. IVF is the most common of current ART

procedures. IVF is used to do preimplantation genetic diagnosis for fertile couples having a high risk for a baby with a genetic disorder (Hershberger & Schoenfeld, 2011; Lobo, 2012).

Embryo transfer (ET), combined with IVF (IVF-ET), has become more common. Gamete intrafallopian transfer (GIFT) and zygote intrafallopian transfer (ZIFT) are modifications in which sperm and ova are placed in open fallopian tubes. Variations of ZIFT include tubal embryo transfer (TET), also known as tubal embryo stage transfer (TEST), that places the conceptus in the fallopian tube later than GIFT. Ultrasound guidance targets the best location to obtain the ova. Intracytoplasmic sperm injection (ICSI) is a technique in which a single spermatozoon, obtained with microsurgical techniques, is injected into the cytoplasm of an ovum (Lobo, 2012).

Most ART procedures are done in an outpatient setting. Each procedure begins with ovulation induction to permit retrieval of several ova to improve the likelihood of a successful pregnancy. Sperm are prepared and concentrated as they are for therapeutic insemination.

Supplemental progesterone is given to the woman to promote implantation and support the early pregnancy (luteal phase support). Because of the supplemental progesterone, the woman will not have a menstrual period even if she is not pregnant. Transvaginal ultrasounds are used to identify whether one or more gestational sacs have implanted with IVF and to identify if an ectopic (tubal) pregnancy occurred after methods such as IUI, GIFT, or ZIFT.

IVF success rates vary among infertility centers. Bypassing the obstructions does not necessarily result in pregnancy. Not every ovum is successfully fertilized when IVF or its modifications are used. Embryos transferred to the woman's uterus may not always implant, which is why several are transferred. However, multiple embryos also

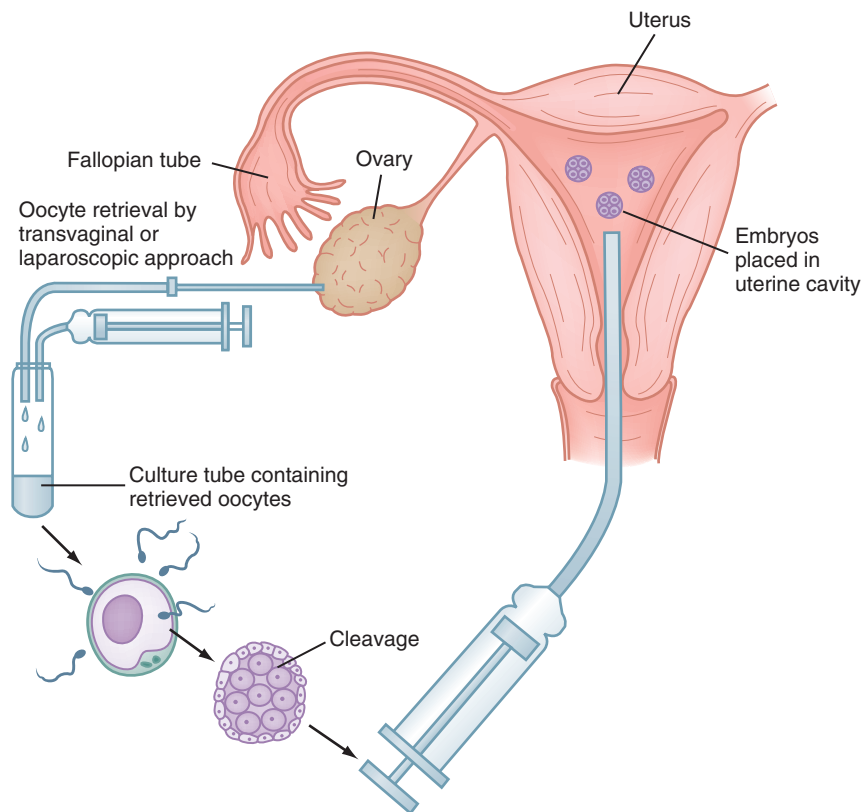

FIG 32-4 In vitro fertilization. Multiple oocytes are obtained by using a transvaginal or laparoscopic approach. The retrieved oocytes are mixed with prepared sperm and incubated 1 to 2 days. Embryos are then transferred to the uterine cavity to allow implantation and continued development.

FIG 32-5 Gamete intrafallopian transfer (GIFT). Multiple ova aspirated from the ovary in this illustration are combined with washed sperm. The mixture of ova and sperm is then transferred directly to a fallopian tube.

may implant. Although twins are the most common multifetal pregnancy, triplets or more may occur, raising issues related to the physical and emotional well-being of parents and their babies and possibly raising ethical issues.

Gamete Intrafallopian Transfer

The woman must have at least one patent fallopian tube for GIFT to be an option. The procedure begins in a manner similar to that of IVF, with retrieval of multiple ova and washed sperm. The retrieved ova are drawn into a catheter that also carries prepared sperm. The mix of sperm and ova are injected into each fallopian tube through a laparoscope. Additional prepared sperm may be injected into the uterus through the cervix to improve the chance of successful fertilization. Progesterone is given as it is in IVF (Figure 32-5).

Zygote Intrafallopian Transfer

ZIFT, often called *tubal embryo transfer (TET)*, is a hybrid of IVF and GIFT. The woman's ova are fertilized outside her body, but the resulting fertilized ova are placed in the fallopian tubes and enter the uterus naturally for implantation. The woman must have at least one patent fallopian tube.

Comparison of In Vitro Fertilization, Gamete Intrafallopian Transfer, and Tubal Embryo Transfer

The primary advantage of GIFT and ZIFT over IVF is that more people and religious groups may find GIFT and ZIFT more natural and therefore more acceptable than IVF. With IVF or ZIFT, evidence of fertilization exists before placement in the uterus or tubes. The GIFT and ZIFT procedures are more invasive, requiring a laparoscopy to place the gametes or fertilized ova in the distal fallopian tube. Tubal pregnancy may result if embryos cannot reach the uterine cavity to implant. For these reasons IVF is used about 99% of the time if a couple requires ART (CDC, 2013).

Intracytoplasmic Sperm Injection (ICSI)

Microsurgical techniques, combined with IVF, may help couples conceive despite severe male factor infertility. Men who have obstructions to their epididymis or absence of an epididymis may be able to father children with the use of percutaneous or microsurgical sperm aspiration. The sperm are retrieved from the epididymis by percutaneous aspiration of a single spermatozoon with a small-gauge needle. Alternatively, a microsurgical incision may be made to aspirate the sperm if the percutaneous approach cannot be used. The sperm obtained are then used to fertilize ova by intracytoplasmic sperm injection (ICSI).

Preimplantation Genetic Testing

Couples with concerns about a specific genetic defect in the family may be offered preimplantation genetic testing of their fertilized ova. As in other types of prenatal screening, preimplantation genetic testing cannot rule out every potential abnormality in the offspring. Rather, the testing allows parents to make informed decisions about whether to implant the fertilized ova into the uterus.

RESPONSES TO INFERTILITY

The desire for children is strong in many people. Even if they delay childbearing, most couples expect to have one or more children before

the end of the woman's reproductive years. Those who chose childlessness earlier may reevaluate their decision when they are older. If a couple does not achieve pregnancy or produce a living child as expected, the man and the woman often experience psychological distress and a threat to their self-images. Either or both partners may feel like failures. Their marital and family relationships may be stressed, and they may withdraw from relationships that they previously found satisfying. Every couple is unique, and many reactions depend on the importance attached to having biologic children. A woman with no male partner may desire a biological child before she is too old. The following discussion describes how infertility can alter the lives of those affected.

Assumption of Fertility

Many couples practice contraception for a number of years before they decide to have a baby. They may want to establish a career and financial security, acquire a comfortable home and lifestyle, or perhaps travel and live freely without the responsibility of a child. They usually assume that they are fertile and must take steps to avoid pregnancy until ready.

When they do want a child, they discontinue contraception and assume that pregnancy will occur within a few months at most. They may plan conception so that the baby will be born at a certain time of year (such as not during the hottest weather) or to avoid major holidays.

Either or both partners may experiment with the role of parent as they anticipate pregnancy. They develop a heightened awareness of children and parenting. Being with others who are expecting or already have children is exciting because they plan to join their ranks shortly. They may discuss issues like full-time parenting by one partner, child care, and imminent lifestyle changes. The woman often finds that she enjoys shopping in the maternity and children's departments. They may begin acquiring toys and furnishings that a child will need. Both partners may develop a fantasy child or a concept of what their baby will be like.

Growing Awareness of a Problem

As the months pass, the couple gradually becomes concerned about the inability to conceive. If the woman is older, they feel the urgency of the limited time before her reproductive years end. The plan to have a baby at a certain time of year is replaced by the desire for a baby any time—and soon.

The couple begins to feel uneasy with child-related activities. Now they are not so sure when they will be parents. They begin to feel hurt when other family members or friends have babies. Events such as baby showers and christenings become melancholy rather than joyful occasions to them. They bypass toy stores and children's departments because of the uncertainty. Family members and friends who are having children may feel guilty when they are around the couple who cannot conceive (Paterno, 2008).

The potential grandparents may feel that their children are waiting too long to start a family or even that they are selfish. If they are aware the couple is trying to conceive, they become even more worried as the months pass without the longed-for announcement of a pregnancy. They are twice saddened—by the lack of a grandchild and the hurt their adult children are enduring.

Seeking Help for Infertility

Eventually, couples must decide whether to seek help to conceive. They may reach this point after only a few menstrual cycles or, at the opposite extreme, may never seek help. Many factors enter into their decision, such as their ages (especially the woman's if menopause is near),

how long they have been unable to conceive, how much they want a biologic child, how they regard adoption, and how they feel about a life without children. If they have a biologic child but are unable to conceive another, the couple may consider adoption sooner, including adopting a child from another country.

Identifying the Importance of Having a Baby

Each partner may place a different priority on having a baby. Conflicts may arise when one partner wants help to conceive sooner than the other. In addition, cultural or religious beliefs influence the way each feels about procreation and whether options such as assisted reproductive procedures or adoption are acceptable. The way in which the couple resolves these differences is crucial to the stability of the relationship.

Men and women often differ in their reactions to infertility although they are equally affected. Women may want to talk about their feelings and frustrations, but men often internalize their feelings or feel that they must be strong for their partners. The woman may interpret her partner's stoicism and reluctance to express his feelings as disinterest or lack of concern and care for her (Paterno, 2008).

Sharing Intimate Information

Although the infertility specialist will limit questions to the necessary ones, evaluation and treatment for infertility require that both partners reveal information about their sexual relationship, such as the frequency and timing of intercourse. This is difficult for those who regard this information as intimate. In addition, infertile couples may feel that the evaluation calls their sexual adequacy into question. They may feel defensive if they perceive a threat to their self-image (Paterno, 2008).

Considering Financial Resources

Financial concerns enter into the couple's decision about whether to seek treatment and how far to carry it. Techniques such as ovulation predictor kits are inexpensive but have limited usefulness in achieving successful pregnancy. Advanced techniques such as IVF are expensive and may have a low likelihood of success for some couples. Health insurance may not cover infertility treatment at all or may not cover all procedures because the problem is not always seen as a health problem. Investigational treatments are usually not covered. The drugs that must be taken to achieve pregnancy are often quite expensive. Expense and restricted coverage limit treatment choices for many low- or middle-income couples. Those who seek and pursue infertility treatment may have greater financial resources than those who do not seek treatment.

Committing to Involvement in Care

Infertility evaluation and treatment require a great commitment from the couple in terms of time, emotional and physical energy, and money. Couples can be involved in this process for several years if they do not set a limit on when they want to stop. They participate daily as they do home assessments, take medications, and keep detailed records similar to what they might do in their jobs. The physical effects of drugs that induce ovulation and support conception can result in many side or adverse effects. For infertility diagnosis and therapy to be most effective, couples must consider their ability and desire to be directly involved in the process over what may be a long time.

Reactions during Evaluation and Treatment

Couples undergoing infertility evaluation and treatment have different reactions to the process. While early evaluations often result in simple

treatment and quick response, a couple's reactions may change as treatment becomes more complex, demanding, and lengthy.

Influences on Decision Making

If their evaluation shows that a treatment or procedure may enable them to conceive, the couple must then decide whether to proceed. The decision-making process begins early and must be repeated during therapy if pregnancy does not occur. A complex array of factors enters into their decisions about beginning and continuing treatment or whether to end their pursuit of pregnancy. Although discussed separately, these factors interact dynamically as the couple makes each decision. The nurse helps them examine each factor and arrive at a decision that is best for them.

Social, Cultural, and Religious Values. Some medically appropriate options are not acceptable to every couple within their personal, social, cultural, and religious frameworks. Surrogate parenting, IVF, and therapeutic insemination (especially with donor sperm) are not consistent with the personal or religious beliefs of many people. If a procedure offers the partners hope for a child but is incompatible with their beliefs, their choices are two: use the technology despite their beliefs or be willing to accept childlessness. Adoption may be a third alternative for some couples if the desire for a biologic child is not absolute. Adoption of a foreign child may be necessary with associated international implications. As in other decisions, couples must work out conflicting personal values about what therapy is acceptable.

Difficulty of Treatment. The couple must consider how difficult, risky, and uncomfortable therapy will be. The level of difficulty involves physical, psychological, geographic, and time factors. Employment constraints also may affect treatment decisions.

Several diagnostic tests and treatments for infertility involve invasive procedures or surgery. The person who undergoes the procedure must be the one who ultimately decides whether to do it. That person alone can decide whether the hope for a child is worth the risks and discomfort of the procedure.

Infertility treatment is stressful. Often partners feel or are willing to tolerate different levels of stress. To reduce the stress, they may abandon treatment completely or take a vacation for a few months from the constant preoccupation with conceiving. Women nearing or in their 40s often do not feel they have the luxury of skipping a treatment cycle.

Some couples encounter geographic difficulties if they must travel a long distance for therapy. Time stresses are substantial. The partners, particularly the woman, feel that achieving pregnancy is their new career. One or both partners may spend many hours every week in pursuit of pregnancy.

Employment constraints may be a barrier to infertility therapy because of the time required for treatment. The impact of time is usually greatest on the woman. Time away from work may burden the employer or co-workers. Stopping work may not be an option because the family needs the money and often needs the insurance coverage that comes with employment.

Probability of Success. Couples often have a biased interpretation of their statistical probability of success, especially when they begin treatment with a new procedure. For example, if a procedure has a 20% likelihood of success with each cycle, they tend to expect that they will be in the successful group rather than in the 80% who do not meet with success. As time goes by, however, they must weigh the likelihood of success of any therapy against financial concerns and their own willingness to accept the discomfort and difficulty associated with it. Again, the woman's age imposes an inescapable limit.

Financial Concerns. Some couples, particularly those with ample resources and a strong desire for a biologic child, pursue expensive

treatments and do so longer than others of more limited means, despite a low probability of success. Couples with financial limitations find that they must abandon treatment sooner than they want. Other couples go heavily into debt, adding financial strain to the other stresses of treatment in their quest for a biologic child.

Psychological Reactions

A couple's initial reaction to infertility often is one of shock because the partners are usually healthy and did not expect to have problems conceiving. Their reactions vary according to how easily their infertility is alleviated, their personality and self-image, and the strength of their relationship.

Guilt. A partner having the only identified problem might feel that he or she is depriving the other of children. This feeling may be compounded if the "normal" partner has children from another relationship. It may be difficult for this person to understand that not all factors affecting fertility are known and what seems like the problem of only one partner is often the couple's problem.

Either partner may feel guilty about past choices that now affect fertility. A woman with adhesions resulting from a sexually transmitted infection may regret her past sexual choices. The man who wanted to delay pregnancy longer than the woman may feel guilty if her age is now reducing her fertility.

Isolation. Infertile couples may withdraw from friends and relatives who have children to insulate themselves from painful reminders of their infertility. Some couples develop supportive relationships with others who also are infertile, which somewhat diminishes their sense of isolation.

Depression. One or both partners may experience depression as their sense of competence and control over their bodies is challenged, especially if therapy is not successful quickly. They often feel as though they are on a roller coaster of hope alternating with despair when the woman has her menstrual period each month. In an attempt to reduce their disappointment, couples with long-term infertility try not to expect too much with each cycle.

The couple may feel envy toward those who conceive easily. They may become judgmental and angry when they see those who seem to "have no business having a baby," such as an adolescent, a woman who abuses drugs, or a poor woman who cannot support an added child.

Stress on the Relationship. Because infertility can challenge a person's identity and self-esteem, partners may find less satisfaction in their relationship. They may feel unlovable or unappealing to their mate.

The man may have difficulty performing on demand for semen specimens or postcoital tests, feeling that others will judge his sexual function. The fact that semen samples are best obtained by masturbation is unacceptable to some men. Both partners are stressed when intercourse must be scheduled to coincide with specific evaluations or ovulation. Intercourse can become a chore more than an expression of love. It may come to be associated with failure rather than fulfillment if a child is not forthcoming.

If sperm from an anonymous donor is used for therapeutic insemination or other techniques, the man may feel that his masculinity is further threatened. He does not want to deprive his wife of a child, but he may be ambivalent about use of sperm from a third party. He may have difficulty distinguishing between fatherhood as a biologic achievement and fatherhood as a relationship.

The partners find their relationship strained if they disagree on which treatments are appropriate and how long they should be pursued. One partner may want to keep trying "one more month," and the other may want to abandon treatment. If they are considering

adoption, their relationship may be strained if they differ on whether to adopt and what kind of child they are willing to accept.

17. What factors must couples consider when they reach decision points during infertility evaluation and treatment?
18. What are possible psychological reactions to infertility?

OUTCOMES AFTER INFERTILITY THERAPY

After infertility therapy, three outcomes are possible. The pregnancy may be lost, resulting in mixed emotions of grief and optimism. The couple may become parents, either biologically or through adoption. Infertility therapy may be unsuccessful, and the couple must decide whether to pursue adoption or to remain childless.

Pregnancy Loss after Infertility Therapy

Couples who suffer pregnancy loss after infertility therapy may interpret the experience with mixed feelings of loss and gain. Couples undergoing infertility evaluation and treatment often are aware of a pregnancy much earlier than fertile couples. They want to hope yet expect to be disappointed again. If a spontaneous abortion occurs, they may grieve profoundly for what they achieved and then lost.

Yet despite their grief about the pregnancy loss, the partners may be encouraged because they have proved that they can achieve a pregnancy. They may feel that if they succeeded once, they can do it again. A miscarriage may give them the courage to continue treatment. They realize that many pregnancies are lost early, often before most women have any idea that they might be pregnant.

When pregnancy loss has occurred because of an ectopic pregnancy, the woman may lose a fallopian tube, although earlier diagnosis reduces the risks of damage or loss of the affected tube (see p. 507). These couples may have an added threat to their fertility because of the uncertainty of getting pregnant again in addition to the possible loss or blockage of one or both fallopian tubes.

Parenthood after Infertility Therapy

Couples who conceive experience varied emotions. If they have been disappointed before, they may hardly believe the good news. They are thrilled but worry about whether they can complete the pregnancy and take home a baby. Pregnancy after infertility therapy is emotionally tentative for many infertile couples, especially those who have been trying to conceive for a long time or have lost a pregnancy. They may distance themselves from the reality of the pregnancy until much later in gestation than normally fertile couples.

The woman has learned to sense and report every symptom and may interpret normal changes of pregnancy as a threat. Preterm labor may stir greater anxiety in the previously infertile couple. The woman may assume that intermittent periods of fetal quiet are abnormal rather than naps that are normal for every fetus.

The previously infertile couple may find little sympathy from those who do not understand their fear of investing in the pregnancy. Others are annoyed because they expect the couple to be overjoyed at a successful and apparently normal pregnancy. Outsiders may feel that the partners are self-centered and cannot decide what they want. Other infertile couples who have been a source of mutual support may either withdraw from the couple who achieve a pregnancy or rejoice in their success.

The parents' anxiety may be heightened during labor. They are afraid that something will go wrong at the last moment. Even after the birth of a healthy infant, some parents need time to relax and grasp the fact that their baby is really here.

These new parents often need much support as they gain experience with their child. Infertile couples who eventually have biologic or adopted children may have unrealistic expectations about parenting. After investing so many financial, physical, and emotional resources in having a child, they may be reluctant to express any unhappiness or frustration over the difficulties of child-rearing.

Choosing to Adopt

Not every couple who seeks treatment for infertility achieves a "take-home" baby. Some couples discontinue treatment sooner than others, depending on their age and tolerance for the fatigue, stress, and expense. Some couples investigate adoption early in infertility treatment because advanced age may make them ineligible to adopt through many agencies or because a nonbiologic child is acceptable to them. A single parent may choose adoption. Agencies that coordinate international adoptions are often consulted.

Couples who consider adoption must confront their personal preferences, limitations, and prejudices. As much as they want a child, many couples are not willing to adopt any child. Most couples prefer to adopt a newborn or an infant of their race. Some prefer an infant but also are willing to adopt an older child, one with special needs, one of a mixed or different race, or a group of siblings. Other couples will not consider adopting these children for a variety of reasons.

Some couples fear adopting a child because the woman might become pregnant. Although pregnancy has been their goal for a long time, they may worry that they would love their adopted child differently from their biologic child. If the couple plans to continue trying for a biologic child, they also must come to grips with this issue.

Couples who decide to adopt face further scrutiny of their personal lives. Agencies investigate their home, financial means (which may have been seriously drained), and fitness as parents. Once again, they may feel that their personal competence is questioned. International adoptions often have many additional requirements that the couple does not encounter in their home country.

The couple who decides on adoption may have emotions similar to those who achieve a pregnancy. They may be slow to invest in the process emotionally because they expect disappointment again. In addition, the adopted child often arrives suddenly and unexpectedly. A delay in the adoption process may also occur, bringing further uncertainty to the couple. Although they may have been waiting months for this happy event, the couple may have little time to adjust to the reality of their new roles as parents.

Menopause after Infertility

A woman or couple may decide when to stop unsuccessful infertility treatment, or natural aging may make that decision for her in menopause. After many attempts to conceive and carry a child to term, the biologic clock that she was watching closely is running out quickly. A woman may find a new sense of self as her body changes are not related to infertility therapy.

19. If the partners become parents, either through birth or adoption, how may they react to parenthood?
20. What are the issues couples must face if they consider adoption?
21. What emotions do couples often experience if they lose a pregnancy after infertility treatment?

APPLICATION OF THE NURSING PROCESS

Care of the Infertile Couple

Nurses may encounter couples facing infertility in many different settings and identify numerous nursing care needs. Regardless of the setting, the nurse often addresses the couple's emotional needs associated with infertility evaluation, treatment, and outcomes of therapy.

Assessment

In many instances, infertile couples previously have had a positive self-image and feelings of competence about themselves. The diagnosis of infertility shakes their positive view. The nurse should be aware that these feelings may be present, regardless of the practice setting in which the couple is encountered.

Determine at what point the couple is in their infertility treatment. Couples who have just discovered that they may have difficulty conceiving may be shocked yet optimistic that therapy will result in a baby. Other couples for whom simple treatments were unsuccessful may face shock again if the more complex treatments such as IVF or ICSI are recommended, particularly if these treatments require them to go into debt. Couples with long-standing infertility may have a deeper sense of failure and a pessimistic outlook. Listen for remarks that are negative, expressing guilt or helplessness.

Evaluate the way infertility has affected the partners' relationship with each other. Are there conflicts or differences in values between the two? Observing their body language, such as eye contact, may provide clues about similarities and differences in their commitment to diagnosis and treatment. Ask them how their relationship has changed. Are they more or less satisfied with their marital relationship than they were before they had problems conceiving? How is each member of the couple adjusting to the situation?

Ask about support systems. Couples suffering from infertility often withdraw from old relationships yet do not form new supportive ones. Do others who are significant in the partners' lives know that they are trying to conceive? Are family members and friends nearby, and are they supportive? Ask whether they have encountered assumptions by others that infertility is the "fault" of one partner or the other. Are they subjected to questions that invade their privacy, such as "When are you two going to have a baby?"

Determine how the couple's culture or religion views infertility and the impact of these values on therapy. Are some therapies unacceptable to one or both partners? The partners may have differing views that can cause conflict during treatment, and they may need help to work these out.

Determine how the couple is coping with the stresses of treatment. How much has infertility cost them in terms of time, money, and discomfort? Identify the successes and failures they have experienced as well as outcomes that have provided them hope or comfort. Their ages, especially the woman's, adds another stressor that cannot be ignored in their decisions.

If the woman is pregnant or has given birth recently or the couple has adopted a child recently, observe for high levels of anxiety in either or both parents. Assess them for negative behaviors and comments, such as reluctance to feel joy or a sense that they will "fail" again.

Nursing Diagnosis

A nursing diagnosis commonly encountered is "Situational Low Self-Esteem related to loss of control secondary to the couple's infertility diagnosis and treatment."

Planning

Three expected outcomes are appropriate for this nursing diagnosis during the early days of evaluation and decision making. The outcomes may apply to the man, the woman, or both partners. The person(s) will do the following:

- Express feelings about infertility and its evaluation and treatment.
- Explore ways to increase control within the situation of infertility.
- Identify aspects of self that are positive.

Interventions

Assist Communication

Therapeutic communication is the primary technique for assessment and intervention related to this nursing diagnosis. Recognize that a man may be reluctant to express his feelings as openly as his partner. A variety of communication techniques such as active listening and exploration may encourage the partners to express their feelings honestly. Provide privacy and acceptance of their feelings. Nurses must recognize the validity of the couple's views and emotions, even if they differ from the nurse's own feelings.

Encourage the partners to accept their feelings, both positive and negative. For example, the couple who has finally achieved pregnancy may be living a lie to some extent. The partners may act elated because they believe they should feel happy, yet inside they are cautious and hesitant about becoming attached to their baby. Explain that feelings are not right or wrong but simply exist. Opening the subject of negative feelings (fear of attachment) within a successful situation (pregnancy or birth) may be helpful to reinforce the normality of their emotions. This technique gives them the opportunity to talk about emotional reactions that they or others feel are inappropriate and might otherwise be reluctant to discuss.

Discuss possible differences in ways that the man and the woman communicate. For example, explain that the woman may feel more comfortable than the man in talking about their problem and concerns about treatment. Explain that these differences in communication style can cause misunderstandings because one partner believes that the other does not care as much about their problem. Encourage them to be open with each other for the best mutual support. Support groups provide another means for communication and ventilation of feelings among those who are most likely to understand what an infertile couple is experiencing.

Increase the Couple's Sense of Control

Explore how the couple has dealt with stressors in the past and how these techniques might be used to cope with the present crisis. A couple's pattern of dealing with stress in other parts of life is likely to carry over into infertility diagnosis and treatment and throughout pregnancy and parenthood. Reinforce positive coping skills such as learning more about infertility and the proposed therapy for it.

Couples who experience undue stress may benefit from relaxation techniques such as visualization and moderate exercise. Frequent strenuous exercise may reduce the woman's ability to ovulate. Although a hot tub is relaxing for many people, it should be avoided because the high temperatures may inhibit spermatogenesis. In addition, the woman could become pregnant with any cycle, and high maternal body temperatures may be associated with fetal anomalies.

Discuss behaviors that enhance the ability to handle stress and provide a good environment for a pregnancy that might occur. Reinforce healthy choices such as good nutrition and a balance between exercise and rest. Teach the couple ways to enhance general health if deficiencies are identified.

Explain any procedures and their purpose in language that the couple can understand. Reinforce any medical explanations that may have been given. Encourage questions so that the couple is fully informed. Have the partners restate what was explained to reduce misunderstandings.

Help the couple explore options at each decision point. The couple must decide the best course of action, but the nurse can help identify pros and cons of each choice so that the partners can arrive at a decision appropriate for them. Be nondirective so that the choices are theirs and do not reflect the biases of the nurse or other caregivers.

Reduce Isolation

Because couples often distance themselves from friends and family relationships that they find painful, they may have little social support. Refer them to available support groups to provide emotional outlets, a sense of belonging, and a source of information.

Couples who achieve pregnancy or adopt a child may again find themselves isolated if infertile couples in their circle of support are no longer comfortable with them. Encourage them to take the initiative to reestablish ties with relatives and friends, who can be an important source of aid during pregnancy and child-rearing. Help them identify ways they can improve communication with these significant others. Remind them that they have undergone significant shifts in self-image, which also have affected those around them.

Promote a Positive Self-Image

Because infertility work often is such a dominant factor in their lives, a continuing inability to conceive erodes the partners' perception of

themselves. Explore with them other areas of competence and activities that make them feel good about themselves. Reinforce positive attitudes and self-evaluations. Encourage them to maintain activities such as hobbies, sports, or volunteer work. The career of either partner may be a source of stress that needs relief, or it may be an avenue that fosters a positive self-perception.

Encourage them to avoid activities such as baby showers if these events make them sad. Help them identify the best way to cope with these activities if they do not want to avoid them.

Some people benefit from self-improvement activities such as continuing education courses or enhancement of appearance. Encourage these activities if they help the individuals feel better about themselves. If the activity might impair fertility treatments, such as strict dieting, also inform the person of this fact.

Evaluation

The goals established are achieved if the individual or both partners can:

- Express their feelings about their situation, usually over a period of time.
- Explore ways to increase personal control over their lives, as evidenced by expressing feelings of reduced helplessness and dependence.
- Identify one or more aspects of self that are perceived as positive and identify areas of competence.

SUMMARY CONCEPTS

- Nurses may encounter persons having infertility problems in a variety of settings other than infertility clinics, such as maternity and gynecology services, urology services, the perioperative area, and the emergency department. Friends and family members also see the nurse as an information resource about infertility care.
- About 20% of infertile couples have no identified problem that is explained by current evaluation techniques.
- Because many unknown factors in reproduction exist, identification and correction of problems in one or both partners does not necessarily resolve their infertility.
- A variety of structural and functional abnormalities may contribute to a couple's infertility. The man may have abnormalities of the sperm or the seminal fluid or with ejaculation. The woman may have ovulation disorders, anatomic problems such as fallopian tube occlusion, or physiologic disorders such as hormone imbalances.
- A systematic evaluation of both partners, proceeding from simple to more complex, identifies therapy that is most likely to be

successful and cost-effective. The couple may decide to stop evaluation or therapy at any point.

- Infertility is a crisis for the couple and often for the extended family. Either or both partners may feel that the inability to conceive represents a personal failure. They may have a variety of psychological reactions.
- Infertile couples must make choices at many points before and during evaluation and therapy. Some major factors that enter into their decisions involve personal, social, cultural, and religious values; difficulty of treatment; probability of success; financial resources; and age, particularly the woman's.
- The possible outcomes after infertility therapy may present new challenges to the couple and their families: unsuccessful therapy and the choice of whether to pursue adoption, pregnancy loss after infertility, and parenthood after infertility.
- Many nursing care needs may be identified as the couple negotiates infertility evaluation and treatment.

Preventive Care for Women

WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain examinations and screening procedures recommended to maintain the health of women.
2. Describe how a nurse can encourage the woman to take charge of improvement in her personal health.
3. Describe how a nurse might make difficult exams (such as pelvic exams) better tolerated by the woman.
4. Describe what is done in female genital mutilation, why it is done, and why most nations want it eradicated.
5. Explain benefits of indicated immunization(s) to a woman.

Women often consider their primary health care provider to be the same provider whom they will see for obstetrics and gynecology. Many obstetricians continue providing gynecologic medical care after retiring from delivering babies. Certified nurse-midwives (CNMs) often provide pregnancy and birth care but also provide basic preventive health care to nonpregnant women. Women's health nurse practitioners (WHNPs) also provide basic reproductive care to women in different settings. This chapter focuses on the **well-woman exam** (WWE), or the primary and preventive care of women: routine assessments, screening procedures, and management of specific health concerns with needed referrals.

NATIONAL EMPHASIS ON WOMEN'S HEALTH

Two national programs have had a major impact on women's health. The Women's Health Initiative (WHI) of the National Institutes of Health (NIH) was a major 15-year research program to address the most common causes of death, disability, and poor quality of life in postmenopausal women: cardiovascular disease, cancer, and osteoporosis. *Healthy People 2020* continues to have a health promotion and disease prevention agenda coordinated by the U.S. Department of Health and Human Services. For more information about these programs, see www.nhlbi.nih.gov/whi/.

It is easy to think that men have the greatest problems with cardiovascular disease and that only women are affected by breast cancer and

osteoporosis. We may forget that both women and men should understand that risks for colorectal cancer increase with age. Care that identifies risks for these problems and changes that may modify these disorders are discussed in this chapter. For greater detail, consult your medical-surgical nursing text.

Healthy People 2020 Goals

The *Healthy People 2020* National Health Promotion and Disease Prevention Initiative has been discussed in other chapters in this text. The *Healthy People 2020* home page may be found at www.healthypeople.gov/2020/. Several **Healthy People 2020 goals** relate to women's health, and many address the goals in the WHI:

- Increase the proportion of adults, 20 years and older, who are at a healthy weight from 30.8% (2005-2008) to 33.9%.
- Lower breast cancer deaths from 22.9 per 100,000 women in 2007 to no more than 20.6 per 100,000 women.
- Reduce deaths from cancer of the cervix from 2.4 per 100,000 women in 2007 to 2.2 per 100,000 women.
- Increase cervical cancer screening, according to the most recent 2008 guidelines, from 84.5% of women to 93%.
- Increase the proportion of adults who receive a colorectal screening, based on the most recent guidelines, from 52.1% in 2008 to 70.5%.
- Increase the proportion of cancer survivors who are living 5 years or longer after diagnosis from 66.2% in 2007 to 72.8%.

- Reduce the hip fracture hospitalizations among women, 65 years and older, from 823.5 hospitalizations per 100,000 women to 741.2 per 100,000 women.
- Reduce the incidence of gonorrhea in women between the ages of 15 and 44 from 285 cases per 100,000 women in 2008 to 257 cases per 100,000.
- Reduce the prevalence of *Chlamydia trachomatis* infections among women 15 to 24 years old who attended a family planning clinic in the past 12 months from 7.4% to 6.7%.
- Reduce congenital syphilis from 10.1 per 100,000 live births in 2008 to no more than 9.1 per 100,000 live births.
- Reduce coronary heart disease deaths from 126 per 100,000 (2007) to 100.8 per 100,000.
- Reduce stroke deaths from 42.2 per 100,000 (2007) to 33.8 per 100,000.

HEALTH MAINTENANCE

Health maintenance refers to measures that can be taken for prevention or early detection of specific diseases. Unfortunately, many women do not take advantage of recommended health maintenance procedures. Some seek care only when they have a problem. For others, the only health care they receive comes from a gynecologist or nurse practitioner, often with their annual checkup. Therefore it is important that those who provide health care for women are familiar with principles of screening and counseling in areas that are not traditionally associated with gynecology, such as assessing risk factors for colon cancer and heart disease.

Health History

The health history identifies risk factors for a variety of conditions and may be obtained from sources such as questionnaires, interviews, and previous records. The focus of a health history depends on the woman's age, but some topics should be discussed with all women. **Box 33-1** provides a summary of information to obtain. These topics include dietary intake, physical activity, habits, and sexual practices. Discussions of drugs must include long-term use of prescription and over-the-counter (OTC) medications. Illicit drugs must also be discussed to provide the safest care for the woman. Questions about use of **complementary and/or alternative medicine (CAM)** should be included in the woman's history. A woman's health history often identifies actions she takes to promote her health.

Many people take herbal or other botanical preparations but do not mention them because they do not consider them drugs. The nurse must specifically ask about use of these preparations or any therapies the woman may use in addition to medically prescribed interventions to obtain the most complete information for the medical history.

Family history identifies many risk factors that cannot be modified. History of diabetes mellitus, hyperlipidemia, heart disease, osteoporosis, and thyroid disease suggests the best choice of screening tests. A list of family members who had cancer, the type of cancer they had, and their ages when it was discovered provides important information about the woman's risk for cancer, particularly breast and colon cancer.

A family history of heart disease is especially important when the woman is postmenopausal because the level of estrogen, which provides some protection against coronary artery disease (CAD), decreases after menopause, and obesity may increase. If family history, obesity, or other factors increase the woman's risk for heart disease, a baseline electrocardiogram, stress test, and analysis of cholesterol and lipid profiles may identify other risk factors.

BOX 33-1 HEALTH HISTORY

Personal History

Demographic data (name, age, marital status or whether living with a partner of either gender)
 Reason for seeking medical care (chief complaint)
 Current and past state of health, previous surgeries
 Height, weight, vital signs
 Allergies (drugs, food, environmental allergens)
 Medications, usual and the reason for taking (over-the-counter, prescribed, illicit)
 Use of complementary or alternative therapies, such as herbal or botanical preparations, acupuncture, chiropractic treatment
 Habits (smoking, use of alcohol, drugs)
 Appetite, usual dietary intake
 Exercise pattern (type, frequency, duration)
 Patterns of elimination (current or chronic problems)
 Sleep and rest patterns
 Degree of stress and stress management techniques

Menstrual History

Age of menarche
 Regularity, duration of menstrual cycle
 Menstrual discomfort (time during cycles, intensity, relief measures)
 Age at menopause, if applicable

Obstetric History

Gravida, para, length of gestation, weight of infant at birth
 Labor experience, medical interventions, and method of delivery

Sexual History

Sexual activity (one partner, multiple partners, age when first sexually active)
 Method of contraception (satisfaction with method, adverse reactions, accuracy of use)
 Previous sexually transmitted infection and treatment
 Knowledge or practice of measures to protect self from sexually transmitted diseases, including human immunodeficiency virus (HIV)

Family History

Cardiovascular problems (anemia, hypertension, clotting disorders, stroke, heart attacks)
 Cancer (breast, uterine, ovarian, bowel, lung, other)
 Osteoporosis

Psychosocial History

Primary language, additional languages spoken or understood, ability to read
 Marital status, employment, occupation, education (relevant to determine financial, social, and emotional support)
 Evaluation for possible domestic violence

A psychosocial assessment helps caregivers determine the best way to teach the woman health promotion behaviors. Inquiry can help identify her means of support and also possible risks to her well-being such as domestic (intimate partner) violence. See also [Chapter 24, p. 497](#), for techniques to assess for possible domestic violence.

CHECK YOUR READING

1. Why is a family history an important part of a health history?
2. What are some important psychosocial assessments in a health history?
3. What questions should be asked when taking a sexual history?

Physical Assessment

A complete physical examination is essential to detect general health problems and to identify positive aspects of health. (See a physical assessment text for a full explanation of the process of physical examination.) Blood pressure, temperature, pulse, respirations, and weight are measured at each visit. Height is taken at the initial examination and yearly after that. Loss of height, abnormal curvature of the vertebral column (dorsal kyphosis or scoliosis), and a thickening waistline in the absence of weight gain are important observations in identifying **osteomalacia** (softening of bones) or **osteoporosis** (increased spaces [porosity] of bone).

The heart is auscultated to determine rate and rhythm and to detect heart murmurs or irregularities. Auscultation of the lungs identifies abnormal sounds that may suggest the presence of fluid secondary to heart dysfunction or malignancy. The extremities are observed for varicosities or edema, and pedal pulses are palpated for strength and equality. Reduced sensation when palpating legs and feet may indicate circulation problems often associated with diabetes. The abdomen is palpated for tenderness, masses, or distention that may indicate the presence of benign or malignant tumors.

Additional assessments are necessary if the woman is in a high-risk group. For instance, if she has a family history of diabetes mellitus, tests such as a glucose tolerance test or hemoglobin A_{1c} (HbA_{1c}) may be indicated. If she has a history of multiple sexual partners or a sexual partner with multiple contacts, testing for sexually transmitted diseases (STDs), including human immunodeficiency virus (HIV) infection, is indicated.

Preventive Counseling

Physical examination provides an excellent opportunity to counsel women about preventive measures that often reduce their physical problems. Major preventable problems are overweight and obesity, inactivity, and smoking.

Overweight and obesity are associated with numerous health problems such as diabetes, hypertension, and CAD, as well as some cancers of the breast and reproductive organs. Overweight is defined as a BMI of 25 to 29.9. Obesity is defined as a BMI of 30 to 39.9. Over one third (35.7%) of U.S. adults are obese. Obesity-related conditions include heart disease, stroke, type 2 diabetes, and certain types of cancer. Some of these obesity-related conditions are leading causes of preventable death. Non-Hispanic blacks have the highest age-adjusted rates of obesity (49.5%) compared with Mexican Americans (40.4%), all Hispanics (39.1%) and non-Hispanic whites (34.3%) (Ogden, Carroll, Kit et al., 2012).

Counseling about self-care measures to improve health should be offered. Positive health behaviors, such as adequate physical activity or making the decision to stop smoking, should be reinforced. Use of latex condoms should be emphasized for high-risk women with multiple sexual partners or those whose partner has multiple sexual partners. Latex condoms provide some protection against transmission of viruses such as HIV and human papillomavirus (HPV).

Counseling about diet may identify measures that improve multiple problems. For example, a weight reduction diet can include measures to improve calcium intake to slow osteoporosis, to lower cholesterol, and to reduce diabetes mellitus severity. Achieving adequate exercise can reduce diabetes effects, lower weight, reduce cholesterol levels, and slow osteoporosis. A woman often feels better physically and emotionally as she achieves her personal goals, and the nurse can provide consistent encouragement.

The history or physical examination may identify other areas for client counseling. These include the dangers of malignant melanoma

BOX 33-2 RISK FACTORS FOR BREAST CANCER

- Female
- Age: For a woman living in the United States, a lifetime risk of 1 in 8
- Race: White women are more likely to develop breast cancer, but black women are more likely to die because they tend to develop breast cancer at an age <40 years and in a more aggressive form. Asian, Hispanic, and Native-American women have a lower risk of developing and dying from breast cancer.
- Early menarche (<12 years), late menopause (>55 years)
- Nulliparity or first pregnancy after 30 years
- Personal history of breast cancer
- Genetic risk factors:
 - Family history in first-degree relatives (mother, sister, daughter)
 - Family history of other cancer
 - Mutations in the *BRCA1* and *BRCA2* genes
 - Mutations in other genes: *CHEK-2* gene, *ATM* (ataxia-telangiectasia mutated) gene, *PTEN* gene
- Previous irradiation of the chest area as a child or a young woman as treatment for another cancer (such as Hodgkin's disease or non-Hodgkin's lymphoma)
- Previous abnormal breast biopsy results:
 - Atypical hyperplasia increases the risk four to five times.
 - Fibrocystic changes without proliferative changes do not change breast cancer risk.
- Long-term hormone replacement therapy with estrogen and progesterone
- Excessive alcohol consumption
- Overweight or obesity
- Physical inactivity

Data from American Cancer Society. (2011). *Breast cancer facts and figures, 2011-2012*. See www.cancer.org.

with repeated exposure to ultraviolet rays of the sun. In addition, counseling and referral for alcohol and other substance abuse may be needed for some women. Domestic violence may be discovered, requiring counseling for the woman to deal with this complex social problem.

Screening Procedures

The value of screening procedures is based on two assumptions: (1) prevention is better than cure, and (2) early diagnosis allows early treatment while the pathologic process is most curable.

Some screening procedures are recommended for all women of reproductive age, including some screening procedures for early detection of breast cancer as well as vulvar self-examination and screening for cervical cancer. Other screening procedures are recommended for older women or those with higher risk (Box 33-2).

Breast Self-Awareness and Breast Self-Examination

Breast self-examination (BSE) is an organized monthly evaluation by the woman. However, increased emphasis is being given to **breast self-awareness**, defined as a woman's awareness of the normal appearance and feel of her breasts. Monthly BSE may be performed with breast self-awareness. Although women often discover their abnormalities first, neither BSE nor breast self-awareness should be a substitute for clinical breast examination (CBE) by a professional and mammography. The concept of breast self-awareness arose because half of breast cancers in women at least 50 years old, and more than 70% of cancer cases in women younger than 50, are discovered by the woman herself (American College of Obstetricians and Gynecologists [ACOG], 2011,

WOMEN WANT TO KNOW

How to Perform Breast Self-Examination and Become Aware

- Look first in good light. Stand in front of a mirror. Place your hands on your hips and press down firmly. Look for dimpling, puckering, redness, or scaliness of your breast skin or nipples. Look for discharge from the nipples, changes in breast size or shape, or a nipple that has pulled inward or to the side.

- Lie down. Flatten your right breast by placing a pillow under your right shoulder. If your breasts are large, use your right hand to hold your right breast while you do the examination with your left hand.

- Use the sensitive pads of the middle three fingers on your left hand and a round massaging motion to feel for lumps or changes in the breast tissue.
- Press firmly enough to distinguish different breast textures: light pressure to feel tissues near the skin, medium pressure to feel slightly deeper, and firm pressure to feel tissues near the chest and ribs.
- Completely feel all parts of the breast and chest area. Examine breast tissue extending from the ribs under the arm to the center of the sternum (or chest bone). Examine breast tissue that extends from the lower ribs up to the neck (or collarbone). The amount of time required to completely feel all the breast tissue depends on the size of the breast. Women with small breasts need at least 2 minutes to examine each breast. Larger breasts take longer.
- Use the same routine or pattern to feel every part of the breast tissue. The up-and-down pattern is the most effective to avoid missing breast tissue. Use overlapping dime-sized circular motions of your finger pads to feel the breast tissue. Use three levels of pressure: light for tissue near the skin, medium for a little deeper, and firm to feel near the bones.
- When you have completely examined your right breast, examine the left breast with your right hand using the same method. Compare what you feel in one breast with the other.

- You may also want to examine your breasts while bathing, when the skin is wet and lumps may be easily felt.
- You can check your breasts in a mirror by raising your arms and looking for an unusual shape, dimpling of the skin, and any changes in the nipple.
- Examine each underarm, either when sitting or when standing, by raising your arm slightly to better feel the area. Raising your arm high will tighten tissues in the area, reducing what you can feel.

Modified from the American Cancer Society (ACS). (2012). *How to perform a breast self-exam*. Retrieved from www.cancer.org and modified from American College of Obstetricians and Gynecologists. (2012). *Patient education fact sheet: The breast self exam*. Retrieved from www.acog.org.

2012; American Cancer Society [ACS], 2011). BSE/breast self-awareness is best performed about 1 week after the onset of menses, when hormonal influences on the breasts are at a low level. If the woman no longer menstruates, she may choose a day that is easy to remember and perform the examination on that day every month.

Clinical Breast Examination

Clinical breast examination (CBE) is similar to BSE, but professional examiners may identify questionable areas that the woman misses. It

should be routinely performed every 1 to 3 years for women ages 20 to 39 years and yearly for those 40 years or older (ACOG, 2011; ACS, 2011). Some conditions require more frequent examinations because they are associated with a higher risk for breast cancer than in the general population. The examination includes inspection and palpation and should be part of every gynecologic examination.

Inspection

1. While the woman is in an upright position, the examiner inspects the breasts for size, symmetry, color, and skin changes. The nipples

and areolae are inspected for differences in size and color, unilateral retraction of a nipple, and asymmetric nipple direction, which may indicate an underlying tumor.

2. The woman raises her hands above her head, and the examiner inspects the sides and underneath portions of the breast for asymmetry and differences in color.
3. The woman places her hands on her hips and presses down to reveal skin dimpling or masses.

Palpation

1. While the woman is in an upright position with her arm relaxed at her side, the axillary, supraclavicular, and suprasternal lymph nodes are palpated for tenderness or enlargement.
2. The woman lies in a supine position for palpation of the breasts. A small pillow or folded towel is placed under the shoulder to stretch the tissue and flatten the breast. The examiner uses the flat part of the first three fingers to palpate the breast, rotating the fingers against the chest wall. Tissue that extends into the axilla, the axillary tail (or tail of Spence), should be palpated. The procedure is repeated on the opposite side. Normal breast tissue is described as firm, lumpy, nodular, tender, and thickened. Abnormal breast tissue is often likened to a raisin, watermelon seed, or grape because a discrete mass can be felt and its size estimated. If a suspicious area is found, follow-up by diagnostic mammography, often ultrasonography, is recommended.
3. The nipples are compressed to detect the presence of discharge. A sample of any discharge should be collected for culture and examination of cells.

Mammography

Mammography may be used either to screen for cancer or to assist in the diagnosis of a palpable mass in the breast. Mammography is a screening tool that can detect breast lumps well before they are large enough to be palpated. This procedure, often accompanied by ultrasound examination, allows early diagnosis and treatment and thereby increases the chance of long-term survival. ACOG (2011) and ACS (2011) recommend annual mammograms for women 40 years old and older. Women at high risk for breast cancer (see Chapter 34 for a summary of risk factors) may need earlier or more frequent mammography and should consult their health care providers.

Despite the known value of mammography, many women have never had a mammogram. Reasons for this include lack of a health care professional's recommendation, expense, fear that radiation exposure will cause cancer, fear of pain, and reluctance to hear "bad news." Nurses provide information and reassurance whenever possible and, in this way, help the woman overcome her objections to the use of this valuable screening tool. Mammography is relatively expensive, but part of its cost is usually covered by health insurance, Medicaid, or Medicare. Screening mammograms may be offered by community agencies at low cost. Acknowledge that brief discomfort occurs when the breast is compressed between two plates while the image is obtained. Scheduling the mammography after a menstrual period, when the breasts are less tender, reduces discomfort. Knowing that mammography has minimal to nonexistent risks, because very-low-dose exposure to radiation is used, may help women to overcome some of their fear.

Vulvar Self-Examination

Vulvar self-examination should be performed monthly by all women older than 18 and by those younger than 18 who are sexually active. Vulvar self-examination is visual inspection and palpation of the female external genitalia to detect signs of precancerous conditions or infections.

The woman should sit in a well-lighted area and use a hand mirror to see her external genitalia. She is taught to examine the vulva in a systematic manner, starting at the mons pubis and progressing to the clitoris, labia minora, labia majora, perineum, and anus. Palpation of the vulvar area should accompany visual inspection. She should report to her health care provider as soon as possible the presence of any new moles, warts, or growths of any kind; ulcers; sores; changes in skin color; or areas of inflammation or itching. Increasing rates of HPV are associated with increased incidence of vulvar intraepithelial neoplasia (VIN).

Pelvic Examination

The complete gynecologic assessment includes a pelvic examination. The woman should schedule the examination between menstrual periods and should not douche or have sexual intercourse for at least 48 hours before the examination. She also is advised not to use vaginal medications, sprays, or deodorants that might interfere with interpretation of specimens that are collected.

The procedure is carefully explained before the examination, and the woman empties her bladder. Although pelvic examinations are relatively painless, most women dislike them and welcome sensitive, considerate support. Women who have undergone female genital mutilation (Box 33-3) need extra consideration. The nurse must avoid displaying shock, despite the fact that most nurses in Western countries have an aversion to this unfamiliar practice. A pediatric vaginal speculum may be needed for these or other women with a very small vaginal opening. Routine preventive pelvic examinations may be impossible for women who have only a tiny opening left for drainage of urine and menstrual blood.

The adolescent having her first examination also benefits from an understanding nurse who takes the time to explain the equipment and steps of the examination carefully before having the adolescent undress. If she is anxious and fidgeting, she will appreciate a hand to hold and an explanation before each step. Some of the breathing techniques used for birth, such as slow, paced breathing, or use of a focal point (see Chapter 15), may be helpful.

The pelvic examination is done usually with the woman in a lithotomy position, with a pillow under her head. If she wishes, she may be placed in a semisitting position and offered a hand mirror so that she can observe the external genitalia and the examination and learn more about her body. She is draped so that only the parts being examined are exposed.

Women who cannot tolerate a lithotomy position, such as a frail elderly woman, may benefit from a side-lying pelvic examination. The pelvic can also be done with the woman in a semi-Fowler's position, with her knees bent and feet on the examination table, rather than using the stirrups and having her hips at the edge of the table. The paraplegic woman, with no control over her lower extremities, usually can be examined with her legs separated in a V shape without her knees being bent.

Necessary equipment to be assembled before the examination begins includes gloves, speculum (several sizes, including pediatric, should be available), slides, cotton swabs, a fixative agent, and a cytobrush and spatula for obtaining material for the cytology specimen, or Pap test (see later in this chapter). A stool specimen may be obtained by the examiner during the rectal examination, and a slide for this specimen also should be available. Equipment for specimens to identify vaginal infections should be available.

External Organs. The pelvic examination is conducted systematically and gently. The external organs are inspected for the degree of development or atrophy of the labia, the distribution of hair, and the character of the hymen. Any cysts, tumors, or inflammation of

BOX 33-3 FEMALE GENITAL MUTILATION (FGM)

Female genital mutilation (FGM), sometimes called *female circumcision* or *female genital cutting*, is the ritual disfigurement and the partial or total removal of a girl's external genitalia or other injury to her external genitalia for cultural, religious, or other nontherapeutic reasons.

The practice occurs in Africa and in some areas of the Middle East and Asia. It may be found in immigrant groups in Europe, Australia, New Zealand, Canada, and the United States. Between 100 and 140 million girls and women are estimated to have undergone female genital mutilation, and another 3 million are at risk annually. About 92 million girls are estimated to have undergone FGM (World Health Organization [WHO], 2008).

The age at which the procedure is performed varies from a few days old to adult. Most are done between infancy and 15 years, an age at which the girl cannot give informed consent for a procedure with lifetime consequences for her health.

Female genital mutilation may be done by a village practitioner using crude tools, such as knives, razor blades, broken glass, thorns, or scissors, and without anesthesia. Parents in more developed countries may obtain the procedure from a physician to ensure pain relief and sterility. However, the increasing trend for performance of FGM by health professionals is strongly discouraged.

Female genital mutilation is considered a part of the coming-of-age ceremonies in some societies, and a girl may not be considered marriageable unless she has undergone the procedure. Some societies believe that the practice enhances female chastity and increases male sexual pleasure. Other societies consider the external female genitalia to be unsightly and dirty. Therefore they are removed to promote hygiene and the woman's attractiveness.

Female genital mutilation is illegal and subject to criminal prosecution in several countries, including the United States.

Four major types of female genital mutilation exist (WHO, 2008):

- Clitoridectomy: Partial or total removal of the clitoris and sometimes the prepuce that surrounds the clitoris
- Excision of part or all of the clitoris and the labia minora, with or without excision of the labia majora
- Infibulation: Narrowing of the vaginal opening with the creation of a covering seal
- Other nonmedical practices of pricking, piercing, incising, scraping, and cauterizing the genitals

Genital mutilation has no benefits and many associated problems. Health consequences may include the immediate results of severe pain, shock, hemorrhage, ulceration, urinary retention, and infection. Tetanus, bacterial sepsis, or human immunodeficiency virus is a concern if unsterile materials are used or if the vaginal opening is so small that anal intercourse is used as an alternative to vaginal intercourse. Infibulation may result in scar formation that causes dyspareunia, difficulty urinating, difficulty with menstruation, recurrent urinary tract infections, and infertility. Painful intercourse and reduced sexual sensitivity may have consequences on psychological health.

A 2008 statement issued jointly between the WHO, United Nations Children's Fund (UNICEF), and the United Nations Population Fund (UNFPA) supports advocacy that opposes FGM. See www.who.int.

Bartholin's glands is noted. The urinary meatus and Skene's glands are inspected for discharge. Perineal scarring resulting from childbirth is noted.

Speculum Examination. A bivalve speculum of the appropriate size is used to inspect the vagina and cervix. The speculum is warmed with tap water and gently inserted into the vagina. Plastic speculums

FIG 33-1 Bimanual palpation provides information about the uterus, fallopian tubes, and ovaries.

do not get as cold as metal ones. Lubrication other than water or water-based lubricant on the cervix interferes with accurate cytology results. The size, shape, and color of the cervix are noted. Samples are taken for the Pap test. Routine testing for gonorrhea and chlamydia is common because of the increased incidence of these two STDs. Additional samples of any unusual discharge are obtained for microscopic examination or culture.

Bimanual Examination. The bimanual examination provides information about the uterus, fallopian tubes, and ovaries. The labia are separated, and the gloved, lubricated index finger and middle finger of one hand are inserted into the vaginal introitus.

The cervix is palpated for consistency, size, and tenderness to motion. The uterus is evaluated by placing the other hand on the abdomen with the fingers pressing gently just above the symphysis pubis so that the uterus can be felt between the examining fingers of both hands. The size, configuration, consistency, and mobility of the uterus are evaluated (Figure 33-1).

Feeling the fallopian tubes is usually impossible, although the ovaries may be palpated between the fingers of both hands. Because ovaries atrophy after menopause, palpating the ovaries of a postmenopausal woman may not be possible.

Cervical Cytology or Pap Test

Purpose. It is known that, in virtually all cases, changes occur in cells of the cervix before cervical cancer develops. These changes have variously been called *cervical intraepithelial neoplasia*, *dysplasia*, *squamous intraepithelial lesions (SILs)*, and *carcinoma in situ*. Cervical cytology, or the **Pap test**, often combined with a test for human papillomavirus (HPV), is the most useful procedure for detecting precancerous and cancerous cells that may be shed by the cervix. As Pap testing became routine in this country during the past half century, preinvasive lesions (precancers) of the cervix became far more common than invasive cancer (ACOG, 2009a; ACS, 2012b).

Procedure. With the speculum blades open and the cervix in view, samples of the superficial layers of the cervix and endocervix are obtained. Samples are best obtained with a spatula and a cytobrush or with a broom-type sampling device. A sample is taken where most lesions develop, at the squamocolumnar junction (the border where developing squamous tissue meets the immature columnar epithelium). In postmenopausal women the squamocolumnar junction recedes into the endocervix, making cervical specimens obtained by the cytobrush or broom-type device important.

Cervical tissue is placed on slides that are then sprayed with or immersed in a fixative solution before being sent to the laboratory for analysis if the older Pap test technique is used. Specimens obtained with the broom-type device, such as those in the liquid-based Thin-Prep or AutoCyte tests for cervical cancer, are stirred into the liquid that preserves the cells for analysis. The liquid-based tests use image processing to select the slides that need additional preparation by a technician for best analysis.

Classification of Cervical Cytology. A great deal of variation existed in how cervical cytology findings were reported until recently. The Bethesda system was devised to offer standard terminology and give a narrative, descriptive diagnosis. It consists of three elements: (1) a statement of specimen adequacy, (2) a general categorization (normal or abnormal), and (3) a descriptive diagnosis regarding abnormal cytology. Additional interpretations not related to cancer include presence of infecting organisms (such as *Trichomonas vaginalis*); changes that may be associated with inflammation, radiation, or intrauterine contraceptives; or atrophy of the cervical cells.

Categories for epithelial cell abnormalities include the following:

- Atypical squamous cells of undetermined significance (ASCUS)
- Squamous intraepithelial lesion, which is subdivided into (a) low-grade SIL (including cellular changes of HPV) and (b) high-grade SIL (previously categorized as carcinoma in situ). High-grade SIL is more likely to become cancerous without definitive treatment.
- Squamous cell cancer
- Glandular cell abnormalities are categorized as follows:
 - Atypical glandular cells of unknown significance (AGCUS)
 - Adenocarcinoma

The woman's follow-up depends on the nature of the abnormality and whether it is persistent. Pap tests that have persistent ASCUS findings after a 3- to 6-month interval are also usually evaluated by colposcopy. Suspicious lesions are examined with colposcopy and biopsy.

Rectal Examination

The anus is inspected for hemorrhoids, inflammation, and lesions. The examiner's lubricated index finger is gently inserted, and sphincter tone is noted. A slide may be prepared to test for the presence of occult blood in stool.

High-sensitivity fecal occult blood testing (FOBT) is a useful yearly screening measure for colorectal cancer beginning at age 50. Only high-sensitivity forms of guaiac-based tests should be used for this purpose. A newer test, the fecal immunochemical test (FIT), may be done, requiring only two samples and having a high-quality stool-based screening and a lower risk of false-positive results (ACS, 2012a).

Special instructions are necessary to prevent false test results when the woman is given materials for FOBT. She should be instructed to do the following:

- Avoid aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen or naproxen for at least 7 days before collecting the specimen.
- Avoid red meat, raw fruits and vegetables, horseradish, and vitamin C for 72 hours before testing.

BOX 33-4 RISK FACTORS FOR CORONARY ARTERY DISEASE IN WOMEN

Cigarette smoking
 Hypertension (including isolated systolic hypertension)
 Serum lipids (dyslipidemia):
 Elevated total cholesterol (normal: ≤ 199 mg/dL; borderline: 200-239 mg/dL; elevated: ≥ 240 mg/dL)
 Low levels of high-density lipoprotein (HDL) cholesterol: < 35 mg/dL (< 40 mg/dL men; < 50 mg/dL women [American Heart Association])
 Cholesterol ratio: The ratio of cholesterol to HDL cholesterol is often used instead of total blood cholesterol. The goal is to keep the ratio lower than 5 (total cholesterol) to 1 (HDL cholesterol), with an optimum ratio of 3.5:1.
 Triglyceride levels: > 150 mg/dL
 Diabetes mellitus
 Overweight and obesity
 Sedentary lifestyle
 Poor nutrition, especially a diet high in saturated fat and cholesterol but low in fiber and fruit
 Age older than 60
 Postmenopause status
 Family history of coronary artery disease

Data from American Heart Association (2012). *What your cholesterol levels mean*. Retrieved from www.heart.org.

- Collect a specimen from three consecutive stools.
- Return slides as directed within 4 to 6 days after the specimens are collected.

Screening Tests

Additional tests depend on the age, history, and risk assessment of the woman and might include the following:

- Testing for STDs, such as gonorrhea, chlamydia, syphilis, and HIV
- Testing for rubella immunity, which is particularly important in the childbearing years, although the overall incidence of the disease is very low in the United States
- Tuberculosis skin testing or chest x-ray examination
- Cholesterol and other lipid profile testing of women at risk for CAD (particularly important after menopause) (Box 33-4)
- Fasting glucose testing or other tests to identify development of diabetes, recommended every 3 years after age 45 or earlier if the woman has high-risk factors such as family history or being overweight
- Urinalysis to detect signs of urinary tract infection
- Thyroid function tests, which may be indicated if the woman exhibits signs of thyroid dysfunction, such as heart palpitations and heat intolerance
- Serum testing for genes associated with specific cancers, such as the *BRCA1*, *BRCA2*, or *p53* genes associated with breast and some other cancers
- Serum testing for CA-125, a tumor marker that may be elevated with ovarian cancer
- Transvaginal ultrasonography, which may be recommended for women who are at increased risk for malignant disorders of the reproductive tract (see Chapter 10)
- Fecal occult blood test yearly
- Bone density every 2 years starting at age 65; an earlier start to bone density screening may be recommended for women at higher risk for osteoporosis

TABLE 33-1 SCREENING PROCEDURES

PROCEDURE	PURPOSE
Breast self-examination (BSE) and breast self-awareness	To assess breasts monthly so that women become aware of their normal appearance and feel
Clinical breast examination (CBE)	To assess monthly for breast changes or masses that might indicate breast tumors
Mammography with additional imaging, such as ultrasonography, as needed ≥ 40 years (routine screening mammography)	To detect masses that women might miss
Diagnostic mammograms and other imaging may be started at a younger age for women having a higher risk for breast cancer or previous breast cancer or other disorders	To detect breast lumps before they become palpable, promoting long-term survival
Cholesterol test	To detect blood levels that raise risk for heart disease; usually combined with additional tests for high-quality screening (lipid profile), such as triglyceride level, high-density (HDL), and low-density (LDL) lipoprotein (see Box 33-4)
Vulvar self-examination	To detect signs of precancerous conditions or infection
Pelvic examination	To confirm that no disease exists or for early detection if disease does exist
Pap test	To detect abnormal cervical cytology as early as possible
Rectal examination	To check for hemorrhoids and lesions and to evaluate sphincter control
Fecal occult blood test (FOBT)	To detect blood in stool, an early sign of colon cancer
Urinalysis	To screen for diabetes and urinary tract infections

ADDITIONAL PROCEDURES MAY BE BASED ON RISK FACTORS

PROCEDURE	RISK FACTORS
Bone density every 2 years starting at 65 years	Family history, fracture history, estrogen deficiency, fall history, physically inactive, underweight, poor nutrition, tobacco or alcohol abuse, chronic steroid use, dementia, European or Asian ancestry
Begin bone density screening earlier than 65 years for high-risk women	Multiple sexual partners of the woman or her partner, history of STDs; seeking treatment for STDs, injection drug use, sexual partner who is HIV-positive or bisexual or injects drugs, recurrent or persistent episodes of infections such as candidiasis and herpes
Sexually transmitted disease (STD) testing; human immunodeficiency virus (HIV) testing	Diabetes, smoking, no estrogen use after menopause, family history of high cholesterol or coronary artery disease
Lipid profile	Overweight, history of gestational diabetes, family history of diabetes
Fasting glucose test	To determine immunity to rubella
Rubella antibodies	Signs or strong family history of thyroid disease
Thyroid-stimulating hormone (TSH)	To determine the degree of higher risk influenced by genetic alterations, improving options for therapy
Blood tests to evaluate risk for reproductive cancers (see Box 34-7 on p. 748)	Family history of ovarian cancer
Transvaginal ultrasound examination	Family history of bowel cancer or older than 50 years
Sigmoidoscopy (every 5 years) or colonoscopy (every 10 years)	To determine infection in a person at higher risk for tuberculosis
Tuberculosis testing	

- A colonoscopy (every 10 years after age 50); a yearly colonoscopy may be recommended if the woman has a family history of colon cancer
See [Table 33-1](#) for a summary of recommended procedures.

Immunizations

Determining the woman's need for immunization is becoming more common at her annual well-woman checkup. Immunization needs will vary with the time of year, the client's age, and history of infections. Public health clinics are another common site to encourage immunization among young and old, male and female. Fear of adverse effects from immunizations may become evident. Updated information about recommended immunizations is available from www.cdc.gov.

Influenza vaccine is often offered during the fall and winter. It is not unusual to hear people say that they had the "flu shot" last year and "got the flu anyway," so teaching is important to encourage the

vaccine. The composition of annual flu vaccines must be determined well before the infections start to emerge, so they may be more effective one year as compared to another year. People often do not realize that their annual vaccines require about 2 weeks to become effective and that they will show signs of the infection if they have already acquired it at the time of their vaccination.

Hepatitis B vaccine may be offered if the woman has not had it. Rubella vaccine may be given if the woman has never had the infection or vaccine and is not pregnant. Pregnancy testing is done and rubella immunization is delayed until after delivery if she is pregnant (see [Drug Guide for Rubella Vaccine, p. 335](#)).

Adults should receive a dose of tetanus and diphtheria (Td) every 10 years. One dose of tetanus, diphtheria, and acellular pertussis vaccine (Tdap) should be given to adults, ages 19 through 64, as a substitute for one of their Td immunizations. This may be done before the woman is discharged after childbirth ([Gerbie & Tan, 2009](#)).

DRUG GUIDE**HUMAN PAPILLOMAVIRUS QUADRIVALENT VACCINE (GARDASIL)**

Classification: Vaccine against human papillomavirus (HPV), types 6, 11, 16, 18.

Indications: Prevention of infections caused by HPV types 16 and 18 that may cause cervical, vaginal, and vulvar cancer. Prevention of genital warts caused by HPV types 6 and 11.

Dosage and Route: *Intramuscular (IM) injection:* Prefilled syringe of 0.5 mL of vaccine suspension at the following schedule: first dose; 2 months after first dose; 6 months after first dose.

Contraindications: Hypersensitivity to any component, including yeast.

Adverse Reactions: Headache is the most common adverse reaction. Others are fever, nausea, dizziness, and pain, edema, itching, and bruising of the injection site. Fainting has occurred.

Nursing Considerations: Teach the woman that HPV vaccine is not treatment for existing genital warts or cervical, vaginal, or vulvar cancers and that regular cervical cancer screening should continue as recommended by her care provider. Cervical, vaginal, or vulvar cancers are not always caused by the HPV viral strains in this vaccine. Observation for 15 minutes after vaccine administration is recommended to reduce risk for fall if fainting occurs.

Human papillomavirus (HPV) vaccine, a series of three injections, is available and currently recommended for females and males from 11 to 12 years old, although the series may be started at age 9 to 26 years. Some strains of HPV are known to cause cervical cancer and genital warts, and the recent HPV vaccine is effective against these strains. The ideal time to immunize is before any sexual activity. As might be expected, parents must grapple with uncomfortable issues when making the decision about immunizing a preteen or adolescent girl or boy, an age younger than age of legal consent, against this sexually transmitted disease. Cost of the three injections may be beyond the family's ability to pay if not covered by insurance or through Medicaid or other public funding. For more information about possible federal and manufacturer funding, see www.gardasil.com or www.cdc.gov and choose HPV vaccination from the CDC A-Z index.

APPLICATION OF THE NURSING PROCESS**■ Promoting Health**

Nurses may find themselves having the pleasure of promoting a woman's health rather than mostly finding problems with it. Promoting health can improve outcomes for families, not just individual women. This Application of the Nursing Process is slightly different in that it uses a case study to demonstrate use of the nursing process but also involves the woman in the process. Our reader should consider what he or she might do as a nurse.

Assessment

Consider a 36-year-old woman who arrives for her annual WWE. She is overweight and states that she eats too much food and "the kind that's bad for you." When giving her annual history, she states that many members of her family have diabetes. She also tells the nurse, "I don't want to be sick all the time like most of my family" and asks, "Can I change anything?"

This single mother also describes her 6- and 10-year-old children as "sitting around too much" and says that they are also overweight. She states that she wants her children not only to stay in school but also to be more active. She is aware that increasing her children's activity level will help prevent excess weight gain.

The woman is being seen for her WWE in an outpatient teaching clinic, and her care is provided by medical residents. She works at a fast food restaurant for varying hours per week. Health insurance is offered by the restaurant chain but she cannot afford the premiums. She does qualify for Medicaid, so that is her major source of funding for medical care.

Nursing Diagnosis

Although the woman has some obvious health problems and has financial limitations, she has indicated a personal desire to have better health for herself and her children. Her statements indicate that she knows she has a need to improve her actions but does not know the best way. A reasonable nursing diagnosis for the woman is "Health-Seeking Behaviors related to expressing a desire to take charge of her own health and influencing the health of her children in a positive way."

Planning

Expected outcomes for this brief clinic visit are that the woman will:

- Describe foods that she likes, can afford, and will help her lose weight.
- Explore how she might increase her own activity level and how she could include her children.

Interventions**Reinforce the Woman's Desire for Change**

Recognizing that the nurse values her desire to improve her health and that of her children helps motivate the woman to search for ways to make the changes that she can accomplish over time. Explain how her actions to improve her own health set a positive example for her children, despite the family's financial limitations. Explain that she will have setbacks but that she does not need to abandon her positive change to improve her health and that of her children.

Identify Food Preferences

Determining what the woman eats regularly and what she enjoys the most helps the nurse identify beneficial aspects of her current diet and changes that might benefit her desire for better health. Ask her about food she eats during an average day, including the frequency and timing of meals. Ask her what foods she eats where she works. Identify what vegetables and fruits she eats and in what form (e.g., fresh or canned fruits or fruit snack cakes that have very little actual fruit and may be more costly). Describe what is good about her choices and basic changes that she should consider. Help her identify beneficial changes from what she says about her personal preferences and explore ways to make those changes within her limited budget.

Ask her if she eats breakfast and what she eats. Is it cereal with milk or is it leftover pizza? Explain to her that a nourishing breakfast for her

and her children might be food that she had not considered. If she starts her day with adequate, nourishing food, even if it is leftovers, explain that she is less likely to overeat or eat non-nourishing food later in the day.

Drinking fewer soft drinks or bottled water might reduce an expense that the woman has not considered. If she says her vegetables are canned, ask her if they are brand name or generic and if she has considered using generic brands of food and other household products.

Teach the woman that information about good nutrition is often available by computer and that computers exist at most public libraries.

Financial Assistance

Ask the woman if she receives any public assistance such as the Supplemental Nutrition Assistance Program (SNAP) (www.nutrition.gov), formerly the Food Stamps program. Refer her to the appropriate source for information about qualifications and application if she does not receive public assistance. Referral to social work may identify other sources for food such as a free lunch program for her children on

school days or church or neighborhood groups that feed hungry people.

Activity

Explain that daily activity helps her burn calories and can improve her energy level. Explore ways she might increase her activity such as walking to work, the grocery store, or the post office. Help her evaluate whether it is realistic for her children to walk to school if she or another adult walks with them. What active games can she play with her children, perhaps at a nearby park?

Evaluation

Although this encounter with the woman is brief, it is an opportunity for the nurse to reinforce her ability to achieve better health. As the woman lists foods she often eats during a day, the nurse can promote those that are good for her health and/or the health of her children but also help her find alternatives to less nutritious foods. Finding that the woman has discovered ways to increase her family's activity level meets the second outcome and can motivate the woman to seek more opportunities that might be possible.

SUMMARY CONCEPTS

- Women's Health Initiative was a 15-year national study to address the best prevention and treatment for three major diseases that affect women as they age: cardiovascular disease, breast cancer, and osteoporosis.
- *Healthy People 2020* goals are health targets for the United States. Many goals address women's issues.
- Many women do not have a primary health care provider, such as a family physician or family nurse practitioner, and depend on their reproductive health provider to do their regular health checks.
- A health history helps identify a woman's health problems and risks for specific problems, actions she can take to promote her health, and other measures needed to further improve her health.
- A complete physical assessment can identify general health problems and guide further testing that should be done.
- Major preventable problems that can create other problems are overweight and obesity, inactivity, and smoking.
- Screening procedures may prevent problems and/or identify a problem early when it is most curable. Some screenings are monthly or annual, some age-based, and others risk-based procedures.
- Pap tests can identify early changes in cervical tissue that may lead to cervical cancer.
- HPV vaccine is designed to prevent infection with four strains of human papillomavirus that can result in genital warts or cervical cancer. The best time for immunization is before the girl engages in any sexual activity, although it can be started after sexual activity.
- Fecal occult blood testing is a yearly test that may identify colon or rectal cancer early.

Women's Health Problems

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain benign disorders of the breast, relate them to usual age of onset, and describe the diagnostic procedures used to rule out cancer of the breast.
2. Describe the incidence, risks, pathophysiology, management, and nursing considerations related to malignant breast tumors.
3. Discuss cardiovascular disease in women, including risk factors, signs and symptoms, and prevention measures.
4. Discuss common menstrual cycle disorders.
5. Explain premenstrual syndrome, management options, and nursing considerations.
6. Discuss medical termination of pregnancy in terms of procedures, possible complications, and follow-up care.
7. Describe the physical and psychological changes associated with menopause and options to alleviate uncomfortable changes.
8. Discuss measures to reduce severity of osteoporosis.
9. Describe the major disorders associated with pelvic relaxation in terms of cause, treatment, and nursing considerations.
10. Discuss the most common benign and malignant disorders of the reproductive tract in terms of signs and symptoms, management, and nursing considerations.
11. Describe care of the woman with an infectious disorder of the reproductive tract, including sexually transmitted diseases, pelvic inflammatory disease, and toxic shock syndrome.

BREAST DISORDERS

Breast disorders that are benign are most common. However, distinguishing between benign and malignant breast lumps from simple palpation alone is not sufficient. Therefore physicians often order additional diagnostic tests to better identify true pathology and the likelihood that a benign disorder may become malignant. For noninvasive imaging such as mammograms, having earlier images for comparison is an advantage but these may not be available.

Diagnostic Evaluation

Ultrasound examination can be used to differentiate fluid-filled cysts from solid tissue, which is more likely to be malignant. Fine-needle aspiration (FNA) biopsy can be done to remove fluid or small tissue fragments for analysis of the cells. Core biopsy uses a larger needle to obtain a cylinder of tissue from an area of questionable breast tissue. Open, or surgical, biopsy is performed

to remove all or part of the lump of breast tissue if other conditions exist:

- Suspicious mass that persists through a menstrual cycle
- Bloody fluid aspirated from a cyst
- Failure of the mass to disappear completely after fluid aspiration
- Recurrence of the cyst after one or two aspirations
- Solid dominant mass not diagnosed as fibroadenoma
- Serous or serosanguineous nipple discharge
- Nipple ulceration or persistent crusting
- Skin edema and erythema suspicious for inflammatory breast carcinoma
- Suspicious mammography or ultrasound findings
- Known or possible genetic abnormality that increases a woman's risk for breast cancer

Benign Disorders of the Breast

Four relatively common benign disorders of the breast tend to occur at different ages.

Fibrocystic Breast Changes

Fibrocystic breast changes are common breast changes during the reproductive years before **menopause**, or permanent cessation of menstruation. Fibrosis, or thickening of the normal breast tissue, occurs in the early stages. Cysts may form in the latter stages and are felt as multiple, smooth, well-delineated nodules that have a tender, movable character. The lumpy, rubbery, or ropelike nodules often vary in size, from less than 1 cm to several centimeters. Fibrocystic changes are not cancerous, although atypical hyperplasia of the terminal breast ducts or lobules is associated with a greater risk for breast cancer. Tissue specimens obtained by fine needle aspiration (FNA) or from an open surgical biopsy are examined to identify the tissue type and any malignant changes (Katz & Dotters, 2012).

The most common symptom of fibrocystic breast changes is pain and tenderness. The pain is often bilateral and most noticeable during the premenstrual phase of the normal cycle. Women with large breasts may have pain associated with stretching of the breast ligaments. Premenstrual pain is believed to be the result of an imbalanced estrogen-to-progesterone ratio. Women with fibrocystic breast changes improve dramatically during pregnancy and lactation because the large amounts of progesterone present during pregnancy block the excess amounts of estrogens present when the woman is not pregnant.

The initial therapy varies with the age of the woman and her risk for breast cancer. Aspiration of cysts may relieve pain with follow-up needed only if the cyst recurs or fluid aspirated is suspicious. The bilateral nature of the changes and pain suggests that the condition is benign, but definitive studies such as **mammogram** (study of breast tissue with low-dose radiography) and ultrasound imaging, FNA of the cysts, or surgical biopsy may be needed to identify malignancy. Fibrocystic breast changes may fall into three categories:

- Nonproliferative lesions
- Hyperplasia without atypical cells
- Atypical hyperplasia

Hyperplastic lesions with atypical cellular changes have an increased risk to become malignant, but most women with fibrocystic breast changes do not have a greater risk for breast cancer.

Specific symptom relief for fibrocystic disease has not proven beneficial, but some methods may be worth trying. Wearing a support bra is a simple way to reduce pain from large breasts that stretch ligaments. Avoiding caffeine and other stimulants (coffee, tea, chocolate, and some soft drinks) reduces levels of methylxanthines, which may increase discomfort during the last half of the menstrual cycle. Oral contraceptives taken during the secretory phase (second half) of the menstrual cycle have been successful, but pain returns if the contraceptives are discontinued. Danazol (Danocrine), an androgenic medication that suppresses estrogen production, may be given for severe pain but for no longer than 4 to 6 months. Other possible drugs include bromocriptine (a prolactin inhibitor) or tamoxifen (an estrogen inhibitor that is usually given in breast cancer treatment). Evening primrose oil is a possible botanical preparation that may relieve pain but should not be taken if the woman has seizure disorders or takes phenothiazines used for treatment of schizophrenia (Box 34-1).

Fibroadenoma

Fibroadenomas are common benign tumors of the breast, and although they may occur at any age, they are most common during the teenage years and the 20s. Fibroadenomas are composed of both fibrous and glandular tissue. They are firm, freely mobile nodules that may or may not be tender when palpated. Fibroadenomas do not change during the menstrual cycle. They are generally located in the

BOX 34-1 COMPLEMENTARY/ ALTERNATIVE THERAPY FOR BREAST PAIN

Evening primrose oil (EPO) has shown mixed results for cyclic and noncyclic breast pain, menopausal symptoms, and bladder symptoms. EPO has a long history of use for eczema and is being studied for use in rheumatoid arthritis (ACOG, 2012b; NCCAM, 2009a).

From Dennis, K.E. (2007). Postmenopausal women and the health consequences of obesity. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 36(5), 511-519.

upper, outer quadrant of the breast, and more than one is often present.

Treatment may involve careful observation for a few months to determine if the mass is stable. FNA or core biopsy of the tumor is done if the mass continues to enlarge. The mass may be excised and the specimen analyzed to rule out malignancy if results of other diagnostic tests are not conclusive (Katz & Dotters, 2012).

Ductal Ectasia

Ductal ectasia usually occurs as a woman approaches menopause. It is characterized by dilation of the collecting ducts, which become distended and filled with cellular debris. This initiates an inflammatory process resulting in:

- A mass near the areola that feels firm and irregular
- Enlarged axillary nodes
- Nipple retraction and discharge

These signs and symptoms are similar to those of breast cancer, and accurate diagnosis through biopsy is vital. Although ductal ectasia is benign, the ducts may be excised to prevent further discharge or to remove an abscess that results from infection (Katz & Dotters, 2012).

Intraductal Papilloma

Intraductal papilloma develops most often just before or during menopause. It occurs when papillomas (small elevations or protuberances) develop in the epithelium of the ducts of the breasts, often under the areola. As the papilloma grows, it causes trauma and erosion within the ducts that result in serous or bloody discharge from the nipple. Ultrasonography and diagnostic mammography aid in the diagnosis of the intraductal papilloma. Treatment consists of excision of the mass and ductal area, plus analysis of nipple discharge to rule out a malignant tumor. Long-term follow-up is essential to identify any malignancy early (Katz & Dotters, 2012).

Nursing Considerations

The nurse must acknowledge the anxiety that all women feel when a breast disorder is discovered. Furthermore, the apprehension continues for most women while they await a final diagnosis. Some women may find it helpful to learn that most breast disorders are benign. Some benign disorders do increase the risk for later occurrence of cancer, however. For others, the most helpful intervention is to encourage them to express their concerns.

The nurse should explain the diagnostic procedures that are planned, such as ultrasound examination, mammography, needle biopsy, or surgical biopsy. Explanations should include what the procedures entail and how long the woman will have to wait for results to be known. The woman's anxiety may be high, and she will likely need reinforcement of explanations that she has forgotten.

1. How are fibrocystic breast changes treated?
2. What diagnostic procedures are used to determine whether a breast disorder is benign or malignant?

Malignant Tumors of the Breast**Incidence**

The lifetime risk for a woman to develop breast cancer in the United States is 1 in 8. Breast cancer in men is rare, but in 2012 the [American Cancer Society \(ACS\)](#) expected 2190 new cases in men, with 410 resulting in death. The lifetime risk in men is estimated to be 1 in 1000. New cases in women were expected to be 226,870 in 2012, and 39,510 of these were expected to be **carcinoma in situ** (malignant neoplasm in surface tissue; noninvasive). Deaths in women were expected to be 1 in 36 cases ([ACS, 2012](#); [Katz & Dotters, 2012](#); [National Cancer Institute \(NCI\): National Institutes of Health \[NIH\], 2012](#)).

Breast cancer is a major type of cancer among women of all races. White women after age 35 in the United States have a higher incidence than African-American women, but African-American women have a higher incidence before age 35. African-American women have a higher risk of dying from breast cancer because they are more likely to have fast-growing tumors and be diagnosed at a more advanced stage. Asian-American, Hispanic, and Native Indian or Alaska Native women have a lower risk for developing cancer than whites or African-Americans. Death rates from breast cancer among certain Asian and Pacific Islander women are much higher than among other ethnic groups ([ACS, 2011](#); [Katz & Dotters, 2012](#); [Mounga & Maughan, 2012](#)).

Risk Factors

Although the actual cause of breast cancer remains unknown, several factors are known to increase the risk for the development of breast and ovarian cancer or other diseases (see [Box 33-2, p. 720](#)). Mutations in two genes (*BRCA1* and *BRCA2*) thought to be responsible for most cases of familial breast and ovarian cancer, including breast cancer in men, continue to be studied. Mutation of the *CHEK-2* gene has shown higher risk for development of breast cancer in both women and men. Mutation of the *p53* tumor suppressor gene has been associated with breast and other cancers. Study of genetic links to many types of cancers and nonmalignant diseases is ongoing. Because research has linked these and other genes to an increased risk for breast or other cancers, testing is offered to the woman having a higher risk or who has developed cancer at a younger age than expected ([Katz & Dotters, 2012](#); [NCI: NIH, 2012](#)).

Knowing risk factors is important to guide breast cancer screening and treatment processes so that a cancer is diagnosed at the earliest stage possible. It is also important for the nurse to convey to women that many breast cancers develop in women with no known risk factors, whereas other women with one or more risk factors do not develop breast cancer.

Pathophysiology

About 65% to 80% of breast cancers are infiltrating ductal carcinoma, which originates in the epithelial lining of the mammary ducts. The cancer becomes invasive when it is no longer confined to the duct and spreads to surrounding breast tissue. Another 10% to 14% of invasive breast cancers are infiltrating lobular cancer that originates in the milk-secreting pockets of breast tissue. Most breast cancers grow in irregular patterns and invade the lymphatic channels, eventually causing lymphatic edema and the dimpling of the skin that resembles an orange

peel (**peau d'orange**). Several types of breast tumors may be present at the same time.

Inflammatory breast carcinoma (IBC) has cutaneous findings with invasive involvement in the dermis. IBC is rare, occurring in 1% to 2% of U.S. women and more likely to occur in younger or African-American women. IBC is aggressive and may manifest as a pink or red skin rash rather than a distinct lump that might show on imaging. Tenderness, itching, or breast edema may be present. These characteristics are typical of infection, so antibiotics are often prescribed. A woman should promptly contact her health professional for follow-up testing if antibiotics do not quickly clear the infection; then the true cause for the woman's signs and symptoms can be determined and cancer treatment can be started, if needed.

Cancer cells are carried by the lymph channels to the lymph nodes, and 40% to 50% of patients have involvement of axillary lymph nodes at the time of diagnosis. By the time a patient consults a physician, breast cancer may already be a systemic disease rather than being confined to the local tissue. Metastasis occurs when the malignant cells are spread by both blood and lymph systems to distant organs. Distant metastases include the lungs, liver, bones, and brain.

Staging

Confirmation of malignancy is the first step in evaluating the woman with cancer, and staging is necessary to understand the severity of the cancer and plan the best therapy. Staging is based on the TNM (tumor, node, and metastasis) system used to describe the cancer's anatomic extent. Stages of breast cancer progress from stage 1, indicating a small tumor without lymphatic involvement in the local area or metastases, to stage 4, which indicates spread to lymph nodes and metastases to distant organs. The stages are used to guide treatment and help provide a prognosis. The type of cancer cell, the presence of hormone receptors, and the proliferative rate of the breast cancer cells are also important factors in the rate of recurrence and determination of the most appropriate treatment.

Management

Many new treatments have emerged over the last decade. A combination of surgical excision of the tumor and locally involved lymph nodes and **adjuvant therapy** (added treatment to enhance action) is recommended. The combination of therapies is individualized for each patient. New techniques, medications, and management emerge frequently, and the nurse who cares for women with cancer should stay informed about changes in therapy.

Surgical Treatment. The surgical procedure depends on the type, stage, and location of the disease. The most common surgeries are the following ([Katz & Dotters, 2012](#)):

- Breast conservation treatment, which involves wide local excision (lumpectomy) of the tumor to microscopically clean margins for tumors that are small relative to the breast size. The excision can be performed without major cosmetic deformity. Varying numbers of axillary lymph nodes are usually removed to identify the stage of the woman's breast cancer.
- *Quadrantectomy* is a more extensive surgery for a breast tumor, removing a quadrant of tissue. Removal of the tumor involves resection of the skin and other tissue in the area to reach a microscopically clear margin of healthy tissue. Analysis of lymph nodes removed during the quadrantectomy allows staging of the cancer.
- Simple mastectomy, which is removal of the entire breast. Axillary dissection is omitted, although some lymph nodes may be removed for staging purposes. It may be recommended for selected cases in which prophylactic removal of the breast is considered for a woman at high risk for development of breast cancer. Simple mastectomy

in the absence of cancer does not eradicate the risk for later breast cancer, however, because a small amount of breast tissue remains.

- Modified radical mastectomy, which involves removal of breast tissue, axillary nodes, and some chest muscles; however, the pectoralis major muscle is preserved. This surgical procedure may be recommended when a single large primary lesion or multiple lesions exist in a relatively small breast because cosmetic results may be less than satisfactory with the other methods described. Other factors include whether the woman can undergo radiation therapy. Radiation therapy after surgery may not be possible if she is pregnant, has had prior breast or chest radiation, or has an autoimmune disease such as systemic lupus erythematosus.

Sentinel lymph node (SLN) biopsy is a technique to remove a few key lymph nodes to evaluate cancer spread rather than removing most of the nodes in the area (**axillary dissection**). A radioisotope suspension or a special dye is injected near the tumor site, where it is transported by the lymphatics toward the axillary nodes and trapped by the first one or two lymph nodes, or the “sentinel” nodes. The nodes identified by one or both of these techniques are excised for evaluation. If cancer has not spread to a sentinel node, the surgeon does not need to remove a large number of lymph nodes for staging of the cancer. Reducing the number of lymph nodes removed helps avoid some of the problems caused by lymphedema.

Adjuvant Therapy. Adjuvant therapy is supportive or additional therapy that is usually recommended after the surgical procedure. Radiation, chemotherapy, hormone therapy, and immunotherapy are adjuvant therapies that are often recommended. The decision about adjuvant therapy is based on the woman's age, the stage of the disease, the woman's preference, and the hormone receptor status of the lesion. Radiation and chemotherapy are known to improve the chance of long-term survival, and one or both are usually recommended after surgical excision of the tumor. Research continues to determine the best uses for these adjuvant therapies when treating breast cancer.

Radiation Therapy. Radiation uses high-energy rays to destroy cancer cells that remain in the breast, the chest wall, and the underarm area after surgery. The lymph nodes above the clavicle and the internal mammary lymph nodes are also irradiated. Radiation may be used to reduce the size of a large tumor before surgery. A radiation oncologist directs use of radiation in cancer therapy. The skin in the treated area may have a reaction similar to sunburn. Lymphedema is more likely to occur if the axillary lymph nodes are treated. A newer technology to limit the adverse effects of radiation on normal tissues while giving a maximum dose of radiation to the tumor site is intensity-modulated radiation therapy (IMRT).

Chemotherapy. Chemotherapy drugs are designed to kill the proliferating cancer cells. The specific combination of drugs and the number of treatment cycles are individualized for factors such as type of cancer cells, the woman's age, the hormone receptor status of malignant cells, whether she is postmenopausal, and other important factors such as medications she needs for nonmalignant disorders. Chemotherapy may both precede and follow tumor removal. Depending on the specific drugs, chemotherapeutics often kill normal cells, especially rapidly dividing cells such as those in the mucosa, the blood cells, and the platelets. For this reason, the woman often has sore, bleeding gums or other bleeding tendencies and may be more susceptible to infection during treatment. Loss of head and body hair or menstrual irregularities are common side effects during treatment. Anemia, with resulting fatigue, is common because erythrocyte production is impaired. Antiemetic drugs control nausea for most women.

Hormone Therapy. Medications to reduce production of estrogen are prescribed because many breast tumors are estrogen and/or progesterone receptor-positive, meaning that their growth is stimulated

by estrogen. Estrogen receptor-positive tumors may occur in both premenopausal and postmenopausal women. Risks and benefits of proposed estrogen-blocking medications are discussed with the oncologist, particularly in premenopausal women because their estrogen and progesterone levels are coordinated with their menstrual cycles.

Tamoxifen is one of the oldest estrogen-blocking drugs given for breast cancer to prevent recurrence. However, tumors in some women become resistant to tamoxifen and the cells actually use the drug to stimulate growth. Laboratory values for calcium, cholesterol, and triglycerides may be elevated with tamoxifen.

Anastrozole (Arimidex), exemestane (Aromasin), and letrozole (Femara) are aromatase inhibitors that hinder production of estrogen because they block conversion of androgens to estrogen in postmenopausal women. Aromatase inhibitors are being studied as alternatives to tamoxifen because they inhibit estrogen in a different way.

Raloxifene (Evista) is an estrogen modifier used to reduce osteoporosis by binding to estrogen receptors; therefore this drug also blocks estrogen effects on the breast. Raloxifene lowers levels of low-density lipoproteins and cholesterol.

Immunotherapy. Trastuzumab (Herceptin) is a biologically based therapy that targets cell pathways that promote cancer growth. Some tumors produce excessive amounts of the HER-2 protein, promoting tumor cell growth. Trastuzumab blocks the effect of this protein to inhibit growth of the cancer cells. Research is ongoing into other immunotherapy for breast and other cancers.

Breast Reconstruction

Timing. Breast reconstruction is often an option in breast cancer treatment, and the timing of reconstruction should be discussed with the woman before surgical treatment. Immediate reconstruction has a psychological appeal, but expected therapy after surgery may have aspects which make later reconstruction the best option. The prospect of having life-threatening breast cancer and simultaneously facing the loss of a breast may be overwhelming for many women. Conversely, delayed reconstruction may give a woman time to learn about the procedure, to heal from the mastectomy, and to consider her values and desires for added surgery.

Methods. Several methods of breast reconstruction are available. The tissue expansion method uses an empty silicone prosthesis fitted with a valve that can be accessed by percutaneous needle puncture. The bag is filled with saline in small increments to slowly expand the tissue. When the desired volume is attained, the incision is reopened, the device is removed, and the expander is exchanged for the appropriate implant. In some models, only the valve must be removed and the expander serves as the permanent implant (ACS, 2012b; Craft, 2009).

Tissue flap procedures move **autogenous** tissue from the back, abdomen, or buttocks to create a breast mound. Although these procedures do not always involve implants of a foreign substance as the tissue expansion method does, they involve at least two incisions: one at the breast and one at the site of the woman's donor tissue. All women are not suitable for muscle flap grafts, particularly those with diabetes or connective tissue disorders and those who smoke, because these procedures involve altering the blood supply to the transplanted tissue, with the possibility of poor wound healing for these women. Thin women may not have sufficient tissue for transplant to the breast (ACS, 2012b; Craft, 2009).

Types of tissue flap procedures include the following:

- Transverse rectus abdominis muscle (TRAM) flap, which uses extra abdominal tissue in two common ways, as follows. A pedicle flap allows the tissue to remain attached to its original blood supply while it is tunneled under the skin to its site for breast reconstruction. The free flap involves removal of the tissue from its original

site for attachment to the breast site. Because blood vessels are disconnected in free flap removal, microsurgery is required to reconnect the vessels and promote tissue-preserving blood flow in the graft.

- Deep inferior epigastric artery perforator (DIEP) flap is a procedure in which skin and fat tissue are detached from the lower abdominal area. Muscle is not used in creation of the new breast. Microsurgery is also required to connect blood vessels.
- Latissimus dorsi flap, in which muscle and skin tissue are moved from the upper back under the skin to the site of breast reconstruction. Weakness of the back, shoulder, or arm may persist after the surgery.
- Gluteal free flap, in which surgical transfer of skin, fat, muscle, and blood vessels is used to recreate the breast.
- Inner thigh or TUG flap, an option that uses muscle and fatty tissue from along the fold of the buttock extending to the inner thigh. Because skin, muscle, and blood vessels are cut and moved to the chest, microscopic surgery must be used to reconnect tiny vessels to their new blood supply.

Nipple and areola reconstruction improves the natural appearance in the reconstructed breast through a small skin graft. Tissue may be taken from the opposite nipple, from skin that covers the prosthesis mound, or from other body tissue. After the nipple has been reconstructed, tattooing promotes natural coloring to the nipple and areola (ACS 2012b; Craft, 2009).

Psychosocial Consequences of Breast Cancer

The time from discovery to treatment of breast cancer is the most stressful time for many women. Factors that contribute to presurgery distress include a sense of uncertainty, incomplete information, the need to make difficult treatment decisions, and scheduling problems. Surgery may be preceded by chemotherapy or adjuvant therapy, or these therapies may also follow surgery. Because of the many complexities to be considered for treatment to be most effective, consultations with several specialists, including a surgeon, a radiation oncologist, a plastic surgeon, and a medical oncologist, are needed. Scheduling difficulties arise when women must travel significant distances for treatment. The many appointments with unfamiliar specialists and studies to determine best treatment often result in frustration and confusion for a woman and her family.

Concerns frequently expressed during treatment for breast cancer include fear of death, uncertainty about the quality of life, changes in body image, the effect on sexuality, and side effects of recommended therapy. For most women the knowledge that they will lose their hair as a result of chemotherapy creates one of the most difficult situations in therapy, adding yet another assault on their body image.

Breast cancer has psychological consequences not only for women but also for their significant others. Women who are diagnosed in their 30s may have young children who cannot understand why their parents are so worried. Difficulties reported include sleep disturbances, eating disorders, and problems with work responsibilities. The marital relationship may be strained, primarily in the areas of sexual relations and communication about matters related to the illness. Women and their partners sometimes differ in regard to how much they want to discuss the illness. Some women have a great need to discuss their diagnosis, treatment, and fears of recurrence. Other women and many men view discussion of such fears as negative thinking that delays adjustment.

Nursing Considerations

The woman who is diagnosed with breast cancer depends on the nurse for emotional support and accurate information. The woman needs

time to express her feelings, and the nurse must convey a sense of empathetic understanding by quiet presence, touch, and close attention to the woman's concerns. Many women feel that they have lost control and that their lives have been taken over by cancer and the recommended treatment. Some women are concerned about family relationships and how their sexual partner or children will respond. Each woman should be allowed to express her fears and worries. In addition to providing time and demonstrating genuine interest in the woman's concerns, the nurse should use communication techniques, such as clarifying, paraphrasing, and reflecting feelings, so that the woman can participate in decisions about her care.

Most women with a clear understanding of procedures and care experience a reduction in anxiety. Preoperative teaching should include significant others to increase their ability to support the woman. Teaching should include the length of the hospital stay and what will happen during that time. The nurse should describe the dressings, drainage tubes, and appearance of incisions for the breast procedure or procedures being planned (lumpectomy, mastectomy, reconstruction). Lymphedema of the arm on the side of the mastectomy is possible because of blocked lymphatic vessels, but it may not appear in the immediate postoperative period. Specific exercises such as arm lifts and pulley exercises may be necessary to promote flexibility in surgical areas.

Lymphedema, caused by blocked drainage of the lymphatic system in the arm on the side of the mastectomy, is possible if most axillary lymph nodes must be removed. Lymphedema may not occur for many years and is not anticipated for women who do not require an extensive lymphatic tissue removal in the axilla. Compression arm sleeves, similar to thromboembolism deterrent (TED) hose, are an available treatment to control lymphedema if needed.

Discharge teaching focuses on self-care and the need for continued care and treatment. Some areas of concern are how to reduce the risk of wound infection, care of the arm on the affected side, side effects of postoperative and adjuvant medications, and signs and symptoms that should be reported to the physician. If the woman will be discharged with the drains in place, she should be taught how to empty them. Most women also benefit from information about groups such as Reach to Recovery through the American Cancer Society (www.cancer.org), which provide support, information, and guidance after mastectomy. Support groups associated with the hospital and oncology center may offer additional support. The Internet may be a resource for support groups. Printed information about local support groups is usually provided at discharge. Relevant diagnoses may include:

- Fear related to uncertain outcome
- Disturbed Body Image related to loss of breast and temporary loss of hair during chemotherapy
- Interrupted Family Processes related to the woman's illness, changes in work and home activity, or inadequate information about the course of the disease
- Ineffective Sexuality Patterns related to concern about altered body structure

CARDIOVASCULAR DISEASE

Cardiovascular diseases include disorders of the heart and blood vessels, such as myocardial infarction (MI), congenital abnormalities, and stroke. Those discussed here primarily relate to diseases of the blood vessels, particularly coronary artery disease (CAD). The topic is extensive, and only an overview will be presented in this text. A medical-surgical text should be consulted for more extensive information about cardiovascular disease and associated nursing care.

Most women fear dying from cancer, often breast cancer, but cardiovascular disease is the leading cause of death in both men and women in the United States. Almost twice as many U.S. women die of heart disease and stroke as from all forms of cancer, including breast cancer. Most people tend to think of heart and other blood vessel

diseases as a male problem, particularly when compared with women before menopause. Deaths from heart disease are the leading cause of death in the United States, and 51% of these are women. After surviving the first heart attack, women 40 or older had a 43% likelihood of having a second heart attack. Statistics in 2006 estimated costs for CAD as \$258 billion in terms of health services, medications, and lost productivity (AHA, 2011; CDC, 2010b).

Recognition of Coronary Artery Disease

- Women are more likely than men to die of CAD, in part because they are usually older and may have other complicating diseases when a myocardial infarction (MI) or acute coronary syndrome (ACS) occurs. However, the MI tends to manifest with atypical, vague symptoms that can delay recognition and treatment. The

EVIDENCE-BASED PRACTICE

Cardiovascular Disease: A Woman's Number One Killer

Many women believe that cancer is their number-one killer, but it is not. Cardiovascular disease (CVD) is the number-one killer of women. Four most common types of CVD are coronary heart disease, ischemic stroke, hypertension, and heart failure.

Only about 54% of women are aware that CVD is the leading cause of death in women. Black (43%), Hispanic (44%), and Asian (34%) women were less aware than white (60%) women of the CVD mortality. Another study found that fewer than 20% of physicians knew that more women than men die each year from CVD. Lower risk awareness among women and clinicians results in less risk reduction, poor response to symptoms by clinicians, and less likelihood that the woman will seek treatment. Despite the need to improve symptom awareness, deaths from CVD declined only 22% from 1996 to 2006.

Stroke can be ischemic if a cerebral artery is blocked or hemorrhagic if a cerebral artery ruptures. Almost 90% of strokes are ischemic. Women in the 45- to 74-year age group have a lower mortality rate than men in this age group. However, women older than 85 years have a higher stroke mortality rate than men in their age group. Metabolic syndrome (abdominal obesity, dyslipidemia, hypertension, and hyperglycemia) doubles the stroke risk in women but does not affect the stroke risk in men. Migraine, particularly with an aura, was found to double the risk of stroke in women younger than 45 and has also been associated with increased CVD risk. Another study found that stroke risk was tripled with use of oral contraceptives.

DeVon, Saban, and Garrett present two case studies using pseudonyms to illustrate two women's risk perception. Ruth Nolan has a CVD event over a week but does not promptly respond to symptoms more common in women than men: severe pain in her upper back, unusual fatigue, and loss of appetite over the week. During the week, Ruth helped her daughter pack to move and cared for three young grandchildren, ignoring the symptoms. On arrival in the emergency department, she was nauseated and sweaty and stated that she had "stomach flu." Ruth was diagnosed with acute coronary syndrome (ACS) with a ST-elevation myocardial infarction (MI), also known as STEMI. (Non-ST elevation MI [NSTEMI] and unstable angina [UA] are the other kinds of ACS.) She was sent immediately for cardiac catheterization for angioplasty and stent placement.

The other case study presented Tom Finnegan and his wife and demonstrated his response to her stroke-like symptoms while they were watching fireworks on July 4. He saw that she was having difficulty speaking and seemed confused but unconcerned as she watched. He knew that she had a history of hypertension. As her symptoms worsened, he knew she needed professional help, so he walked to concessions where bystanders called 911. Following a computerized tomography (CT) in the emergency department (ED), and reperfusion interventions, her symptoms subsided. His wife eventually made a full recovery from her ischemic stroke.

These two case studies illustrate the benefit of quick response to symptoms that may not seem "bad." Ms. Nolan did not seek treatment for a week despite persistent symptoms of fatigue and loss of appetite and then severe upper back pain and nausea. The case study demonstrates how her significant delay in seeking care reduced the effectiveness of fibrinolytics, angioplasty, or stent placement in reperfusion. Ms. Nolan arrived too late for reperfusion therapy that might have prevented the actual MI. Ms. Finnegan's case, however, illustrates the benefits of quick and accurate response. Her husband's prompt recognition of her worsening symptoms and taking action to get her to the ED made it possible for reperfusion therapy to be effective and give her a full recovery.

Research has found that women often experience symptoms with MI that are atypical of men: unusual fatigue, upper back pain, nausea and/or vomiting, loss of appetite, dizziness, palpitations, jaw pain, and neck pain. Two tables summarizing appropriate responses to ACS and stroke in this article help the nurse give patient education related to ACS and ischemic stroke encouraging prompt response to either rather than delaying care. Inclusion of family provides added information about response to significant symptoms. The nurse should emphasize when teaching patients that these lifesaving therapies are time dependent.

Symptoms of ischemic stroke appear to have few gender differences. Traditional symptoms include arm and/or leg weakness and speech disturbance. Less common symptoms include facial weakness, loss of sensation in arm and/or leg, headache, and nonorthostatic dizziness. Other researchers reported mental status changes, lightheadedness, and face or other pain on one side of the body as "nontraditional." Four groups have researched looking for gender differences and reported inconsistent findings.

Authors list some reasons why women often ignore symptoms and delay or miss effective treatment: lack of awareness of their risk, tendency to be more passive than men, failure to recognize symptoms of MI, attribution of their symptoms as being "old age," and barriers to self-care, often putting others' needs before their own. Authors also list possible areas for future research.

Nurses should maintain awareness to identify possible risk factors in the women they encounter in care so appropriate teaching and referrals can be made if needed. The nurse often has the chance to raise a woman's awareness of her risks in the obstetrics and gynecologic setting which helps her respond appropriately to get the care she needs. The nurse should also share knowledge about risk factors and symptoms of CVD with the health care provider so referrals to specialists or appropriate laboratory tests are done. An environment of collaborative and participatory care may help women adopt health-promoting behaviors and receive specialized care when needed. And it may help women achieve better health with weight control and exercise.

classic crushing or stabbing chest pain or pressure in the chest is not the usual symptom in women, as it is in men. Women often report having vague symptoms such as fatigue for several weeks before seeking care that results in diagnosis of an imminent acute MI or one that has already occurred. Some of the symptoms of CAD in women include the following (Keresztes & Wcisel, 2009a, b):

- Fatigue, weakness, unexplained anxiety
- **Angina pectoris** (chest pain with exertion) or pain at rest
- Dyspnea, sometimes called **paroxysmal nocturnal dyspnea** because it occurs during sleep
- Dizziness, faintness, lightheadedness
- Upper abdominal pain, heartburn, loss of appetite
- Nausea, vomiting, sweating
- Pain in the upper body, but other than the chest (arm, neck, back, jaw, throat, teeth)

Because the pain may be subtle or unlike that which she associates with a heart attack, the woman may not consider MI as a possibility. Caregivers must be aware that the woman's symptoms could be cardiac related. For example, a dentist must consider that a woman with a toothache but no apparent tooth disease could have cardiac ischemia and an MI.

Risk Factors

Many factors increase risk for cardiovascular disease, but common ones include hypertension, inadequate physical activity, overweight and obesity, and a diet of poor nutritional quality. These and other risk factors often contribute to development of other problems that further increase the risk for cardiovascular disease, such as type 2 diabetes. Each risk factor may add to the risk for developing another of the problems listed here.

Risk factors may be fixed or may be factors that can or cannot be changed. Aging is a major risk factor, because the woman loses the protection that estrogen, secreted before menopause, exerts on the blood vessels. Estrogen's protective effect delays onset of cardiovascular disease, making most women older at the onset of the disease than men. Other risk factors are listed in **Box 33-4, p. 724**, and are similar to those for men. Several risk factors deserve additional discussion in this chapter.

The leading preventable cause of CAD and other diseases in women and men is smoking. Cigarette smoking adds to the burden of heart, blood vessel, and respiratory disorders; cancers; and many other diseases in women. Smoking is often more attractive to a woman if her family and friends smoke, she believes that smoking helps control her weight, or she believes that smoking reduces her anxiety.

Both systolic and diastolic blood pressure elevations are associated with CAD and other vascular disorders. Adequate control of hypertension reduces death and disability from MI, stroke, and other blood vessel disorders. The person may not consider hypertension to be a problem because no symptoms are present. Smoking, overweight, and diabetes further contribute to hypertension. Hypertension is more prevalent in African-Americans than in whites.

Inadequate exercise contributes to many of the risk factors listed. Overweight and obesity are more likely when a person is sedentary, and these weight problems increase the likelihood that diabetes and hypertension will occur. **Dyslipidemia** (abnormal fat and cholesterol levels) is more likely in both women and men who do not get adequate exercise, adding further to the risk.

Prevention

Prevention is the key to reducing death and illness from all cardiovascular diseases among women. Although once thought to reduce a

woman's risk for cardiovascular disease, estrogen's benefits for this have not proven true when hormone replacement therapy (HRT) is chosen after natural estrogen levels decline at menopause.

WOMEN WANT TO KNOW

How to Reduce the Risk for Coronary Artery Disease

Most of the health-promoting actions in this list apply equally to men.

- **Stop smoking.** Your risk begins to decrease within a few months of stopping and reaches the level of a person who has never smoked within 3 to 5 years. Stopping also reduces your risk for lung cancer and many other respiratory diseases.
- **Maintain a normal weight.** Your risk is much higher if your weight is 30% or more over your ideal weight. See your health care provider about an ideal weight management plan, which usually includes a balanced diet and moderate exercise to lose weight gradually.
- **Eat right.** A variety of fruits, vegetables, grains, low-fat or nonfat dairy products, fish, legumes, poultry, and lean meats provides a basic healthy eating pattern. Substitute unsaturated fat from vegetables, fish, legumes, and nuts for foods high in saturated fats and cholesterol. Limit salt to less than 6 grams per day.
- **Limit alcohol to 1 drink per day if you are a woman.** Do not drink when pregnant or trying to become pregnant to avoid fetal alcohol syndrome, and do not drink when breastfeeding.
- **Control high blood pressure.** Even modest blood pressure elevations can be deadly, causing heart attack and stroke. Measures to reduce your blood pressure include weight reduction, exercise, diet improvement, and stress management. If your physician prescribes drugs to control your blood pressure, take them faithfully, even if you feel fine. Let the doctor know if you are having problems with your drugs for high blood pressure; a change in the drug may be possible.
- **Exercise.** Aerobic exercise helps reduce your blood pressure, control your weight, and keep your blood glucose levels normal. Resistance and weight-bearing exercise also helps slow osteoporosis. You need at least 30 minutes of moderate-intensity exercise 4 to 6 days each week.
- **Control diabetes.** Diabetes in a woman cancels many of estrogen's protective benefits, so you must work harder to control your diabetes as well as your cardiovascular risks.

To learn more about cardiovascular disease and its prevention, visit these websites: the American Heart Association, www.americanheart.org, and the Academy of Nutrition and Dietetics (formerly the American Dietetic Association), www.eatright.org.

HYPERTENSION

People may be unaware of current definitions for the levels of blood pressure and do not seek the information because hypertension can be a disease that causes subtle damage over long periods of time. Current standards that define hypertension are lower than what many people expect (CDC, 2012):

- Normal: <120 mm Hg systolic; <80 mm Hg diastolic
- Prehypertension: 120-139 mm Hg systolic; 80-89 mm Hg diastolic
- Hypertension: ≥140 mm Hg systolic; ≥90 mm Hg diastolic

Lowering hypertension, including isolated systolic hypertension in older women, to levels less than 140 mm Hg systolic and less than 90 mm Hg diastolic reduces the risk of CAD and stroke. Even borderline, or prehypertension, can be dangerous. Medication should be considered if regular aerobic exercise, weight reduction, improved nutrition, and stress management do not lower the blood pressure

adequately (DeMartinis, 2009). The Dietary Approaches to Stop Hypertension (DASH) diet plan from the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health (NIH) is often recommended to maintain good blood pressure control and can be retrieved at www.nhlbi.nih.gov.

Smoking Cessation

Stopping smoking may cause a woman to gain weight, particularly if she increases caloric intake or reduces her activity. However, smoking cessation has a positive effect on reducing angina and stopping the progression of CAD. Stopping smoking also reduces the risk for lung cancer, the number-one cancer in men and women. Improvement in other respiratory conditions is likely as well. Medication patches may be prescribed to gradually reduce nicotine intake and may be helpful for some, whereas stopping “cold turkey” may be best for others. Working with a partner or in a group also may be beneficial.

Diet and Glucose Control

Women with diabetes have a relatively greater risk for CAD than men, so maintaining weight and glucose levels within normal limits is especially important. Diet is the primary means to control the lipid profile. Diet recommendations should be individualized, but general guidelines are that fat intake should be a maximum of 30% of daily calories and that no more than 10% of daily calories should come from saturated fat (found in foods such as meat, butter, cream, and cheese). Cholesterol intake maintained lower than 200 mg/day is ideal. Increased evidence shows that fish, especially fatty fish, confers cardiovascular benefits, and at least two servings per week are recommended. Eating a diet high in vegetables, fruits, and low-fat dairy products and limiting salt intake to under 6 g per day and alcohol to a maximum of one drink per day have shown to be beneficial at reducing blood pressure in women (Keresztes & Wcisel, 2009a).

Increased Activity

Aerobic exercise helps control weight, blood pressure, the lipid profile, and glucose level. It reduces body fat while increasing muscle mass and improving muscle tone. The Surgeon General has recommended at least 30 minutes of moderate physical activity daily such as a brisk walk or stair climbing. Low- to moderate-intensity exercises also have some benefits.

Aspirin

Low-dose aspirin therapy (81 mg or “baby aspirin”) each day has shown to be beneficial to inhibit platelet aggregation, which can increase clot formation and lead to CAD. Acute chest pain should be treated with a single adult-dose tablet (325 mg, equivalent to four baby aspirin tablets) as soon as MI is suspected to reduce clot formation and increase the chances of full recovery. For those unable to tolerate aspirin or who have recent gastrointestinal bleeding, prescription drugs such as clopidogrel (Plavix) may be prescribed. Individual needs are based on age, risk factors, and history.

8. What are the symptoms of CAD, such as an MI, in a woman?
9. List appropriate measures to reduce the risk for CAD.

MENSTRUAL CYCLE DISORDERS

The four most common menstrual cycle disorders are absence of menses (**amenorrhea**), abnormal uterine bleeding, pain associated

with the menstrual cycle, and cyclic mood changes, including premenstrual syndrome (PMS). Although most of the disorders are benign, all require comprehensive gynecologic assessment. Nurses must be knowledgeable about underlying processes, diagnostic procedures, and expected treatment in order to fulfill the basic core of nursing activities, which include client advocacy, education, and supportive counseling.

Amenorrhea

Amenorrhea can indicate either normal physiologic processes or pathology in the reproductive system. Amenorrhea before **menarche** (onset of menstruation), during pregnancy, during the puerperium and lactation, and after menopause is normal. Amenorrhea at other times is abnormal, and it is called either *primary* or *secondary amenorrhea*, depending on when it occurs.

Primary Amenorrhea

Absence of menses may create a great deal of concern for the young woman and her family. Amenorrhea is a symptom, not a diagnosis, and they may worry that it indicates a serious disease. Menstruation is a unique function of women, and absence of menstruation may provoke concerns about femininity and the ability to have children. Concern increases if a cause cannot be found or medical treatment is not successful.

Menstrual periods should begin within 2 years of breast development, between ages of about 9 and 15 years. Lack of breast development or other secondary sexual development or a shortened growth spurt in addition to the absence of menstruation provides additional diagnostic clues. Primary amenorrhea is considered if onset of menstrual periods has not occurred by 16.5 years, particularly if associated sexual changes have not taken place. Primary amenorrhea may be suspected if the girl is more than 1 year older than the ages at which her mother and sisters had menarche. The causes for primary amenorrhea may be genetic (ovarian failure) or systemic or may involve anomalies of the reproductive tract (Cromer, 2011; Lobo, 2012d).

Ovarian failure may occur in girls who have Turner's syndrome, in which only one of the normal two X chromosomes is present. They have a total of 45 chromosomes, with a single X chromosome. If secondary sex characteristics are present, incomplete development of internal reproductive organs may be the cause of amenorrhea. Other causes may include hormonal imbalances, systemic disease such as cancer with its associated therapy, and abnormalities of the hypothalamic-pituitary axis that result in hormone imbalance.

A common systemic cause of primary amenorrhea is low body weight for height. This may occur in competitive athletes and dancers but also occurs in girls with eating disorders, such as anorexia nervosa, who have a very low body weight. If a girl began sexual development and then restricted calories (or began an intense exercise program), her sexual development may be arrested at the point of the calorie restriction. Other systemic causes of primary amenorrhea include chronic stress, hypothyroidism, abnormal steroid secretion, central nervous system diseases, and drug use (therapeutic or illicit). Obesity is often associated with insulin resistance and chronic anovulation related to high androgen levels (Cromer, 2011; Lobo, 2012d).

Abnormalities in the uterus, vagina, or hymen can obstruct the outflow of the menstrual flow. Congenital enzyme abnormalities may disable different aspects of the reproductive cycle.

Medical management depends on the cause identified in a diagnostic workup. Counseling for eating disorders, such as anorexia nervosa, and reducing excessive exercise to allow adequate weight gain may prove helpful. Hormone therapy may establish normal menses if the cause is hormone imbalance. However, some conditions cannot be successfully treated. For example, if the cause is reproductive tract or

congenital anomalies, normal menses and fertility may not be possible, and psychological support becomes the most important therapy.

Secondary Amenorrhea

Secondary amenorrhea is the cessation of menstruation for 6 months or more in a woman who has established a pattern of menstruation, or absence for the duration of three normal cycles. In addition to pregnancy, there may be a variety of causes, including systemic diseases such as diabetes mellitus, tuberculosis, hypothyroidism, or central nervous system lesions. Hormonal imbalances, strenuous aerobic exercise, poor nutrition, use of hormonal contraceptives, and ovarian tumors also may be causes. Events such as divorce, death of a close friend or family member, moving, or a job change often result in stressors that occur with secondary amenorrhea (Lobo, 2012a, d).

Assessment includes a thorough medical and obstetric history and questions about eating habits, history of dieting, and current exercise pattern. Women are also questioned about their use of drugs, such as oral contraceptives, phenothiazines, and antihypertensives, which can cause secondary amenorrhea.

Medical treatment aims at identifying and correcting the underlying cause after ruling out pregnancy and determining if the woman wants children. Pregnancy testing is done for a sexually active woman, and medications that are potentially teratogenic must be withheld until pregnancy is ruled out. Other treatment may include testing levels of hormones related to the menstrual cycle, therapy to improve timing of the cycle, treatment of anovulation, and identification of other abnormalities that may be related to the disorder. Excess androgen levels may cause polycystic ovary syndrome (PCOS), characterized by acne and excess weight and body hair, as well as the anovulation that results in amenorrhea.

Nursing Considerations

Emotional support is essential if medical diagnostics are needed to evaluate the cause of absent menses, particularly if the problem is primary amenorrhea. Adolescence is a time when being different from peers is often painful, especially if a correctable cause for the difference cannot be identified. Teaching includes the importance of adequate nutrition and discouragement of rigorous dieting. The nurse should explain that although exercise is beneficial, strenuous workouts or aerobic training can cause amenorrhea. Effective weight control may reduce factors related to PCOS. Referral for psychological counseling may be needed for eating disorders.

Abnormal Uterine Bleeding

The normal menstrual cycle was described in Chapter 4. Dysfunctional bleeding includes prolonged or heavy bleeding (**menorrhagia**); bleeding that occurs irregularly and often between menstrual periods (**metrorrhagia**); or bleeding that occurs irregularly and more frequently (**menometrorrhagia**), which is essentially a combination of the other two terms. Complications of an unrecognized pregnancy, such as spontaneous abortion, must be considered when making the diagnosis.

Etiology

The most common causes of abnormal bleeding fall into five basic categories:

1. Pregnancy complications, such as spontaneous abortion
2. Anatomic lesions, either benign or malignant, of the vagina, cervix, or uterus
3. Drug-induced bleeding, such as breakthrough bleeding that may occur in women taking hormonal contraceptives

4. Systemic disorders, such as diabetes mellitus, uterine myomas (fibroids), and hypothyroidism
5. Failure to ovulate

Management

Evaluation of abnormal uterine bleeding may include a sensitive pregnancy test, coagulation studies, and tests to determine whether ovulation is occurring. Hormone and liver function tests, plus tests to determine if the woman is anemic, often are done. Ultrasonography or hysteroscopy may be used to look for polyps and check the condition of the uterine lining.

A common hormone treatment is progestin-estrogen combination oral contraceptives that suppress ovulation and allow a more stable endometrial lining to form. Surgical therapy may include dilation and curettage (D&C) to remove polyps or to diagnose **endometrial hyperplasia** (excess normal uterine lining cells), which may be treated with progesterone to suppress excess uterine lining. Hysterectomy may be performed if the uterus is enlarged as a result of fibroids or adenomyosis (benign invasive growth of the endometrium into the muscular layer of the uterus) and if the woman does not want more children. Laser ablation may be used to permanently remove the endometrial lining without hysterectomy. Treatment of iron deficiency anemia is needed by many women with excessive vaginal bleeding (Lobo, 2012a).

Nursing Considerations

Nurses should encourage women to seek medical attention promptly when irregular or prolonged bleeding occurs. Nurses also help the woman keep a record of the bleeding episodes and the amount of blood lost. This involves keeping a calendar and noting any vaginal bleeding (spotting, menses) that occurs in addition to the number of pads and tampons saturated each day.

The nurse teaches the importance of adequate nutrition and discourages rigorous dieting. For women who are concerned about amenorrhea, the nurse should explain that although exercise is beneficial, excessive workouts or aerobic training can cause amenorrhea. In addition, the nurse teaches methods to reduce stress and promote relaxation. Finally, nurses must provide support for women who fear that irregular bleeding indicates a serious disease, such as cancer. Offering false reassurance is unwise, but information about diagnostic procedures, such as pelvic examination, the Pap test, and other tests, is helpful.

CHECK YOUR READING

10. How does primary amenorrhea differ from secondary amenorrhea in terms of onset, cause, and treatment?
11. What are possible causes of dysfunctional uterine bleeding, and why should it not be ignored?

Cyclic Pelvic Pain

Cyclic pelvic pain must be distinguished from acute pelvic pain. Acute pelvic pain is sudden in onset and is not experienced with each menstrual cycle. It may indicate a serious disorder, such as ectopic pregnancy or appendicitis. Cyclic pelvic pain occurs repetitively and predictably in a specific phase of the menstrual cycle. The most common causes of cyclic pelvic pain are **mittelschmerz**, primary **dysmenorrhea** (painful menstruation), and **endometriosis** (tissue resembling endometrium outside uterine cavity). Secondary dysmenorrhea, or pelvic pain that is not cyclic, is usually related to pelvic pathology.

Mittelschmerz

Mittelschmerz (“middle” pain) is pelvic pain that occurs midway between menstrual periods at the time of ovulation. The pain results from growth of the dominant follicle within the ovary or rupture of the follicle and subsequent spillage of follicular fluid and blood into the peritoneal space. The pain is fairly sharp and is felt on the right or left side of the pelvis. It generally lasts from a few hours to 2 days, and slight vaginal bleeding may accompany the discomfort. Generally, women do not need medical treatment beyond simple explanation of the discomfort or mild analgesics.

Primary Dysmenorrhea

Primary dysmenorrhea is menstrual pain without identified pathology. Its onset is usually 1 to 3 years after menstruation begins, when ovulatory menstrual cycles are well established, and it is most common in young, nulliparous women. Commonly called “cramps,” primary dysmenorrhea causes significant loss of school or work hours. The pain begins within hours of the onset of menses, and it is spasmodic or colicky in nature because of increased prostaglandins secreted at this time. It is felt in the lower abdomen but often radiates to the lower back or down the legs. Nausea, vomiting, loose stools, or dizziness may also occur. The duration of the pain is usually 48 to 72 hours.

Two recommended treatments of primary dysmenorrhea provide marked relief: oral contraceptives and prostaglandin inhibitors. Oral contraceptives decrease the amount of endometrial growth that occurs during the menstrual cycle and thereby reduce the production of endometrial prostaglandins. For women who do not wish to take oral contraceptives, prostaglandin inhibitors offer relief. The most effective prostaglandin inhibitors are nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen (Motrin, Advil) and naproxen (Naprosyn, Anaprox). To be effective, the NSAID should be taken around the clock for at least 48 to 72 hours beginning when menstrual flow starts. Other possible therapies include the levonorgestrel-releasing intrauterine system (LNG-IUS), with greatest pain relief early in the life of the contraceptive device (Lentz, 2012b).

Simple relief measures supplement medical interventions and may be sufficient for a woman. Rest in a comfortable position and application of warmth often provide additional relief.

Endometriosis

Pathophysiology

Endometriosis is defined as the presence outside the uterus of tissue that resembles the endometrium in both structure and function. The response of this tissue to the stimulation of estrogen and progesterone during the menstrual cycle is identical to that of the endometrial tissue. That is, it grows and proliferates during the follicular and luteal phases of the cycle and then sloughs during menstruation. However, the menstruation from endometriosis lesions occurs in a closed cavity, which causes pressure and pain on adjacent tissue. In addition, prostaglandins secreted by the endometriosis lesions irritate nerve endings and stimulate uterine contractions that further increase pain. Cyclic bleeding into the pelvic cavity can cause chronic inflammatory changes that may make conception and implantation difficult. The most common sites of endometriosis lesions are illustrated in Figure 34-1.

The estimated incidence of endometriosis is about 10% but the true prevalence is unknown. Some women with significant endometriosis may be asymptomatic, and the endometrial tissue is found on pelvic organs during an unrelated surgery. The cause remains unknown. One theory is that reflux of the menstrual flow through the fallopian tubes allows the endometrial cells to attach to nearby structures and proliferate, creating spots of endometrial tissue. Endometrial tissue has been

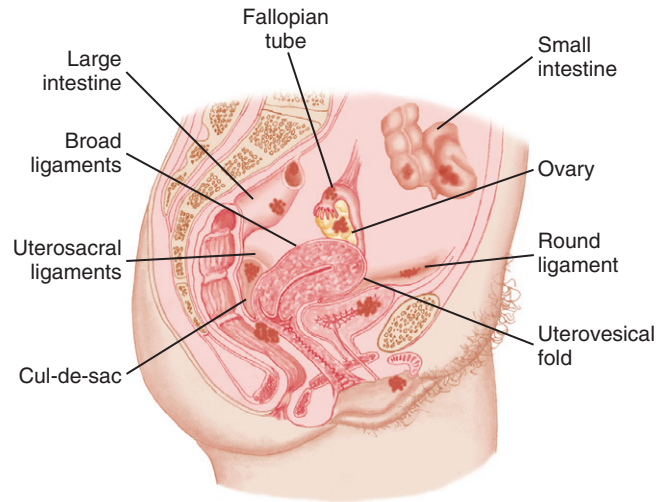

FIG 34-1 Common sites of endometriosis.

found in distant sites such as the lungs, raising the possibility that the cells are spread by blood circulation. Spread of the endometrial cells by the lymphatics has been implicated. Endometriosis of the anterior abdominal wall has been found after a cesarean delivery near the incision line, leading to the theory that microscopic endometrial tissue may have been implanted during the cesarean and then stimulated to grow with later menstrual cycles. Studies have also shown a familial predisposition (Bloski & Pierson, 2008; Lobo, 2012b).

Most women with endometriosis are in their 30s and nulliparous, and many have had infertility problems. Signs and symptoms of endometriosis usually regress after menopause unless a woman takes estrogen supplementation.

Signs and Symptoms

The two major problems associated with endometriosis are cyclic pain and infertility. Endometriosis should be considered in a woman seeking infertility treatment even if she does not have the typical pain. Pain of endometriosis differs from that of primary dysmenorrhea. Endometriosis pain is deep, unilateral or bilateral, and either sharp or dull. It is constant, as opposed to the spasmodic or colicky pain of primary dysmenorrhea. **Dyspareunia** (painful intercourse) may occur, usually with deep penetration. Rectal pain may occur during defecation. Diarrhea, constipation, and sensations of rectal pressure or urgency are other symptoms of endometriosis. Although causes of infertility may not be known, some factors may be retrograde menstruation, endometrium transplant via lymphatics, immunologic changes, or familial predisposition (Lobo, 2012b).

Management

Treatment may be either medical or surgical. A woman must often weigh her need for pain relief and the desire to maintain fertility against the side effects that accompany many treatment regimens when choosing therapy. Growth and bleeding of displaced endometrial tissue depends on adequate production of ovarian hormones during the menstrual cycle. Other factors to be considered include symptom severity, desire for future fertility, the woman's age, and the effect of the endometriosis on nearby organs, such as obstruction of the urinary or gastrointestinal tracts (Lobo, 2012b).

Continuous oral contraceptives for 6 to 12 months suppress endometrial tissue proliferation, particularly in a woman who desires pregnancy after medical treatment. Both the testosterone derivative danazol

and gonadotropin-releasing hormone (GnRH) agonists such as leuprolide acetate (Lupron) and nafarelin (Synarel) interfere with hormones needed for ovulation and the menstrual cycle, creating a “pseudomenopause” while taken. The woman may have hot flashes, vaginal dryness, insomnia, decreased libido, and reduced bone density. In addition, danazol may produce masculinizing effects, such as deepening of the voice, facial and body hair, and weight gain. The woman takes the drug for a varying period of time, often between 3 and 6 months, depending on the drug and the degree of her endometriosis. Surgical treatment of endometriosis may have different options because of the varied size, number, and location of lesions; the age of the affected woman; and whether endometriosis contributes to her infertility. **Laparoscopy** (insertion of an illuminated tube into the abdominal cavity) may be performed for lysis of adhesions and laser vaporization of the lesions of endometriosis. This procedure is used especially when infertility is a problem. For women with severe pain who no longer wish to have children, a hysterectomy, sometimes including removal of one or both ovaries and fallopian tubes, and removal of all lesions offer relief. The appendix is often removed at the same time, and pathology examination often finds endometrial tissue attached. Removal of both ovaries causes loss of their hormone production, resulting in an early menopause. Postoperative hormone replacement therapy may be recommended if most endometrial lesions are removed (Lobo, 2012b).

Nursing Considerations

Dysmenorrhea varies from mild “menstrual awareness” to incapacitating pain that affects the quality of life for several days each month. Too often the pain is belittled (“It’s just cramps”). One of the most important nursing actions is to acknowledge the pain: “I understand this is really uncomfortable, and you are concerned that you have this much pain every month.” Infertility may be accompanied by the cyclic increase in pain of endometriosis.

The nurse should suggest nonpharmacologic pain-relief measures, such as frequent rest periods, application of heat to the lower abdomen, moderate exercise, and a well-balanced diet (Box 34-2). The woman should avoid scheduling stress-provoking situations during the menstrual period if possible. The nurse should counsel the woman about expected effects of over-the-counter (OTC) or prescribed medications. The woman should also be instructed about side or adverse effects specific to the medications recommended that should be reported.

The nurse must allow time for the woman to express her concerns about the therapy. The woman should be taught expected effects of drugs given for endometriosis and about each drug’s precautions and side or adverse effects that may occur. Some women benefit from information about measures that promote sleep and relaxation and, most importantly, from the knowledge that someone is available to provide support and guidance when needed. A woman may demonstrate emotional distress if she has not had all the children she desires but must decide whether to have a hysterectomy to reduce physical pain that simpler measures have not relieved.

BOX 34-2 PAIN RELIEF FOR PREMENSTRUAL SYNDROME

Women should be instructed in nonpharmacologic measures to relieve pain, such as frequent rest periods, application of heat to the lower abdomen, moderate exercise, and a well-balanced diet. If they want to try an herbal remedy, they should be advised to consult their health care provider about safety and effectiveness, particularly because the possibility of unrecognized pregnancy is present in younger women.

Premenstrual Syndrome (PMS)

Many women notice some minor physical and emotional changes related to their menstrual cycles. However, some women have severe problems associated with these cyclic changes. PMS, also called *premenstrual dysphoric disorder* (PMDD), affects about 5% to 10% of women severely enough to cause significant disruption with their daily lives. Although PMDD is the official diagnostic name for the diagnostic criteria, PMS is now a term ingrained in lay culture and will be used in this chapter. After exclusion of other diagnoses the following criteria must be met for the condition to be diagnosed as PMS (Lentz, 2012b):

- The signs and symptoms must be cyclic and recur in the luteal phase (after ovulation) of the menstrual cycle.
- The woman should be free of symptoms during the follicular phase (before ovulation) of the menstrual cycle, and the cycle must include 7 symptom-free days.
- Symptoms must be severe enough to have an impact on work, lifestyle, and relationships.
- Diagnosis should be based on the woman’s *prospective* symptom recording, or charting of symptoms as they occur rather than recall of symptoms that occurred in the past.

Some women who have medical or psychiatric disorders have an increased intensity of symptoms during the last half of their cycles, often leading them to assume that they have PMS. Examples of these are depression, panic disorder, and generalized anxiety disorder. A psychiatric illness such as bipolar disorder may have symptoms unrelated to PMS, but the two disorders may coexist. Occupational or personal stress may worsen PMS.

Numerous symptoms have been ascribed to PMS, but a relatively small number make up the majority of complaints. They can be divided into behavioral and physical symptoms. Box 34-3 lists those that are most common. Several PMS diaries with varied amounts of detail are available for the woman to record her symptoms and their severity, lifestyle impact, and medications.

Etiology

Although the cause of PMS is unknown, several theories or predisposing factors have been proposed. The current theory of PMS etiology is that normal fluctuations in gonadal hormones during a cycle, chiefly estrogen and progesterone, trigger central biochemical responses, specifically serotonin. The premenstrual fall in serotonin levels occurs in most women, but a susceptible woman may show psychiatric symptoms as her estrogen, progesterone, and serotonin levels fall during the luteal phase. Most women show a rapid postmenstrual return to a feeling of well-being.

Impact on Family

PMS puts a consistent strain on family relationships because symptoms recur monthly. The episodes of PMS affect the functioning of the entire family. Clinical descriptions of severe family disruptions include increased family conflict, disrupted communication, and decreased family cohesion. Of particular concern is the group of women who report symptoms of loss of control, child battering, self-injury, and increased accidents. Work and social relationships may suffer.

BOX 34-3 SYMPTOMS OF PREMENSTRUAL SYNDROME

Physical Symptoms

Headaches, dizziness
 Abdominal bloating or swelling; swelling of the extremities
 Breast tenderness
 Hot flashes
 Abdominal cramps
 Generalized muscle and joint pain
 Fatigue
 Appetite changes: binge eating, cravings
 Sleep changes: excessive sleep or insomnia
 Reduced sexual interest

Behavioral Symptoms

Depressed mood
 Feelings of hopelessness
 Marked anxiety
 Confusion, forgetfulness, poor concentration
 Accident proneness
 Irritability and anger
 Emotional lability: tearfulness or readiness to cry, loneliness, mood instability
 Reduced interest in activities of living
 Social avoidance
 Lethargy or high energy

Management

Treatment of PMS is based on the symptom profile of each woman after ruling out other problems, especially psychiatric diagnoses such as depression. Supportive therapy such as reassuring the woman that PMS is a common problem that has a physiologic basis may reduce her anxiety and should be part of other treatments. Relaxation therapy has shown benefits to women with the more severe PMS symptoms. Exercise has been shown to reduce PMS symptoms and also has many other benefits to a woman's health. Modifying the diet to reduce salty foods, caffeine, chocolate, red meat, dairy products, and alcohol may be helpful. Small and frequent meals may reduce mood swings.

Clinical trials have shown that supplementation with calcium (1200 mg/day) has some effectiveness and that magnesium supplementation (200 to 400 mg/day) is minimally effective. Carbohydrate-rich foods and beverages may improve the mood and reduce food cravings in some women. Reducing caffeine intake and taking vitamin E (400 international units [IU]/day) during the luteal phase of the cycle may reduce breast pain (mastalgia) in some women. Evening primrose oil also may have some benefit in reducing breast pain. Aromatase inhibitors are being investigated for possible use in treatment for PMS (ACOG, 2012b).

Women with physical, emotional, and cognitive symptoms may be prescribed antidepressant medications, oral contraceptives to suppress ovulation, or both. Estrogen therapy may relieve premenstrual migraines. Danazol taken in low doses may relieve breast pain and other symptoms. Bromocriptine (Parlodel) during the luteal phase may relieve breast pain. Selective serotonin reuptake inhibitors (SSRIs) taken at lower doses than those used to treat depression—such as fluoxetine (Sarafem), sertraline (Zoloft), or paroxetine (Paxil)—have been shown to be very effective for most women with correctly diagnosed PMS. The SSRI may be initially prescribed for the luteal phase

WOMEN WANT TO KNOW

How to Relieve Symptoms of Premenstrual Syndrome

Diet

- Decrease consumption of caffeine (coffee, tea, colas, chocolate), which increases irritability, insomnia, anxiety, and nervousness.
- Avoid simple sugars (cookies, cake, candy) to prevent high blood glucose levels followed by a rapid decline and a period of low blood glucose levels (hypoglycemia).
- Decrease intake of salty foods (chips, pickles) to reduce fluid retention.
- Drink at least 2000 mL (2 quarts) of water per day, and do not include other beverages in this total.
- Eat six small meals a day to prevent hypoglycemia. Meals should be well balanced, with emphasis on fresh fruits and vegetables, complex carbohydrates, and nonfat milk products.
- Avoid alcohol, which aggravates depression.

Exercise

- Increase physical exercise to relieve tension and to decrease depression. Aerobic activity, such as jogging or walking, several times a week is recommended.

Stress Management

- During the time when there are no symptoms of PMS, acknowledge the effect of PMS on daily life and make plans to avoid stressful situations during the premenstrual period when symptoms are acute.
- Use guided imagery, conscious relaxation techniques, warm baths, and massage to reduce stress.

Sleep and Rest

To reduce fatigue and combat insomnia:

- Adhere to a regular schedule for sleep.
- Drink a glass of milk, which is high in tryptophan and known to promote sleep, before bedtime.
- Schedule exercise in the morning or early afternoon rather than late afternoon.
- Engage in relaxing activities, such as reading, before bedtime, and avoid excitement at this time.

only; however, if ineffective, it can then be prescribed for continuous intake (Lentz, 2012b).

Nursing Considerations

Many women experience some of the symptoms and diagnose themselves as having PMS. Nurses must discourage this practice because serious systemic disease can be missed if the criteria for diagnosis are ignored. Instead of self-diagnosis, nurses should recommend that the woman consult with her health care provider so that a complete history and physical examination can be performed to rule out other causes or a problem that may coexist with PMS. Psychoactive drugs may be ineffective or contraindicated if a woman's true problem is not PMS.

Once the diagnosis of PMS is confirmed, nurses can educate the family about lifestyle changes that may help (Box 34-4). Nurses should acknowledge that dietary changes are particularly difficult because many women crave salty or sweet foods, which should be restricted. Women also benefit from education about expected cyclic changes. As they learn to predict the pattern of symptoms and gain a sense of control over them, the symptoms often diminish.

BOX 34-4 COMPLEMENTARY/ ALTERNATIVE THERAPY FOR PREMENSTRUAL SYNDROME

Complementary and/or alternative therapy may help some women. Measures include acupuncture, biofeedback, exercises, hypnosis, mind-body interventions, psychotherapy, spirituality, and stress management. Ongoing scientific information is available at www.nccam.nih.gov.

Education and support must be expanded to include the family. When the woman exhibits symptoms of PMS, family members often respond by withdrawing or confronting the woman. Family members should also be encouraged to express their feelings so that anger and resentment within the family can be diminished.

Nurses must help the woman make concrete arrangements to obtain relief when she feels she is losing control or when she fears that she may harm herself or a child. A neighbor, friend, or family member should be identified to provide immediate relief, without questions or explanations, when the woman feels she is losing control.

It is more helpful if the family acknowledges feelings they believe the woman is experiencing. For instance, saying, "It must be disturbing to feel so irritable. What can I do to help?" provokes a different emotional response than comments that are confrontational or blaming.

The family also should be encouraged to express their feelings so that anger and resentment within the family can be diminished.

ELECTIVE TERMINATION OF PREGNANCY

Elective termination of pregnancy, also called *induced abortion*, is a voluntary method of ending a pregnancy at the request of the woman but not for reasons of impaired maternal health or fetal disease. Therapeutic termination is usually performed to preserve the health of the mother, to prevent the birth of an infant with severe birth defects, or to end a pregnancy caused by rape or incest. A woman may choose elective termination of pregnancy for a variety of reasons, possibly economic or social. Therapeutic and elective abortions involve many social and ethical issues (see [Chapter 3](#); [Crandell, 2012](#)). Recent abortion surveillance may be found at www.cdc.org ([Pazol, Creanga, Zane et al., 2012](#)).

Methods of Elective Termination of Pregnancy

The technique used to terminate a pregnancy depends on the length of gestation. Abortion techniques based on medications may be options within 7 weeks of the woman's last menstrual period. Inducing uterine contractions with specific medications to end pregnancy early makes the process more private, eliminates risks such as uterine trauma or perforation, and does not require anesthesia.

Some drugs, such as misoprostol, also may be used in spontaneous abortion (miscarriage) care. Drugs that may be used in medical abortion regimens to terminate a pregnancy up to 9 weeks include:

- Mifepristone (Mifeprex, or RU-486), an antiprogesterone drug, followed by misoprostol (Cytotec), a prostaglandin drug commonly used to reduce gastric acid secretion. Oral or vaginal use of misoprostol in medical abortion is unlabeled by the manufacturer. The current preferred regimen of misoprostol for second-trimester pregnancy termination is 400 mg intravaginally every 6 hours. The woman usually expels the early pregnancy within 14 days of her first visit ([Jensen & Mishell, 2012](#)).
- Methotrexate (Folex, Mexate) is an antimetabolite also used to treat certain types of cancer. Although not FDA-approved for medical abortion, individualized doses have been successfully used for

medical pregnancy termination. Misoprostol may be prescribed to enhance expulsion of uterine contents.

Surgical abortion techniques are needed if the woman has been pregnant for more than 7 weeks or if her medical abortion failed and she still desires pregnancy termination. Through 12 weeks of gestation, vacuum aspiration with curettage is the method of choice. The cervix is dilated after locally injecting anesthetic in the area, and a plastic cannula is inserted into the uterine cavity. The contents are aspirated with negative pressure, and the uterine cavity may be scraped with a curet to ensure that the uterus is empty. Cramping may last 20 to 30 minutes after the procedure is completed. Complications may include uterine perforation, hemorrhage, cervical lacerations, and adverse reactions to the anesthetic agent.

For second-trimester abortions, dilation with removal of the fetus and placenta is generally performed. The procedure is similar to vacuum curettage but requires greater cervical dilation and a larger aspirator because the products of conception have grown in size and must be removed gradually. Dilation begins with insertion of laminaria—rounded, cone-shaped materials that absorb water—into the cervix 24 hours before the procedure. Other osmotic dilators include Dilapan and Lamicel. The laminaria draw fluid from the cervical canal and expand, causing the cervix to dilate slowly and with minimal trauma. If needed before aspiration and removal of the products of pregnancy, additional cervical dilation is done.

Medical methods exist for abortion in the second trimester, but these involve labor. Retention of the placenta often occurs, requiring a D&C to fully clean the uterus. Laminaria are inserted about 12 hours before the procedure to start cervical dilation. Prostaglandin E₂, which stimulates contractions, may be given via vaginal suppository or intraamniotic infusion. Oxytocin is not effective at starting labor because of the early gestation, but it may shorten labor after it has been established by other methods. Because of the emotional distress caused by the longer procedure and the increased risks involved, medical termination of pregnancy is not often chosen in the second trimester ([Jensen & Mishell, 2012](#)).

Nursing Considerations

The nurse's role in caring for women seeking elective abortion is one of providing physical and emotional support and information. History

WOMEN WANT TO KNOW

Guidelines for Self-Care after Elective Termination of Pregnancy

Normal activities may be resumed, but strenuous work or exercise should be avoided for a few days.

Bleeding or cramping may occur for 1 or 2 weeks. If either becomes severe, medical advice should be sought. Light "spotting" may occur for about a month.

Sanitary pads should be used instead of tampons for the first week after the abortion to avoid possible infection.

Intercourse should be curtailed for 1 week after the abortion because of the possibility of infection until the uterine lining heals.

Birth control measures should be used if sex is resumed before menstruation begins because it is possible to become pregnant during this time. Menstruation usually resumes in 4 to 6 weeks.

Temperature should be taken twice a day to detect possible infection; a temperature above 37.8°C (100°F) should be reported to the health care provider.

It is important to keep the follow-up appointment in 2 weeks or as recommended.

taking and collection of laboratory data depend on the routine of the health care setting in which the nurse is functioning. Counseling and lending emotional support are nursing responsibilities, although a designated counselor may also perform these services.

Nurses are also responsible for providing information about self-care after an elective abortion. Self-care is similar to that after spontaneous abortion or miscarriage: observation for excessive bleeding or signs of infection (temperature $>37.8^{\circ}\text{C}$ [100°F], foul-smelling vaginal drainage). Nurses also provide information about follow-up visits and contraception. The Rh-negative woman should receive Rho(D) immune globulin (RhoGAM).

MENOPAUSE

Menopause means the end of menstruation. However, most people use the term to include the array of endocrine, somatic, and psychic changes that occur at the end of the reproductive period. The entire process, often called the “change of life,” is correctly termed the *climacteric*. *Premenopause* refers to the early part of the climacteric, before menstruation ceases but after the woman experiences some of the climacteric symptoms, such as irregular menses. Perimenopause includes premenopause, menopause, and at least 1 year after menopause. *Postmenopause* refers to the phase after menopause, when menstrual periods have ceased.

Unexpected postmenopausal bleeding should be investigated as soon as possible because it suggests endometrial cancer. Conversely, planned or scheduled postmenopausal bleeding is generally not a cause for concern. It occurs when the woman who takes estrogen and progesterone sequentially stops taking the drugs, usually once a month. This allows the uterine lining to be sloughed and prevents endometrial hyperplasia.

Age of Menopause

The average age for natural menopause is 51.5 years (Lobo, 2012c). The natural climacteric takes place over 3 to 5 years. Menopause can be induced or created artificially, however, at any age. Surgical removal of the ovaries or destruction of the ovaries by radiation or chemotherapy causes abrupt, permanent cessation of ovarian function, including the production of estrogen. The most common reason for performing these procedures is treatment of cancer or endometriosis. Young women who experience artificial menopause often have more symptoms associated with menopause than do women who go through the process naturally because theirs is not a gradual process as it is for the older woman.

Women can now expect to live another 30 years after natural menopause. During this period they must deal with physical, psychological, and social changes that often require a reevaluation of their primary roles and restructuring of personal goals.

Physiologic Changes

During the normal reproductive cycle, the ovaries respond to gonadotropins (follicle-stimulating hormone and luteinizing hormone) in a predictable pattern: (1) a follicle matures, (2) the ovary secretes

estrogen, (3) ovulation occurs, and (4) the corpus luteum produces progesterone. During the premenopausal period, however, the ovaries are less responsive to gonadotropins, and, although increased amounts of follicle-stimulating hormone are secreted, ovulation is sporadic and menstrual periods are irregular. With progressive aging, the ovaries become unresponsive, even to high levels of gonadotropins, and ovulation, menstruation, and the secretion of ovarian hormones (estrogen and progesterone) cease.

Estrogen is responsible for the secondary sex characteristics of women. When estrogen levels decline, the organs of reproduction undergo regression. The labia become thin and pale. The vaginal mucosa atrophies, and vaginal tissue loses its lubrication and therefore is easily traumatized. Dyspareunia is not uncommon, and bacterial invasion of the epithelium may occur and lead to frequent vaginal infections. This entire process is referred to as **atrophic vaginitis**. Breasts become smaller, and atrophy of the uterus and ovaries occur. However, a concurrent benefit is that uterine myomas (fibroids) and endometriosis lesions also atrophy. Estrogen deficit can also result in atrophic changes in the bladder and urethra that may cause loss of urethral tone and frequent atrophic cystitis.

In addition, absence of estrogen is associated with an adverse change in serum lipids. Serum levels of low-density lipoproteins (LDLs), which carry cholesterol to blood vessels, increase. At the same time, levels of high-density lipoproteins (HDLs), which are known to carry cholesterol to the liver and to protect against the development of CAD, decrease.

Many menopausal women experience hot flashes or flushes, which are the result of vasomotor instability. The cause of vasomotor instability is not known, but it is closely associated with increased secretion of gonadotropins. Hot flashes are characterized by a sudden feeling of heat or burning of the skin, followed by perspiration. They occur more frequently during the night, and fatigue as a result of interrupted sleep is a major problem for some women. Hot flashes are often more frequent and severe in younger women who undergo the climacteric, particularly if loss of ovarian function was abrupt because of medical therapy. Many women in the climacteric have few annoyances from the hot flashes, however.

Psychological Responses

It is easy to understand why menopause is called the “change of life.” It is accompanied by physical, psychological, and social changes, and individual responses vary widely. Many women are relieved that their childbearing and child-rearing tasks are ending. They see this as an exciting time, when they can pursue personal development. Other women grieve that the possibility of childbearing is past. This may be particularly true for women who have never had a child, whether because of infertility or because of lack of a male partner. However, artificial reproductive techniques have blurred the line that defines the age at which it is and is not possible to bear a child (see Chapter 32).

Menopause requires a woman to come to terms with aging. It may be difficult to accept aging in a society that reveres youth, and many women become extremely concerned with measures that slow the signs of aging. Many women become grandmothers at this time, which also confirms aging and requires a major adjustment in how the woman views herself. A large population of “baby boomers”—those born from 1946 to 1964—have entered menopause. These women are likely to change many of society's ideas about menopause because of the sheer size of their group and because they have changed the social fabric of the United States dramatically as they have grown up and matured.

Some symptoms do not have a physiologic explanation, but they are no less real to women who experience them. Depression, mood

swings, irritability, and agitation are common climacteric complaints. Insomnia and fatigue are often mentioned as major problems.

One of the most puzzling aspects of menopause is the wide variation in both physical and psychological symptoms that women experience. For some women, the only changes are mild, infrequent hot flashes and amenorrhea. Other women experience severe, debilitating hot flashes; atrophic vaginitis; and multiple psychological symptoms, such as irritability and prolonged depression.

Therapy for Menopause

Although many women comfortably undergo the age-associated changes of menopause, others seek relief for discomforts such as hot flashes, interrupted sleep, or vaginal dryness. The psychological perception that increasing reproductive hormones might slow the aging process and promote a more youthful appearance has strengthened use of HRT during the climacteric. Additional beneficial effects were thought to be a reduction in cardiovascular disease, colorectal cancer, breast cancer, and osteoporosis, as well as other medical-surgical conditions associated with aging.

As greater research emerged, risk factors as well as benefits of hormone therapy emerged. Two groups of perimenopausal women were included in the hormone studies of the WHI research:

- Estrogen and progesterone were given to women with a uterus. Combining progesterone with estrogen therapy prevents uterine hyperplasia, a precursor to uterine cancer, in this group.
- Estrogen therapy alone was given to women who have had a hysterectomy because uterine hyperplasia is not a risk.

The combination of estrogen and progesterone replacement is usually called *hormone replacement therapy*, whereas the estrogen-only replacement therapy may be called *estrogen-replacement therapy* (ERT). It is common to see HRT used for either or both therapies, however.

The WHI and other hormone-replacement studies showed increasing evidence that estrogen plus progesterone therapy significantly increased risks of some disorders, primarily breast cancer and heart disease. The estrogen-progesterone arm of the WHI study was stopped in 2002. A woman enrolled in the estrogen-progesterone arm was not obligated to stop taking estrogen-progesterone therapy, but she had to make choices based on both the benefits and the unexpected risks that emerged with the early results. Rather than receive estrogen-progesterone supplements through the study, the women could continue the combined hormones via prescription from their health care provider. The estrogen-only arm of the study continued until 2004 when an increase in strokes among this group was identified.

Although once routinely prescribed to reduce the annoying changes of menopause for many women, the decision about hormone therapy is more complex because both the benefits and the risks associated with a prescribed hormonal drug must be considered. In addition, complementary therapy often has a greater usefulness for women having mild menopausal changes (see [Boxes 34-5](#) and [34-6](#)).

Risks

HRT was not considered safe for all women before the WHI findings. For example, women who have had estrogen receptor–positive or progesterone receptor–positive breast cancer or blood coagulation disorders influenced by estrogen or progesterone do not qualify. A woman who has had breast cancer may take a drug to block the effects of estrogen and reduce the risk of recurrence. Likewise, a woman who has a close family history of breast cancer might not want to take it. Unexplained uterine bleeding and endometrial cancer are contraindications. Smoking, hypertension, diabetes, cardiovascular disease, and renal or liver disease are often contraindications for hormone therapy, whether therapy includes both estrogen and progesterone or estrogen only.

BOX 34-5 CONTRAINDICATIONS AND CAUTIONS RELATED TO ESTROGEN REPLACEMENT THERAPY

Previous episode of breast or ovarian cancer or other estrogen-dependent tumor
 Close family history of breast cancer (first-degree relative)
 Uterine cancer
 Active thromboembolic disease or prior thromboembolic disorder when taking estrogen
 Risk for cardiovascular disease
 Stroke
 Acute or chronic liver disease
 Undiagnosed abnormal vaginal bleeding
 Gallbladder or pancreatic disease
 Diabetes mellitus
 Conditions that may be aggravated by fluid retention, such as migraine, epilepsy, cardiac or renal dysfunction, depression

WOMEN WANT TO KNOW

About Hormone Replacement Therapy

Hormone replacement therapy is highly individualized owing to research findings about possible unfavorable cardiovascular effects of estrogen-progesterone supplementation during the climacteric. However, women may continue using the estrogen-only HRT or the estrogen-progesterone HRT for significant discomforts that are unrelieved by other methods or for beneficial effects such as reduction in osteoporosis. The woman and her health care provider must consider both benefits and risks of HRT to make the decision about whether to use the hormone replacement.

- Take the medication with meals to reduce nausea.
- If you miss a dose, take the medication as soon as you remember, but not immediately before the next scheduled dose. *Do not take double doses.*
- Expect withdrawal bleeding (if your uterus is present) when estrogen and progestin are temporarily discontinued.
- Report unexpected bleeding to your health care provider.
- Stop smoking to reduce the risk of thromboembolism.
- Use sunscreen and protective clothing to prevent increased pigmentation.
- Continue follow-up physical examinations, including blood pressure measurements, Pap tests, and examinations of breasts, abdomen, and pelvis.

Other possible contraindications include seizure disorders, migraines, and gallbladder or pancreatic disease.

Nursing Considerations

Nursing care focuses on helping women understand the physical and psychological changes that may occur during the perimenopause. If the woman chooses hormone therapy, nurses must reinforce both the prescribed regimen as well as the risks and benefits of the therapy. For instance, women should be told that although hormone replacement therapy effectively treats atrophic vaginitis and reduces dyspareunia, it may not correct the loss of libido that some women experience ([Box 34-5](#)).

If HRT is contraindicated, nurses are often the primary source of information about measures that reduce problems and promote comfort:

BOX 34-6 COMPLEMENTARY/ ALTERNATIVE THERAPY FOR MENOPAUSE

All patients should be asked about their use of complementary and alternative therapy methods, and their response should be documented.

"Natural" should not be assumed to be safe or therapeutic.

Errors are possible with natural products because of nonstandardized dosing, inconsistent quality control, errors in compounding, and incorrect labeling of the actual plant compound in a container.

Many biological products should not be used by a woman considering becoming pregnant or during pregnancy and lactation. Natural biological products cannot be assumed to be safe for children.

Botanical products that may be used for hot flashes, although effectiveness is not yet well supported by research, include the following:

- Black cohosh: Reduced sweating; suppression of luteinizing hormone; no influence on endometrial thickness, levels of follicle-stimulating hormone, estrogenic or prolactin levels; should not be used with estrogen therapy, anticoagulants, and antihypertensives.
- Soy products: Contain **phytoestrogens** that may serve as weak estrogenic compounds, stimulating estrogen receptors; no convincing evidence that soy products reduce hot flashes more than placebos in some studies; should be avoided in women with estrogen-dependent tumors such as breast, ovarian, or endometrial cancer because tumor growth may be stimulated; possible interaction between estrogen replacement therapy or the drug tamoxifen; should be avoided in pregnant or lactating women.
- Dong quai: May be used with other herbal products; contains coumarin products that have vasodilation and antispasmodic effects; more study needed to determine effects on hot flashes although it is a traditional Chinese medicine product.
- Vitamin E: A fat-soluble vitamin supplement having antioxidant properties; inhibits platelet aggregation and low-density lipoprotein (LDL) oxidation, possibly interfering with therapeutic effects of anticoagulant chemotherapy, or statin drugs designed to normalize levels of lipids; has been associated with gastrointestinal disturbances; recent results have shown an association with heart failure.
- Chasteberry: Possible reduction in premenstrual symptoms of mood alteration and menopausal symptoms; NCCAM is funding research.

From American College of Obstetricians and Gynecologists. (2012d). *Use of botanicals for management of menopausal symptoms*. Practice Bulletin No. 28. Washington, DC: Author; National Center for Complementary and Alternative Medicine. (2009a). *Herbs at a glance: Evening primrose oil*; National Center for Complementary and Alternative Medicine. (2009b). *Herbs at a glance: Chasteberry*; National Center for Complementary and Alternative Medicine. (2009c). *Get the facts: Menopausal symptoms and CAM*.

- Using water-soluble lubricants such as K-Y Liquid, K-Y Silk-E, Lubrin, or Replens to relieve vaginal dryness and dyspareunia. Oil-based lubricants should not be used because they adhere to the mucous membrane for long periods of time and provide a medium for bacterial growth.
- Discussing alternatives to estrogen, such as botanical preparations, if the woman does not want estrogen replacement therapy. The woman should discuss these with her health care provider, because some have side or adverse effects or interactions with other drugs. Research is often minimal for these therapies. The website for the National Center for Complementary and Alternative Medicine of the NIH, www.nccam.nih.gov, contains updated information (Box 34-6) (Kupferer, Dormire, & Becker, 2009).

- Doing Kegel exercises to increase muscle tone around the vagina and urinary meatus and counteract the effects of genital atrophy.
- Drinking at least eight glasses of water a day decreases the concentration of urine, flushes urine from the bladder, and reduces bacterial growth, thereby preventing atrophic cystitis.
- Wiping from front to back after urination and defecation reduces the transfer of bacteria from the anus to the urinary meatus and helps prevent cystitis.

CHECK YOUR READING

19. What are the effects of estrogen depletion at menopause (either natural or artificial) on the body?
20. What are the major psychological symptoms associated with menopause?
21. How does hormone replacement affect menopausal and postmenopausal women? What concerns were raised by the WHI research?

Osteoporosis

Osteoporosis is one of the greatest hazards of the postmenopausal years. It is characterized by decreased bone density, leaving the bones porous, fragile, and susceptible to fractures. The vertebrae, wrists, and hips are the most common sites of fractures, with forearms, feet, and toes also susceptible. More than 40 million people in the United States already have osteoporosis and more osteoporosis-related fractures are expected as the age of the U.S. population rises with boomers (National Institute of Arthritis and Musculoskeletal and Skin Diseases [NIAMS], 2011).

More than 44 million people in the United States presently have the public health threat of low bone mass or osteoporosis, and 68% of them are women. However men are also at risk for osteoporosis, with their risk increasing at age 70. One in two women over age 50 will have a fracture related to osteoporosis in their lifetime. Osteoporosis causes as many as 300,000 hip fractures, 700,000 vertebral fractures, and 250,000 wrist fractures, in addition to other fractures (Brown, 2009; NIAMS, 2011). Hip fractures increase the risk of reduced mobility and death in the elderly.

Risk Factors

The combination of peak bone density and the rate of bone loss influences the severity of osteoporosis. Small-boned, fair-skinned white women of northern European descent and Asian women are at greatest risk for osteoporosis, but African-American and Hispanic women also are at risk. Other risk factors may include a family history of the disease, late menarche, early menopause, and a sedentary lifestyle. Women who smoke, drink alcohol, or consume excessive amounts of caffeine have an increased risk for osteoporosis. Drug intake such as corticosteroids, some anticonvulsants, or aromatase inhibitors for breast cancer may reduce bone density. Inadequate lifetime intake of calcium or vitamin D is a risk factor. Women usually reach their peak bone mass between 18 and 25 years. Bone loss in women usually accelerates with menopause. Osteoporosis occurs as a woman loses too much bone, makes too little bone, or both (National Osteoporosis Foundation [NOF], 2013).

Signs and Symptoms

Osteoporosis has been called the "silent thief" because bone mass is lost over many years with no signs or symptoms. The first noticeable evidence is loss of height and back pain that occurs when the vertebrae collapse. Later signs include the "dowager's hump," which occurs when the vertebrae can no longer support the upper body in an upright

FIG 34-2 With progression of osteoporosis, the vertebral column collapses, causing loss of height and back pain. *Dowager's hump* is the term used for this curvature of the upper back.

position. Secondary to this, the waistline disappears and the abdomen protrudes as the rib cage moves closer to the pelvis. Depending on the number of fractures, several inches of height may be lost. [Figure 34-2](#) illustrates progressive changes in posture associated with osteoporosis.

Diagnosis of osteoporosis requires a thorough history, physical examination, and bone mineral analysis. Conventional x-ray examination is of little help because more than 30% of the bone mass must be lost before changes are apparent. Dual-energy x-ray absorptiometry (DEXA or DXA) is a highly accurate, fast, and relatively inexpensive method for measuring bone mineral density and involves low exposure to radiation. Results can be evaluated with risk factors to direct management. Bone density examination cannot only confirm the presence of osteoporosis but also detect low density before a fracture and predict the risk for fracture. Repeating bone density imaging helps determine the rate of bone loss and monitor treatment effectiveness ([Brown, 2009](#); [NIAMS, 2011](#)).

Prevention and Medical Management

The major goal of treatment is to prevent or slow osteoporosis and to stabilize remaining bone mass. Although research has upheld estrogen therapy to reduce osteoporosis by inhibition of bone resorption, fewer women are choosing hormone therapy because of its potential adverse effects. Also many breast cancer survivors take medications such as aromatase inhibitors that suppress or block estrogen because of its effects on tumor cells.

Drug Therapy. Other drug categories to reduce osteoporosis include ([NIAMS, 2011](#); [NOF, 2012](#)):

- Calcitonin (Calcimar, Miacalcin, Fortical), a synthetic hormone, is usually prescribed as a daily nasal spray to reduce factors that cause loss of calcium and increase reabsorption of calcium in the gastrointestinal tract.

- Bisphosphonates inhibit osteoclasts, reducing bone turnover. Alendronate (Fosamax), risedronate (Actonel), and ibandronate (Boniva) are used to prevent and treat postmenopausal osteoporosis. Oral bisphosphonates may be contraindicated for women with ulcers or an inflammatory gastrointestinal disease such as dysphagia or esophagitis. Alendronate and risedronate are also approved to treat bone loss that results from glucocorticoids and to treat men with osteoporosis. Zoledronic acid (Reclast) is approved for treatment of postmenopausal osteoporosis and is given by intravenous (IV) infusion yearly. Headache or flu-like pain in muscles or joints may occur for 2 or 3 days after zoledronic acid infusion.
- Raloxifene (Evista), a selective estrogen receptor modulator (or SERM), binds to estrogen receptors to reduce bone loss. Because of the combined estrogen agonist and estrogen antagonist effects of SERMs, raloxifene is being studied to see if its effects also improve cardiac health without raising breast or uterine cancer.
- Teriparatide (Forteo) is an injectable parathyroid hormone approved for postmenopausal women and men at high risk of fracture. Current approved duration of use is a maximum of 24 months. Teriparatide stimulates new bone formation, reducing the risk of both vertebral and nonvertebral fractures. Nausea, dizziness, and leg cramps are side effects.
- Denosumab (Prolia) is a recently approved receptor activator of nuclear factor-kappa B (RANK) ligand (RANKL) inhibitor that inhibits osteoclasts. Increased RANKL in postmenopausal women results in greater bone resorption with the osteoclasts. Denosumab reduces bone loss by inhibiting osteoclasts produced by higher RANKL levels ([NIAMS, 2011](#); [Wilton, 2011](#)).

Calcium and Vitamin D. Although calcium does not prevent bone loss, other therapies cannot be effective if calcium is deficient. A woman older than 50 years needs 1200 mg of calcium daily, and a woman 65 years or older needs 1500 mg/day. Daily calcium supplements are recommended because it is difficult to ingest these quantities through food intake only. Vitamin D is necessary for calcium to be absorbed from the intestine. Supplemental vitamin D, 400 to 800 units, is often recommended.

Exercise. Weight-bearing and resistance exercise has been shown to be beneficial in slowing loss of bone mass to maintain density if there is adequate calcium and vitamin D intake. Most of the bone mass is acquired by age 18, but muscle-strengthening exercise may continue to build bone into the 30s. High-impact exercise improves bone mineral density but should be avoided in a person who already has fragile vertebrae from osteoporosis. At least 30 minutes of daily therapeutic exercise is needed. Other exercises, such as swimming or water-based exercises, often improve cardiovascular and respiratory fitness while managing weight, although their primary use is not to limit bone loss.

Nursing Considerations

Nurses often counsel women about lifestyle factors that contribute to bone loss, such as cigarette smoking, excessive alcohol or caffeine intake, and the importance of following the recommended medical regimen. Adolescents and young women should be counseled about factors that impair as well as promote their ideal amount of peak bone density. Nurses are also concerned about how to prevent falls and thereby reduce the risk of fractures, particularly in older women or those with mobility impairments. A major responsibility is to help the woman make her environment as safe as possible. Lighting should be ample, with switches easily accessible. Loose electrical cords should be kept out of the way, and area rugs should have nonskid backing. The bathtub should have nonskid devices, and grab bars should be installed near toilets and tubs. Stairways should have handrails, and loose items

should be kept out of the walking pathways. Consultation with an occupational or physical therapist may be needed if the woman has serious mobility problems. See www.niams.nih.gov/bone for added information.

Nursing Diagnoses

A variety of nursing diagnoses may be relevant for the woman with osteoporosis, depending on the severity of the condition. Examples include:

- Pain related to pressure and inflammation of nerves that exit the vertebral column
- Activity Intolerance related to discomfort and fear of falling
- Disturbed Body Image related to postural and functional limitations
- Self-care Deficit (specify) related to physical limitations and depression

23. How can osteoporosis be prevented?
24. What can nurses do to help women with osteoporosis prevent fractures?

PELVIC FLOOR DYSFUNCTION

Pelvic floor dysfunction occurs when muscles, ligaments, and fascia that support the pelvic organs are damaged or weakened. This relaxation of pelvic support allows the pelvic organs to prolapse into, and sometimes out of, the vagina. Pelvic disorders generally occur in the perimenopausal period and may be the delayed result of traumatic childbirth or the effects of aging. While 50% of women over 50 have some degree of pelvic organ prolapse, fewer than 20% seek treatment. Pelvic floor dysfunction may occur in a woman who had a hysterectomy (Lentz, 2012a, c).

Vaginal Wall Prolapse

The vagina may prolapse at either the anterior or the posterior wall. Anterior wall prolapse involves the bladder and urethra and is called **cystocele**. Prolapse of the posterior wall produces enterocele or **rectocele**.

Cystocele

When the weakened upper anterior wall of the vagina is no longer able to support the weight of urine in the bladder, cystocele develops. The bladder protrudes downward into the vagina, resulting in incomplete emptying of the bladder. Cystitis is likely to occur because of the stagnant urine. Urethral displacement, formerly termed *urethrocele*, may occur when the urethra bulges into the lower anterior vaginal wall, producing stress urinary incontinence (Figure 34-3, A).

Stress incontinence is the loss of urine that occurs with a sudden increase in intraabdominal pressure, such as that generated by sneezing, coughing, laughing, lifting, or sudden jarring motions. The two most common causes of stress incontinence are damage to the normal supports of the bladder neck and urethra that occurs during pregnancy and childbirth, and tissue atrophy that occurs after menopause.

Enterocele

Enterocele is prolapse of the upper posterior vaginal wall between the vagina and rectum. This is almost always associated with herniation of the pouch of Douglas (a fold of peritoneum that dips down between

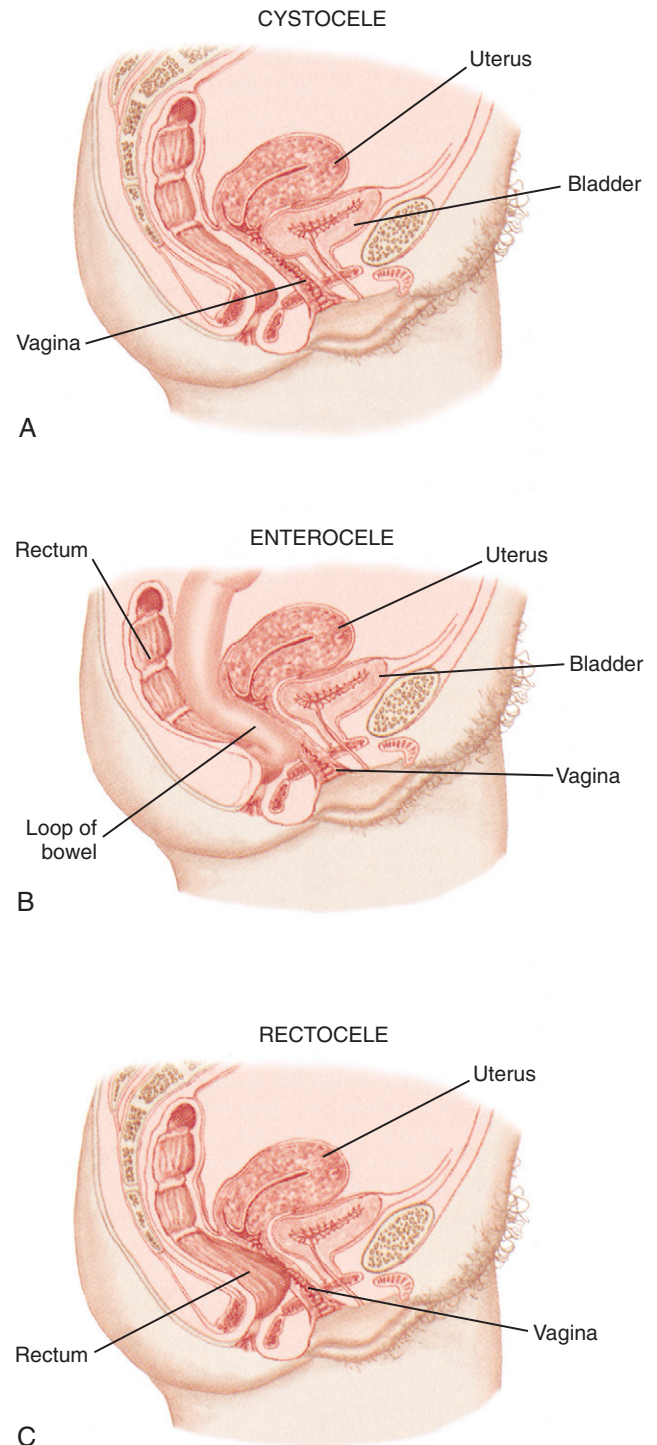

FIG 34-3 Three types of vaginal wall prolapse. **A**, Note bulging of bladder into the vagina. **B**, Note loop of bowel between rectum and uterus. **C**, Note bulging of rectum into vagina.

the rectum and the uterus) and may contain loops of bowel. Enterocele often accompanies uterine prolapse (see Figure 34-3, B).

Rectocele

Rectocele occurs when the posterior wall of the vagina becomes weakened and thin. Each time the woman strains at defecation, feces are pushed against the thinned wall, causing further stretching, until

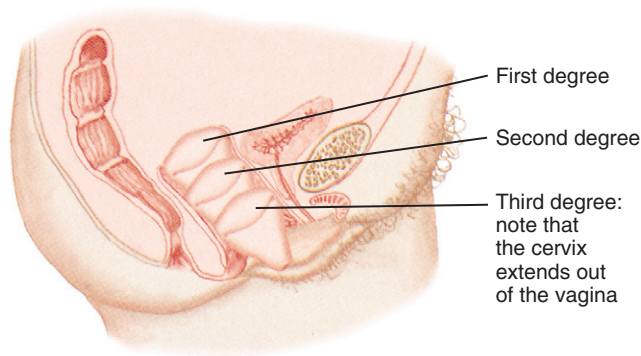

FIG 34-4 Three degrees of uterine prolapse.

finally the rectum protrudes into the vagina. Many rectoceles are small and produce few symptoms. If the rectocele is large, the patient may have difficulty emptying the rectum. Some women facilitate bowel elimination by applying digital pressure along the posterior vaginal wall to keep the rectocele from protruding during a bowel movement (see Figure 34-3, C).

Uterine Prolapse

Uterine prolapse occurs when the cardinal ligaments, which support the uterus and vagina, are unduly stretched during pregnancy and do not return to normal after childbirth. This allows the uterus to sag backward and downward into the vagina. Uterine prolapse is less common than in the past, largely because of a reduction in traumatic vaginal deliveries. The condition continues to exist, however, particularly when the woman has had many vaginal deliveries or when the infants were large. Figure 34-4 illustrates three degrees of uterine prolapse from first degree, in which the uterus remains in the vagina, to third degree, in which the cervix protrudes from the vagina (Lentz, 2012a).

Symptoms

Symptoms of pelvic floor dysfunction generally become obvious during the menopausal period. This is because estrogen diminishes at this time, resulting in atrophic changes in the supporting structures. The most common symptoms of vaginal wall prolapse are feelings of pelvic fullness, a dragging sensation, pelvic pressure, and fatigue. Low backache and a feeling that “everything is falling out” are sometimes described. Sexual problems related to arousal, orgasm, and painful vaginal intercourse may occur with pelvic floor dysfunction.

Symptoms relate to the structures involved and the level at which support has decreased. For instance, urinary frequency and urgency and urinary incontinence are seen in patients with cystocele because support of the urethra and lower vaginal wall has decreased. Constipation, flatulence, and difficulty defecating are major symptoms of rectocele. Regardless of the location or structure involved, symptoms become worse after prolonged standing, and they are relieved by lying down.

Symptoms of uterine prolapse are produced by the weight of the descending structures and may include sensations of pelvic pressure, backache, and fatigue. Cervical ulceration and bleeding occur if the cervix protrudes from the vaginal introitus.

Management

Treatment of disorders related to pelvic floor dysfunction depends on the woman's age, physical condition, sexual activity, and degree of prolapse. Surgical procedures provide the most satisfactory therapy for

women who have significant discomfort. The most common procedures are the anterior and posterior colporrhaphy, often called an A&P repair. The anterior colporrhaphy involves suturing the pubocervical fascia to support the bladder and urethra when a cystocele exists. If a rectocele exists, a posterior colporrhaphy (suturing the fascia and perineal muscles that support the perineum and rectum) is performed. Vaginal hysterectomy may be combined with anterior and posterior repair.

If surgery is contraindicated, a pessary (a device to support pelvic structures) may be inserted into the vagina. The pessary must be inspected and changed frequently by a physician or nurse practitioner to prevent vaginal ulceration, fistula formation, stool impaction, and infection. Vaginal estrogen cream may improve the woman's tolerance of the pessary. Topical or systemic estrogen treatment may be indicated for the woman (Lentz, 2012a).

Nursing Considerations

Pelvic Exercises. Pelvic floor muscle training is directed toward strengthening the levator ani and pubococcygeal muscles which affect urethral closure and pelvic floor support. Kegel exercises are isometric, and one possible application is for the woman to consciously contract and relax these muscles slowly eight to 12 times for a count of 6 to 8 seconds each and repeat this series for three sets. Before teaching pelvic floor muscle training, determine if the woman can contract the muscles by asking her to sit with her legs apart while she urinates and to squeeze the muscles to stop the stream of urine. If she can accomplish this, the muscles are contracted and it is possible for her to perform the exercise. Muscles of abdomen, thighs, and buttocks should *not* tighten during pelvic floor muscle training. Women should be taught to exhale and keep the mouth open to avoid bearing down when contracting their pelvic muscles, and then gradually relax the muscle contraction. Variations exist about how frequently to repeat pelvic muscle contractions each day. To maintain pelvic muscle tone, the woman should continue pelvic floor or Kegel exercises for the rest of her life (Lentz, 2012a; NIDDKD, 2012a, b).

Graduated weight cones may be used as an adjunct to pelvic muscle exercise. Incrementally weighted cones are inserted into the vagina, and the woman attempts to hold the weights in place. As the weight of the cones increases, the resistance against which the pelvic muscles contract increases, thereby strengthening the pelvic muscles (Lentz, 2012c).

Measures that help reduce the symptoms of pelvic relaxation may also prove helpful. These include lying down with the legs elevated for a few minutes several times a day. Some women are relieved by assuming a knee-chest position for a few minutes. In addition, teaching may include measures to prevent constipation.

Urinary Incontinence. Evaluation of the characteristics of a woman's urinary incontinence guides treatment. Three major patterns are (Lentz, 2012c; NIDDKD, 2012b):

- Stress incontinence, with urine leakage occurring as the woman increases her intraabdominal pressure. Examples of times when intraabdominal pressure may increase sufficiently include coughing, sneezing, laughter, or physical exertion such as picking up a full shopping bag or heavier load.
- Urge incontinence, characterized by urine leakage that accompanies a woman's strong need to void promptly.
- Mixed incontinence, in which a woman's urine leakage has associated factors from both the stress and the urge incontinence patterns.

Overactive bladder (OAB) may occur with both urge and mixed incontinence. OAB is characterized by frequent sensations of urgency and nocturia and may accompany neurologic, anatomic, or structural disorders.

Direct questions such as “Do you have trouble with your bladder?” or “Do you ever unintentionally lose urine?” may encourage women to discuss urine control problems. After the subject is introduced, follow-up questions are asked to determine urinary frequency. For instance, can she sit through a 2-hour movie without emptying her bladder? How many times does she get up to urinate each night? Does she often feel that she must hurry to empty her bladder and that she will lose urine while going to the restroom?

Nursing research has shown that continence can be improved by teaching specific health promotion activities, such as pelvic floor exercises and bladder training, which involves adhering to a prescribed schedule for emptying the bladder. Women who cannot execute even a weak pelvic muscle contraction or are unable to implement bladder training may benefit from biofeedback or electrical stimulation provided by a skilled practitioner (Lentz, 2012c; NIDDKD, 2012b).

Women often benefit from knowing about some of the commercial products that protect the skin and prevent odor. These products are made of material that traps urine and prevents constant contact with the skin.

Women often restrict fluids, believing that this will decrease urinary incontinence. Restricting fluids may actually make the condition worse because the bladder does not fill to its normal capacity. Furthermore, decreased fluid intake can lead to concentrated urine that can irritate bladder mucous membranes and increase the urge to void. Alcohol and caffeine can also irritate the bladder and worsen incontinence. Obesity is associated with urinary incontinence, increasing the benefits for a woman to achieve her ideal weight range.

Drug treatment may enhance bladder control. Drugs that may be prescribed include (Lentz, 2012c; NIDDKD, 2012b):

- Vaginal estrogen using a cream, tablet, or vaginal ring to reduce atrophy of the urinary and vaginal areas
- Anticholinergic drugs, including their long-acting versions, such as oxybutynin (Ditropan) or tolterodine (Detrol)
- Other drugs are being studied for possible use in improving bladder control.

DISORDERS OF THE REPRODUCTIVE TRACT

Benign Disorders

The most common benign conditions of the reproductive tract include cervical polyps, uterine leiomyomas (fibroids), and ovarian cysts.

Cervical Polyps

Polyps are small tumors, usually only a few millimeters in diameter, that are generally on a pedicle (a stalk or stemlike structure). They are caused by proliferation of cervical mucosa and often cause intermittent vaginal bleeding.

Cervical polyps are surgically removed in an outpatient setting, and the specimen is sent for pathologic examination to rule out malignancy.

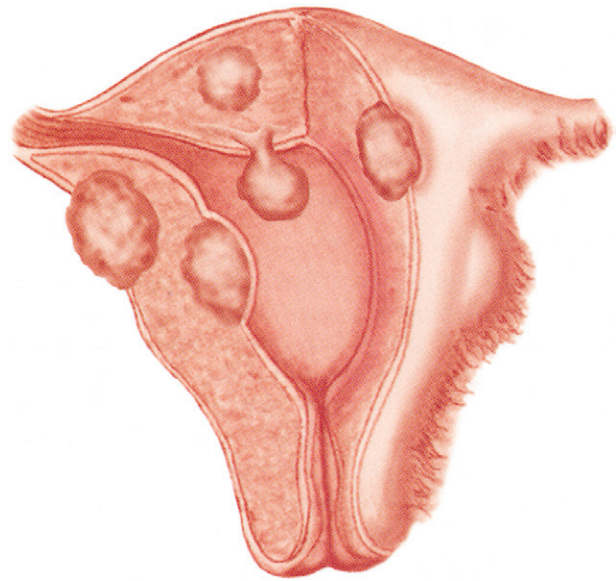

FIG 34-5 Sites within the uterus where fibroids commonly occur.

Uterine Leiomyomas

Leiomyomas, also called *fibroids*, are one of the most common gynecologic conditions encountered. Although the cause is unknown, they develop from uterine smooth muscle cells and are estrogen dependent. As a result, they grow rapidly during the childbearing years, when estrogen is abundant, but shrink during menopause unless growth is maintained by HRT for menopausal symptoms. Fibroids may occur throughout the muscular layer of the uterus and may be prominent near the end of pregnancy as the estrogen levels are high and the uterus is large (Figure 34-5).

Uterine fibroids do not often cause symptoms. Uterine size is sometimes increased, and excessive menstrual bleeding may occur. Excessive bleeding may result in anemia, weakness, and fatigue. Infertility may be related to uterine fibroids. Additional symptoms include feelings of pelvic pressure, bloating, and urinary frequency that occur when the tumor applies pressure on the bladder. Pressure on the ureter may cause hydronephrosis (dilation of the ureter). Many symptoms of fibroids depend on the location of the benign uterine tumors.

Treatment depends on multiple factors, including the size, number, and location of the fibroids; the symptoms experienced; whether future childbearing is desired; and how near the woman is to natural menopause. In the absence of symptoms, treatment may consist of observation only. If abnormal bleeding is a problem, surgical intervention may be necessary. Hysterectomy may be appropriate for the woman who does not desire future childbearing. Myomectomy, or removal of the fibroid from uterine muscle, may be an option for the woman who desires future children. Uterine artery embolization (UAE) is a procedure focused on reducing the fibroid size by introducing obstruction in the arteries that supply the fibroid. Pregnancy after UAE is often more likely to have intrauterine growth restriction or preterm birth (Katz, 2012a).

Medical treatment with progesterone-only or combination estrogen-progesterone oral contraceptives may reduce excess menstrual flow. Short courses of GnRH agonists may be effective in reducing the size of myomas and lessen symptoms before surgical removal. GnRH agonists cause hot flashes, vaginal dryness, and other discomforts similar to those of menopause, and therefore are not tolerated well by some women. Loss of bone mineral density is an adverse effect of long-term therapy (Katz, 2012a).

Ovarian Cysts

An ovarian cyst may be either follicular or luteal. If the ovarian follicle fails to rupture during ovulation, a follicular cyst may develop. These cysts are usually asymptomatic and may be an incidental finding on an ultrasound. They generally regress during the subsequent menstrual cycle. A lutein cyst may develop if the corpus luteum becomes cystic and fails to regress. A lutein cyst is more likely to cause pain and delay in the next menstrual cycle. Occasionally, an ovarian cyst can rupture or twist on its pedicle and become infarcted, causing pelvic pain and tenderness (Katz, 2012a).

Treatment depends on differentiating a cyst from a solid ovarian tumor that is more likely to indicate cancer. If the woman is in her childbearing years, when the risk of ovarian cancer is less, the physician may wait until after the next menstrual cycle and examine the woman again. Transvaginal ultrasound examination is useful to determine if it is a fluid-filled cyst or a solid tumor. Laparoscopy may be helpful in ruling out endometriosis. **Laparotomy** (visualization of abdominal or pelvic organs through incision) may be necessary to remove the cyst from the ovary for examination by a pathologist.

Malignant Disorders

The primary sites for cancer in the female reproductive organs are the uterus, ovaries, and cervix. Cancer of the vagina, vulva, and fallopian tubes is relatively uncommon. Although cancer can occur at any age, the incidence increases with age.

CRITICAL TO REMEMBER

Symptoms That Should Always Be Investigated

- Irregular vaginal bleeding
- Unexplained perimenopausal or postmenopausal bleeding
- Unusual vaginal discharge
- Dyspareunia
- Persistent vulvar or vaginal itching
- Elevated or discolored lesions of the vulva
- Persistent abdominal bloating or constipation
- Persistent anorexia or vomiting
- Blood in stools

Signs and Symptoms

Cancer of the reproductive organs may not be diagnosed until it is advanced because few symptoms are experienced in the early stages. When symptoms occur, they are often nonspecific and could be caused by infection or other benign conditions. Cancer of the ovaries is particularly difficult to diagnose because it may remain “silent” until far advanced, when the chance of long-term survival is greatly reduced.

Risk Factors

Risk factors vary according to the site of the cancer. Risk factors for cervical cancer include a history of sexually transmitted diseases (STDs), particularly **condyloma acuminatum**, also known as genital warts, caused by human papillomavirus (HPV). Prolonged use of unopposed estrogen replacement therapy (ERT) (estrogen-only) predisposes to overgrowth (hyperplasia) of endometrial tissue and is a significant risk factor for uterine cancer. See **Box 34-7** for a summary of risk factors for cancer of the reproductive organs.

Diagnosis

Early diagnosis is strongly associated with long-term survival. Many screening and diagnostic tests are useful. Screening tests include

BOX 34-7 RISK FACTORS FOR CANCER OF THE REPRODUCTIVE ORGANS

Uterus

African-Americans: higher risk for leiomyosarcoma
 Obesity
 Nulliparity
 Middle-aged and elderly
 Late menopause (>52 years old)
 Diabetes mellitus
 Breast, colon, or ovarian cancer
 Estrogen replacement therapy

Cervix

Human papillomavirus (HPV) infection
 Sexual risks: Young age at start of intercourse (<20 years), multiple sexual partners, uncircumcised male partners
 Many pregnancies
 Obesity
 Diet low in fruits and vegetables
 Smoking
 Lower socioeconomic status (may be related to infrequent gynecologic examinations)
 History of sexually transmitted diseases, such as chlamydia or human immunodeficiency virus (HIV) infection

Ovaries

Menses started at <12 years of age
 No child or first child after 30 years of age
 Late menopause (>55 years old)
 Infertility; infertility drugs
 Family history of ovarian, breast, or colorectal cancer
 Personal history of breast cancer

periodic pelvic examinations, Pap tests, ultrasonography, and serum tests for tumor markers such as CA-125, which may be increased with ovarian or other cancers. Genes linked to other cancers, such as *BRCA1* or *BRCA2* mutations (p. 730), may lead to more diagnostic procedures than if the genetic risk is not apparent. Significant family history of specific cancers of the reproductive organs or linked cancers such as breast and ovarian cancers may alter the risk for a woman's development of cancer. Diagnostic procedures such as endometrial biopsy for endometrial cancer and **colposcopy** (examination with a colposcope to magnify cells) can identify patterns of abnormality near the cervical os, where most cancers of the cervix develop. Specific strains of human papillomavirus (HPV) infection are a significant risk factor for cervical cancer even if the original infection has healed.

Management

Treatment of cancer of the reproductive organs is based on the location and extent of the disease and the age and desire of the woman to have children. The extent of surgical treatment for these cancers varies with the tumor size, degree of malignancy, and extent of spread beyond the primary tumor site. Chemotherapy and radiation oncology therapy supplement surgical treatment for many invasive cancers.

Treatment of one type of cancer may be based on previous cancer treatment in the same or related organs. For instance, treatment of previous breast cancer with the chemotherapy drug adriamycin often means that the woman has reached the maximum lifetime amount that

she can take because of the drug's effects on her heart. Drugs such as anastrozole (Arimidex) and exemestane (Aromasin), aromatase inhibitors, may reduce estrogen secretion that increases cancer growth in most breast and reproductive organs.

Cervical Cancer. Testing for HPV often reveals the cervical infection that contributes to cancer. A biopsy of the suspicious area and an endocervical curettage are done for diagnosis if the woman is not pregnant. A vaccine against the HPV strains that are most likely to cause genital warts and cervical cancer (Gardasil) has been released. HPV vaccine is most likely to be effective before sexual activity begins, with the first dose of three being given at 13 to 26 years or as young as 9 years. See p. 726 for more information about the HPV vaccine.

A lesion of early cervical cancer is usually a squamous intraepithelial lesion (SIL). Early treatment of cervical cancer may consist of cryosurgery, destruction of abnormal tissue by laser, loop electrosurgical excision procedure (LEEP), or surgical conization to remove the central cervix. Regular surveillance following cervical cancer therapy is recommended to identify recurrence, particularly in the woman who had a high-grade SIL, whose risk for repeated cervical cancer is greater.

Treatment for advanced cervical cancer usually consists of a total abdominal hysterectomy and bilateral salpingo-oophorectomy. Removal of the uterus and ovaries and **sentinel lymph node biopsy (SLN)** may be done via laparoscopy. Adjuvant therapy with radiation and chemotherapy is likely (Jhingran & Levenback, 2012).

Endometrial Cancer. Abnormal vaginal bleeding, usually near or after menopause, is the most common presentation for endometrial cancer. Estimated new cases of endometrial (uterine) cancer in the United States is expected to be 49,650 in 2013 and 8180 deaths from uterine cancer during the same period (ACS, 2012c). Although endometrial cancer occurs more often in a postmenopausal woman, about one fourth of the cases may occur in premenopausal women. However, endometrial cancer in the older woman is likely to be more advanced. The highest cure rate is with surgery (hysterectomy and salpingo-oophorectomy) followed by adjuvant chemotherapy and/or radiation therapy. Poor surgical candidates may be treated with only chemotherapy or radiation (Soliman & Lu, 2012).

Ovarian Cancer. Women with ovarian cancer may be asymptomatic, or they may seek care for abdominal or pelvic pain, increased abdominal girth, and sometimes abnormal bleeding. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and removal of ovarian tissue in the pelvis may be curative for women in the earliest stages of ovarian cancer. Surgery for more advanced ovarian cancer improves diagnostic information, allows more accurate staging, and permits surgical reduction of the cancer. Ovarian cancer is usually treated by surgery followed by chemotherapy. However, it may be treated by chemotherapy to reduce the tumor's size, followed by hysterectomy and bilateral salpingo-oophorectomy. A second surgery may be done to determine if more surgical or adjuvant treatment is needed. Chemotherapy is required after surgery for all but the very early cancers. The 5-year survival rate varies with the stage at diagnosis and response to chemotherapy (Coleman, Ramirez, & Gershenson, 2012).

INFECTIOUS DISORDERS OF THE REPRODUCTIVE TRACT

Infections of the reproductive tract may cause a variety of problems for women of all ages. Although some (such as candidiasis) are mostly annoying, others (such as the immunodeficiency virus) may be lethal. Some infections are seldom associated with sexual activity, whereas others are almost exclusively spread in this way. Infections may spread silently in the reproductive organs, allowing damage to the organs before the woman has symptoms.

Candidiasis

Candidiasis, also known as *moniliasis* and *yeast infection*, is the most common form of vaginitis. The cause is believed to be related to a change in vaginal pH that allows accelerated growth of *Candida albicans*, a yeastlike fungus commonly found in the digestive tract and on the skin. Some conditions, such as pregnancy, diabetes mellitus, oral contraceptive use, and systemic antibiotic therapy, result in changes in vaginal pH and flora that favor accelerated growth of *C. albicans*. Although not considered an STD (also abbreviated STI for sexually transmitted infections), recurrent candidiasis in sexually active women may occur. A small number of male partners may have erythema and itching of their glans penis (balanitis).

The main symptoms for candidiasis are vaginal and perineal itching. Vulvar and vaginal tissues are inflamed, causing burning on urination. Vaginal discharge is white with a typical "cottage cheese" appearance. Diagnosis is made by identifying the spores of *C. albicans*.

Treatment may consist of nonprescription or prescription medications. Medications available without prescription include butoconazole, miconazole, clotrimazole, terconazole, and tioconazole by vaginal application. The duration for most of the nonprescription medications for candidiasis ranges from 3 to 7 days, depending on the specific medication. Women should be advised to seek medical attention with the first infection or if the infection persists or recurs frequently. Oral fluconazole is a prescription medication for treatment of candidiasis with a single dose. Patients with a more severe candidiasis may need another dose of fluconazole in 4 days. Recurrent yeast infections that resist treatment are associated with diabetes mellitus or HIV infection.

Sexually Transmitted Diseases

Many diseases can be transmitted through sexual activity. For some diseases, such as syphilis, gonorrhea, and chlamydial infection, sexual activity is almost the only method of transmission. For other diseases, such as bacterial vaginosis, sexual activity may or may not be the mode of transmission.

Incidence

Sexually transmitted diseases are most frequent among adolescents and young adults. Because the vagina and microscopic tears in mucosa from intercourse provide favorable conditions for infection, women are twice as likely as men to get a sexually transmitted disease. The number of untreated infected individuals with no symptoms is most likely immense. For many reasons these infections remain a major health problem despite advancements in the development of antibiotics. The age of the first sexual experience has been declining steadily, and sexual activity is high among adolescents and young adults. The immature vaginal mucosa of the young adolescent is more easily injured during sexual activity. Multiple sexual partners, inadequate knowledge of transmission and prevention, and feelings of invincibility are common among this age group (CDC, 2010a).

Methods of contraception have a significant impact on the risk of STDs. Barrier methods, such as condoms and female condoms, offer the best protection from infection. Diaphragms, cervical caps, and spermicidal foams and jellies do not offer the same protection as condoms, although they can decrease the risk of cervical and upper genital tract infections. When counseling teen girls and boys, nurses must emphasize that oral contraceptives can prevent pregnancy but do nothing to prevent exposure to STDs.

Major concerns include the following:

- The vulnerability of women, especially teens, to STDs
- The resistance of some organisms to antibiotics
- The relationship between HIV infection and other STDs
- Failure of asymptomatic persons to seek treatment when their sexual partner is infected

See [Chapter 25](#) for the impact of STDs on pregnancy and the fetus.

Types of Sexually Transmitted Diseases

Trichomoniasis. Trichomoniasis is caused by *Trichomonas vaginalis*, a protozoon that thrives in an alkaline environment. The presenting symptoms include a purulent vaginal discharge that is thin or frothy, malodorous, and yellow-green or brownish gray. The pH of the discharge is usually greater than 4.5. Vulvar itching, edema, and redness may be present. The diagnosis is made by identifying the organism in a wet mount preparation.

Treatments of choice are metronidazole (Flagyl) 2 g or tinidazole (Tindamax) 2 g in a single oral dose. *Alcohol ingestion when taking metronidazole may result in a disulfiram-like (Antabuse) reaction.* Women should be advised to avoid using alcohol during treatment with metronidazole and for 24 hours after treatment is complete.

Sexual partners should refrain from intercourse until a cure is established. Reinfection may result when the woman's partner is not treated. In particular, emphasize that all sexual partners should be treated and that condoms should be used with a new partner (CDC, 2010a; Eckert & Lentz, 2012).

Bacterial Vaginosis. This infection, previously referred to as nonspecific vaginitis, is associated with organisms that replace normal lactobacilli with *Gardnerella vaginalis* or *Mycoplasma hominis* or with anaerobic bacteria, such as *Prevotella* or *Mobiluncus*. Causes of the bacterial proliferation are not known, although tissue trauma and vaginal intercourse have been identified as contributing factors. Multiple partners, douching, and lack of vaginal lactobacilli are associated with bacterial vaginosis.

Chief signs and symptoms are a thin, grayish white vaginal discharge that typically exudes a fishy odor. The diagnosis is made by preparing a saline wet mount and identifying characteristic clue cells (epithelial cells with numerous bacilli clinging to their surface).

Treatment for bacterial vaginosis is directed toward reestablishing the balance of flora in the vagina. Metronidazole has been shown to relieve symptoms and to improve vaginal flora. Clindamycin is an alternative treatment. The woman should refrain from sexual intercourse until cured, or her partner should use a condom. Treatment of her partner has not proved beneficial (CDC, 2010a; Eckert & Lentz, 2012).

Chlamydial Infection. The most common STD in Western countries is caused by the gram-negative bacterium *Chlamydia trachomatis*. The incidence is particularly high in sexually active teens and young adults. Chlamydial infection is often asymptomatic in women, which makes diagnosis and control of the disease difficult. It should be suspected when the male sexual partner is treated for nongonococcal urethritis and when the culture results for gonorrhea are negative, yet the woman exhibits symptoms similar to those of gonorrhea, such as

a yellowish vaginal discharge and painful urination. Gonorrhea and chlamydial infections often coexist.

Diagnosis of chlamydial infection can be made by isolating the bacterium in tissue culture, by enzyme-linked immunosorbent assay (ELISA), or by direct fluorescent monoclonal antibody. Tissue culture of the organism is most accurate but requires more time.

Untreated, chlamydial infection ascends from the cervix to involve the fallopian tubes, and is one of the chief causes of tubal scarring that results in pelvic inflammatory disease (PID), infertility, or ectopic pregnancy. Treatment is usually directed to eradicate both chlamydia and gonorrhea because the two often coexist. Treatment options include azithromycin (Zithromax), doxycycline (Vibramycin), ofloxacin (Floxin), levofloxacin (Levaquin), and erythromycin. Treatment of all sexual partners is essential to prevent recurrence and further spread. Use of condoms until a cure is established is essential as well.

Gonorrhea. Gonorrhea is an infection of the genitourinary tract that is caused by the gonococcus *Neisseria gonorrhoeae*. Gonorrhea may be asymptomatic in women, but when symptoms do occur, they usually include purulent discharge, **dysuria**, or painful urination, and dyspareunia. Diagnosis is based on a positive culture for the gonococcus. Gonorrhea is associated with PID (which increases the risk of tubal scarring and can result in infertility or ectopic pregnancy), as is chlamydial infection.

Dual treatment of gonorrhea and chlamydia infections is often routine. Additional drugs to those previously discussed for chlamydia with gonorrhea infections include cefixime (Suprax), ceftriaxone (Rocephin), and ciprofloxacin (Cipro). All sexual partners should be treated simultaneously, and intercourse should be avoided or the man should use a condom until a cure is confirmed.

Syphilis. Syphilis is caused by the spirochete *Treponema pallidum*, and it is divided into primary, secondary, and tertiary stages. The first sign of primary syphilis is a painless chancre that develops on the genitalia, anus, or lips or in the oral cavity. At this time, diagnosis is made by identifying the spirochete on dark-field microscopy in material scraped from the base of the chancre. Serologic test results are generally negative in the primary stage. If untreated the chancre heals in about 6 weeks. The disease is highly infectious at the primary stage.

Although the chancre disappears, the spirochete lives and is carried by the blood to all parts of the body. About 2 months after the initial infection, infected people exhibit symptoms of secondary syphilis, including enlargement of the spleen and liver, headache, anorexia, and a generalized maculopapular skin rash. Skin eruptions, called *condylomata lata*, may develop on the vulva during this time. Condylomata lata resemble warts; they contain numerous spirochetes and are highly contagious. Serologic test results are generally positive at this time.

If untreated, the disease enters a latent phase that may last for several years. Tertiary syphilis, which follows the latent phase, may involve the heart, blood vessels, and central nervous system. General paralysis and psychosis may result.

In addition to identification of the spirochete in material scraped from a chancre, diagnosis is also made by serology. The usual screening test is the Venereal Disease Research Laboratory (VDRL) serum test, which is based on the presence of antibodies produced in response to the infection. The rapid plasma reagin (RPR) and fluorescent treponemal antibody absorption (FTA-ABS) tests are more specific and are often done to confirm a positive VDRL test.

The best treatment of all stages of syphilis is with parenteral penicillin G. A woman who is allergic to penicillin can be admitted to the hospital for desensitization to penicillin followed by administration of the drug (CDC, 2010a).

Herpes Genitalis. Herpes genitalis is an STD caused by the herpes simplex virus (HSV). Two types of HSV have been identified: type 1

and type 2. HSV-2 usually causes genital lesions, and HSV-1 usually causes oropharyngeal infection. However, either organism may infect the less-frequent location. Transmission occurs through direct contact with an infected person. A person infected with HSV-1 develops antibodies that may reduce the severity of the first HSV-2 infection. A primary HSV-2 infection is one in which the person had no preceding HSV-1 infection, and therefore has no antibodies. Transmission may occur from a partner who is infected but has no visible lesions or symptomatic viral shedding.

Within 2 to 12 days after the primary infection, vesicles (blisters) appear in a characteristic cluster on the vulva, perineum, or perianal area. The initial lesions may cause severe vulvar pain and tenderness as well as dyspareunia. Lesions may also occur on the cervix or in the vagina. With primary infection, the woman may also experience flulike symptoms, including fever, general malaise, and enlarged lymph nodes. The vesicles rupture within 1 to 7 days and form ulcers that take an average of 7 to 10 days to heal.

When symptoms abate, the virus remains dormant in the nerve ganglia and periodically reactivates, particularly in times of stress, fever, and menses. Recurrent episodes are seldom as extensive or painful as the initial episode, but they are just as contagious. Diagnosis is often based on clinical signs and symptoms and confirmed by viral culture of fluid from the vesicle.

No cure exists, but antiviral drugs reduce or suppress symptoms, shedding, and recurrent episodes. Antiviral drugs include acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex). Women should be advised to abstain from sexual contact while the lesions are present to avoid transmission to their partner. If it is an initial infection, they should continue to abstain until they become culture-negative, because prolonged viral shedding may occur in such cases.

Human Papillomavirus (HPV). Condylomata acuminata, also known as venereal or genital warts, are caused by HPV. The dry, wart-like growths may be small and discrete, or they may cluster and resemble cauliflower (Figure 34-6). Common sites include the vagina, labia, cervix, and perineal area.

Condylomata acuminata are of particular concern because of the association of HPV with cervical cancer. Colposcopy, examination by

a magnifying instrument called the colposcope, is generally recommended to evaluate abnormal cervical tissue and to identify HPV. Women with condylomata acuminata should be advised to have Pap tests more frequently to detect cervical **dysplasia** (abnormal tissue development).

The goal of treatment is to remove the warts, which easily transmit the HPV back and forth between sexual partners. Treatment is determined by the site and extent of the warts and the woman's preference. Topical treatment options include podophyllin, trichloroacetic acid (TCA), and bichloroacetic acid (BCA). More extensive warts or those that do not respond to topical therapy may require removal by **cryotherapy** (extreme cold), laser vaporization, LEEP, or conization. Interferon, an antineoplastic drug, is sometimes used to treat condylomata acuminata in women older than 18 years of age who have not responded to conventional therapy.

The woman must understand that none of these treatments eradicate the virus and that she may have recurrences. Furthermore, all sexual partners must be treated. Sexual contact should be avoided until all lesions are healed, and the use of condoms is recommended to reduce transmission. HPV vaccine is discussed in [Chapter 33, p. 726](#).

Acquired Immunodeficiency Syndrome. Acquired immunodeficiency syndrome (AIDS), caused by HIV, remains the most devastating sexually transmitted disease in the world today, although new treatments have improved the outlook considerably. HIV has been isolated from blood, semen, vaginal secretions, urine, saliva, tears, cerebrospinal fluid, amniotic fluid, and breast milk. The primary modes of transmission are intimate contact with infected bodily secretions, exposure to infected blood and blood products, and perinatal transmission from mother to infant.

HIV testing is routine for all pregnant women so treatment can be started if needed, possibly avoiding transmission to the fetus. A woman's risk for infection through a heterosexual relationship has surpassed the risk that her HIV infection stems from injectable drug use. Diagnosis of another sexually transmitted disease is an indication for HIV testing, as is the client who has repeated infections such as herpesvirus or candidiasis. The health care provider should address concerns if a pregnant woman refuses testing or if she refuses retesting with subsequent pregnancies because the first test was negative. Consent for HIV testing should be incorporated into the plan of care (verbally or written). Clients also have the right to decline or "opt-out" of routine HIV testing ([CDC, 2010a](#)).

No medications have been shown to cure HIV and AIDS. Research continues about the benefits and safety of drug regimens that interrupt production of the virus. See [Chapters 26 and 30](#) for a discussion of HIV and AIDS management in pregnant women and neonates. Updated guidelines for HIV and AIDS treatment in the pediatric, adult, and perinatal groups may be found at the AIDS Info website, a service of the National Institutes of Health: www.aidsinfo.nih.gov.

Nursing Considerations

As teachers and counselors, nurses can play a major part in preventing the spread of STDs and treating specific infections. Women must often be encouraged to use preventive measures to avoid infection, including HIV infection, from a man who does not want to use condoms as a barrier to infection. To fulfill this role, nurses must be prepared to do the following:

- Teach the signs and symptoms that require medical attention.
- Explain diagnostic or screening tests and follow-up testing needed for some infections.
- Teach preventive measures and follow-up care to ensure a cure for non-HIV infections.

FIG 34-6 Condylomata acuminata, also called *venereal* or *genital warts*, are caused by the human papillomavirus (HPV).

WOMEN WANT TO KNOW

About Sexually Transmitted Diseases

What are the most common signs and symptoms of sexually transmitted diseases (STDs)?

- Unexpected nonbloody vaginal discharge (increased amount, unusual color, or odor) or vaginal bleeding
- Vulvar itching or swelling
- Pelvic pain, including painful intercourse, painful urination, and abdominal tenderness
- Skin eruptions or changes (rashes, ulcers, warts, blisters)
- Flulike symptoms (fever, swollen or painful lymph glands, loss of appetite, nausea or vomiting)
- Presence of symptoms in a sexual partner, even if symptoms are absent in the woman

What are the common methods of diagnosis?

- Culture (vaginal discharge, cervix, lesions) to identify organism
- Blood test (serology) to determine if antibodies for specific diseases are present
- VDRL, RPR, or FTA-ABS test for syphilis; HIV test for human immunodeficiency virus

How can STDs be prevented?

- Establish monogamous relationship with uninfected partner.
- Limit number of sexual partners.
- Use mechanical and chemical barriers such as a latex condom with every act of intercourse.
- Remember that one episode of an STD offers no protection from future infection.
- Make sure partner is simultaneously treated to prevent reinfection. What are the most important things to know about the treatment?
- The entire course of medication must be completed even if symptoms subside.
- Comply with follow-up evaluation as recommended by the health care provider.
- Curtail sexual intercourse until free of infection.
- Partner must be examined and treated and a follow-up evaluation done before sexual intercourse is resumed.
- Side effects of medications, such as skin rashes, difficulty breathing, or headaches, must be reported.
- Not all STDs can be cured (herpes, AIDS, venereal warts), and treatment is aimed at slowing the disease and preventing complications.

Are there measures that provide comfort and prevent secondary infections?

- Keep the vulva clean but avoid strong soaps, creams, and ointments unless prescribed by the health care provider.
- Keep the vulva dry; using a hair dryer on low heat is helpful.
- Wear absorbent cotton underwear and avoid pantyhose and tight pants as much as possible.
- Take analgesics (aspirin or acetaminophen) as directed by the health care provider.
- Cool or tepid sitz baths may provide relief from itching.
- Wipe vulva from front to back after urination or defecation, and then carefully wash hands.

AIDS, Acquired immunodeficiency syndrome; *FTA-ABS*, fluorescent treponemal antibody absorption; *HIV*, human immunodeficiency virus; *RPR*, rapid plasma reagin; *VDRL*, Venereal Disease Research Laboratory.

- Identify STD preventive measures that are compatible with age, language, male-female relationships in the woman's culture, values for her own well-being, frequency of intercourse, number of partners, and many other factors that may be identified when the woman seeks care.
- Refer the woman to support groups and HIV specialists for best treatment options and follow-up if she has HIV infection.

Pelvic Inflammatory Disease

PID, infection of the upper genital tract, is a serious health problem in the United States. About 1 million women develop PID each year in the United States and many of them have ectopic pregnancy or infertility as added complications. Women who are more likely to develop PID are under 25 because the cervix is not fully matured, increasing their susceptibility to infectious organisms that ascend into the uterus, fallopian tubes, ovaries, and other pelvic organs. Exposure to multiple sexual partners increases the risk of acquiring an infection that causes PID. Douching increases the risk for PID because it changes the natural vaginal flora that helps resist infection and pushes infectious organisms toward the uterine cavity (CDC, 2011; Eckert & Lentz, 2012).

Etiology

Most PID cases are caused by *C. trachomatis* and *N. gonorrhoeae* infections. The remainder are caused by a variety of aerobic and anaerobic organisms such as *Escherichia coli*, *G. vaginalis*, *Streptococcus*, group B *Streptococcus*, *Peptostreptococcus*, *Peptococcus*, *Bacteroides* species, *Prevotella*, *Mycoplasma genitalium*, *Ureaplasma*, and cytomegalovirus (CMV) (CDC, 2010a, 2011). These organisms invade the endocervical canal, where they cause cervicitis. Microorganisms ascend and infect the endometrium, fallopian tubes, and pelvic cavity. The chronic inflammatory response results in tubal scarring and peritubal adhesions, which interfere with conception or with transport of the fertilized ovum through the obstructed fallopian tubes to the uterus. Inadequate treatment of a vaginal infection increases the risk that the organisms will ascend into the uterus, infecting deeper reproductive structures and causing PID.

Symptoms

Signs and symptoms of PID vary widely. Some women are asymptomatic or have subtle symptoms, whereas others experience pelvic pain, fever, purulent vaginal discharge, nausea, anorexia, and irregular vaginal bleeding. Findings during physical examination may include abdominal or **adnexal** (accessory organs) tenderness and tenderness of the uterus and cervix when they are moved during bimanual examination (cervical motion tenderness). Laboratory evaluation may reveal a marked leukocytosis and increased sedimentation rate. A urinalysis is needed to rule out urinary tract infection. Cultures for *N. gonorrhoeae*, *C. trachomatis*, or other suspected infectious organisms help diagnose and best treat PID.

Management

Women with serious infection, as manifested by fever, abdominal pain, and leukocytosis, may be admitted to a hospital. They are most often treated with intravenous administration of broad-spectrum antibiotics such as ceftriaxone plus azithromycin or doxycycline, or cefixime plus azithromycin or doxycycline. Intravenous antibiotic treatment can usually be changed to oral treatment after 48 hours, and the total duration of antibiotic therapy should be 14 days. Laparoscopy may be required to rule out surgical emergencies such as appendicitis or ectopic pregnancy, which have similar signs and symptoms, and to obtain specimens for culture. Pelvic abscess often requires surgical treatment. Outpatient treatment is appropriate for some women who are not as ill and will comply with the recommended regimen (CDC, 2011; Fantasia, 2013).

Nursing Considerations

Nurses can play an important role in preventing PID by teaching women how to prevent STDs in themselves and in their partners. Prevention can be thought of as occurring on two levels: primary and secondary. Primary prevention involves avoiding exposure to these diseases or preventing acquisition of infection during exposure. Primary preventive measures include limiting the number of sexual partners and avoiding intercourse with those who have had multiple partners or other high-risk behaviors such as injectable drug use, which is associated with HIV infection. Barrier methods (latex condoms) used consistently and correctly during all sexual activity help prevent STDs.

Secondary prevention involves keeping a lower genital tract infection from ascending to the upper genital tract or from being further transmitted within the community. This involves seeking medical attention promptly after having unprotected sex with someone who is suspected of having an STD and when vaginal discharge or genital lesions are apparent. Periodic medical assessment is necessary if a woman is not in a mutually monogamous relationship, even if she is asymptomatic. Additional measures include taking medication as prescribed and returning for follow-up evaluation. Periodic medical evaluations may be recommended for a woman who is asymptomatic yet engages in sexual activity that increases risk.

Toxic Shock Syndrome

Although **toxic shock syndrome** is rare, it is a potentially fatal condition caused by toxin-producing strains of *Staphylococcus aureus*. The toxin alters capillary permeability, which allows intravascular fluid to leak from the blood vessels, leading to hypovolemia, hypotension, and

shock. The toxin also causes direct tissue damage to organs and precipitates serious defects in coagulation.

If toxin-producing strains of *S. aureus* inhabit the vagina, certain factors increase the risk that the toxin will gain entry into the bloodstream. These include the use of high-absorbency tampons during menstruation and barrier methods of contraception (cervical cap or diaphragm), both of which may trap and hold bacteria if left in place for a prolonged time. However about 50% of cases are not related to menses. Persons having had nasal surgery or previous *S. aureus* wound infections also have a greater risk.

Symptoms of toxic shock syndrome include a sudden spiking fever (38.9°C [102°F]) and flulike symptoms (headache, sore throat, vomiting, diarrhea), hypotension, a generalized rash resembling sunburn, and skin peeling from the palms of the hands and the soles of the feet 1 and 2 weeks after the onset of the illness.

Treatment consists of fluid replacement, administration of vasopressor drugs, and antimicrobial therapy. Corticosteroids may be used to treat skin changes.

Nurses are often responsible for providing information that may help to prevent toxic shock syndrome. Nurses should instruct women to do the following:

- Tampon use:
 - Wash the hands thoroughly to remove bacteria before inserting tampons.
 - Change tampons at least every 4 hours to prevent excessive bacterial growth on a tampon that is left in place for a longer time.
 - Do not use superabsorbent tampons at any time because they may be left in the vagina for a prolonged period, allowing bacteria to proliferate.
 - Use pads rather than tampons during hours of sleep, which usually exceeds 4-hour segments of tampon use.
- Diaphragm or cervical cap use:
 - Wash hands thoroughly before inserting a diaphragm or cervical cap.
 - Do not use a diaphragm or cervical cap during menstrual periods.
 - Remove a diaphragm or cervical cap within the time recommended by the health care provider.

37. What organisms cause PID?
38. How can the risk of toxic shock syndrome be reduced?

SUMMARY CONCEPTS

- Disorders of the breast may be benign, such as fibrocystic changes that occur in relation to the menstrual cycle, or malignant. The discovery of any breast disorder creates anxiety in women, and nurses must be prepared to explain diagnostic procedures, such as mammogram, ultrasound, fine-needle aspiration biopsy, core needle biopsy, and surgical biopsy.
- One in eight women in the United States develops breast cancer. Besides gender, the greatest risk factors are advancing age, a prior history of breast cancer, and genetic mutations in the *BRCA1*, *BRCA2*, and *p53* genes. Additional factors include family history (mother, sister, daughter) of breast cancer and previous uterine, ovarian, or colon cancer. Lifestyle factors such as a high intake of dietary fat, smoking, and consumption of alcohol are also suspected to increase risk.
- Management of breast cancer includes surgical removal of the tumor plus varying amounts of surrounding tissue and lymph glands. Adjuvant therapy includes radiation, chemotherapy, hormone therapy, and immunotherapy.
- Breast reconstruction is an integral part of the surgical management of breast cancer. Methods include tissue expansion and autogenous grafts. Reconstruction at the time of surgical tumor removal or a later reconstruction are options for many women.
- Nursing care for women with breast cancer focuses on providing emotional support and accurate information.
- Cardiovascular disease kills more women than breast cancer. Preventive measures include modifying risk factors that can be modified, such as maintaining a normal weight and stopping smoking. Added preventive measures include controlling hypertension, diet,

Continued

SUMMARY CONCEPTS—cont'd

- and glucose level; increasing activity; and, for many women, using low-dose aspirin on a daily basis.
- Menstrual cycle disorders include amenorrhea, abnormal uterine bleeding, cyclic pelvic pain, and premenstrual syndrome. Some of the disorders, such as premenstrual syndrome, respond to lifestyle alterations such as changes in diet, exercise habits, and stress management.
 - Elective termination of pregnancy may be performed by medical or surgical methods, and each method is associated with social and ethical conflicts.
 - The climacteric is a combination of endocrine, somatic, and psychic changes that occur at the end of the reproductive cycle. Menopause is the final menstrual period, although most people use the term interchangeably with *climacteric*. Women's responses to menopause vary widely, but all women are in a permanent state of estrogen deficit after menopause that can result in bone loss (osteoporosis), increased risk for coronary artery disease, and atrophic vaginitis.
 - Hormone replacement therapy may be prescribed to manage the symptoms of estrogen deficit, such as hot flashes and atrophic vaginitis, and to decrease bone mineral loss that results in osteoporosis. Each woman and her health care provider must individually evaluate whether hormone replacement therapy is beneficial.
 - Hormone replacement therapy has risks and benefits and is contraindicated for women who have thromboembolic disease, undiagnosed vaginal bleeding, previous episodes of breast cancer or untreated uterine cancer, or chronic liver disease. For these women, alternative measures are needed to control the symptoms of menopause.
 - Relaxation of pelvic support structures occurs as a delayed result of traumatic childbirth and becomes troublesome when a deficiency in estrogen hastens genital atrophy as menopause nears.
 - Many infections of the reproductive tract are transmitted by sexual contact. The incidence of sexually transmitted diseases is reduced by barrier methods of contraception, particularly the condom, which prevents contact between infected skin or mucosal surfaces and prevents potentially infected ejaculate from entering the woman's lower genital tract.
 - Pelvic inflammatory disease is often a complication of untreated sexually transmitted diseases, and a large number of cases are caused by chlamydial or gonorrheal infections. Pelvic inflammatory disease can cause infertility or ectopic pregnancy because of scarring of fallopian tubes resulting from inflammatory processes in the pelvic cavity.
 - Toxic shock syndrome is a life-threatening condition resulting from infection with toxin-producing strains of *Staphylococcus aureus*. Some infections may be related to use of high-absorbency tampons that trap and hold bacteria in nutrient-rich menstrual blood for an extended time. Tampons and other items that trap bacteria, such as cervical caps and diaphragms, should be removed as directed by the health care provider.

A

Use of Drug and Botanical Preparations during Pregnancy and Breastfeeding

FDA PREGNANCY RISK CATEGORIES

The U.S. Food and Drug Administration (FDA) has assigned pregnancy risk categories to many drugs on the basis of their known relative safety or danger to the fetus and whether safer alternative drugs exist. Drugs may carry different risk categories depending on fetal effects at different points during pregnancy. For many drugs, little is known about the fetal risk because deliberate testing is not done on women who are of childbearing age. Evidence for safety of a drug for humans accumulates over time when it must be given to a pregnant woman because the benefits of the drug outweigh the fetal risk or when it is not known that the woman is pregnant when the drug is taken (Food & Drug Administration [FDA], 2009). See www.fda.gov for more information about drug use during pregnancy and lactation and about MedWatch: The [FDA Safety Information and Adverse Event Reporting Program](#) (FDA, 2013). TOXNET is the Toxicology Data Network of the National Library of Medicine at <http://toxnet.nlm.nih.gov>, if needed.

Current FDA categories for use in pregnancy are as follows:

- A:** No evidence of risk to the fetus exists.
- B:** Animal reproduction studies have not demonstrated a risk to the fetus. No adequate and well-controlled studies have been done in pregnant women.
- C:** Animal reproduction studies have shown an adverse effect on the fetus, but no adequate, well-controlled studies have been done in humans. Potential benefits may warrant use of the drug in pregnant women despite fetal risks. Or animal studies show adverse effect on fetus, but human studies with pregnant women have not demonstrated a risk to the fetus in any trimester of pregnancy.

D: Positive evidence of human fetal risk exists based on adverse reaction data, but potential benefits may warrant use of the drug in pregnant women despite fetal risks. Essentially, no safer alternatives to the drug are available.

X: Positive evidence of human fetal risk exists based on animal or human studies and/or adverse reaction data. The risks of using the drug in pregnant women clearly outweigh potential benefits. Safer alternatives to these drugs may be available.

DRUG USE DURING LACTATION

The effects of many drugs when used during lactation have not been studied. In general, if a drug is safe for use in infants, it is probably safe for the lactating woman to take. Other drugs are known not to be excreted in breast milk or excreted in an inactive form or very low concentrations. Modifying the time of maternal ingestion may reduce transfer of the drug to the infant. Some drugs are undesirable because they suppress lactation, which is a problem primarily in the earliest stages of breastfeeding.

Maternal use of social and illicit drugs during pregnancy or breastfeeding is discussed in [Chapters 24](#) and [30](#).

Categories for safety in lactation are not clearly established, but this textbook will use five categories established by Thomas W. Hale, MD, for drugs in lactation if information is available:

- L1:** Safest
- L2:** Safer
- L3:** Moderately safe
- L4:** Possibly hazardous
- L5:** Contraindicated

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
Amebicides Metronidazole (Flagyl)	<i>Risk category B.</i> Previous concern about teratogenic effects on fetus have not been supported (CDC, 2010; Hale, 2010). Treatment of choice for trichomoniasis but may also be chosen as part of drug regimen for inflammatory bowel disease or postpartum endometritis.	<i>Risk category L2.</i> Breastfeeding may be discontinued for 12-24 hr during single-dose treatment of mother. However, few known adverse infant effects.
Analgesics Aspirin	<i>Risk category C (D in third trimester).</i> Has been linked to fetal gastroschisis and small intestine atresia. Low-dose aspirin has shown relative safety during pregnancy and generally positive effects on pregnancy outcomes in women with antiphospholipid antibodies and history of recurrent pregnancy loss.	<i>Risk category L3.</i> Single doses not associated with risk to breastfeeding infant. Greater potential risk if mother requires higher doses for disorders such as arthritis. Associated with Reye's syndrome.

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
Acetaminophen (Tylenol, Datril, Tempra)	<i>Risk category B.</i> Problems have not been documented, but drug crosses placenta in low concentrations. Maximum dose 4 g/24 hr. Drug often combined with other medications and should be considered when determining maximum daily dose received.	<i>Risk category L1.</i> Very small amounts secreted into breast milk.
<i>Opiate analgesics:</i> butorphanol (Stadol), fentanyl (Sublimaze), hydrocodone (Duocet, Lortab, Norco, Vicodin, Zydone), hydromorphone (Dilaudid), meperidine (Demerol), morphine, nalbuphine (Nubain), oxycodone (Percocet, Tylox, Percodan)	<i>Most are risk category B or C.</i> Neonatal respiratory depression is most significant adverse effect when large amounts of opiates are used during labor, making them a category D at this time. Neonatal withdrawal may occur if woman is addicted to an opiate drug.	<i>Risk category L2 or L3.</i> Most narcotics given briefly and in therapeutic doses are compatible with breastfeeding, including intrathecal (before epidural catheter removal) morphine given postoperatively. Prolonged infant sedation during early postpartum period may occur with maternal meperidine analgesia.
<i>Nonsteroidal antiinflammatory drugs (NSAIDs):</i> fenoprofen (Nalfon), flurbiprofen (Ansaid), ibuprofen (Advil, Motrin, Nuprin), indomethacin (Indocin), ketoprofen (Actron, Orudis), naproxen (Aleve, Anaprox)	<i>Risk category B or C; category D in third trimester.</i> May prolong pregnancy or labor because of antiprostaglandin effects. Indomethacin associated with premature closure of fetal ductus arteriosus or oligohydramnios in fetus but may be given in limited doses to stop preterm labor or reduce excess amniotic fluid in hydramnios.	<i>Risk levels vary from L1 through L3.</i> Ibuprofen, indomethacin, and naproxen are American Academy of Pediatrics (AAP) approved. All should be used cautiously because of potential for infant bleeding. Indomethacin has been used for treatment of neonatal patent ductus arteriosus (PDA).
<i>COX-2 inhibitors:</i> celecoxib (Celebrex)	<i>Risk category C (D during third trimester).</i> Associated with oligohydramnios and constriction of ductus arteriosus. Greater risk of adverse cardiovascular effects has caused withdrawal of two related COX-2 inhibitors (rofecoxib [Vioxx], valdecoxib [Bextra] withdrawn from market).	<i>Risk category L2.</i> No adverse effects reported via milk. Observe for infant gastrointestinal (GI) cramping, diarrhea; similar effects to those reported in adults.
<i>Migraine agents:</i> almotriptan (Axert), frovatriptan (Frova), naratriptan (Amerge), rizatriptan (Maxalt), sumatriptan (Imitrex)	<i>Risk category C.</i> Few well-controlled studies about fetal safety during pregnancy. Health care workers urged to report prenatal exposure to the drug manufacturer.	<i>Risk category L3.</i> No identified pediatric concerns via breast milk but caution recommended. Pumping and discarding milk for 24 hr after medication administration prevents transfer to infant.
Antiallergics		
Antihistamines (see middle column for drugs)	<i>Risk category B:</i> chlorpheniramine (Chlor-Trimeton), clemastine (Contac, Tavist), diphenhydramine (Benadryl), loratadine (Claritin), meclizine (Antivert, Dramamine). <i>Risk category C:</i> astemizole (Hismanal), brompheniramine (Dimetane), phenylephrine (Neo-Synephrine), terfenadine (Seldane), triprolidine (Alleract).	<i>Risk category L1; category L3 or 4 for others.</i> All should be used with caution. Most are safe but may cause infant drowsiness. If these adverse effects occur, a different drug may be tried. Clemastine noted by AAP to be given with caution because of one case of infant irritability, refusal to feed, neurologic symptoms, seizures, and high-pitched cry.
Antiasthmatic Drugs		
<i>(See also Decongestants, Hormones, Corticosteroids other than Inhalers)</i>		
<i>Corticosteroid inhalers:</i> beclomethasone (Beclivent, Vanceril); fluticasone (Flonase); triamcinolone (Aristocort, Azmacort, Nasacort)	<i>Risk category C.</i>	<i>Risk category L2.</i> Safety in lactation not fully known but none reported following breast milk.
<i>Nonsteroidal, antiinflammatory asthma medications:</i> cromolyn (Intal, NasalCrom, Opticrom)	<i>Risk category B.</i>	<i>Risk category L1.</i> Minimal oral absorption. No reported adverse effects via milk.
Epinephrine (Adrenalin, Sus-Phrine, Primatene)	<i>Risk category C.</i> To treat bronchospasm in acute asthma attack.	<i>Risk category L1.</i> Observe for brief infant stimulation after maternal drug use.
<i>Leukotriene pathway modulators:</i> montelukast (Singulair), zafirlukast (Accolate), zileuton (Zyflo)	<i>Risk category B (zafirlukast, montelukast) and C (zileuton).</i>	<i>Risk category L3.</i> No reported problems via breast milk; little published experience.
<i>Bronchodilators:</i> albuterol (Proventil, Ventolin), metaproterenol (Alupent)	<i>Risk category C.</i> May inhibit uterine contractions.	Unknown if secreted in milk; use cautiously.

Continued

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
Anticoagulants		
Enoxaparin (Lovenox)	<i>Risk category B.</i> Not interchangeable with heparin.	<i>Risk category L3.</i> Unlikely to produce clinically relevant levels in breast milk because of large molecular size.
Heparin	<i>Risk category C.</i>	<i>Risk category L1.</i> Not excreted in breast milk.
Warfarin (Coumadin)	<i>Risk category X.</i> Known teratogen that should be used during pregnancy only if benefits outweigh risks. Associated with CNS and facial malformations, mental retardation, prenatal growth deficiency, and other fetal defects.	<i>Risk category L2.</i> Small amounts secreted in milk. Infant bleeding abnormalities may result. Avoiding breastfeeding during therapy may be recommended.
Anticonvulsants		
Carbamazepine (Tegretol), oxcarbazepine (Trileptal)	<i>Risk category C or D.</i> Associated with craniofacial abnormalities, underdeveloped fingernails, neural tube defects, and developmental delay.	<i>Risk category L2.</i> Small amounts secreted in breast milk; accumulation does not seem to occur. Observe infant for sedation.
Clonazepam (Klonopin)	<i>Risk category D.</i> No firm evidence that clonazepam is teratogenic. Infant after birth may display mild sedation, hypotonia, poor sucking.	<i>Risk category L3.</i> Enters breast milk in a possibly relevant quantity.
Levetiracetam (Keppra)	<i>Risk category C.</i> Unknown whether crosses placenta.	<i>Risk category L3.</i> Unknown whether enters breast milk.
Magnesium sulfate	<i>Risk category A</i> during early pregnancy. Infants exposed to magnesium sulfate 2 hr before birth may exhibit respiratory depression, hypotonic muscle tone, depressed reflexes, hypocalcemia, or cardiac dysrhythmias. Although infant risks exist when used during labor, complications of preeclampsia and eclampsia are greater.	<i>Risk category L1.</i> Milk levels return to normal about 24 hr after drug is stopped.
Phenobarbital	<i>Risk category D.</i> Fetal addiction with subsequent withdrawal is possible but rare at dose levels used for seizure control. Abnormalities similar to those seen in infants exposed to carbamazepine, phenytoin, and valproic acid have been reported.	<i>Risk category L3.</i> Infant serum levels approximately one third of adult levels. Psychomotor delay and sedation possible.
Fosphenytoin (Cerebyx), phenytoin (Dilantin)	<i>Risk category D.</i> Few studies of fosphenytoin. Phenytoin's risk for fetal malformations, specifically congenital heart defects and cleft palate, is double that of general population.	<i>Risk category L2.</i> Methemoglobinemia, drowsiness, and poor sucking have been reported. Most studies do not suggest problems.
Primidone (Mysoline)	<i>Risk category D.</i> Increased risk for infant with cleft lip and palate.	<i>Risk category L3.</i> Drug and its metabolites are secreted into breast milk. Has been associated with neonatal sedation.
Topiramate (Topamax)	<i>Risk category C.</i>	<i>Risk category L3.</i> No studies available. Use with caution.
Valproic acid (Depakene)	<i>Risk category D.</i> Associated with neural tube defects and craniofacial, cardiac, and hand abnormalities.	<i>Risk category L2.</i> Secreted in small amounts. May cause drowsiness. Used for treatment of infant seizures.
Antidiabetic Agents		
Insulin	<i>Risk category B and C.</i> Insulin is drug of choice during pregnancy because it does not cross placenta.	<i>Risk category L1.</i> Orally ingested insulin would be destroyed in infant's gastrointestinal tract.
<i>Oral hypoglycemic agents:</i> metformin (Glucophage), nateglinide (Starlix), pioglitazone (Actos), repaglinide (Prandin), rosiglitazone (Avandia)	<i>Risk category B</i> for metformin. <i>Risk category C</i> for remaining drugs.	<i>Risk categories L1</i> (metformin), <i>L3</i> (pioglitazone, rosiglitazone), and <i>L4</i> (repaglinide). Safety not established for most oral hypoglycemics; unknown for nateglinide. Observe for infant hypoglycemia if used.
Antifungals		
Fluconazole (Diflucan), miconazole (Monistat), nystatin (Mycostatin), terconazole (Terazol)	<i>Risk category B</i> (nystatin) and <i>C</i> (fluconazole, miconazole, terconazole).	<i>Risk category L1</i> (nystatin); <i>L2</i> or <i>L3</i> for all others. Fluconazole excreted in breast milk at levels similar to mother's plasma level. Most considered safe if ingested in breast milk.

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
Antihypertensives <i>(See also Diuretics)</i>		
ACE inhibitors: benazepril (Lotensin), captopril (Capoten), enalapril (Vasotec), fosinopril (Monopril), lisinopril (Prinivil, Zestril), quinapril (Accupril), ramipril (Altace), trandolapril (Mavik)	<i>Risk category D</i> (primarily second and third trimesters). Renal dysplasia leading to oligohydramnios may result in pulmonary hypotension and death after birth. Enalapril, captopril, and lisinopril are now contraindicated in pregnancy because of fetal cardiovascular and CNS defects. Oligohydramnios may not appear until after irreversible renal injury. FDA does not plan to change the category of ACE inhibitors because of this single small study (Buhimschi & Weiner, 2009; FDA, 2009, 2013).	<i>Risk categories L2</i> (benazepril, captopril, enalapril, quinapril) and <i>L3</i> (lisinopril, ramipril). Fosinopril and lisinopril are <i>risk category L4</i> in newborn period. Observe for infant hypotension. Less safety data available for newer agents.
Beta-adrenergic blockers: acebutolol (Monitan, Sectral), atenolol (Tenormin), betaxolol (Kerlone), labetalol (Normodyne), metoprolol (Lopressor, Toprol), nadolol (Corgard), penbutolol (Levitol), pindolol (Visken), propranolol (Inderal)	<i>Risk categories C</i> (betaxolol, labetalol, metoprolol, nadolol, penbutolol, and propranolol) and <i>D</i> (acebutolol, atenolol). <i>Risk category B</i> (pindolol). Possible fetal or neonatal effects include intrauterine growth restriction, neonatal hypotension, bradycardia, transient tachypnea, respiratory depression, and hypoglycemia.	<i>Risk categories L2</i> (labetalol) and <i>L3</i> (acebutolol, atenolol, metoprolol). <i>L4</i> for nadolol because of long half-life in mother. Propranolol is safe (Weiner & Buhimschi, 2009). Caution advised for other drugs. Observe infant for possible effects listed in "Use during Pregnancy" column.
Calcium channel blockers: amlodipine (Norvasc), diltiazem (Cardizem), nifedipine (Cardene), nifedipine (Adalat, Procardia), verapamil (Calan, Isoptin)	<i>Risk category C</i> . May benefit fetus by reducing resistance to placental blood flow. Nifedipine and verapamil may be given to reduce preterm contractions, prolonging pregnancy.	<i>Risk categories L2</i> (nicardipine, nifedipine, verapamil) and <i>L3</i> (amlodipine, diltiazem).
Centrally acting antihypertensives: clonidine (Catapres), guanabenz (Wyntensin), guanadrel (Hylorel), guanfacine (Tenex), methyl dopa (Aldomet)	<i>Risk categories B</i> (guanadrel, guanfacine, methyl dopa) and <i>C</i> (clonidine, guanabenz). Methyl dopa is an accepted antihypertensive drug during first trimester of pregnancy.	<i>Risk categories L2</i> (methyl dopa) and <i>L3</i> (clonidine, guanfacine). Little information about effects of other centrally acting antihypertensive drugs on lactation. Observe infant for hypotension.
Vasodilators: eprosartan (Teveten), hydralazine (Apresoline), minoxidil (Loniten), nitroprusside (Nipride, Nitropress)	<i>Risk category C</i> ; <i>risk category D</i> in second and third trimesters for eprosartan. Hydralazine is drug of choice for hypertension during pregnancy. Nitroprusside given in carefully titrated doses to control severe hypertension during pregnancy.	<i>Risk categories L2</i> (hydralazine), <i>L3</i> (minoxidil), and <i>L4</i> (nitroprusside). Nitroprusside is a concern because of drug's conversion to a potentially toxic thiocyanate metabolite (Hale, 2010; Weiner & Buhimschi, 2009).
Antimicrobials		
Aminoglycosides: gentamicin (Garamycin), streptomycin, tobramycin (Tobrex, Nebcin)	<i>Risk categories C</i> (gentamicin, streptomycin) and <i>D</i> (tobramycin). Associated with hearing loss and renal toxicity. Monitoring of blood levels reduces risk of adverse effects.	<i>Risk categories L2</i> (gentamicin) and <i>L3</i> (streptomycin, tobramycin). Most drugs in this class are considered safe because minimal amounts are secreted in breast milk and the drugs are poorly absorbed if orally ingested. Observe for changes in GI flora.
Macrolides: azithromycin (Zithromax), clarithromycin (Biaxin), erythromycin (EES, Erythrocin, Ilotycin)	<i>Risk categories B</i> (azithromycin, erythromycin) and <i>C</i> (clarithromycin).	<i>Risk categories L1</i> (clarithromycin, erythromycin) and <i>L2</i> (azithromycin). Appear to be safe. Drugs available in pediatric preparations.
Cephalosporins (first- through fourth-generation drugs)	<i>Risk category B</i> .	Most are considered safe for breastfeeding.
Chloramphenicol (Chloromycetin)	<i>Risk category D</i> . Not recommended for use near term because it is associated with neonatal "gray baby syndrome" (rapid respirations, ashen and pale color, poor feeding, abdominal distention, vasomotor collapse, death).	<i>Risk category L4</i> . Generally unsafe in breastfeeding mothers because of potential toxicity and "gray baby syndrome" risk for newborns.
Fluoroquinolones: ciprofloxacin (Cipro), levofloxacin (Levaquin), norfloxacin (Chibroxin), ofloxacin (Floxin)	<i>Risk category C</i> . Animal studies have shown skeletal abnormalities.	<i>Risk categories L2</i> (ofloxacin) and <i>L3</i> (ciprofloxacin, levofloxacin, norfloxacin). Ofloxacin and ciprofloxacin reach breast milk concentrations similar to or higher than maternal plasma. Observe infant for diarrhea.

Continued

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
<i>Nitrofurantoin</i> : Furadantin, Macrochantin	<i>Risk category B</i> . Crosses placenta. Reassuring animal studies and no evidence of being a teratogenic drug.	<i>Risk category L2</i> . Avoid if infant is younger than 1 month. Risk for hemolytic anemia if infant has an enzyme (G6PD) deficiency.
<i>Penicillins</i> : amoxicillin (Amoxil), ampicillin (Omnipen, Polycillin), penicillin G	<i>Risk category B</i> . No reported adverse fetal effects. Penicillins combined with beta-lactamase inhibitors (amoxicillin/clavulanate [Augmentin], ticarcillin/clavulanate [Timentin], and ampicillin/sulbactam [Unasyn]) also are risk category B.	<i>Risk category L1</i> . Low concentrations of penicillins in breast milk, including those combined with beta-lactamase inhibitors. Observe for infant diarrhea or candidiasis.
<i>Sulfonamides</i> : sulfadiazine (Coptin), sulfamethoxazole (Gantanol), sulfisoxazole (Gantrisin)	<i>Risk category C</i> .	<i>Risk categories L2</i> (sulfisoxazole) <i>and L3</i> (sulfamethoxazole). AAP recommends caution in use of breast milk if infant has jaundice or G6PD deficiency and in ill or preterm infant.
Tetracycline	<i>Risk category D</i> . Can interfere with tooth enamel formation and cause discolored teeth. Prenatal exposure does not affect permanent teeth.	<i>Risk category L2</i> . Thought to be compatible with breastfeeding. Oral ingestion appears to be safe although few well-controlled studies exist.
Vancomycin (Vancocin)	<i>Risk category B</i> . Used for maternal methicillin-resistant <i>Staphylococcus aureus</i> infections and prophylaxis to prevent endocarditis.	<i>Risk category L1</i> . Thought to be safe because oral absorption by breastfeeding infant is minimal.
Antiretroviral Agents		Antiretroviral agents have questionable passage into human breast milk.
<i>Nucleoside reverse transcriptase inhibitors (NRTIs)</i> : abacavir (ABC, Ziagen), didanosine (ddl, Videx), lamivudine (3TC, Epivir), stavudine (d4T, Zerit), tenofovir DF (Viread, TDF), zalcitabine (ddC, Hivid), zidovudine (ZDV, Retrovir)	<i>Risk category B</i> (didanosine) <i>or C</i> (abacavir, lamivudine, stavudine, tenofovir DF, zalcitabine, zidovudine). Zidovudine is recommended for HIV-seropositive women to reduce risk for perinatal transmission of the virus.	Breastfeeding not recommended because of possibility of HIV transmission to infant.
<i>Nonnucleoside reverse transcriptase inhibitors (NNRTIs)</i> : delavirdine (DLV, Rescriptor), efavirenz (Sustiva, EFV), nevirapine (NVP, Viramune)	<i>Risk category C</i> . Efavirenz is <i>category D</i> .	Breastfeeding not recommended because of possibility of HIV transmission to infant.
<i>Fusion inhibitors</i> : enfuvirtide (Fuzeon, T-20)	<i>Risk category B</i> .	Breastfeeding not recommended because of possibility of HIV transmission to infant.
<i>Protease inhibitors (PIs)</i> : amprenavir (Agenerase), indinavir (Crixivan), nelfinavir (Viracept), ritonavir (Norvir), saquinavir (Invirase)	<i>Risk category B</i> (nelfinavir, ritonavir, saquinavir) <i>or category C</i> (amprenavir, indinavir).	Breastfeeding not recommended because of possibility of HIV transmission to infant.
Antituberculosis Agents (See also <i>Antimicrobials</i>)		
Ethambutol (Myambutol)	<i>Risk category B</i> . No evidence of increased abnormalities. Optic neuritis is an adult concern (Hale, 2010; Weiner & Buhimschi, 2009).	<i>Risk category L2</i> . Small amounts of ethambutol are excreted into breast milk.
Isoniazid (INH)	<i>Risk category C</i> .	<i>Risk category L3</i> . Scant drug levels found in breast milk. Observe infant for hepatitis, vision changes.
Pyrazinamide	<i>Risk category C</i> . No adverse experience with this widely prescribed agent.	<i>Risk category L3</i> . None reported in breast milk.
Rifampin (Rifadin)	<i>Risk category C</i> .	<i>Risk category L2</i> . Trace amounts in breast milk.
Antitussives and Expectorants		
Dextromethorphan (Robitussin-DM)	<i>Risk category C</i> .	<i>Risk category L1</i> . No reported adverse effects.
Guaifenesin (Robitussin)	<i>Risk category C</i> . Usefulness as an expectorant is questionable.	<i>Risk category L2</i> . No reported adverse effects.

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
Antiviral Agents		
<i>Genital herpes infection:</i> acyclovir (Avirax, Zovirax), foscarnet (Foscavir), oseltamivir (Tamiflu), valacyclovir (Valtrex)	<i>Risk categories B</i> (acyclovir, valacyclovir) and <i>C</i> (foscarnet, oseltamivir).	<i>Risk categories L1</i> (valacyclovir), <i>L2</i> (acyclovir, oseltamivir), and <i>L4</i> (foscarnet). Foscarnet associated with higher milk levels than other drugs. Wash topical drug from area before nursing and consult with physician about breastfeeding safety if lesion is present on nipple (Hale, 2010; Weiner & Buhimschi, 2009).
Ribavirin (Virazole)	<i>Risk category X.</i> Administered by aerosol, usually to young children only. Women who are pregnant or may become pregnant should avoid exposure.	<i>Risk category L4.</i> Drug is most often given to young children hospitalized with respiratory syncytial virus (RSV), so transfer to breast milk is not likely. However, caution urged.
Bronchodilators, Decongestants		
Ephedrine, epinephrine (EpiPen, Sus-Phrine)	<i>Risk category C.</i> Ephedrine is also used to support blood pressure during epidural or subarachnoid block during intrapartum period.	<i>Risk category L1.</i> Acute, one-time use of ephedrine or epinephrine is typical.
<i>Nasal sprays:</i> fluticasone (Flonase), oxymetazoline (Afrin, Coricidin, Dristan), phenylephrine (Neo-Synephrine), phenylpropanolamine (Kleer, Propan)	<i>Risk category C.</i> Avoid during third trimester.	<i>Risk categories L2</i> (phenylpropanolamine) and <i>L3</i> (phenylephrine, fluticasone). Minimal amounts secreted in milk (oxymetazoline and phenylephrine).
Pseudoephedrine (Clarinet-D, Suphedrine, Sudafed, Zyrtec-D)	<i>Risk category C.</i> Avoid during first trimester because fetus may have higher risk for gastroschisis or small intestinal atresia.	<i>Risk category L3.</i> Considered safe for breastfeeding if used occasionally rather than chronically (<i>risk category L4</i>).
Cardiac Medications		
<i>Antiarrhythmics for serious dysrhythmias:</i> amiodarone (Cordarone, Pacerone), bretylium (Bretylol)	<i>Risk category C</i> (bretylum) or <i>D</i> (amiodarone). May reduce uterine blood flow. Possible neurotoxic effects of amiodarone.	<i>Risk category L5.</i> Used for life-threatening dysrhythmias; woman unlikely to be nursing.
Digitoxin (Crystodigin), digoxin (Lanoxin)	<i>Risk category C.</i> Has been used to treat fetal cardiac dysrhythmias.	<i>Risk categories L2</i> (digoxin) and <i>L3</i> (digitoxin).
Lidocaine (used as antiarrhythmic) (Xylocaine)	<i>Risk category B.</i>	<i>Risk category L2.</i> Considered safe for breastfeeding.
Diuretics		
<i>Carbonic anhydrase inhibitors:</i> acetazolamide (Diamox), methazolamide (Neptazane)	<i>Risk category C.</i>	Acetazolamide is considered safe. Safety of methazolamide unknown.
<i>Loop diuretics:</i> ethacrynic acid (Edecrin), furosemide (Lasix), torsemide (Demadex)	<i>Risk category B</i> (ethacrynic acid and torsemide) or <i>C</i> (furosemide).	<i>Risk category L3.</i> Few well-controlled studies; effects probably minimal. Maternal use could suppress lactation.
<i>Potassium-sparing diuretics:</i> amiloride (Midamor), spironolactone (Aldactone), triamterene (Dyrenium)	<i>Risk categories B</i> (amiloride), <i>C</i> (triamterene), and <i>D</i> (spironolactone).	Amiloride concentrated in breast milk. Few studies of triamterene. Spironolactone considered safe by AAP; <i>risk category L2.</i> <i>Risk category L3</i> (triamterene).
<i>Thiazide diuretics:</i> chlorothiazide (Hydrodiuril), hydrochlorothiazide (HydroDIURIL)	<i>Risk category B</i> (hydrochlorothiazide) or <i>D</i> (chlorothiazide). Decreased intravascular volume may reduce uteroplacental perfusion and result in growth retardation. Metabolic disturbances and thrombocytopenia may occur in mother and fetus.	<i>Risk categories L2</i> (hydrochlorothiazide) and <i>L3</i> (chlorothiazide). Considered safe during lactation.
<i>Thiazide-like diuretics:</i> chlorthalidone (Hygroton), indapamide (Lozide, Lozol), metolazone (Mykrox, Zaroxolyn)	<i>Risk categories B</i> (indapamide) and <i>D</i> (chlorthalidone).	<i>Risk category L3.</i> Chlorthalidone considered safe during lactation by AAP, but may reduce milk supply.

Continued

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
Hormones		
<i>Corticosteroids:</i> beclomethasone (Vanceril, Beclvent), betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), prednisolone (Delta-Cortef, Prelone), prednisone (Deltasone)	<i>Risk category C.</i> Prednisone or prednisolone (<i>category B</i>) is common for asthmatic woman who needs steroids. Betamethasone and dexamethasone are used to accelerate maturation of fetal lungs if preterm delivery is likely.	<i>Risk category L2.</i> Prednisone and prednisolone compatible with breastfeeding. Delay nursing 4 hr after dose to reduce transfer to infant. Remove from nipples before nursing if applied topically.
Clomiphene citrate (Clomid)	<i>Risk category X.</i> Questionable association with neural tube defects. Drug is discontinued after pregnancy is achieved.	Unlikely to be given during lactation because drug is for infertility treatment.
Danazol (Danocrine)	<i>Risk category X.</i> May cause virilization of female fetus.	Breastfeeding not advised.
Estrogens (Azumon, Conjugen, Ovest, Premarin)	<i>Risk category X.</i> No indication for estrogens during pregnancy.	<i>Risk category L3.</i> Try to delay drug until breastfeeding is firmly established.
Estradiol (Alora, Climara, Estrace, Estraderm, Estring, FemPatch, Vivelle)	<i>Risk category X.</i> Contraceptives; not indicated during pregnancy.	<i>Risk category L3.</i> Safe during lactation. Early use sometimes reduces milk volume secreted.
<i>Estrogen-progestin combinations</i>	<i>Risk category X.</i> Risks and benefits must be individually evaluated because a higher risk for cardiovascular disease was found in women who take combination for menopausal symptoms. Doses much higher than those for oral contraceptives and are associated with masculinization of genitalia of female fetus.	Avoid until lactation is well-established for best quantity and quality of breast milk.
Progesterone (Gesterol 50, Lutolin-S, Progestagect-50, Prometrium, Crinone)	<i>Risk category D.</i> Most often given for amenorrhea, hormone replacement therapy, infertility (luteal phase support only during pregnancy).	<i>Risk category L3.</i> Generally considered safe when breastfeeding.
Psychoactive Drugs		
<i>Benzodiazepines:</i> alprazolam (Xanax), chlordiazepoxide (Librium, Libritabs), clonazepam (Klonopin), diazepam (Valium), flurazepam (Dalmane), lorazepam (Ativan), midazolam (Versed), oxazepam (Serax), temazepam (Restoril), triazolam (Halcion)	<i>Most are risk category D.</i> Some reports of mild facial abnormalities and developmental delay, but no conclusive studies. Use during third trimester may slow infant's neurologic development and result in sedation after birth. Midazolam is primarily used as a brief maternal perioperative sedative. The following sedative-hypnotic drugs in this class are <i>risk category X</i> : flurazepam, temazepam, and triazolam.	<i>Risk categories L2 (midazolam) and L3 (all other benzodiazepines).</i> Greatest hazard caused by long half-lives of many drugs in this class and potential development of dependence. Few reported adverse effects, but observe infant for sedation, poor feeding.
<i>Anxiolytic:</i> meprobamate (Equanil, Miltown)	<i>Risk category D.</i> Has been associated with cardiac malformations.	<i>Risk category L3.</i> Concentrations in milk are higher than in maternal serum. Observe for infant sedation.
<i>Antipsychotic:</i> lithium (Eskalith, Lithobid)	<i>Risk category D.</i> Slightly increased risk for cardiac abnormalities.	<i>Risk category L3.</i> Infant's blood concentration of lithium reaches $\frac{1}{3}$ to $\frac{1}{2}$ of mother's concentration. Infant drug levels should be evaluated. T-wave abnormalities and decreased muscle tone have been noted.
<i>Atypical antidepressants:</i> bupropion (Wellbutrin), mirtazapine (Remeron), nefazodone (Serzone), trazodone (Desyrel), venlafaxine (Effexor)	<i>Risk category B</i> (bupropion); <i>risk category C</i> (mirtazapine, nefazodone, trazodone, venlafaxine).	<i>Risk category L2</i> (trazodone minimally excreted in breast milk). <i>L3</i> (mirtazapine, venlafaxine). <i>Risk category L4</i> (nefazodone; recommendations not to use for mothers of young infants or infants who are premature, subject to apnea, or otherwise weakened).
<i>Nonbenzodiazepines:</i> eszopiclone (Lunesta); zolpidem (Ambien)	<i>Risk category C.</i> Sedative and hypnotic effects.	<i>Risk category L3.</i> Minimal excretion into breast milk.

DRUG	USE DURING PREGNANCY	USE DURING BREASTFEEDING
<p><i>Phenothiazines:</i> chlorpromazine (Thorazine), prochlorperazine (Compazine), thioridazine (Mellaril)</p> <p><i>MAO (monoamine oxidase) inhibitors:</i> phenelzine (Nardil), tranylcypromine (Parnate)</p> <p><i>Tricyclic antidepressants:</i> amitriptyline (Elavil), amoxapine (Asendin), clomipramine (Anafranil), desipramine (Norpramin), doxepin (Adapin, Sinequan), imipramine (Tofranil), nortriptyline (Aventyl, Pamelor), protriptyline (Vivactil)</p> <p><i>SSRIs:</i> citalopram (Celexa), escitalopram (Lexapro), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), sertraline (Zoloft)</p>	<p><i>Risk category C.</i> Risk of malformations is uncertain but these are probably safe for use in humans. Alcohol may increase CNS depression. Taking other drugs with phenothiazines may alter serum levels of one or more of the drugs taken.</p> <p><i>Risk category C.</i> Documented interactions between opioids and MAO inhibitors. Potential risks if taken near time other drugs were taken. Consult a detailed drug guide or pharmacist. Little documentation of fetal effects.</p> <p><i>Risk category C</i> for most tricyclics. <i>Risk category D</i> for imipramine and nortriptyline, however. Several studies have shown that tricyclic antidepressant use during pregnancy is most likely not teratogenic.</p> <p><i>Most risk category C; paroxetine, risk category D.</i></p>	<p>Neonatal hypoglycemia has been reported with chlorpromazine. <i>Risk categories L3</i> (prochlorperazine) and <i>L4</i> (thioridazine). Neonatal apnea associated with phenothiazines.</p> <p>Few published reports related to entry of these MAO inhibitor drugs into breast milk.</p> <p><i>Risk category L2</i> for most tricyclic antidepressants. <i>Risk category L5</i> for doxepin because of infant plasma levels equal to mother. Infant apnea and drowsiness have been described with maternal doxepin intake.</p> <p><i>Risk category L2.</i> Most considered safe for breastfeeding infant. Citalopram and escitalopram have been associated with excessive somnolence, decreased intake, and infant weight loss.</p>
<p>Thyroid Drugs</p> <p><i>Antithyroids:</i> methimazole (Tapazole), propylthiouracil (PTU)</p> <p>Potassium iodide (SSKI, Thyro-Block)</p> <p><i>Thyroid replacement hormone:</i> levothyroxine (Levoxyl, Synthroid)</p>	<p><i>Risk category D.</i> May result in neonatal goiter or hypothyroidism, although uncommon at usual therapeutic doses. Methimazole has possible association with scalp defects. PTU is drug of choice during pregnancy.</p> <p><i>Risk category D.</i> Long-term exposure may produce fetal thyroid enlargement or hypothyroidism.</p> <p><i>Risk category A.</i> Crosses placenta only to limited extent.</p>	<p><i>Risk categories L2</i> (propylthiouracil) and <i>L3</i> (methimazole). Approved by AAP. Neonatal thyroid function apparently unaffected by maternal treatment.</p> <p><i>Risk category L4.</i> May cause rash or suppress infant's thyroid function. Dose should not be higher than RDA (recommended daily allowance).</p> <p><i>Risk category L1.</i> Apparently safe during breastfeeding.</p>
<p>Vitamins and Retinoids</p> <p><i>Retinoids:</i> isotretinoin (Accutane)</p> <p>Vitamin A</p> <p>Vitamin D</p>	<p><i>Risk category X.</i> Related to vitamin A. Associated with severe fetal malformations (microcephaly, ear abnormalities, cardiac defects, central nervous system abnormalities).</p> <p><i>Risk category C.</i> Oral treatment for deficiency in adult or child ≥ 8 yr. PO: 100,000-500,000 IU/day \times 3 days; 50,000 IU/day \times 14 days. Maintenance dose 10,000-20,000 IU \times 2 months. Dose based on severity of deficiency (<i>X</i> at doses higher than RDA limits). Excess intake may lead to abnormalities noted for isotretinoin.</p> <p><i>Risk category A (risk category C</i> at doses above RDA). Excess intake associated with malformations, including aortic stenosis, facial abnormalities, and mental retardation.</p>	<p><i>Risk category L5.</i> Contraindicated for use during breastfeeding because of severe fetal effects.</p> <p><i>Risk category L3.</i> Breast milk usually supplies sufficient vitamin A to infant.</p> <p><i>Risk category L2.</i> AAP approved. Infant serum level assessment recommended if mother taking a therapeutic dose.</p>
<p>Miscellaneous Drugs</p> <p>Nicotine gum; nicotine transdermal</p>	<p><i>Risk category C</i> (nicotine gum) or <i>D</i> (transdermal nicotine). <i>Risk category X</i> if used in overdose. Stopping nicotine intake by ceasing smoking lowers complications such as preterm birth.</p>	<p><i>Risk category L2.</i> Lactation safe, although passed into breast milk. Infant exposure to passive environmental nicotine smoke is not considered safe, however.</p>

HERBAL AND BOTANICAL PREPARATIONS

BOTANICAL PREPARATION	USES	RISKS FOR USE DURING PREGNANCY AND LACTATION
Black cohosh (black snakeroot, bugbane, squaw root, rattle root)	Antispasmodic effects may reduce discomfort of dysmenorrhea. Adequate evidence for use of black cohosh as an alternative to estrogen therapy in menopausal women.	<i>Pregnancy risk category X</i> because of uterine stimulant effects. <i>Lactation risk category L4</i> . May reduce milk production with estrogenic effects.
Blue cohosh (blue ginseng, squaw root, papoose root, yellow ginseng)	Uterine stimulant with oxytocic effects. Should be avoided during pregnancy. Pharmacologic effects similar to nicotine and may result in myocardial ischemia. Maternal use at term has resulted in neonatal seizures, renal failure, and respiratory distress (Hale, 2010; Skidmore-Roth, 2010).	<i>Pregnancy risk category X</i> . Considered a high-risk herbal supplement. <i>Lactation risk category L5</i> , contraindicated with breastfeeding.
Capsaicin (Zostrix, Axsain, Capsin, Capzasin-P, NO PAIN, Absorbine Jr. Arthritis, ArthriCare)	Topical application for pain associated with osteoarthritis, fibromyalgia, peripheral neuropathy, shingles.	<i>Pregnancy risk category C</i> . <i>Lactation risk category L3</i> . Topical application to nipple or areola should be removed before nursing.
Chamomile (German chamomile, Hungarian chamomile, pinheads, wild chamomile)	Antiinflammatory, antispasmodic, sedative. Treatment of nausea, GI spasms, diarrhea, insomnia. Topical treatment of hemorrhoids. Caution required in those with asthma or allergic to ragweed.	No proven increase in malformations (Hale, 2010; Skidmore-Roth, 2010). Uterotonic effects with unknown risk. <i>Lactation risk category L3</i> . Should be avoided in lactation, although the German Commission E considers it safe (Hale, 2010; Skidmore-Roth, 2010).
Echinacea (Black Susan, snakeroot, comb flower, sunflower, scurvy root, and others.)	Antiviral, antibiotic effects to reduce cold and flu symptoms, stimulate wound healing. Long-term daily doses may suppress rather than stimulate immune response. Should not be taken by those with autoimmune disease.	<i>Pregnancy risk category C</i> . Contraindicated in pregnancy because of possible immune suppression. No data on lactation effects. <i>Lactation risk category L3</i> . Should not be used >8 weeks (Hale, 2010).
Evening primrose oil (buckles, butter rose, cowslip, fairy caps, key flower, key of heaven king's-cure-all, palsywort, peagles, plumrocks password)	Premenstrual syndrome (PMS), mastalgia, menopausal symptoms. Has been used successfully to treat cardiovascular disease, digestive disorders, and rheumatoid arthritis. Seizure risk increased if combined with antipsychotics.	Should not be used during pregnancy and lactation until more research is available.
Feverfew (bachelor button, featherfew, midsummer daisy, Santa Maria)	Prevention of migraines. Should not be used with prescription headache drugs.	Contraindicated in pregnancy and lactation. May cause uterine contraction or abortion. Reduced migraine symptoms in small study when taken for 4 months.
Glucosamine	Treatment of osteoarthritis to reduce pain and improve movement. Often combined with chondroitin.	Increases blood glucose levels. <i>Lactation risk category L3</i> . Avoid in pregnancy and probably lactation.
Goldenseal (eye balm, eye root, goldsiegel, ground raspberry, Indian dye, Indian tumeric, jaundice root, orange root, turmeric root, yellow paint, wild curcuma)	Antibiotic, antiseptic, antiinflammatory effects. Uses include wound healing, treatment of upper gastrointestinal tract infections, uterine bleeding; enhances insulin utilization	Contraindicated in pregnancy and lactation. May cause premature contractions. Short-term use only because product may cause inflammation of mucosa. Should not be used by those with cardiovascular conditions such as arrhythmias, heart block, or hypertension.
Kava (also known as <i>kava-kava</i>) (Awa, Kew, Tonga)	Anxiety, stress, restlessness; sedation or sleep enhancement. Effects similar to alcohol. Mixing with alcohol increases toxicity.	Contraindicated in pregnancy and lactation. <i>Lactation risk category L5</i> .
St. John's wort (Amber, goatweed, hardhay, John's rosin rose, witches' herb)	Mild to moderate depression. Possible interaction with therapeutic drugs and other herbal preparations: cyclosporine, digoxin, ACE inhibitors, indinavir, ginseng, chamomile, goldenseal, kava, valerian. Investigation into use as an antiretroviral for HIV treatment.	Contraindicated in pregnancy. May cause increased muscle tone of uterus. <i>Pregnancy risk category C</i> . <i>Lactation risk category L2</i> , probably safe. Infant effects may include colic, drowsiness, lethargy.
Valerian (valerian root)	Sedative for insomnia, sleeping disorders associated with anxiety, restlessness. Adult concerns with use are ataxia, hypothermia, muscle relaxation, headaches, excitability, and cardiac disturbances.	<i>Pregnancy risk category C</i> . Should not be used during pregnancy because of inadequate data to determine effects. Sedative effects discourage use for lactating woman although <i>lactation risk category L3</i> .

Equipment and Supplies

Sterile and nonsterile gloves
Lubricant
Urine specimen containers
Amniotic membrane perforator (Amnihook)
Emesis basin
Bedpan
Disposable underpads
Extra linens
Fetal monitoring equipment and related supplies
Electronic fetal monitor and supplies
Doppler transducer
IV fluids, tubing, venipuncture supplies, IV pumps
Urinary catheters (indwelling and straight)
Oxygen equipment, including water, tubing, and face masks
Emergency cart (“crash cart”)
“Precip tray” (for emergency birth)
Neonatal warmer
Neonatal oxygen equipment and resuscitation supplies

Normal Assessments

Fetus

Gestation. 38 to 42 weeks.

Fetal Heart Rate (FHR). Lower limit of 110 to 120 beats/minute and upper limit of 150 to 160 beats/minute at term. The rate may slow during contractions but should return to its original level by the end of the contraction.

Amniotic Fluid. Clear (may have particles of white vernix); no foul odor.

Woman

Temperature. Lower than 38°C (100.4°F).

Blood Pressure. Near baseline levels established during pregnancy. (Report elevations of 140 mm Hg [systolic] or 90 mm Hg [diastolic] or higher.)

Pulse Rate. 60 to 100 beats/minute.

Respirations. 12 to 20 breaths/minute.

Contractions. No more frequent than every 1½ min (or 5 contractions within 10 minutes). No more than 90 to 120 seconds in duration, with at least 30 seconds of uterine relaxation between the end of one contraction and the beginning of the next.

Bloody Show. Dark blood mixed with mucus (has a distinct mucous component). The amount varies but increases as full cervical dilation nears.

Lochia (Fourth Stage). No more than one saturated pad in 1 hour. (Perineal pads containing cold packs absorb less and are saturated sooner than standard pads.) Lochia may accumulate under the lower back for the woman who is lying in bed.

Fundus (Fourth Stage). Firm, between the symphysis and the umbilicus, midline.

Nursing Care

Clinical experiences in the intrapartum setting are primarily observational. The nursing student works with an experienced nurse when caring for the laboring woman. Primary responsibilities of the novice are to promote family attachment, provide comfort and support to the woman and her family, and report maternal or fetal assessments that are not expected.

To conform with standard precautions, personal protective equipment (PPE), such as gloves and water-repellent gowns or aprons, must be worn whenever the possibility of contact with body fluids (amniotic fluid, blood, lochia, colostrum, breast milk, urine, or stool) exists. Protective eyewear also must be worn if splash or spray contamination of the eyes is a possibility.

Assessments

Unless directed otherwise by the experienced nurse, use the following guidelines to assess the woman and the fetus with no complications or medications that require special monitoring:

1. FHR with continuous electronic fetal monitoring or intermittent auscultation: every hour during the latent phase; every 30 minutes during the active phase; every 15 minutes during the second stage of labor for the low-risk woman.
2. The woman's temperature every 4 hours unless her membranes have ruptured, then every 2 hours.
3. The woman's blood pressure, pulse, and respirations every hour.
4. Contractions: Assess at same time as FHR.
5. If the woman's membranes rupture, assess FHR for at least 1 minute, and observe the color, odor, and amount of fluid. Notify an experienced nurse that the woman's membranes have ruptured.
6. After birth, during the recovery phase, assess the mother's uterine fundus, lochia, blood pressure, pulse, and respirations every 15 minutes for the first hour.

Interventions

1. Assess the woman and the fetus using the preceding guidelines or according to the facility's policy. Document all assessments, *and report any findings that do not fall within the expected limits.*
2. If no contraindication exists, give the woman ice chips or juice and encourage her to change position as much as she desires. Ask an experienced nurse to be sure.
3. The woman can usually walk to the bathroom if she is not in advanced labor and has not had analgesia or anesthesia that impairs mobility (such as epidural block). Record each time she voids or has a bowel movement.
4. Help the woman cope with labor:
 - A cool, damp washcloth often feels good on her face, arms, and abdomen.
 - If her back hurts, offer to rub it or apply firm pressure in the sacral area. Ask her where and how firmly to press. Encourage her to try alternate positions.
 - Give generous praise and encouragement for her efforts to give birth. Praise the partner's efforts as a coach.
5. Offer a snack to the woman's partner, or encourage the partner to take a break and have a meal.
6. Look at the woman's perineum if she says that the baby is coming or begins making grunting sounds or bearing down. Summon the experienced nurse with the call bell immediately, but *do not leave the woman.*
7. When the infant is born, focus on the respiratory efforts, dry the infant, and maintain warmth. Use a bulb syringe to suction excess secretions. Keep the infant under a radiant warmer or in skin-to-skin contact with the mother, or wrap the infant in warmed blankets. Do not get between the radiant heat source and the infant. The infant should not wear a cap when under the warmer.
8. Observe parent-infant attachment behaviors such as making eye contact, talking in soft, high-pitched tones, and making remarks about the infant. Assist the mother to breastfeed immediately if possible (see [Chapter 22](#) and page 771 in this appendix).
9. In many facilities, the infant remains with the parents during the recovery period, and the same nurse cares for both the mother and the newborn. If so, continue to observe the infant's respiratory effort and maintain the temperature. Infant glucose levels are usually assessed under facility guidelines.

 REEDA (redness, edema, ecchymosis, drainage, approximation)

Equipment and Supplies

Thermometer
 Blood pressure equipment
 Watch
 Stethoscope
 Flashlight
 Nonsterile gloves
 Peripads
 Peribottle
 Clean linen
 Disposable underpads

Normal Assessments

Vital Signs

Temperature. Lower than 38°C (100.4°F).

Blood Pressure. Near the baseline levels established during pregnancy.

Pulse Rate. 60 to 90 beats/minute. 40 to 50 beats/minute may occur. Bradycardia reflects the increased amount of blood returning to the central circulation.

Respirations. 12 to 20 breaths/minute. Should be unchanged from preconception levels; the lungs should be free of adventitious breath sounds.

Breasts

1. First 24 hours: Soft.
2. Days 2 to 3: Firm to very firm, as milk comes in.
3. Nipples: Free of redness, abraded areas, blisters, bruising, and fissures.

Gastrointestinal System

1. Mother is hungry and thirsty.
2. Abdomen is soft. Temporary constipation may occur because of dehydration and decreased intake during labor.
3. Hemorrhoids may be obvious, particularly during the first 24 hours.

Genitourinary System

1. Fundus should be firm, midline, and located approximately at the umbilicus.
2. Lochia rubra should be scant to moderate with a fleshy, earthy odor.
3. Episiotomy edges should be approximated and without redness or edema.
4. Perineum, labia, or both may be slightly bruised or swollen.

- Abdominal dressing, if present, should be dry and intact. Follow agency protocol or physician orders for removal. The edges of the surgical incision should be approximated and without signs of infection.
- Diuresis is normal for the first 2 to 5 days. Mothers often do not feel the need to urinate even if the bladder is full.
- After the woman voids, the bladder should not be palpable and the fundus should remain firm in the midline of the abdomen, and at the level of the umbilicus.

Nursing Care

Preparation before approaching the new mother helps the nurse recognize unusual or abnormal data and initiate the necessary nursing interventions.

Nonsterile gloves must be worn whenever the possibility of contact with body fluids (blood, lochia, colostrum, breast milk, urine, or stool) exists.

The sequence in which postpartum assessments are performed is important because they should progress from areas that are least likely to be contaminated, such as the breasts, to areas that are associated with pathogenic organisms, such as the perineum and anal areas. The following sequence is recommended.

Assessments

- Explain the purpose of the assessments: "I know we do these assessments several times a day, but they help us determine if everything is progressing as it should. It is also a good time for you to ask any questions you might have."
- Assess vital signs, usually every 4 to 12 hours, depending on facility protocols, time since delivery, and the condition of the mother.
- Auscultate breath sounds and the ability to breathe deeply and cough if the woman had a cesarean birth, if she smokes, or if she has a history of respiratory disorders.
- Ask the mother to unfasten her bra or to lower the bra flaps to assess the nipples for redness, fissures, or blisters that may occur with breastfeeding. Note nipple size and shape that may make breastfeeding more difficult (flat, retracted, inverted). Palpate the breasts and ask how well breastfeeding is progressing and whether she has any questions.
- Lower the head of the bed, and ask the mother to flex her knees for comfort. If the woman had a cesarean birth, auscultate the abdomen for bowel sounds and ask if she is passing flatus. Palpate the abdomen to determine if it is soft or distended.
- If a dressing covers the incision, observe for intactness and drainage. If no dressing is present, observe the cesarean incision for REEDA and note whether a topical skin adhesive, staples, or adhesive strips are in place.
- Assess for bladder distention (observable or palpable bulge above the symphysis pubis) and time and amount of last voiding (can be validated from the chart before beginning the assessment). If an indwelling catheter is in place, note the color and amount of urine.
- Palpate the lower extremities for the presence and extent of edema. Press the thumb on the pretibial area and the feet to determine whether pitting edema is present. Note how long it takes for the pit to disappear.
- Observe and palpate the lower extremities for signs of thrombophlebitis (areas of redness, warmth, tenderness, swelling). Dorsiflex the foot to elicit Homans' sign.
- Lower the perineal pad(s) and observe flow of lochia while palpating the fundus for firmness and location.
- Observe the perineal pad(s) for color and amount of lochia and presence of unpleasant or foul odor. Ask how long since the peripad(s) was (were) changed, to determine the amount of flow.
- Ask the mother to turn onto her side, and assess the episiotomy or laceration (if she has one) and perineum for REEDA. Note the number and size of hemorrhoids.
- Evaluate the mother's ability to ambulate, and elicit information about dizziness, weakness, or lightheadedness during ambulation. Observe her gait for steadiness and balance.
- Ask the mother about particular problems and concerns. How is her appetite? How much rest is she getting? Does she have discomfort (where, when)? Does she require medication?

Interventions

- Changes in vital signs may be within expected limits, or they may indicate the beginning of serious problems. Tachycardia or lower-than-expected blood pressure may indicate excessive bleeding and should be reported. Blood pressure that is higher than expected may indicate preeclampsia. Temperature above 38°C (100.4°F) suggests infection rather than dehydration and should be reported. Diminished or abnormal breath sounds (wheezes or crackles), as well as difficulty breathing or coughing, should be reported at once.
- Nipple trauma provides a portal for entry of pathogenic organisms and creates discomfort during breastfeeding. The new mother often needs information, guidance, and encouragement with breastfeeding.
- Intervene at once if you are unable to locate the fundus, if the fundus feels soft (boggy), or if it is above the umbilicus or displaced from the midline. Massage a boggy fundus and expel clots when the fundus becomes firm. Assist the mother to void, or catheterize her if she is unable to empty her bladder.
- Report calf pain that may be a positive Homans' sign or muscle pain. Also report areas of redness, edema, or tenderness of the legs. Assist the woman to ambulate if her gait is unsteady or she experiences lightheadedness when she ambulates.
- If necessary, teach self-care measures such as perineal care and sitz bath to reduce perineal discomfort and prevent infection.
- Provide medication for afterpains or perineal discomfort according to the physician's orders. Reassure the mother that very little of the medication administered for discomfort crosses into the breast milk and the infant should not be affected.

POSTPARTUM CARE: PSYCHOSOCIAL ASPECTS

Engrossment

Entrainment

Fingertipping

Letting-go

Reciprocal bonding behaviors

Taking-hold

Taking-in

Normal Assessments

Maternal Touch. During the first 24 hours, the mother progresses from the discovery phase, when she “fingertips” the infant, to holding the infant close and demonstrating consoling behaviors.

Verbal Expressions. The mother progresses from referring to the infant as “it” to using “he” or “she” and finally to calling the infant by a given name. Some parents have called the infant by name since seeing an ultrasound performed during pregnancy.

Taking-In Phase. Mothers are concerned with their own physical needs and the need to talk about details of their labor and delivery.

Taking-Hold Phase. Mothers become more independent and focus on learning how to care for themselves and the infant.

Letting-Go Phase. Mothers “let go” of their previous role of being without children or having one less child. They give up the “fantasy baby” they had during pregnancy to adapt to the baby they have.

Fathers. Fathers demonstrate intense fascination with the infant and often respond gently to infant signals such as fussing and crying. They may lack confidence in providing infant care and need teaching.

Family. Family support is obvious when the grandparents or other relatives call or visit, offer to assist the mother, and demonstrate interest in the newborn.

Nursing Care

To prepare for the psychological assessment, the nurse should review expected maternal behaviors, progression of maternal touch, and verbal interactions.

Assessments

1. Collect data from the woman’s chart or Kardex computer file, (age, gravida, para, time and type of birth, gender and weight of infant, unusual characteristics or anomalies of the infant, time the mother was last medicated for discomfort) to identify factors that might affect adjustment.
2. Begin the psychosocial assessment during the physical assessment, and continue to make observations throughout the day.
3. Observe maternal mood, general energy level, and activity.
4. Ask about the mother’s comfort, how she slept, and whether she has special concerns.
5. Note the focus of the mother’s attention—is it on her own needs or care of the infant? Does she require assistance with hygiene and self-care measures? How much does she talk about the birth experience and what does she say?
6. Observe the mother’s interaction with the infant and her readiness to participate in infant care. Note her tone of voice and verbal interaction.
7. Watch how the mother touches the infant and how she responds to infant cues, such as crying and fussing.
8. Note the father’s participation in infant care and his comfort in handling the infant.
9. Notice infant behavior (awake, sleepy, gazing, response to parents’ voices). Observe how the infant responds to the parents and whether the parents are successful in consoling the infant.
10. Observe visitors, particularly the grandparents and family, who may provide assistance to the parents during the early weeks at home.

Interventions

1. Anticipate the mother’s needs, and provide physical care and comfort measures that are particularly important in the early hours after childbirth.

2. Allow time to listen, which is very important in establishing rapport and assisting the mother to integrate the birth experience into her reality system.
3. Promote bonding and attachment by providing long periods of uninterrupted contact between the parents and the infant. Model behaviors such as gently responding when the infant cries and talking to the infant in a high-pitched voice. Point out positive characteristics of the infant to the parents.
4. Prepare to teach basic infant care, including explanations, demonstrations, pamphlets, and videos for both parents.
5. Answer questions or demonstrate care as the mother indicates a readiness to learn.

Thermometer
Tape measure
Vitamin K, syringe, filter needle, alcohol wipes
Eye medication
Bulb syringe

Normal Assessments

Vital Signs

Temperature. Axillary: 36.5° to 37.5°C (97.7° to 99.5°F).

Heart rate. 120 to 160 beats/minute.

Respirations. 30 to 60 breaths/minute (average 40 to 49 breaths/min).

Blood Glucose

40 to 60 mg/dL during the first day and then 50 to 90 mg/dL by screening tests.

Measurements

Weight. 2500 to 4000 g (5 lb, 8 oz to 8 lb, 13 oz).

Length. 48 to 53 cm (19 to 21 inches).

Head Circumference. 32 to 38 cm (13 to 15 inches).

Chest Circumference. 30 to 36 cm (12 to 14 inches).

Nursing Care

A typical order in which assessments and care are performed in the labor, delivery, recovery unit, or the admission nursery is given here. The assessment may be performed while the infant is held by the mother immediately after birth if all is normal. The elements actually included and the order in which they are performed depend on the facility's routine and the circumstances.

Adhere to standard precautions at all times. Wear nonsterile gloves whenever handling the infant until the bath is given and all blood is removed from the skin. After the bath, wear gloves when soiling with body fluids may occur.

Include family members who are present. They often are very interested in explanations of the assessments and care being given. Promote bonding by encouraging them to touch and talk to the infant.

Assessments

Begin with a quick overall assessment of the infant's general condition. Attend to major problems, such as severe respiratory distress, before continuing the more detailed assessment and routine care. Observe for signs of distress or abnormality in the early hours after birth, when they are most likely to appear. Report and take action, as necessary, for any abnormal findings.

1. Perform a quick general assessment to identify gross abnormalities.
Be constantly alert for signs of respiratory distress.
2. Assess vital signs. Report and follow up on abnormalities immediately.
3. Weigh infant and measure length and head and chest circumferences.
4. Assess blood glucose level according to signs of hypoglycemia and agency policy.
5. Perform an in-depth assessment (see Table 20-2).
6. Continue monitoring vital signs every 30 minutes until infant has been stable for 2 hours. Assess more often if necessary. Once the infant is stable, vital signs should be checked every 8 to 12 hours or more frequently if abnormal.

Interventions

1. Suction the infant's secretions as necessary.
2. Take footprints, if not done previously (according to agency routine).
3. Administer antibiotic ointment to the eyes, and administer vitamin K injection. **NOTE:** Do not give vitamin K until after the bath or the leg is well cleaned if the mother is positive for hepatitis B or human immunodeficiency virus (HIV).
4. Allow the infant to rest quietly under a radiant warmer or with the mother between assessments and care. When the initial assessment and procedures are completed and the temperature is stable, wrap the infant in two blankets, place a hat on the infant's head, and give the infant back to the parents.
5. When the temperature is stable, bathe the infant under a radiant warmer to remove blood and excess vernix. Keep the infant warm by drying as quickly as possible and removing wet linens. Dry the hair thoroughly to prevent heat loss.
6. Assist the mother with the initial feeding. If the infant is formula fed, give no more than 1 oz. Burp the infant halfway through the feeding.

7. Watch continuously for circumoral or central cyanosis, choking, or lack of breathing during sucking. Stop the feeding, suction with a bulb syringe, and stimulate the infant by rubbing the back. Continue feeding when the infant has regained color.
8. Complete a gestational age assessment.
9. Prepare for transfer from the radiant warmer to a crib if all assessments are normal. Place clothing and blankets under the warmer to heat. Take the last set of vital signs, dress the infant, apply a hat, and wrap the infant in two warmed blankets. Complete all charting.
10. Give report if another nurse is taking over care of the infant. Include gravida, para, length of labor, medications and anesthesia used in labor and birth, time of rupture of membranes, any complications during birth, any problems in the early hours, feeding, voids and stools, and any other pertinent information.

Normal Assessments

Vital Signs

Temperature. Axillary: 36.5° to 37.5°C (97.7° to 99.5°F).

Heart Rate. 120 to 160 beats/minute.

Respirations. 30 to 60 breaths/minute.

Blood Glucose

50 to 90 mg/dL by screening tests after the first day or according to agency policy.

Nursing Care

Assess and care for infants using the following list as a guide. Keep in mind that the role of the nurse is to continue to observe for abnormalities and complications, as well as to assess the progress of mother-infant bonding and the mother's ability to care for the infant.

Assessments

1. **Vital signs.** Assess vital signs once every 8 to 12 hours and more often if any abnormalities are present. Before disturbing a sleeping infant, check the respirations and pulse rate. Temperature should be stable after the first day. Action is needed if it is abnormal. Continue to listen for abnormal heart sounds. Murmurs heard earlier may disappear after the first day as transition to neonatal

circulation becomes complete. Note acrocyanosis or central cyanosis. Breath sounds should be clear.

2. *Weight.* Weigh infants daily at the same time of day according to agency routine.
3. *Neurologic.* Note the state of alertness (six stages), movement of extremities, and reflexes (especially Moro, rooting, sucking). Observe the eyes for signs of inflammation (redness, drainage), which may result from a reaction to eye medication or infection. Cleanse drainage with sterile water from the inner to outer canthus, ensuring that drainage from one eye does not contaminate the other. Watch for signs of hypoglycemia (jitteriness, tremors). Check fontanel with the infant in an upright position. It should be soft and flat. *Report fullness, bulging, depression.*
4. *Skin.* Assess all skin areas to observe for new marks or changes in existing ones. Compare with previous assessments. Expect the skin to be dry and peeling. Look for redness, scratches (keep hands covered), rashes, signs of skin breakdown, and infection. Erythema toxicum may become more apparent. Resolution of caput succedaneum may occur as early as 12 hours or may take several days. Cephalhematoma resolves in 2 to 3 months. Physiologic jaundice may begin to develop after the first 24 hours. Blanch the skin over the nose and bony prominences, and note the color and how far down the body the jaundice extends. Check the cord and base of the cord for redness, foul odor, and serosanguineous or purulent drainage. Note how well the cord is drying. Remove the clamp when the end of the cord is dry and crisp (about 24 hours).
5. *Musculoskeletal.* Note the movement of extremities and muscle tone. The infant should resist when the extremities are extended. Note stiffness, arching of the infant's back, or molding of the infant to the caregiver's body.
6. *Gastrointestinal.* The abdomen should be soft and bowel sounds present. If the mother is giving all feedings, observe at least a part of several feedings. Ask the mother how she feels the feedings are going. Assess for suck and swallow coordination, choking, length of time the feeding lasts, amount taken, and any regurgitation. Note the type and number of stools. Know whether the infant has had a stool during the current shift and when the last stool occurred. (The first stool is generally passed within 12 to 48 hours of birth.)
7. *Genitourinary.* Note the number of voidings and the color of urine on diapers. Know whether the infant has voided on the present shift and when the last voiding occurred. Teach the parents to expect at least one to two wet diapers per day during the first 2 days of life and at least six wet diapers per day by the fourth day. (The first voiding should occur within 12 to 24 hours.) Observe the circumcision site for drainage (purulent, serous, sanguineous, frank bleeding, or oozing). Determine whether the infant is voiding after a circumcision is performed.
8. *Bonding.* Observe bonding behaviors in the mother and infant. Note how the mother holds the infant, whether she talks to the infant, calls the infant by name, and so on. Note response of the infant to the mother's care.
9. *Teaching.* Assess in which areas the mother (or the parents) need teaching.

Interventions

The following care of the infant is typical for every shift. In addition, make rounds frequently (at least every hour) to monitor the mother's progress in infant care and determine the need for further interventions.

1. *Cord care.* Perform cord care according to agency policy. Generally nothing is applied to the cord. It is kept clean and dry, and the diaper is folded below the cord so it is not contaminated with urine.

2. *Care of the circumcision site.* Assess the parents' knowledge of care of the circumcision site, and teach as necessary. If a Plastibell was used, no special care is necessary other than observation for complications. If a Gomco clamp was used, instruct parents to squeeze petroleum jelly liberally over the circumcision site (and apply gauze if part of agency routine) at each diaper change for the first 4 to 7 days. Assess the incision throughout the shift for redness, edema, purulent or sanguineous drainage, and odor.
3. *Identification.* If the mother and the infant are separated at any time, use the proper identification process each time the infant is reunited with the mother.
4. *Protection.* Maintain vigilance against kidnappers at all times. Follow agency procedures to provide for infant security.
5. *Feedings.* Determine whether the infant is taking feedings adequately (every 2 to 3 hours if breastfed, every 3 to 4 hours if formula fed). Record each feeding, including the type, the amount (or how long the infant nursed at each breast), how feedings are taken, and any regurgitation. Teach the parents as necessary.
6. *Elimination.* Record each wet diaper and stool. Note the color, amount, and consistency.
7. *Continue observation.* Observe for problems throughout the shift.
8. *Continue teaching.* Provide additional parent teaching as needed along with the "scheduled" teaching that was planned at the beginning of the shift.

Mothers Want to Know: Is my baby getting enough milk?

Mothers Want to Know: Solutions to common breastfeeding problems

Mothers Want to Know: Breastfeeding after the birth of more than one infant

New Terms

Latch-on

Non-nutritive suckling or sucking

Nutritive suckling or sucking

Normal Assessments

1. The infant is positioned facing the breast, and the infant's body is well supported.
2. The mother is comfortable and holds her breast so that the infant can take it into the mouth without interference.
3. The infant's mouth covers the nipple and 1 to 1.5 inches of the areola.
4. Suckling includes audible swallowing.

Nursing Care

This is a summary of information that nurses can use to help the inexperienced mother, especially during the first breastfeeding sessions.

Assessments

1. Assess the mother's knowledge about breastfeeding techniques.
2. Assess the mother's breasts to identify engorgement, flat or inverted nipples, or nipple trauma.
3. Assess the infant's behavior state, sucking reflex, and coordination of sucking and swallowing.

Interventions

1. Plan with the mother when the infant will be fed, and note any questions or concerns that she has about breastfeeding. Be sure that she is comfortable (pain relief needs met) and not in the middle of other care (hygiene, meals). However, if the infant must eat immediately because of concerns about hypoglycemia, meet the mother's needs quickly or postpone her care and help her begin the feeding.
2. Explain that breastfeeding is a learned skill for both the mother and the infant and that practice is required to perfect the skill.
3. Begin the feeding when the infant is awake and showing hunger cues. Do not wait until the infant is ravenously hungry and upset.
4. Assist the mother to position herself and the infant. Use pillows or blankets for comfort, to protect an abdominal incision, and to raise the infant to nipple level.
 - a. *Sitting.* Place the bed in a high-Fowler's position. Position pillows behind the mother's back and under her elbow to support her arm.
 - b. *Cradle hold.* Place the infant in the mother's arms, with the head at or near the antecubital space (and at nipple level) and the mother's arm extending along the infant's body. The mother's other hand positions the breast. The infant should be totally on his or her side facing the breast so that turning of the head is not necessary.
 - c. *Cross-cradle hold.* The mother holds the infant's head in the hand opposite the breast to be used and supports the infant's body across her lap with the arm. She supports the breast with the hand on the same side as the breast. The infant is turned to the side and facing the breast.
 - d. *Football hold.* Place the infant's head in the mother's hand, with the body along her side supported by pillows or blankets.
 - e. *Side-lying.* Place pillows behind the mother's back and between her legs. Her lower arm may go under her head or around the infant, while her upper hand positions the breast. Place the infant on the side facing the breast, using pillows to pad the side rails and to maintain the position.
5. Demonstrate the proper hand position, with the hand cupped around the breast in a "C" position, the thumb on top, and the fingers supporting the breast below. Keep the fingers and thumb behind the areola.
6. Elicit latch-on. Brush the nipple against the infant's lips until the infant opens the mouth wide. Bring the infant toward the breast while inserting the nipple and areola into the infant's mouth.
7. Assess the mouth position. The infant's lips should be 1 to 1½ inches (2.5 to 3.8 cm) from the base of the nipple with the lips flared. Remove the infant from the breast and start over if the cheeks dimple or clicking or smacking sounds occur.
8. Assess the infant's suck. Nutritive suckling is smooth and continuous with occasional pauses. A swallow follows every one to three sucks and has a "ka" or "ah" sound. Non-nutritive suckling is choppy with no swallowing. Do not jiggle the breast in the infant's mouth to stimulate suckling, or the infant may lose the grip and chew on the nipple.
9. When swallowing stops and does not resume shortly or is choppy, non-nutritive suckling occurs, remove the infant from the breast and burp the infant, change sides, awaken, or let the infant sleep if the feeding is finished.
10. Demonstrate removal from the breast. Have the mother insert a finger into the corner of the infant's mouth between the gums to release suction. Remove the infant immediately.
11. Instruct the mother to nurse approximately 10 to 15 minutes or more on each breast per feeding. Burp the infant between breasts. Instruct her to nurse every 2 to 3 hours. She should feed 8 to 12 times in 24 hours.
12. Observe the mother at intervals after the feeding begins. Help her switch sides to observe for difficulty. Then observe the mother at other feedings to give reinforcement and correct technique as needed. Offer praise generously because feeding the infant may affect the mother's view of her mothering abilities.

Answers to Check Your Reading

CHAPTER 1

- High rates of maternal and infant mortality among poor women led to federal programs to improve the health of mothers, infants, and young children. Distribution of health care remains inequitable between poor women and more affluent women because many physicians and other health care providers practice in an area in which payment for care is more certain.
- Family-centered care provides safe, quality care that adapts to both the physical and the psychological needs of the entire family during reproduction and greatly increases the responsibilities of nurses providing care. Family-centered care and support is often part of women's health care in nonchildbearing years as well.
- Birthing centers provide professional care during pregnancy and childbirth in a homelike environment for women with low-risk pregnancies. They are associated with a nearby hospital to which the woman can be transferred in case of unexpected complications. Although the home setting provides comfort and closeness, it may not have adequate equipment or personnel to handle unexpected developments. Family members and friends must assist with care of other children, the mother, and her new infant. LDR and LDRP rooms offer a comfortable setting that promotes family involvement for birth but within the hospital, where emergencies can be handled more easily.
- Cost-containment strategies have shortened the length of stay in the birth facility for mothers and their infants. This has created concern for nurses, who must provide information for fatigued parents in a very short time. Nurses can also use the demand for cost containment to research the development of innovative programs for family education.
- Clinical pathways are guidelines that define expected outcomes for clients along a time line. Pathways may include the expected length of stay and the time and sequence of interventions that will accomplish the desired outcomes. Variances may be positive (accomplished faster) or negative (accomplished in a longer time).
- A variety of standards guide both agency and community care for perinatal nurses. Standards include agency and organizational standards that define the preparation, responsibilities, and actions of nurses. Legal standards define the scope of practice, and other regulatory bodies such as OSHA, CDC, and FDA provide guidelines. Accrediting agencies such as The Joint Commission and CHAP give approval when standards reach a certain level.
- Safety is the major concern with the use of complementary and alternative medicine because these modalities are largely unregulated. Additionally, clients usually refer themselves to practitioners and either may delay care from a conventional health care provider or may not tell the conventional provider about substances they are taking that may be harmful when combined with other medications. Some organic substances have active pharmacologic ingredients of varying strengths.
- Traditional families are headed by a man and a woman, usually married, who view parenting as the major priority in their lives and whose energies are less likely to be depleted by poverty, illness, or substance abuse. Nontraditional families are defined by their unique structure and include single-parent families, blended families, extended families, same-sex parent families, and adoptive families.
- Families may be identified as high risk if they are below the poverty level, are headed by a single teenage parent, have a preterm, ill, or disabled infant, or have lifestyle problems such as substance abuse or family violence.
- A healthy family can adapt without undue stress to the changes precipitated by childbirth. Members communicate openly, are flexible in role assignment, agree on the basic principles of parenting, are adaptable to change, and volunteer assistance to aid family members.
- Factors that interfere with family functioning include lack of family resources, absence of adequate family support, birth of an infant who requires specialized care, unhealthy habits (such as smoking and substance abuse), and the inability to make mature decisions.
- Nurses should examine their own cultural values and beliefs to determine ways in which their beliefs may generate conflict with those who hold different cultural beliefs.
- Differences in language create the greatest difficulty. Differences in communication style or knowledge about the dominant family member may result in conflicts.
- Culture is difficult to understand because, like an iceberg, only the tip (the behavior) is visible. Reasons for the behavior (for example, religious beliefs and moral values) are hidden, much like the submerged part of an iceberg, requiring study.
- The infant mortality rate is lower today than in the early 1900s because of improved neonatal care, public awareness of preventive measures such as those to prevent SIDS, and availability of prenatal care, including at public clinics.
- The higher incidence of poverty among African-Americans is associated with inadequate prenatal care and the birth of premature or low-birth-weight infants with short-term or long-term health problems.
- With regard to infant mortality rate, the United States ranks 27th among developed nations.

CHAPTER 2

- Therapeutic communication is purposeful, goal directed, and focused.
- Major communication techniques include clarifying, paraphrasing, reflecting, silence, structuring, pinpointing, questioning, directing, and summarizing.

3. Major blocks to communication include conveying a lack of interest or haste, displaying a closed posture, interrupting, providing false reassurance, offering inappropriate self-disclosure, giving advice, and failing to acknowledge comments or feelings.
4. Major principles of teaching and learning include readiness to learn, participation, repetition, positive feedback, and acknowledgment of frustration. Effective methods include role modeling, presenting simple tasks before more complex material, and using a variety of teaching methods.
5. Factors that affect learning include developmental level, language, culture, previous experience, physical environment, and the organization and skill of the teacher.
6. Nursing practice based on the best evidence available rather than tradition or intuition is now an expectation for producing the most effective and efficient patient outcomes.
7. The purpose of critical thinking is to identify and overcome habits or impulses that result in poor decisions or inappropriate actions and to make the best clinical judgments.
8. Steps that may be helpful in learning critical thinking can be organized into an “ABCDE” pattern. They include recognizing assumptions; examining possible personal biases; determining the need for closure; developing the ability to collect, organize, and analyze data in an expert manner; and acknowledging how emotions or environmental factors may interfere with the ability to think critically.
9. Reflective skepticism means to suspend judgment to avoid making decisions in haste or with insufficient data.
10. The screening assessment gathers information about all aspects of the patient’s health. The focused assessment gathers information about an actual health problem or one for which the patient appears to have a higher risk. A woman’s desire to improve health may be identified during both types of assessment.
11. Actual nursing diagnoses reflect health problems that can be validated by the presence of defining characteristics. Risk nursing diagnoses indicate that risk factors are present that make the person vulnerable to the development of a particular problem that has not yet developed.
12. The terms *goals* and *expected outcomes* (outcome criteria) are often used interchangeably to describe desired endpoints of care, but they are different. Broad goals do not have the specific criteria of outcome criteria. Expected outcomes should (1) be stated in terms of the patient, (2) be observable and measurable, (3) have a time frame, (4) be realistic, and (5) be worked out with the woman and family.
13. Nursing interventions that are not specific and do not identify exactly what is to be done are difficult to implement. Clearly written interventions that provide detailed, objective instructions correct the problem.
4. Assessment is used to gather data from all concerned persons. Ethical theories and principles are analyzed to determine whether an ethical dilemma exists. Planning involves identifying as many options as possible and choosing a solution. Interventions must be identified to implement the chosen solution, and the results are evaluated.
5. The Supreme Court decision in *Roe v. Wade* declared that abortion was legal anywhere in the United States and that existing state laws prohibiting abortion were unconstitutional because they interfered with a woman’s right to privacy. Stipulations in terms of the trimester of pregnancy were part of *Roe v. Wade*.
6. The belief that abortion is a private choice conflicts with the belief that abortion is taking a life.
7. States cannot give a husband veto power over his spouse’s decision to have an abortion; states do not have an obligation to pay for abortions, physicians are given broad discretion to determine fetal viability, and states may restrict abortions of viable fetuses. States may require parental consent for minors to obtain an abortion if an alternative (e.g., judge’s approval) is available, states may require a woman to wait 24 hours before seeking and obtaining an abortion, and states may not require a married woman to inform her husband before obtaining an abortion. Whether risks to a woman’s health can be considered in late abortion has led to several changes in state and national laws.
8. At the time they are employed, nurses must disclose their beliefs about caring for women having an abortion. Nurses must inform a supervisor so that appropriate care can be arranged.
9. Punitive approaches are against the ethical principles of autonomy, bodily integrity, and personal freedom. Although the intended plan may be to protect the fetus, such a plan can have unexpected outcomes, causing the woman to avoid prenatal care or be dishonest with care providers, causing greater harm to her fetus.
10. Problems involved in the use of advanced reproductive techniques include high cost, low success rate, limitation to the affluent, control of unused embryos, and problem or unexpected pregnancy outcomes. Another issue is that the offspring born after menopause are more likely to be orphaned than those of younger mothers.
11. Computer terminals may be in hallways, patient rooms, or nursing stations, so log off when access is complete. Maintain secret identity codes that access private information. Maintain a low volume in phone reports. Direct reports to another professional should be done on a “need to know” basis rather than reporting to those who do not need to know. Verbal reports should be done in a private area. Care must be taken not to violate client or institutional confidentiality when having any discussion on the Internet.
12. Advantages of electronic medical records include reduced fragmentation of care and errors, rapid access in an emergency, and clarity of orders that are not handwritten. Disadvantages of electronic medical records may include high initial costs and maintenance of privacy when transmitted.
13. Poverty is the underlying factor that causes problems such as inadequate access to health care. The lack of access to health care is a major reason for the large number of low-birth-weight infants and the high infant mortality rate.
14. The focus has long been on treatment and cure of illness, often with expensive technology. However, prevention is less expensive and provides care for greater numbers of people.
15. Although the late preterm infant may appear similar to a term infant, the higher costs of complications such as respiratory distress, poor temperature regulation, hypoglycemia, feeding

CHAPTER 3

1. Ethics examines conduct and distinctions between right and wrong to determine the best course of action. Bioethics applies specifically to the ethics of health care.
2. The deontologic model applies ethical principles to determine what is right. It does not vary the solution according to individual situations. The utilitarian model analyzes the benefits and burdens to determine a course of action that provides the greatest amount of good in a given situation. Belief that every client has basic human rights is the basis for the human rights model.
3. Ethical principles may conflict when the application of one principle violates another.

problems, apnea, bradycardia, jaundice, and sepsis may require an extended hospital stay, often in the neonatal intensive care unit rather than the normal newborn nursery. Hospital readmissions are common in this group of babies.

16. State boards of nursing administer the individual states' nurse practice acts, which establish what the nurse is allowed and expected to do when practicing nursing in that state.
17. Standards of care and agency policies influence judgment about malpractice because they describe the level of care that can be expected from practitioners at the time of care.
18. Nursing actions that help defend malpractice claims include securing informed consent appropriately, keeping documentation that provides evidence that the standard of care has been maintained, acting appropriately as a client advocate in terms of taking a problem through the chain of command, and maintaining expertise.
19. Concerns about the use of unlicensed assistive personnel include whether this use compromises the quality of care and if the high workload of the nurse restricts the time available to supervise unlicensed personnel adequately.
20. Short lengths of stay lead to concerns about the woman's ability to care for herself and her infant, potential complications that new parents may not identify, and the fact that parents will not have had time to absorb the necessary teaching. Follow-up phone calls help alleviate some concerns and identify some problems that develop after discharge. In nonmaternity medical situations, many older women are often discharged early from the hospital. Because the cognitive abilities of a woman may decline with advanced age, in these situations it is important to also provide teaching to the woman's care provider.
21. Facilities that use phone-call triage must have regularly reviewed and updated protocols, good documentation forms, and specific instructions to the client about actions to take if further problems develop.

CHAPTER 4

1. Development of the breasts is the first sign of puberty in girls. In boys, growth of the testes is the first sign, followed by growth of the penis about 1 year later.
2. Asians and Native Americans usually have less and finer body hair than either whites or African-Americans. African-Americans usually have body hair that is coarser and curlier than Asians, Native Americans, or whites.
3. The female pelvis has a wide, rounded, basinlike shape that favors efficient passage of the fetus during birth. The male pelvis is heavier and narrower and structurally suited for tasks requiring load-bearing.
4. Males generally attain a greater adult height than females because they begin their growth spurt about 1 year later than girls and continue growing for a longer period of time.
5. Female secondary sex characteristics include round hips and breasts, pubic hair, finer skin texture, and a higher-pitched voice. Male secondary sex characteristics include facial and pubic hair, a deeper voice, broader shoulders, and greater muscle mass.
6. The female external reproductive organs are collectively called the *vulva*. The labia majora extend from the mons pubis to the perineum. The labia minora are within and parallel to the labia majora. The clitoris is at the anterior junction of the labia minora. The urinary meatus and vaginal introitus are found within the vestibule (the area enclosed by the labia minora). The hymen partially closes the vaginal opening. The perineum extends from the fourchette (posterior rim of the vaginal opening) to the anus.
7. The three divisions of the uterus are the corpus (body), isthmus (transition zone between corpus and cervix), and cervix (neck). The uterine fundus is the part of the corpus that lies above the entry points of the fallopian tubes.
8. The myometrium is the middle layer of thick uterine muscle between the perimetrium and endometrium. The myometrium includes three types of muscle fibers: (1) longitudinal fibers, mostly in the fundus, to expel the fetus during birth; (2) interlacing figure-eight fibers to compress bleeding blood vessels after birth; and (3) circular fibers to provide constrictions near the fallopian tubes and the internal cervical os, enabling the proper implantation of the fertilized ovum and preventing the reflux of menstrual blood into the fallopian tubes.
9. The fallopian tubes are lined with cells with cilia that beat rhythmically toward the uterine cavity to propel the ovum through the fallopian tube. The fertilized ovum undergoes its early cell divisions in the fallopian tube so that implantation is most likely to occur in the uterine fundus.
10. The two functions of the ovaries are to produce hormones (primarily estrogen and progesterone) and mature an ovum for release during each reproductive cycle.
11. The pelvis is located at the lower end of the spine. The true pelvis is located below the linea terminalis. The true pelvis is most relevant during birth.
12. Pelvic muscles enclose the lower pelvis and support internal reproductive, urinary, and bowel structures. Ligaments maintain internal reproductive organs and their nerve and blood supplies in the proper positions in the pelvis.
13. The ripening follicle secretes estrogen to form new endometrial epithelium and endometrial glands. After ovulation, the follicle (now called the *corpus luteum*) secretes large amounts of both estrogen to continue thickening of the endometrium and progesterone to cause the endometrium to secrete substances to nourish a fertilized ovum.
14. Three ovarian phases of the female reproductive cycle are the follicular (maturation of an ovum), ovulatory (release of the mature ovum), and luteal (secretion of estrogen and progesterone by the corpus luteum). The length of the follicular phase varies more among women than the other two phases.
15. The three endometrial phases are the proliferative, secretory, and menstrual phases. The proliferative phase occurs during the first half of the cycle, during which the endometrium thickens in preparation for a fertilized ovum. The secretory phase occurs during the second half of the cycle and is characterized by continued growth of the endometrium, growth of blood vessels and glands, and secretion of substances to nourish a fertilized ovum. If pregnancy does not occur, the endometrium becomes ischemic and necrotic as secretion of estrogen and progesterone from the corpus luteum declines. The old endometrium is shed in the menstrual phase.
16. The cervical mucus becomes thin, clear, and elastic during ovulation to facilitate entrance of sperm from the vagina into the uterus and fallopian tube, thereby enhancing the chances for conception.
17. Montgomery's tubercles secrete a substance during pregnancy and lactation that keeps the nipples soft.
18. A woman's breast size is not related to the amount of milk she can produce. Breast size is influenced by the amount of fatty tissue in the breast.
19. Milk secretion does not occur during pregnancy because estrogen and progesterone produced by the placenta inhibit its production.

- Estrogen and progesterone stimulate the growth of the alveoli and ductal system during pregnancy.
- As a urinary organ, the penis transports urine from the bladder to outside the body during urination. As a reproductive organ, it carries and deposits semen into the vagina during coitus.
 - The two types of erectile tissue in the penis are the corpus spongiosum that surrounds the urethra and the two columns of corpus cavernosum tissue on each side of the penis. The function of erectile tissue is to facilitate entry of the penis into the female's vagina.
 - The scrotum holds the testes away from the body to keep them cooler than the core body temperature, thus facilitating sperm production.
 - The testes function as endocrine glands to produce testosterone and the male gametes (spermatozoa).

CHAPTER 5

- DNA is the building block of genes. A varying number of genes makes up each chromosome.
- Genes are too small to be seen under a microscope. They can be studied by analysis of the products they instruct cells to produce, by direct study of the DNA, or through their close association with another gene that can be studied by one of these other methods.
- Chromosomes can be seen under a microscope when living nucleated cells are dividing. Cell division during the metaphase is a common time for analysis because each chromosome is compact. Fluorescent in situ hybridization (FISH) identifies chromosomal abnormalities in more than one stage of cell division, allowing rapid test results. Spectral karyotyping (SKY) assigns a color to each chromosome to better identify rearrangements and small additions or deletions of chromosomal material that may cause abnormalities.
- 46,XY describes the chromosome makeup of a normal human male. 46,XX describes the chromosomes of a normal human female. Abnormalities are described beginning with the total number of chromosomes, followed by the sex chromosome complement, and followed by the abbreviation that describes the chromosome abnormality.
- The child of a parent with an autosomal dominant disorder has a 50% chance of having the same disorder.
- Blood relationship (consanguinity) of parents increases the likelihood that both share some of the same harmful autosomal recessive genes, increasing the chance that their offspring will be affected with a disorder. The closer the parents' blood relationship, the more genes they are likely to share.
- If both parents carry an abnormal gene for an autosomal recessive disorder, each child has a 25% chance of receiving both copies of the defective gene and having the disorder. Each child also has a 50% chance of receiving only one copy of the defective gene and being a carrier like each parent. Each child also has a 25% chance of receiving the normal gene from each parent, thereby being neither a carrier nor affected and having no chance of passing the gene to future generations.
- Males are more likely to have X-linked recessive disorders because they do not have a compensating X chromosome with a normal gene. Each son of a female carrier has a 50% chance of having the trait and a 50% chance of being unaffected. Each daughter of the female carrier has a 50% chance of being a carrier and a 50% chance of being unaffected.
- A trisomy exists when each body cell contains an extra copy of one chromosome. Down syndrome is the most common trisomy and involves three copies of chromosome 21, for a total of 47 chromosomes in each cell.
- A monosomy exists when each body cell is missing a chromosome. Turner's syndrome (a female with a single X chromosome) is the only monosomy compatible with postnatal life.
- Genetic material can be lost or duplicated when a chromosome has a structural abnormality. Also, the position of genes on the chromosome may be altered, preventing them from functioning normally.
- A parent with a balanced chromosomal translocation may have a child with completely normal chromosomes, or the child may have a balanced chromosomal translocation like that of the parent. The offspring may also receive an unbalanced amount of chromosomal material (too much or too little), which often results in spontaneous abortion or birth defects.
- Multifactorial disorders are typically present and detectable at birth. They are usually isolated defects rather than being present with other unrelated defects. However, sometimes the primary multifactorial defect alters further development and results in other related defects.
- Factors that may affect the likelihood that a multifactorial disorder will occur or recur include the following: the number of affected close relatives, severity of the defect in those affected, gender of the affected person, geographic location, and seasonal variations.
- The woman may be able to prevent exposing her fetus to teratogens by being immunized against infections such as rubella at least 28 days (1 month) before pregnancy, eliminating the use of non-therapeutic drugs such as alcohol and illicit drugs, changing therapeutic drugs to those having a lower risk to the fetus, and avoiding radiation exposure when she may be pregnant.
- A pregnant woman who has phenylketonuria should return to her low-phenylalanine diet when she is pregnant to prevent buildup of toxic products that would damage the developing fetus.
- Adequate folic acid intake of at least 0.4 mg (400 mcg) has been associated with a lower incidence of neural tube defects. Because the neural tube begins closure at 4 weeks of gestation, the woman should have adequate intake beginning before conception to ensure the best outcome.

CHAPTER 6

- Meiosis is a type of cell division that halves the number of chromosomes so that only one of each chromosomal pair goes into each gamete. Meiosis also promotes genetic variation by the process of crossing over, or exchange of chromosomal material between each member of the pair of chromosomes. The union of male and female gametes at conception restores the number of chromosomes to 46 in the offspring.
- Each oogonium produces one mature ovum after two meiotic divisions. The first meiotic division begins in fetal life and is not completed until shortly before that ovum undergoes ovulation. The second meiotic division begins at ovulation but is not completed unless fertilization occurs.
- Each spermatogonium undergoes two meiotic divisions to result in four mature spermatozoa. Meiosis begins at puberty, and both meiotic divisions are completed before the sperm mature and are ejaculated.
- Fertilization usually occurs in the distal third of the fallopian tube (the ampulla), near the ovary.
- Seminal fluid nourishes and protects the sperm from the acidic environment of the woman's vagina.

6. As sperm approach the ovum, they secrete hyaluronidase to digest a pathway through the corona radiata and zona pellucida. When one spermatozoon finally penetrates the ovum, changes in the zona pellucida prevent other spermatozoa from entering. The cell membranes of the ovum and sperm fuse to allow the sperm to penetrate the ovum. The ovum also completes its second meiotic division.
7. Fertilization is complete when the nuclei of the ovum and spermatozoon unite.
8. Implantation begins 6 days after conception and is complete by the tenth day.
9. The upper uterus is the ideal location for implantation for three reasons: (1) it has a rich blood supply for fetal gas exchange and nutrition, (2) the thick uterine lining prevents the placenta from attaching too deeply, and (3) the strong interlacing muscle fibers contract to limit blood loss after birth.
10. Nutritive fluids produced in the thick decidua pass to the conceptus by diffusion before a placental circulation is established. Primary chorionic villi, which will form the fetal side of the placenta, extend from the conceptus into the decidua basalis, which will become the maternal side of the placenta, to tap these nutrients.
11. During the first 8 weeks after conception, all major organ systems develop. The woman may be unaware that she is pregnant and may inadvertently expose the embryo to harmful substances. These substances may damage organs that are developing.
12. At 4 weeks the trachea develops as a bud of the upper digestive tract. After the trachea separates from the upper digestive tract, it branches into the two bronchi, which then divide to form the three lobes of the right lung and the two lobes of the left. Branching continues until terminal air sacs develop.
13. The intestines are contained mostly within the umbilical cord until 10 weeks because they grow more rapidly than the abdominal cavity and the liver and kidneys are relatively large. By 10 weeks after conception, the abdominal cavity has caught up with the growth of its contents and can accommodate them.
14. Gestational age is calculated from the woman's last menstrual period and is about 2 weeks longer than fertilization age. Gestational age is most commonly used because the menstrual period provides a specific marker. Ultrasound imaging may further clarify gestational age.
15. The fetus usually assumes a head-down position because this position best fits the egg shape of the uterus. Also, the head is heavier and tends to go downward with gravity in the pool of amniotic fluid.
16. Vernix caseosa protects fetal skin from constant exposure to amniotic fluid. Lanugo helps vernix adhere to the skin. Brown fat helps the infant maintain temperature stability in the cooler external environment. Surfactant keeps the lung alveoli from collapsing with each expiration, thus making breathing easier after birth.
17. The placenta gradually takes over the function of the corpus luteum and secretes estrogen and progesterone.
18. Exchange of oxygen, nutrients, and waste products between the woman and the fetus takes place in the intervillous spaces of the placenta.
19. Maternal and fetal blood may be of incompatible blood types and thus should not mix.
20. The fetus can thrive in a relatively low-oxygen environment because of the following:
 - a. Fetal hemoglobin carries more oxygen than adult hemoglobin.
 - b. The fetus has a higher hemoglobin and hematocrit level than does the newborn or adult.
 - c. Rapid diffusion of carbon dioxide into the maternal blood causes the mother to release oxygen more readily and causes oxygen to combine with fetal blood more readily.
21. Human chorionic gonadotropin (hCG) causes the corpus luteum of the ovary to persist and secrete estrogens and progesterone, which are essential to maintain the uterine lining for implantation. It also facilitates fetal testosterone secretion in the male fetus. Human placental lactogen promotes normal fetal nutrition and growth and maternal breast development. Estrogens cause enlargement of the woman's uterus and genitalia and enlargement and development of the breasts. Progesterone maintains the secretory endometrium and changes the endometrium into the decidua to nourish the conceptus; progesterone also reduces uterine contractions to prevent spontaneous abortion. Progesterone facilitates growth and development of the mother's breasts and the cells that will secrete milk. Progesterone may allow immune tolerance of the conceptus.
22. The fetal membranes contain the amniotic fluid that cushions the fetus and circulation within the umbilical cord, maintains a stable temperature, and promotes normal prenatal structural development.
23. Oxygenated blood enters the fetus through the umbilical vein. Half the blood goes to the liver, and the rest passes through the ductus venosus to the inferior vena cava. Blood enters the right atrium, where a small amount passes to the right ventricle and the rest flows through the foramen ovale to the left atrium and then to the left ventricle. Some blood from the right ventricle goes to the lungs to nourish their tissue, and the rest passes through the ductus arteriosus, where it joins blood ejected from the left ventricle. After circulation through the fetal body, deoxygenated blood returns to the placenta through the two umbilical arteries.
24. Monozygotic twins are conceived when one spermatozoon fertilizes one ovum and the resulting conceptus later divides into two inner cell masses that will become two fetuses.
25. The placentas and chorions may fuse before birth, making it difficult to determine whether the twins are monozygotic or dizygotic.
26. Dizygotic twins develop from two ova that are each fertilized by a spermatozoon and are like other siblings in a family.

CHAPTER 7

1. The fundus is midway between the symphysis and the umbilicus at 16 weeks, at the level of the umbilicus by 20 weeks, and to the xiphoid process at 36 weeks of gestation.
2. In late pregnancy, 17% of the cardiac output goes to the uterus and placenta with almost 90% of it going to the placenta.
3. The cervical mucous plug blocks ascent of bacteria from the vagina into the uterus, thereby protecting the fetus from possible infection.
4. The major purpose of progesterone in early pregnancy is to stop contractions, help prevent fetal tissue rejection, and, with estrogen, prevent ovulation.
5. During pregnancy the breasts enlarge and become more vascular; the areolae increase in size and become more pigmented; the nipples darken, enlarge, and become more erect; and Montgomery's tubercles become more prominent.
6. Expanded blood volume is needed for the added maternal tissues of pregnancy, to provide blood flow to the placenta, and to allow for loss of blood at childbirth.

7. Physiologic anemia of pregnancy is caused by a greater increase in plasma volume than in RBCs, resulting in a dilution but not inadequate hemoglobin concentration. Iron deficiency anemia is caused by a true lack of iron that affects hemoglobin levels.
8. In the supine position, the weight of the uterus on the vena cava and aorta impedes blood flow to and from the lower extremities, resulting in decreased cardiac output and supine hypotensive syndrome.
9. During pregnancy, increased circulation through the kidneys is needed to remove metabolic wastes generated by the mother and the fetus. Increased circulation through the skin is necessary to dissipate heat that is generated by accelerated metabolism.
10. Progesterone causes slight hyperventilation and increases sensitivity of the respiratory center to carbon dioxide leading to a feeling of dyspnea.
11. Flaring of the ribs, widening of the substernal angle, and increased circumference of the chest allow adequate intake of air with each breath.
12. Estrogen causes hyperemia of the gums that may lead to bleeding or gingivitis. Vascular hypertrophy of the gums (epulis) may occur. Excessive salivation (ptyalism) is a problem for some. Progesterone relaxes smooth muscle in the gastrointestinal tract, which may lead to heartburn and constipation. Emptying time of the gall bladder is increased and thicker bile and gallstones may result.
13. Expectant mothers are at increased risk for urinary tract infection because compression of the ureters between the uterus and the pelvic bones and dilation of the ureters and kidney pelvis cause stasis of urine allowing time for bacteria to multiply.
14. Relaxation of pelvic connective tissue and joints by relaxin and progesterone creates instability and results in a wide stance and “waddling” gait. Lordosis occurs when the large uterus causes the woman to lean backward to maintain her balance.
15. The hormones FSH and LH are suppressed during pregnancy by high levels of estrogen and progesterone to prevent ovulation. Progesterone maintains the endometrium and prevents menstruation.
16. Maternal hormones create increasing resistance of maternal tissues to insulin to provide glucose for the fetus. Normally, the mother produces more insulin to meet her needs.
17. Most, but not all, presumptive signs are subjective. Probable signs are objective. Both can have causes other than pregnancy.
18. Many things such as gas, peristalsis, or pseudocyesis (false pregnancy) can be mistaken by the woman for fetal movement.
19. Common causes of inaccurate pregnancy test results include a urine specimen that is too dilute or contains protein or blood, maternal ingestion of certain drugs such as some diuretics, anticonvulsants, antiparkinson drugs, hypnotics, or tranquilizers, incorrect testing procedure, or testing too early in the pregnancy.
20. A preconception visit identifies factors that may cause harm to the fetus or the mother so that steps can be taken before pregnancy occurs to avoid problems.
21. Medical, surgical, and obstetric histories are necessary to identify chronic conditions or past difficulties that might affect the outcome of the pregnancy.
22. All caregivers should use the same techniques to measure blood pressure because position and how the blood pressure is taken affect the results.
23. Major risk factors during pregnancy are age under 16 or over 35 years, low socioeconomic status, nonwhite race, multiparity, obesity, previous problem pregnancies, preexisting medical disorders or infections, and use of substances such as alcohol, tobacco, or illicit drugs.
24. The usual schedule of antepartum visits begins in the first trimester and continues every 4 weeks until 28 weeks, then every 2 weeks until 36 weeks, and weekly from 37 weeks to birth.
25. A gradual, predictable increase in uterine size occurs as gestation advances. From approximately 16 weeks until 38 weeks, fundal height in centimeters is nearly equal to gestational age in weeks within 3 cm (in women who are not obese) for a single fetus.
26. In multifetal pregnancies, increased blood volume results in additional work for the heart of the mother. The greatly increased size of the uterus causes greater elevation of the diaphragm and more compression of the large vessels, ureters, and bowel. Nausea and vomiting are more frequent.
27. Increased levels of estrogen and hCG and relaxation of the smooth muscle of the stomach are believed to be responsible for “morning sickness.”
28. Correct posture and body mechanics and exercises such as pelvic rocking can help alleviate backache during pregnancy. Wearing low-heeled shoes and application of heat or acupuncture may also help.

CHAPTER 8

1. The fetus seems vague and unreal during the first trimester. Gradually, physical changes (uterine growth, weight gain, quickening) confirm that a fetus is developing, and the expectant mother begins to perceive the fetus as a separate though dependent being.
2. The pregnant woman may have increased interest in sex during the first trimester unless she has nausea or fears miscarriage. Interest is often increased in the second trimester because of pelvic vasocongestion and a general feeling of well-being. The discomforts of the third trimester may decrease sexual responsiveness. Some expectant fathers are more interested in sex during pregnancy, but others find the pregnant woman unattractive and fear harming the fetus.
3. The pregnant woman explores the role of mother to develop a sense of herself in the role and selects behaviors that confirm her idea of fulfilling the role.
4. Pregnancy brings the realization that the woman will have to give up certain aspects of her previous life. This causes a temporary sadness.
5. Seeking safe passage involves going to a health care provider and following recommendations of the provider and of her culture.
6. **Reality boosters** include seeing the fetus via ultrasound, hearing the fetal heart, and feeling the fetus move. They are important in making the coming child seem real.
7. Nurses can help men gain recognition as parents by focusing on the father as well as the mother, encouraging the father’s questions, and including him in the plan of care.
8. Information about infant behavior and care is more relevant and therefore more useful after the infant is born.
9. The age of the grandparents, the number and spacing of other grandchildren, and their perceptions of their role help shape the way grandparents respond to an expected grandchild.
10. Toddlers do not understand that a birth is expected and should be told shortly before the expected date. Preschoolers may expect the infant to be a playmate near their age. School-age children may like to be involved and to help prepare for the birth. Adolescents may be embarrassed by evidence of their parents’ sexuality, indifferent to the pregnancy, or very involved in preparations.

11. Parents can make any changes in sleeping arrangements several weeks before the infant is born so that other children do not feel displaced by the newborn. They can increase time and attention to older children and reassure them of their love and acceptance.
12. Priorities of low-income families often focus primarily on present needs such as food and shelter and focus less on preventive activities such as prenatal care.
13. Some health care workers are unsympathetic to the plights of indigent families, who may experience long waits at understaffed health care facilities, hurried examinations, and rudeness.
14. Cultural differences that cause conflict between health care workers and families during pregnancy occur most often in the areas of health care beliefs, communication, and time orientation.
15. Cultural negotiation includes acknowledging that the family may hold different views, being sensitive to special concerns, and providing information in an acceptable manner.

CHAPTER 9

1. Weight gain helps determine fetal growth. Too little weight gain may be associated with low birth weight, and too much gain may be associated with large infants.
2. The average woman should gain 11.5 to 16 kg (25 to 35 lb). Underweight women and those carrying more than one fetus should gain more, and overweight women should gain less.
3. The average woman should gain approximately 0.5 to 2 kg (1.1 to 4.4 lb) the first trimester and 0.35 to 0.5 kg (0.8 to 1 lb) per week in the second and third trimesters.
4. Although no additional calories are needed during the first trimester, the recommendation for the second and third trimesters is 340 calories and 452 calories.
5. Approximately 71 g of protein per day, an increase of 25 g above prepregnancy needs, is recommended during pregnancy.
6. Fat-soluble vitamins (such as A, D, E, K) are stored in the fat and available longer than the water-soluble vitamins (such as B₆, B₁₂, folic acid, thiamine, riboflavin, niacin, C), which must be replenished daily. Excessive intake of fat-soluble vitamins is more likely to cause toxicity.
7. All women of childbearing age should have 400 mcg (0.4 mg) of folic acid daily to prevent birth of infants with neural tube defects from folic acid deficiency. Once pregnancy occurs 600 mcg (0.6 mg) of folic acid should be taken daily.
8. Iron, calcium, and folic acid are often below the recommended amounts in the diets of pregnant women.
9. Excessive intake of vitamins and minerals may result in toxicity and interfere with absorption of other vitamins and minerals.
10. During pregnancy a woman should drink 8 to 10 cups of fluids (mostly water) daily.
11. During pregnancy the woman should eat 7 to 9 oz of whole grains, 3 to 3 1/2 cups of vegetables, 2 cups of fruits, 3 or more cups or the equivalent from the dairy group, and servings equal to 6 to 6 1/2 oz from the protein group.
12. The nurse should consider traditional foods from the woman's culture, the degree to which she follows the traditional diet, and her inclusion of nontraditional foods in her diet.
13. The nurse should assess the woman's financial resources for food purchase, need for financial assistance, and education about nutrition.
14. The vegan can include nonanimal sources of iron, calcium, zinc, riboflavin, and vitamin B₆, B₁₂ and D and combine incomplete protein foods to ensure intake of all essential amino acids. She may also need to take supplements.
15. Lactose-intolerant women can choose calcium-containing foods such as leafy green vegetables, broccoli, peanuts, tofu, salmon, and sardines.
16. Other nutritional risk factors during pregnancy are excessive nausea and vomiting, anemia, abnormal prepregnancy weight, eating disorders, food cravings and aversions (including pica), multiparity, closely spaced pregnancies, multifetal pregnancy, and substance abuse.
17. The adolescent may skip meals and vitamin-mineral supplements and eat snacks and fast foods of low nutrient value to be like her peers.
18. The lactating woman needs more of many nutrients than the woman who is not pregnant. She needs to eat 330 more calories than her nonpregnant needs during the first 6 months of lactation and 170 calories will be drawn from her fat stores. During the second 6 months the lactating woman needs 400 calories daily more than the nonpregnant woman.
19. The woman who is not breastfeeding should decrease calories to her prepregnant level, continue to eat a well-balanced diet including enough protein and vitamin C, and plan to lose extra weight slowly.

CHAPTER 10

1. Major reasons for ultrasonography during the first trimester are to confirm pregnancy, verify gestational age, locate the embryo or fetus, determine multifetal pregnancy and gestational age, confirm viability, identify markers that suggest fetal abnormalities, and identify and guide chorionic villus sampling (CVS). Indications during the second and third trimesters are to confirm fetal viability, gestational age, and growth; evaluate fetal anatomy, umbilical cord and vessels, and placenta; evaluate multifetal pregnancies; locate the placenta; determine fetal presentation; evaluate amniotic fluid volume and fetal activity for biophysical profile; and guide needle placement for amniocentesis and umbilical cord sampling.
2. Transvaginal ultrasonography is most often performed during the first trimester, when the uterus lies within the pelvis. A transabdominal procedure is more common during the second and third trimesters, when the uterus is above the pelvic brim and the contents are clearly visible.
3. Major advantages of ultrasonography are that it allows clear visualization of the fetus and surrounding structures; it is safe, non-invasive, and relatively comfortable; and the results are available immediately. The major disadvantage is the cost. Also, ultrasonography may reveal findings that might indicate a problem but for which data are inadequate to make a clear diagnosis, thereby requiring further decisions by the woman and her support person.
4. MSAFP must be viewed as the first step in a series of diagnostic procedures offered if abnormal concentrations are found.
5. Elevated MSAFP may be caused by open neural tube defects, esophageal obstruction, open abdominal wall defects, and undetected fetal demise. Additional causes include multifetal gestation, inaccurate fetal age or maternal weight, and maternal diabetes.
6. Low levels of AFP suggest chromosomal abnormalities or inaccurate gestational age and maternal weight. Gestational trophoblastic disease may also cause low AFP levels.
7. Multiple-marker screening, often called *triple-marker screening* or other names, determines maternal serum levels of AFP, hCG, and unconjugated estriols. Elevation of hCG level with low levels of

AFP and estriols suggests chromosome abnormalities. Further testing with amniocentesis to positively identify the fetal karyotype will be offered to the woman if triple-marker screening is abnormal. A fourth marker that increases identity of chromosome abnormalities in the woman younger than 35 years is becoming more common and is often called a *quad screen*.

8. CVS is performed slightly sooner than even early amniocentesis, at 10 to 12 weeks of gestation. Obtaining information about fetal anomalies earlier in the pregnancy allows the woman to make a decision about pregnancy termination before the second trimester. CVS is more expensive than amniocentesis and does not provide amniotic fluid for analysis of the AFP level that might be needed to clarify MSAFP results.
9. Pregnancy loss after CVS is similar to loss rates after amniocentesis. The likelihood that chromosome findings will be questionable and lead to additional testing such as amniocentesis is greater.
10. Amniocentesis is most often performed to detect chromosomal abnormalities and other prenatally detectable genetic disorders or to identify if maternal sensitization to Rh-negative blood has affected the fetus. Additional indications include investigating abnormal levels of MSAFP, determining fetal lung maturity, and evaluating the fetus affected by Rh isoimmunization.
11. Fetal lung maturity is confirmed by a 2:1 ratio of lecithin/sphingomyelin and the presence of other lipoproteins such as PG and PI, which comprise pulmonary surfactant. A newer test (TDx) evaluates the quantity of surfactant in the amniotic fluid.
12. The degree of bilirubin staining of amniotic fluid reflects the degree of erythrocyte destruction in an Rh-positive fetus whose mother is Rh-sensitized.
13. Early amniocentesis has the same advantage as CVS: Information is available early in the pregnancy, allowing parents to make decisions about the pregnancy as early as possible. However, the amount of amniotic fluid that can be withdrawn may be inadequate for the indicated test(s) and there is a higher fetal loss rate.
14. A nonstress test (so-called because the fetus is not challenged or stressed to obtain data) measures acceleration of the fetal heart in response to fetal movement. Acceleration, even without fetal movement felt by the mother, provides reassurance of fetal health.
15. In vibroacoustic stimulation, an instrument similar to an artificial larynx is used to stimulate fetal movement and accelerations using sound and vibrations. Fetal accelerations are expected after stimulation. Otherwise, the procedure and interpretation are the same as those in a nonstress test. VAS should not be done earlier than 33 weeks' gestation.
16. A contraction stress test indicates fetal response to periodic hypoxia that occurs as a result of uterine contractions. Contractions are usually initiated by breast stimulation or by intravenous administration of oxytocin. As contractions compress the placental arterioles that supply oxygen to the fetus, a recurrent decrease occurs in fetal oxygen levels. No breast stimulation or oxytocin infusion is needed for the CST if the woman is having three spontaneous contractions in a 10-minute time frame.
17. Late decelerations in a CST indicate fetal oxygen reserves are not adequate to tolerate contractions, and fetal acidosis, myocardial depression, or both may result.
18. Loss of fetal tone in a biophysical profile indicates advanced hypoxia and fetal acidosis. Fetal tone develops early in gestation and is one of the parameters of the biophysical profile that is most resistant to the effects of hypoxia.
19. Decreased amniotic fluid volume is associated with prolonged fetal hypoxia, in which blood is shunted away from the fetal lungs

and kidneys, which produce amniotic fluid, and toward vital organs such as the fetal heart and brain.

CHAPTER 11

1. The goals of perinatal education are to help women and their support persons become knowledgeable consumers, active participants in pregnancy and childbirth, and to provide coping techniques for pregnancy, birth, and parenting.
2. Couples must choose their health care provider, birth setting, support person(s), presence of siblings, and education for preparation (if any).
3. Early pregnancy classes emphasize adapting to pregnancy changes, self-care, coping with common discomforts, and learning what to expect in later pregnancy. Later classes discuss preparation for childbirth, the postpartum period, breastfeeding issues, and parenting concerns.
4. Every couple has a chance that cesarean birth may be needed. Therefore all women need to know about cesarean birth.
5. Classes for family members help ease family transition by providing information and opportunities for discussing common feelings.
6. Education, relaxation, and conditioning reduce pain and increase coping ability for childbirth by helping to decrease muscle and mental tension.
7. Cutaneous stimulation and imagery help reduce pain by sending other messages to the brain so that pain messages are not recognized as strongly and perception of pain is reduced.
8. Breathing techniques are used to enhance relaxation to help the woman work with her labor during labor.
9. Having a support person during labor increases a woman's satisfaction by helping her cope with stress, focus on her learned techniques, and feel that her experience is being shared.
10. Various support roles include active assistance and physical care, verbal encouragement, minimal physical assistance, and presence without active involvement.
11. Specific techniques used by support persons during labor include assistance with relaxation and breathing, encouragement, sacral pressure, massage, and comfort measures such as back rubs, ice chips, and fanning the woman.

CHAPTER 12

1. Effacement and dilation of the cervix occur because contractions pull the cervix upward over the fetus and amniotic sac while pushing the fetus and amniotic sac downward against the cervix. The muscle fibers of the upper uterus become shorter to maintain these forces between contractions. In addition, the uterus changes shape and becomes more elongated and narrow to maintain pressure of the fetus and amniotic sac against the cervix.
2. The cervix of the nullipara effaces more before it dilates. The cervix of a multipara is usually thicker than that of a nullipara during the entire labor.
3. Maternal changes occurring during labor include the following:
 - a. *Cardiovascular system*—A slight increase in blood pressure and decrease in pulse rate occur as each contraction temporarily stops blood flow to her uterus. Supine hypotension may occur if she lies on her back because the heavy uterus compresses her inferior vena cava and reduces blood flow to her heart.
 - b. *Respiratory system*—The depth and rate of respirations increase.

- c. *Gastrointestinal system*—Although a controversial belief, many authorities think that peristalsis slows during labor.
- d. *Urinary system*—The sensation of a full bladder is reduced.
- e. *Hematopoietic system*—Leukocyte counts are as high as 25,000/mm³ or more, and levels of clotting factors are elevated.
4. Uterine contractions temporarily stop blood flow to the placenta. If the contractions were sustained, the fetus could not receive freshly oxygenated blood and nutrients and dispose of waste products through the placenta.
 5. Labor and vaginal birth benefit the newborn by increasing absorption of fetal lung fluid and compressing the upper airways, causing some lung fluid to be expelled. These effects reduce the amount of lung fluid remaining in the newborn's respiratory tract when breathing begins. Labor also stimulates the fetus to secrete catecholamines, which help speed clearance of the lung fluid after birth, stimulate cardiac contraction and breathing, and aid in temperature regulation.
 6. The power of labor during the first stage of labor involves uterine contractions. Powers during the second stage include uterine contractions, augmented by the woman's voluntary pushing efforts.
 7. The three divisions of the true pelvis are the inlet, midpelvis, and outlet.
 8. The vertex presentation, in which the fetal head is fully flexed forward, allows the smallest diameter of the fetal head to enter the pelvis. It also more effectively dilates the cervix.
 9. ROP: The fetal landmark is the occiput, indicating a vertex presentation. It is located in the mother's right posterior pelvic quadrant. OA: The fetal landmark is the occiput, which is located in the mother's anterior pelvis and is not directed toward her left or her right. This is often the presentation just before birth. RSA: The fetal landmark is the sacrum, indicating that the fetus is in a breech presentation. It is located in the mother's right anterior pelvis. LMA: The fetal landmark is the mentum, or chin, indicating that the fetus is in a face presentation. The chin is in the mother's left anterior pelvis.
 10. If the fetus is in a face presentation, the occiput is not accessible to the examiner's fingers during vaginal examination. For this reason the fetal chin (mentum) is used to describe the position (such as RMA [right mentum anterior]).
 11. The woman may note several changes as labor approaches: increased strength and frequency of Braxton Hicks contractions, lightening, increased vaginal mucus, bloody show, an energy spurt, and a small weight loss.
 12. False labor tends to differ from true labor in three major ways. True labor is characterized by contractions that progressively become more frequent, last longer, and are more intense. The discomfort of true labor begins in the lower back and sweeps to the lower abdomen, whereas the discomfort of false labor is more often in the abdomen or groin and is often simply annoying. In true labor, progressive effacement and dilation of the cervix occur, which is the most significant difference from false labor.
 13. The transverse diameter of the pelvic inlet is slightly larger than the inlet's anteroposterior diameter. The anteroposterior diameter of the fetal head (in line with the sagittal suture) is slightly larger than the transverse diameter. Therefore the fetal head best fits the pelvis if the sagittal suture is aligned with the pelvic transverse diameter at entry.
 14. Because the woman's pelvic outlet is usually slightly larger in its anteroposterior diameter than its transverse diameter, the fetal head turns in the mechanism of internal rotation so that the sagittal suture aligns with the anteroposterior diameter as the fetus descends.
 15. During the first stage, latent phase, the woman is often sociable, excited, and somewhat anxious. During the first stage, active phase, the woman becomes less sociable and is inwardly focused. During the first stage, transition phase, the woman may become irritable and temporarily lose control. During the second stage, the woman usually concentrates her energy toward pushing her baby out and interacts little with others. She often regains a feeling of control and active participation in the birth during second stage.
 16. Contractions vary among women, but the general pattern includes increasing frequency, duration, and intensity throughout labor. In the first stage, latent phase, contractions gradually increase until they are about 5 minutes apart, lasting for 30 to 40 seconds with mild to moderate intensity. In the first stage, active phase, contractions increase to about 2 to 5 minutes apart with a duration of about 40 to 60 seconds and moderate to strong intensity. In the first stage, transition phase, contractions are strong with a frequency of 1½ to 2 minutes apart and a duration of 60 to 90 seconds. In the second stage, contractions are strong and about 2 to 3 minutes apart and have a duration of about 40 to 60 seconds.
 17. Signs that the placenta may have separated include a spherical uterine shape, the rising of the uterus upward in the abdomen, protrusion of the umbilical cord farther outward from the vagina, and a gush of blood.
 18. Hemorrhage may occur if the uterus does not remain contracted after birth of the placenta because open blood vessels at the site will not be compressed by the interlacing muscle fibers of the uterus.

CHAPTER 13

1. The nurse should show warmth, concern, and friendliness when the woman and her family enter the hospital or birth center. Determining the woman's and family's expectations about birth, conveying confidence, assigning a primary nurse, and respecting cultural values are specific skills that the nurse can use throughout labor. In addition, a nonjudgmental attitude facilitates communication and shows respect to the woman as an individual.
2. The nurse should try to identify and incorporate beneficial or neutral cultural practices into care during labor and birth by asking about specific practices that are important during birth and facilitating communication by obtaining a fluent interpreter who is acceptable to the woman and her family.
3. The nurse should promptly evaluate the maternal and fetal conditions and the nearness of birth when a woman comes to the hospital or birth center. Prompt assessments should include checking the maternal vital signs, fetal heart rate and patterns, and progress of labor.
4. A lower limit of 110 bpm and an upper limit of 160 bpm with a regular rhythm are reassuring. When assessing FHR with a continuous electronic fetal monitor, accelerations and the absence of nonreassuring decelerations from the baseline also are reassuring.
5. Impending birth should be suspected if the woman is grunting, bearing down, sitting on one buttock, or urgently signifying that her baby is about to be born. In that case, the nurse should abbreviate the initial assessment and collect other information after the birth.
6. Two tests assist the nurse, nurse-midwife, or physician to determine whether a woman's membranes have ruptured: the pH test and examination of the amniotic fluid under a microscope for ferning.

7. Hypertonic contractions (too frequent, too long, or an inadequate rest period) reduce blood flow to and from the placenta. This interferes with fetal oxygenation and waste disposal.
 8. Routine FHR assessments in uncomplicated labor are documented at least hourly during latent (early) labor, every 30 minutes during active labor, and every 15 minutes during the second stage. The FHR should be assessed after the membranes rupture to detect whether the fetal umbilical cord was displaced with the gush of fluid and is being compressed between the fetal presenting part and maternal pelvis.
 9. Greenish amniotic fluid contains meconium, which may have been passed by the fetus in response to transient hypoxia. Cloudy, yellowish, or foul-smelling fluid suggests infection in the amniotic sac.
 10. Frequent vaginal examinations may cause infection because microorganisms from the perineal area can be introduced into the uterus.
 11. The woman may specifically request other pain management measures including epidural analgesia or other medication, express ineffectiveness of nonpharmacologic measures, show muscle tension during and between contractions, have a tense facial expression, and express an inability to tolerate the pain.
 12. Hypotension reduces blood flow to the placenta and therefore reduces fetal oxygenation because it diverts blood away from the uterus to better supply the mother's brain, heart, and kidneys. Hypertension may result in vasospasm that can reduce exchange of oxygen, nutrients, and waste products in the placenta. Fetal hypoxia and acidosis can be the ultimate result of maternal hypotension and hypertension.
 13. The supine position allows the heavy uterus to compress the mother's inferior vena cava, reducing blood return to her heart and reducing placental blood supply. A small wedge under her hip, such as a small pillow or rolled towel, is effective to relieve vena cava compression.
 14. General physical comfort measures during labor include soft, dim lighting, a comfortable temperature, maintenance of cleanliness, mouth care, observations for a full bladder, positions for comfort, and a warm bath or shower. Caring for the support person includes respect for the couple's wishes about partner involvement in the birth process. The nurse should provide support that the partner cannot and should consider physical needs for food and rest.
 15. Shortly before birth, the woman's perineum bulges and the fetal head becomes visible as the mother pushes. At this time birth can occur suddenly.
- absolute indications exist for continuous electronic fetal monitoring, most hospitals use it in both low- and high-risk intrapartum care.
 4. Intermittent auscultation promotes the laboring woman's mobility and creates a more natural atmosphere. However, it can assess the fetus for only part of labor, may be distracting for some women, and may require more staff. Continuous electronic fetal monitoring provides more data, is often expected by parents, and can assist the nurse to better observe more than one woman. It allows the nurse to devote more time to coaching the woman and her partner. Its primary drawbacks are reduced maternal mobility, adjustments to the equipment, and its technical atmosphere.
 5. The upper grid on the paper strip of the electronic fetal monitor records the constant changes in the fetal heart rate. The lower grid records contractions as a series of bell-shaped curves. Other information that may be printed on the strip includes maternal blood pressure and information charted by the nurse with data entry devices. Fetal pulse oximetry data may be recorded on monitors equipped with this technology. The "paper strip" may be on a computer screen rather than printed.
 6. The Doppler ultrasound transducer senses fetal heart motion and translates the motion into a heart rate.
 7. Four factors may affect the accuracy of the external uterine activity monitor: fetal size, maternal abdominal fat thickness, maternal position, and location of the transducer.
 8. The two types of internal uterine activity catheters are the solid and the fluid-filled catheter. The solid catheter tends to record higher intrauterine pressures because it senses fluid pressure above its sensor inside the uterus. The fluid-filled catheter can be affected by its height in relation to the mother's transducer.
 9. Fetal heart rate accelerations are a reassuring sign of fetal responsiveness and nonacidosis.
 10. In early decelerations, the fetal heart rate slows after the contraction begins and returns to the baseline rate by the end of the contraction. Early decelerations are caused by fetal head compression and are reassuring. Late decelerations are characterized by slowing of the fetal heart rate late in the contraction cycle after the peak. They do not return to the baseline until after the contraction has ended. Late decelerations are associated with decreased uteroplacental perfusion and are nonreassuring.
 11. Variable decelerations show a fetal heart rate that rises and falls abruptly. They are not consistent in appearance and may not occur at similar times in relation to the contractions. They are caused by compression of the umbilical cord.
 12. Fetal scalp stimulation or vibroacoustic stimulation may be done to clarify fetal heart rate patterns as reassuring (normal), indeterminate (equivocal, ambiguous), or nonreassuring (abnormal) when they are vague. The reassuring response to stimulation is an increase in the fetal heart rate, peaking 15 bpm above the baseline for at least 15 seconds in the term fetus. This suggests that the fetus has a normal oxygen and acid-base balance.
 13. Cord blood gas and pH analysis assesses the newborn's oxygen and acid-base status immediately after birth and identifies if the fetus was adjusting to the stresses of labor.
 14. Basic nursing actions for nonreassuring (abnormal) fetal heart rate patterns vary according to the pattern. They include identifying the cause of a nonreassuring pattern by vaginal examination; taking corrective actions such as taking maternal vital signs, reviewing medications, or applying internal monitoring; increasing placental perfusion by reducing excess uterine activity and positioning the woman on her side; giving the mother oxygen;

CHAPTER 14

1. Fetal oxygenation depends on normal maternal blood flow and volume; normal oxygen saturation of the maternal blood; adequate oxygen-carbon dioxide exchange in the placenta; patent umbilical cord vessels; and normal fetal circulatory and oxygen-carrying function.
2. When the umbilical cord is compressed, the umbilical vein is compressed first, resulting in slight fetal hypotension and acceleration of the fetal heart rate. Continued compression obstructs the umbilical arteries, resulting in fetal hypertension and slowing of the fetal heart rate. As compression is relieved, these changes are reversed.
3. Fetal monitoring should be done more frequently if risk factors are present. These may include antepartum factors in the woman's history or course of pregnancy. They may also include problems in the woman or fetus that develop intrapartally. Although no

and reducing cord compression by position changes and amnioinfusion.

15. A tocolytic drug reduces the intensity and frequency of uterine contractions, thus allowing more time for the placenta to be supplied with oxygen-rich maternal blood.
16. Amnioinfusion may be used to replace the fluid cushion around the umbilical cord, reducing compression. It may also be used to dilute thick meconium to reduce its aspiration by the newborn, although evidence has not proven amnioinfusion effective for this purpose.

CHAPTER 15

1. Childbirth pain differs from other painful experiences because it is part of a normal process, the woman has time to prepare for it, it is self-limited and intermittent, and it ends with the birth of the baby.
2. Excessive, unrelieved labor pain may result in a stress response (diverting blood flow from the uterus and compromising fetal oxygenation), maternal acid-base imbalance, and fetal acidosis. It may increase the length of labor. Poor pain relief can lessen the joy of childbirth for the woman and her partner and may have lasting psychological effects.
3. Physical and psychological factors interact to alter the ability to tolerate pain. For example, relaxation and working with the forces of labor enhance the chance that the woman who has a large baby and a small pelvis will give birth vaginally.
4. Four sources of pain present in most labors are cervical dilation, uterine ischemia, pressure and pulling on pelvic structures, and distention of the vagina and perineum.
5. Physical factors that influence pain include the following:
 - a. A short, intense labor may be more painful because dilation, effacement, and fetal descent occur rapidly.
 - b. A cervix that does not efface or dilate easily is likely to be associated with a longer and more uncomfortable labor.
 - c. An abnormal fetal position may cause a longer labor as the woman's body maneuvers it into a better position. Back pain is especially noticeable if the fetus is in an occiput posterior position.
 - d. Variations in the mother's pelvic size or shape may result in abnormal fetal presentations or positions and in a longer labor because the fetus does not fit through the pelvis easily.
 - e. Fatigue reduces the woman's pain tolerance and ability to use coping skills.
6. Psychosocial factors that influence labor pain include culture, anxiety and fear, previous experiences, preparation for childbirth, and the mother's support system.
7. The gate control theory of pain assumes that a gating mechanism in the dorsal horn of the spinal cord controls the transmission of painful impulses to the brain for interpretation. Pain impulses are transmitted through small-diameter fibers, whereas other sensations, such as tactile sensations (e.g., massage, heat, cold), are transmitted more quickly through large-diameter fibers. Therefore the impulses transmitted through the large-diameter fibers interfere with or "close the gate" to transmission of pain impulses. Impulses from the brain, such as responses to auditory stimuli (listening to music, for instance), can also impede pain transmission.
8. Nursing actions to promote relaxation include arranging for environmental comfort, maintaining the woman's general comfort, reducing factors that cause anxiety and fear, and using specific relaxation techniques such as helping the woman focus on relaxing specific tense muscles.
9. Accurate information and a focus on the normal aspects of childbirth help reduce anxiety and fear. Avoid referring to the woman as a *client* or *patient* because these words are associated with illness in a hospital. Call her and her partner by the names they requested when admitted. Empowerment of the birthing partners helps them see themselves as competent to give birth successfully.
10. Self-massage might include effleurage, rubbing the hands together, patting or banging the hands on the rail. Massage by others helps relax tense muscles and aids relaxation. Counterpressure, which may include sacral pressure or other variations, is often used to reduce back pain when the fetus is in an occiput posterior position. Acupressure uses directed pressure for pain management. Warmth relaxes muscles, promoting relaxation. Warmth may be in the form of a shower, tub bath, or whirlpool. Cool often feels better to the laboring woman who may be hot, or she may want cool only in a local area or ice in her mouth.
11. Hydration must be adequate to offset the diuresis that often occurs with immersion in water. Diuresis could reduce placental perfusion if plasma volume is low. Water temperature must be controlled to prevent hyperthermia or hypothermia, which could raise the mother's metabolic rate, increasing her oxygen and glucose consumption. These changes could reduce oxygen and glucose delivered to the fetus. Hyperthermia in the mother increases fetal body temperature and increases fetal demand for oxygen.
12. The more complex breathing techniques are more effective for greater pain, but they are tiring. Advancing from simpler to more complex breathing techniques too quickly can cause the mother to become fatigued when she most needs to use these methods.
13. The cleansing breath has four purposes: (a) to release tension; (b) to increase oxygen intake to combat myometrial hypoxia; (c) to clear the woman's mind so she can focus on relaxing through the contraction; and (d) to signal her labor partner that a contraction has begun.
14. Lengthy pushing in second stage has shown greater maternal fatigue, more operative births, and nonreassuring fetal heart rate (FHR) patterns and does not significantly shorten second stage. Strenuous directed pushing has shown a greater risk for structural and neurogenic injury to a woman's pelvic floor. Closed glottis pushing delivers less blood to the placenta possibly resulting in fetal hypoxia and nonreassuring fetal heart monitor patterns.
15. Drugs taken by the mother can affect the fetus directly, such as by decreasing fetal heart rate variability, or indirectly, such as by causing maternal hypotension that reduces placental blood flow and fetal oxygen supply.
16. Aortocaval compression should be offset by placing a wedge under the woman's hip if a supine position is required. Tilting the patient table during surgery reduces compression until the infant is born. The woman is more sensitive to general anesthesia and may have a greater fall in oxygenation when general anesthesia is induced. Reduced peristalsis and tone of the sphincter at the junction of the esophagus and stomach can lead to regurgitation and aspiration of gastric contents, primarily with general anesthesia. Lower doses of anesthetic agents will be needed for epidural or subarachnoid blocks.
17. Drugs (prescribed, over-the-counter, or illicit), botanical preparations, and alcohol may interact with one another. These interactions may be harmful to the woman, the fetus, or both. Knowledge of exactly what drugs she uses allows the safest choices in pharmacologic pain-relief methods.

18. Neonatal respiratory depression is the primary drawback to the use of opioid analgesia. This effect can be reduced by timing the dose to reduce the amount transferred to the fetus (which varies according to the drug) and by giving the narcotic in small, frequent, IV doses at the beginning of the contraction. Naloxone (Narcan) is the drug that may be given to reverse opioid-induced respiratory depression in the neonate, with bag-and-mask ventilation being the initial method to oxygenate the infant.
19. Because naloxone's effects are shorter than those of the narcotic, the nurse must observe the newborn for a recurrence of respiratory depression.
20. To prevent possible tissue damage from the vesicant, or blistering, effects of promethazine, IV administration should be done in a highly diluted form and follow facility protocol.
21. The two major advantages of regional pain management are that the woman can have pain relief and remain alert.
22. Epidural and subarachnoid blocks can cause maternal hypotension. The fall in blood pressure may result in reduced placental blood flow, compromising fetal oxygen supply. Giving the woman IV fluids before the block reduces this effect. Other less serious adverse effects are bladder distention, prolonged second stage of labor (epidural), and postdural puncture headache (usually only subarachnoid block).
23. Epidural or intrathecal opioid analgesics may cause nausea, vomiting, itching, or a combination of these. They may also result in delayed respiratory depression (up to 24 hours), depending on the drug used. Management includes promethazine for nausea and vomiting; diphenhydramine, naloxone, or naltrexone for itching; and pulse oximetry and monitoring of respirations while the opioid is given and up to 24 hours after administration ends, depending on the drug.
24. Maternal regurgitation with aspiration of acidic gastric contents is the major potential adverse effect of general anesthesia. The risk may be reduced by limiting intake to clear fluids, giving drugs to raise the gastric pH, giving drugs to reduce gastric secretions or speed emptying of the stomach, and using cricoid pressure (Sellick maneuver) to block the esophagus while the endotracheal tube is being inserted. Respiratory depression, primarily in the infant, is minimized by delaying general anesthesia until the surgery team is prepared and by keeping the anesthesia level as light as possible until the umbilical cord is cut.
 - c. Starting the oxytocin infusion slowly
 - d. Increasing the rate of infusion gradually
 - e. Monitoring uterine contractions and FHR
6. Labor may be augmented if it stops or contractions become ineffective. The woman whose labor is augmented with oxytocin usually needs less of the drug than the woman whose labor is being induced, because her uterus is more sensitive to its effects.
7. The fetus may have an adverse reaction to oxytocin, manifested by nonreassuring FHR patterns such as bradycardia, tachycardia, late decelerations, or decreased FHR variability.
8. Signs of tachysystole, or hypertonic uterine activity, include contraction durations >90 to 120 seconds or <2 minutes apart, incomplete relaxation of the uterus between contractions, or rest periods <30 seconds. With internal contraction monitoring, tachysystole may be evidenced by a uterine resting tone >20 mm Hg, peak pressures >90 mm Hg during first stage, or Montevideo units exceeding 400, which may result in inadequate placental blood flow and a fall in fetal oxygenation. Nonreassuring FHR patterns may occur even if these signs of tachysystole are not present.
9. Administration of oxytocin for a prolonged time may lead to postpartum hemorrhage because the fatigued uterus cannot contract properly to compress bleeding vessels at the placenta site (uterine atony).
10. The FHR should be monitored before external version to identify nonreassuring patterns that would preclude the procedure and to establish a baseline. It should be monitored (by Doppler or real-time ultrasound) as much as possible during and after external version to detect cord compression that can occur if the umbilical cord becomes entangled during change of the fetal presentation. FHR assessment will continue if induction is started after a successful version.
11. Uterine activity should be observed after external version for possible onset of labor because this procedure may cause uterine irritability or possible abruptio placentae; therefore the procedure is done near term.
12. Forceps and vacuum extraction are used to provide traction to assist the mother in rotation, expulsion, or both, of the fetal head. Special forceps (Piper) can be used to deliver the aftercoming head of the fetus in a breech presentation, but a vacuum extractor can be used only with a cephalic presentation. Forceps may cause fetal injury such as facial bruising and nerve injury. The vacuum extractor may create an artificial caput called a *chignon*. No more than 3 "pop-offs" should be done and these should not be followed by forceps attempts at vaginal birth.

CHAPTER 16

1. Three major risks of amniotomy are prolapsed umbilical cord, infection, and abruptio placentae.
2. The FHR is assessed before the membranes are ruptured to identify whether the fetus has a normal rate and pattern and to establish a baseline. It is checked after the membranes are ruptured to identify patterns that suggest umbilical cord compression and other problems.
3. Green amniotic fluid contains meconium, passed from the fetal intestines. It may be seen in post-term gestation or placental insufficiency.
4. Signs of chorioamnionitis include fetal tachycardia (often the first sign), elevated maternal temperature, and amniotic fluid that has a foul or strong odor or a cloudy or yellowish appearance.
5. Five precautions that promote safe oxytocin induction or augmentation of labor include the following:
 - a. Dilution of the oxytocin in an isotonic solution
 - b. Piggybacking the oxytocin solution into the port of the primary nonadditive (maintenance) IV line that is nearest the venipuncture site
13. Catheterization before forceps are used eliminates a full bladder, which would reduce available room in the pelvis. Emptying the bladder also reduces the risk of bladder injury.
14. Use of cold immediately (for the first 12 hours) after episiotomy reduces pain, edema, and formation of hematomas. The nurse should also observe for continuous, bright red bleeding that suggests a vaginal wall laceration. Warmth after at least 12 hours of cold application promotes resolution of the edema and hematoma.
15. The infant with an asymmetric facial appearance when crying may have facial nerve injury, usually a temporary condition that sometimes occurs when forceps are used to assist birth.
16. The low transverse uterine incision is less likely to rupture during another pregnancy than either of the two vertical incisions. There are, however, valid reasons for the use of vertical incisions.

17. The woman expecting a cesarean birth should be taught about the following regarding the operating room and recovery area:
 - a. Preoperative procedures, such as skin preparation and insertion of an indwelling catheter
 - b. Personnel who will be present and their functions
 - c. The narrow table, safety strap, and positioning measures
 - d. When her partner or support person can come in
 - e. If a regional anesthetic is planned, she will be awake and feel pulling and pressure sensations but should not expect pain. If a general anesthetic is planned, all preparations will be made before anesthesia is induced but the surgery will not begin before she is asleep and she will not awaken during it.
 - f. In the recovery area, use of oxygen, pulse oximeter, and automatic blood pressure cuff for vital signs; checking of her fundus, incision, lochia, and pain-relief needs
18. The woman who has cesarean birth needs care similar to that of the woman who delivers vaginally, in terms of vital signs and fundus and lochia assessments. Additional care includes assessment of oxygen saturation and respiratory status, observation of urine output from the indwelling catheter, observation of the incision line pain needs, and respiratory care (turning, coughing, deep breathing). Anesthesia-related care includes level of consciousness (primarily if general anesthesia was used) and return of movement and sensation (primarily if epidural or subarachnoid block was used).
 9. Breastfeeding delays the return of both ovulation and menstruation.
 10. Women lose approximately 4.5 to 5.8 kg (10 to 13 lb) during childbirth. They often lose another 3.2 to 5 kg (7 to 11 lb) by the end of the first week.
 11. Orthostatic hypotension results from engorgement of visceral blood vessels from decreased intraabdominal pressure after delivery. Signs and symptoms include a 15 to 20 mm Hg drop in systolic blood pressure, dizziness, lightheadedness, or faintness when the woman moves from lying down to sitting or standing.
 12. When tachycardia is noted, assessment of BP, temperature, location and firmness of the fundus, amount of lochia, estimated blood loss at delivery, hemoglobin, hematocrit, and degree of pain are necessary to help identify the cause. Excitement, pain, anxiety, fatigue, dehydration, anemia, infection, or hypovolemia may cause tachycardia.
 13. Uterine massage is necessary when the uterus is not firmly contracted. The nurse places the nondominant hand above the woman's symphysis pubis to anchor and support the uterus during massage.
 14. A cervical or vaginal laceration may cause excessive bleeding even when the uterus is firmly contracted.
 15. Assessment of pain, frequent respiratory assessments, auscultation of breath sounds and bowel sounds, inspection of the surgical dressing and wound, and intake and output are necessary for the postcesarean mother.
 16. Hypostatic pneumonia can be prevented by frequent turning, coughing, breathing deeply, and ambulating early and frequently.
 17. Early ambulation, tightening and relaxing the abdominal muscles, restriction of carbonated beverages and straws for drinking, pelvic lifts, and simethicone or rectal suppositories as ordered prevent or minimize abdominal distention.
 18. Wearing a well-fitting bra or sports bra helps suppress lactation. Avoiding warm water directly on the breasts and not pumping or massaging the breasts are also important.
 19. Providing adequate information in a short time is a major problem in preparing parents for discharge.
 20. Before discharge, the nurse should be sure that the mother has no complications and all assessments and laboratory work are normal. Ambulation and ability to eat and drink should be normal. The mother should indicate understanding of self-care instructions, signs of complications and proper responses, and infant care. Postpartum follow-up care should be arranged. She should have adequate support during the early days after discharge.

CHAPTER 17

1. The three processes involved in involution are contraction of muscle fibers, catabolism, and regeneration of uterine epithelium.
2. The fundus is expected to descend 1 cm (approximately 1 finger-breadth) per day so that by the fourteenth day after birth it cannot be palpated in the abdomen.
3. A multipara is expected to experience afterpains because repeated stretching of the uterus makes continuous uterine contraction more difficult. Overdistention of the uterus and breastfeeding also cause afterpains. Afterpains are treated with analgesics. Lying in a prone position also provides relief.
4. Lochia rubra is red, consists mostly of blood, and lasts for 1 to 3 days. Lochia serosa is pink to brown-tinged and usually lasts from the third to tenth days. Lochia alba is white, cream, or yellowish and may last until 3 to 6 weeks after delivery.
5. The WBC count is normally elevated to an average of 14,000 to 16,000/mm³ after childbirth, although it may rise to 30,000/mm³. If the woman has a fever or is at increased risk for infection, the nurse should be especially alert for a WBC count that increases over 30% in 6 hours and other signs of infection.
6. The postpartum woman is at risk for urinary retention because her bladder is less sensitive to fluid pressure, decreasing the urge to void even when the bladder is distended. Trauma of childbirth and lingering effects of regional anesthesia may also make it difficult to void. Urinary tract infection is more likely because stasis of urine allows time for bacteria to multiply. Excessive postpartum bleeding may occur because a full bladder displaces the uterus, causing the uterine muscles to relax.
7. Hyperpigmentation decreases because estrogen, progesterone, and melanocyte-stimulating hormone decrease rapidly after childbirth.
8. Menses will resume about 6 to 8 weeks for 40% to 45% of women who are formula feeding, for 75% by 12 weeks, and for all by 6 months. The breastfeeding woman may begin menses between 12 weeks and 18 months after childbirth.

CHAPTER 18

1. Bonding describes the initial attraction felt by the parents for the infant. Attachment is the development of an enduring, loving relationship between parents and child. It is progressive and requires response from the infant.
2. Maternal touch may progress from fingertipping in the discovery phase to stroking, then enfolding the infant, and then to consoling behaviors.
3. Parents progress from referring to the newborn as "it" to "he" or "she" and then to using the given name. Parents who know the sex of the baby before birth may call the infant by name from before birth.
4. The mother is focused primarily on her own needs during the taking-in phase. She often is passive and dependent and repeatedly recounts her birth experience. In the taking-hold phase, she

- becomes more independent, focuses on the infant, and exhibits a heightened readiness to learn.
5. In the letting-go phase, parents relinquish previous lifestyle patterns to assume the parenting role.
 6. The anticipatory stage begins during pregnancy as women prepare for the birth. The formal stage begins with birth as they become acquainted with the baby. During the informal stage, parents respond to their infant's unique cues rather than relying on directions from others. The personal stage is attained when the mothers feel comfortable with their roles as parents.
 7. "Heading toward a new normal" involves appreciating the body, settling in, and becoming a new family.
 8. Postpartum blues may be related to emotional letdown, discomfort, fatigue, and anxiety about parenting and body image. Nurses can provide reassurance to the mother and teach the family about the condition, the length of time it may last, and the mother's needs at this time.
 9. Fathers who are sometimes ignored and not included in infant care may feel left out and unneeded.
 10. Siblings may feel jealousy and fear that they will be replaced by the newborn in the affection of the parents.
 11. Time must be allowed for the parents to form attachment with each newborn individually after a multifetal pregnancy. Concerns over the health of the infants and about finances may interfere with attachment.
9. Stools progress from thick, greenish-black meconium to loose greenish-brown transitional stools to milk stools that are frequent, soft, seedy, and mustard-colored if the infant is breastfed, and pale yellow or light brown, firmer, and less frequent if formula fed.
 10. Hypoglycemia is a problem for the newborn because glucose is the major source of energy in the brain.
 11. Infants have an immature liver and more hemolysis of erythrocytes than adults. Trauma at birth, poor early feeding, and an intestinal enzyme that deconjugates bilirubin also increase jaundice.
 12. Physiologic jaundice occurs in normal newborns after the first 24 hours of life as a result of hemolysis of unneeded red blood cells and immaturity of the liver. Nonphysiologic jaundice is generally a result of excessive destruction of erythrocytes, causing bilirubin levels to rise faster and higher than in physiologic jaundice. It begins within the first 24 hours and may necessitate phototherapy. True breast milk jaundice lasts longer than physiologic jaundice and may result from substances in the milk.
 13. The newborn's body is composed of a greater percentage of water with more located in the extracellular compartment than the adult's body.
 14. Newborns receive passive immunity to infections when IgG crosses the placenta *in utero*. After birth, infants produce IgM and IgA to protect against infection. IgM rises in response to infection. IgA helps protect the gastrointestinal and respiratory tracts from infection and is present in breast milk.
 15. During both periods of reactivity, newborns are active and alert, may be interested in feeding, have elevated pulse and respiratory rates, and may have transient signs of respiratory distress.
 16. In the deep or quiet sleep state, the infant is in a deep sleep with regular respirations and little response to outside stimuli. In active sleep, infants move about and may have irregular respirations. The drowsy state is the time between sleep and waking. In the quiet alert state, the infant is awake and interested in stimuli. The active alert state is a fussy period that may lead to the crying state if the infant's needs are not met.

CHAPTER 19

1. Hypoxia causes decreased Po_2 and pH and increased Pco_2 . These, along with cool air and handling at birth, affect chemoreceptors and sensors that stimulate the respiratory center to cause initiation of respirations at birth.
2. Surfactant reduces surface tension in the alveoli and allows them to remain partially open on expiration, reducing the work of breathing.
3. Fetal lung fluid begins to move into the interstitial spaces shortly before birth and when air enters the lungs at birth. It is absorbed from the interstitial spaces by the lymphatic and vascular systems. A small part of the fluid is squeezed out during birth.
4. The ductus arteriosus closes as a result of increases in blood oxygen and decreased prostaglandins from the placenta. The foramen ovale closes when pressure in the left atrium exceeds that in the right atrium. The ductus venosus closes when the vessels of the cord become occluded.
5. At birth, increasing oxygen causes the pulmonary blood vessels to dilate. In addition, movement of fetal lung fluid into the interstitial tissues allows more room for expansion of the pulmonary vessels. The ductus arteriosus constricts because of the increased oxygen in the blood when the neonate begins to breathe.
6. Newborns have thinner skin with less subcutaneous fat than older children and adults. They have blood vessels close to the surface and a larger skin surface area. These all contribute to greater loss of heat than in older children or adults.
7. Newborns respond to low temperatures by increasing activity, flexion, and metabolism, vasoconstriction, and nonshivering thermogenesis. This raises oxygen and glucose consumption and may cause respiratory distress, hypoglycemia, acidosis, and jaundice.
8. Newborns have higher levels of erythrocytes and hemoglobin than adults because the available oxygen is lower before birth than after birth. More red blood cells with fetal hemoglobin are needed to adequately oxygenate the cells.

CHAPTER 20

1. Focused assessments of the infant immediately after birth help detect serious abnormalities that need immediate attention. They focus on cardiorespiratory status, thermoregulation, and the presence of anomalies. A more complete assessment follows when the infant is stable.
2. The cardiovascular assessment includes evaluation of history, airway, color, heart sounds, and pulses. Blood pressure is assessed if indicated.
3. Taking a rectal temperature is dangerous because it risks perforation of the rectum, which turns sharply to the right after about 3 cm (1.2 inches).
4. Molding of the head is a change in the shape because of normal temporary overriding of bones during birth. Caput succedaneum is localized swelling from pressure against the cervix, which can cross the suture lines. Cephalhematoma is bleeding between the periosteum and the bone that never crosses suture lines. Molding and caput disappear within a few days, but cephalhematoma may last for 2 to 3 months.
5. Measurements of the infant help determine if *in utero* growth was adequate for gestational age and if complications are present.
6. Some signs of hypoglycemia are jitteriness, poor muscle tone, respiratory distress (tachypnea, dyspnea, apnea, and cyanosis),

- high-pitched cry, diaphoresis, low temperature, poor suck, lethargy, irritability, seizures, and coma.
7. Using an incorrect site for heel punctures risks injury to the bone, nerves, or blood vessels of the heel.
 8. Newborn reflexes provide information about the status of the neonate's central nervous system.
 9. The first feeding allows the nurse to evaluate the newborn's ability to suck, swallow, and breathe in coordination and assess for signs of esophageal atresia or tracheoesophageal fistula.
 10. Infants should void within 12 to 48 hours. Infants void at least one to two times during the first 2 days and at least 6 times a day by the fourth day.
 11. The nurse documents location, size, color, elevation, and texture of marks on the skin; explains marks to parents; and offers emotional support as needed.
 12. The gestational age assessment provides an estimate of the infant's age since conception and alerts the nurse to possible complications related to age and development.
 13. The periods of reactivity are important because the infant may need nursing intervention for low temperature, elevated pulse and respirations, and excessive respiratory secretions. During the sleep period, the infant will have relaxed muscle tone and no interest in feeding.

CHAPTER 21

1. Newborns receive vitamin K to prevent vitamin K–dependent bleeding. The eyes are treated with an antibiotic ointment to prevent ophthalmia neonatorum.
2. Nurses can prevent heat loss in newborns by keeping them dry, covered, and away from cold objects or surfaces, drafts, and outside windows and walls; and by teaching parents.
3. When infants show signs of hypoglycemia, the nurse should follow agency policy to check the blood glucose level and temperature, feed the infant, and watch for signs of other complications.
4. Interventions for preventing jaundice include ensuring the infant is feeding well by working with mothers and infants having difficulty and teaching parents about jaundice and what observations they should make.
5. Nurses can prevent a baby being given to the wrong parents by always checking the infant's identification and parent's identification every time the two are reunited.
6. Nurses and parents can prevent infant abductions by always being alert for suspicious behavior and stopping anyone who might be taking a baby. Nurses must teach parents how to identify hospital staff and that they should never allow anyone without proper identification to remove their infant from them.
7. Scrupulous handwashing by staff and all who come in contact with newborns is the most important way to prevent infections in newborns.
8. Parents choose circumcision because of the decreased incidence of urinary tract infections, penile cancer, and some sexually transmittable diseases; religious dictates; parental preference; and lack of knowledge about care of the foreskin. Parents decide against circumcision because it causes pain and the risk of hemorrhage, infection, poor cosmetic result, stenosis or fistulas of the urethra, adhesions, necrosis, or other injury to the glans penis. They also question the need for surgery to prevent uncommon conditions.
9. Teach parents not to retract the foreskin on an uncircumcised penis until it begins to separate from the glans later in childhood. They can teach the child to retract it to clean after separation occurs. Teach parents of circumcised infants to watch for bleeding and infection and to apply petroleum jelly as instructed unless a Plastibell was used.
10. Planning parent teaching includes coordinating teaching to include all topics, setting priorities based on parents' needs, using a variety of teaching techniques, modeling behavior, including other family members, and considering culture and language.
11. The first hepatitis B vaccine is given at the birth facility to infants of uninfected mothers as well as to those whose mothers are positive for hepatitis B. Hepatitis B immune globulin is also given to infants of infected mothers.
12. Newborn screening tests should be performed as close to discharge as possible, as the blood tests are more sensitive after the first 24 hours of life. If infants are discharged earlier, they should be retested so that any disorders can be diagnosed early.

CHAPTER 22

1. Infants lose weight after birth because of insufficient intake and normal loss of meconium and extracellular fluid.
2. Colostrum is rich in protein, vitamins, minerals, and immunoglobulins but more lactose, fat, and calories than colostrum. Mature milk appears less rich than colostrum and transitional milk, but it supplies all nutrients needed.
3. Breast milk nutrients are in an easily digested form and in proportions required by the newborn. Commercial formulas contain cow's milk adapted to simulate human milk. Infants may develop allergies to modified cow's milk and may need other types of formula, but they are unlikely to be allergic to human milk.
4. Breast milk contains bifidus factor to help establish intestinal flora, leukocytes, lysozymes that are bacteriolytic, lactoferrin to bind iron in bacteria, and immunoglobulins.
5. Commercial formulas include modified cow's milk formula, soy-based or hydrolyzed formulas, and formulas for preterm infants or those with special needs.
6. Support from her partner, family and friends, cultural influences, employment demands, knowledge about each method, and education may influence a woman's choice of feeding method.
7. Suckling causes release of oxytocin, which produces the let-down reflex. Suckling and removal of milk cause the release of prolactin to increase milk production. Therefore the more frequently the infant breastfeeds, the more milk is produced. Infrequent feedings decrease prolactin output and milk production.
8. During pregnancy, identification of flat and inverted nipples is important. Soap should not be used on the nipples. No other preparation is necessary.
9. The nurse can help the mother establish breastfeeding in the beginning by initiating early feeding, helping position the infant at the breast, and showing the mother how to position her hands. The nurse also can help the infant latch on to the breast, assess the position of the mouth on the breast, check for swallowing, and remove the infant from the breast properly.
10. The mother should feed the infant every 1.5 to 3 hours (8 to 12 times each day) for about 10 to 15 minutes on each side or longer if the infant wishes. Length of feedings may vary but should average at least 20 minutes of effective suckling.
11. To wake up a sleepy infant, unwrap the infant's blankets, talk to the infant, change the diaper, rub the infant's back, place the baby skin to skin with you, and express colostrum onto the breast.
12. Sucking from a bottle requires pushing the tongue against the nipple to slow the flow of milk. Suckling from the breast requires

drawing the nipple far into the mouth so that the gums compress the areola.

13. To help the mother with engorged breasts, the nurse can encourage nursing frequently, applying heat and cold, massaging, and expressing milk to soften the areola.
14. The nurse should advise the mother with sore nipples to ensure proper positioning of the infant at the breast, vary the position of the infant, apply colostrum or compresses to the nipples, and expose the nipples to air.
15. The mother who plans to work and breastfeed should be taught use of a breast pump, proper storage of milk, and ways to maintain her milk supply.
16. There is no one right time for weaning. Breastfeeding for at least 1 year is often recommended. Weaning should be done gradually to help the mother avoid engorgement and help the infant adjust.
17. A mother might ask about the types of formula available, how to prepare it correctly, frequency and amount of feedings, and feeding techniques.
18. Propping bottles risks aspiration of milk. Infants who sleep with a propped bottle have more ear infections and may develop cavities when the teeth come in.

CHAPTER 23

1. Parents obtain information about infant care from friends, family, nurses, health care providers, child care classes, television, books, magazines, and the Internet.
2. Nurses may provide follow-up phone calls, home visits, clinic visits, and child care classes.
3. All equipment should be checked for safety, and parts should be inspected to ensure that they are functioning properly.
4. Car seats must be chosen according to the size of the infant and must be used correctly to maintain safety. Newborns should be placed in rear-facing car seats in the back seat of the car.
5. Infants are not “spoiled” by prompt attention to their needs. Prompt, consistent response to crying may decrease overall crying later.
6. Nurses can assist parents of crying infants to determine the cause and teach them appropriate techniques for coping with a crying infant. Therapeutic communication techniques can be used to help parents with negative feelings.
7. Diaper rash can be prevented by keeping the area clean and dry and avoiding products to which the infant seems sensitive. If rash occurs, parents should expose the area to air and apply creams sparingly.
8. Infants should not start solid foods until 4 to 6 months old.
9. Regurgitation is expulsion of small amounts of milk, often along with a burp. Vomiting involves larger amounts that are expelled with more force.
10. Understanding the infant’s changing capabilities helps parents assess situations and the home environment to prevent accidents.
11. Well-baby checkups allow the health care provider to assess the infant’s growth and development, provide parent teaching, and give immunizations.
12. Immunizations prevent infants from becoming infected with very serious communicable diseases.
13. Immediate help should be obtained if infants have difficulty breathing, are cyanotic, or are hard to arouse from sleep.
14. The cause of SIDS remains unknown, but the risk may be increased with sleeping in a prone position or on soft, loose bedding,

overheating, maternal smoking, and sleeping with another person or on an adult bed or sofa. Infants should sleep alone in a supine position at all times.

CHAPTER 24

1. Pregnancy interrupts developmental tasks such as the achievement of a stable identity, development of a personal value system, completion of educational goals, and achievement of independence from parents.
2. Teenage mothers experience greater risk for anemia, nutritional deficiencies, pregnancy-associated hypertension, HIV and other STDs, a short interval until the next pregnancy, and depression. Infants are at greater risk for preterm birth, low birth weight, neonatal death, and SIDS.
3. A variety of teaching methods such as visual aids, DVDs, group classes with other teens, and one-to-one counseling may be effective for teenagers.
4. Infants develop a sense of trust, which is necessary for future development, when their needs are met promptly and gently. Crying indicates a need and does not mean the infant is “spoiled.”
5. Mature primigravidas often have maturity, problem-solving skills, and emotional and financial resources that may be unavailable to younger women.
6. The fetus of a mature woman is at increased risk for chromosomal anomalies that may be detected by prenatal screening.
7. The older mother may have less energy than younger mothers, and conserving her energy for care of herself and her infant is important.
8. The effects of smoking on the neonate include low birth weight, prematurity, and increased perinatal loss. Later effects include SIDS and neurodevelopmental problems.
9. Fetal alcohol syndrome is characterized by slow growth, central nervous system disorders, cognitive impairment, and cranial and facial anomalies.
10. Neonates exposed to cocaine have irritability, lethargy, and poor response to interaction with others. Long-term effects are unclear but may include attention and language problems and increased risk of SIDS.
11. Pregnant heroin users are placed on methadone to provide a long-acting, steady drug dose to the fetus to avoid the problems of intrauterine overdosage and withdrawal. Buprenorphine may also be used.
12. Prenatal behaviors that suggest substance abuse include prenatal care sought late in pregnancy, failure to keep appointments, inconsistent follow-through with recommended regimens, poor grooming, inadequate weight gain, needle punctures, thrombosed veins, signs of cellulitis, defensive or hostile reactions, and severe mood swings.
13. Signs and symptoms of recent cocaine use include profuse sweating, high blood pressure, tachycardia, irregular respirations, lethargic response to labor, dilated pupils, increased body temperature, sudden onset of severely painful uterine contractions, fetal tachycardia, and excessive fetal activity. Emotional signs include anger, caustic or abusive reactions to the caregiver, emotional lability, and paranoia.
14. Interventions are focused on preventing maternal or fetal injury and may require setting limits in a firm, nonjudgmental manner with a woman who may be abusive and in great pain.
15. Parents experience less anxiety when they are gently told about the condition of the infant and allowed to hold their newborn as soon as possible.

16. Facial, genital, and irreparable defects are likely to affect parenting most.
17. The reaction of parents can be described in terms of a grief response. Initial reactions include shock and disbelief. Denial, anger, and guilt are common.
18. Nurses can promote bonding by handling the infant gently, emphasizing normal traits, helping parents hold and cuddle the infant, and using communication skills to help parents come to terms with their feelings.
19. Discharge planning should include special feeding and other techniques that the infant may require, the follow-up care needed, and referral to agencies and organizations that may be helpful.
20. The way in which the stillborn infant is presented creates memories that the parents will retain. The infant should be washed and taken to the parents while still warm and soft, wrapped in a soft, warm blanket.
21. A memory packet that includes photographs of the baby, handprints, footprints, a birth identification band, crib card, blanket, cap, and, if possible, a lock of hair help parents grieve.
22. Mothers see adoption as an act of sacrifice and love when they give up the infant to those who can provide a better life.
23. Adoptive parents must be taught how to care for an infant and what to expect in terms of growth and development.
24. Battering may start or become worse during pregnancy. The face, arms, buttocks, abdomen, and breasts are frequent targets for battery. Women may start prenatal care late and miss appointments. They may have STDs and postpartum depression.
25. Nurses can examine their own biases to determine whether they accept a common myth that blames the victim. In addition, nurses can consciously practice in ways that empower women and make it clear that the woman owns her body and no one deserves to be beaten.
26. The battered woman often appears hesitant, embarrassed, or evasive. She may avoid eye contact and appear ashamed, guilty, or frightened. Signs of present and past injury may be present, such as bruising, swelling, lacerations, burns, scars, and old fractures, as well as genital injuries.
27. Nurses can help establish short-term goals by helping the woman acknowledge the abuse, develop a plan for protecting herself and her children, and identify community resources that provide protection.

CHAPTER 25

1. Bleeding is the most common sign of threatened abortion. It may be accompanied by rhythmic cramping, backache, or feelings of pelvic pressure. Gross rupture of membranes and subsequent uterine cramping and bleeding make the abortion inevitable.
2. Recurrent spontaneous abortions (also called *miscarriages*) most often occur as a result of genetic or chromosomal abnormalities of the embryo or anomalies of the maternal reproductive tract. Additional causes are believed to be hormonal and immunologic factors or systemic diseases or infections.
3. Nurses can facilitate the grief response by being aware that although many couples grieve over an early pregnancy loss, they often feel a lack of support from family, friends, and health care personnel. When nurses demonstrate empathy and unconditional acceptance of the feelings expressed, they support the grief response. Providing information about the grieving and referrals to additional support groups also may be helpful.
4. Disseminated intravascular coagulation is a life-threatening disorder in which procoagulation and anticoagulation factors are activated simultaneously, resulting in profuse bleeding from any vulnerable area. It may occur with missed abortion (primarily if the pregnancy had reached the second trimester when fetal death occurred), abruptio placentae, severe pregnancy-induced hypertension, amniotic fluid embolism, and other conditions such as sepsis.
5. Ectopic pregnancy remains the leading cause of maternal death because of hemorrhage, and it can reduce the woman's chance of subsequent pregnancies because of damage to a fallopian tube. Also, the condition that caused the ectopic pregnancy in the tube may be present in the opposite tube.
6. The increase in incidence of ectopic pregnancy may occur as a result of pelvic inflammatory disease that may complicate untreated sexually transmitted infections. Scarring of the fallopian tubes that may result from the infection may make it difficult for the fertilized ovum to pass through the obstructed tube. Ectopic pregnancy is also more likely to occur in women who have assisted reproduction for infertility, ovulation disorders, contraceptive devices, and use of progesterone agents. Treatment for ectopic pregnancy may be medical (chemotherapeutic agent) or surgical (salpingostomy or salpingectomy).
7. Hydatidiform mole is a form of gestational trophoblastic disease that involves abnormal development of the placenta as the fetal part of the pregnancy fails to develop. The first phase of treatment is evacuation of the molar pregnancy from the uterus. The second phase is follow-up to detect malignant changes in remaining trophoblastic tissue.
8. Painless vaginal bleeding in the latter half of pregnancy is the classic sign of placenta previa. Strict bed rest, no sexual intercourse, an adult caregiver present at all times, and availability of emergency transportation to the hospital are essential for home care. The woman must also be taught to monitor fetal movement and to report a decrease in movement or increase in vaginal bleeding.
9. The five classic signs of abruptio placentae are (a) bleeding, which may be evident vaginally or concealed behind the placenta; (b) uterine tenderness; (c) uterine irritability, with poor relaxation between contractions; (d) abdominal pain; and (e) a high uterine resting tone if an intrauterine pressure catheter is being used.
10. Hemorrhagic shock is the major danger of placental abruption for the mother; anoxia, excessive blood loss, and delivery before maturity are major dangers for the fetus.
11. Both morning sickness and hyperemesis gravidarum begin in the first trimester. Morning sickness is self-limiting and causes no serious complications. Hyperemesis is persistent, uncontrollable vomiting that may cause excessive weight loss, dehydration, and electrolyte or acid-base imbalance.
12. Goals of management are to maintain hydration, replace electrolytes and vitamins, maintain nutrition, and provide emotional support.
13. Nurses must use critical thinking to examine personal biases that may result in lack of comfort and support for women with hyperemesis. Helping the woman identify any reluctance to accept her pregnancy may lead to solutions that can reduce the intensity of hyperemesis.
14. Persistent vasospasm of uterine arterioles may result in fetal hypoxemia, intrauterine growth restriction, or even fetal death.
15. Classic signs of preeclampsia include hypertension and possibly proteinuria. Nonspecific edema that is severe and generalized is often seen but is no longer considered a classic sign of preeclampsia. Headache, hyperreflexia, visual disturbances, and epigastric pain indicate the disease is worsening. Rest, especially in a lateral

- position, increases maternal cardiac return and circulatory volume, thus improving perfusion of vital organs. Increased renal perfusion decreases angiotensin II levels, thus lowering blood pressure.
16. Vasospasms cause rupture of cerebral capillaries and small cerebral hemorrhages.
 17. Magnesium sulfate prevents seizures by reducing central nervous system irritability and decreasing vasoconstriction. The primary adverse effect is central nervous system depression, which includes depression of the respiratory center.
 18. Pulmonary edema, circulatory or renal failure, and cerebral hemorrhage are complications of eclampsia. HELLP syndrome, which demonstrates coagulation and liver function abnormalities, is more likely to occur when a woman has severe preeclampsia or eclampsia. DIC may cause unexpected bleeding as levels of coagulation factors decline.
 19. Assessments for the woman with preeclampsia include daily weights, location and degree of edema, vital signs, hourly urinary output, urine for protein, deep tendon reflexes, and subjective signs such as headache, visual disturbances, and epigastric pain. The fetal heart rate should be assessed for nonreassuring patterns. Respiratory rate, oxygen saturation level, consciousness level, and laboratory data such as creatinine, liver enzymes, and magnesium levels should be evaluated. Psychosocial assessment should include the reaction of the woman's family and support system. Nursing assessment helps determine whether the condition is responding to medical management, is stable, or if the disease is worsening.
 20. To prevent seizures, maintain a quiet environment, reduce environmental stimuli, and maintain a therapeutic level of magnesium. Nurses must remain with the woman and call for help if a seizure occurs. Attempt to turn the woman on her side before the onset of a seizure. Note the sequence and time of the seizure. Insert an airway after the seizure, and suction the woman's nose and mouth, administer oxygen, administer medications, and prepare for additional medical interventions.
 21. To prevent seizure-related injury, the side rails should be padded and raised. The bed should be in the lowest position with the wheels locked. Oxygen and suction should be readily available. Necessary equipment and medications should be kept in the room.
 22. Signs of magnesium toxicity include respiratory rate below 12 breaths per minute, hyporeflexia, sweating or flushing, altered sensorium (lethargy, drowsiness, disorientation), and serum magnesium level beyond the therapeutic range. If toxicity occurs, notify the physician so the dose can be altered or the drug discontinued. Calcium gluconate is an antidote for magnesium toxicity.
 23. *H*, Hemolysis; *EL*, elevated liver enzymes; *LP*, low platelets. Major symptoms are pain and tenderness in the right upper quadrant. Additional signs and symptoms may include nausea, vomiting, and severe edema. Laboratory data include a low hematocrit level, abnormal liver studies, coagulation abnormalities, and often abnormal renal studies. Palpating the liver could cause trauma, including rupture of a subcapsular hematoma.
 24. Preeclampsia occurs only during pregnancy and the early postpartum period. Chronic hypertension is present before pregnancy or before the twentieth week of gestation and persists after the postpartum period. Hypertension that remains several weeks postpartum suggests that the woman has chronic hypertension even if her blood pressure measurements were normal when she entered care. Treatment may be similar during pregnancy; however, chronic hypertension may be treated with antihypertensive medications before and during pregnancy. Preeclampsia may further complicate chronic hypertension.
 25. Administration of Rh₀(D) immunoglobulin prevents development of maternal anti-Rh antibodies and is recommended after any procedure that includes the possibility of maternal exposure to Rh-positive fetal blood.
 26. Maternal anti-Rh antibodies cross the placental barrier and destroy fetal Rh-positive red blood cells. The fetus becomes anemic, bilirubin concentration increases, and in severe cases severe neurologic disease can result.
 27. Many women with blood type O have anti-A or anti-B antibodies before they become pregnant, so the first pregnancy can be affected. The effects of ABO incompatibility are milder than Rh sensitization because fewer maternal antibodies cross into fetal blood.

CHAPTER 26

1. The hormones of pregnancy cause resistance of maternal cells to insulin, which increases the availability of glucose for the fetus.
2. The mother is at risk to develop preeclampsia, urinary tract infections, ketoacidosis, and preterm labor. Possible fetal and neonatal effects include congenital malformations; small or large fetal size, depending on the placental vascular supply; fetal hypoxemia; and polycythemia. Neonatal effects include hypoglycemia, hypocalcemia, hyperbilirubinemia, and respiratory distress syndrome.
3. Insulin needs decrease during the first trimester and increase sharply during the second and third trimesters (when placental hormones initiate insulin resistance). During the muscular exertion and reduced oral intake associated with labor, insulin needs must be determined by frequent checks of blood glucose levels to keep the maternal glucose level within normal limits. In the postpartum period, insulin needs decrease as levels of placental hormones decline.
4. Glycosylated hemoglobin gives an accurate evaluation of blood glucose level for the past 2 to 3 months and is not affected by recent intake of food.
5. Gestational diabetes mellitus is first diagnosed during pregnancy with none of the classic signs of type 1 diabetes: thirst, heavy urine excretion, and weight loss despite heavy food intake. Type 1 diabetes mellitus usually emerges during childhood or early adulthood and requires insulin for control. Type 2 diabetes usually occurs in adulthood and is usually managed by diet and/or oral hypoglycemics if not pregnant. Gestational diabetes is often managed by diet and exercise, although insulin may be needed if fasting or postprandial capillary blood glucose values are persistently high. Oral hypoglycemics are not commonly used.
6. A glucose challenge test (GCT) is a screening procedure only and requires no fasting before the woman drinks a 50-g glucose solution and has a serum glucose drawn 1 hour later. A 3-hour oral glucose tolerance test (OGTT) is performed to diagnose diabetes mellitus, including gestational diabetes. The OGTT requires measurement of a fasting blood glucose level followed by intake of 100 g of glucose solution. Blood glucose levels are determined hourly after the solution is taken, at 1, 2, and 3 hours.
7. Maternal effects of gestational diabetes mellitus include increased incidence of urinary tract infections, hydramnios (excessive amniotic fluid), premature rupture of membranes, and development of hypertension. Fetal effects may include macrosomia, which can result in shoulder dystocia or cesarean birth. The newborn is at risk for hypoglycemia. Preexisting diabetes has similar maternal effects as gestational diabetes, but fetal and infant effects may be

- more severe if the disease is not well controlled. The infant may have intrauterine growth restriction (IUGR) if the woman's diabetes has caused vascular impairment, or macrosomia if her glucose level is poorly controlled and no vascular impairment exists. Congenital anomalies are increased in preexisting diabetes, especially if the diabetes is poorly controlled at conception and during early gestation.
- Increased intravascular volume and increased cardiac output (particularly stroke volume) place an added burden on the heart of a woman who has a cardiac defect.
 - Rheumatic and congenital heart disease are the two major categories of heart disease during pregnancy. Acute problems such as myocardial infarction or conduction disorders may also occur during pregnancy. Functional classification depends on the person's ability to tolerate activity. Class I indicates no limitation on activity. Class II indicates slight restriction if necessary. Class III is associated with marked limitation. Class IV indicates that the person has symptoms such as dyspnea at rest.
 - Goals of treatment are to prevent anemia so the supply of red blood cells is adequate to transport oxygen and thus reduce the demands on the heart, limit physical activity so cardiac demand does not exceed the capacity of the heart, and limit weight gain, which would add further demands on the heart.
 - With every contraction, blood is shifted from the uterus and placenta into the central circulation. This can lead to fluid overload if fluids are administered rapidly.
 - An additional 500 mL of blood is returned to the central circulation with delivery of the placenta. Also, the compression of the vena cava that characterized much of pregnancy is gone. This increases the load on the heart and can lead to further compromise of the heart.
 - Most women begin pregnancy with marginal iron stores, do not have adequate iron stores to meet the demands of pregnancy, and have difficulty meeting the high iron needs of pregnancy with diet alone.
 - The fetus usually receives adequate iron, even at a cost to the mother. Therefore neonatal effects of moderate maternal anemia are rare. With very severe maternal anemia, however, the fetus may become hypoxic.
 - The fetal and neonatal effects of folic acid deficiency are increased risk of spontaneous abortion, abruption of the placenta, and fetal anomalies, particularly neural tube defects.
 - Pregnancy may worsen sickle cell disease, and the risk of "sickle cell crisis" is increased.
 - Frequent measurements of hemoglobin, blood count, serum iron, and iron-binding capacity as well as folate are necessary to determine the degree of anemia. Frequent fetal surveillance and monitoring for signs of sickle cell crisis are also necessary. The nurse must also be aware that the woman's pain could be a pregnancy complication rather than a result of sickle cell crisis.
 - Thalassemia is associated with increased iron absorption and storage, making women with this disorder susceptible to iron overload.
 - The maternal and fetal effects of systemic lupus erythematosus are increased incidence of abortion, fetal death, and preterm delivery. Congenital heart block, often permanent, is a serious complication for the newborn. Pregnancy can exacerbate the disease, and renal complications pose a special risk.
 - Rheumatoid arthritis often markedly improves during pregnancy. However, relapse often occurs soon after childbirth.
 - Hypothyroidism in the woman may cause adverse effects on the mental development of the fetus through birth and childhood. A greater risk for miscarriage, preterm birth, and preeclampsia exists if it is not corrected.
 - Anticonvulsant drugs may be teratogenic. Many have probable or known adverse effects on the fetus. However, generalized seizures may also have adverse fetal effects, so maintaining the anticonvulsant dose as low as possible is important. Newer anticonvulsants have less data related to their possible fetal effects.
 - The recommended supportive care for women with Bell's palsy includes eye patching, applying ointment or drops to prevent trauma to the cornea, facial massage, and psychological support. Corticosteroids may be given.
 - Primary maternal infection is more likely to result in fetal and neonatal infection. About 90% of newborns are not affected, but about 10% will have symptoms at birth. About 10% of this group will show full CMV inclusion disease. Another 10% of this birth group will show late onset signs. Problems include enlarged spleen and liver, CNS abnormalities, developmental delay, dental defects, jaundice, chorioretinitis, hearing loss, and growth impairment.
 - The first trimester is the time of organogenesis, when damage can be done to all developing organ systems.
 - A vaccine is available to prevent rubella, but it cannot be given during pregnancy. During pregnancy a woman can only avoid situations in which she is likely to contract rubella. Rubella immunization should be given to the woman before discharge after birth, and she should be taught that pregnancy should be avoided for 4 weeks (1 month) after the immunization.
 - Immunization with varicella-zoster immune globulin is recommended. Because of viral shedding, infected mothers and infants must be isolated from those who are not immune.
 - Vertical transmission of herpesvirus occurs when organisms ascend after rupture of membranes and during birth when the fetus comes into contact with infectious tissue and secretions.
 - The fetal and neonatal effects of parvovirus B19 infection are failure of red blood cell production, severe fetal anemia, hydrops, and heart failure.
 - Hepatitis B virus is transmitted by contact with infected blood, saliva, vaginal secretions, semen, or breast milk. A newborn whose mother is known to carry the hepatitis B surface antigen should receive hepatitis B immune globulin soon after birth, followed by hepatitis B vaccine. The infant should receive the second and third doses of vaccine at regularly scheduled times.
 - Avoid sexual transmission by abstinence, avoiding intercourse with infected persons, or using recommended barrier methods such as a condom. Intravenous drug users who refuse rehabilitation must avoid transmission that occurs when needles are shared with those who are infected. Use standard precautions to avoid contact with secretions that may carry the virus.
 - Several combinations of antiretroviral medication regimens may be administered to delay replication of the virus. Opportunistic diseases are treated. Good hygiene reduces transmission of infectious organisms to the susceptible person, and nutritious meals reduce the risk for opportunistic infection. Zidovudine therapy reduces vertical transmission of HIV to the infant and ideally begins during the second trimester of pregnancy. Additional zidovudine continues after birth for the infant. Individualized maternal therapy may include multiple antiretrovirals.
 - Toxoplasmosis can be prevented by cooking meat thoroughly, not touching mucous membranes while handling raw meat, washing kitchen surfaces and hands thoroughly after handling raw meat, avoiding uncooked eggs and unpasteurized milk, washing vegetables and fruit before consumption, and avoiding contact with materials that may be contaminated with cat feces.

34. Risk factors for the mother transmitting GBS to her infant include a prior infant with GBS infection, presence of GBS organisms in the urine in the present pregnancy, preterm birth (before 37 weeks), maternal fever in labor, and prolonged membrane rupture (≥ 18 hours). Intravenous antibacterial therapy is used to prevent colonization in the newborn in the GBS-positive mother or if her status is unknown.
35. Isoniazid, rifampin, and ethambutol are given for 2 months followed by isoniazid and rifampin daily or twice per week for 7 months to treat tuberculosis in the mother. Pyridoxine (vitamin B₆) is added to prevent neurotoxicity. The infant is skin-tested at birth and may be prescribed isoniazid. Isoniazid is usually continued for the infant until the mother's tuberculosis has been inactive for at least 3 months. Infant tuberculosis medication may stop if the mother and family members are well treated and show no additional disease. If the skin test result shows conversion to positive, a full course of drug therapy should be given to the infant.

CHAPTER 27

1. Hypotonic labor dysfunction usually occurs during the active phase of first-stage labor (4-cm cervical dilation or more), whereas hypertonic dysfunction usually occurs during the latent phase (within the first 3 cm of cervical dilation). Uterine contractions become weaker, shorter, and less frequent in hypotonic dysfunction. In hypertonic dysfunction, contractions are painful but inefficient and the uterine resting tone is high. Hypotonic dysfunction is not painful because the contractions decrease, although the woman may become tired. Hypertonic dysfunction is characterized by a cramping type of pain. Management of both depends on the identified cause. Hypotonic dysfunction often is managed by ensuring adequate intake of fluids and electrolytes, position changes, amniotomy if the membranes are not ruptured, and oxytocin augmentation. Hypertonic dysfunction may be managed by mild sedation or tocolytic drugs to reduce excess uterine activity. Oxytocin in very low doses may be used occasionally to help coordinate uterine activity in hypertonic labor.
2. Maternal position changes encourage the fetus to rotate from an occiput transverse or occiput posterior position to an occiput anterior position, similar to nesting two spoons together. The convex surface of the rounded fetal back rotates toward the convex surface of the anterior uterus. The squatting position also increases pelvic diameters and straightens the pelvic curve to facilitate both fetal rotation and descent.
3. Other complications are associated with a fetus in a breech presentation that may cause problems, regardless of the method of birth. These include low birth weight, fetal anomalies, and associated pregnancy or labor complications.
4. The staff must be prepared for care of multiple infants. Duplicate staff and equipment should be ready for every infant expected.
5. Bladder distention during labor can occupy available room in the woman's pelvis, thus impeding labor progress and fetal descent. In addition, it is a potential source of discomfort.
6. Psychological support reduces stress that otherwise can consume energy the uterus needs, inhibit uterine contractions, reduce placental blood supply, impair the woman's pushing efforts, and increase the woman's pain experience.
7. The average nullipara's cervix dilates about 1.2 cm per hour and expected fetal descent is 1 cm per hour. The average parous woman's cervix dilates about 1.5 cm per hour, with minimal descent of 2 cm per hour. Variations such as epidural analgesia may change rates of dilation and descent, so this must be considered.
8. Nursing care for the woman who has prolonged labor is similar to that for dysfunctional labor. Promoting comfort, energy conservation, position changes, and assessments for related complications such as infection should be done.
9. Trauma is the primary maternal risk of a precipitate labor and may include uterine rupture, cervical lacerations, and hematomas. Fetal risks may include trauma, such as intracranial hemorrhage or nerve damage, and hypoxia. Abruption placentae may cause maternal hemorrhage and fetal hypoxia because of the premature detachment of the placenta from the uterus.
10. Premature rupture of the membranes (PROM) occurs before true labor any time during pregnancy. Preterm premature rupture of the membranes (PPROM) occurs before 37 weeks of gestation and may be accompanied by contractions. PPRM is more likely to be associated with preterm labor and birth.
11. Infection may be both a cause and a result of premature rupture of the membranes, particularly if birth is not desired because of fetal immaturity.
12. Labor may be induced if the woman is at or near term and it does not begin spontaneously. Other factors include whether her cervix is favorable and the fetal lungs are mature. Induction may be delayed up to 24 hours to allow for more cervical softening and to start antibiotics. Steroids are not indicated if the fetus is 34 or more weeks of gestation. The physician must consider multiple factors such as risk for infection (mother and fetus/newborn) and risk for preterm complications if the fetus is less than 34 weeks of gestation.
13. The nurse should assess the woman's vital signs and FHR and teach her to avoid insertion of anything into the vagina, avoid breast stimulation, maintain activity restrictions, and note any uterine contractions or foul odor to vaginal discharge. Teach her how to observe fetal kick counts or other fetal activity. Temperature should be taken at least four times per day.
14. Symptoms of preterm labor often are vague. They include uterine contractions that may often be painless, the fetus "balling up," menstrual-like cramps, backache, pelvic pressure, changed or increased vaginal discharge, abdominal cramps, thigh pain, and a sense of "feeling bad."
15. Early identification of preterm labor enables management that may delay birth and allow further maturation of the fetus or permit transfer to a facility equipped to care for an immature infant. Corticosteroids may be given to the mother of a fetus between 24 and 34 weeks of gestation to accelerate maturation of the lungs before preterm birth.
16. Classifications of drugs to inhibit preterm contractions include magnesium sulfate, calcium channel blockers such as nifedipine, prostaglandin synthesis inhibitors such as indomethacin, and beta-adrenergics such as terbutaline.
17. To accelerate maturation of the fetal lungs, corticosteroids are given to the woman who is likely to deliver prematurely. The greatest benefits occur if steroids are in the mother's system at least 24 hours before birth. The newborn who delivers before 24 hours after the mother receives corticosteroids may also benefit.
18. The three potential fetal or newborn risks are reduced placental function and umbilical cord compression before birth and meconium aspiration after birth.
19. If umbilical cord prolapse occurs, the priority of care is to reduce compression of the cord and restore normal blood flow through the cord while giving the mother oxygen to maximize her blood

- oxygen concentration. At the same time, the nurse should summon help to expedite delivery, usually by cesarean birth.
20. Stimulated contractions are potentially more powerful than natural ones and may cause the pressure in the uterus to exceed the uterine wall's ability to withstand that pressure.
 21. Shock and hemorrhage are rapidly developing complications of uterine inversion. They are managed by rapid IV fluid and blood replacement, often using two IV lines. A drug that relaxes the uterus is given to allow uterine replacement to its proper position, and general anesthesia may be needed. Oxytocin is given *after* the uterus is returned to the proper position. Hemodynamic monitoring may be required to ensure stabilization.
 22. For intrapartum emergencies, nursing considerations include the following: *Prolapsed umbilical cord*—Relieve pressure on the cord to restore adequate blood flow through it until the baby can be delivered. *Uterine rupture*—Attempt its prevention by cautious intrapartum use of uterine stimulants and close monitoring of uterine contractions. *Uterine inversion*—Avoid pressure on the poorly contracted fundus after birth; assess for and correct shock. *Amniotic fluid embolism*—Provide cardiorespiratory support and hemodynamic monitoring and observe for coagulation deficits.
 23. The fetus may suffer direct injury such as skull fracture or intracranial hemorrhage related to maternal injuries such as pelvic fracture, penetrating wounds, or blunt trauma. Fetal injury from indirect causes includes abruptio placentae and disruption of placental flow because of maternal hemorrhage or shock.
 10. Signs and symptoms of superficial venous thrombosis include swelling, tenderness, warmth, and redness.
 11. Heparin remains the long-term treatment of the pregnant woman with deep venous thrombosis because warfarin (Coumadin) may be teratogenic and predisposes the fetus to hemorrhage. Heparin is changed to warfarin in the postpartum period.
 12. Bed rest is prescribed for the woman with deep vein thrombosis to decrease swelling and to promote venous return from the leg.
 13. The nurse assesses mothers receiving anticoagulants for unexplained bruising, petechiae, bleeding from the nose, bladder or gums, or increased vaginal bleeding. Signs of hemorrhage, such as tachycardia, falling blood pressure, or other signs of shock, also should be noted.
 14. The nurse should assess family structure and function that will need to change as a result of prolonged treatment for the mother. The nurse should evaluate mother-infant interaction and determine what support system may be available to provide assistance.
 15. Cesarean birth or the use of vacuum extraction or forceps may result in trauma that provides a portal of entry for infectious organisms.
 16. All parts of the reproductive tract are connected, and organisms can move from the vagina through the cervix, uterus, and fallopian tubes and into the peritoneal cavity. Alkalinity of the vagina during labor, necrosis of the endometrium, and the presence of lochia encourage bacterial growth.
 17. When labor is prolonged, organisms have time and opportunity to ascend from the vagina into the uterus, increasing the risk of infection. Also, there may be more vaginal examinations and ruptured membranes for a longer time.
 18. Fever, chills, lethargy, malaise, anorexia, abdominal pain and cramping, uterine tenderness, and purulent foul-smelling lochia, tachycardia, and subinvolution are signs and symptoms of endometritis. It usually is treated by IV administration of antibiotics, antipyretics, and oxytocics to promote involution.
 19. Wound infection most often occurs in cesarean incisions, episiotomies, and lacerations.
 20. Incisions and lacerations should be inspected for redness, tenderness, edema, and approximation of the edges of the wound, which may pull apart with infection.
 21. To prevent urinary tract infection, the woman should be advised to drink at least 2500 to 3000 mL of fluid each day, empty her bladder every 2 to 3 hours during the day, and practice meticulous hygiene. Cystitis and pyelonephritis may be treated with oral antibiotics on an outpatient basis. Severe pyelonephritis or infection during pregnancy may require hospitalization and IV antibiotics.
 22. Measures to prevent mastitis include correct positioning of the infant during nursing, frequent emptying of the breasts, and avoiding nipple trauma and supplemental feedings. In addition, the woman should avoid continuous pressure on the breasts caused by tight bras or infant carriers.
 23. The symptoms of postpartum depression differ from those of postpartum "blues" by the number, intensity, and persistence of symptoms. In postpartum depression, the symptoms are present daily for at least 2 weeks. They include a loss of interest in one's surroundings, a loss of usual emotional responses, and feelings of unworthiness, guilt, and shame.
 24. Nurses can demonstrate caring, provide anticipatory guidance, help the mother verbalize her feelings, and make appropriate referrals.

CHAPTER 28

1. The nurse examines a woman's previous records to identify factors that would predispose her to complications such as postpartum hemorrhage.
2. Overdistention of uterine muscles makes their contraction more difficult and excessive bleeding more likely.
3. The nurse cannot be certain that bleeding is controlled because concealed bleeding can occur in soft tissue and produce a hematoma.
4. Initial management of uterine atony focuses on measures to contract the uterus, such as massaging, expressing clots, and emptying the bladder. Pharmacologic measures include fluid replacement and administration of oxytocin, methylergonovine, or other drugs such as carboprost.
5. Large hematomas may require incision and evacuation of clots, as well as ligation of the bleeding vessel. Small hematomas do not require treatment.
6. It may be difficult to recognize hypovolemia because of compensatory mechanisms, such as carotid and aortic baroreceptors, which constrict peripheral blood vessels. This shunts blood to the central circulation, maintains blood pressure, and increases the heart rate.
7. The major signs of subinvolution are prolonged lochial discharge, irregular or excessive uterine bleeding, pelvic pain and heaviness, backache, fatigue, and malaise.
8. Nurses must teach the mother how to palpate the fundus, estimate fundal height, and to report abnormalities of lochia, a foul odor, or pelvic pain.
9. Venous stasis increases during pregnancy because of compression of the large vessels by the enlarging uterus. At birth, stasis may occur when the woman is in stirrups. Changes in the coagulation and fibrinolytic systems during pregnancy and the postpartum period elevate the factors that favor coagulation and decrease the factors that favor lysis of clots.

25. Postpartum psychosis usually requires hospitalization, psychotherapy, and appropriate medication.

CHAPTER 29

1. Preterm infants appear frail and weak and are small, with limp extremities, poor muscle tone, red skin, and immature ears, nipples, areolae, and genitals.
2. Factors that increase respiratory problems in preterm infants include lack of surfactant, poor cough reflex, small air passages, and weak muscles.
3. Nursing responsibilities include working with respiratory therapists to manage equipment, monitoring the infant's changing oxygen needs, positioning infants to promote drainage, and suctioning.
4. Nurses wean infants to the open crib by making gradual changes in the environmental temperature, dressing the infant, and using blankets and a hat when the infant is out of the incubator.
5. To measure intake and output for infants, all fluids (IV and oral), including medications, are measured. Diapers are weighed to calculate urine output, and drainage, regurgitation, and stools are measured.
6. Preterm infants' kidneys do not concentrate or dilute urine well, and they have large insensible water losses. They lack passive antibodies from the mother and have an immature immune system. Pain causes physiologic and behavioral responses and can have long-term effects.
7. Nonpharmacologic methods to reduce pain in infants include positioning, swaddling, facilitated tucking, sucking, sucrose, skin-to-skin positioning, and breastfeeding.
8. The nurse can diminish overstimulation by organizing care to provide for rest periods, reducing environmental stimuli, minimizing pain, and discussing the plan of care with others.
9. Feeding tolerance is assessed by checking gastric residual volume before gavage feedings, measuring abdominal girth, testing stools for reducing substances and blood, and observing for regurgitation. During nipple feedings, the nurse watches for signs of respiratory difficulty, decreased oxygenation, and fatigue.
10. When allowed to set the pace of feedings, infants can stop to rest to conserve energy, regulate breathing, and control the flow of milk. Moving the nipple in the infant's mouth may cause fatigue and choking.
11. The nurse can help breastfeeding mothers of preterm infants by helping them pump and store milk, by teaching breastfeeding techniques adapted to the preterm infant's needs, and by providing support and encouragement.
12. The nurse can help parents feel comfortable with preterm infants by providing warm support, realistic encouragement, and information about the NICU environment, the infant's condition and characteristics, and the equipment and care. Involving the parents in care also helps.
13. Beginning early in hospitalization, the nurse should help parents take on gradually increasing responsibility for care of the infant which will help them prepare for discharge. Helping them prepare their home for the infant is also important.
14. Postmature infants may be thin and may have loose skin folds, cracked and peeling skin, minimal vernix, long nails and meconium staining.
15. Postmature infants may have polycythemia, meconium aspiration, hypoglycemia, and poor temperature regulation.
16. In symmetric growth restriction, all body parts are proportionately small. In asymmetric growth restriction, the head is normal in size but seems large for the body, the weight is decreased, and the length is generally normal.
17. LGA infants may have birth injuries such as fractures, nerve injury, cephalhematoma, hypoglycemia, and polycythemia.

CHAPTER 30

1. Waiting to give an Apgar test to an infant who needs resuscitation delays treatment unnecessarily and may make resuscitation more difficult. The Apgar scores can be given during the resuscitation process.
2. The nurse's role in asphyxia is to begin resuscitation promptly, assist the team, and provide follow-up and parental support.
3. Transient tachypnea of the newborn is caused by failure of fetal lung fluid to be absorbed completely in infants who are usually full-term or late preterm. Respiratory distress syndrome occurs in preterm infants as a result of inadequate surfactant.
4. Meconium staining is most likely to occur when infants are post-term, SGA, have decreased amniotic fluid and cord compression.
5. Infants with PPHN have constriction of the pulmonary blood vessels from inadequate oxygen levels. This increases resistance to blood flow from the heart into the lungs and causes blood to flow through the foramen ovale and patent ductus arteriosus.
6. Kernicterus can be prevented by identifying women whose infants are at risk for blood incompatibilities, giving Rh-negative mothers Rh immune globulin, recognizing infants with bilirubin levels that are not normal, and instituting phototherapy when it is needed.
7. Nurses can help reduce bilirubin in an infant receiving phototherapy by ensuring that the lights or blankets are functioning and positioned properly; reducing the infant's time out of phototherapy; ensuring adequate milk intake to increase removal of bilirubin by frequent stools; preventing cold stress or hypoglycemia, which would decrease albumin-binding sites for bilirubin; and turning the infant frequently to expose all areas to the lights.
8. The role of the nurse in sepsis is to use infection prevention methods, identify infants at risk, watch for early signs, notify the physician, coordinate treatment, observe for change, and support the family.
9. Macrosomia occurs in IDMs because of excessive transfer of glucose, amino acids, and fatty acids from the mother to the fetus. This results in fetal production of insulin and excessive growth in the fetus.
10. IDMs may develop hypoglycemia after birth because they have high levels of insulin even though they no longer receive glucose from the mother. Infants may need early feeding as a result.
11. The nurse can help the drug-exposed infant to rest by minimizing stimulation, swaddling in a flexed position, organizing care to avoid interruptions, and providing a pacifier.
12. The nurse can promote bonding in cases of prenatal drug abuse by helping the mother feel welcome, encouraging her to participate in infant care, teaching her how to respond to the infant's behavior and about the infant's care, and modeling parenting behaviors.

CHAPTER 31

1. Almost all contraceptive methods are used by women, and failure will most affect women.
2. The nurse's role in helping women with contraception is to provide information to help women choose contraceptives appropriately and use them correctly.

3. Important considerations in choosing contraceptive techniques include safety, protection from STDs, effectiveness, acceptability, convenience, education needed, benefits, side effects, effect on spontaneity, availability, expense, preference of the woman and her partner, religious and personal beliefs, and culture.
4. Sterilization, hormonal contraceptives, intrauterine devices, and implants may require signed informed consents.
5. Adolescents may have incorrect beliefs, such as that they cannot conceive during first intercourse, without orgasm, or without having menstruated a certain length of time or that douching will prevent pregnancy.
6. Adolescents may not seek contraception because they may fear lack of acceptance, loss of sexual privacy, pelvic examination, or adverse effects of contraception on their health.
7. The nurse can teach adolescents effectively by showing sensitivity to their feelings, being accepting, providing extensive teaching without hurry, and using understandable terms and audiovisual materials.
8. Women who are over age 35 and who smoke should not use estrogen-containing contraceptives. Healthy women in the 40s who do not smoke and are not obese can use combined hormonal contraceptives.
9. Important factors to consider when choosing a method of sterilization include time involved, cost, need for hospitalization, and feelings of each partner about a permanent end to the ability to have more children.
10. Education for women choosing intrauterine devices includes information about side effects, when and how to check the threads, and when to seek medical treatment.
11. Hormonal contraceptives alter normal hormone changes preventing ovulation and making the cervical mucus thicker.
12. Menstrual changes and spotting are the reason some women stop using some hormonal contraceptives.
13. Women using OCs need to know that the pills must be taken consistently and in the right order every day, what to do if pills are missed, common side effects, and signs that may indicate a problem.
14. EC should be taken as soon as possible after unprotected intercourse and within 120 hours.
15. Barrier methods kill sperm or prevent them from entering the cervix or both.
16. Natural family planning methods avoid drugs, chemicals, and devices; are inexpensive; and are acceptable to most religions. Couples need extensive education and high motivation, however, and they risk pregnancy if they make an error.
3. Erection problems exist if the man cannot initiate and maintain a penile erection that is sufficient to allow intercourse and deposit of seminal fluid with sperm near the woman's cervix. Ejaculation abnormalities may result from retrograde ejaculation, hypospadias, or abnormal ejaculation response (premature, slow, or absent).
4. Abnormalities of the sperm, ejaculation, or the seminal fluid can result from factors such as abnormal hormone stimulation, systemic illness, infections or abnormalities of the reproductive tract, anatomic abnormalities of the reproductive system, exposure to toxins, therapeutic medications, excessive alcohol intake, illicit drug use, elevated scrotal temperature, obstruction, and immunologic factors.
5. Abnormal ovulation can occur because of hormone disruptions caused by cranial tumors, stress, obesity, anorexia, systemic disease, and abnormalities in the ovaries or other endocrine glands.
6. Hormone abnormalities associated with ovulation problems interfere with normal buildup and decline of the endometrium. Menstrual periods may be absent, scant, or very heavy.
7. Fallopian tube obstruction may be caused by scarring or adhesions secondary to infections, endometriosis, or pelvic surgery. Congenital anomalies of the reproductive structures also can cause mechanical interference with successful pregnancy.
8. Abnormal cervical mucus can trap sperm and prevent them from entering the uterus and fallopian tube or prevent their preparation (capacitation) for fertilization.
9. Anatomic abnormalities of the woman's reproductive tract may prevent normal fertilization or implantation. They also may prevent normal placental or fetal growth, or they may increase the risk for miscarriage or previsible birth.
10. Endocrine abnormalities associated with repeated pregnancy loss include inadequate progesterone secretion, inadequate endometrial response to progesterone, hypothyroidism and hyperthyroidism, and maternal diabetes.
11. Immunologic causes of repeated pregnancy loss include an intolerance of the embryo's foreign tissue and systemic lupus erythematosus.
12. Elements included in the history and physical examination include a reproductive history, a medical history, and an examination for undiagnosed endocrine disturbances, tumors, chronic disease, and abnormalities of the reproductive organs. Chromosome analysis is sometimes done. Imaging studies are done if structural abnormalities are suspected.
13. Medications used to induce ovulation include clomiphene citrate, chorionic gonadotropins, gonadotropin-releasing hormone, and human gonadotropins. Clomiphene is a common drug for this purpose. Additional drugs may be given to increase the formation and release of ova and to support a resulting pregnancy.
14. Screening tests related to use of donor sperm include those for blood type and Rh factor, possible genetic abnormalities and infection. In addition, the man's history, physical examination, and lifestyle are reviewed for possible problems that might not be revealed by standard tests. Donor sperm are frozen for 6 months to allow identification of infections or other problems that are not evident at the time of collection.
15. In vitro fertilization mixes the male and female gametes outside the body and places embryos back into the uterus. Gamete intrafallopian transfer retrieves ova and then places the ova and sperm into the fallopian tubes, where fertilization occurs. Zygote intrafallopian transfer mixes male and female gametes to allow fertilization and places the fertilized ova into the fallopian tubes. Intracytoplasmic sperm injection (ICSI) is used to retrieve sperm

CHAPTER 32

1. Infertility is strictly defined as the inability to conceive after 1 year of unprotected regular intercourse. A more workable definition that considers the age and other individual factors is the inability of a couple to conceive when desired. Primary infertility is that which occurs in couples who have never conceived. Secondary infertility occurs in those who have conceived before and cannot conceive again.
2. The normal average number of sperm released at ejaculation is 35 to 200 million. Twenty million per milliliter is probably the minimum required for unassisted fertility. At least 30% of the sperm must be living and normal, and half must have normal forward movement. The amount of seminal fluid should be 2 to 6 mL, and it should liquefy within 30 minutes.

- from the epididymis by using percutaneous aspiration or a microsurgical incision to aspirate a single sperm. The sperm obtained are then used to fertilize ova.
- Factors that couples consider when seeking infertility help include their age, the length of their attempt to conceive, their desire for a biologic child, and their feelings about adoption or a child-free life. Financial constraints and difficulty coordinating work or travel and treatment may be other considerations.
 - When deciding about infertility evaluations and treatments, the couple considers their personal, social, cultural, and religious values; how difficult treatment may be; the probability of success with treatment; and financial concerns.
 - Psychological reactions to infertility may include guilt, isolation, depression, or stress on the relationship.
 - Parenthood after infertility may be marked by anxiety about the pregnancy, loss of support from infertile couples, or unrealistic expectations about their parenting abilities.
 - Couples considering adoption must confront their personal preferences, limitations, and prejudices.
 - Couples who lose a pregnancy after a period of infertility often experience grief, but sometimes the grief is mixed with optimism because they were able to achieve pregnancy, even if completion was not possible.

CHAPTER 33

- Family history is an important part of a health history to assess risk factors for conditions such as heart disease, breast and colon cancers, osteoporosis, and other health problems that should be studied.
- A psychosocial evaluation helps caregivers identify best teaching approaches for the individual woman. Evaluating the woman's family and other support helps determine stresses in her life and may identify if counseling regarding domestic violence is needed.
- When taking a sexual history, the nurse should ask about sexual activity, number of partners, age when sexual activity began, method of contraception, and knowledge about and measures used for protection from sexually transmitted diseases (STDs).
- Three screening procedures for cancer of the breast are breast self-examination, clinical breast examination by a professional, and mammography, often with ultrasound or other additional imaging.
- Vulvar self-examination is recommended to detect signs of precancerous conditions or infections.
- A Pap test is a cytology specimen of the superficial layers of the cervix and endocervix to detect precancerous and cancerous cells of the cervix.
- Fecal occult blood testing is important to detect colon or rectal cancer.
- Human papillomavirus (HPV) vaccine is ideally started at 11 to 13 years, an age younger than the age of legal consent. Therefore the adult who is qualified to give permission, usually a parent, must face the issue of possible sexual activity at a young age.
- Ultrasound examination, fine-needle aspiration biopsy, core biopsy, or surgical biopsy is used to determine whether a breast disorder is benign or malignant.
- Staging of breast cancer is important to determine the extent of the breast cancer and to plan appropriate therapy.
- Adjuvant therapy is supportive or additional therapy recommended after surgery to improve the chance of long-term survival. Adjuvant therapy may include radiation therapy, chemotherapy, hormonal therapy, and immunotherapy.
- Breasts may be reconstructed during the initial surgery or later. Two major methods are the tissue expansion method and autogenous grafts from another area of the woman's body. Tissue grafting cannot be done in every woman.
- Teaching should include the length of the hospital stay and what will happen during that time, dressings, drainage tubes, and appearance of incisions for the expected procedures (lumpectomy, mastectomy, reconstruction). Lymphedema may occur in the immediate postoperative period, but it usually does not appear until well after discharge. Specific exercises such as arm lifts and pulley exercises will be taught as needed before discharge.
- Discharge planning after breast cancer treatment should emphasize the need for continued care, methods to reduce the risk of infection on the affected side, postoperative medications that should be taken, and signs and symptoms that should be reported to the physician. Referral to local support groups also may be helpful.
- Although a woman may have the "classic" crushing chest pain that is associated with a myocardial infarction, she is more likely to have atypical pain that often is confused with other conditions. These symptoms include fatigue or weakness; anxiety; angina or pain at rest; dyspnea; dizziness or faintness; upper abdominal pain, heartburn, or loss of appetite; nausea, vomiting, or sweating; and pain in the upper body other than the classic chest area (arm, neck, back, jaw, throat, and tooth).
- Measures to reduce the risk for coronary artery disease include smoking cessation and control of hypertension; diet and glucose control to maintain normal weight and optimum fat and cholesterol intake; increase in activity level; and, for many women, daily aspirin therapy.
- Primary amenorrhea is menstruation that fails to occur by 16.6 years, within 2 years of breast development, and within 1 year after onset of menses of her mother and a sister. Causes include hormonal imbalances, congenital anomalies, chromosomal defects, systemic diseases, and rigorous dieting and exercise. Treatment is aimed at identifying and treating the underlying cause. Secondary amenorrhea is cessation of menstruation for a period of at least 6 months in a woman who has an established pattern of menstruation. Pregnancy is the most common cause. Other causes include systemic disorders, hormonal imbalances, low weight for height, stress, poor nutrition, drug therapy for other disorders, and tumors of the ovary, pituitary, or adrenal gland. Once pregnancy is ruled out, treatment may include correction of the underlying cause, hormonal replacement therapy, and ovulation stimulation.
- Possible causes of dysfunctional uterine bleeding include complications of pregnancy; benign or malignant lesions of the vagina, cervix, or uterus; drug-induced bleeding; systemic diseases, which require prompt treatment; and failure to ovulate.
- Primary dysmenorrhea has no identified pathology. High levels of endometrial prostaglandin diffuse into endometrial tissue, causing painful uterine contractions, uterine ischemia, and tissue

CHAPTER 34

- Early treatment of fibrocystic breast changes begins with reducing the intake of caffeinated foods and some medications that contain caffeine. Other medications that may be tried include oral contraceptives during the second half of the menstrual cycle. Danazol, bromocriptine, and tamoxifen are other possibilities, but their use is temporary. Evening primrose oil may help some women.

- hypoxia often called *cramps*. Effective treatment includes rest, application of warmth, oral contraceptives, and prostaglandin inhibitors.
13. Endometriosis lesions grow and proliferate during the follicular and luteal phases of the menstrual cycle and then slough during menstruation. The menstruation from endometriosis lesions occurs in deeper tissue, causing pressure or pain that is deep, bilateral or unilateral, and dull or sharp. Treatment varies with the woman's age, whether she is nearing menopause, her desire for children, her willingness to take the drugs that inhibit excessive tissue growth, and the problems caused to nearby organs by endometriosis. In addition to delaying pregnancy, drug therapy may induce menopausal symptoms.
 14. Side effects of danazol include headache, dizziness, irritability, decreased libido, and masculinizing effects. The most common side effects of GnRH agonists are hot flashes, vaginal dryness, decreased libido, and loss of bone mineral density.
 15. Symptoms of PMS must be cyclic and recur in the luteal phase of the menstrual cycle; the woman should be symptom free during the follicular phase; symptoms must be severe enough to alter the work, lifestyle, and relationships of the woman; and the diagnosis must be based on the woman's charting of her symptoms in a diary as they occur rather than by recall.
 16. Common nursing education includes planning exercise therapy, incorporating dietary measures to reduce fluid retention and other symptoms (such as restricting salty or sweet foods, chocolate, caffeine, and others), educating the family about how to relate to a woman who is very irritable, and helping the woman to make arrangements so that she can avoid harming her child if she becomes very agitated.
 17. Mifepristone, methotrexate, and misoprostol are drugs that may be used for elective termination of pregnancy.
 18. The nurse should teach the woman self-care measures, similar to self-care following spontaneous abortion or miscarriage: observation for excessive bleeding or signs of infection, information about follow-up visits, and contraception information.
 19. Without estrogen, the reproductive organs begin to atrophy and the vagina and labia are thinner and more fragile. The breasts become smaller and atrophy. Bladder changes associated with atrophy make the woman more vulnerable to cystitis. Levels of total cholesterol and low-density lipoproteins ("bad" cholesterol) increase, while levels of high-density lipoproteins ("good" cholesterol) decrease, increasing the woman's risk for coronary artery disease. Hot flashes occur because of vasomotor instability. Bone mineral loss accelerates in the first few years of the climacteric. Loss of estrogen also appears to increase the risk for Alzheimer's disease.
 20. Depression, mood swings, and irritability are common psychological symptoms of menopause as the woman comes to term with aging. A woman may also greet menopause as freedom from earlier obligations in life as she shifts responsibility to her adult children.
 21. Estrogen replacement controls hot flashes, alleviates genital atrophy, and protects against osteoporosis. Estrogen replacement must begin early in perimenopause to provide significant protection against osteoporosis. If the woman has a uterus, progesterone is given for part of the cycle to prevent excessive buildup of the endometrium. Although once thought to reduce the incidence of cardiovascular disease and breast cancer, estrogen-progesterone replacement showed the opposite effect in the Women's Health Initiative study. At this time a woman must make a careful choice after weighing the benefits and drawbacks of HRT. Women with a history of estrogen- and/or progesterone-positive breast cancer should not take HRT.
 22. Osteoporosis is called the *silent thief* because no signs or symptoms may be apparent until posture changes as the vertebrae collapse or fractures occur.
 23. Osteoporosis can be prevented by medications to enhance calcium absorption and inhibit calcium loss (such as calcium and vitamin D supplementation) and by weight-bearing exercises that strengthen muscles and increase bone mass. HRT also enhances calcium retention, but potential problems with HRT limit its usefulness for many women.
 24. Nurses can help women with osteoporosis avoid falls by making their environment as safe as possible and enhancing their exercise programs. Adolescents and young women can also be taught the value of exercise in maintaining long-term bone health. Foods with higher calcium can increase a person's intake.
 25. With a cystocele, the weakened upper anterior wall of the vagina cannot support the weight of urine, and the bladder protrudes downward into the vagina, resulting in incomplete emptying of the bladder and consequent cystitis and stress incontinence. With a rectocele, the rectum protrudes into the vagina as the upper posterior wall of the vagina becomes weakened, which may result in difficulty emptying the rectum.
 26. Uterine prolapse is caused when the cardinal ligaments are stretched excessively, often with pregnancy, and do not return to normal. This condition is usually treated surgically according to severity and coexisting pelvic floor disorders.
 27. Pelvic exercises and bladder training may alleviate symptoms of pelvic floor relaxation and urinary incontinence. Additional measures include teaching about the need to maintain hydration and restrict alcohol and caffeine intake, adhere to weight control programs to reach optimal weight, and use of commercial products to protect the skin and prevent odor. Teaching about any prescribed medications may be indicated.
 28. Signs and symptoms of leiomyomas are increased uterine size and excessive vaginal bleeding, which often results in anemia. Other symptoms are pelvic pressure, bloating, and urinary frequency, depending on the size and location of the fibroids. Treatment depends on size, symptoms, and whether the woman desires more children. Surgical treatment options include removal of the fibroids (myomectomy) or hysterectomy. Uterine artery embolization may be an option for the woman who does not want surgery.
 29. Ultrasound is used to distinguish a fluid-filled ovarian cyst from a solid tumor, which requires additional evaluation to determine if the solid tumor is malignant.
 30. Signs and symptoms that may indicate cancer of the reproductive organs are irregular vaginal bleeding, unexplained postmenopausal bleeding, unusual vaginal discharge, dyspareunia, persistent vaginal itching, elevated or discolored lesions of the vulva, abdominal bloating, persistent constipation, anorexia, or nausea. Reproductive organ cancers such as ovarian cancer may have no symptoms in the early stages.
 31. Cervical cancer may be treated by cryosurgery, destruction of tissue by laser, loop electrosurgical excision procedure (LEEP), electrocoagulation surgical conization, or hysterectomy with chemotherapy for more advanced cases. Endometrial cancer is best treated with hysterectomy and bilateral salpingo-oophorectomy plus radiation. Radiation only may be used if the woman is a poor surgical candidate. Ovarian cancer is usually treated by surgery followed by chemotherapy; however, chemotherapy to reduce tumor size followed by surgery to remove malignancy may also be

- done. A second surgery may be performed to determine if more treatment is needed.
32. Pregnancy, diabetes mellitus, oral contraceptive use, and antibiotic therapy may result in vaginitis caused by *Candida albicans*.
 33. Candidiasis causes a thick, white discharge, often with “cottage-cheese” characteristics. Trichomoniasis causes a thin or frothy, malodorous, and yellow-green or gray discharge.
 34. Barrier methods of contraception (particularly condoms) prevent potentially infected ejaculate from entering the genital tract and prevent contact between the penis and vagina.
 35. The major symptom of primary syphilis is a painless chancre that disappears in about 6 weeks; the disease is highly infectious during the primary stage. Symptoms of secondary syphilis are enlargement of the liver and spleen, headache, anorexia, and skin rash. Condylomata lata that contain numerous spirochetes and are highly contagious may develop.
 36. Condylomata acuminata (genital warts) are caused by HPV, which is associated with cervical cancer.
 37. *Chlamydia trachomatis* and *Neisseria gonorrhoeae* cause most cases of PID. Other pathogens, including *Escherichia coli*, *Gardnerella vaginalis*, *Streptococcus*, *Peptostreptococcus*, *Bacteroides*, *Prevotella*, *Mycoplasma*, *Ureaplasma*, and cytomegalovirus, may cause PID. Other aerobic and anaerobic microorganisms may also cause PID.
 38. The risk of toxic shock syndrome can be reduced by changing tampons at least every 4 hours, avoiding use of superabsorbent tampons, and using pads rather than tampons during hours of sleep. The diaphragm or cervical cap should not be used during menstruation, and the device should be removed within the time limits recommended. Careful handwashing should be done before and after use of tampons, pads, diaphragm, or cervical cap for all women.

Answers to Critical Thinking Exercises

CHAPTER 3

Critical Thinking Exercise 3-1

1. The deontologic view is that taking organs necessary for life from one human being to give to another is wrong, even when the donor cannot survive. Maintenance of life at all costs is the goal.
2. The utilitarian view is that anencephalic infants cannot survive, but that their organs could benefit other infants (beneficence). Because this family feels strongly that helping other infants allows good to come from their own tragedy, the greatest good would be for an organ transplant.
3. This view disapproves of aggressive treatment necessary to maintain perfusion to the organs until a recipient is located because treatment does not help the dying infant and may increase suffering.
4. This concern invokes the principle of nonmaleficence. Despite the inability of this infant to survive, the human rights view is that his or her care and comfort needs are primary.

CHAPTER 7

Case Study 7-1, Introduction, Critical Thinking Exercise

1. If pregnant now, Sally is gravida 3, para 1 (the twin birth counts as one pregnancy and one parous experience).
2. Amenorrhea, nausea, and vomiting are only presumptive indications of pregnancy because they can be caused by conditions other than pregnancy.
3. Count back 3 months to August 16, and add 7 days. This brings the date to August 23. Add 1 to the current year.

Case Study 7-1, Critical Thinking Exercise

1. The nurse should use therapeutic communication techniques to listen to Sally's concerns. Once Sally has expressed her frustration, the nurse can teach her the reason for each assessment and make suggestions that might be helpful.
2. To assess the growth of the fetus, Sally's weight gain is compared to what is expected according to the weeks of gestation. Protein in the urine and elevated blood pressure are signs of a serious complication of pregnancy, preeclampsia. The fetal heart rate is checked at each visit to help determine if the fetus is progressing normally.
3. Sally should talk to her physician about her concerns. She should ask questions about what care is needed and the frequency of visits. She may be a candidate for fewer prenatal visits. She might be able to schedule her visits at less busy times so she does not have to wait so long. She should bring a list of questions with her and let the physician know she needs more information. Questions are often forgotten if they are not written down.

CHAPTER 8

Critical Thinking Exercise 8-1

1. The nurse should use therapeutic communication techniques to encourage each woman to talk more about her concerns. This shows interest and may identify other concerns as well.
2. These multiparas will have more concerns about lack of time and increased fatigue than a primigravida. In addition, they will have concerns about the effect of another baby on their other children and the time and energy required to meet the needs of all children.
3. Although both have 2-year-olds, Ruth will be concerned about her son's response to sharing her time and attention. Elisa has experienced this before and may be more worried about the effect of another baby on her economic situation and her ability to manage yet another child.
4. Suggest that any changes in sleeping arrangements be made early so that the other child(ren) will not feel displaced by the infant. Recommend that they plan ways to have time alone with the older child(ren) when the baby arrives, and review measures to reduce sibling rivalry. Ask Elisa about measures that were helpful when her last two children were born, and suggest that she involve the older children in preparing for the new baby.

CHAPTER 9

Case Study 9-1, Introduction, Critical Thinking Exercise

1. If Holly feels the nurse is disapproving of her actions, she is unlikely to trust the nurse with further confidences. Because she will probably not completely end her pica, especially without help, a disapproving nurse will cause her to withdraw and continue to practice it in secret.
2. Being accepting and nonjudgmental is important when responding to Holly. The nurse should use therapeutic communication to explore Holly's feelings about her cravings. A discussion of feelings can lead to teaching about nutrition.

The nurse reassures Holly that expected weight gain during the first trimester is only about 0.5 to 2 kg (1.1 to 4 lb). Holly is weighed and is only slightly below what is expected for this point in gestation. It appears that Holly's pica is not severe and her ice intake is not interfering unduly with her weight gain at this time.

The nurse should determine the amount of ice Holly eats each day, whether she has other cravings, and how these affect her intake of important nutrients. Holly and the nurse can work together to find acceptable ways to modify the diet to include possible nutritious substitutions for the ice. Holly should be referred to a dietitian for further counseling, but the nurse should also continue to watch Holly's weight gain carefully and discuss her diet at each prenatal visit.

Critical Thinking Exercise 9-1

1. Cheryl has gained an excessive amount of weight for this point in pregnancy. If she continues to gain weight at this rate, she will have a large amount of weight to lose after giving birth, and that may be difficult. Excessive weight gain in pregnancy can lead to obesity, gestational diabetes, labor complications, and postpartum weight retention. It can also cause increased birth weight of the infant and complications such as asphyxia, low Apgar scores, and hypoglycemia.
2. The nurse should look at Cheryl's eating habits and identify what may be leading to the excessive weight gain. The negative effects on the fetus of severe diet restrictions should be explained to Cheryl. The nurse should discuss a plan for limiting calories while still meeting the recommendations for calories and nutrients in pregnancy. If Cheryl is sedentary, a plan for moderate daily exercise may also be helpful.

CHAPTER 11

Case Study 11-1, Introduction, Critical Thinking Exercise

Carmen should take an early pregnancy class at this time. That class will focus on topics Carmen needs to know for this stage of pregnancy. It will also give her an opportunity to learn more about the hospital where she will deliver and what other classes are offered there.

Critical Thinking Exercise 11-1

Liz and her support person should attend classes because they may have forgotten some information, especially since it has been over 5 years since the last class. Birthing care and options may have changed since the last birth. Couples often have concerns and questions about their last experience, and the nurse can discuss these issues and help them feel more positive about the impending birth. The needs of other children can also be addressed, including practical suggestions about easing the transition.

CHAPTER 12

Critical Thinking Exercise 12-1

1. Additional information is needed. Ask to talk to Heather and find out the following:
 - a. Is there any leaking or gush of fluid? If so, what did it look like, and what color was it?
 - b. Is there any vaginal bleeding other than spotting or pinkish mucus?
 - c. Has the baby's activity level been "normal"?
 - d. Are the contractions regular? How often do they occur? Is this closer together or further apart than earlier in the day?
 - e. How long do the contractions last? Is this longer or shorter than earlier in the day?
 - f. Has the strength of the contractions increased, or does it vary? Other than not being able to sleep, how are you coping?
 - g. Have you had other children/labor? How does this compare? How long was your labor with other child(ren)?
 - h. How far away from the hospital do you live?

You want to speak with Heather. By putting her on the phone, you can assess her anxiety level and how she responds to any contractions that she has while you are talking to her.

Questions a, b, and c: If there is possible rupture of the amniotic membranes, vaginal bleeding, or decreased fetal activity, Heather

needs to come in for an assessment regardless of whether or not she is in labor.

Questions d, e, and f: You are trying to determine if the contractions are labor or Braxton Hicks. Labor contractions will be regular with increasing frequency, duration, and intensity. Braxton Hicks contractions will be irregular in timing, duration, and intensity. If the contractions are regular, you need to know the current frequency, duration, and intensity to anticipate whether she is in latent or active phase. You also need to assess Heather's coping ability.

Questions g and h: If Heather has had other labors, you need to know if they were usually fast. If so, you may want her to come in earlier in the labor than someone who has a history of longer labors. Multigravida women typically labor faster than primigravida women do. You may instruct her to come in a little earlier in the labor so that she will have time to arrive at the hospital without undue anxiety.

2. Recommend that Heather stay home if you determine that her membranes are intact, she is not bleeding, and the fetus is active; that she is either primigravida or does not have a history of rapid labors, that she lives near the hospital and is either having Braxton Hicks contractions or is in latent phase of first stage labor. Explain to Heather that she is most likely having Braxton Hicks contractions. Some of them may feel very intense, but others will not. However, they are important to prepare her body for active labor. Suggest that she walk around for a while, stay well hydrated, and take a warm bath or shower to relax. Instruct her to come to the hospital when the contractions are regular and every 5 minutes for 1 hour (every 10 minutes if she is a multigravida), if she has a gush or leaking of fluid or bright red vaginal bleeding, if the baby's movements substantially decrease, or if she is not able to cope effectively with the contractions.

Critical Thinking Exercise 12-2

Carmelita is in the latent phase of first-stage labor. The occiput of the baby's head is toward the right side of her spine. This fetal position is typically associated with slower, more painful labors. Nursing interventions should include activities to promote rotation of the fetus to an OA position. You would expect Carmelita to be excited and sociable at this time. She will probably complain of back pain, which may begin to encircle her abdomen. An increase in frequency, duration, and intensity of contractions indicates that she is making rapid progress. If she becomes serious, with an inward focus, anxious, or expresses feelings of hopelessness, she has probably progressed to the active phase of labor. If she progresses very rapidly to transition, she may become irritable and lose control.

CHAPTER 13

Critical Thinking Exercise 13-1

The woman is either insulted that the nurse asked such a question or has indeed used drugs or herbal preparations. In either case, it may be beneficial for the nurse to stop the interview and explain that the question is asked of all women who are admitted and why the information is important to the care of a woman in labor and her baby. If other people are in the room, the nurse should continue the interview when the patient is alone. Assure her of the confidentiality of her medical record, but be honest with her if any drug tests will be performed on her or her baby.

Critical Thinking Exercise 13-2

The most important nursing action at this time is assessment of the fetal heart rate. When the membranes rupture, the umbilical cord may be washed into the vagina with the fluid. The fetal head may then compress the cord and cut off its own blood supply. This is an obstetric emergency known as a prolapsed umbilical cord. If the cord is prolapsed, the FHR will be low (<110 bpm, probably much lower than that). If the fetal heart rate has dropped, the nurse should perform a vaginal exam to feel for the cord and elevate the presenting part off of the cord until an emergency cesarean birth can be performed. See Chapter 27.

CHAPTER 14

Critical Thinking Exercise 14-1

The pattern described is one of late decelerations, probably caused by excess uterine activity secondary to the use of oxytocin. Appropriate nursing actions are based on enhancing fetal oxygenation. Jackie's initial action should be to stop the oxytocin infusion and increase the rate of nonadditive IV fluid, which is Ringer's lactate in Nancy's case. Oxygen should be given through a snug face mask at 8 to 10 L/min. Nancy should be placed on her side, if she is not already in this position, to increase placental blood flow. After the immediate corrective actions are completed, Jackie should contact Nancy's physician or nurse-midwife, documenting the EFM pattern, interventions, and the content of the call.

Critical Thinking Exercise 14-2

The nursing student should call the RN to the room to evaluate the patient. A change of position may relieve possible cord compression. These changes include turning from side to side or assuming a hands-and-knees position to release the cord from its entrapped position. Positioning LaShonda with her hips higher than her head may also relieve pressure on the cord. The monitoring strip should be evaluated by an experienced RN or the physician/midwife to clarify whether a variable deceleration pattern truly exists or if the pattern was an isolated dip in the rate. Evaluation should continue to determine if the decreases in FHR are repetitive or isolated.

LaShonda's oxygenation and hydration should be considered as well. Oxygen at 8 to 10 L/min by face mask and increasing the plain intravenous fluid can correct inadequacies in these areas.

CHAPTER 16

Critical Thinking Exercise 16-1

1. FHR is elevated from the usual range of 120-160 bpm, possibly because the fetal temperature may be one degree more than mother's temperature, making it near 38.3°C (101°F). The amount of amniotic fluid is normal, but the pale yellow color and strong odor suggest chorioamnionitis, or infection of the amniotic sac. The risk for chorioamnionitis increases as the duration of ruptured membranes increases, but it can be apparent at any time, including at initial rupture. Accelerations with fetal movement are a reassuring sign of fetal well-being. The maternal temperature, pulse, and respirations are slightly elevated. Epidural analgesia is sometimes associated with temperature elevation. Accurately interpreting these values is difficult because the baseline values at the time of admission are not stated. The contractions are typical for a woman entering the active phase of first-stage labor.
2. Notify other medical staff of the woman's present situation that were not involved in the amniotomy, such as anesthesia professionals.

Observe temperature at least every 2 hours for elevation. The nurse should continue to assess the fetus for tachycardia, which often precedes maternal fever. Assess the woman's temperature at least every 2 hours for temperature of 100.4°F (38°C) or higher. Report abnormalities to the physician. Also observe for fetal tachycardia and signs of fetal compromise that may occur with maternal infection.

Critical Thinking Exercise 16-2

1. The nurse must consider that the FHR and pattern and contractions are externally monitored. However, contractions are difficult to monitor without palpation because of the thick abdominal fat pad (also called a *pannus* or *apron*). The frequency of contractions is not yet excessive at every 2 minutes (no more than 5 in a 10-minute time span). The duration of contractions is within the normal limits of 90 to 120 seconds. However, the relaxation time of the uterus is inadequate because it never fully relaxes. Inadequate uterine relaxation can be identified in two ways: (a) contractions with a frequency of every 120 seconds and a duration of 100 seconds means that only 20 seconds of timed uterine relaxation occur; (b) palpation by the nurse to compensate for the abdominal fat that interferes with external uterine activity monitoring identifies that the uterus never fully relaxes before the next contraction begins.
2. Although the fetus is tolerating labor now, fetal oxygenation may be compromised if the excessive contractions and lack of full uterine relaxation continue. Reduce or stop the oxytocin infusion to decrease uterine stimulation. Increase the primary (nonadditive) IV infusion as needed to maintain adequate fluid volume and ensure maximum uterine blood flow. Keep the woman in a lateral position to reduce aortocaval compression and increase placental blood flow. Oxygen at 8 to 10 L/min with a snug face mask increases her blood oxygen saturation, making more available to the fetus. Promptly notify the physician to report on assessment of excessive contractions and interventions. The nurse should continue to observe for presence of other reassuring fetal signs such as FHR accelerations and spontaneous fetal movement or onset of nonreassuring signs or persistence of inadequate uterine relaxation (pp. 267-269).

CHAPTER 17

Case Study 17-1, Critical Thinking Exercise

1. The birth of a large infant and multiparity increase the risk of postpartum hemorrhage. Saturation of pads in a short time suggests heavy bleeding. The boggy consistency of the fundus and its location above the umbilicus and displaced to the side indicate that the cause of bleeding might be a distended bladder.
2. Massaging the uterus and assisting the mother to void are the priority nursing actions. If, after voiding, the fundus is located at the level of the umbilicus and firmly contracted, the cause of the bleeding was probably a distended bladder, which made it difficult for the uterus to contract firmly. The location and consistency of the uterus, amount of lochia, BP, and pulse should be assessed frequently so that further excessive bleeding can be identified and controlled. If bleeding continues, clots should be expressed from the uterus when the fundus is firm. The health care provider should be notified if there is further bleeding.
3. Jenny may not experience the urge to void because the bladder has not regained the muscle tone lost during pregnancy and the sensitivity to pressure is decreased.

Critical Thinking Exercise 17-1

1. Any time a patient has more pain than would be expected, further assessment is necessary to determine the cause. Ask Lani to rate her pain. Exactly where is the pain located? What type of pain is it: burning, pressure, dull ache? Ask her whether she urinated a large or small amount. How did the amount compare with her usual voidings? How much lochia does she have, compared with previous assessments?
2. Regardless of the amount she thinks she voided previously and Lani's lack of the sensation of needing to void, assist her to the bathroom to see if she can void. If she urinates, measure the amount to see if it is adequate (approximately 300 mL) and determine if she feels relief after voiding. If she is unable to void and an order is available, catheterize her. If no order exists, call the health care provider to obtain an order.
3. A distended bladder is the most likely cause of Elizabeth's pain. However, she may have a very low pain tolerance or need a different kind of analgesic. In this case, however, Lani had surgery yesterday and has received pain medication since that time. A low pain tolerance would already have been noted. Some surgical complication may exist. If the pain continues, refer the problem to the provider.

CHAPTER 18

Critical Thinking Exercise 18-1

1. Callie's priority needs are for physical care and comfort. She also needs to make the experience of childbirth part of her reality and does this by recounting the details of the birth and trying to fill in the missing pieces about the cesarean birth.
2. Callie is in the taking-in phase. She is getting acquainted with her "real" baby by exploring with her fingertips. This usually is the first maternal touch observed.
3. Callie's priorities are to assume control of her own body functions and manage her care so that she can "take hold" and assume care of the baby.
4. Callie has become more independent and now initiates breastfeeding. She demonstrates readiness to learn by requesting the assistance of the lactation consultant.
5. Anticipatory guidance should focus on ways she can manage the care of the infant while still getting adequate rest and nutrition. Keeping a flexible schedule, resting while the infant rests, and preparing easy, nutritious meals are some of the most important items to emphasize.
6. Assisting her in identifying friends and neighbors who might provide some support while her husband is away would be most helpful. If this is not possible, she should have telephone numbers for community resources such as the hospital "baby line." A follow-up home visit, visit to a postpartum clinic, or telephone call initiated by the nurse would be very helpful. The nurse could assess the mother and infant, reinforce teaching, and provide encouragement.

CHAPTER 19

Critical Thinking Exercise 19-1

If an opening were present between the right and left atria after birth, blood would flow from the left atrium, where pressures are high after birth, into the right atrium, where pressures are low after birth. This is the reverse of the blood flow through the foramen ovale during fetal life. The blood would then flow to the right ventricle, the pulmonary

artery, and to the lungs. This would cause an increased workload on the lungs and could lead to serious complications.

Critical Thinking Exercise 19-2

Some sources of heat loss are:

- Evaporation—liquid on the body at birth or during bathing, contact with wet towels or blankets, regurgitation, urine on the skin, increased insensitve water loss while under a radiant warmer or under phototherapy lights
- Conduction—cool blankets, clothing, mattress, scale, stethoscope, circumcision restraint board, hands of caregivers
- Convection—air conditioning or fans, drafts, movement of people around the infant, open windows, cold oxygen
- Radiation—placement of crib or being held near an outside wall or window (open or closed), cool walls in poorly heated room

CHAPTER 20

Critical Thinking Exercise 20-1

Failure of the reflexes to fade on schedule may interfere with normal development. For example, the palmar grasp reflex must disappear so that the infant can learn to grasp voluntarily and later to release objects at will. Persistence of the plantar reflex would interfere with walking. Retention of reflexes beyond the age at which they should disappear indicates pathology and should prompt further investigation.

Critical Thinking Exercise 20-2

Begin by expanding your assessment of the facts. First, check through the chart to be sure that no stool is recorded. Did the infant pass meconium at delivery? Check the delivery notes. Ask the mother if she has changed a diaper with stool in it. Instruct her to inform the nurse if she does. If agency policy permits, carefully taking a rectal temperature may stimulate peristalsis and passage of meconium and verifies that the anus is patent. However, even with a patent anus, obstruction of the intestine above the anus is possible.

Consider the infant's intake. How often is the infant feeding and how well are feedings being taken? If the infant has been sleepy and has fed poorly, increase the feedings. Asking the nursing mother to feed more often or offering the neonate extra formula may make the difference.

Alert other caregivers to watch for a stool, and let the mother know that the infant is being watched for stools without alarming her. Although some infants do not have a stool until nearly 48 hours after birth, the primary caregiver may wish to know about the situation at 24 hours.

CHAPTER 21

Case Study 21-1, Critical Thinking Exercise

1. Determine whether Nicholas is showing signs of inadequate thermoregulation, hypoglycemia, or both. Reassure and teach Vicki as assessments and interventions are completed.
2. While taking the infant's temperature, assess for skin temperature, jitteriness, and general behavior. Check the blood glucose level if indicated. Also assess the environment for possible causes of heat loss.
3. If the baby's temperature is slightly low, change any wet linens, double-wrap him in warm blankets, and put a hat on his head. Or place him skin-to-skin with Vicki with a blanket over both of them. Have Vicki feed him if it is near a feeding time or if the blood glucose level is low. Recheck the temperature in 30 minutes.

If it is still low, place Nicholas under a radiant warmer. Notify the physician if the infant continues to have difficulty maintaining temperature.

4. Praise Vicki for being so observant of her son. If the temperature is normal and Nicholas is not jittery, discuss the fact that peripheral circulation is sluggish in newborns and that their hands and feet tend to be cool. If the “shakiness” is the Moro reflex or normal newborn behavior, discuss the reflex and the immaturity of the central nervous system. Show Vicki how to wrap Nicholas so he stays warm and the Moro reflex is not elicited. Discuss methods of temperature control and be sure that Vicki knows how to read a thermometer. Explain all interventions.

Case Study 21-1, Critical Thinking Exercise

Explain to the grandmother and the parents that although infants have slept on the abdomen without harm, research has shown that infants sleeping in this position have a higher chance of dying from sudden infant death syndrome (SIDS) than those who sleep on the back. To prevent flattening of the head, babies should spend time on the abdomen every day while they are awake. “Tummy time” helps keep the head rounded and helps develop the infant’s muscles. The infant should always be supervised when lying prone. Occasionally placing the infant at alternate ends of the crib changes the pressure on the head because an infant is more likely to look toward the door.

CHAPTER 23

Critical Thinking Exercise 23-1

1. The major priorities are to support the parents in their new role and to determine if Susan is progressing normally.
2. Use therapeutic communication techniques to allow Mary and Skip to express their feelings adequately. If Susan appears to be progressing normally, emphasize that she is doing well. Point out that the problems they are encountering are quite common for both biologic and adoptive parents.
3. Information should be based on the parents’ concerns. Explain normal characteristics and behaviors of the newborn. Determine if Mary and Skip need more information about basic infant care, such as feeding, cord care, and signs of illness. Provide frequent opportunities for them to ask questions.
4. Obtain more information about Susan’s sleep patterns. Discuss normal sleep in newborns and methods of helping infants sleep. Offer suggestions for methods of coping with crying. Help Mary and Skip work out a plan for sharing the burdens and the joys of parenthood.

CHAPTER 24

Critical Thinking Exercise 24-1

1. The nurse may have assumed that the husband’s behavior indicated concern for his wife. Instead, it may have been a manifestation of *hovering husband syndrome*, which occurs in the honeymoon phase of the cycle of violence.
2. Facial injury, signs of previous bruising that resemble “grab marks,” and abdominal bruising should make the nurse question Mandy’s explanation. Mandy’s story of falling and hurting herself is not congruent with the location of abdominal injury and injuries on her arms. Mandy’s lethargy and avoidance of eye contact also suggest that she is afraid.
3. The nurse should not question Mandy’s explanation of the injury in the presence of the husband because this can increase the danger

of escalating violence when the mother and the infant are discharged.

4. The nurse should respond, “No one deserves to be hurt and it’s not your fault. You have a right to be respected and safe. There are resources to help you.” Nurses must examine their own thinking to be certain that they do not accept a common bias that physical abuse is deserved by the victim.
5. Mandy needs information about protecting herself and the coming infant from future harm. This is not, however, the appropriate time to give her this information. The nurse must inform the physician and the postpartum staff of the problem and must make the necessary referrals to the hospital’s social service department for follow-up.

CHAPTER 25

Critical Thinking Exercise 25-1

Nurses often assume that patients possess and know how to use a thermometer and that they know the signs of infection. Many nurses assume that patients realize the connection between blood loss and the tendency to develop infection. As a result, nurses may not emphasize the need for a diet that is high in nutrients that increase hemoglobin and hematocrit (iron and vitamin C). Nurses also may assume incorrectly that women know foods that contain these nutrients.

Critical Thinking Exercise 25-2

1. Many people wrongly assume that early pregnancy loss does not produce the grieving that accompanies loss at a later stage. Telling a woman that she is lucky when this happens ignores her feelings and invalidates any grief she feels.
2. The nurse also mistakenly assumes that little cause for grief exists over the loss of this pregnancy if later children are possible. However, a unique relationship exists between the woman and this fetus. She may experience an emotional upheaval when this special relationship comes to an abrupt end. Another pregnancy is not guaranteed to any woman.
3. It would be beneficial if the nurse examined her assumptions before having the interaction with a woman experiencing early fetal loss. The patient might feel free to express her feelings and acknowledge the grief that she is feeling.

CHAPTER 26

Critical Thinking Exercise 26-1

1. The team has apparently assumed many things about this woman, such as that she knows the importance of frequent follow-up for gestational diabetes and that she has the transportation and available time off from work to return weekly. The team has assumed that the diet has food that is affordable and fits with her food preferences.
2. To improve compliance and identify specific patient needs, the team needs to ask the woman about her food preferences with the diet and possibly its affordability. Lack of transportation and time off from work may present another need. The team should ask questions that may reveal other needs for diabetes-related pregnancy care.
3. The nurse could agree that a large baby might be a normal family trait but emphasize that measures to keep glucose normal are important to the well-being of her baby, regardless of size.
4. These tests provide reassurance that pregnancy is progressing well and identify problems that need to be addressed.

CHAPTER 27**Critical Thinking Exercise 27-1**

1. When the fetus is in one of the occiput posterior positions, back pain is usually persistent because the fetal head presses on the mother's sacrum with each contraction, often called *back labor*. Additionally, the fetal head has to rotate internally through a wider arc to ultimately reach an occiput anterior position for birth. This process prolongs labor in most women.
2. The nurse should take actions to make the woman more comfortable and promote rotation of the fetal head to an occiput anterior position. The nurse should encourage the woman to change positions regularly. Positions that cause her uterus to fall forward reduce pressure on her sacrum and straighten the pelvic curve somewhat to encourage fetal rotation. Examples of these are leaning forward while sitting, kneeling, or standing, or a hands-and-knees position. Lunging toward her right side provides slightly more room on that side of her pelvis. If she wants to lie in bed, a left side-lying position favors fetal rotation toward an occiput anterior position. Analgesia may be helpful.

CHAPTER 28**Critical Thinking Exercise 28-1**

1. Her history of multiparity, birth of a large infant, and rapid labor and delivery indicate that Dawn is at risk for postpartum hemorrhage. The nurse should increase the frequency of her assessments of the fundus, lochia, vital signs, and skin temperature and color.
2. Massage the fundus and express clots that may have accumulated in the uterus. Massage stimulates uterine contractions that compress torn myometrial blood vessels and stop excessive bleeding. If any clots have formed inside the uterus, they must be expelled to allow the uterus to contract. Continued assessment of the fundus and lochia is imperative to determine whether the uterus relaxes again, leading to resumption of bleeding.
3. Assist Dawn to void because a distended bladder lifts the uterus, making contraction more difficult and resulting in excessive bleeding.
4. Continue to massage the fundus and turn on the call light to ask a colleague for help. Ask that another nurse notify the health care provider because excessive bleeding requires the combined efforts of primary health care providers and nurses to prevent postpartum hemorrhage. Start IV fluids or increase the flow rate of an existing IV and give medications according to orders or hospital protocol. Insert a catheter to ensure that urine output can be measured easily.

Critical Thinking Exercise 28-2

1. The nurse assumed that Aricella's feelings are the transient, self-limiting moods of depression that occur in many women who give birth. The nurse fails to obtain additional data that may indicate whether Aricella is experiencing postpartum depression that requires additional therapy. She could quickly screen for PPD by asking (a) do you feel down, depressed or hopeless and (b) do you feel little interest or pleasure in doing things?
2. The nurse's response is not helpful because it minimizes the feelings Aricella has expressed and it offers no measures for coping with them. Aricella is unlikely to tell the nurse more about her feelings because the nurse has implied that they are unimportant.
3. The nurse should acknowledge Aricella's feelings and ask follow-up questions that allow her to express her feelings fully.

4. The nurse must convey genuine interest and caring. She can do this best by:
 - a. Indicating awareness that something may be wrong.
 - b. Sharing as much time as Aricella needs to express her feelings.
 - c. Providing hope by reassuring Aricella that these feelings are common, that the condition is not her fault, that it can be cured, and that it is acceptable to talk about these feelings and seek help.
 - d. Making appropriate referrals to provide as much continuity of care as possible. Provide Aricella phone numbers and Internet addresses for a crisis center and support groups.

CHAPTER 29**Critical Thinking Exercise 29-1**

1. The mother may be intimidated by the equipment and fear she might break it or cause it to malfunction if she touches it. If alarms sound frequently, she may be especially uneasy. She may be frightened of the infant's small size and afraid she might cause harm by touching her baby. She may be experiencing anticipatory grieving because her infant may not survive. She may also be too overwhelmed to be able to participate in touching her infant at this time and may need more time.
2. To assist the mother, the nurse can use therapeutic communication techniques to help her express her feelings and fears. The purpose of equipment and reasons for alarms should be explained. Involving the mother in small tasks, such as handing the nurse a blanket or holding a bottle of formula, may help her feel more a part of her baby's care. The nurse should continue to suggest that the mother touch the baby and to suggest ways it might be appropriate. For example, the nurse might ask the mother to hold the infant's hand to comfort the infant during minor procedures. As she becomes more comfortable, she might be amenable to holding the baby in kangaroo care.

Case Study 29-1, Critical Thinking Exercise

Compared with the full-term infant, Giovanni will need more frequent feedings with special formula in smaller amounts. He will start by having tube feedings in very small amounts. Gradually the amount will increase. When he shows signs of readiness for feeding from a bottle, he will be given a small amount of feeding by bottle and will finish with tube feedings. After a while he will be able to take all of his feeding by bottle. (See Nursing Care Plan 29-1 for interventions appropriate for bottle feeding the preterm infant.)

Case Study 29-1, Critical Thinking Exercise

Explain the concept of corrected or developmental age to the mother. Since the infant was born 10 weeks early, the corrected age at this time is 4 weeks. This is the chronological age (14 weeks) minus the number of weeks the infant was born early (10 weeks). Therefore the infant can be expected to turn from prone to supine at $6\frac{1}{2}$ to $7\frac{1}{2}$ months chronological age, which is 4 to 5 months corrected or developmental age.

CHAPTER 30**Critical Thinking Exercise 30-1**

Patches hide the eye area, and an irritation or infection might not be noticed with patches in place. The warm, dark, moist area under the patches provides a good breeding ground for organisms to grow. Removal of the patches at feedings allows inspection for signs of infection such as redness, edema, and drainage. Removal also allows a time

of visual sensory stimulation for the infant. Parental visits should be coordinated with feedings, if possible, so parents can see the infant's whole face while they visit. This will help the infant appear more normal to them and enhances attachment.

CHAPTER 31

Critical Thinking Exercise 31-1

1. Find a private place to talk without interruption. Use therapeutic communication techniques to explore her feelings further. Help her think through the ways in which a pregnancy might change her life and how she would feel about those changes.
2. Explore what the teenager feels would be most embarrassing about seeing a physician. Would a female nurse practitioner, nurse-midwife, or physician be more acceptable? Discuss what happens when a woman is examined during a visit for contraceptive counseling. Let her know that a pelvic examination is not necessary if she is not having any problems and that the provider may prescribe contraceptives without an examination. Discuss common contraceptive methods and determine her understanding and concerns about them.
3. Discuss negotiation skills for condom use because condoms are important for prevention of STDs as well as pregnancy. Try role playing, with the adolescent acting in the role of her partner and the nurse taking the role of the adolescent.

GLOSSARY

ΔOD450 (delta OD 450) A test used to measure the change (delta, or δ) in optical density of the amniotic fluid caused by staining with bilirubin.

abortion A spontaneous or elective termination of pregnancy before the 20th week of gestation based on the date of the last menstrual period. Spontaneous abortion is frequently called *miscarriage*.

abruptio placentae Premature separation of a normally implanted placenta.

abstinence syndrome A group of signs and symptoms that occurs when a person who is dependent on a specific drug withdraws or abstains from taking that drug.

acidosis Condition resulting from accumulation of acid (hydrogen ions) or depletion of base (bicarbonate); acid-base balance measured by pH.

acme Peak, or period of greatest strength, of a uterine contraction.

acrocyanosis Bluish discoloration of the hands and feet caused by reduced peripheral circulation.

adjuvant therapy Additional treatment that increases or enhances the action of the primary treatment.

adnexa Accessory parts or organs, such as the fallopian tubes and ovaries associated with the uterus.

afterpains Cramping pain after childbirth caused by alternating relaxation and contraction of uterine muscles.

agonist Substance that causes a physiologic effect.

allele An alternate form of a gene.

alpha-fetoprotein (AFP) Plasma protein produced by the fetus.

ambiguity (ambiguous) Lack of clarity or certainty; having more than one meaning.

ambivalence Simultaneous conflicting emotions, attitudes, ideas, or wishes.

amenorrhea Absence of menstruation. Primary amenorrhea is a delay of the first menstruation, and secondary amenorrhea is cessation of menstruation after its initiation.

amniocentesis Transabdominal puncture of the amniotic sac to obtain a sample of amniotic fluid that contains fetal cells and biochemical substances for laboratory examination.

amnioinfusion Infusion of a sterile isotonic solution into the uterine cavity during labor to reduce umbilical cord compression; may also be done to dilute meconium in amniotic fluid and reduce the risk that the infant will aspirate thick meconium at birth.

amniotic fluid embolism An embolism in which amniotic fluid with its particulate matter is drawn into the pregnant woman's circulation, lodging in her lungs.

amniotic fluid index (AFI) An ultrasound examination in which the vertical depth of the largest fluid pocket in each of the four quadrants of the uterus is measured and totaled.

amniotomy AROM—artificial rupture of the fetal membranes (i.e., the amniotic sac).

analgesic Systemic agent that relieves pain without causing loss of consciousness.

anaphylactoid syndrome A disorder in which amniotic fluid with its particulate matter enters the

pregnant woman's circulation, lodging in her lungs. Previously called *amniotic fluid embolism*.

anesthesia Loss of sensation, especially to pain, with or without loss of consciousness.

anesthesiologist Physician who specializes in administration of anesthesia.

angina pectoris Myocardial pain usually caused by physical activity or stress; usually called simply *angina*.

anorexia nervosa Refusal to eat because of a distorted body image and feeling of obesity.

anovulation Menstrual cycles that occur without ovulation.

antagonist Substance that blocks the action of another substance or of body secretions.

antepartum Pertaining to the time during pregnancy before the onset of labor.

apnea A pause in breathing lasting 20 seconds or more, or accompanied by cyanosis, pallor, bradycardia, or decreased muscle tone.

apneic spells Cessation of breathing for more than 20 seconds or accompanied by cyanosis, pallor, bradycardia, or hypotonia.

asphyxia Insufficient oxygen and excess carbon dioxide in blood and tissues.

aspiration pneumonitis Chemical injury to the lungs that may occur with regurgitation and aspiration of acidic gastric secretions.

assisted reproductive technologies (ART) Medical, surgical, laboratory, and micromanipulation techniques used with ova and sperm to improve chances of conception.

assumptions Beliefs taken for granted without examination.

atony Absence or lack of usual muscle tone.

atrophic vaginitis Inflammation that occurs when the vagina becomes dry and fragile, usually as a result of estrogen deficit after menopause.

attachment Development of strong affectional ties as a result of interaction between an infant and a significant other (such as mother, father, sibling, caretaker).

attitude Relationship of fetal body parts to one another.

augmentation of labor Artificial stimulation of uterine contractions that have become ineffective.

autogenous Tissue that is moved from one part of the body to another part of the same person's body.

autosome Any of the 22 pairs of chromosomes other than the sex chromosomes.

axillary dissection Removal of most lymph nodes in the area of a tumor to determine the degree of tumor spread in the area.

azoospermia Absence of sperm in semen.

baroreceptors Cells that are sensitive to blood pressure changes.

basal body temperature Body temperature at rest.

baseline data Information that describes the status of the client before treatment begins.

baseline risk The risk, usually in reference to birth defects or spontaneous abortion, of the general population of pregnant women who have no identified high-risk factors or invasive procedures.

bias A prejudice that sways the mind.

bicornuate (bicornate) uterus Malformed uterus having two horns.

bilirubin Unusable component of hemolyzed (broken down) erythrocytes.

bilirubin encephalopathy Acute manifestation of bilirubin toxicity occurring in the first weeks after birth.

bioethics Rules or principles that govern right conduct, specifically those that relate to health care.

biophysical profile (BPP) Method for evaluating fetal status during the antepartum period based on five variables originating with the fetus: fetal heart rate, breathing movements, gross body movements, muscle tone, and amniotic fluid volume.

birth defect An abnormality of structure, function, or body metabolism present at birth that results in physical or mental disability or is fatal (March of Dimes Birth Defects Foundation, 2006a).

birth plan A plan describing a couple's preferences for their birth experience. (Also called a *family preference plan*.)

bloody show Mixture of cervical mucus and blood from ruptured capillaries in the cervix; often precedes labor and increases with cervical dilation.

body image Subjective view of one's physical appearance and capabilities; derived from one's own observations and the evaluation of significant others.

bonding Development of a strong emotional tie of a parent to a newborn. (Also called *claiming* or *binding-in*.)

Braxton Hicks contractions Irregular, usually mild uterine contractions that occur throughout pregnancy and become stronger in the last trimester.

breast self-awareness Women's awareness of the normal appearance and feel of their breasts; can include breast self-examination as part of it.

breast self-examination (BSE) Organized monthly evaluation by the woman of her breasts; supplements clinical breast examination.

bronchopulmonary dysplasia Chronic pulmonary condition in which damage to the infant's lungs requires prolonged dependence on supplemental oxygen. (Also called *chronic lung disease*.)

brown fat (or brown adipose tissue) Highly vascular specialized fat that provides more heat than other fat when metabolized.

bulimia Eating disorder characterized by ingestion of large amounts of food followed by induced vomiting, fasting, or use of laxatives or diuretics.

café-au-lait spots Light-brown birthmarks.

CAM Abbreviation for complementary and/or alternative medicine.

caput succedaneum Area of edema over the presenting part of the fetus or newborn resulting from pressure against the cervix; often called simply *caput*.

carcinoma in situ Malignant neoplasm in surface tissue that has not extended into deeper tissue.

catabolism Destructive process that converts living cells into simpler compounds; process

- involved in involution of the uterus after childbirth.
- caudal regression syndrome** A malformation that results when the sacrum, lumbar spine, and lower extremities fail to develop.
- cephalhematoma** Bleeding between the perosteum and skull from pressure during birth; does not cross suture lines.
- cephalopelvic disproportion** Fetal head size that is too large to fit through the maternal pelvis at birth. (Also called *fetopelvic disproportion*.)
- cerclage** Encircling the cervix with sutures to prevent recurrent spontaneous abortion caused by early cervical dilation.
- cervical cap** A small cuplike device placed over the cervix to prevent sperm from entering.
- cesarean birth** Surgical birth of the fetus through an incision in the abdominal wall and uterus.
- Chadwick's sign** Bluish purple discoloration of the cervix, vagina, and labia during pregnancy as a result of increased vascular congestion.
- chemical dependence** Physical and psychological dependence on a substance such as alcohol, tobacco, or drugs, either legal or illicit.
- chemoreceptors** Cells that are sensitive to chemical changes in the blood, specifically changes in oxygen and carbon dioxide levels, and changes in acid-base balance.
- chignon** Newborn scalp edema created by a vacuum extractor.
- choanal atresia** Abnormality of the nasal septum that obstructs one or both nasal passages.
- chordee** Ventral curvature of the penis.
- chorioamnionitis** Inflammation of the amniotic sac (fetal membranes); usually caused by bacterial and viral infections. (Also called *amnionitis*.)
- chorionic villus sampling (CVS)** Transcervical or transabdominal procedure to obtain a sample of chorionic villi (projections of the outer fetal membrane) for analysis of fetal cells.
- chromosomes** Organization of DNA of specific genes into strings within the cell nucleus.
- cilia** Hairlike processes on the surface of a cell that beat rhythmically to move the cell or to move fluid or other substances over the cell surface.
- climacteric** Endocrine, body, and psychic changes occurring at the end of a woman's reproductive period. (Also informally called *menopause*, although this term does not encompass all changes.)
- clinical breast examination (CBE)** Breast examination by a professional that may identify problems that the woman has not identified with BSE.
- closure** Reaching a decision.
- cocaine** Powerful stimulant of the central nervous and cardiovascular systems and causes euphoria.
- coitus** Sexual union between a male and a female.
- coitus interruptus** Withdrawal of the penis from the vagina before ejaculation.
- colostrum** Breast fluid secreted during pregnancy and the early days after childbirth.
- colposcopy** Examination of the vaginal and cervical tissue with a colposcope for magnification of cells.
- complementary and alternative medicine (CAM)** Non-mainstream or unconventional health care treatments and practices that are generally not used in hospitals and often not reimbursed by insurance companies.
- complete protein food** Food containing all the essential amino acids.
- compliance** Stretchability or elasticity of the lungs and thorax that allows distention without resistance during respirations.
- conceptus** Cells and membranes resulting from fertilization of the ovum at any stage of prenatal development.
- condyloma acuminatum** A wartlike growth of the skin seen on the external genitalia, in the vagina, on the cervix, or near the anus; may be caused by human papillomavirus (*condyloma acuminatum*) or by syphilis (*condyloma latum*).
- congenital** Present at birth.
- congenital anomaly** Abnormal intrauterine development of an organ or structure.
- congestive heart failure** Condition resulting from failure of the heart to maintain adequate circulation; characterized by weakness, dyspnea, and edema in body parts that are lower than the heart.
- consanguinity** Blood relationship.
- contentment** A method of increasing comfort in infants by swaddling or other means to keep the extremities in a flexed position near the body.
- contraception** Prevention of pregnancy.
- contraction stress test (CST)** Method for evaluating fetal status during the antepartum period by observing response of the fetal heart to the stress of uterine contractions that may induce recurrent episodes of fetal hypoxia.
- corpus luteum** Graafian follicle cells remaining after ovulation that produce estrogen and progesterone.
- corrected age** Gestational age that a preterm infant would be if still in utero; the chronologic age minus the number of weeks the infant was born prematurely. (May also be called *developmental age*.)
- couvades** Pregnancy-related rituals or a cluster of symptoms experienced by some prospective fathers during pregnancy and childbirth.
- craniosynostosis** Premature closure of the sutures of the infant's head.
- crowning** Appearance of the fetal scalp or presenting part at the vaginal opening.
- cryotherapy** Destruction of tissue using extreme cold.
- cryptorchidism** Failure of one or both testes to descend into the scrotum.
- culture** Sum of values, beliefs, and practices of a group of people that is transmitted from one generation to the next.
- cystocele** Prolapse of the urinary bladder through the anterior vaginal wall.
- deciduas** Name applied to the endometrium during pregnancy. All except the deepest layer is shed after childbirth.
- decrement** Period of decreasing strength of a uterine contraction.
- deontologic model** Ethical model stating that the right course of action is the one dictated by ethical principles and moral rules.
- developmental task** A step in growth and maturation that one must complete before additional growth and maturation are possible.
- diabetes mellitus** A disorder of carbohydrate metabolism caused by a relative or complete lack of insulin secretion; characterized by glycosuria (glucose in the urine) and hyperglycemia.
- diabetogenic** Refers to a condition such as pregnancy that produces the effects of diabetes mellitus.
- diaphragm** A latex dome that covers the cervix and prevents entrance of sperm; must be used with a spermicide to be effective.
- diastasis recti** Separation of the longitudinal muscles of the abdomen (rectus abdominis) during pregnancy.
- dietary reference intakes** A label for several terms that estimate nutrient needs; includes recommended dietary allowance, adequate intake, tolerable upper intake level, and estimated average requirement.
- dilation** Opening.
- dilation and curettage (D&C)** Stretching of the cervical os to permit suctioning or scraping of the walls of the uterus. The procedure is performed to obtain samples of endometrial tissue for laboratory examination, during the postpartum period to remove retained fragments of placenta.
- dilation and evacuation (D&E)** Wide cervical dilation followed by mechanical destruction and removal of fetal parts from the uterus. After complete removal of the fetus, a vacuum curet is used to remove the placenta and remaining products of conception.
- diploid** Having a pair of chromosomes that represents one copy of every chromosome from each parent; the number of chromosomes (46 in humans) normally present in body cells other than gametes.
- dominant** Gene for which a single copy on either the maternal or paternal chromosome can cause the trait to be expressed.
- doula** A trained labor support person who provides labor or postpartum support or both.
- duration** Period from the beginning of a uterine contraction to the end of the same contraction.
- dyslipidemia** Abnormal fat and cholesterol levels.
- dysmenorrheal** Painful menstruation.
- dyspareunia** Difficult or painful coitus in women.
- dysplasia** Abnormal development of tissue.
- dystocia** Difficult or prolonged labor; often associated with abnormal uterine activity and cephalopelvic disproportion.
- dysuria** Painful urination often associated with urinary tract infection.
- eclampsia** Form of hypertension of pregnancy complicated by generalized (grand mal) seizures.
- ectopic pregnancy** Implantation of a fertilized ovum in any area other than the uterus; the most common site is the fallopian tube.
- EDD** Estimated date of delivery; may also be abbreviated EDB (*estimated date of birth*).
- effacement** Thinning and shortening.
- effleurage** Massage of the abdomen or another body part performed during labor contractions.
- egocentrism** Interest centered on the self rather than on the needs of others.
- ejaculation** Expulsion of semen from the penis.
- emancipated minor** An adolescent younger than the age of majority (usually 18 years) who is considered developmentally competent to make certain medical decisions independent of a parent or guardian.

- embolus** A mass that may be composed of a thrombus (blood clot) or amniotic fluid released into the bloodstream to cause obstruction of pulmonary vessels.
- embryo** The developing baby from the beginning of the third week through the eighth week after conception.
- en face** Position that allows eye-to-eye contact between the newborn and a parent.
- endometrial hyperplasia** Excessive proliferation of normal cells of the uterine lining; may be caused by administration of estrogen during the postmenopausal period.
- endometriosis** Presence of tissue resembling the endometrium outside the uterine cavity.
- endometritis** Infection of the inner lining of the uterus.
- endometrium** Lining of the uterus.
- endomyometritis** Infection of the muscle and inner lining of the uterus.
- endoparametritis** Infection of the muscle and inner lining of the uterus as well as the surrounding tissues.
- endorphin** Substance similar to opioids that occurs naturally in the central nervous system and modifies pain sensations; related to enkephalins.
- engagement** Descent of the widest diameter of the fetal presenting part to at least a zero station (the level of the ischial spines in the maternal pelvis).
- engorgement** Swelling of the breasts resulting from stasis and distention of the vascular and lymphatic circulations and accumulation of milk as lactation is established.
- engrossment** Intense fascination and close face-to-face observation between the father and newborn.
- enkephalin** Substance similar to opioids that occurs naturally in the central nervous system and modifies pain sensations; related to endorphins.
- enteral feeding** Nutrients supplied to the gastrointestinal tract orally or by feeding tube.
- entrainment** Newborn movement in rhythm with adult speech, particularly high-pitched tones, which are more easily heard.
- epidural space** Area outside the dura, between the dura mater and the vertebral canal.
- episiotomy** Surgical incision of the perineum to enlarge the vaginal opening.
- epispadias** Abnormal placement of the urinary meatus on the dorsal side of the penis.
- erectile dysfunction** Consistent inability of a man to achieve or maintain an erection of the penis that is sufficiently rigid to permit successful sexual intercourse. (Also called *impotence*.)
- erythema toxicum** Benign rash of unknown cause in newborns, with blotchy red areas that have white or yellow papules or vesicles in the center.
- erythroblastosis fetalis** Agglutination and hemolysis of fetal erythrocytes resulting from incompatibility between maternal and fetal blood. In most cases, the fetus is Rh-positive, and the mother is Rh-negative.
- esophageal atresia** Condition in which the esophagus is separated from the stomach and ends in a blind pouch.
- essential amino acids** Amino acids that cannot be synthesized by the body and must be obtained from foods.
- ethical dilemma** A situation in which no solution seems completely satisfactory.
- ethics** Rules or principles that govern right conduct and distinctions between right and wrong.
- ethnic** Pertaining to religious, racial, national, or cultural group characteristics, especially speech patterns, social customs, and physical characteristics.
- ethnicity** Condition of belonging to a particular ethnic group; also refers to ethnic pride.
- ethnocentrism** Opinion that the beliefs and customs of one's own ethnic group are superior.
- extremely-low-birth-weight infant** An infant weighing 2 lb, 3 oz (1000 g) or less at birth.
- extrusion reflex** Automatic nervous system response that causes an infant to push anything solid out of the mouth.
- familial** Presence of a trait or condition in a family more often than would be expected by chance alone.
- fantasies** Mental images formed to prepare for the birth of a child.
- fern test** Microscopic appearance of amniotic fluid resembling fern leaves when the fluid is allowed to dry on a microscope slide. (Also called *ferning*.)
- fertilization age** Prenatal age of the developing baby, calculated from the date of conception. (Also called *postconceptional age*.)
- fetal alcohol spectrum disorders** All disorders resulting from maternal use of alcohol during pregnancy; includes fetal alcohol syndrome.
- fetal alcohol syndrome** A group of physical, behavioral, and mental abnormalities that are the most severe effects of fetal alcohol exposure.
- fetal growth restriction** Failure of a fetus to grow as expected for gestational age.
- fetal lie** Relationship of the long axis of the fetus to the long axis of the mother.
- fetal lung fluid** Fluid that fills the fetal lungs, expanding the alveoli and promoting lung development.
- fetus** The developing baby from 9 weeks after conception until birth; used in everyday practice to describe a developing baby during pregnancy, regardless of gestational age.
- fingertipping** First tactile (touch) experience between the mother and newborn in which the mother explores the infant's body, mainly with her fingertips.
- first period of reactivity** Period beginning at birth in which newborns are active and alert. It ends when the infant first falls asleep.
- fontanel** Space at the intersection of sutures connecting fetal or infant skull bones.
- foremilk** First breast milk received in a feeding.
- fornix (Pl. fornices)** An arch or pouchlike structure at the upper end of the vagina. (Also called a *cul-de-sac*.)
- fourth trimester** First 12 weeks after birth; a time of transition for parents and siblings.
- frequency** Period from the beginning of one uterine contraction to the beginning of the next.
- gamete** Reproductive cell or germ cell; in the female an ovum and in the male a spermatozoon.
- gametogenesis** Development and maturation of the sperm and ova.
- gastroschisis** Protrusion of the intestines through a defect in the abdominal wall. The intestines are not covered by a peritoneal sac or skin.
- gate-control theory** A theory about pain based on the premise that a gating mechanism in the dorsal horn of the spinal cord can open or close a "gate" for transmission of pain impulses to the brain.
- gene** Segment of DNA that directs the production of a specific product needed for body structure or function.
- general anesthesia** Systemic loss of sensation with loss of consciousness.
- genetic** Pertaining to the genes or chromosomes.
- genetic sex** Sex determined at conception by union of two X chromosomes (female) or an X and a Y chromosome (male). (Also called *chromosomal sex*.)
- genotype** Genetic makeup of an individual.
- gestational age** Prenatal age of the developing baby (measured in weeks) calculated from the first day of the woman's last menstrual period; approximately 2 weeks longer than the fertilization age. (Also called *menstrual age*.)
- gestational surrogate** A woman who carries the embryo of an infertile couple and relinquishes the child to the couple after birth.
- gestational trophoblastic disease** Spectrum of diseases that includes both benign hydatidiform mole and gestational trophoblastic tumors such as invasive moles and choriocarcinoma.
- gluconeogenesis** Formation of glycogen by the liver from noncarbohydrate sources such as amino and fatty acids.
- glycosuria** Glucose in the urine.
- gonad** Reproductive (sex) gland that produces gametes and sex hormones. The female gonads are ovaries and the male gonads are testes.
- gonadotropic hormones** Secretions of the anterior pituitary gland that stimulate the gonads, specifically follicle-stimulating hormone and luteinizing hormone. Chorionic gonadotropin is secreted by the placenta during pregnancy.
- Goodell's sign** Softening of the cervix during pregnancy.
- graafian follicle** A small sac within the ovary that contains the maturing ovum.
- gravida** A pregnant woman; also refers to a woman's total number of pregnancies, including the one in progress, if applicable.
- gynecologic age** The number of years since menarche (first menstrual period).
- habituation** Decreased response to a repeated stimulus.
- haploid** Having one copy of a chromosome from each pair (23 in humans, or half the diploid number); normal for gametes.
- Healthy People 2020 goals** National health promotion and disease prevention goals.
- Hegar's sign** Softening of the lower uterine segment that allows it to be easily compressed at 6 to 8 weeks of pregnancy.
- hematoma** Localized collection of blood in a space or tissue.
- heme iron** Iron obtained from meat, poultry, or fish sources; the form most usable by the body.
- heterozygous** Having two different alleles for a genetic trait.

- hindmilk** Breast milk received near the end of a feeding; contains higher fat content than foremilk.
- homologous** Chromosomes that pair during meiosis, one received from the person's mother and one from the father.
- homozygous** Having two identical alleles for a genetic trait.
- human rights model** Ethical model based on the belief that every person has human rights.
- hydramnios** Excessive volume of amniotic fluid, more than about 2000 mL at term. (Also called *polyhydramnios*.)
- hydrops fetalis** Heart failure and generalized edema in the fetus secondary to severe anemia resulting from destruction of erythrocytes.
- hyperbilirubinemia** Excessive amount of bilirubin in the blood.
- hypercapnia** Excess carbon dioxide in the blood, evidenced by an elevated PCO_2 .
- hyperemia** Excess blood in an area of the body.
- hypertonic contractions** Uterine contractions that are too long or too frequent, have too short a resting interval, or have an inadequate relaxation period to allow optimal uteroplacental exchange.
- hypertonic labor dysfunction** Ineffective labor characterized by erratic and poorly coordinated contractions. Uterine resting tone is higher than normal.
- hypospadias** Abnormal placement of the urinary meatus on the ventral side of the penis.
- hypotonic labor dysfunction** Ineffective labor characterized by weak, infrequent, and brief but coordinated uterine contractions. Uterine resting tone is normal.
- hypovolemia** Abnormally decreased volume of circulating fluid in the body.
- hypovolemic shock** Acute peripheral circulatory failure resulting from loss of circulating blood volume.
- hypoxemia** Reduced oxygenation of the blood, evidenced by a low PO_2 .
- hypoxia** Reduced availability of oxygen to the body tissues.
- iatrogenic** Term used to describe an adverse condition resulting from treatment.
- impotence** See *Erectile dysfunction*.
- incompetent cervix** Inability of the cervix to remain closed long enough during pregnancy for the fetus to reach a maturity sufficient to survive.
- incomplete protein food** Food that does not contain all the essential amino acids.
- increment** Period of increasing strength of a uterine contraction.
- independent nursing interventions** Nurse-prescribed actions used in both nursing diagnoses and collaborative problems.
- induction of labor** Artificial initiation of labor.
- infant mortality rate** Number of deaths per 1000 live births that occurs within the first 12 months of life.
- inference** The act of drawing a conclusion or making a deduction.
- infertility** Inability of a couple to conceive after 1 year of regular intercourse (two to three times weekly) without using contraception; also, the involuntary inability to conceive and produce viable offspring when the couple chooses. Primary infertility occurs in a couple who has never conceived; secondary infertility occurs in a couple who has conceived at least once before.
- intensity** Strength of a uterine contraction.
- intermittent monitoring** Variation of electronic fetal monitoring in which an initial strip is obtained on admission. If patterns are reassuring the woman is remonitored for 15 minutes at regular intervals (such as every 30 minutes).
- interval** Period between the end of one uterine contraction and the beginning of the next.
- intrapartum** Time of labor and childbirth.
- intrauterine device** A mechanical device inserted into the uterus to prevent pregnancy.
- intraventricular hemorrhage** Bleeding around and into the ventricles of the brain. (Also called *germinal matrix hemorrhage* and *periventricular-intraventricular hemorrhage*.)
- introversion** Inward concentration on the self and body.
- involution** Retrogressive changes that return the reproductive organs, particularly the uterus, to their nonpregnant size and condition.
- jaundice** Yellow discoloration of the skin and sclera caused by excess bilirubin in the blood.
- judgment** An opinion.
- kangaroo care** A method of providing skin-to-skin contact between infants and their parents.
- karyotype** A display of a cell's chromosomes, arranged from largest to smallest pairs with sex chromosomes displayed as a separate pair.
- Kegel exercises** Alternate contracting and relaxing of the pelvic floor muscles to strengthen the muscles surrounding the urinary meatus and vagina.
- kernicterus** Staining of brain tissue caused by accumulation of unconjugated bilirubin in the brain. Bilirubin encephalopathy is the brain damage that results from these deposits.
- ketosis** Accumulation of ketone bodies (metabolic products) in blood; frequently associated with acidosis.
- kilocalorie** A unit of heat; used to show the energy value in foods (commonly called *calorie*).
- lactation** Secretion of milk from the breasts; also describes the period during which a child is breastfed.
- lactogenesis** The production of milk.
- lacto-ovovegetarian** A vegetarian whose diet includes milk products and eggs.
- lactose intolerance** Inability to digest most dairy products because of a deficiency of the enzyme lactase.
- lactovegetarian** A vegetarian whose diet includes milk products.
- lanugo** Fine, soft hair that covers the fetus.
- laparoscopy** Insertion of an illuminated tube into the abdominal cavity to visualize contents, locate bleeding, and perform surgical procedures.
- laparotomy** Incision through the lower abdominal wall to examine the abdominal or pelvic organs or perform other surgical procedures.
- large-for-gestational-age infant** An infant whose size is above the 90th percentile for gestational age.
- latch** Attachment of the infant to the breast.
- late deceleration** The slowing of the fetal heart rate after the onset of a uterine contraction and persisting after the contraction ends.
- late preterm infant** An infant born between 34% and 36% weeks of gestation.
- lecithin/sphingomyelin ratio (L/S ratio)** Ratio of two phospholipids in amniotic fluid used to determine fetal lung maturity; ratio of 2:1 or greater usually indicates fetal lung maturity.
- let-down reflex** See *Milk-ejection reflex*.
- letting-go** A phase of maternal adaptation that involves relinquishment of previous roles and assumption of a new role as a parent.
- libido** Sexual desire.
- lightening** Descent of the fetal head into the pelvic cavity before labor.
- linea nigra** Pigmented line extending in the midline of the abdomen from the fundus to the symphysis pubis.
- linear salpingostomy** Incision along the length of a fallopian tube to remove an ectopic pregnancy and preserve the tube.
- lipogenic** Substance such as insulin that stimulates the production of fat.
- lochia** Vaginal drainage after birth.
- lochia alba** White, cream-colored, or light yellow vaginal discharge that follows lochia serosa. Occurs when the amount of blood is decreased and the number of leukocytes is increased.
- lochia rubra** Reddish or red-brown vaginal discharge that occurs immediately after childbirth; composed mostly of blood.
- lochia serosa** Pink or brown-tinged vaginal discharge that follows lochia rubra and precedes lochia alba; composed largely of serous exudate, blood, and leukocytes.
- low-birth-weight infant** An infant weighing less than 5 lb, 8 oz (2500 g) at birth.
- maceration** Discoloration and softening of tissues and eventual disintegration of a fetus that is retained in the uterus after its death.
- macrosomia** Infant birth weight above the 90th percentile for gestational age. Some sources use more than 4000 g (8 lb, 13 oz) or 4500 g (9 lb, 15 oz).
- malpractice** Negligence by a professional person.
- mammogram** Study of breast tissue using very-low-dose radiography; primary tool in the diagnosis of breast tumors.
- Marfan syndrome** A hereditary condition that involves weakness in connective tissue, bones, and muscles; the vascular system is affected, particularly the aorta.
- mastitis** Infection of the breast.
- maternal mortality rate** Number of maternal deaths from births and complications of pregnancy, childbirth, and puerperium (the first 42 days after the pregnancy ends) per 100,000 live births.
- mature milk** Breast milk that replaces transitional milk.
- meconium aspiration syndrome** Obstruction and air trapping caused by meconium in the infant's lungs, which may lead to severe respiratory distress.
- meiosis** Reduction cell division in gametes that halves the number of chromosomes in each cell.
- melasma** Brownish pigmentation of the face during pregnancy. (Also called *chloasma* and "mask of pregnancy.")

- menarche** Onset of menstruation, usually between 10 and 16 years of age or within 2 years of the start of breast development.
- meningocele** Protrusion of the meninges through a defect in the vertebrae; a form of neural tube defect.
- menometrorrhagia** Uterine bleeding that is irregular in frequency and excessive in amount.
- menopause** Permanent cessation of menstruation during the climacteric.
- menorrhagia** Excessive bleeding at the time of menstruation in number of days' duration, amount of blood lost, or both.
- methadone** A synthetic compound with opiate properties; used as an oral substitute for heroin and morphine in the opiate-dependent person.
- metritis** Infection of the decidua, myometrium, and parametrial tissues of the uterus.
- metrorrhagia** Bleeding from the uterus at any time other than during the menstrual period.
- milia** White cysts, 1 mm in size, on the face.
- miliaria (prickly heat)** Rash caused by heat.
- milk-ejection reflex** Release of milk from the alveoli into the ducts. (Also known as the *Let-down reflex*.)
- mimicry** Copying the behaviors of other pregnant women or mothers as a method of "trying on" the role of advanced pregnancy or motherhood.
- mitosis** Cell division in body cells other than the gametes.
- mittelschmerz** Low abdominal pain that occurs at ovulation.
- molding** Shaping of the fetal head during movement through the birth canal.
- mongolian spots** Bruiselike marks that occur mostly in newborns with dark skin tones.
- monosomy** Presence of only one of a chromosome pair in every body cell.
- Montevideo unit** Method to quantify intensity of labor contractions with uterine activity monitoring. The baseline intrauterine pressure for each contraction in a 10-minute period is subtracted from the peak pressure.
- mortality rate** Number of deaths that occur each year by different categories.
- morula** Fertilized ovum that resembles a mulberry when it contains 12 to 16 cells.
- motor block** Loss of voluntary movement caused by regional anesthesia.
- multifetal pregnancy** A pregnancy in which the woman is carrying two or more fetuses. (Also called *multiple gestation*.)
- multigravida** A woman who has been pregnant more than once.
- multipara** A woman who has delivered two or more pregnancies at 20 or more weeks of gestation; also informally used to describe a pregnant woman before the birth of her second child.
- multiple-marker testing/screening** Analysis of maternal serum for abnormal levels of alpha-fetoprotein, human chorionic gonadotropin, and estriols that may predict chromosomal abnormalities of the fetus; often called *triple-screen*. Addition of tests such as inhibin A has improved accuracy.
- mutation** Alteration in DNA sequence in a gene, usually one that adversely affects its function.
- mutual recognition** Nurse licensure that allows nurses to hold licenses in their states of residence and practice in other states that also recognize the home state's license. (Also known as a *multistate licensure compact*.)
- myelomeningocele** Protrusion of the meninges and spinal cord through a defect in the vertebrae; a form of neural tube defect.
- nadir** Lowest point, such as the lowest pulse rate in a series.
- narcissism** Undue preoccupation with oneself.
- natural family planning** Method of predicting ovulation based on normal changes in a woman's body.
- necrotizing enterocolitis** Serious inflammatory condition of the intestines.
- negligence** Failure to act in the way a reasonable, prudent person of similar background would act in similar circumstances.
- neonatal abstinence syndrome** A cluster of physical signs exhibited by the newborn exposed in utero to maternal use of substances such as heroin. (See also *Abstinence syndrome*.)
- neonatal mortality rate** Number of deaths per 1000 live births occurring at birth or within the first 28 days of life.
- neural tube defect** A congenital defect in closure of the bony encasement of the spinal cord or skull. Includes defects such as anencephaly, spina bifida, meningocele, myelomeningocele, and others.
- neutral thermal environment** Environment in which body temperature is maintained without an increase in metabolic rate or oxygen use.
- nevus flammeus** Permanent pink to dark reddish-purple birthmark. (Also called *port-wine stain*.)
- nevus simplex** Flat, pink area on the nape of the neck, on the mid-forehead, or over the eyelids resulting from dilation of the capillaries. (Also called *stork bites*, *salmon patches*, or *telangiectatic nevi*.)
- nevus vasculosus** Rough, red collection of capillaries with a raised surface that disappears with time. (Also called *strawberry hemangioma*.)
- nidation** Implantation of the fertilized ovum (zygote) in the uterine endometrium.
- noncompliance** Resistance of the lungs and thorax to distention with air during respirations.
- nonheme iron** Iron obtained from plants and fortified foods.
- nonnutritive sucking** Sucking during which little or no milk flow is obtained or sucking on an object such as a pacifier or finger.
- nonshivering thermogenesis** Process of heat production, without shivering, by oxidation of brown fat.
- nonstress test** A method for evaluating fetal status during the antepartum period by observing the response of the fetal heart rate to fetal movement.
- nuchal cord** Umbilical cord around the fetal body, often the neck.
- nullipara** A woman who has never completed a pregnancy beyond 20 weeks' gestation.
- nurse anesthetist** A registered nurse who has advanced education and certification in administration of anesthetics; also, certified registered nurse anesthetist (CRNA).
- nurse practice acts** Laws that determine the scope of nursing practice in each state.
- nutrient density** The quality and quantity of protein, vitamins, and minerals per 100 calories in foods.
- nutritive suckling (sucking)** Steady, rhythmic suckling at the breast or sucking at a bottle to obtain milk.
- occult prolapse** See *Prolapsed cord*.
- oligohydramnios** Abnormally small amount of amniotic fluid, less than about 500 mL at term.
- oligospermia** A decreased number of sperm in semen, usually considered to be under 20 million per milliliter.
- omphalocele** Protrusion of the intestines into the base of the umbilical cord.
- oogenesis** Formation of gametes (ova) in the female.
- opiate** Any narcotic-containing opium or a derivative of opium.
- oral contraceptive** Drug that inhibits ovulation; contains progestins alone or in combination with estrogen.
- osmotic diuresis** Secretion and passage of large amounts of urine as a result of increased osmotic pressure that can result from hyperglycemia.
- osteomalacia** Softening of bones; precedes osteoporosis.
- osteoporosis** Increased spaces (porosity) of bone; process usually accelerates after menopause.
- ovovegetarian** A vegetarian whose diet includes eggs.
- ovulation** Release of the mature ovum from the ovary.
- pain threshold (or pain perception)** The lowest level of stimulus one perceives as painful; relatively constant under different conditions.
- pain tolerance** Maximum pain one is willing to endure. Pain tolerance may increase or decrease under different conditions.
- Pap test** Evaluation of cells taken from cervix for evaluation of possible cervical cancer.
- para** A woman who has given birth after a pregnancy of at least 20 weeks of gestation; also designates the number of a woman's pregnancies that have ended after at least 20 weeks of gestation.
- paroxysmal nocturnal dyspnea** Respiratory distress occurring when lying down; often associated with congestive heart failure.
- peau d'orange** Dimpled skin condition in which skin resembles an orange peel; associated with lymphatic edema and often seen over the area of breast cancer.
- pedigree** A graphic representation of a family's medical and hereditary history and the relationships among the family members. (Also called a *genogram*.)
- percutaneous umbilical blood sampling (PUBS)** Procedure for obtaining fetal blood through ultrasound-guided puncture of an umbilical cord vessel to detect fetal problems such as inherited blood disorders, acidosis, or infection. (Also called *cordocentesis*.)
- perinatologist** Physician who specializes in the high-risk pregnancy care of the mother, fetus, and infant during the perinatal period (from approximately the 20th week of pregnancy to 4 weeks after childbirth). (Also known as a *maternal-fetal medicine specialist*.)
- periodic breathing** Cessation of breathing lasting 5 to 10 seconds followed by 10 to 15 seconds of

- rapid respirations without changes in skin color or heart rate.
- persistent pulmonary hypertension** Vasoconstriction of the infant's pulmonary vessels after birth; may result in right-to-left shunting of blood flow through the ductus arteriosus, the foramen ovale, or both.
- pH test** A paper or commercial swab used to test pH; helps determine whether the amniotic sac has ruptured. Nitrazine test.
- phenotype** The outward expression of a person's genetic makeup; observed characteristics produced by the interaction of genes and environment.
- phimosis** Tightening of the prepuce.
- phosphatidylglycerol (PG)** A major phospholipid of surfactant whose presence in amniotic fluid indicates fetal lung maturity.
- phosphatidylinositol (PI)** A phospholipid of surfactant that is produced and secreted in increasing amounts as the fetal lungs mature.
- physiologic anemia of pregnancy** Decrease in hemoglobin and hematocrit values caused by dilution of erythrocytes from expanded plasma volume rather than by an actual decrease in erythrocytes or hemoglobin.
- phytoestrogen** Estrogen substance of plant origin.
- pica** Ingestion of nonnutritive substances such as laundry starch, clay, or ice.
- placenta** Fetal structure that provides nourishment and removes wastes from the developing baby and secretes hormones necessary for the continuation of pregnancy.
- placenta accreta** A placenta that is abnormally adherent to the uterine muscle. If the condition is more advanced, it is called *placenta increta* (the placenta extends into the uterine muscle) or *placenta percreta* (the placenta extends through the uterine muscle).
- placenta previa** Abnormal implantation of the placenta in the lower uterus at or very near the cervical os.
- plagioccephaly** Flattening or asymmetry of the back of the head.
- point of maximum impulse** Area of the chest in which the heart sounds are loudest when auscultated.
- polycythemia** Abnormally high number of erythrocytes.
- polydactyly** More than 10 digits on the hands or feet.
- polydipsia** Excessive thirst.
- polymerase chain reaction (PCR)** A technique to rapidly analyze sequences of genes for in vitro diagnosis of infections; many hereditary characteristics can also be analyzed by the technique.
- polymorphism** Alternate form of a gene found in the population at a frequency greater than 1%.
- polyphagia** Excessive ingestion of food.
- polyplody** Having additional full sets of chromosomes, such as 69 (triploidy) or 92 (tetraploidy).
- polyuria** Excessive excretion of urine.
- position** Relation of a fixed reference point on the fetus to the quadrants of the maternal pelvis.
- postictal** Unresponsive state after a seizure.
- postmaturity syndrome** Condition in which a postterm infant shows characteristics indicative of poor placental functioning before birth. (Also called *dysmaturity syndrome*.)
- postpartum** Refers to the first 6 weeks after childbirth.
- postpartum blues** Temporary, self-limited period of tearfulness experienced by many new mothers beginning the first week after childbirth.
- postterm infant** An infant born after 42 weeks of gestation.
- precipitate birth** A birth that occurs without a trained attendant present.
- precipitate labor** An intense, unusually short labor (less than 3 hours).
- preclampsia** A hypertensive disorder of pregnancy characterized by hypertension and proteinuria.
- premature rupture of the membranes** Spontaneous rupture of the membranes before the onset of labor (term, preterm, or postterm gestation).
- presentation** Fetal part that enters the pelvic inlet, or the presenting part.
- preterm birth** A birth that occurs after the 20th week and before the end of the 37th week of gestation.
- preterm infant** An infant born before the beginning of the 38th week of gestation. (Also called *premature infant*.)
- preterm labor** Onset of labor after 20 weeks and before the beginning of the 38th week of gestation.
- primigravida** A woman who is pregnant for the first time.
- primipara** A woman who has given birth after a pregnancy of at least 20 weeks of gestation; also used informally to describe a pregnant woman before the birth of her first child.
- progesterin** Any natural or synthetic form of progesterone.
- prolapsed cord** Displacement of the umbilical cord in front of or beside the fetal presenting part. An occult prolapse is one that is suspected on the basis of fetal heart rate patterns; the umbilical cord cannot be palpated or seen.
- pseudomenstruation** Vaginal bleeding in the newborn resulting from withdrawal of placental hormones.
- psychoprophylaxis** Method of prepared childbirth that emphasizes mental concentration and relaxation to increase pain tolerance.
- psychosis** Mental state in which a person's ability to recognize reality, communicate, and relate to others is impaired.
- puberty** Period of sexual maturation accompanied by the development of secondary sex characteristics and the capacity to reproduce.
- puerperal infection** A temperature of 38° C (100.4° F) or higher after the first 24 hours and occurring on at least 2 of the first 10 days following childbirth.
- puerperium** Period from the end of childbirth until involution of the reproductive organs is complete; approximately 6 weeks.
- pulmonary embolus** A potentially fatal complication that occurs when the pulmonary artery is obstructed by a blood clot that was swept into circulation from a vein or by amniotic fluid.
- pulse oximetry** Method of determining the level of blood oxygen saturation by sensors attached to the skin.
- pulse pressure** The difference between systolic and diastolic blood pressures.
- quickening** The first movements of the fetus felt by the mother.
- recessive** Gene that requires two copies, one from the maternal and one from the paternal chromosome, for the trait to be expressed.
- reciprocal attachment behaviors** Repertoire of infant actions that promotes attachment between the parent and newborn.
- recommended dietary allowance (RDA)** Level of nutrient intake considered to meet the needs of healthy individuals.
- rectocele** Herniation (protrusion) of the rectum through the posterior vaginal wall.
- REEDA** Acronym for redness, ecchymosis, edema, discharge, and approximation; useful for assessing wound healing or the presence of inflammation or infection.
- reflection** Meditation, attentive consideration.
- regional anesthesia** Anesthesia that blocks pain impulses in a localized area without loss of consciousness.
- respiratory distress syndrome** Condition caused by insufficient production of surfactant in the lungs; results in atelectasis (collapse of the lung alveoli), hypoxia (decreased oxygen [O₂] concentration), and hypercapnia (increased carbon dioxide [CO₂] concentration).
- retinopathy of prematurity** Condition in which injury to blood vessels may cause decreased vision or blindness in preterm infants.
- retrograde ejaculation** Discharge of semen into the bladder rather than from the end of the penis.
- ripening** Softening of the cervix as labor nears as the result of an increase in water content and the effects of relaxin on the connective tissue of the cervix.
- role transition** Changing from one pattern of behavior and one image of self to another.
- ruga (PI. rugae)** Ridge or fold of tissue, as on the male's scrotum and in the female's vagina.
- salpingectomy** Surgical removal of a fallopian tube.
- seborrheic dermatitis (cradle cap)** Yellowish, crusty area of the scalp.
- second period of reactivity** Period of 4 to 6 hours after the first sleep following birth when the newborn may have an elevated pulse rate and respiratory rate and excessive mucus.
- secondary sex characteristics** Physical differences between mature males and females that are not directly related to reproduction.
- semen** Spermatozoa with their nourishing and protective fluid; discharged at ejaculation.
- sensory block** Loss of sensation caused by regional anesthesia.
- sentinel lymph node (SLN) biopsy** Technique to remove a minimal number of key lymph nodes to determine spread of the tumor.
- seroconversion** Change in a blood test result from negative to positive, indicating the development of antibodies in response to infection or immunization.
- servocontrol** Mechanism on a radiant warmer or incubator to regulate the amount of heat produced.

- sex chromosome** The X or Y chromosome; females have two X chromosomes and males have one X and one Y chromosome.
- short bowel syndrome** A condition caused by a bowel that is shorter than normal.
- shoulder dystocia** Delayed or difficult birth of the fetal shoulders after the head is born.
- skepticism** Doubt in the absence of conclusive evidence.
- small-for-gestational-age infant** An infant whose size is below the 10th percentile for gestational age.
- somatic cells** Body cells other than the gametes, or germ cells.
- somatic sex** Gender assignment as male or female on the basis of form and structure of the external genitalia.
- spermatogenesis** Formation of male gametes (sperm) in the testes.
- spermicide** A chemical that kills sperm.
- spina bifida** Defective closure of the bony spine that encloses the spinal cord; a type of neural tube defect.
- spinnbarkeit** Clear, slippery, stretchy quality of cervical mucus during ovulation.
- standard of care** Level of care that can be expected of a professional as determined by laws, professional organizations, and health care agencies.
- standard procedures** Procedures determined by nurses, physicians, and administrators that allow nurses to perform duties usually part of the medical practice.
- station** Measurement of fetal descent in relation to the ischial spines of the maternal pelvis. (See also *engagement*.)
- sterility** Total inability to conceive.
- strabismus** A turning inward (“crossing”) or outward of the eyes caused by poor tone in the muscles that control eye movement.
- striae gravidarum** Irregular pink to purple streaks on the woman’s abdomen, breasts, or buttocks resulting from tears in connective tissue.
- subarachnoid space** Space between the arachnoid mater and the pia mater containing cerebrospinal fluid.
- subinvolution** Delayed return of the uterus to its nonpregnant size and consistency.
- suckling** Giving or taking nourishment from the breast. Sometimes used interchangeably with *sucking*, which refers only to drawing into the mouth with a partial vacuum, as with a bottle or pacifier.
- sudden infant death syndrome (SIDS)** Sudden death of an infant that is unexplained by history, autopsy, or examination of the scene of death.
- surfactant** Combination of lipoproteins produced by the lungs of the mature fetus to reduce surface tension in the alveoli, thus promoting lung expansion after birth.
- surrogate mother** A fertile woman who is inseminated with the purpose of conceiving and relinquishing a child to an infertile couple.
- suspend** To delay or bring to a stop temporarily.
- sutures** Narrow areas of flexible tissue that connect fetal skull bones, permitting slight movement during labor.
- syndactyly** Webbing between fingers or toes.
- tachypnea** Respiratory rate greater than 60 breaths per minute in the newborn after the first hour of life.
- taking-hold** Second phase of maternal adaptation during which the mother assumes control of her own care and initiates care of the infant.
- taking-in** First phase of maternal adaptation during which the mother passively accepts care, comfort, and details about the newborn.
- telemetry** Wireless transmission of electronic fetal monitoring data to the bedside or central monitor unit.
- teratogen** An environmental agent that can cause defects in a developing baby during pregnancy.
- term** Refers to the period of time a pregnancy is expected to last. (Also known as *full term*.)
- thermogenesis** Heat production.
- thermoregulation** Maintenance of body temperature.
- thrombophlebitis** Occurs when the vessel wall develops an inflammatory response to the thrombus. This further occludes the vessel.
- thrombus** Collection of blood factors, primarily platelets and fibrin, that may cause vascular obstruction.
- tocolytic** Drug that inhibits uterine contractions.
- total parenteral nutrition** Intravenous infusion of all nutrients known to be needed for metabolism and growth.
- toxic shock syndrome** Rare, potentially fatal disorder usually caused by toxin produced by *Staphylococcus aureus*; has been associated with improper use of tampons.
- tracheoesophageal fistula** Abnormal connection between the esophagus and the trachea.
- transcultural nursing** concerned with the provision of nursing care in a manner that is sensitive to the needs of individuals, families, and groups.
- transdermal contraceptive patch** Adhesive patch containing estrogen and progestin, which are absorbed through the skin to prevent pregnancy.
- transducer** Device that translates one physical quantity to another, such as fetal heart motion into an electrical signal for rate calculation, generation of sound, or a written record.
- transient tachypnea of the newborn** Condition of rapid respirations caused by inadequate absorption of fetal lung fluid.
- transitional milk** Breast milk that appears between secretion of colostrum and mature milk.
- translocation** Exchange of genetic material between nonhomologous chromosomes.
- trimester** One of three equal, 13-week parts of a full-term pregnancy.
- trisomy** Presence of three copies of a chromosome in each body cell.
- tubal sterilization** Cutting or mechanically occluding the fallopian tubes to prevent passage of ova or sperm, thus preventing pregnancy. (May also be called *tubal ligation*.)
- ultrasound** Use of sound waves for visualizing deep structures of the body by recording the reflections (echoes) of high-frequency sound waves directed into the tissue.
- uterine inversion** Turning of the uterus inside out after birth of the fetus.
- uterine resting tone** Degree of uterine muscle tension when the woman is not in labor or during the interval between labor contractions.
- uterine rupture** A tear in the wall of the uterus.
- uteroplacental insufficiency** Inability of the placenta to exchange oxygen, carbon dioxide, nutrients, and waste products properly between the maternal and fetal circulations.
- utilitarian model** Ethical model stating that the right course of action is the one that produces the greatest good.
- vacuum curettage (vacuum aspiration)** Removal of the uterine contents by application of a vacuum through a hollow curet or cannula introduced into the uterus.
- vaginal contraceptive ring** Flexible ring releasing small amounts of estrogen and progesterone to prevent pregnancy.
- validate** To make certain that the information collected is accurate.
- varicocele** Abnormal dilation or varicosity of veins in the spermatic cord.
- vasa previa** Branching of umbilical cord vessels in the amniotic sac rather than inserting into the placenta.
- vasectomy** Cutting or occluding the vas deferens to prevent passage of sperm, thus preventing pregnancy.
- vasoconstriction** Narrowing of the lumen of blood vessels.
- VBAC** Acronym for vaginal birth after cesarean.
- vegan** A complete vegetarian who does not eat any animal products.
- vegetarian** An individual whose diet consists wholly or mostly of plant foods and who avoids animal food sources.
- vernix caseosa** Thick, white substance that protects the skin of the fetus.
- version** Turning the fetus from one presentation to another before birth, usually from breech to cephalic.
- very-low-birth-weight infant** An infant weighing 3 lb, 5 oz (1500 g) or less at birth.
- vibroacoustic stimulation** Use of sound stimulation to elicit fetal movement and acceleration (speeding up) of the fetal heart rate.
- well-woman exam** Verbal history, physical examination, and screening tests for a woman with no complaints of serious diseases, usually done annually. Often abbreviated WWE.
- zygote** The developing baby from conception through the first week of prenatal life.

Page numbers followed by f indicate figures; t, tables; b, boxes.

SPECIALTY MATERNAL-NEWBORN ABBREVIATIONS

Note that capitalization may vary. Some of these abbreviations are always capitalized (such as IUPC), but others may or may not be capitalized.

Ab	abortions (does not distinguish whether they were spontaneous or elective)	MFM	maternal-fetal medicine
ABO-Rh	ABO and Rh blood factors	MLE	median (or midline) episiotomy
AFE	amniotic fluid embolism	MSF	meconium-stained fluid
AGA	average for gestational age	NIBP	noninvasive blood pressure (the usual way of taking it)
AROM	artificial rupture of membranes	NICU	neonatal intensive care unit (often pronounced "nick-u")
beta-strep or β strep	beta strep, a microorganism that is a common cause of neonatal sepsis	P	para or pulse
BOWI	bag of waters intact	peri care	perineal care
BTL	bilateral tubal ligation	peripad	perineal pad
CMV	cytomegalovirus	Pit	Pitocin (Oxytocin), a uterine stimulant
ctx or contr	contraction	PP	postpartum
DTR	deep tendon reflexes	pres	presentation
eff	effacement	PROM	premature rupture of membranes
EFM	electronic fetal monitor or electronic fetal monitoring	PPROM	preterm premature rupture of membranes
epi or epid	epidural	ROM	rupture of membranes
epis	episiotomy	SCN	special care nursery
ETT	endotracheal tube	SGA	small for gestational age
Gr or gr	gravida	SROM	spontaneous rupture of membranes
GBS	group B strep (see also beta strep)	sta	station
GDM	gestational diabetes mellitus	SVE	sterile vaginal exam
gest	gestation	terb	Terbutaline (Brethine)
H-Big	hepatitis-B immune globulin (also H-B IG or HBIG)	TL	tubal ligation (same as bilateral tubal ligation; also t-lig)
HbSAg	hepatitis B surface antigen (also HBsAg)	toco	tocodynamometer or tocolytic(s)
HBV	hepatitis B virus (also hep-B)	U	refers to umbilicus as the reference point when assessing the uterine fundus postpartum, such as "U-2" (umbilicus minus 2, or 2 fingerwidths below the woman's umbilicus level)
HPV	human papilloma virus	US or UTZ	ultrasound
I&O cath	in and out catheterization; also called straight catheterization ("straight cath")	VBAC	vaginal birth after cesarean
IDM	infant of a diabetic mother		
IFM	internal fetal monitoring		
IUPC	intrauterine pressure catheter		
LGA	large for gestational age
