Maternal-Newborn
and **Women's Health**
Nursing

BRIEF TABLE OF CONTENTS

PART I FOUNDATIONS FOR NURSING CARE OF CHILDBEARING FAMILIES

- 1 Maternity and Women's Health Care Today, 1
- 2 The Nurse's Role in Maternity and Women's Health Care, 16
- 3 Ethical, Social, and Legal Issues, 29
- 4 Reproductive Anatomy and Physiology, 43
- 5 Hereditary and Environmental Influences on Childbearing, 57

PART II THE FAMILY BEFORE BIRTH

- 6 Conception and Prenatal Development, 73
- 7 Physiologic Adaptations to Pregnancy, 93
- 8 Psychosocial Adaptations to Pregnancy, 124
- 9 Nutrition for Childbearing, 142
- 10 Antepartum Fetal Assessment, 165
- 11 Perinatal Education, 183

PART III THE FAMILY DURING BIRTH

- 12 Processes of Birth, 196
- 13 Nursing Care during Labor and Birth, 220
- 14 Intrapartum Fetal Surveillance, 253
- 15 Pain Management during Childbirth, 278
- 16 Nursing Care during Obstetric Procedures, 304

PART IV THE FAMILY FOLLOWING BIRTH

- 17 Postpartum Physiologic Adaptations, 328
- 18 Postpartum Psychosocial Adaptations, 351

- 19 Normal Newborn: Processes of Adaptation, 368
- 20 Assessment of the Normal Newborn, 383
- 21 Care of the Normal Newborn, 415
- 22 Infant Feeding, 436
- 23 Home Care of the Infant, 462

PART V FAMILIES AT RISK DURING THE CHILDBEARING PERIOD

- 24 The Childbearing Family with Special Needs, 476
- 25 Complications of Pregnancy, 504
- 26 Concurrent Disorders during Pregnancy, 536
- 27 Intrapartum Complications, 568
- 28 Postpartum Maternal Complications, 598
- 29 High-Risk Newborn: Complications Associated with Gestational Age and Development, 621
- 30 High-Risk Newborn: Acquired and Congenital Conditions, 651

PART VI WOMEN'S HEALTH CARE

- 31 Family Planning, 679
- 32 Infertility, 701
- 33 Preventive Care for Women, 718
- 34 Women's Health Problems, 728

APPENDIXES

- A Use of Drug and Botanical Preparations during Pregnancy and Breastfeeding, 756
- B Keys to Clinical Practice: Components of Daily Care, 766
- C Answers to Check Your Reading, 773
- D Answers to Critical Thinking Exercises, 799

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*For Skip, whose love and support make it all possible.
For my daughters, Vicki, Holly, and Shannon, who make me proud.
For Marina, Nicholas, and Giovanni, who provide future hope.
In memory of my parents, Clare and AV Smith, who showed the way.
And for my students, clients, and co-workers who made teaching a joy.*

Sharon Murray

*To my students, colleagues, and the many families I have cared
for these many years, thank you.
And I am grateful for God's blessing me with my helper husband,
Michael, and the hard work of our
two daughters, Cathy and Amy.
And for our next generation, Victoria Emmaline Hobbs.*

Emily McKinney

This page intentionally left blank

Our challenge as educators and providers of nursing care in many settings is to keep up with the rapid changes in health care while preparing students to stay focused on the *care* of nursing. In clinical rotations that seem to grow shorter each year, the nursing faculty must teach the student ways to use the nursing process, drugs, and technology that are beneficial while imparting the values of patient-centered care. Our text tries to help the student learn to balance “high-touch” care with “high-tech,” often lifesaving, care in different settings.

Although health care delivery has changed dramatically, with greater emphasis now on outcome management and use of clinical pathways to decrease the length of stay in the inpatient facility, the family’s need for education and support does not lessen. Nurses have responded to families’ needs by developing alternative means of education that use every possible moment before admission and during their stay in the health care facility. A student’s clinical experience often includes the home and a variety of community clinics.

Women’s health care extends over many more years than just the childbearing years, often from adolescence to old age. The women’s health nurse may need to understand how to best teach the 15-year-old girl and the 80-year-old woman on the same day. Many women consider their women’s health provider to be their primary care provider. Women’s health content is focused on in [Chapters 33](#) (Preventive Care for Women) and [34](#) (Women’s Health Problems). However, family planning ([Chapter 31](#)) and infertility ([Chapter 32](#)) are also part of women’s health care in our book.

An effective textbook must present comprehensive content that can be read with ease because nursing students differ in learning abilities, experience, and primary language. Documentation of care in the office, clinic, or acute care setting is mainly on computer. Many of our learners have grown up using computers and may be less familiar with their patients who do not have the same computer literacy, mainly the oldest ones. Our objective for the sixth edition of *Foundations of Maternal-Newborn and Women’s Health Nursing* continues to be presenting complex material as simply and clearly as possible. We again provide step-by-step instruction in assessments and interventions so that students can function quickly in the clinical area at a beginning level. To this end, proven learning aids, such as summaries, illustrations, tables, and highlights are used generously throughout the book.

CONTENT

Nurses must be flexible to accommodate women and their families from different cultures and who communicate in different languages and hold different health beliefs. Nurses must use critical thinking skills to devise culture-specific care that includes providing necessary education and support. The six elements we consider most important are a scientific base of information, nursing process, communication, client teaching, critical thinking, and cultural diversity.

Scientific Base

Effective nursing care depends on having a sound understanding of the basis for medical treatments and nursing actions. Although anatomy and physiology courses are part of every curriculum, students often need a review, particularly of the specific content related to childbearing. Because of this, we have incorporated principles of physiology and pathophysiology throughout the book. We have presented

these scientific concepts in a clear and understandable manner so that the reader can comprehend the forces underlying both health and dysfunction.

We have included research evidence that supports specific nursing care methods when available. An addition to our book in several chapters is a short summary of a published nursing research article. At the end of the research summary we ask a mix of questions to challenge the thought processes of readers. We want readers to think about how they might apply the article’s information now, identify what else we need to know about the topic, or think of how the information might apply outside the maternal-newborn and women’s health specialties.

[Chapters 4, 5, and 6](#) provide general information about reproductive physiology, genetics, and the process of conception and fetal development. [Chapters 7, 12, 17, and 19](#) explain physiologic adaptations during pregnancy, birth, and the postpartum period and in the newborn. Part V, Families at Risk during the Childbearing Period, describes the pathophysiologic, psychological, and social bases of complications in the mother and in the newborn. Women’s health includes many of the cascade of problems that result from obesity, now a problem of epidemic proportions in the United States. Other chapters in the book include the impact of obesity when it is applicable.

The Nursing Process

The nursing process is the accepted framework for assessment and analysis of the patient’s needs. It is used to plan and provide nursing care and evaluate the person’s response to care. A person’s needs often are a mixture of those for which nurses have the primary accountability and those for which another discipline provides definitive therapy yet for which nurses have some responsibility. Therefore for analyzing patient needs we have chosen either a *nursing diagnosis* or a *collaborative problem*, depending on whether nurses are primarily responsible for helping the person meet those needs. All nursing diagnoses are drawn from the most recent list of those approved by the North American Nursing Diagnosis Association International (NANDA-I) at the time of revision.

The nursing process is treated two ways in our text: in a narrative format and in nursing care plans. In each method we lead the reader through the five steps of the nursing process. In the narrative format, basic information about the condition is presented and general nursing care follows, organized by the steps of the nursing process. Interventions are general rather than patient specific and are explained by rationales. Because nursing students often have difficulty transferring general information to the care of a specific person, we have created nursing care plans based on scenarios of patient care situations often encountered in maternity, newborn, and women’s health nursing. These patients and their nurses have fictitious names.

Communication

Although they seldom are included as core content in maternal-newborn nursing texts, communication skills are essential to providing adequate care for a childbearing family. We reinforce the student’s previous learning and give practical examples of ways in which communication skills can be used in the maternity, newborn, and women’s health settings.

Guidelines and examples of effective communication and potential blocks are reviewed in [Chapter 2](#). Color-highlighted *communication*

cues in the text give tips on how to interact with women and families. Tips include ways to avoid potentially embarrassing situations, role modeling of effective communication styles, and reading nonverbal signals.

In addition, dialogues throughout the text present realistic possible nurse-client interactions. As the interaction develops, we identify communication techniques and explain their rationales. Because no one is perfect, we occasionally insert communication blocks, identify them, and suggest alternate responses.

Teaching

Childbearing families are entitled to comprehensive information about how to achieve the best pregnancy outcome and how to best care for the mother and her baby after birth. Women of all ages need current information about maintaining their health, including when they are not pregnant. Nurses are their primary instructors in most areas of maternal-newborn and women's health nursing, and they must be well prepared and well organized to be effective. A women's health nurse practitioner (WHNP) or a family nurse practitioner (FNP) may be the woman's only health provider and health teacher at her yearly well-woman exams. We present patient teaching in three ways:

- Teaching-learning principles are discussed in [Chapter 2](#).
- Chapters are organized to highlight key content so that the student can gather information and translate it into teaching that is individualized for the person or group of people. For example, [Chapter 22](#), Infant Feeding, lays a foundation of basic information, discusses some common problems, identifies relevant assessments, and presents nursing interventions devoted to teaching parents ways to feed their infant successfully.
- Teaching guidelines are highlighted in *Want to Know* features, which give ideas on ways to answer the most common questions on a topic. These features are constructed to show students ways to present information in everyday language rather than in professional language so that the family will better understand the teaching. For instance, the feature "When to Go to the Hospital or Birth Center" (p. 221 [Chapter 13](#)) addresses the concern of many expectant parents that they will not recognize the onset of labor.

Critical Thinking

Nurses must learn critical thinking skills to overcome habits or impulses that can lead to poor clinical decisions. [Chapter 2](#) discusses steps in critical thinking and describes how critical thinking is used in each step of the nursing process. In addition, critical thinking exercises are presented in two ways. First, exercises based on clinical scenarios of common situations with questions to stimulate critical thinking are placed throughout the text. Answers to the questions are found in Appendix D and provide reinforcement for learning. Second, patient-specific nursing care plans (described earlier) contain critical thinking exercises that require participation by the learner. This makes the care plans interactive and reinforces the concept of critical thinking in clinical practice.

Cultural Diversity

Cultural values are among the most significant factors that influence a woman's perception of childbirth, and effective nursing care must be culture specific. This requires nurses to consider their own cultural values and examine how these values may create conflict with those whose values are different.

[Chapter 1](#) offers an overview of Western cultural values and identifies some areas such as communication and health beliefs that may be sources of conflict. Because many different cultural groups exist in the

United States and Canada, emphasis is placed on ways to do a cultural assessment. Plans for care then can show how understanding a family's culture helps nurses provide care that shows respect for cultural differences and traditional healing practices.

New information is integrated throughout the book in all areas, such as the antepartum period, nutrition, birth, the postpartum period, and care of the newborn. Women's health has been divided into two chapters, [Chapter 33](#) covering recommended preventive health care and [Chapter 34](#) covering common problems among women from adolescence through old age.

The Internet is often used by lay people and professionals as a source of health information. We provide the addresses for many websites throughout our text that contain reliable, current information relevant to maternal, newborn, and women's health nursing. Examples of these sites are the March of Dimes, Centers for Disease Control and Prevention, National Institutes of Health, and American Cancer Society. Websites for professional associations and other reliable sources are included when appropriate.

ORGANIZATION

The sixth edition of *Foundations of Maternal-Newborn and Women's Health Nursing* is divided into six parts. Part I, Foundations for Nursing Care of Childbearing Families, presents an overview of contemporary nursing care of the family, including ethical, social, and legal aspects. A review of reproductive anatomy and physiology and the hereditary and environmental factors that affect care are also presented. This material is especially important for students who have not recently completed a full anatomy and physiology course.

Part II, The Family before Birth, begins with conception and prenatal development. These chapters also cover the physiologic and psychosocial adaptations to pregnancy and include a thorough explanation of recommended nutrition during pregnancy and after childbirth. A chapter that includes antepartum fetal assessments and their purpose is included in Part II.

Part III, The Family during Birth, addresses the physiologic processes of birth and nursing care during labor and birth. These chapters include intrapartum fetal monitoring, pain management, and obstetric procedures such as cesarean birth.

Part IV, The Family following Birth, describes care of the new mother and infant. Alternative methods for continuing care, such as home visits and telephone follow-up, also are covered. Separate chapters address infant feeding and home care of the infant.

Part V, Families at Risk during the Childbearing Period, includes a chapter on the family with special needs such as age-related concerns, childbearing in a substance-abusing or violent environment, birth of an infant with congenital anomalies, and responses to fetal or neonatal death. Additional chapters describe the most common complications of pregnancy, childbirth, and the postpartum and neonatal periods. Prematurity continues to be a major health concern in the United States. Measures to reduce the rate, severity, and long-term effects of prematurity on the child and family are discussed in several chapters.

Part VI, Women's Health Care, focuses on family planning, care of the infertile couple, and women's health care.

FEATURES

- *Visual Appeal*. The book is visually appealing, with numerous up-to-date full-color illustrations and photographs that clarify concepts and reinforce learning. Beautiful color pictures also illustrate a childbirth story and cesarean birth.

- **Objectives.** Each chapter begins with a list of objectives that spells out the purposes of the chapter.
- **Glossary.** A glossary at the back of the book contains key terms and their definitions from all chapters and other terms related to this course.
- **Check Your Reading.** Questions to help students monitor their understanding of the material presented are placed at intervals throughout each chapter. Answers to questions are placed in Appendix C so that students can have immediate feedback.
- **Critical Thinking Exercises.** Clinical situations are boxed and set apart to stimulate critical thinking. We believe strongly that immediate feedback is a powerful learning tool, so answers to critical thinking exercises in the text appear in Appendix D.
- **Evidence-Based Practice:** These research reviews include the latest evidence-based guidelines for various topics and reinforce the importance of integrating research-based guidelines into nursing practice.
- **Critical to Remember and Safety Alerts.** Condensed summaries of the essential facts to remember are boxed and set apart to reinforce critical information.
- **Want to Know.** This feature can be used by students who must begin patient teaching very early in their clinical rotations. These include answers to the most common questions asked by women and parents, often phrased in lay terms or as the nurse would actually answer a patient.
- **Procedures.** Illustrated procedures that are specific to maternity, newborn, and women's health nursing, such as assessment of the uterine fundus, are presented in a step-by-step format with rationales for each step.
- **Drug Guides.** Guides for medications often administered in maternal-newborn and women's health care are available in appropriate chapters. Information about additional drugs may be given in tables, the narrative, or in Appendix A.
- **Communication Cues.** This feature is integrated within the text and provides guidance for interpreting client and family statements and behaviors.
- **Unfolding Case Studies.** In some chapters Case Studies are used to follow one patient through aspects of childbearing presented in the chapter. The Case Studies include a Nursing Care Plan and may include other features, such as Critical Thinking Exercises, Want to Know boxes, or Communication Cues.
- **Complementary and Alternative Therapies.** We have included content about these therapies when appropriate throughout the text. Several herbal and botanical preparations are found in Appendix A, Use of Drug and Botanical Preparations during Pregnancy and Breastfeeding.
- **Summary Concepts.** A concise review of content is provided at the end of each chapter. In addition, tables and flow charts are frequently used to summarize complex material.
- **Keys to Clinical Practice.** A description of how to prepare for clinical experience is presented in Appendix B. This feature provides care guides for assessments and interventions for the woman in labor, the woman after childbirth, and the infant. It also provides teaching on key topics such as assisting the inexperienced mother to breast-feed. This feature is designed to help students through their earliest clinical experiences in mother-baby care before they have had much theory.

ANCILLARIES

Materials that complement *Foundations of Maternal-Newborn and Women's Health Nursing* include:

For Students

- **Evolve:** Evolve is an innovative website that provides a wealth of content, resources, and state-of-the-art information on maternity nursing. Learning resources for students include Animations, Case Studies, Content Updates, Glossary, Printable Key Points, Nursing Skills, and NCLEX-Style Review Questions.
- **Simulation Learning System (SLS):** The Simulation Learning System (SLS) is an online tool kit that helps instructors and facilitators effectively incorporate medium-to high-fidelity simulation into their nursing curriculum. Detailed patient scenarios promote and enhance the clinical decision-making skills of students at all levels. The SLS provides detailed instructions for preparation and implementation of the simulation experience, debriefing questions that encourage critical thinking, and learning resources to reinforce student comprehension. Each scenario in the SLS complements the textbook content and helps bridge the gap between lecture and clinical. The SLS provides the perfect environment for students to practice what they are learning in the text for a true-to-life, hands-on learning experience.
- **Study Guide:** This manual presents a variety of additional activities designed to help students master content and become more proficient in the clinical area. Review questions at various levels of difficulty are included.
- **Virtual Clinical Excursions: Virtual Hospital and Workbook Companion:** A Virtual Hospital and workbook package has been developed as a virtual clinical experience to expand student opportunities for critical thinking. This package guides the student through a virtual clinical environment and helps the user apply textbook content to virtual patients in that environment. Case studies are presented that allow students to use this textbook as a reference to assess, diagnose, plan, implement, and evaluate "real" patients using clinical scenarios. The state-of-the-art technologies reflected in this virtual hospital demonstrate cutting-edge learning opportunities for students and facilitate knowledge retention of the information found in the textbook. The clinical simulations and workbook represent the next generation of research-based learning tools that promote critical thinking and meaningful learning.

For Instructors

Evolve includes these teaching resources for instructors:

- **Electronic Test Bank in ExamView format** contains more than 900 NCLEX-style test items, including alternate format questions. An answer key with page references to the text, rationales, and NCLEX-style coding is included.
- **TEACH for Nurses** includes teaching strategies, in-class case studies, and links to animations, nursing skills, and nursing curriculum standards such as QSEN, concepts, and BSN Essentials.
- **Electronic Image Collection,** containing more than 350 full-color illustrations and photographs from the text, helps instructors develop presentations and explain key concepts.
- **PowerPoint Slides,** with lecture notes for each chapter of the text, assist in presenting materials in the classroom. **Case Studies** and **Audience Response Questions** for i-clicker are included.
- A **Curriculum Guide** that includes a proposed class schedule and reading assignments for courses of varying lengths is provided. This gives educators suggestions for using the text in the most essential manner or in a more comprehensive way.

ACKNOWLEDGMENTS

We give special thanks to Laurie Gower, Content Manager, and Heather Bays, Senior Content Development Specialist in Editorial, who helped organize the project and guide it to completion. Bridget Healy, Project Manager in Book Production, helped us refine and clarify our writing with her suggestions and critiques. We also thank Paula Catalano, Book Designer, for the beautiful cover and the clear and attractive page layouts.

Finally, we want to thank Trula Myers Gorrie, our co-author on the first two editions of this textbook. Tru has continued to be our colleague, mentor, and coach as we have continued with the subsequent editions. Most of all, Tru is a great friend to us. Although we miss her company as our co-author, we wish Tru only the best as she enjoys a well-earned retirement.

Maternity and Women's Health Care Today

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe changes in maternity care, from home birth with lay midwives to the emergence of medical management.
2. Compare current settings for childbirth both within and outside the hospital setting.
3. Describe settings for delivery of women's health care.
4. Identify trends that led to the development of family-centered care.
5. Describe current trends that affect perinatal nursing and women's health nursing, such as cost containment, outcomes management, evidence-based practice, community-based care, advances in technology, and increased use of complementary and alternative medicine.
6. Explain changes in family structure and discuss their impact on family functioning.
7. Compare Western cultural values with those of differing cultural groups.
8. Describe the effect of cultural diversity on nursing practice.
9. Discuss the downward trends in infant and maternal mortality rates and compare current infant mortality rates among specific racial groups and nations.

Major changes in maternity care occurred in the first half of the twentieth century as childbirth moved from the home to a hospital setting. Change continues and confusion abounds as health care providers and payers attempt to control the increasing cost of care and the rapid growth of expensive technology. Despite these challenges, health care professionals try to maintain quality of care. Health problems such as obesity, diabetes, and hypertension impact a woman throughout life and often have a negative impact not only during childbearing years but also throughout middle age and beyond.

Alterations in family structure and function and differing cultural beliefs and customs also affect nursing care. Although improvements in health care have resulted in a significant decline in maternal and infant mortality rates in the United States, statistics show a wide disparity between outcomes among races.

HISTORICAL PERSPECTIVES ON CHILDBEARING

Granny Midwives

Before the twentieth century, childbirth occurred most often in the home with the assistance of a "granny" midwife, whose training was obtained through an apprenticeship with a more experienced

granny, or lay, midwife. Women who were charity cases might give birth in a hospital where medical students were educated. The preferred attendant for wealthy women was a midwife, who attended a home birth.

Many women and infants fared well when a midwife assisted with birth in the home, but maternal and infant death rates from childbearing were high for both hospital and home births. The primary causes of maternal death were postpartum hemorrhage, postpartum infection (also known as *puerperal sepsis*, or "childbed fever"), and toxemia, now known as *preeclampsia* or *gestational hypertension*. The primary causes of infant death were prematurity, dehydration from diarrhea, and contagious diseases.

Emergence of Medical Management

In the late nineteenth century, developments that were available to physicians, but not always to midwives, led to a decline in home births and an increase in physician-assisted hospital births. Significant discoveries that set the stage for a change in maternity care included the following:

- Discovery by Semmelweis that puerperal infection could be prevented by hygienic practices

- Development of forceps to facilitate birth
- Discovery of chloroform, which was used to control pain during childbirth and was available only to physicians
- Use of drugs to start or induce labor and increase uterine contractions (augmentation of labor)
- Advances in operative procedures such as cesarean birth

With good intentions to prevent infections, hospitals hurried to develop policies and procedures to meet the needs of physicians and take advantage of technology. By 1960, 90% of all births in the United States occurred in hospitals.

Maternity care became highly regimented for most women. Physicians managed all **antepartum** (before onset of labor), **intrapartum** (time of labor and birth), and **postpartum** (first 6 weeks after childbirth) care. Lay midwifery became illegal in many areas, and nurse-midwifery was not well established. The woman's role in childbirth was seen as passive: The physician "delivered" her infant. The primary functions of nurses were to assist the physician and follow prescribed medical orders after childbirth. Teaching and counseling were not valued nursing functions at that time. Nursing research to improve practice did not formally exist, although individual nurses often found actions that "worked better" than the accepted practice.

Unlike home births, hospital births hindered bonding between parents and infants. During labor, the woman received medication such as "twilight sleep," a combination of a narcotic and scopolamine that provided pain relief but left her disoriented, confused, and heavily sedated. Because of this practice and the lack of knowledge regarding the importance of early contact between parent and child, the mother often did not see her infant for several hours after birth. The father was sent to a waiting area and was not allowed to see the mother until some time after the birth of the infant.

Despite technologic advances and the move from home to hospital, maternal and infant mortality rates declined slowly. The slow decline primarily resulted from problems that could have been prevented, such as poor maternal nutrition, infectious diseases, and inadequate prenatal care. These stubborn problems have remained because of inequalities in health care delivery. Affluent families could afford comprehensive medical care early in the pregnancy, but poor families had very limited access to prenatal care or information about childbearing. Two concurrent trends, federal government involvement and consumer demands, led to additional changes in maternity care.

Government Involvement in Maternal-Infant Care

High rates of maternal and infant mortality among poor women provided the impetus for federal involvement in maternity care. The Sheppard-Towner Act of 1921, the first federally sponsored program, provided funds for state-managed programs for mothers and children. Although the Sheppard-Towner Act was later repealed, it set the stage for future allocation of federal funds. Today, the federal government supports several programs to improve the health of mothers, infants, and young children (Table 1-1). Although government funds partially solved the problem of maternal and infant mortality, the distribution of health care remains inequitable. Most physicians practice in urban or suburban areas in which more people have insurance through their work and can better afford to pay for medical services. However, insurance costs are rising fast, and employers must shift greater responsibility to the employee or discontinue health insurance as a benefit. Health care coverage may be unavailable to women who are poor or working part-time or minimal income jobs. Work-related health coverage may be unavailable or too expensive, and they have no realistic alternatives. Middle-income families may find that costs of employer-sponsored health plans are so high that they do not have enough remaining

TABLE 1-1 FEDERAL PROJECTS FOR MATERNAL CHILD CARE

PROGRAM	PURPOSE
Title V of Social Security Act	Provides funds for maternal-child health programs
National Institute of Health and Human Development	Supports research and education of personnel needed for maternal and child health programs
Title V Amendment of Public Health Service Act	Established the Maternal and Infant Care (MIC) projects to provide comprehensive prenatal and infant care in public clinics
Title XIX of Medicaid	Provides funds to facilitate health care access by pregnant women and young children
Head Start	Provides educational opportunities for low-income children of preschool age
Women, Infants, and Children (WIC) Program	Provides supplemental food and nutrition information
Temporary Assistance to Needy Families (TANF)	Provides temporary money for basic living costs of poor children and their families, with eligibility requirements and time limits varying among states; tribal programs available for Native Americans; replaced the Aid to Families with Dependent Children (AFDC) program
National Center for Family Planning	A clearinghouse for information on contraception
Healthy Start	Enhances community development of culturally appropriate strategies designed to decrease infant mortality and causes of low birth weight

income to support their families, and they decline available coverage. Some areas of the United States continue to have a high unemployment rate.

The ongoing problem of providing health care for women and children with inadequate health care coverage left the door open for nurses to expand their roles, and advanced educational programs prepared nurses as certified nurse-midwives (CNMs), nurse practitioners, and clinical nurse specialists (see Chapter 2).

Effects of Consumer Demands on Health Care

In the early 1950s, consumers began to insist on their right to be involved in their own health care. Pregnant women were no longer willing to accept only what was offered. They wanted information about planning and spacing their children, and they wanted to know what to expect during pregnancy. Fathers, siblings, and grandparents wanted to be part of the extraordinary time of pregnancy and childbirth. Parents wanted more "say" in the way their child was born.

Early in the 1950s, Dr. Grantly Dick-Read proposed a method of childbirth that allowed the mother to control her fear and thus control her pain during labor, allowing for birth without pharmacologic intervention. Methods such as Lamaze and Bradley also gained favor (see Chapter 11). A growing consensus among child psychologists and nurse researchers affirmed that early parent-newborn contact outweighed the risks of infection. Knowledgeable parents insisted that their infants remain with them at all times. The practice of separating the infant from the family was abandoned when infections did not

increase in nurseries, and family-centered maternity care became the standard.

Development of Family-Centered Care

Family-centered care describes safe, high-quality care that recognizes and adapts to both the physical and psychosocial needs of the family, including the newborn. The goal is to foster family unity while maintaining physical safety.

The basic principles of family-centered care are as follows:

- Childbirth is usually a normal, healthy event in the life of a family.
- Childbirth affects the entire family, and family relationships will need to be restructured.
- Families are capable of making decisions about care if they are given adequate information and professional support.
- Maintaining a focus on family or other support can benefit a woman as she seeks to maintain health.

Family-centered care greatly increased the responsibilities of nurses.

Nurses now assume a major role in teaching, counseling, and supporting families in their decisions about childbirth. Family-centered care is often a significant part of women's health (see [Chapters 33](#) and [34](#)). (See [Chapter 2](#) for additional information regarding the nurse's role.)

CURRENT SETTINGS FOR CHILDBIRTH

Traditional Hospital Setting

In the childbirth settings of the past, labor occurred in a functional labor room, similar to a small hospital room or an emergency department room. The mother was moved to a delivery area similar to an operating room when birth was imminent. The mother was transferred to a recovery area for 1 to 2 hours of observation after birth and then taken to the postpartum unit, which resembled a standard hospital room. The infant was usually moved to the newborn nursery when the mother was transferred to the recovery area. Mother and infant were reunited when the mother was settled in the postpartum unit. The nurse who cared for the mother in the postpartum unit was rarely the same nurse who cared for her baby. Beginning in the 1970s, the father or another significant support person could usually remain with the mother throughout labor, birth, and recovery in this setting.

Although birth in a traditional hospital setting was safe, the setting was impersonal, and the multiple moves were uncomfortable for the mother. The move from the labor room to the delivery room just before the birth of the baby was particularly difficult for the mother. Furthermore, each move disrupted the family's time together and often separated the parents and the infant. Because of these disadvantages, hospitals began to devise settings that were more comfortable and enhanced family participation.

Labor, Delivery, and Recovery Rooms

Today, the most common location for vaginal birth is the labor, delivery, and recovery (LDR) room. In an LDR room, normal labor, birth, and recovery from birth take place in one setting ([Figure 1-1](#)). LDR rooms are homelike, often with refrigerators, entertainment media, and soothing lighting. The furniture can be transformed quickly, turning the LDR into a birthing room, when needed. Decorative items are moved to expose suction and oxygen apparatus, ceiling spotlights are activated, and wood chests open to reveal fetal monitors and equipment for the birth. Because families in the childbearing age group now expect technology such as computer charting, intravenous pumps, and fetal monitoring, concealing equipment is often less common than when LDR rooms were first implemented.

During labor, the woman's significant others are allowed to remain with her. These people may include relatives, friends, and her other

FIG 1-1 A typical labor, delivery, and recovery room. Homelike furnishings (**A**) can be adapted quickly to expose the necessary technical equipment (**B**).

children, depending on the policies of the agency and the mother's desires. After she has given birth, the mother typically remains in the LDR room for 1 to 2 hours, after which she is transferred to her postpartum room for the remainder of her hospital stay. The healthy infant may remain with the mother throughout her stay in the LDR room, receiving continuing evaluation for adaptation to neonatal life. When the mother is transferred to her postpartum room, the infant may be transferred to the nursery for more extensive assessment or may remain with the mother in a mother-baby postpartum room while being assessed (see also [Chapter 21](#)).

The major advantages of LDR rooms are that the setting is more comfortable and homelike and the family can remain with the mother throughout her stay. However, if the family members prefer a low-intervention birth, they may perceive technologic components of the LDR room as disadvantages.

Labor, Delivery, Recovery, and Postpartum Rooms

Some hospitals offer rooms similar to LDR rooms in layout and function, with the exception that the mother is not transferred to a postpartum unit after recovery. She and the infant remain in the labor, delivery, recovery, and postpartum (LDRP) room until discharge. The father or the woman's primary support person is encouraged to stay with the mother and the infant, and sleeping facilities for that person may be provided.

Birth Centers

Freestanding birth centers are designed to provide maternity care to low-risk women outside a hospital setting. Many centers also provide gynecologic services such as annual well-woman examination (WWE) and contraceptive counseling. The mother usually attends classes at the

birth center or elsewhere to prepare for childbirth, breastfeeding, and infant care. Both the mother and the infant continue to receive follow-up care during the first 6 weeks after birth. This may include help for breastfeeding problems, a postpartum examination at 4 to 6 weeks, family planning information, and examination of the newborn. Birth is often assisted by the CNM who has provided care for the woman throughout her pregnancy and will continue to provide primary care for the mother and the infant.

Birth centers are less expensive compared with traditional hospitals, which provide advanced technology that may be unnecessary for low-risk women. Moreover, women who want a safe birth in a familiar, homelike setting with personnel they have known throughout their pregnancies often express satisfaction with birth centers.

The main disadvantage is that most independent birth centers are not equipped for major obstetric emergencies. If unforeseen difficulties develop during labor, the woman must be transferred by ambulance to a nearby hospital to the care of a back-up physician who has agreed to perform this duty. Although procedures have been designed for these situations, a sudden transfer is frightening for the family. Liability issues also affect the CNM's decision to transfer the woman, possibly sooner than might have occurred in the recent past.

Home Births

In the United States, only a small number of women give birth at home. Because malpractice insurance for midwives who attend home births is expensive and difficult to obtain, only a small number of CNMs offer this service. Many CNMs have moved their practices to hospitals or birth centers and are often in practice with physicians. Mothers who once sought home births have found that they can have many of the advantages of family-centered care in the safe environment of a hospital or birth center and yet retain the nurse-midwife's care and low-intervention approach that they prefer.

Home birth provides the advantage of keeping the family together in its own familiar environment throughout the childbirth experience. When all goes well, birth at home can be a growth-enhancing experience for every family member. Young siblings are not separated from their mothers and are able to establish positive relationships with the new baby immediately after birth. Bonding with the infant is unimpeded by hospital routines, and breastfeeding is highly encouraged and supported. Women who have their babies at home maintain a feeling of control because they actively plan and prepare for each detail of the birth.

Giving birth at home also has disadvantages. Women who plan a home birth must be screened carefully to make sure that they have a very low risk for complications. If transfer to a nearby hospital becomes necessary, the time required may be too long in an emergency. Other problems associated with home birth include the need for the parents to provide a setting and adequate supplies for the birth. Moreover, the mother must take care of herself and the infant without the immediate help she would have in a hospital or birth center setting.

CURRENT TRENDS IN PERINATAL AND WOMEN'S HEALTH CARE

Government, insurance companies, health care facilities, and health care providers have all made a concerted effort to control the increasing cost of health care in the United States. Reform has involved a change in the ways and the settings in which money is spent. In the past, most of the health care budget was spent in acute care settings, in which the facility charged for services after they were provided. Because the facility was paid for any services billed, hospitals had no incentive to be efficient or cost conscious. Many services occur today in nonacute community settings such as day surgery, wound care, and pain management.

In the midst of these trends, the Affordable Care Act was passed in 2010, and the recent Supreme Court ruling in 2012 has upheld the legislation. The deadline for most of the changes to be implemented is 2014. Many issues such as the costs to implement the Affordable Care Act and who assumes those costs still remain. See www.HealthCare.gov for *The Health Care Law and You: What's Changing and When* and for likely updates.

Cost Containment

One attempt to control costs is with a prospective form of payment. The insurer will no longer pay whatever a facility or a care provider charges for a service. Instead, the facility, the providers, and the payers agree in advance on a fixed amount of money for necessary services for specifically diagnosed conditions. An example of this approach is diagnosis-related groups (DRGs). Treatment for conditions such as pressure ulcers is no longer covered by Medicare and Medicaid because they are considered preventable with proper care.

Diagnosis-Related Groups

DRGs classify related medical diagnoses based on the type or complexity of services generally required by a person with that condition. This method became a standard in 1987 when the federal government set the amount of money that Medicare would pay for each DRG. If a person requires more services than a specific DRG will pay or if the services are more costly, the facility must absorb the costs. Conversely, a facility keeps the remaining money if it delivers the care at a lower cost than the payment for that DRG. Acute care hospitals benefit financially if they can reduce the person's length of stay (LOS) in the facility and thereby reduce the costs for service. Although the DRG system originally applied only to Medicare patients, most states have adopted the system for Medicaid payments, and most insurance companies use a similar system.

Capitated Care

Capitation may be incorporated into any type of managed care plan. In a pure capitated care plan, the payer of the health insurance (usually the employer or the government) pays a set amount of money each year to a network of primary care providers (PCPs). The contracted amount paid to the PCP may be adjusted for the age and gender of the client group. PCPs include physicians and often include advanced practice nurses in community clinics or private practices with physicians. In exchange for access to a guaranteed client base, the PCP agrees to provide general health care to each person under contract and to pay for all other covered services such as laboratory work, specialist visits, and hospital care.

Capitated plans are of interest to employers and government because the plans allow payers of health care to predictably budget for health care for a plan year. Health care consumers do not have unexpected financial burdens from illness. The disadvantage to consumers

is that they lose most of their freedom of choice regarding their health care providers. PCPs can lose money if they refer too many patients to specialists, who may have no restrictions on their fees, or if they order too many diagnostic tests. Many providers and consumers fear that this method of cost containment will inevitably affect treatment decisions.

Effects of Cost Containment on Maternity Care

Prospective payment plans have had major effects on maternity care, primarily with regard to LOS. Mothers who have a normal vaginal birth are typically discharged with their newborns from the hospital at 48 hours, and mothers who give birth by cesarean section leave at 96 hours. Many mothers and infants developed problems with shorter LOS, often called *drive-through deliveries*, which were mandated under early prospective pay arrangements. The problems might require disruptive readmission and more expensive treatment than needed with earlier identification of the actual or possible problem. As a result, many states passed legislation requiring a minimum 48-hour LOS for vaginal births and 4 days (96 hours) for cesarean births unless the woman and her health care provider choose an earlier discharge time. Some insurance plans use a compromise, in which the woman who elects to leave 24 hours after vaginal birth is provided one or more home visits by a nurse to check on her status and that of her baby.

Unfortunately, 48 hours is still a short time to accomplish the teaching needed before discharge, particularly when the new mother is tired and uncomfortable from the birth. She may or may not have had prenatal classes to prepare her for the care she and her infant will need, and she may not have had prenatal care at all. Support of family or friends after discharge may not exist for all new mothers.

Reduced lengths of stay have also affected caregivers, particularly nurses. Since the mid-1990s, nurses have become increasingly concerned about meeting the needs of families who leave the hospital a short time after the birth of an infant. Nurses find it especially difficult to provide adequate information about self-care and infant care when the mother is still recovering from childbirth.

Managed Care. Health insurance companies also examined the cost of health care and instituted a health care delivery system that has been called *managed care*. Managed care organizations may include health maintenance organizations (HMOs), point of service (POS) plans, and preferred provider organizations (PPOs). HMOs provide relatively comprehensive health services for persons enrolled in the organization for a set fee or premium. However, HMOs usually have limited referral to specialists within an HMO, and care outside the HMO group may not be covered. POS plans provide more flexibility in that the primary care physician within the POS organization can make referrals to specialists not in the network. Similarly, PPOs are groups of health care providers who agree to provide health care services to a specific group of patients at a discounted cost. When the patient needs medical treatment, managed care includes strategies such as payment arrangements and preadmission or pretreatment authorization to control costs. Procedures or treatments that can be done at home by the woman, family, or a health care professional such as a nurse may be arranged. Co-payments for non-network providers are often higher for the consumer.

Appropriate provision of managed care can increase access to many types of health care providers and services, but it must be closely monitored. Nurses serve as advocates in the areas of preventive, acute, and chronic care, often as case managers. Teaching begins the moment a woman enters the health care system, whether she enters for routine prenatal care or for answers concerning postmenopausal bleeding.

Case Management. *Case management* is a practice model that uses a systematic approach to identify specific patients and to manage

their care in a coordinated way by all members of the health care team to ensure best outcomes through access to the best available resources. A case manager or case coordinator, usually a nurse who focuses on both quality and cost outcomes, coordinates services needed by the patient. Guidelines established in 1995 by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), now called simply The Joint Commission (TJC) (www.jointcommission.org), require an interdisciplinary, collaborative approach to patient care. This concept is at the core of case management. Nurses who provide case management evaluate patient needs, establish needs documentation to support reimbursement, and may be part of long-term care planning in the home or a rehabilitation facility.

Outcomes Management. Regardless of how health care costs may be controlled, the determination to lower health care costs while maintaining the quality of care has led to a clinical practice model called *outcomes management*. This is a systematic method to identify patient outcomes and to focus care on interventions that will accomplish the stated outcomes for specific case types such as the woman who has just given vaginal birth. The planning tools used by the health care team to identify and meet stated outcomes are *clinical pathways*. Other names for clinical pathways include *critical or clinical paths*, *care paths*, *care maps*, *collaborative plans of care*, *anticipated recovery paths*, and *multidisciplinary action plans*.

Clinical Pathways. Clinical pathways are standardized, interdisciplinary plans of care devised for patients with a specific health need. Clinical pathways identify desired patient outcomes, specify timelines for achievement of those outcomes, direct appropriate interventions and sequencing of interventions, include interventions from a variety of disciplines, promote collaboration, and involve a comprehensive approach to care. Although the concept of clinical pathways is not new, it has only recently been widely accepted as the use of case management has become widespread in various health care settings. The purpose, as in managed care and case management, is to provide high-quality care while controlling costs.

Facilities differ in how they use clinical pathways. For instance, they may be used for change-of-shift reports to indicate information about LOS, individual needs, and priorities of the shift for each patient. They may also be used for documentation of the patient's nursing care plan and his or her progress in meeting the desired outcomes. Many pathways are particularly helpful in identification of families that need follow-up care. Computer-based systems are replacing most printed pathways.

Variations. Deviations, often called *variances*, may occur, either in the timeline or in the expected outcomes. A variance is the difference between what was expected and what actually happened. A variance may be positive or negative. A positive variance occurs when a patient progresses faster than expected and is discharged sooner than planned. A negative variance occurs when progress is slower than expected, outcomes are not met within the designated time frame, and the LOS is prolonged.

Students' Use of Clinical Pathways. Clinical pathways are guidelines for care. Although a pathway provides insight into the scheduling of assessments and care, it is not meant to teach nursing skills and procedures. One purpose of this book is to provide ample information so that students can *use* clinical pathways in a clinical setting. This involves teaching *why and how to perform assessments* and interpreting the significance of the data obtained. Moreover, this book emphasizes ways of providing information, care, and comfort to women and their families as they progress along a clinical pathway.

Evidence-Based Nursing Care. Closely related to outcomes management is a change in focus referred to as *evidence-based* or *research-based* clinical practice guidelines to provide safe and effective

care. Nurses and other professionals no longer perform assessments and care solely because “we’ve always done it that way.” They rely on research data rather than tradition or habit to determine care measures that improve both quality and outcomes of patient care to achieve the *best practice* outcomes at the lowest cost.

The Agency for Healthcare Research and Quality (AHRQ), a branch of the U.S. Public Health Service, actively sponsors research in health issues facing mothers and children. From research generated through this agency, as well as others, high-quality evidence can be accumulated to guide the best and lowest-cost clinical practices. Clinical practice guidelines are an important tool in developing parameters for safe, effective, and evidence-based care to mothers, infants, children, and families. AHRQ has developed several guidelines related to adult and child care, as have other organizations and professional groups concerned with health care. Quality and safety improvements, enhanced primary care, access to quality care, and specific illnesses, are addressed in available practice guidelines. See the website at www.guidelines.gov.

The Institute of Medicine (IOM) has published standards for developing practice guidelines to maximize the consistency within and among guidelines, regardless of guideline developers. The IOM recommends inclusion of information and process steps in every guideline. This includes ensuring diversity of members of a clinical guideline group; full disclosure of conflict of interest; in-depth systematic reviews to inform recommendations; provision of a rationale, quality of evidence, and strength of recommendation for each recommendation made by the guideline committee; and external review of recommendations for validity (IOM, 2011). Standardization of clinical practice guidelines will strengthen evidence-based care, especially for guidelines developed by nurses or professional nursing organizations.

Another resource for evidence-based practice in perinatal nursing is the Cochrane Collaboration, which provides coordination of research results by an international network of individuals and institutions. The results in the Cochrane database do not prescribe policies, procedures, or protocols that a facility should follow. However, the evaluations of research identify and distill results from available research so that the best practices may be incorporated into facility practices. The Internet address for the Cochrane Collaboration is www.cochrane.org.

Community-Based Perinatal and Women’s Health Nursing

Community-based care has increased in perinatal and women’s health nursing because an acute care setting is the most expensive for delivery of health care services. Advances in portable technology and wireless transmission allow nurses in many practice areas to perform procedures in the home that were once limited to the hospital. Documentation and data retrieval may be available by secure wireless Internet connections. Additionally, women and their families are taught to manage less severe problems at home under the supervision of a nurse, entering the hospital only for possible worsening of the problem. Consumers often prefer home care because of decreased stress on the family when a woman or newborn does not need to be separated from the family support system for hospitalization.

Ample evidence shows that the health care system of the future will be community oriented and involve care for greater numbers of patients in the home and through community agencies. Community-based or home care nursing is discussed for specific conditions throughout the text. Public health agencies have existed for many years, and many women obtain all antepartum, postpartum, and neonatal care in these clinics. Other community facilities such as neighborhood

health centers, shelters for women and children, school-age mothers’ programs, and nurse-managed postpartum centers also provide care to a variety of patients.

Nurses need a broad array of skills to function effectively in community-based care, whether that care takes place in individuals’ homes or in large clinics. They must understand the communities in which they practice and the diversity within those communities. Nurses need skills to work with a multidisciplinary team. They are often responsible for assisting patients through high-technology choices and therefore need to be proficient in communication and teaching skills.

Perinatal nursing services delivered in a community setting encompass antepartum, postpartum, and neonatal care. Because care may be given in an environment physically separate from acute care settings, nurses must be able to function independently and have superior clinical and critical thinking skills. They should be proficient in interviewing, counseling, and teaching. They assume a leadership role in the coordination of the services a family may require in a complex case, and they frequently supervise the work of other care providers.

Common Types of Perinatal Home Care

Antepartum Home Care. Most preconceptional and low-risk antepartum care takes place in private offices or public clinics. High-risk conditions that may be seen in home-based perinatal nursing include preterm labor, hyperemesis gravidarum (intractable vomiting during pregnancy), bleeding problems, preterm premature rupture of membranes, hypertension, and diabetes during pregnancy. Severity of these problems and gestational age affect how each will be handled.

Postpartum and Neonatal Home Care. Even with legislation to limit discharge requirements of managed care agencies, providing the necessary education to new mothers about their self-care, basic care of their infants, and signs of problems they should report after discharge is a challenge for health care professionals. Before the woman is discharged, hospitals may offer classes, closed-circuit television programs, written materials (often in multiple languages), individual teaching and demonstration, and DVDs with many relevant topics that a family can take home for later reference.

After the woman is discharged, various services are offered for home care. These services may include telephone calls, home visits, information lines, and **lactation** consultations (breastfeeding assistance). In addition, nurse-managed outpatient clinics provide care for mothers and infants in some areas. (See **Chapters 18** and **23** for additional information about home care for mothers and infants.)

Home Care for High-Risk Neonates. Neonatal home care nurses may provide care to infants who are discharged from the acute care facility with serious medical conditions. Parents of preterm or low-birth-weight infants require a great deal of information and support. Infants with congenital anomalies such as cleft palate may require care adapted to their conditions. Increasing numbers of technology-dependent infants such as those who require ventilator assistance, total parenteral nutrition (TPN), intravenous medications, and apnea monitoring, are now cared for at home.

The coordination of care for the high-risk newborn is a major challenge for home care nurses. Involvement of multiple specialty providers such as physicians, nurses, respiratory therapists, and equipment vendors may result in duplication or fragmentation of services. Duplication of services results in unnecessary costs, and fragmentation of services can result in dangerous gaps in care. (See **Chapter 29** for home care for high-risk infants.)

STANDARDS OF PRACTICE FOR PERINATAL AND WOMEN'S HEALTH NURSING

Both community-based and acute care services must meet guidelines for practice established by the agency itself, appropriate specialty practice organizations, and accrediting agencies.

Agency Standards

Health care agencies are required to have policies, procedures, and protocols to define and guide all elements of care. These standards, which must comply with established national standards, must be kept current and accessible to the nursing personnel. Manuals for these agency standards are often available online within the agency for easier access. Updates and periodic reviews are required to maintain validity of care guidelines.

Organizational Standards

Organizational standards provide broader guidelines that are nationally recognized. The Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN) is recognized as the national professional organization for perinatal and women's health nursing services, publishing standards, education guides, monographs, professional issues, and nursing practice guidelines. Standards set by other professional organizations, such as the American Congress of Obstetricians and Gynecologists (ACOG), the American Academy of Pediatrics (AAP), and the National Association of Home Care and Hospice, may influence standards for perinatal and women's health nurses.

Legal Standards

Nurses who practice in any health care delivery system must understand the definition of nursing practice and the rules and regulations that govern its practice in their work settings. Nurses must also be aware of their scope of practice in varying locations as defined by state nurse practice acts. (Chapter 3 gives additional information on legal aspects of nursing.)

Other regulatory bodies such as the Occupational Safety and Health Administration (OSHA), the U.S. Food and Drug Administration (FDA), and the Centers for Disease Control and Prevention (CDC) also provide guidelines for practice in those areas. Accrediting agencies such as TJC and the Community Health Accreditation Program (CHAP) give their approval after visiting facilities and observing whether standards are being met in practice. Approval from these accrediting agencies affects reimbursement and funding decisions as well.

ADVANCES IN TECHNOLOGY

As with other areas of health care, perinatal care must keep pace with technologic advances. Health care professionals and patients have online access to information from a variety of databases that are often updated, and many of these include data used in this text. Adequate interpretation of words is essential, but today's nurse must be as much at ease with a keyboard, mouse, and pointer as yesterday's nurse was with pen and paper. Fetal monitoring data may be stored on electronic media rather than on paper. Video and digital imaging methods are used to preserve and recall crisp images and allow image overlay and computerized comparison, often at distant locations. Personal computer systems are linked to share information about staffing, scheduling, communication, and employee benefits. Today's nursing student routinely communicates with instructors by electronic mail (e-mail) and receives grades and completes tests and assignments over the Internet. Laptop computers are common ways to take notes in class or at a

meeting. The personal digital assistant (PDA), often with security features, can be used to support nurses with drug information, send and receive wireless e-mail, maintain contacts, and download journal articles from publications such as the *Journal of Obstetric, Gynecologic, and Neonatal Health* and *Nursing for Women's Health*, formerly *AWHONN Lifelines*. Maintaining security is essential to ensure appropriate privacy for personal and professional information.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Complementary and alternative medicine (CAM) is common, and its use is not restricted to recent immigrants to North America, although some techniques originated thousands of years ago in Eastern cultures. CAM can be defined as those systems, practices, interventions, modalities, professions, therapies, applications, theories, and claims that are currently not an integral part of the conventional medical system in North America (ACOG, 2010). The therapies may be used alone (alternative therapy), combined with other therapies, or used in addition to conventional medical therapy (complementary therapy). The term *integrative medicine* is now used by a growing number of practitioners. Table 1-2 gives examples of therapies for complementary or alternative care.

In 2008, National Center for Complementary and Alternative Medicine (NCCAM) and the National Center for Health Statistics (NCHS) released new findings on American use of CAM (NCCAM, 2008a). About 38%, or 4 in 10, adults and 12% of, or 1 in 9, children in the United States use CAM. Adult use of CAM is higher in baby-boomer women with higher education and income levels. Children are more likely to use CAM if their parents use it. CAM use is more common in American Indian and Alaskan Natives at about 50%, with whites at 43%, Asians at 40%, blacks at 25%, and Hispanics at 23%. Reasons for the use for CAM stated by respondents included the following:

- Back or neck pain
- Arthritis, joint pain
- Head or chest cold
- Anxiety, depression
- Upset stomach
- Severe headache, migraine
- Insomnia

A press release from NCCAM (2011) described a survey conducted with the American Association of Retired Persons (AARP) that found two thirds of people older than age 50 years use some form of CAM but fewer than one third have ever discussed it with their health care provider. The following are the most common reasons stated by those surveyed:

- The physician never asked.
- They did not know they should discuss CAM.
- There was not enough time during an office visit.

Safety is a major concern with the use of CAM. Many people who use these techniques or substances are self-referred. They may delay necessary care from a conventional physician or nurse-midwife, or they may ingest herbal remedies or other substances that are harmful during pregnancy or lactation. Some CAM therapies are harmful if combined with conventional medications or when taken in excess. Because herbs and vitamins are classified as foods rather than medications, they are not strictly regulated, if at all. Therefore, people may consume variable amounts of active ingredients from these substances. Herbal therapies may be used for infertility, premenstrual syndrome, dysmenorrhea, menopausal symptoms, pregnancy and perineal discomforts, and lactation discomforts. Also, many people may not consider some therapies as "alternative" because they are considered mainstream in their cultures, in which Western medicine is considered

TABLE 1-2 COMPLEMENTARY AND ALTERNATIVE MEDICINE CATEGORIES

CATEGORY	EXAMPLES
Mind–body interventions: Behavioral, psychological, social, and spiritual approaches to health	Yoga, relaxation response techniques, meditation, tai chi, hypnotherapy, music therapy, spirituality, and biofeedback; some such as support groups and cognitive-behavioral therapy are now mainstream
Manipulative and body-based methods: Based on manipulation or movement of one or more parts of the body	Chiropractic or osteopathic manipulation; massage
Alternative medical systems: Systems developed outside the Western biomedical approach or that evolved apart from the early conventional medical approach in the United States	Examples of systems developed within Western cultures include homeopathy, naturopathic, and chiropractic medicine; non-Western approaches include traditional Chinese medicine, ayurveda, Native American medicine, and acupuncture
Biologically based therapies: Use of substances found in nature such as herbs, foods, and vitamins	Dietary supplements, herbal products or medicinal plants such as ginkgo biloba, ginseng, echinacea, saw palmetto, witch hazel, bilberry, aloe vera, feverfew, and green tea; aromatherapy
Energy therapies: Two types involve the energy fields Biofield therapies: Presumed to affect energy fields that surround the body	Biofield therapies have not been scientifically proved; examples include qi gong, reiki, and therapeutic touch
Bioelectromagnetic-based therapies: Unconventional use of electromagnetic fields	Examples of bioelectromagnetic-based therapies include pulsed fields, magnetic fields, and alternating-current or direct-current fields

“alternative.” (See [Cultural Perspectives in Childbearing](#) on page 10 for more information on health practices used in specific cultures.) Use of CAM therapies is becoming more common for many patient assessments in medicine, nursing, pharmacy, and other health care specialties (Darby, 2009). The *NCCAM (2008b)* provides both patient and provider tips for discussion of CAM.

Nurses may find that their professional values do not conflict with many of the CAM therapies. As a profession, nursing supports a self-care and preventive approach to health care, in which individuals bear much of the responsibility for their health. Nursing practice has traditionally emphasized a holistic, or body–mind–spirit, model of health that fits with CAM. Nurses may already widely practice some CAM therapies such as therapeutic touch. The rising interest in CAM provides opportunities for nurses to participate in research related to the legitimacy of these treatment modalities.

THE FAMILY

Families are sometimes categorized into three groups: traditional, non-traditional, and high-risk. In theory, traditional families require care that differs from that needed by nontraditional or high-risk families.

Traditional Families

Traditional families, or nuclear families, are headed by a father and mother who view parenting as a major priority in their lives and whose energies are less likely to be depleted by stressful conditions such as poverty, illness, or substance abuse. Generally, traditional families are motivated to learn all they can about pregnancy, childbirth, and parenting. These families are best served by providing information as the need arises. Traditional families can be single-income or dual-income

families. Today, the family structure that is composed of two married parents and their children represents 66% of families with children, down from 77% in 1980 ([Forum on Child and Family Statistics, 2011](#)).

Single-income families in which one parent, usually the father, is the sole provider constitute a minority among households in the United States. Most two-parent families depend on two incomes, either to make ends meet or to provide nonessentials that they could not afford on one income. One or both parents must often travel as a work responsibility. Dependence on two incomes has created greater stress on parents, subjecting them to many of the same problems that single-parent families face. For instance, reliable, competent child care is an issue that has increased the stress and financial burdens many families experience. A high consumer debt load gives them less cushion for financial setbacks such as job loss. It may be difficult for parents in these families to have the time and flexibility to attend to the requirements of both their careers and their children.

Nontraditional Families

Nontraditional families are defined by their unique structure and may be single parent, blended, or extended. As with traditional families, nontraditional families require information. They often benefit from referrals to meet specific needs such as single-parenting classes, classes for parents of multiple births, and group classes for adoptive families.

Single-Parent Families

Millions of families are now headed by a single parent, most often the mother, who must function as a homemaker and caregiver and is often the major financial provider for the family's needs. Divorce is the most common cause of single-parent families, although childbirth among unmarried women is also a factor. Births to a single mother have risen from 28% in 1970 to over 50% in 2009. Widowhood of the parent sometimes occurs as well. Today, 23% of families consist of children who are raised by a single mother, and single-father families make up 3% of this group. Families headed by unmarried mothers and fathers of the children now compose 3% of families. Children in families headed by neither parent make up 4% of families ([Forum on Child and Family Statistics, 2011](#); [NCHS, 2012](#)).

Single-parent families headed by women are more likely to have an income below the poverty level (44%) than families headed by a married couple (11%), an increase since 2001 ([Forum on Child and Family Statistics, 2011](#)). Single parents may feel overwhelmed by the prospect of assuming all child-rearing responsibilities and may be less prepared for illness or loss of a job compared with two-parent families.

Nurses can support and encourage single-parent families with a focus on the unique problems of each specific family. Nurses are often the primary source of information about health care for many of these families and are often instrumental in the initiation of the necessary referrals to social and governmental agencies.

Blended Families

Blended families are formed when divorced or widowed parents remarry and bring children from a previous marriage into the new relationship. In many situations, the members of the couple desire children with each other, which creates a family structure commonly described as “yours, mine, and ours.” These families may have difficulty forming a cohesive family unit unless they can overcome differences in parenting styles and values. Differing expectations of children's behavior and development and differing beliefs about discipline often cause family conflict. Financial hardships may occur in the blended family when a parent must pay child support for children from a previous relationship.

Extended Families

The extended family includes members from at least three generations living under one roof. This family structure is becoming increasingly common in the United States and has given rise to the term *boomerang families*. Elderly parents may live with their adult children, or single or married adults with children of their own return to their parents' homes because they either are unable to support their families or want the additional support that grandparents provide for grandchildren. By living in one home, adult children and their children may also provide much of the care their aging parents need. Extended families are vulnerable to generational conflicts and may require education and referral to prevent disintegration of the family unit. However, extended families can also provide a great deal of support to all members.

Because of the inability of the parents to care for the children, grandparents or other older family members now head a growing number of households with children. The strain of raising children a second time may cause tremendous physical, financial, and emotional stress.

Same-Sex Parent Families

Although families headed by same-sex parents are relatively uncommon, they are recognized increasingly in the United States. Children in these families may be from previous heterosexual unions, adopted, or conceived by an assisted reproductive technique such as in vitro fertilization. These families may face challenges from a community that is unaccustomed to alternative lifestyles. The children's adaptation depends on the parents' psychological adjustment, the degree of participation and support of the absent biologic parent, and community acceptance and support.

Adoptive Families

People who adopt a child may have problems that biologic parents do not face. Biologic parents have the long period of gestation and the gradual changes of pregnancy to help them adjust emotionally and socially to the birth of a child. Although an adoptive family may have waited a long time for their adopted child to arrive, both parents and

siblings are expected to make the same adjustments suddenly when the adopted child arrives, possibly from another country. Adoptive parents add pressure on themselves if they have unrealistically high standards for parenting. Additional issues with adoptive families may include the following:

- Little knowledge of the child's health history
- Difficulty assimilating if the child is adopted from another country
- Unknown developmental or growth delays in the child
- Deciding when and how to tell the child about the adoption

Adoptive parents as well as biologic parents need information, support, and guidance to prepare them to care for the infant or child and to maintain their own relationship.

Adoptive parents may be older when the adoption is finalized. Friends in their age group may have children who are much older than the newly adopted child, particularly if the parents adopt an infant. This difference may make adoptive parents feel somewhat out of step with their peers, who are attending their children's soccer games and drill team practice while the adoptive parents are changing diapers and doing night feedings.

Characteristics of a Healthy Family

In general, healthy families are able to adapt to changes that occur in the family unit. Pregnancy and childbirth create some of the most powerful changes in a family. The relationship between adults must change to include the care of a helpless infant. Children must learn to share their parents' attention with a new sibling. The healthy, viable family is able to adapt to these changes without undue stress, but the family that is unprepared for change may suffer conflict.

Healthy families exhibit some common characteristics that provide a framework the nurse can use to assess the way all families function. These characteristics include the following:

- Members of healthy families communicate openly with each other to express the concerns and needs of each family member.
- Healthy families remain flexible in role assignment so that if one person is unable to complete the assigned tasks, another member offers assistance.
- Adults in healthy families agree on the basic principles of parenting so that discord about such things as discipline and sleep schedules is minimal.
- Healthy families are adaptable and not overwhelmed by changes that occur in the home and relationships as a result of childbirth. For instance, adaptable families can tolerate less-than-perfect housekeeping, an irregular schedule of meals, and interrupted sleep, all of which are common when an infant is added to the family structure.
- Members of healthy families volunteer assistance without waiting to be asked. Some young parents feel guilty if they must ask for help with the tasks of parenting but are relieved when assistance is offered.

Factors That Interfere with Family Functioning

Nurses need to recognize factors that interfere with the family's ability to provide for the individual needs of family members. These factors include lack of financial resources, absence of adequate family support, birth of an infant who requires specialized care, presence of unhealthy habits such as smoking or substance abuse, and inability to make mature decisions that are necessary to provide care to an infant.

High-Risk Families

High-risk families include those that live below the poverty level, those headed by a single teenage parent, and those with unanticipated stress such as an infant who is preterm, ill, or handicapped. In addition,

families with lifestyle problems such as alcoholism, substance abuse, and family violence are considered at high risk for problems in providing adequate care for the infant.

Many high-risk families require specialized services. In such cases, the major responsibility of nurses is to refer these families to agencies that can provide comprehensive care. The most common referrals are to social service agencies for financial assistance, crisis intervention, home visits, and drug rehabilitation programs (see [Chapter 24](#)).

CULTURAL PERSPECTIVES IN CHILDBEARING

Culture is the sum of the beliefs and values that are learned, shared, and transmitted from generation to generation in a particular group. Cultural values guide the thinking, decisions, and actions of a group, particularly in pivotal events such as childbearing. **Ethnic** pertains to religious, racial, national, or cultural group characteristics such as speech patterns, social customs, and physical characteristics. **Ethnicity** is the condition of belonging to a particular group that shares race, language and dialect, religious faiths, traditions, values, and symbols, as well as food preferences, literature, and folklore. Cultural beliefs and values vary among different groups, and nurses must be aware that individuals often believe their cultural values and patterns of behavior are superior. This belief, termed **ethnocentrism**, forms the basis for many conflicts that occur when persons from different cultural groups have frequent contact. **Transcultural nursing** is concerned with the provision of nursing care in a manner that is sensitive to the needs of individuals, families, and groups. *Culture-specific care* considers values, beliefs, and behaviors that are often unique to a group. *Culture-universal care* refers to commonly shared values, beliefs, and behaviors (DeLapp, 2013; Mattson, 2011).

Nurses must be aware that culture has visible and invisible layers that could be said to resemble an iceberg ([Figure 1-2](#)). Observable behaviors can be compared with the visible part—the tip of the iceberg. The history, beliefs, values, and religion are not observed, but they are

FIG 1-2 Visible and hidden layers of culture are like the visible and submerged parts of an iceberg. Many cultural differences are hidden below the surface.

the hidden foundation on which behaviors are based and can be likened to the large submerged part of the iceberg. A full comprehension of cultural behavior includes knowledge of the hidden beliefs expressed by behaviors.

Implications of Cultural Diversity for Perinatal Nurses

The population of North America is now composed of many cultural and ethnic groups. Perinatal and women's health nurses in most localities will provide care for culturally diverse families. To provide effective care, nurses must be aware that culture is among the most significant factors that influence perception of health care. For more information see the Office of Minority Health website at www.omhrc.gov.

Western Cultural Beliefs

Nursing practice in the United States is based largely on Western beliefs. Nurses must recognize that these beliefs may differ significantly from those of other societies and that the differences may cause conflict.

Leininger (1978) identified seven dominant Western cultural values. These values, described in the following list, greatly influence the thinking and action of nurses in the United States but may not be shared by their patients.

1. Democracy is a cultural value not shared by families that believe decisions are made by elders or other higher authorities in the group. Fatalism, or a belief that events and results are predestined, may also affect health care decisions.
2. Individualism conflicts with the values of many cultural groups in which individual goals are subordinated to the greater good of the group.
3. Cleanliness is an American “obsession,” which many others view with amazement.
4. Preoccupation with time, which is measured by health care professionals in minutes and hours, is a major source of conflict with those who mark time by different standards such as seasons and body needs.
5. Reliance on machines and equipment may intimidate families that have not reached a level of even minimal comfort with technology.
6. The belief that optimal health is a right is in direct conflict with beliefs in many cultures in which health is not a major emphasis or even an expectation.
7. Admiration of self-sufficiency and financial success may conflict with beliefs of other societies that place less value on wealth and more value on less tangible factors such as spirituality.

Communication

Communication may also be a source of conflict between “dominant culture” and “other culture” health care professionals. This is particularly true of Southeast Asians, Hispanics (or Latinos), African-Americans, and Middle Easterners.

Southeast Asians. Language is the greatest barrier to health care for families that have recently immigrated to North America, including people from Southeast Asia. Many women of childbearing age in these families are often born in the United States or Canada, but the elders may not have learned English. Besides the national languages of Vietnam, Cambodia, and Laos, dialects or written characters may be familiar to the family. People from Southeast Asia also speak softly and avoid prolonged eye contact, which they consider rude, in contrast to the Western belief that eye contact denotes honesty and forthrightness. They invariably show respect to the elderly, priests, and physicians. When medication or therapy is recommended, they seldom say “no.” They may accept the prescription or medication sample but not take

the medicine, or they may agree to undergo a procedure but not keep the appointment (Appel, 2013).

Hispanics. Hispanics, also called *Latinos*, include those whose origin is Mexico, Central and South America, and Puerto Rico. The background of approximately 66% of Hispanics in the United States is Mexican. Most Hispanics of Mexican background reside in the southern or western states, whereas Puerto Ricans (9%) often live in the northeast United States and those from Cuba (3.4%) tend to reside in Florida. Hispanics are part of a rapidly growing population in the United States and now represent 16% of the total U.S. population. Education and unstable employment are often problems in the Hispanic population. Two in five Hispanics have not graduated from high school. Lower pay and unemployment or seasonal work, which accompany incomplete education, are also more likely (Humes, Jones, & Ramirez, 2011; Owen, Gonzalez, & Esparat, 2013; U.S. Census Bureau, 2009).

Men usually serve as head of household and are considered strong (“macho”). Women are the homemakers. Hispanics usually have a close extended family and place a high value on children. Spanish is the primary language for many Hispanics in their homes, although they may speak English fluently at their workplaces.

Hispanics tend to be polite and gracious in conversation. Preliminary social interaction is important, and Hispanics may be insulted if a problem is addressed directly without taking time for “small talk.” This is counter to the value of “getting to the point” for many whites in the United States and may cause frustration for the patient as well as for the health care worker.

A strong association exists between religion and health. The *curandero*, a folk healer, may be consulted for health care before a professional health care worker is consulted.

African-Americans. The population of blacks, also referred to as *African-Americans*, has increased by 12%. Blacks alone and Blacks combined with other races total 15% of the U.S. population. The black population grew more slowly compared with most other races. Blacks are often part of a close extended family, although heads of household are often single women. They have a sense of loyalty to their people and community but sometimes distrust the majority group. African-Americans sometimes use a communication style that may cause conflict when they seek health care. They may use idioms, colloquial expressions, or speech patterns that are unfamiliar to many health care workers. Nurses must often clarify what is being said so that misunderstandings can be avoided and teaching can be effective. The African-American minister is influential, and religious rituals or prayer may be used in coping with illness (Cherry & Giger, 2013; Rastogi, Johnston, Hoeffel et al., 2011).

Native Americans. Native Americans include American Indians and Alaska Natives. This group makes up 1.5% of the total U.S. population. Many who consider themselves Native Americans are of mixed race. The largest American Indian tribal groups include Cherokee, Navajo, Latin American Indian, Choctaw, Sioux, and Chippewa. The largest tribe among Alaska Natives is the Eskimos.

Native Americans may consider a willful child to be strong and a docile child to be weak. They have close family relationships, and respect for their elders is the norm. Native Americans may consider health to be a state of harmony with nature and may believe that supernatural influences have a great impact on health and illness. Native Americans may highly respect a medicine man, who they believe has been given power by supernatural forces. The use of herbs and rituals is part of the medicine man's curative practice (DeLapp, 2013; Hanley, 2013; Norris, Vines, & Hoeffel, 2012).

Native Hawaiian and Pacific Islanders. As European colonists settled in Hawaii to establish Christian colonies over 200 years ago,

they brought many new diseases with them. The indigenous people of Hawaii had no immunity against them, and many died. The state government is now committed to maintaining Hawaii's native culture and people. See these websites: www.oha.org; www.waiolachurch.org.

The U.S. census now has a racial choice for people of native Hawaiian or Pacific Islander ancestry and refers to a person having origins in any of the original peoples of Hawaii, Guam, Samoa, or other Pacific Islands. These people may claim links to other races in addition to Hawaiian and Pacific Islander. Many native people may no longer live in these islands, but most of those who have moved to the continental United States live in one of the west coast states (Hixon, Hepler, & Kim, 2012).

Middle Easterners. Middle Eastern immigrants come from a variety of countries, including Lebanon, Syria, Arabia, Egypt, Turkey, Iran, Iraq, and Palestine. Islam is the dominant, and often the official, religion in these countries; its followers are known as *Muslims*. Obtaining health care information from this group may be difficult because Islam dictates that family affairs be kept within the family. Afghans have a legal name, which may be rarely used, and a familiar name by which the family and other Afghans identify them. Strangers are not given a woman's legal or familiar name but refer to her by title. This pattern is changing, as legal names are more often required on documents such as passports. Personal information is shared only with personal friends, and health assessment must be done in a gradual manner. Decisions are usually made by the male head of the household. Interpreters should be from the same country and religion as the patient, if possible, because of regional differences and hostilities (Iqbal, Lipson, & Omidian, 2013).

Islam requires believers to kneel and pray five times a day: at dawn, noon, afternoon, after sunset, and after nightfall. Muslims do not eat pork and do not use alcohol. Many are vegetarians.

Cross-Cultural Health Beliefs

More than 100 different ethnocultural groups exist in the United States, and numerous traditional health beliefs are observed among these groups. Culturally based definitions of health are common. Women of Asian origin may believe health as the balance between “yin” and “yang.” Those of African or Haitian origin may define health as “harmony with nature.” People from Mexico, Central and South America, and Puerto Rico often consider health as a balance between “hot” and “cold.”

Traditional Methods to Prevent Illness. The traditional methods of illness prevention rely on the causes of a given illness as ascribed by a person's culture. These causes may include the following:

- Agents such as hexes, spells, or the “evil eye,” which may strike a person (often a child) and cause injury, illness, or misfortune
- Phenomena such as soul loss or accidental provocation of envy, jealousy, or hatred of a friend or an acquaintance
- Environmental factors such as bad air and natural events such as solar eclipses

Practices to prevent illness developed from beliefs regarding the cause of illness. A believer must avoid those persons known to transmit hexes and spells. Elaborate methods are used to prevent inciting envy or jealousy of others and to avoid the evil eye. Protective or religious objects such as amulets with magic powers or consecrated religious objects (such as talismans) are frequently worn or carried to prevent illness. Also, numerous food taboos and traditional combinations are prescribed in traditional belief systems to prevent illness. For instance, people from many ethnic backgrounds eat raw garlic to prevent illness. Those of African origin may consume substances for pica such as starch to facilitate labor.

Traditional Practices to Maintain Health. Several traditional practices are used to maintain health. Proper clothing such as scarves may prevent being chilled by drafts and thus maintain the health of a woman who is pregnant and believes she must avoid cool air. Another example is a proper diet. Women of Asian origin eat rice daily. Mental health and spiritual health are maintained by activities such as silence, meditation, and prayer. Many people view illness as punishment for breaking a religious code and adhere strictly to religious morals and practices to maintain health.

Traditional Practices to Restore Health. Traditional practices to restore health often conflict with Western medical practice. Some of the most common practices include the use of natural substances such as herbs and plants to treat illness. Religious charms, holy words, and traditional healers may be tried before a medical opinion is sought. Religious medals, prayer cards, and sacrifices may also be used to treat illness.

A variety of substances may be ingested for the treatment of illnesses. The nurse should make an effort to identify the substance and determine whether its active ingredient may alter the effects of prescribed medication.

Dermabrasion, which is the rubbing or irritation of the skin to relieve discomfort, is a common health care practice in cultures such as those of Vietnam and Cambodia. The most popular form is *coining*, in which an area is covered with an ointment and the edge of a coin is rubbed over the area. All dermabrasion methods leave marks resembling bruises or burns on the skin and may be mistaken for signs of physical abuse (D'Avanzo, 2008).

Cultural Assessment

All health care professionals must develop skills in performing a cultural assessment so that they can understand the meaning of childbirth in different cultural groups. The following questions might be considered in making such an assessment:

- What is the family's ethnic affiliation?
- Is childbearing viewed as a normal process, a time of vulnerability, or a state of illness?
- What are the prescribed practices, customs, and rituals related to diet, activity, and behavior during pregnancy and childbirth?
- What maternal restrictions or precautions are considered necessary during pregnancy and childbirth? Are women exempted from any religious expectations at this time? Are any religious expectations required to be met after birth?
- Who provides support during pregnancy, childbirth, and beyond?
- What are the prescribed practices and restrictions related to care of the newborn?
- Who in the family hierarchy makes health care decisions?
- How is time marked—by minutes and hours or by seasons and body needs?
- What are the views of life and death, including predestination and fatalism?
- How can health care professionals be most helpful?

After such an assessment, plans for care should show respect for cultural differences and traditional healing practices. (Additional information is presented throughout this book relating to culture-specific areas such as nutrition, pregnancy, birth, and the postpartum period.)

STATISTICS ON MATERNAL, INFANT, AND WOMEN'S HEALTH

Statistics is the science of collecting and interpreting numeric data. In the health and medical sciences, data often focus on mortality rates within a given population. **Mortality rates** indicate the number of deaths that occur each year by different categories. They are important sources of information about the health of groups of people within a country. They may also be an indication of the value a society places on health care and the kind of health care available to the people. The newest statistics about maternal and infant health can be obtained from the National Center for Health Statistics (www.cdc.gov/nchs).

Maternal and Infant Mortality

Throughout history, mortality rates among women and infants have been high, especially in relation to childbirth. Infant and maternal mortality rates began to fall with the improved health of the general population, application of basic principles of sanitation, and increase in medical knowledge. Improvements in health care, including widely available antibiotics, public health facilities, and increased prenatal care, further reduced infant mortality. Today, mothers seldom die in childbirth, and infant mortality rates continue a downward trend. However, this downward trend is greater for whites than for blacks.

Maternal Mortality

In 2010, the **maternal mortality rate** was 12.7 per 100,000 live births among all women in the United States. Non-Hispanic black women are more likely to die from birth-related causes compared with white women. The maternal mortality rate for Non-Hispanic black women is 34.8 per 100,000, whereas for white women it is 11 per 100,000 (Hoyert, 2007; NCHS, 2012; www.facethefactsusa.org, 2012). The rate is higher if compared with that in previous years because deaths whose cause was aggravated by pregnancy are now included, even if the deaths occurred more than 42 days after the end of pregnancy.

Infant Mortality

The **infant mortality rate** (death before the age of 1 year) has decreased to 6.14 per 1000 in 2010. A comparable drop in **neonatal mortality rate** (death before 28 days of life) is 4.04 deaths per 1000 live births in the same period. The fall in infant mortality is attributed to better neonatal care and public awareness campaigns such as the "Back to Sleep" campaign to reduce the occurrence of sudden infant death syndrome (SIDS) (Murphy, Xu, & Kochanek, 2012). Early and more consistent prenatal care, including that provided at public clinics, reduces pregnancy complications and allows early identification of problems. However, women do not consistently receive the best care because they may not enter prenatal care until their pregnancy nears term.

Although infant mortality rates in the United States have declined overall to 6.1 per 1000 in 2010, rates have declined faster for whites than for non-Hispanic black infants. The 2010 mortality rate for white infants was 5.2 per 1000, whereas for non-Hispanic black infants, the mortality rate is 2.2 times the rate for white infants, at 11.6 per 1000 (Murphy, Xu, & Kochanek, 2012). **Figure 1-3** compares the rates of infant mortality for all races and for whites and African-Americans since 1960.

Disparity across Racial Groups

The disparity in maternal and infant mortality rates is most obvious between whites and non-Hispanic blacks, who constitute the largest minority group. The discrepancy is primarily because of greater numbers of premature and low-birth-weight (less than 2500 grams)

FIG 1-3 Infant mortality rates from 1960 to 2010 based on deaths before 1 year per 1000 live births. (From Murphy, S. L., Xu, J., & Kochanek, K. D. (2012). Deaths: Preliminary data for 2010. *National Vital Statistics Reports*, 60(4). Retrieved from www.cdc.gov.)

infants among black women. Premature and low-birth-weight infants have a greater risk for short-term and long-term health problems such as respiratory disorders, developmental delay, or sudden infant death syndrome (SIDS) (March of Dimes, 2011; Murphy, Xu, & Kochanek, 2012).

Poverty, not race, is an important factor. The rate of poverty is higher for nonwhites than for whites in the United States. People who live below the poverty level are unlikely to be in good health, be well nourished, have adequate housing, and obtain adequate preventive health care. Obtaining care becomes vital during pregnancy and infancy, and lack of care is reflected in the high mortality rates in all categories.

The following *Healthy People 2020* objectives relate to perinatal through infant mortality in the United States (U.S. Department of Health and Human Services, 2012b):

- Reduce perinatal mortality (28 weeks to 7 days after birth) to 5.9 per 1000 live births and fetal deaths
- Reduce infant mortality from the 1998 rate of 7.2 per 1000 live births to 4.5 per 1000 live births in 2010
- Reduce neonatal mortality from the 1998 rate of 4.8 per 1000 live births to 2.9 per 1000 live births in 2010
- Reduce the percentage of low-birth-weight infants from 7.6 to 5
- Reduce the percentage of very-low-birth-weight infants from 1.4 to 0.9.

Infant Mortality across Nations

A country such as the United States, which has one of the highest gross national products (GNPs) in the world, is expected to have one of the lowest infant mortality rates. Yet in 2008, the most recent year for which comparative data among countries are available, the infant mortality rate in the United States ranked twenty-seventh among developed nations (Table 1-3).

Although the United States has an improved standing from twenty-ninth at our last publication, unequal access to health care for women of all socioeconomic levels and low birth weight and complications of prematurity continue to impact infant mortality. Congenital anomalies, SIDS, newborn problems after pregnancy complications, and respiratory distress syndrome are also leading causes of infant mortality.

TABLE 1-3 INFANT MORTALITY RATES FOR SELECTED COUNTRIES (BASED ON 2008 DATA)

COUNTRY	INFANT MORTALITY (PER 1000 LIVE BIRTHS)
Iceland, Sweden	2.5
Finland, Japan	2.6
Greece, Norway	2.7
Czech Republic	2.8
Italy, Portugal, Spain	3.3
Germany, Republic of Korea	3.5
Austria, Belgium	3.7
France, Ireland, Israel, Netherlands	3.8
Denmark, Switzerland	4.0
Australia	4.1
United Kingdom	4.7
New Zealand	5.0
Hungary, Poland	5.6
Slovak Republic	5.9
United States	6.6

From National Center for Health Statistics. (2012). *Health United States, 2011 with special feature on socioeconomic status and health*. Hyattsville, MD: NCHS; Mathews, T. J., & MacDorman, M. L. (2012). Infant mortality statistics from the 2008 period. Linked birth/infant death data set. *National Vital Statistics Reports*, 60(5). National Vital Statistics System, National Center for Health Statistics. Retrieved from www.cdc.gov.

Late preterm births (34 to 36 completed weeks of gestation), that is, babies born 1 to 3 weeks short of term, have risen by 20% from 1990 to 2006. Delivery by induction of labor or cesarean section has risen markedly in this group. Births at longer gestations of 40 weeks or more have declined. The rise in late preterm births is important because these babies are immature and have more health complications and higher death rates compared with infants born at term (Craighead, 2012; Martin, Kirmeyer, Osterman et al., 2009).

Adolescent Pregnancy

Teen birth rates have fallen, and the 2009 rate was 37% lower than the most recent high of 62 births per 1000 in 1991. Teen pregnancy rates fell for ages 10 to 14 years, 15 to 17 years, and 18 to 19 years (Martin, Hamilton, Ventura et al., 2011).

Women's Health

Cardiovascular disease (CVD) and the many accompanying problems affect females from adolescence through old age. CVD is the leading cause of death in the United States, and 51% of the deaths occur in women. The epidemic of obesity contributes to the growing problems of hypertension, high blood cholesterol, and diabetes mellitus. See Chapters 33 and 34 for more information about preventive care for women and treatment for some common problems that affect women.

CHECK YOUR READING

15. Why is the infant mortality rate so much lower today than at the beginning of the twentieth century?
16. Why are black women and infants more likely to die compared with white women and infants?
17. How does the infant mortality rate in the United States compare with the rates in other countries?

SUMMARY CONCEPTS

- Technologic advances, increasing knowledge, government involvement, and consumer demands have changed maternity care in the United States.
- Alternative settings for childbirth are now available in hospitals and freestanding birth centers. Home birth is less frequently selected as an alternative.
- Family-centered maternity care, which is based on the principle that families can make decisions about health care if they have adequate information, has greatly enhanced the role of nurses.
- “Drive-through deliveries,” or very short lengths of stay mandated by prospective payment plans, resulted in costly maternal and infant problems. Many states passed laws requiring a minimum stay of 48 hours after vaginal birth or 96 hours after cesarean birth. The woman and her care provider have the right to choose an earlier discharge time.
- Reduced lengths of stay make it more difficult for the nurse to provide information regarding self-care and infant care to the woman who is recovering from the fatigue and discomfort of birth.
- Clinical pathways are interdisciplinary guidelines for assessments and interventions that will accomplish the identified outcomes in the shortest time. A variance is a deviation in the timeline or the expected outcomes of the pathway and may indicate either faster or delayed progression.
- Students must learn why and how to perform assessments and interventions so that they can use clinical pathways to determine whether patients are achieving identified outcomes.
- Social trends such as poverty, early unplanned pregnancy, and the increased rate of divorce have altered family structure and function and have increased the need for information and support provided by nurses.
- To provide care for culturally diverse patients, nurses must examine their own beliefs and become familiar with different cultural values and customs encountered in their practice settings.
- Infant mortality rates have declined dramatically in the last 50 years. However, the United States continues to have a higher infant and maternal mortality rate than many other developed nations, and variation of mortality rates across ethnic groups is still wide.

The Nurse's Role in Maternity and Women's Health Care

Evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain the roles of nurses with advanced preparation in maternal-newborn or women's health nursing, including the roles of nurse-midwives, nurse practitioners, and clinical specialists.
2. Discuss the roles for nurses in maternity care and women's health care.
3. Explain the importance of critical thinking in nursing practice and describe how it may be refined.
4. Relate the five steps of the nursing process to maternal-newborn and women's health nursing.
5. Explain how the nursing process relates to critical thinking.
6. Discuss the importance of nursing research in clinical practice.

As maternity care changed from regimented care of mother and newborn to a family-centered approach, maternity nursing evolved to a new level of independence. Women's health has evolved from nursing that did not focus on the care of women from the early years of adolescence to late life. Little was known about how men and women might differ in the best care for the same condition.

For the best care during the years preceding childbearing through the time after the reproductive years, nurses must communicate and teach effectively. They must be able to think critically and use the nursing process to develop a plan of care that meets the unique needs of each family. Nurses are expected to base their practice on valid and current research and to collaborate with other health care providers. Moreover, many nurses complete advanced programs of education that allow them to provide primary care to girls and women before, during, and after their childbearing years. Within the rising expectations for high-quality nursing practice is the real crisis of too few nurses.

SHORTAGE OF NURSES

Shortages of nurses have been intermittent and brief for many years. The recent downturn in the U.S. economy that put many registered nurses (RNs) back into full-time or part-time work plus the increasing number of nursing graduates from expanded programs that might have trouble finding work may make one think that "the worst is over" for this nursing shortage. But it is not over (Staiger, Auerbach, & Buerhaus, 2012).

Many current nurses are baby boomers (those born in the years 1946 to 1964), and they are nearing retirement age or have already retired. Baby boomers, or "boomers," are a large population group, and their need for health care is expected to increase as they age. A 2008 survey by the Health Resources and Services Administration (HRSA, 2010) showed that the average age of an RN was 47 years, exceeding the 2000 average of 45 years and the 1996 average of 44 years. Defining the older RN as 50 years or older and the younger RN as younger than 50 years, the HRSA survey showed that older nurses made up almost 45% of the total nurse population in 2008, higher than 41% in 2004 and 33% in 2000. Nurses 60 years or older increased from almost 14% in 2004 to 15% in 2008.

Many nursing schools increased enrollment with the realization that more RNs will be needed for care of baby boomers in the future and that large numbers of their faculty will likely retire soon. Studies have shown that higher RN-to-patient ratios have reduced hospital mortality, reinforcing the need for an increase in their numbers as boomers retire. The Institute of Medicine (IOM, 2010) identifies the need for 80% of new RNs to be prepared at the baccalaureate or higher level by 2020, yet only 50% of the current workforce meets this recommendation. Almost 60% of nursing faculty with a master's or doctoral degree were 50 years or older in 2008, and they are moving faster toward retirement and reducing the number of qualified student applicants that an accredited nursing program can admit. Availability of sufficient clinical and classroom facilities for basic nursing education adds another limitation to how many qualified applicants can be

admitted. Almost 1100 faculty vacancies for 2011-2012 were identified in one study, emphasizing the need for education of new faculty (American Association of Colleges of Nursing [AACN], 2012a, 2012b; Fang & Li, 2011).

With inadequate nurse staffing and increasing patient loads as the population ages, nurses face greater work stress and fatigue, leading some to leave acute care or leave the profession. Lengthy shifts of 12 hours in most acute care facilities may be too much for the aging nurse, but these shifts may also be too demanding for the nurse who is a new parent, caregiver for an older adult, or trying to earn a higher degree while working. Fatigue of long work hours can impact both the nurse's health and the patient's safety (Trinkoff, Geiger-Brown, Brady et al., 2006). Many health care facilities continue not only to support education of new nurses but also to retain older nurses. Nursing scholarships from a facility may be available to their non-RN employees, usually after completion of the prerequisite courses. Joint appointment of RNs promotes sharing of the nurse's skills and knowledge between a school and a clinical facility. However, the school and clinical facility must clearly limit RN time demands for each facility. Hospitals earning the "Magnet status" recognition® from American Nurses Credentialing Center (ANCC) are often more attractive at acquiring and retaining nurses. Measures to maintain safety for both patients and working staff reduce the risks of injury and lost productivity. Greater flexibility in scheduling may be a way for acute care facilities to retain both younger and older nurses (Johnson, 2007; Zolnierok, 2008).

ADVANCED PREPARATION FOR MATERNAL-NEWBORN AND WOMEN'S HEALTH NURSES

Greater complexity of care and the need to contain costs have increased the need for nurses with various types of advanced preparation. Advanced practice nurses may practice as certified nurse-midwives (CNMs), nurse practitioners, nurse educators, and nurse researchers. Preparation for advanced practice involves obtaining a master's or doctoral degree. Prescriptive authority is often part of the advanced practice certification, but its extent may vary in different states. Nurses working in midlevel or higher management are often required to have at least a master's degree in health care administration or the specialty that they lead.

Certified Nurse-Midwives

Certified nurse-midwives (CNMs) are RNs who have completed an extensive program of study and clinical experience. They must pass a certification test administered by the American College of Nurse-Midwives. CNMs are qualified to take complete health histories and perform physical examinations. They can provide complete care during pregnancy, childbirth, and the postpartum period. They attend the mother and infant as long as the mother's progress is normal. CNMs are committed to providing information to prevent problems during pregnancy and to facilitate normal pregnancy and childbirth. They spend a great deal of time counseling and supporting the child-bearing family. The CNM also provides annual well-woman examinations (WWEs), gynecology services, and family-planning information and counseling. The practice approach of the CNM to childbirth is noninterventionist and supportive. Pregnancy and birth are regarded as normal processes.

The effectiveness of care provided by nurse-midwives has a long history that continues to be validated. In the 1930s, the Maternity Center Association, founded to provide care for indigent women, began to educate public health nurses in midwifery. Around the same time, Mary Breckinridge, a nurse-midwife from England, founded the Frontier Nursing Service to provide primary care (including midwifery services) to poor families in the remote mountains of Kentucky.

Despite the proven effectiveness of care, physicians opposed the widespread use of nurse-midwives. For many years, the scope and locations of their practices were restricted. In 1970, however, many restrictions were removed when the American College of Obstetricians and Gynecologists (ACOG) and the Nurses' Association of the American College of Obstetricians and Gynecologists (NAACOG)—now known as the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN)—issued a joint statement that admitted CNMs as part of the health care team. In 1981, Congress authorized Medicaid payments for the services of CNMs. This measure has resulted in increased use of nurse-midwives in health maintenance organizations (HMOs), physician practices, birth centers, and hospitals.

Nurse Practitioners

Nurse practitioners are RNs with advanced preparation that allows them to provide primary care for specific groups of clients. They can take a complete health history, perform physical examinations, order and interpret laboratory and other diagnostic studies, and provide primary care for health maintenance and health promotion. Most nurse practitioners collaborate with physicians with regard to administering treatments and medications, but depending on their scope of practice and the board of nursing mandates for their practice in their state, they may work independently and prescribe some medications. Nurse practitioners now specialize in many areas of practice, including women's health. Nurse practitioner programs in all specialties are a popular track for master's degree nursing preparation.

The women's health nurse practitioner (WHNP) provides wellness-focused, primary, reproductive, and gynecologic care over a woman's life span, beginning from adolescence. Common responsibilities include performing WWEs, screening for sexually transmitted diseases (STDs), and providing family planning services. Hospitals may employ WHNPs to assess and screen women who arrive at an obstetric triage unit. Many of these women have nonobstetric problems during pregnancy.

Family nurse practitioners (FNPs) are prepared to provide preventive, holistic care for young as well as older family members. They may care for women during uncomplicated pregnancies and provide follow-up care to mothers and infants after childbirth. Unlike CNMs, FNPs do not assist with childbirth.

Neonatal nurse practitioners (NNPs) assist in the care of high-risk newborns in the immediate post-birth care or in a neonatal intensive care unit. Pediatric nurse practitioners (PNPs) provide health maintenance care to infants and children who do not require the services of physicians. They may see infants at well-baby visits and to provide treatment for common illnesses.

Clinical Nurse Specialists

Perinatal clinical specialists are RNs who, through study and supervised practice at the graduate level (master's or doctorate), have acquired expertise in the care of childbearing women with complex problems. Core competencies for the clinical nurse specialist (CNS) include direct care, consultation, systems leadership, collaboration, coaching, research, and ethical decision making (National Association of Clinical Nurse Specialists [NACNS], 2012). Unlike nurse practitioners, clinical nurse specialists do not provide primary care.

CHANGING ROLES FOR NURSES

Nurses now work in a variety of highly specialized areas such as fetal diagnostic centers, infertility clinics, and facilities offering genetic counseling, as well as in acute care settings. Home-based care is an option for some perinatal conditions such as risk for preterm birth.

Nurses also assume primary responsibility for independent functions such as teaching, counseling, and intervening for a wide variety of nonmedical problems that affect the childbearing family.

Because of the added responsibilities of teaching and counseling, possibly distant from the acute care facility, all nurses must develop and maintain additional interpersonal skills. These skills include communication, effective teaching, critical thinking, and the use of the nursing process to identify and intervene for a variety of problems.

Therapeutic Communication

Unlike social communication, therapeutic communication is purposeful, goal directed, and focused. Although it may seem simple, therapeutic communication requires conscious effort and considerable practice. Communication is emphasized throughout this book for three reasons: (1) to review the process, (2) to emphasize the importance of communication in women's health and maternal-newborn nursing, and (3) to provide examples for using therapeutic communication with families. Examples of nontherapeutic communication will also appear in the text.

Guidelines for Therapeutic Communication

Therapeutic communication requires great flexibility and cannot depend on a specific set of learned techniques. However, the following guidelines may prove helpful:

1. A restful setting that provides privacy, reduces distractions, and minimizes interruptions is ideal.
2. Interactions should begin with introductions and clarification of the nurse's role: "My name is Claudia. I am here to complete the discharge teaching that was started yesterday." This introduction acknowledges the nurse's purpose and sets the scene to discuss concerns about the family's discharge from the hospital birth center.
3. Therapeutic communication should be focused and directed toward meeting the needs expressed by the family. One method of focusing the interaction is to begin with an open-ended question: "How do you feel about going home today?" Redirection of the conversation may also be necessary: "Thanks for showing me the beautiful pictures of the baby. I understand you're having some trouble getting him to nurse?"
4. Nonverbal behaviors may communicate more powerful messages than the spoken word. For example, facial expressions and eye movements could confirm or contradict what the woman says. Repetitive hand gestures such as finger tapping and twirling a lock of hair may indicate frustration, irritation, or boredom. Body posture, stance, and gait could convey energy, depression, or discomfort. Voice tone, pitch, rate, and volume may indicate joy, anger, or fear. Grooming also conveys messages about the way the woman feels about herself. If she is tired or depressed, she may neglect her own grooming, although she may not verbalize a problem.
5. Active listening requires that the nurse "attend" to the words being said and to nonverbal clues. Attending behaviors that convey the nurse's interest and a sincere desire to understand include the following:
 - Eye contact, which signals a readiness to interact
 - Relaxed but erect posture, with the upper portion of the body inclined toward the woman
 - Minimal cues and leads such as nodding, leaning closer, and smiling. Verbal cues include "Uh-huh, go on," "Tell me about that," and "Can you give me an example?"
 - Touch, which can be a powerful response when words would break a mood or fail to convey the depth of feeling experienced between the woman and nurse
6. Cultural differences influence communication. In some cultures such as certain Asian cultures prolonged eye contact is perceived as confrontational and initiates a great deal of concern. People from some cultures such as Middle Eastern and Native American cultures may be uncomfortable with touch and would be disturbed by unsolicited touching.
7. Clarifying communication involves a unique process in which the listener receives the message as the sender intended. The nurse may need to ask questions to clarify a statement. For instance, the nurse may say, "I'm not sure I understand," or "So you are undecided about breastfeeding?"
8. Emotions are part of communication, and nurses must often reflect feelings that are expressed verbally or nonverbally: "It sounds as if you were looking forward to delivery in a birth center and are disappointed that a **cesarean** (surgical) **birth** was necessary."

Therapeutic Communication Techniques

Therapeutic communication involves responding and listening, and nurses must learn to use responses that facilitate rather than block communication. These facilitative responses, often called *communication techniques*, focus on both the content of the message and the feeling accompanying the message. The techniques are useful at many ages and for those who are significant in the person's life. Communication techniques include clarifying, **reflecting** (meditating or attentive consideration), maintaining silence, questioning, and directing (Table 2-1). In addition, nurses must be aware of blocks to communication (Table 2-2).

CHECK YOUR READING

1. How does therapeutic communication differ from social communication?
2. What are the major communication techniques?
3. What are the major blocks to communication?

The Nurse's Role in Teaching and Learning

Nurses are significant teachers on the health care team because of their relationships with clients. Women often perceive nurses as less threatening than physicians and may expect nurses to have the time to respond to concerns that a physician may find trivial. Physicians are also under time pressure related to the number of clients that they must see within a specific period. Nurses teach in several settings, including one-on-one interactions, formal classes, and group discussions (Figure 2-1). To teach effectively, nurses must be familiar with the basic principles of teaching and learning.

Principles of Teaching and Learning

Application of the following principles helps nurses become effective teachers in the childbearing setting:

- Real learning depends on the readiness of the individual or the family to learn and the relevance of the content. Many childbearing families are highly motivated to learn. The parents want to be effective, and any content relevant to the health of either mother or child is eagerly sought.
- Active participation increases learning. Whenever possible, the learner should be involved in the educational process and not act as a passive listener or viewer. Therefore, learning is enhanced when the family and nurse mutually develop goals and when time for questions and explanations is ample. A discussion format, in which all can participate, stimulates more learning than does a straight lecture.
- Repetition of a skill increases retention and feelings of competence. For example, parents experience real learning when they are allowed

TABLE 2-1 COMMUNICATION TECHNIQUES

DEFINITION	EXAMPLES
<p>Clarifying</p> <p>Clearing up or following up to understand both content and feelings expressed, to check the accuracy of how the nurse perceives the message</p>	<p>"I'm confused about your plans. Could you explain?"</p> <p>"Tell me what you mean when you say you don't feel like yourself."</p> <p>"Are you saying that _____?"</p> <p>"Tell me more about _____."</p>
<p>Paraphrasing</p> <p>Restating in words other than those used by the woman what she seems to express; a form of clarification</p>	<p><i>Example 1</i></p> <p>Woman: "My boyfriend won't even come into the room for the birth. I'm furious with him." Nurse: "You seem to be angry because he won't be here."</p> <p><i>Example 2</i></p> <p>Woman: "My baby cries all the time. We aren't getting any sleep." Nurse: "You say that you're exhausted, and it seems like your baby cries a great deal. What is a typical day like?"</p>
<p>Reflecting</p> <p>Verbalizing comprehension of what the patient said and what she seems to be feeling</p> <p>It is important to link content and feeling and to reflect the woman as a mirror reflects a person</p> <p>The opinion, values, and personality of the nurse should not be in the reflected image</p>	<p><i>Example 1</i></p> <p>Woman: "I don't know what to do. My husband doesn't think a cesarean is needed, but the doctor says the baby is showing some stress." Nurse: "You're confused and frightened because they don't agree?"</p> <p><i>Example 2</i></p> <p>Woman in early labor: "It was my husband's idea to have a baby. I wasn't too excited about it at first." Nurse: "I'll bet the dad will be a pushover as a father." The nurse's statement reflects the nurse's opinion and fails to acknowledge the mother's statement. A better response might be: "Your husband was more excited early in the pregnancy than you were?"</p>
<p>Silence</p> <p>Waiting and allowing time for the patient to continue</p> <p>Verbal communication need not be constant</p>	<p>The nurse waits quietly for the woman to continue.</p>
<p>Structuring</p> <p>Creating guidelines or setting priorities</p>	<p>"You said you don't know how to take care of the baby and also that you're afraid of getting pregnant again. What should we talk about first?"</p>
<p>Pinpointing</p> <p>Calling attention to differences or inconsistencies in statements</p>	<p>Nurse talking to an 8-year-old child: "You said you didn't want your mother to spend the night with you, but you cry every night after she leaves. It can be scary being alone. I'll sit with you, and we can talk about asking your mother to stay tomorrow night."</p>
<p>Questioning</p> <p>Eliciting information directly; using open-ended questions to avoid "yes" or "no" answers and to prevent controlling the answers</p>	<p>"How do you feel about being pregnant?" instead of "Are you happy to be pregnant?"</p> <p>"How do you feel about your brother being very sick?" instead of "Are you frightened because your brother is very sick?"</p>
<p>Directing</p> <p>Using nonverbal responses or succinct comments to encourage the person to continue</p>	<p>Nodding. "Um-mm." "You were saying?" "Please go on."</p>
<p>Summarizing</p> <p>Reviewing the main themes or issues that were discussed</p>	<p>"You had two major concerns today." "We have talked about breastfeeding and how to bathe the baby today."</p>

to bathe, feed, and diaper the infant more than once. This learning often begins during infant care classes presented during the prenatal period and may continue during home or clinic visits after the mother and infant leave the birth facility.

- Praise and positive feedback are powerful motivators for learning and are particularly important when the family is trying to

master a frustrating task such as breastfeeding an unresponsive infant.

- Role modeling is an effective method to demonstrate behavior. Parents benefit greatly from watching a competent nurse respond to their infant. Nurses must be aware that their behaviors are scrutinized carefully at all times and may be copied later.

TABLE 2-2 BEHAVIORS THAT BLOCK COMMUNICATION

BEHAVIOR	EXAMPLE	ALTERNATIVE
Conveying lack of interest	Looking away, fidgeting	Attending behaviors such as eye contact, nodding
Conveying sense of haste	Checking the time, standing near the door	Sitting at bedside
Closed posture	Arms crossed over chest, holding laptop computer in front of body	Leaning forward with arms relaxed
Interrupting, finishing sentences	Woman: "I'm not sure how to . . ." Nurse: "We'll have a bath demonstration later."	"Go on, _____." "You were saying _____."
Providing false reassurance	"You're going to be okay."	"I sense you are concerned about how to care for the baby. I will help you give the bath today."
Inappropriate self-disclosure	To woman in labor: "I was in labor for 12 hours, and then I had a cesarean."	"What concerns you most about labor?"
Giving advice	"You should _____." "If I were you, I would _____."	"How do you feel about that?" "What do you think is most important?"
Failure to acknowledge comments or feelings	Woman: "Being a parent is hard work. I never have time for myself." Nurse: "It's going to get worse before it gets better. Parenting is hard work."	"Parenting is hard work. Let's talk about some ways that you might get a break."

FIG 2-1 In the prenatal clinic the nurse teaches a woman in a one-on-one setting.

- Conflicts and frustration impede learning. Conflicts should be recognized and resolved for learning to progress. For instance, couples sometimes do not agree about the way the infant should be fed (breastfeeding versus formula feeding). This issue and the feelings it generates must be acknowledged before teaching about breastfeeding can be effective.
- Learning is enhanced when teaching is structured to present simple tasks before more complex material. For instance, the nurse should teach simple umbilical cord care before teaching the more difficult task of how to bathe and shampoo the infant.
- A variety of teaching methods may maintain interest and illustrate concepts. Posters, videos, and printed materials supplement lectures and discussion. Models may be especially useful for teaching family planning or the processes of labor.

- Retention is greater when material is presented in small segments over time. Brief hospital stays do not promote this practice, making follow-up care particularly important.

Factors That Influence Learning

Many factors, including the family's developmental level, primary language, cultural orientation, and previous experiences, influence learning.

Developmental Level. Not surprisingly, teenage parents have different concerns from those of older parents. Younger parents may learn better in different ways than their parents did in their thirties. For example, very young parents often do not benefit from printed material to the same degree as older parents do. New parents of any age often learn well from videos, computer-based lessons, and group discussions with those who share similar concerns. Women's health care applies from adolescence through old age, so the nurse in this setting may need to provide the same educational material in different ways. To be effective, the nurse must acknowledge this difference and structure the teaching-learning sessions to meet the family's primary concerns.

Language. Understanding the language used determines how well the family learns from the nurse's teaching. Those from countries other than the United States may know two or more languages, including English, even if they are most comfortable with their country's main language. They may know multiple languages because family members are from several countries. Newly arrived immigrants might speak English well, but they may not understand the idioms, nuances, medical terms, or slang words that are frequently used. Words that are acceptable to those from one part of a country may have a different meaning and be unacceptable to a person from a different region of the same country. The nurse must create a climate in which families feel free to ask questions when they do not understand something.

One helpful method is to ask those who speak a different language to describe what they have learned and how they will use the information. The nurse may also want to determine whether the new information conflicts with the information the parents learned previously.

Culture. Background and culture influence learning. People tend to forget content that they disagree with. For instance, if the family is from a culture that believes the mother should eat certain foods after childbirth, family members may disregard other foods recommended

by the nurse. Also, if the recommendations of the family's elders and the teachings of the nurse or physicians conflict, young parents often follow the advice of the elders. Therefore, the nurse should determine the cultural beliefs and attempt to reach an understanding about what information will be useful before beginning to teach.

Previous Experiences. Parents who already have children have unique concerns. These families may not need instruction in newborn care, but they may be very concerned about how their older children will accept a new infant. They may need advice about checking used toys and equipment to ensure the infant's safety. Personal changes of menopause are new to every woman, if that is likely in the near future, although she may have friends and family who have undergone the "change of life."

Physical Environment. The physical environment also influences learning. The hospital room is generally suitable for individual teaching. If group instruction is planned, the instructor should arrange comfortable chairs in a circle or around a table so that all persons can hear and participate in face-to-face communication.

Organization and Skill of the Instructor. The instructor must determine the objectives of the class, develop a plan for meeting the objectives, and gather all material before the teaching session begins. If the objective is that participants will observe and participate in a bath demonstration, the nurse must decide how to demonstrate the bath, when to present care of the umbilical cord and circumcision, and which major principles should be addressed. Return demonstration by each participant who bathes his or her baby helps the nurse to identify if added teaching is needed and helps participants learn from each other.

A summary of the major principles discussed is helpful after the teaching session. For example, after a bath demonstration, the nurse might conclude by asking participants to identify and explain important points to remember such as the following:

- Prevent the baby from becoming chilled.
- Be sure the baby does not fall.
- Start at the face, which is the cleanest area.
- Bathe the baby's bottom, which is the dirtiest area, last.

Effects of Early Discharge

Self-care after birth and infant teaching often begin during prenatal care or on admission for birth. Teaching infant care may begin in the birthing or postanesthesia room to enhance family connection. Although the principles of teaching and learning should be used whenever possible, early discharge of the mother and infant often requires modifications (Figure 2-2). There may not be enough time for repetition and return demonstrations of infant care. Many

FIG 2-2 Often, the nurse must condense teaching by using a "check-off" sheet because mothers and infants leave the birth facility within a short time after birth.

families leave the hospital before they have attained much comfort with infant care.

Innovative methods have been developed to provide a safety net for families and make them feel more secure. These include follow-up telephone calls, home visits, information lines, videos on infant care, and mother–infant outpatient clinics. Teaching self-care and infant care during the prenatal period is emphasized. This information must be reviewed before the mother and infant leave the birth facility, but review is generally less time consuming than the initial presentation. Printed materials are provided to women at their first prenatal visit and to parents at discharge. Other teaching materials will be given to the woman when appropriate during her life.

The Nurse's Role as Collaborator

Nurses collaborate with other members of the health care team, often coordinating and managing a woman's or infant's care. Care is improved by an interdisciplinary approach as nurses work together with dietitians, social workers, physicians, and others.

Managing the transition from an acute care setting to the home involves discharge planning and collaboration with other health care professionals. The nurse must be knowledgeable about community and financial resources to promote a smooth transition. Cooperation and communication are essential to best encourage women to participate in their care and meet the needs of newborns.

The Nurse's Role as Researcher

Nurses contribute to their profession's knowledge base by systematically investigating theoretic or practice-related issues in nursing. Nursing does not merely "borrow" scientific knowledge from medicine and basic sciences. Nursing generates and answers its own questions based on research of its unique subject matter. The responsibility for research within nursing is not limited to nurses with graduate degrees. It is important that all nurses apply valid research findings to their practices, rather than basing care decisions merely on intuition or tradition. Evidence-based practice is no longer just an ideal but an expectation of nursing practice. Nurses can contribute to the body of professional knowledge by demonstrating an awareness of the value of nursing research and assisting in problem identification and data collection to identify best practices. Nurses should keep their knowledge current by networking and sharing research findings at conferences, by publishing, and by reading research in professional journals. A minimal number of continuing education (CE) hours is needed for license renewal in each U.S. state and territory.

The Nurse's Role as Advocate

An advocate speaks on behalf of another person. As the health care environment becomes increasingly complex, care may become impersonal. As the health professional who is closest to the woman, the nurse is in an ideal position to humanize care and to intercede on her behalf. As an advocate the nurse considers the family's wishes in planning and implementing care. The nurse provides information to women and their families to ensure that they are involved in decisions and activities related to the care of the newborn. Nurses must be advocates for health promotion of vulnerable groups such as victims of domestic violence or women unable to pay for low-cost preventive care such as yearly well-woman examinations.

The Nurse's Role as Manager

The role of nurses has changed from that of primary caregiver to that of manager and teacher with cost-containment measures such as brief inpatient stays or treatment at outpatient clinics. Nurses may provide less direct patient care and delegate tasks such as ambulation

or taking vital signs to others. As a result, nurses spend more time teaching women and families and supervising unlicensed personnel. Nursing case managers often provide coordination of care for many patients. Nurses are expected to understand the financial “squeeze” resulting from cost-containment strategies and to contribute to their institutions’ economic viability. At the same time they must continue to act as patient advocates and maintain standards of care (see Chapter 3).

4. What are the major principles of teaching and learning?
5. What factors affect learning?
6. Why is nursing becoming more active in the application of research?

CRITICAL THINKING

In recent years critical thinking has received widespread attention in nursing. Clearly, nurses must be concerned with developing critical thinking skills, needed not only to pass the National Council Licensure Examination (NCLEX) but also to function clinically. Nurses must be concerned with learning and refining the critical thinking skills needed to function in the rapidly changing clinical arena. Critical thinking is controlled and purposeful rather than undirected. It is outcome-focused toward finding solutions for problems. Examples of how people think critically in their daily lives are deciding when to pay a bill in relation to its due date and their payday, determining ways to make their grocery dollars go farther, and choosing a vehicle with features that are necessary and are the most economical to buy and to use. Ads for new drugs may not always be best for women or children, and their long list of cautions at the end is a clue.

For effective critical thinking, nurses must gain insight into their own thought processes and analyze their own thinking by taking it apart for examination and criticism. Critical thinking includes recognizing and acknowledging specific habits and responses that may interfere with productive thinking.

Critical thinking is based on reason rather than preference or prejudice. It also seeks to examine feelings to understand how emotions affect thinking. Finally, critical thinking requires the suspension of **judgment** (opinion) until evidence is adequate to support **inferences** or for drawing conclusions.

Purpose

The purpose of critical thinking is to help nurses make the best clinical judgments. The process begins when nurses realize that accumulating a fund of knowledge from texts and lectures is not enough. They must also be able to apply this knowledge to specific clinical situations and thus reach conclusions that provide the most effective care in each situation. Critical thinking is an ongoing process and must be refined further after graduation.

In addition, nurses must honestly examine their own thought processes for flaws that could lead to inaccurate conclusions or poor judgments. Although this examination requires self-analysis, a series of steps makes the process easier. Critical thinking exercises are presented throughout the book to help students develop skills in critical thinking and application of knowledge in possible real-life situations.

Steps

A series of steps may help clarify the way critical thinking is learned. These steps may be called the *ABCDEs of critical thinking*. They include recognition of *assumptions*, examination of personal *biases*, analysis of the amount of pressure for *closure*, examination of how *data* are

collected and analyzed, and evaluation of how *emotions* may interfere with critical thinking.

Recognizing Assumptions

Assumptions are ideas, beliefs, or values that are taken for granted without basis in fact or reason. Such assumptions may lead to unexamined thoughts or unsound actions. For instance, the following assumptions may have negative consequences: “Anyone who wants a job can get one”; “Teenagers don’t listen”; “Every woman wants a baby.”

A list of everything known about a specific situation may help in the identification of assumptions. Each item on the list should be analyzed to determine whether it is true, whether it could be true, and whether it is untrue or evidence is insufficient to determine its truth.

Examining Biases

Biases are prejudices that sway the mind toward a particular conclusion or course of action on the basis of personal theories or stereotypes. Biases are based on unexamined beliefs, and many are widespread—for instance, “Fat people are lazy”; “Women are bad drivers”; “Men are insensitive.”

People may be biased against those of different races, religions, or lifestyles. When faced with a predisposition to judge a person or a group of persons, it may be wise to ask oneself or a co-worker a series of questions:

- “Why do you think that?”
- “What if this was a different person?”
- “What if there were different circumstances?”
- “What might someone who disagrees say?”
- “What is influencing my thinking?”

Determining the Need for Closure

Many persons look for immediate answers and experience a great deal of anxiety until a solution is found for any problem. In other words, they have little tolerance for doubt or uncertainty, which is sometimes called **ambiguity**. As a result, they feel pressure to come to a decision or to reach **closure** as early as possible. This is one of the most important aspects of critical thinking because those who feel pressure to reach an early decision or find a quick solution often do so with insufficient data.

To overcome pressure to reach an early conclusion, a conscious effort must be made to **suspend** (delay or bring to a stop) judgment. This is sometimes called *reflective skepticism*, or doubt in the absence of conclusive evidence. The first step is to acknowledge the anxiety created by postponed decisions. The next step involves deliberately waiting to make a decision. One method is to follow the example of judges who take information “under advisement” and announce they will “render a decision” at a later date. The “time-out” before a surgical procedure is another example as all staff members verify patient name, procedure, operative site, and implants, if applicable.

Persons who jump to conclusions often stop with one answer. To overcome this tendency, they should always look for a second “right” answer. They could also imagine the problem from the perspective of someone else. They might ask a series of questions:

- “What alternatives do we have?”
- “What else might work?”
- “What information supports this?”
- “What effect would that have?”
- “Is there good evidence to support that decision?”
- “Is there reason to doubt that evidence?”

On the other hand, some persons can tolerate a great deal of doubt and uncertainty. They are comfortable with data collection and analysis but feel uncomfortable making decisions. They may procrastinate

or postpone the decision for as long as possible. This procrastination may be of little consequence in some situations. For instance, a family might collect information about getting a pet for a considerable time, and the decision may be of slight importance.

Failure to make a decision in the clinical area may have serious consequences for clients and their families. Several questions may help overcome the tendency to postpone reaching a decision:

- “What signs indicate something is wrong?”
- “Do I need to do something about it?”
- “How much time do I have?”
- “What happens if I don't do something about this?”
- “What should I do first?”
- “What resources can help me?”

This step might also be called *priority setting*, and it is one of the most important aspects of critical thinking in nursing.

Becoming Skillful in Data Management

Expertise in collecting, organizing, and analyzing data involves developing an attitude of inquiry and learning to live with questions such as: “Why?” “What if?” “What else?” “Is this relevant?” “How does it relate to that?” “How can I organize the data?” “Do the data form patterns?” “What can I infer from those patterns?”

Collecting Data. To obtain complete data, nurses must develop skill in verbal communication. Open-ended questions elicit more information than questions that require only a one-word answer. Follow-up questions are often needed to clarify information or pursue a particular thought.

Validating Data. Nurses should **validate** unclear or incomplete information to make certain that the information collected is accurate. This process may involve rechecking physical signs, collecting additional information, or determining whether a perception is accurate. For instance, the comment “You seem uncomfortable” may result in the patient's denial or acknowledgment of discomfort.

Organizing and Analyzing Data. Data are more useful when organized into patterns or clusters. The first step is to separate relevant data from data that may be interesting but are unrelated to the current situation. For example, the fact that her neighbor is pregnant with twins has little bearing on how a new mother breastfeeds her infant.

The next step is to compare data with expected norms to determine what is within the expected range (normal) and what is not (abnormal). Abnormal results provide cues that can be grouped or clustered so that conclusions can be made. For example, all data that may indicate excessive bleeding, such as pulse rate, blood pressure, amount of vaginal bleeding, and skin color, may seem more meaningful when grouped. Organizing data into clusters often reveals that additional data are needed before a decision can be reached.

Acknowledging Emotions and Environmental Factors

Several emotions and environmental factors may influence critical thinking. For instance, the clinical area is often a noisy, fast-paced, and hectic environment with time limitations and distractions that make calm reflection and reasoning difficult. Fatigue also reduces the ability to concentrate during a 12-hour shift. As nurses age they may find 12-hour shifts impossible to provide the high-quality care they value. Inexperienced nurses and students may lack confidence in their knowledge and often feel anxious, which may reduce the ability to think critically. Fatigue in older, experienced nurses reduces their ability to mentor new graduates or nurses with less experience in the specialty.

Many nurses, both experienced and inexperienced, have a strong need to protect their self-image. As a result, they become defensive when they have said or done something wrong. This response is a serious barrier to critical thinking, which requires that all health care

professionals learn to acknowledge mistakes and become comfortable with constructive criticism.

Extreme emotions such as anger and frustration impede critical thinking by narrowing the focus to only data that support the intense feeling. For example, persons who are extremely frustrated may often repeat the perceived cause of their frustration and may be unable to move on to other information to address the problem.

The first step is to recognize and acknowledge factors or emotions that impede thinking. For example, nurses may find it necessary to say, “I feel flustered by all the activity and need to find a quiet spot for a few minutes of concentration.” To develop critical thinking skills, the nurse must learn to admit mistakes and become comfortable saying, “I was wrong.” Asking for assistance, verification, or validation is wise when fatigue is a problem or when lack of confidence creates anxiety.

The person who experiences intense frustration or anger must recognize these emotions and their influence on rational thought. A trusted colleague may be asked to point out signs of these emotions such as repetitive vehement comments. Some persons use other methods of control such as visualizations, breathing exercises, and brief, self-imposed “time-outs” from the precipitating situation, if possible.

APPLICATION OF THE NURSING PROCESS

■ Maternal-Newborn and Women's Health Nursing

The nursing process forms the basis for maternal-newborn and women's health nursing, as for all nursing. The nursing process consists of five distinct steps: (1) assessment, (2) nursing diagnosis, (3) planning, (4) implementation, and (5) evaluation. In maternal-newborn and women's health nursing, the nursing process applies to a population that is often healthy and experiencing a life event that holds the potential for both growth and problems. Nursing activity in these settings is often devoted to the assessment and diagnosis of patient strengths and healthy functioning to achieve a higher or more satisfying level of wellness. This focus often differs from that of providing care for adults or children who are usually ill when the nurse encounters them.

The nursing process is written in the text as a linear, step-by-step process. However, with knowledge and experience, the nurse applies the nursing process in the clinical setting dynamically. For example, the nurse may discover that the woman has a full bladder early in a postpartum assessment. The nurse skips to an intervention and helps the woman to the restroom to urinate before completing the assessment. This action is taken by the nurse to prevent patient discomfort and possible excessive bleeding caused by a full bladder. In another example, the nurse goes to the woman's room to give her an injection of RhoGAM and discovers the woman nursing her baby, who is eagerly suckling for the first time in several hours. On the basis of critical thinking, the nurse delays the injection (an intervention), which would require that the woman change her position. The nurse realizes that the few minutes required for the infant to complete the feeding are more important than the short delay in giving the injection.

Assessment

Nursing assessment should be accomplished systematically and deliberately and include physiologic data and information related to psychological, social, and cultural considerations. Although the woman or infant may be the primary patient, nurses must assess the belief systems, available support, perceptions, and plans of other family members to provide the best nursing care. Two levels of nursing assessment are used to collect comprehensive data: (1) screening assessments and (2) focus assessments.

Screening Assessment

The screening, or database, assessment is usually performed at the first contact with the person. Its purpose is to gather information about all aspects of the person's health. This information, called **baseline data**, describes their health status before interventions begin. It forms the basis for the identification of both strengths and problems.

A variety of methods may be used to organize the assessment. For example, information may be grouped according to body systems. Assessment may also be organized around nursing theory models such as Roy's adaptation to stress theory, Gordon's functional health patterns, the human response patterns of the North American Nursing Diagnosis Association International (NANDA-I), or Orem's self-care deficit theory.

Focused Assessment

A focused assessment is used to gather information specifically related to an actual health problem or a problem that the woman or family is at risk for acquiring. A focused assessment is often performed at the beginning of a shift and centers on areas relevant to childbearing, newborn, or women's health nursing. For instance, in care of the mother and infant after birth the nurse should assess the breasts and nipples because the mother is at risk for problems if she does not have adequate information about breastfeeding or care of the nipples. A focused assessment may also reveal strengths that nursing care will enhance.

Nursing Diagnosis

The data gathered during assessment must be analyzed to identify existing or potential strengths or problems and their causes. Data are

validated and grouped in a process of critical thinking to determine cues and inferences. Health needs for which nurses can provide **independent nursing interventions** and for which they are legally accountable are termed *nursing diagnoses*. At present, more than 200 nursing diagnoses have been identified by NANDA-I.

Each nursing diagnosis identified by NANDA-I consists of the following components:

1. The title, which offers a broad description of the health problem, although a few wellness diagnoses focus on positive client responses
2. Defining characteristics, which refer to a cluster of signs and symptoms or cues often seen with that particular diagnosis
3. Etiologic and related factors, which are factors that can cause or contribute to the problem or wellness findings. The etiology may be pathophysiologic, situational, or maturational. Although the majority of nursing diagnoses address actual or potential health problems, wellness diagnoses are often appropriate for the maternal, newborn, and women's health areas. An example of a wellness NANDA-I nursing diagnosis is "Readiness for Enhanced Breastfeeding."

Diagnoses may be actual, risk, or wellness nursing diagnoses (Table 2-3). Actual nursing diagnoses indicate that the diagnosis exists at the time of assessment and can be validated by the presence of defining characteristics. Risk nursing diagnoses are appropriate when the diagnosis does not exist but the individual or family is at risk to develop it based on contributing factors. Wellness nursing diagnoses are appropriate when the individual or family is moving from a specific level of wellness to greater wellness. Any nursing diagnosis may occur in maternal-newborn or women's health clients, although some diagnostic categories are common.

Planning

The third step in the nursing process involves planning care for problems that were identified during assessment and reflected in the nursing diagnoses. During this step, nurses set priorities, develop goals or outcomes, and plan interventions to accomplish these goals.

Setting Priorities

Setting priorities includes (1) determining which problems need immediate attention (life-threatening problems) and taking immediate

TABLE 2-3 EXAMPLES OF ACTUAL, RISK, AND WELLNESS NURSING DIAGNOSES

Actual Nursing Diagnoses		
PROBLEM	ETIOLOGY	SIGNS AND SYMPTOMS
Imbalanced Nutrition: Less Than Body Requirements	Lack of knowledge about nutritional needs during lactation	Weight loss of 5 kg and daily caloric intake <1500 calories
Ineffective Breastfeeding	Nipple trauma	Cracked nipples and reports of discomfort during nursing
Risk Nursing Diagnoses		
PROBLEM	RISK FACTORS	
Risk for Imbalanced Nutrition: Less Than Body Requirements	Knowledge deficit of nutritional needs during lactation issue	
Risk for Ineffective Breastfeeding	Lack of knowledge of correct positioning of infant and appropriate breast care	
Wellness Nursing Diagnoses		
TOPIC	SELECTED DEFINING CHARACTERISTICS	
Readiness for Enhanced Self-Health Management	Expressed or observed desire to seek information for health promotion	
Readiness for Enhanced Nutrition	Follows an appropriate standard for food intake such as MyPlate or American Diabetic Association guidelines	

action; (2) determining whether potential problems call for a physician's order for diagnosis, monitoring, or treatment; and (3) identifying actual nursing diagnoses that take precedence over risk nursing diagnoses.

Establishing Goals and Expected Outcomes

Although the terms *goals* and *expected outcomes* are sometimes used interchangeably, they are different. Generally, broad goals do not state the specific outcome criteria and are less measurable than outcome statements. Broad goals should be linked with more specific and measurable outcome criteria. For example, if the goal is that the parents will demonstrate effective parenting by discharge, expected outcomes that serve as evidence might include prompt, consistent responses to infant signals and competence in bathing, feeding, and comforting the infant.

The following rules apply to written expected outcomes:

- Outcomes should be stated in client-oriented terms, identifying who is expected to achieve the goal. This is usually the woman, the infant, or the family.
- Measurable verbs must be used. For example, *identify*, *demonstrate*, *express*, *walk*, *relate*, and *list* are observable and measurable verbs. Examples of verbs that are difficult to measure are *understand*, *appreciate*, *feel*, *accept*, *know*, and *experience*. For instance, "Ms. Brown will experience less anxiety about assuming care of her infant" poses a problem because determining whether she experiences less anxiety is difficult. This outcome can be reworded as "Ms. Brown will state that she feels less anxious about assuming care of her infant and will participate in infant care (umbilical cord, circumcision, bathing) before discharge."
- A time frame is necessary. When is the person expected to perform the action? By the first postpartum day? After teaching? By discharge? Within the second trimester?
- Goals and expected outcomes must be realistic and attainable. For instance, if a nursing diagnosis of "Pain related to lack of knowledge about pain control" is chosen, a realistic expected outcome might be "Sandra will state that her pain during labor is manageable using techniques taught by Vicki, her nurse." A goal such as "will remain free of pain throughout labor" is not attainable by nursing interventions only and is not realistic.
- Goals and expected outcomes are collaborated with the client and family to ensure their participation in the plan of care.

Developing Nursing Interventions

After the goals and expected outcomes are developed, nurses write nursing interventions that will help the client meet the established outcomes.

Interventions for Actual Nursing Diagnoses. Nursing interventions for actual nursing diagnoses are aimed at reducing or eliminating the causes or related factors. For instance, the nursing diagnosis is "Impaired Parenting related to interruption of bonding process secondary to illness of infant as manifested by absence of attachment behaviors (eye contact, holding)." The desired outcome might be that the parents will demonstrate progressive attachment behaviors such as touching, palming, eye contact, and participation in infant care within 1 week. Nursing interventions focus on increasing contact between parents and their baby and demonstrating some attachment behaviors.

Interventions for Risk Nursing Diagnoses. Interventions are aimed at (1) monitoring for onset of the problem, (2) minimizing risk factors, and (3) preventing the problem. For example, the nursing diagnosis for Baby Sam is "Risk for Impaired Skin Integrity related to

frequent, loose stools." The planned outcome is that the skin remains intact. Nursing interventions include monitoring the condition of the skin at prescribed intervals for signs of skin impairment and initiating measures to keep the skin clean and dry to reduce the risk of skin impairment.

Interventions for Wellness Nursing Diagnoses. Interventions focus on health enhancement for wellness nursing diagnoses. Nursing care seeks to promote client success through the teaching of self-care measures. Examples of wellness interventions include teaching related to weight reduction, exercise to lower chronic hypertension, or reconditioning the body after birth.

Implementing Interventions

Implementing nursing interventions may be a problem if written interventions are not specific. Nursing interventions should be as specific as physician's orders and may be formulated with computerized care plans. If a physician orders "hydrocodone with acetaminophen, 5 mg/500 mg, 1 tablet PO (orally) every 6 hours as needed for pain," the order specifies the combination drug to be given, the dose to be given, the route of administration, the time, and the reason. A well-written nursing intervention is equally specific: "Teach woman not to break, chew, or crush the drug tablet."

Conversely, poorly written interventions such as "Assist with breastfeeding" provide generalizations rather than specific steps. Specific methods that the nurse should use to assist breastfeeding are more effective. For example, "Demonstrate correct positioning in cradle and football hold at first attempt to breastfeed. Teach mother to elicit rooting reflex by stroking infant's lips with nipple. Demonstrate how to latch infant to nipple, and request a return demonstration before mother and baby are discharged."

Evaluation

The evaluation determines the effectiveness of the plan and its goals or expected outcomes. The nurse must assess the status of the client and compare the current status with the goals or outcome criteria developed during the planning step. The nurse then judges the person's progression toward goal achievement and makes a decision: Should the plan be continued? Modified? Abandoned? Are the problems resolved or the causes diminished? Is another nursing diagnosis more relevant?

The nursing process is dynamic, and evaluation frequently results in expanded assessment and additional or modified nursing diagnoses and interventions. Nurses are cautioned not to view lack of goal achievement as a failure but as a signal to reassess and begin the process anew.

Individualized Nursing Care Plans

Nurses are responsible for documenting nursing diagnoses, expected outcomes, and interventions for each problem. This information is often communicated to colleagues through a written plan of care. Many institutions have standards of care for groups of clients such as those who have had normal spontaneous vaginal births. However, individual nursing care plans may be necessary on the basis of needs or problems identified during the assessment step of the nursing process. When nurses write individualized plans of care, they implement the plans through interventions that direct the care (Box 2-1). *Foundations, 6th edition*, continues to use situations for individualized care that have name(s) for a person receiving nursing care. Some patient situations end with a single office visit while others progress over time such as normal or complicated birth. Specific planned nursing care may be documented by office, clinic, or hospital computer systems, and the systems may be linked to improve continuity.

BOX 2-1 DEVELOPING INDIVIDUALIZED NURSING CARE THROUGH THE NURSING PROCESS

Although the nursing process is the foundation for nursing, initially it is a challenging process to apply in the clinical area. It requires proficiency in focused assessments of the new mother and infant and the ability to analyze data and plan nursing care for individual clients and families. Asking questions at each step of the nursing process may be helpful.

Assessment

1. Did some data not fit within normal limits or expected parameters? For example, the woman states that she feels “dizzy” when she tries to ambulate, or the postmenopausal woman describes vaginal bleeding at her annual well-woman examination (WWE).
2. If so, what else should be assessed? (What else should I evaluate? What might be related to this symptom? How do my assessments compare with previous assessments?) For example, what are the blood pressure, pulse rate, skin color, temperature, and amount of lochia if the woman feels dizzy? Is my assessment similar to earlier ones, or has there been a change?
3. Did the assessment identify the cause of the abnormal data? What are the laboratory values for her hemoglobin and hematocrit? What was her estimated blood loss at childbirth? Did she lose excessive blood during the hours and days after birth?
4. Are other factors present? Did she receive medication during labor? What kind of medication? Did she receive an anesthetic for labor pain? When? What medication is the woman now taking? How long has it been since she has eaten? Is the environment a related factor (crowded, warm, unfamiliar)? Is she reluctant to ask for assistance?

Nursing Diagnosis

1. Are adequate data available to reach a conclusion? What else is needed? (What do you wish you had assessed? What would you look for next time?)
2. What is the major concern? (On the basis of the data, what are your concerns?) The woman who is dizzy may fall as she ambulates to the bathroom, particularly if she does not ask for help. The woman with postmenopausal vaginal bleeding will need evaluation by a physician or nurse-practitioner for possible cancer.
3. What might happen if no action is taken? (What might happen to the person if you do nothing?) She may suffer an injury or a complication.
4. Is there a NANDA-I-approved diagnostic category that reflects your major concern? How is it defined? Suppose that during analysis you decide the major concern is that the patient will faint and suffer an injury. What diagnostic category most closely reflects this concern? “Risk for Injury”? Definition: The state in which an individual is at risk for harm because of a perceptual or physiologic deficit, a lack of awareness of hazards, or maturational age.

NANDA-I, North American Nursing Diagnosis Association International.

5. Does this diagnostic category “fit” this woman? Is she at greater risk for a problem than others in a similar situation? Why? What are the additional risk factors?
6. Is this a problem that nurses can manage independently? Are medical interventions also necessary?
7. If the problem can be managed by nurses, is it an actual problem (defining characteristics present) or a risk problem (risk factors present)?

Planning

1. What expected outcomes are desired? That the woman will remain free of injury during the hospital stay? That she will demonstrate position changes that reduce the episodes of vertigo?
2. Would the outcomes be clear, specific, and measurable to anyone reading them?
3. What nursing interventions should be initiated and carried out to accomplish these goals or outcomes?
4. Are your written interventions specific and clear? Are action verbs used (*assess, teach, assist*)? After you have written the interventions, examine them. Do they define exactly what is to be done (when, what, how far, how often)? Will they prevent the woman from suffering an injury?
5. Are the interventions based on sound rationale? For instance, dehydration possible during labor causes weakness that may result in falls; loss of blood during delivery often exceeds 500 mL, which results in hypotension that is aggravated when the woman stands suddenly. A woman who has recently delivered after receiving an epidural block may have lingering effects from this form of labor pain relief.

Implementing Nursing Interventions

1. What are the expected effects of the prescribed intervention? Are adverse effects possible? What are they?
2. Are the interventions acceptable to the woman and family?
3. Are the interventions clearly written so that they can be carefully followed?

Evaluation

1. What is the status of the woman at this time?
2. What were the goals and outcomes? Were they specific and measurable or should they be clarified?
3. Compare the current status of the woman with the stated goals and outcomes.
4. What should be done now?

The Nursing Process Related to Critical Thinking

Although the nursing process and critical thinking are similar and overlap in many respects, major differences exist (Figure 2-3). The five steps of the nursing process provide a logical method for problem solving. Problem solving begins with a specific problem and ends with

a solution. Conversely, critical thinking is open ended; it goes before and beyond problem solving. Critical thinking may be triggered by a problem, a positive event, or an opportunity to improve. It focuses on appraisal of the way the individual thinks, and it emphasizes reflective skepticism. Critical thinking is used throughout each step of the nursing process (Table 2-4).

CHECK YOUR READING

10. How does screening assessment differ from focused assessment?
11. How do actual nursing diagnoses differ from risk nursing diagnoses?
12. How should goals and expected outcome criteria be stated?
13. Why are interventions sometimes difficult to implement? How can this difficulty be overcome?

NURSING RESEARCH

As maternal-newborn nursing and the health care system change, nurses are challenged to demonstrate that their work improves client outcomes and is cost effective. To meet this challenge, nurses must generate, participate in, and use research. With the establishment of

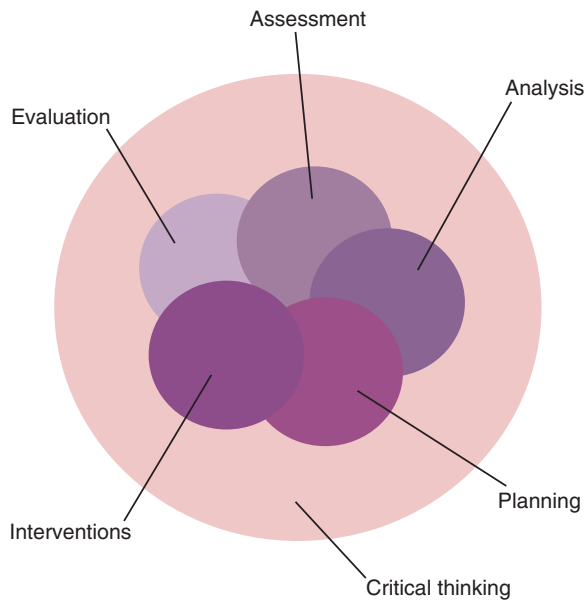

FIG 2-3 Relationship between the nursing process and critical thinking.

the National Institute of Nursing Research (NINR) in the National Institutes of Health (NIH) (www.nih.gov/ninr), nurses now have an infrastructure to ensure the support of nursing research and the education of well-prepared nurse researchers. The NINR seeks to establish a scientific basis for nursing care of clients throughout life. The translation of scientific advances into cost-effective, quality care is inherent to the mission of the NINR.

Clinically based nursing research is increasing rapidly, as nurse researchers strive to develop an independent body of knowledge that demonstrates the value of nursing interventions. AWHONN has an ongoing commitment to develop and disseminate evidence-practice guidelines through the association's Research-Based Practice Program. Implementation of evidence-based guidelines promotes application of the best available scientific evidence for nursing care rather than care based on tradition alone (AWHONN, 2003). See www.awhonn.org for current research priorities and for completed research projects to improve practice.

TABLE 2-4 USE OF CRITICAL THINKING IN THE NURSING PROCESS

NURSING PROCESS	CRITICAL THINKING SKILLS
Assessment	Collecting complete data, validating data Clustering data (normal versus abnormal, important versus unimportant, relevant versus irrelevant)
Analysis	Identifying emotions Identifying cues and making inferences Reflecting and suspending judgment Examining thought processes for biases and assumptions Identifying alternatives
Planning	Determining priorities Examining need for closure Searching for alternative solutions Validating plan with patient or co-worker Communicating plan Acknowledging defensive behavior
Implementation	Applying knowledge Testing plan Carrying out plan
Evaluation	Examining insights gained Recognizing new ways of thinking or acting Examining options and criteria for action Appraising self and others in the situation

Students and inexperienced nurses may not initiate research projects, but they may participate in nursing research planned by experts and use updated knowledge from research as they enter nursing practice. Refereed professional nursing journals such as *Journal of Obstetric, Gynecologic, and Neonatal Nursing*; *Nursing for Women's Health*; *Nursing Research*; *Journal of Perinatal and Neonatal Nursing*; and *Journal of Neonatal Nursing* are sources of verified information about maternal, newborn, and women's health nursing that help validate nursing actions and remove measures that have not proved valid.

SUMMARY CONCEPTS

- Registered nurses with advanced education are prepared to provide primary care for women and children as certified nurse-midwives and nurse practitioners.
- Perinatal clinical nurse specialist roles include expert direct care, consultation, systems leadership, collaboration, coaching, research, and ethical decision making.
- Nurses must be adept at communication techniques and communication blocks to meet their responsibilities as educators and counselors.
- A major nursing responsibility covered in this book is to provide information on women's health issues.
- Nurses must use the principles of teaching and learning to fulfill the role of educator.
- Nurses must refine their critical thinking abilities by examining their own thought processes for flaws that could lead to inaccurate conclusions or poor clinical judgments.
- The nursing process begins with assessment and includes analysis of data that may result in nursing diagnoses. Nurses are legally accountable for identifying and managing these problems independently.
- Collaborative problems are usually physiologic complications that require both physician-prescribed, and independent, or nurse-prescribed, interventions.
- Nurses must base their practices on the evidence generated by research. Professional journals are the best sources for the latest research.

Ethical, Social, and Legal Issues

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Apply theories and principles of ethics to ethical dilemmas.
2. Describe how the steps of the nursing process can be applied to ethical decision making.
3. Discuss ethical conflicts related to reproductive issues such as elective pregnancy termination, forced contraception, and infertility therapy.
4. Discuss the maintenance of patient, institutional, and colleague confidentiality when using electronic communication.
5. Relate how major social issues such as poverty and access to health care affect maternal-newborn and women's health nursing.
6. Describe the legal basis for nursing practice.
7. Identify measures to prevent or defend malpractice claims.
8. Describe the nursing implications of current trends in health care.

Nurses often grapple with ethical and social dilemmas that affect individuals and families for whom they provide care. Nurses must know the way to approach these issues in a knowledgeable and systematic way. Some ethical and social issues result in the passage of laws that regulate reproductive practice. The nurse must understand the legal basis for his or her scope of practice to reduce vulnerability to **malpractice** (negligence by a professional nurse) claims.

ETHICS AND BIOETHICS

Ethics involves determining the best course of action in a certain situation. Ethical reasoning is the analysis of what is morally right and reasonable. **Bioethics** is the application of ethics to health care. Ethical behavior for nurses is discussed in codes such as the American Nurses Association *Code for Nurses* (www.nursingworld.org/ethics). Ethical issues have become more complex as technology has created more options in health care. These issues are controversial because agreement over what is right or best does not exist and because moral support is possible for more than one course of action.

Ethical Dilemmas

An **ethical dilemma** is a situation in which no solution is completely satisfactory. Opposing courses of action may seem equally desirable,

or all possible solutions may seem undesirable. Ethical dilemmas are among the most difficult situations in nursing practice. To find solutions, nurses and other health care personnel must apply ethical theories and principles and determine the burdens and benefits of any course of action (Callister & Sudia-Robinson, 2011; Capiello, Beal, & Gallogly-Hudson, 2013).

Ethical Theories

Three models guide ethical decision making: deontologic, utilitarian, and human rights (Boggs, 2011). Few people use one decision-making model exclusively. Instead, they make decisions by examining models and determining which is most appropriate for the circumstances.

Deontologic Model. The **deontologic model** determines what is right by applying ethical principles and moral rules. It does not vary the solution according to individual situations. One example is the rule, "Life must be maintained at all costs and in all circumstances." Strictly used, the deontologic model would not consider the quality of life or weigh the use of scarce resources against the likelihood that the life maintained would be near-normal.

Utilitarian Model. The **utilitarian model** approaches ethical dilemmas by analyzing the benefits and burdens of any course of action to find one that will result in the greatest amount of good. Appropriate actions may vary with the situation when using the utilitarian model.

BOX 3-1 ETHICAL PRINCIPLES IN HEALTH CARE

Autonomy—People have the right to self-determination. This includes the right to respect, privacy, and information necessary to make decisions based on their personal values and beliefs.

Beneficence—Make a decision that produces greatest good or the least harm.

Nonmaleficence—Avoid risking or causing harm to others.

Justice—All people should be treated equally and fairly regardless of disease or social or economic status.

Fidelity—Keep promises, and do not make promises that cannot be kept.

Truth (veracity)—Tell the truth.

Confidentiality—Keep information private.

Accountability—Accept responsibility for actions as a health care professional.

From Alfaró-LeFevre, R. (2009). *Critical thinking and clinical judgment: A practical approach* (4th ed.). Philadelphia: Saunders; and Boggs, K. U. (2011). Clinical judgment: Applying critical thinking and ethical decision making. In E. C. Arnold & K. U. Boggs (Eds.), *Interpersonal relationships: Professional communication skills for nurses* (6th ed., 44–61). Philadelphia: Saunders.

The utilitarian approach is concerned more with the consequences of actions than the actions themselves. In its simplest form, the utilitarian approach is “The end justifies the means.” If the outcome is positive, the method of arriving at that outcome is less important.

Human Rights Model. The belief that each person has human rights is the basis for the **human rights model** to making ethical decisions. The nurse may find personal difficulty in the right of a person to refuse care that the nurse and possibly other care providers believe is best. A nurse’s goal is usually to save lives but what if the person’s life is intolerable or care is refused?

Ethical Principles

Ethical principles or rules are also important for solving ethical dilemmas. Four of the most important principles are beneficence, nonmaleficence, respect for autonomy, and justice. Other important ethical principles such as accountability, confidentiality, truth, and keeping promises are derived from these four basic principles (Box 3-1). These principles guide decision making, but in some situations, the application of one principle conflicts with another. In such cases, one principle may outweigh another in importance (Callister & Sudia-Robinson, 2011; Callister, 2011).

Treatments designed to do good may also cause harm. For example, a cesarean birth may prevent permanent harm to a fetus in jeopardy. However, the surgery that saves the fetus also harms the mother, causing pain, temporary disability, and possible financial hardship. Also, certain basic surgical risks to the mother do exist. Both the mother and the health care providers may decide that the principle of beneficence outweighs the principle of nonmaleficence. If the mother does not want surgery, the principles of autonomy and justice also must be considered. Is the mother’s right to determine what happens to her body more or less important than the right of the fetus to fair and equal treatment?

Solving Dilemmas in Daily Practice

Nurses are often involved in supporting parents when tragedy strikes during a birth. They must be knowledgeable regarding the disease process and the appropriate nursing care in these situations and also be able to support family’s needs when ethical dilemmas arise. However, ethical challenges often arise during day-to-day professional practice. Nurses and other professionals should learn to analyze and solve these

dilemmas. Personal values and cultural and language differences are some of the issues that often impact the solving of ethical dilemmas.

Ethical dilemmas, a situation in which no solution seems completely satisfactory, also may have legal ramifications. For example, although the American Medical Association has stated that anencephalic organ donation is ethically permissible, it may be illegal. In many states, the legal criteria for death include cardiopulmonary as well as brain death. Therefore, donor organs from the baby with anencephaly are likely unusable for transplantation because of lengthy anoxia.

CRITICAL THINKING EXERCISE 3-1

The parents of an infant with anencephaly state that they would like to donate the organs from their dying infant to another infant who might live as a result. They believe that in this way their own infant will live on as a part of another baby. Although such transplantations have been performed in the past, they are not currently practiced because of ethical concerns.

Questions

1. What is the deontologic view of this decision?
2. How would the utilitarian view differ?
3. Does the human rights model fit in this situation?
4. What ethical principles are involved? If such transplantations become routine, what problems might arise?

Greater understanding about conflicts and misunderstandings that may arise from the differences among people helps nurses find better solutions to ethical dilemmas and other problems common to daily life. Many approaches can be used to solve ethical dilemmas in nursing practice. No single approach guarantees a right decision, but it provides a logical, systematic method for decision making. Because the nursing process is also a method of problem solving, nurses can use a similar approach when faced with ethical dilemmas (Box 3-2).

Decision making in ethical dilemmas may seem straightforward, but it rarely results in answers acceptable to everyone. Health care agencies often have bioethics committees to formulate policies for ethical situations, provide education, and help make decisions in specific cases. The committees include a variety of professionals such as nurses, physicians, social workers, ethicists, and clergy members. The family members most closely affected by the decision also participate, if possible. A satisfactory solution to ethical dilemmas is more likely to occur when people work together.

BOX 3-2 APPLYING THE NURSING PROCESS TO SOLVE ETHICAL DILEMMAS

Assessment—Gather data to clearly identify the problem and the decisions necessary. Obtain viewpoints from all who will be affected by the decision and applicable legal, agency policy, and common practice standards.

Analysis—Decide whether an ethical dilemma exists. Analyze the situation using ethical theories and principles. Determine whether and how these conflict.

Planning—Identify as many options as possible, determine their advantages and disadvantages, and conclude which options are most realistic. Predict what is likely to happen if each option is followed. Include the option of doing nothing. Choose the solution.

Implementation—Carry out the solution. Determine who will implement the solution and how. Identify all interventions necessary and what support is needed.

Evaluation—Analyze the results. Determine whether further interventions are necessary.

Ethical Issues in Reproduction

Reproduction issues often involve conflicts in which a woman behaves in a way that may cause harm to her fetus or that is disliked by some or most members of society. Conflicts between a mother and fetus occur when the mother's needs, behavior, or wishes may injure the fetus. The most obvious instances involve abortion, substance abuse, and a mother's refusal to follow the advice of caregivers. Health care workers and society may respond to such a woman with anger rather than support. However, the rights of both mother and fetus must be examined.

2. How do the deontologic, utilitarian, and human rights models differ within ethical theories?
3. When might two ethical principles conflict?
4. How do the steps of the nursing process relate to ethical decision making?

Elective Pregnancy Termination

Abortion, or elective termination of pregnancy, was a volatile legal, social, and political issue even before the *Roe v. Wade* decision by the U.S. Supreme Court in 1973. Before that time, states could outlaw abortion within their boundaries. In *Roe v. Wade*, the Supreme Court stated that abortion was legal in the United States and that existing state laws prohibiting abortion were unconstitutional because they interfered with the mother's constitutional right to privacy. This decision stipulated that (1) a woman could obtain an abortion at any time during the first trimester, (2) the state could regulate abortions during the second trimester only to protect the woman's health, and (3) the state could regulate or prohibit abortion during the third trimester, except when the mother's life might be jeopardized by continuing the pregnancy. Since 1973, many state laws have been upheld or rejected by Supreme Court decisions (Box 3-3).

For many people the woman's constitutional right to privacy conflicts with the right to life of the fetus. However, the Supreme Court did not rule on when life begins. This omission provokes debate between those who believe that life begins at conception and those who believe that life begins when the fetus is viable, or capable of living outside the uterus. Those who believe life begins at conception may be opposed to abortion at any time during pregnancy. Those who believe life begins when the fetus is viable (20 to 24 weeks of gestation) may oppose abortion after that time. Nurses need to understand abortion laws and the conflicting beliefs that divide society on this issue.

Conflicting Beliefs about Abortion. Some people believe abortion should be illegal at any time because it deprives the fetus of life. In contrast, others believe that women have the right to control their reproductive functions and that political discussion of reproductive rights is an invasion of a woman's most private decisions. Another issue is whether late abortion is legal if the woman's health is at risk by continuing the pregnancy.

Belief That Abortion Is a Private Choice. Central to political action to keep abortion legal is the conviction that women have the right to make decisions about their reproductive functions on the basis of their own ethical and moral beliefs and that government has no place in these decisions. Many women who support this view state that they would not choose abortion for themselves. Still, they support the right of each woman to make her own decision and view government action as interference in a very private part of women's lives. Many people who support the legality of abortion prefer to call themselves *pro-choice* rather than *pro-abortion* because they believe that *choice* more accurately expresses their philosophic and political position.

BOX 3-3 SUPREME COURT DECISIONS ON ABORTION SINCE ROE V. WADE

- 1976—States cannot give a husband veto power over his spouse's decision to have an abortion.
- 1977—States do not have an obligation to pay for abortions as part of government-funded health care programs. (This is considered by abortion rights advocates to be unfair discrimination against poor women who are unable to pay for an abortion.)
- 1979—Physicians have broad discretion in determining fetal viability, and states have leeway to restrict abortions of viable fetuses.
- 1979—States may require parental consent for minors seeking abortions if an alternative (such as a judge's approval) is also available.
- 1989—A Missouri law barring abortions performed in public hospitals and clinics or performed by public employees was upheld. Also, the law required physicians to conduct tests for fetal viability at 20 weeks of gestation.
- 1990—States may require notification of both parents before a woman under the age of 18 years has an abortion. A judge can authorize the abortion without parental consent.
- 1992—A Pennsylvania law imposing restrictions on abortions was validated. The restrictions upheld include the following:
 - A woman must be told about fetal development and alternatives to abortion.
 - She must wait at least 24 hours after this explanation before having an abortion.
 - Unmarried women under the age of 18 must obtain consent from their parents or a judge.
 - Physicians must keep detailed records of each abortion, subject to public disclosure.
 - Struck down only one requirement of the Pennsylvania law: that a married woman must inform her husband before having an abortion.
- 1993—The so-called "gag rule," which restricted counseling that health care professionals (with the exception of physicians) could provide at federally funded family planning clinics, was rescinded.
- 1995—A ruling that states cannot withhold state funds for abortions in cases of pregnancies resulting from rape or incest or when the mother's life is in danger was upheld.
- 2000—A Nebraska law making late-term abortions illegal was struck down. The court held that the law placed undue burden on the pregnant woman because no provision had been made for late abortion performed to protect the woman's health.
- 2003—The bill that bans late-term abortions was signed by President George W. Bush. The law did not make an exception to protect the woman's health.
- 2007—The Supreme Court upheld the 2003 law banning late-term abortions without the exception to protect the woman's health. Different Supreme Court justices ruled on the 2003 law than those that ruled on the 2000 Nebraska law.

Each year, more than 800,000 legal abortions are performed in the United States. In 2008, the rate was 16 abortions for every 1000 women ages 15 to 44 years, and the abortion ratio was 234 per 1000 live births. Women ages 20 to 29 years had the highest abortion rates, whereas the youngest and oldest women had the lowest (Centers for Disease Control and Prevention [CDC], 2011). Advocates of the legal right to abortion point out that the performance of abortion, either legal or illegal, has always been a reality of life and will continue regardless of legislation or judicial rulings. Advocates also express concern regarding

the unsafe conditions associated with illegal abortion, citing the deaths that resulted from illegal abortions performed before the *Roe v. Wade* decision.

Belief That Abortion Is Taking a Life. Many people believe that legalized abortion condones taking a life and feel morally bound to protect the lives of fetuses. This position is called *pro-life*. The term has become an emotionally charged one, and some believe it polarizes opinion and implies that those who do not agree with the anti-abortion position are not concerned about life or are “anti-life.”

Persons opposed to abortion have demonstrated their commitment by organizing as a potent political force. They have willingly been arrested for civil disobedience during attempts to prevent admissions to clinics that perform abortions. Political candidates are expected to state their positions on abortion in campaigns for many U.S. offices, and the abortion issue is often a topic in debates.

Implications for Nurses. Nurses have several responsibilities that cannot be ignored in the conflict about abortion. First, they must be informed about the complexity of the abortion issue from legal and ethical standpoints and know the regulations and laws in their state. Second, they must realize that for many people, abortion is an ethical dilemma, which results in confusion, ambivalence, and personal distress. Next, they must also recognize that for many others, the issue is not a dilemma but a fundamental violation of the personal or religious views that give meaning to their lives. Finally, nurses must acknowledge the sincere convictions and strong emotions of those on all sides of the issue, including themselves.

Personal Values. Nurses respond to abortion issues in ways that illustrate the complexity of the issue and the ambivalence it often produces. For instance, some nurses have no objection to participation in performing abortions. Others do not assist with abortions but may care for women after the procedure. Some nurses will assist with a first-trimester abortion but may object to later abortions. Many nurses are comfortable assisting with abortion if the fetus has severe anomalies but are uncomfortable in other circumstances. Some nurses feel that they could not provide care before, during, or after an abortion but are bound by conscience to try to dissuade a woman from the decision to end the pregnancy. A nurse may or may not oppose abortion if pregnancy endangers the woman’s health, possibly raising other ethical dilemmas such as whether the fetus can survive if the mother’s health declines.

Professional Obligations. Nurses have no obligation to support a position with which they disagree. The nursing practice acts of many states allow nurses to refuse to assist with the procedure if it violates their ethical, moral, or religious beliefs. However, nurses are obligated to disclose this information before they are employed in an institution that performs abortions. It is unethical for a nurse to withhold this information until assigned to care for a woman having an abortion and then refuse to provide care. As always, nurses must respect the decisions of women who look to nurses for care. If nurses believe they are not able to provide compassionate care because of personal convictions, they must inform a supervisor so that appropriate care can be arranged.

CHECK YOUR READING

- How did the *Roe v. Wade* ruling affect state laws related to abortion in the United States?
- What are the major conflicting beliefs about abortion?
- What are some Supreme Court decisions that have modified the *Roe v. Wade* ruling?
- What are nurses’ responsibilities if they are morally opposed to abortion?

Mandated Contraception

The availability of contraception that does not require taking a regular oral dose such as using a hormone-releasing patch or having hormone injections or an intrauterine device (IUD), has led to speculation about whether certain women should be forced to use this method of birth control. Requiring contraception has been used as a condition of probation, allowing women accused of child abuse to avoid jail terms.

Some people believe that mandated contraception is a reasonable way to prevent additional births in the case of women who are considered unsuitable parents and to reduce government expenses for dependent children. A punitive approach to social problems does not provide long-term solutions. Requiring poor women to use contraception to limit the money spent on supporting them is legally and ethically questionable and does not address the obligations of the children’s father. Such a practice interferes with a woman’s constitutional rights to privacy, reproduction, refusal of medical treatment, and freedom from cruel and unusual punishment. In addition, medication may pose health risks to the woman. Surgical sterilization (tubal ligation) also carries risks and must be considered permanent. Access to free or low-cost information on family planning would be more appropriate and ethical.

Fetal Injury

If a mother’s actions cause injury to her fetus, the question of whether she should be restrained or prosecuted has legal and ethical implications. In some instances, courts have issued jail sentences to women who have caused or who may cause injury to the fetus. This response punishes the woman and places her in a situation in which she cannot further harm the fetus. In other cases, women have been forced to undergo cesarean births against their will when physicians have testified that such a procedure was necessary to prevent injury to the fetus.

The state has an interest in protecting children, and the U.S. Supreme Court has ruled that a child has the right to begin life with a sound mind and body. Many state laws require that evidence of prenatal drug exposure be reported. Women have been charged with negligence, involuntary manslaughter, delivery of drugs to a minor, and child endangerment.

However, forcing a woman to behave in a certain way because she is pregnant violates the principles of autonomy, self-determination of competent adults, bodily integrity, and personal freedom. Because of fear of prosecution, this practice could impede, not advance, health care during pregnancy.

The punitive approach to fetal injury also raises the question of how much control the government should have over a pregnant woman. Laws could be passed to mandate maternal human immunodeficiency virus (HIV) testing with no right to refuse, fetal testing, intrauterine surgery, or even the foods the woman eats during pregnancy. The decision with regard to just how much control should be allowed in the interests of fetal safety is difficult.

Fetal Therapy

Fetal therapy is becoming more common as techniques improve and knowledge grows. Although intrauterine blood transfusions are relatively standard practice in some areas, fetal surgery is still relatively uncommon.

The risks and benefits of surgery for major fetal anomalies must be considered in every case. Even when surgery is successful, the fetus may not survive, may have other serious problems, or may be born severely preterm. The mother may require weeks of bed rest and a cesarean birth. Yet, despite the risks, successful fetal surgery may result in birth of an infant who could not otherwise have survived.

Parents need help to balance the potential risks to the mother and the best interests of the fetus. They might feel pressured to have surgery or other fetal treatment they do not understand. As with any situation involving informed consent, women need adequate information before making a decision. They should understand if procedures are still experimental, the known chances of a procedure's success, and if any alternative treatments are available and their chances of success.

Issues in Infertility

Infertility Treatment. Perinatal technology has found ways for some previously infertile couples to bear children (see Chapter 32). Many techniques are more successful, but ethical concerns include the high cost and overall low success of some infertility treatments. Because many of these costs are not insured, their use is limited to the affluent. Techniques may benefit only a small percentage of infertile couples. Despite treatment, many couples never give birth, regardless of the costs or invasiveness of therapy. Successful treatment may lead to multiple gestations, usually twins, and complications related to maternal age.

Other ethical concerns focus on the fate of unused embryos. Should they be frozen for later use by the woman or someone else or used in genetic research? What if the parents divorce or die? Who should make these decisions? In multiple pregnancies with more fetuses than can be expected to survive intact, reduction surgery may be used to destroy one or more fetuses for the benefit of those remaining. The ethical and long-term psychological implications of this procedure are also controversial.

Assisted reproductive techniques now allow postmenopausal women to become pregnant. What are the ethical implications of conceiving and giving birth to children whose mother is several decades older than their friends' mothers and is more likely to die when the children are relatively young? Should the age and health of the parents be a factor in determining whether this treatment is offered? Should a consideration be the risk these women face for complications that might result in unhealthy infants? Should average life expectancy enter the decision?

Surrogate Parenting. In surrogate parenting, a woman agrees to bear an infant for another woman. Conception may take place outside the body using ova and sperm from the couple who wish to become parents. These embryos are then implanted into the surrogate mother, or the surrogate mother may be inseminated artificially with sperm from the intended father. Donated embryos may also be implanted into a surrogate mother.

Cases in which the surrogate mother has wanted to keep the child have created controversy. No standard regulations govern these cases, which are decided individually. Ethical concerns involve who should be a surrogate mother, what her role should be after birth, and who should make these decisions. Screening of parents and surrogates is necessary to determine whether they are suited for their roles. Who should perform the screening? Should it be left to the private interests of those involved, or should government become involved? Answers to these questions are not definite at this time.

An issue closely related to surrogate parenting is the use of donor gametes or unused embryos from another infertile couple. Will the use of donor gametes or embryos violate religious or moral beliefs of the parents? Does the child thus conceived have a right to know the identity of the biologic parents? What are the rights of the biologic parents?

Ethical and Legal Reproductive Issues

Many issues cross the boundary between ethics and legality and apply to all caregivers. These are issues that apply to many fields of care, including reproduction and women's health.

Privacy Issues

Many people are concerned about the possible misuse of their health information. They may fear that health information in the wrong hands, whether that information is accurate or not, may cost them a job, promotion, loan, or something equally valuable. Privacy concerns and fear of health care or other insurance loss may cause a person to withhold genetic or other medical history information from a provider. Quality of genetic counseling may be impaired if family members refuse to release their medical records (see Chapter 5).

Government Regulations

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 was designed to reduce fraud in the insurance industry and make it easier for people to remain insured if they move from one job to another. Also within HIPAA's provisions was the mandate that Congress pass a law to protect the privacy of personal medical information by August 1999. Congress failed to do so, and the U.S. Department of Health and Human Services (HHS) Secretary proposed interim regulations in October 1999 to protect personal medical privacy as required by HIPAA. The HHS regulations provide consumers with significant new power over their records, including the right to see and correct their records, the application of civil and criminal penalties for violations of privacy standards, and protection against deliberate or inadvertent misuse or disclosure. See www.hhs.gov for additional information.

Online Communications. A person's health data are being converted to various computerized formats. One example involves the computerized storage of electronic fetal monitoring data, including background information, interventions, and graphics. Although this allows nearly instantaneous exchange of data among providers in an emergency situation, it also carries the potential for greater violation of privacy than data maintained on paper. However, another advantage of electronic storage of health data is that it reduces the chance of losing paper files. Terminals may be placed in hallways or patient rooms to facilitate quick entry and retrieval of information for staff. The nurse must remember that this information may also be easily accessed by a computer-savvy person despite the use of passcodes and other security measures.

Nurses must take care to avoid violating patient confidentiality when using electronic patient data formats. For example, nurses must promptly log off terminals when finished so that unauthorized people cannot gain access to the system. Security codes should remain secret and committed to memory and should not be words or combinations that another person can easily guess. Suspected loss of a password should be promptly reported to the system administrator. Most systems require regular changes of security codes. Random codes may be issued by the computer network itself, based on an employee's clearance, to limit what others know about the individual's security code. When nurses and physicians have a single code to be used for appropriate applications such as charting, monitoring, using e-mail, and retrieving policies and procedures, the likelihood that they will write down the many codes often required by different applications can be reduced.

Other privacy precautions include care when using the phone to report to another professional so that the identity of the patient is not audible to others in the area, turning over items with labels so the patient name cannot be viewed, and placing items with labels (such as laboratory specimens) in a secure location outside the public view. Discussions about a patient with other professionals should be restricted to those who need to know and should occur in a private location.

Internet discussion lists allow nurses to exchange information and nursing care tips that can improve practice. These forums also have the potential to allow lapses of patient or institutional confidentiality because their communications cannot be considered private. When participating in discussion lists or using e-mail, nurses must respect the confidentiality of patients, colleagues, and institutions. Institutional documents such as chart forms, policies, and procedures should not be shared without the facility's approval. A personal message should not be forwarded without the original sender's permission.

Online Document Exchange. Health care is one of few industries that relies on paper records in the twenty-first century. Electronic medical records (EMRs) are more common in efforts to streamline patient information exchange among providers, and this became standard for providers beginning October 2012. EMRs are seen as a way to reduce the higher costs of care fragmentation and inaccessibility of records if a person needs care at different facilities. Rapid access to a patient's records may be lifesaving in an emergency. Changes expected include rules for a secure, confidential exchange of health information. Reducing paperwork, costs, and medical errors are anticipated to improve the quality of care for patients, whether their care is outpatient or inpatient (U.S. Department of Health and Human Services [HHS], 2012). See www.healthcare.gov for more information and a timeline for implementation of the Affordable Care Act of 2010 (ACA).

12. List some of the advantages and disadvantages of online exchange of medical records.

SOCIAL ISSUES

Nurses are exposed to many social issues that influence health care and often have ethical and legal implications. Some issues that affect maternity care include poverty, homelessness, access to care, allocation of health care resources, and care versus cure.

Poverty

Poverty remains an underlying factor in problems such as homelessness and inadequate access to health care. Poverty in the United States increased by 1%, from 14.3% in 2009 to 15.3% in 2010. The number of people below 125% of their poverty threshold increased from 18.8% to 20.1% and those below 50% of their poverty threshold increased from 6.3% to 6.8%. Poverty affected 3.3 million more people in 2010 than in 2009 (Bishaw, 2011). Because of adverse living conditions, poor health care, and poor nutrition, infants born to women in low-income groups are more likely to begin life with problems such as low birth weight.

Poverty often breeds poverty. In poor families, children may leave the educational system early, making them less likely to learn skills necessary to obtain good jobs. Childbearing at an early age is common and further interferes with education and the ability to work. The cycle of poverty may continue from one generation to the next as a result of hopelessness and apathy (Figure 3-1).

As health care costs have risen, the ability to pay for employer-sponsored health insurance has become more difficult for low- and middle-income workers. Rising unemployment in the late 2000s

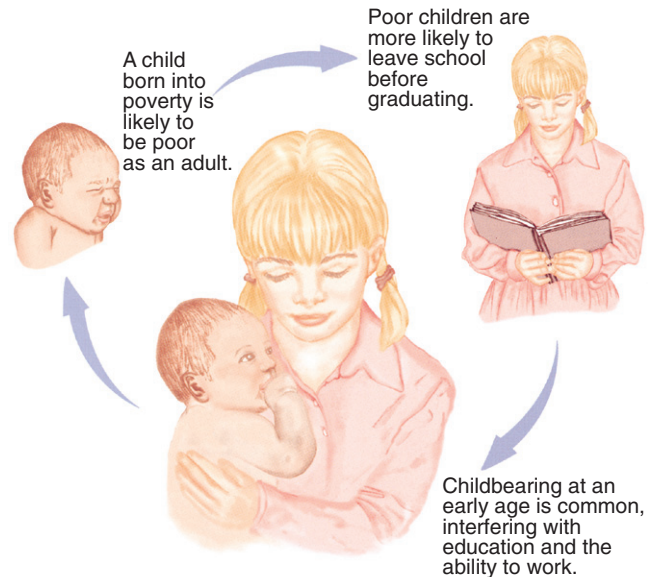

FIG 3-1 The cycle of poverty.

further eroded coverage in the United States. Effectiveness of the ACA remains to be seen now that all parts were upheld by the Supreme Court. Changes in Medicaid, Medicare, and Children's Health Insurance Program (CHIP) to cover children from low-income groups not already on Medicaid, are addressed within the ACA. Smaller companies have had to enroll employees who can pay their entire premium or discontinue health insurance as a benefit altogether. The working poor have jobs but receive wages that barely meet their day-to-day needs or may work just under the full-time hours that qualify them for employer insurance and other benefits. These jobs may not offer health insurance at all, or high premiums may be the only option. The working poor have little opportunity to save for emergencies such as serious illness.

Nationwide in 2010, 16% of the population under age 65 years had no health insurance, and 22.3% of those age 18 to 64 years were uninsured. Public insurance such as Medicare or Medicaid covered 22% of those under age 65 years. Ten million, or 33.9% of adults age 19 to 25 years, were uninsured. Among children under age 18 years, 7.8% were uninsured, and 39.8% had a public health plan (Cohen, Ward, & Schiller, 2011). Millions of other people have limited insurance and would not be able to survive financially in the event of serious illness. People without insurance seek care only when absolutely necessary. Health maintenance and illness prevention may seem costly and unnecessary to them. Some women receive no health care during pregnancy until they arrive at the hospital for birth.

Various government programs are available to help the poor. One such program is Temporary Assistance to Needy Families (TANF), which provides money for basic living costs of indigent children and their families. Created by the Welfare Reform Law of 1996, this replaced the Aid to Families with Dependent Children (AFDC) program of the older welfare system. TANF imposes time limits on the aid given to the family, unlike AFDC. Eligibility requirements, income limits, allowances for homelessness, and time limitations vary among states.

Homelessness

A snapshot view from the [National Alliance to End Homelessness \(2012\)](#) reports that 643,067 people are homeless on any night. Families make up 239,110 (37%) of this number, and individuals make up another 404,957 (63%). Seventeen percent are considered chronically

homeless, and 12% are veterans. Homeless families are often composed of single women and their children, and domestic violence is often part of their history as they attempt to escape the violence. Homeless people may wait till health problems are severe because of shame at becoming homeless and inability to pay for the care needed. Ongoing care for diabetes, HIV/AIDS, or addiction is often missed. Mental illness such as depression, bipolar disorder, or schizophrenia is more common among the homeless and may be left untreated. Care is delayed till the homeless person enters the emergency room and the needed care at that point is far more costly to a hospital than the preventive care that the homeless person could not afford.

The pregnant homeless woman, often a teen, is less likely to seek prenatal care that might catch complications such as maternal hypertension and diabetes, or she may be a user of alcohol or drugs. Inadequate maternal weight gain adds to the risk for prematurity and low birth weight (March of Dimes, 2008). Pregnancy interferes with one's ability to work and may reduce income to the point that housing is unattainable. Prostitution to earn money may result in pregnancy and add to its problems with such factors as infections, violence, and inadequate health care. Homeless teens are more likely to have poor eating habits, to smoke, to have greater risks for preterm labor, anemia, and hypertension during pregnancy, and to deliver a low-birth-weight infant. The mother is more likely to drop out of school, and her children are more likely to have lower school achievement and drop out of high school, be incarcerated at some time during adolescence, give birth as a teenager, and face unemployment as a young adult (CDC, 2012a).

Access to Health Care

The United States ranks twenty-seventh in infant mortality compared with other developed countries (see Chapter 1). Data for 2010 showed that 6.14 infants per 1000 live births died before their first birthday (Murphy, Xu, & Kochanek, 2012). Many of these deaths are related to low birth weight, prematurity, and other prenatal factors.

Prenatal Care in the United States

Prenatal care is widely accepted as an important element in a good pregnancy outcome. Prenatal care in 2008 was near the same as in 2007 (Martin, Hamilton, Ventura et al., 2011). Early prenatal care for all races during the first trimester was 70.7% and late (third trimester) or no prenatal care was 7%. Racial differences are apparent in these statistics. First trimester prenatal care for women was 72.2% in whites, 59.1% in blacks or African-Americans, 64.2% in Hispanics or Latinas, 55.8% in American Indians or Alaska Natives, and 77.4% in Asians or Pacific Islanders. Late or no prenatal care for women was 6.4% for whites, 11.5% in blacks or African-Americans, 9.1% in Hispanics or Latinas, 12.4% in American Indians or Alaska Natives, and 5.1% in Asians or Pacific Islanders. Lack of access to prenatal care adds to the infant mortality rate and the large number of low-birth-weight infants born each year in the United States. Because preterm infants are the largest category of those needing intensive care, millions of dollars could be saved each year by ensuring adequate prenatal care and good maternal nutrition. Even a small improvement in birth weight or gestational age reduces complications and hospital time.

In addition to the ACA, the first National Prevention and Health Promotion Strategy, or National Prevention Strategy, was released in 2011 as a critical component of the ACA to improve health of Americans. The U.S. Surgeon General Regina M. Benjamin, M.D., led a group of 17 heads of departments, agencies, and offices across the Federal government who are committed to promoting prevention and wellness. Dr. Benjamin states in her introduction that the National Prevention Strategy will move us from a system of sick care to one

BOX 3-4 FACTORS RELATED TO POOR ACCESS TO HEALTH CARE

- Poverty
- Unemployment
- Lack of medical insurance
- Adolescence
- Minority group
- Inner city residence
- Rural residence
- Unmarried mother status
- Less than high school education
- Inability to speak English

based on wellness and prevention and provides the leadership necessary to engage not only the federal government but a diverse array of stakeholders, from state and local policymakers, to business leaders, to individuals, their families and communities, to champion the policies and programs needed to ensure the health of Americans prospers (National Prevention Council, 2011).

Factors that limit access to care must be addressed to increase the use of preconception and prenatal care. Box 3-4 summarizes some of the factors that interfere with access to care. Many factors overlap. For example, poverty is often associated with the other characteristics listed. In the United States, minority women are more likely to be indigent, less likely to seek prenatal care, and more likely to die in childbirth when compared with white women. Pregnancy-related mortality in the United States was 15.1 per 100,000 in 2006-2007, with 11 per 100,000 among whites, 34.8 per 100,000 among blacks, and 15.7 per 100,000 among women of other races (CDC, 2012b; www.facethefactsusa.org, 2012).

Adolescent pregnancy is also associated with many factors listed in Box 3-4. Although teen births have declined to historic lows of 39.1 per 1000 in 2009, teenage pregnant girls are likely to need additional care. About 25% of teens who give birth will have their second baby within 2 years of the first. Teen mothers are less likely to complete their education and more likely to be poor compared with adult mothers. The teen mother is not likely to marry the baby's father, and fathers pay less than \$800 per year in child support often because they are also poor (CDC, 2012a; Martin et al., 2011; National Campaign to Prevent Teen Pregnancy, 2010). Teen mothers may be repeating the path that their mothers took. See also Chapter 24.

In some situations, women can obtain prenatal care, but choose not to do so. These women may not understand the importance of the care or may deny they are pregnant. Some have had unsatisfactory past experiences with the health care system, avoiding care for as long as possible. Others want to hide substance use or other habits from disapproving health care workers. When women have major life problems, prenatal care is not a priority for them. Language and cultural differences also play a part in whether a woman seeks prenatal care. Although these are not access issues as such, they must be addressed to improve health care (Friedman, Heneghan, & Rosenthal, 2009).

Government Programs for Health Care

Medicaid. Medicaid provides health care for indigent persons, older adults, and persons with disabilities. Pregnant women and young children are especially targeted. Medicaid is funded by both the federal and individual state governments. The states administer the program and determine which services are offered. Although the qualifying level of poverty varies among states, all women whose income is

below 133% of the current federal poverty level are eligible for perinatal care.

Women who do not have private insurance or Medicaid may receive prenatal care at public clinics. However, such clinics are often understaffed and have large numbers of patients. Clinics may be located in areas not easily accessible to pregnant women who have transportation problems. Long waits for appointments may require time off from work, resulting in loss of pay for a worker on hourly wages. A mother may not be able to find child care for older children while she visits the clinic. These problems decrease the chance that women will take steps to obtain care.

Shelters and Health Care for the Homeless. Federal funding has assisted homeless people with shelter and health care. However, the homeless have additional difficulties in obtaining health care because of lack of transportation, inconvenient hours, and poor continuity of care.

Quality and quantity of care in clinics may be poor because of inadequate funding. Nurses have been instrumental in opening shelters, clinics, and outreach services for the homeless, with nurse practitioners often playing a major role. Clinics headed by nurse practitioners are often opened in underserved rural and inner city areas. Nurses also help inform the public and legislatures about the needs of the homeless and others with few health care options. Nursing students often find that some of their clinical practice occurs in clinics such as these rather than in an acute care hospital.

Innovative Programs. Innovative programs to ensure that all women receive good prenatal care are necessary to improve pregnancy outcomes. Some outreach programs are designed to improve health in women who traditionally do not seek prenatal care. Bilingual health care workers and bilingual educational classes are part of some programs. Programs may be located in schools, shopping centers, churches, workplaces, and neighborhoods that are easily accessible to people. Mobile vans outfitted with basic equipment bring prenatal care to women who are unable or unwilling to attend care at fixed locations or in more distant neighborhoods. (Such vans often provide neighborhoods with additional programs such as dental care, immunizations, well-child care, women's health care, and screening mammography.) The number of such neighborhood programs is insufficient to make adequate health care for women and children a reality.

Allocation of Health Care Resources. In 2009, the United States spent \$2.5 trillion on health care, an average of \$8000 per person annually (National Center for Health Statistics, 2012). Expenditures for health care continue to rise. Areas that must be addressed include ways to provide care for indigent persons, the uninsured or underinsured, and those with long-term care needs. Distribution of the limited funds available for health care among all these areas is a major concern.

Care versus Cure

One problem to be addressed is whether the focus of health care should be on preventive and caring measures or cures for diseases. In the past, medicine has centered more on treatment and cure rather than on prevention and care. Yet, prevention avoids suffering and is less expensive than treating diseases after diagnosis.

The focus on cure has resulted in technologic advances that have enabled some people to live longer, healthier lives. However, the costs of technology must be balanced against the benefits obtained and by the number of people who benefit.

Although low-birth-weight (LBW) infants constitute a small percentage of all newborns, they require a large percentage of total hospital expenditures. The expenses of one preterm infant for a single day in an intensive care nursery are more than enough to pay for care of the mother throughout her pregnancy and birth. Yet, if the mother had

received prenatal care early and regularly, the infant might have avoided intensive care.

In addition, quality-of-life issues are important with regard to technology. Neonatal nurseries are able to keep very-low-birth-weight (VLBW) babies alive because of advances in high-technology for their group. Some of these infants go on to lead normal or near-normal lives. Others gain time but not quality of life. Families and health care professionals face difficult decisions about when to treat, when to end treatment, and how to recognize that the suffering outweighs the benefits.

Late Preterm Infants

Higher costs for caring for the late preterm infant are significant because these babies comprise a larger percentage of newborns than do LBW infants. Birth rates are rising for late preterm infants, also called *near-term infants*. The late preterm infant is born between 34 and 36 completed weeks of pregnancy. In 2005, the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) launched a multiyear initiative to address the special needs of this group of newborns. In 2012, the data analysis is complete and outcome articles are expected. See www.awhonn.org.

Although the initial appearance, birth weight, and responses of late preterm infants may appear similar to those of term infants, subtle problems often emerge that extend hospitalization and the cost of care. Compared with term infants, late preterm newborns have more complications, including respiratory distress that often requires ventilatory support, poor thermoregulation, hypoglycemia, feeding problems, apnea, bradycardia, jaundice, and sepsis before hospital discharge. Readmission rates for problems such as poor feeding or jaundice are higher for late preterm infants than for those born at term, adding to the cost of care. Neonatal mortality rates at 34 to 35 weeks are significantly higher than mortality rates in babies born at 37 or more weeks of gestation (American College of Obstetricians and Gynecologists [ACOG], 2011b; McIntire & Leveno, 2008). See Chapter 29 for more information.

LEGAL ISSUES

The legal foundation for the practice of nursing provides safeguards for patients and sets standards by which nurses can be evaluated. Nurses need to understand how the law applies specifically to them. When nurses do not meet the standards expected, they may be held legally accountable.

Safeguards for Health Care

Three categories of safeguards determine the law's view of nursing practice: (1) nurse practice acts, (2) standards of care set by professional organizations, and (3) rules and policies set by the institution employing the nurse.

Nurse Practice Acts

Every state has a **nurse practice act** that determines the scope of practice of registered nurses in that state. Nurse practice acts define what

the nurse is allowed to do when caring for patients. The acts also specify what the nurse is expected to do when providing care. Some parts of the law may be very specific. Others are stated broadly to allow flexible interpretation of the role of nurses. Nurse practice acts vary among states, and nurses must understand these laws wherever they practice. Nurses should have a copy of the nurse practice act for their state and refer to it for questions about their scope of practice. Most state nurse practice acts are available on the Internet. The website of the National Council of State Boards of Nursing (NCSBN) (www.ncsbn.org) has information on nurse practice acts for all states, all territories, and the District of Columbia, as well as other information related to licensing and practice.

Laws relating to nursing practice also delineate methods, called **standard procedures** or *protocols*, by which nurses may assume certain duties commonly considered part of medical practice. The procedures are written by committees of nurses, physicians, and administrators. They specify the nursing qualifications required for practicing the procedures, define the appropriate situations, and state the education required. Standard procedures allow the role of the nurse to change to meet the needs of the community and expanding knowledge.

By the middle of 2012, 24 states had adopted a **mutual recognition** model for nursing licensure, or a multistate nurse licensure compact (NLC). States involved in the compact, available at the NCSBN website, agree to recognize an unrestricted license to practice nursing issued by another state in the compact. This gives the license holder the authority to practice in the state in which the license was issued and in those states that recognize the license. The nurse must abide by the rules and regulations in each state. Some advantages include reduced duplication and more cost-effective interstate practice. Guidelines were developed by the NCSBN in 2002 for a separate advanced practice nurse (APRN) compact but by the middle of 2008 only Utah had entered that compact. See the NCSBN website for updated information about NLC or APRN.

Concerns have been raised about the NCSBN interstate compact model by the AWHONN, the major organization for maternal-newborn and women's health nurses in the United States (AWHONN, 1999). This organization recognizes that nursing practice must change to facilitate telehealth, transport nursing, and greater mobility of nurses. However, AWHONN opposes the proposed compact model for several reasons, including concerns about constitutionality; licensure changes from the state of practice to the state of residence, possibly making it more difficult for consumers to file complaints; and confidentiality of malpractice or complaint data filed against nurses in a centralized database maintained by NCSBN. Additional concerns include increased costs if a claim must be defended in multiple jurisdictions.

Standards of Care

Court decisions have generally held that nurses must practice according to established standards and health agency policies in addition to nurse practice acts. Standards of care are set by professional associations and describe the level of care that can be expected from practitioners. For example, perinatal nurses are held to the national standards published by AWHONN, which are based on research and the agreement of experts. AWHONN also publishes practice resources, position statements, and other guidelines for nurses. Nurses should be familiar with the latest standards of care that cover their own practices.

Agency Policies

Each health care agency sets specific policies, procedures, and protocols that govern nursing care. All nurses should be familiar with those that apply in the agencies in which they work. Nurses are frequently involved in writing and revising nursing policies and procedures. In

the event of a malpractice claim, the applicable policy, procedure, or protocol is likely to be used as evidence. The case of the professionals is strengthened if all agency policies are followed properly. These policies should be revised and updated regularly.

Accountability. A recurrent issue that pertains to nursing accountability is inadequate staffing often related to budget cuts or unavailability of nurses. A nurse has the duty to communicate concerns immediately through established channels. However, a nurse will not be excused from responsibility for errors such as late medication administration or patient injury related to inadequate supervision that leads to a fall.

Accountability also involves competency. If a nurse is not competent to perform a nursing task (e.g., to administer a new chemotherapeutic drug), or if a patient's status worsens to the point at which the care needs are beyond the nurse's competency level (e.g., a person requiring hemodynamic monitoring), the nurse must immediately communicate this fact to the nursing supervisor or the physician. The fact that a patient's transfer to the intensive care unit (ICU) was requested but denied because the ICU was at full capacity is an insufficient defense in a charge of nursing negligence. In addition, the fact that a call was placed to a physician but no return call was received is no excuse for harm caused to a person because of delayed treatment. The nurse has an obligation to pursue needed care through the established chain of command at the facility.

Malpractice: Limiting Loss

Negligence is the failure to perform as a reasonable, prudent person of similar background would act in a similar situation. Negligence may consist of doing something that should not be done or failing to do something that should be done.

Malpractice is negligence by professionals such as nurses and physicians in the performance of their duties. Nurses may be accused of malpractice if they do not perform according to established standards of care and in the manner of a reasonable, prudent nurse with similar education and experience in a similar situation. Four elements must be present to prove negligence: duty, breach of duty, damage, and proximate cause.

CRITICAL TO REMEMBER

Elements of Negligence

- Duty*—The nurse must have a duty to act or give care to the patient. It must be part of the nurse's responsibility.
- Breach of duty*—A violation of that duty must occur. The nurse fails to conform to established standards in performing that duty.
- Damage*—An actual injury or harm to the patient as a result of the nurse's breach of duty must occur.
- Proximate cause*—The nurse's breach of duty must be proved to be the cause of harm to the patient.

Malpractice claims continue to be a major cost in health care. As a result of awards from such claims, the cost of malpractice insurance has risen for all health care workers. More health care workers practice defensively and accumulate evidence that their actions are in the patient's best interests. For example, nurses must be careful to include detailed data on charts. This responsibility is especially important in perinatal nursing because most suits occur in this area.

Many reasons exist for perinatal malpractice claims. Complications are usually unexpected because parents view pregnancy and birth as normal. The birth of a child with a problem is a tragic shock, and parents may look for someone to blame. Although very small preterm

infants may survive, some have long-term disabilities that require expensive care. Statutes of limitations vary among different states, but plaintiffs often have more than 20 years for filing lawsuits that involve a newborn. Therefore, the period during which a malpractice suit may be filed is longer.

Health care agencies and individual nurses must work together to prevent malpractice claims. Nurses are responsible and accountable for their own actions. Therefore, they must be aware of the limits of their knowledge and scope of practice, and they must practice within those limits.

Prevention of claims is sometimes referred to as *risk management* or *quality assurance*. Although prevention of all malpractice claims is impossible, nurses can prevent malpractice judgments against themselves by following guidelines for informed consent, refusal of care, and documentation; acting as a patient advocate; and maintaining their levels of expertise.

Informed Consent

When patients receive adequate information, they are less likely to file malpractice suits. Informed consent is an ethical concept that has been enacted into law. Patients have the right to decide whether to accept or reject treatment options as part of their right to function autonomously. To make wise decisions, they need full information about treatments offered.

CRITICAL TO REMEMBER

Requirements of Informed Consent

- Patient's competence to consent
- Full disclosure of information needed
- Patient's understanding of information
- Patient's voluntary consent

Competence. Certain requirements must be met before consent is considered informed. First, the patient must be competent, or able to think through a situation and make rational decisions. Infants, children, and patients who are comatose or severely cognitively impaired are incapable of making such decisions. A patient who has received drugs that impair the ability to think is temporarily incompetent. In these cases, another person is appointed to make decisions for the patient.

In most states, the age of majority (the age at which a person can give consent to medical treatment) is 18 years. However, in some states, younger adolescents can consent independently to some treatments such as those for mental illness, abortions, contraceptives, drug abuse, and sexually transmitted diseases (STDs). An **emancipated minor** is younger than the age of majority, usually 18 years, and considered medically competent to make some medical decisions independent of a parent or guardian. Pregnant adolescents may be considered emancipated minors in some states. Nurses must be familiar with laws governing age of consent in their practice area.

Another exception to the usual requirement of informed consent is in emergency circumstances because in such situations, consent is considered implied. Treatment may proceed if evidence that the patient does not want the treatment is lacking. *Emergency* may be specifically defined by state law and is usually restricted to unforeseen conditions that, if uncorrected, would result in severe disability or death. Emergency consent applies only for the emergency condition and does not extend to any other nonemergency problem that coexists with the emergency condition.

Patient information about advance directives such as a living will, durable power of attorney for health care, and an alternate decision maker for the patient must be assessed on admission to the health care facility. Often, hospitals are required to inform patients about advance directives during the nursing admission assessment. The person who has not made advance directives must be offered the opportunity to make these choices (American Hospital Association, 2012).

Full Disclosure. The second requirement is full disclosure of information, including details of what the treatment entails, the expected results, and the meaning of those results. The risks, side effects, benefits, and other treatment options must be explained to patients. The person also must be informed about the consequences if no treatment is chosen.

Understanding of Information. The third requirement is that the person must comprehend information about proposed treatment. Health care professionals must explain the facts in terms that the person can understand. If a patient does not speak English, an interpreter is required. A patient with hearing impairment must have a sign-language interpreter of the appropriate level to sign all explanations before consent is given. If the information to be provided or obtained is sensitive, foreign language or sign-language interpreters should not be family or friends because these people may interpret selectively rather than objectively. Additionally, patient confidentiality is compromised when nonprofessional interpreters are used for sensitive information. Nurses must be advocates for the patient when they find that the patient does not fully understand or has questions about a treatment. If it is a minor point, the nurse may be able to explain it. Otherwise, the nurse must inform the physician that the patient's misconceptions need to be clarified.

Voluntary Consent. The fourth requirement is that patients must be allowed to make choices voluntarily without undue influence or coercion from others. Although others may give information, the patient alone makes the decision. Patients should not feel pressured to choose in a certain way, and they should not believe that their future care depends on their decision.

Refusal of Care. Occasionally, some persons decline treatment offered by health care workers. Patients refuse treatment when they believe that the benefits of treatment are insufficient to balance the burdens of the treatment or their quality of life after treatment. Patients have the right to refuse care, and they can withdraw agreement to treatment at any time. When a person makes this decision, a number of steps should be taken (Aiken, 2009).

First, the physician or nurse should establish that the patient understands the treatment and consequences of refusal. If the physician is unaware of the patient's decision, the nurse should notify that physician accordingly. The nurse documents on the chart the patient's refusal, explanations given to the patient, and notification of the physician. If the treatment is considered vital to the patient's well-being, the physician discusses with the patient the importance of the treatment and documents the results. Opinions by other physicians may be offered to the patient as well.

Patients may be asked to sign forms indicating that they understand the possible results of treatment refusal. This measure is to defend against any subsequent lawsuit in which a patient claims lack of knowledge of the possible results of a decision. If no ethical dilemma exists, the patient's decision stands.

In cases of an ethical dilemma a referral may be made to the hospital ethics committee. In rare situations, the physician may seek a court ruling to force treatment. For example, when a woman refuses a cesarean birth, her decision may gravely harm the fetus. This situation is the only legal instance in which a person is forced to undergo surgery for the health of another. However, court action is avoided, if possible,

because it places the woman and her caregiver in adversarial positions. In addition, it invades the woman's privacy and interferes with her autonomy and right to informed consent. If legally mandated surgery were to become widespread and cause women to avoid health care during pregnancy, the resulting harm would affect more women and infants than those who would be protected by the surgery.

Coercion is illegal and unethical in obtaining consent. Even though the nurse may strongly believe that a woman should receive the treatment, she should not feel forced to submit to unwanted procedures. Nurses must be sure that personal feelings do not adversely affect the quality of their care. People have the right to good nursing care, regardless of their decisions to accept or reject treatment.

Documentation

Nurses are expected to meet the **standard of care**, or the level of care expected of a professional as determined by laws, professional organizations, and health care agencies. Documentation is the best evidence that a standard of care has been maintained. It includes nurses' notes, fetal monitoring strips, electronic data, flow sheets, care paths, consent forms, and any other data recorded on paper, recorded electronically, or both. In many instances, notations in hospital records are the only proof that care has been given. Unfortunately, the lack of accurate and thorough documentation of care is the most common area found lacking in malpractice cases (Simpson, 2008). When documentation is not present, juries often assume that care was not given.

Documentation must be specific and complete in perinatal nursing. This careful step is critical because of the long statute of limitations when a newborn is involved. Nurses are unlikely to remember situations that happened years in the past and, if sued, must rely on their documentation to explain their care. Documentation must show that nurses assessed the patient appropriately, continually monitored for problems, identified problems and instituted correct interventions, and reported changes in the patient's condition to the primary care provider.

Documenting Fetal Monitoring. Fetal monitor paper strips or stored electronic data are important sources of information about the mother and fetus during labor and birth. Nurses record a great deal of information about nursing care on the monitor strip. Sometimes, the patient requires the nurse's full attention, and completion of other charting must be delayed temporarily. In this situation, the nurse's notes on the monitor strip provide the basis for later charting.

Although monitor strips are a legal part of the chart, paper strips may become lost or separated from the chart, and data on electronic media may be accidentally erased. These risks increase the importance of nurses recording summaries about the fetal condition in the available flow sheets at appropriate intervals. Complete, detailed charting ensures that the nurse's actions will be apparent many years later in a court, even without the monitor strip.

Documenting Discharge Teaching. Discharge teaching is important to ensure that patients know how to take care of themselves and their infants after they leave the facility. To prevent or defend against lawsuits, nurses must document the teaching they perform and the patient's understanding of that teaching. Various documentation forms verify teaching and the degree of understanding about important topics. The nurse should also note the need for reinforcement and the method of providing that reinforcement.

Documenting Incidents. Another form of documentation used in risk management is the incident report, sometimes called a *quality assurance report* or *variance report*. The nurse completes a report when something occurs that might result in legal action, for example, injury to a patient, visitor, or staff member. The report warns the agency's

legal department that a problem may exist. It also identifies situations that might endanger patients in the future. Incident reports are not a part of the patient's chart and should not be referred to on the chart. When an incident occurs, documentation on the chart should include the same type of factual information about the patient's condition that would be recorded in any other situation.

Late entries in documentation may be necessary after an emergency in which the nurse must provide patient care quickly. Late entries must be accurate and objective rather than defensive, especially if the outcome was negative in the entry (Simpson, 2008).

The Nurse as Patient Advocate

The plaintiff may win a malpractice suit if the nurse fails in the role of patient advocate. Nurses are ethically and legally bound to act as the patient's advocate. When nurses feel that the patient's best interests are not being served, they are obligated to seek help from appropriate sources. This usually involves relaying the problem through the facility's chain of command. The nurse consults a supervisor and the patient's physician. If the results are not satisfactory, the nurse continues through administrative channels to the director of nurses, hospital administrator, and chief of the medical staff, if necessary. All nurses should know the chain-of-command process for their workplaces.

Nurses must document their efforts to seek help for patients. For example, when postpartum patients are experiencing excessive bleeding, nurses document the methods used to control the bleeding. They also document each time they call the physician, the information given to the physician, and the response received. When nurses cannot contact the physician or do not receive adequate instructions, they should document their efforts to seek instruction from others such as the supervisor. They should also complete an incident report. Nurses must continue their efforts until the patient receives the care needed.

Maintaining Expertise

The nurse can also reduce malpractice liability by maintaining expertise. To ensure that nurses maintain their expertise in provision of safe care, states require proof of continuing education for renewal of nursing licenses. Nursing knowledge grows and changes rapidly, and all nurses must keep current. New information from classes, conferences, and professional publications can help nurses perform as would a reasonably prudent peer. Nurses should analyze research articles to determine whether changes in patient care are indicated by the research evidence.

Employers often provide continuing education classes for their nurses through conferences, satellite television systems, computer networks, and other means. Membership in professional organizations such as state branches of the American Nurses Association (ANA) or in specialty organizations such as AWHONN, gives nurses access to new information through publications, nursing conferences, and other educational offerings. Continuing nursing education is also widely available on the Internet.

Expertise is a concern when nurses are "floated," or required to work with patients whose needs differ from those of the nurses' usual patients. A nurse may be floated from one maternal-newborn setting to another or to a nonmaternity setting. In these situations, nurses need cross-training, which includes orientation and education to perform care safely in new areas. The employer must provide appropriate cross-training for nurses who float. Nurses who work outside their usual area of expertise must assess their own skills and avoid performing tasks or taking responsibilities in areas until they have been educated to be competent in those areas.

COST CONTAINMENT AND DOWNSIZING

Measures to lower health care costs continue to directly and indirectly affect nurses' work (see [Chapter 1](#)). Two measures of special concern are the use of unlicensed assistive personnel and brief length of stay (LOS) for patients.

Delegation to Unlicensed Assistive Personnel

Delegation of care to an unlicensed person may allow the nurse to focus on greater needs within their group of patients. Orientation and education of unlicensed assistive personnel (UAP) must be completed and is competency based in both initial training and ongoing evaluations. UAP must be identified to the patient as a nonlicensed person.

Nurses must be aware that they remain legally responsible for patient assessments and must make the critical judgments necessary to ensure patient safety when delegating tasks to UAP. Nurses must know the capabilities of each unlicensed person who is caring for patients and must supervise them sufficiently to ensure his or her competence. The ANA, the AWHONN, and the state boards of nursing have issued statements to help nurses understand their roles in working with UAP. The ANA is in the process of revising *Principles for Delegation by Registered Nurses to Unlicensed Assistive Personnel (UAP)*, July 2012. The AWHONN's revised and reaffirmed position statement is titled *The Role of Unlicensed Assistive Personnel in the Nursing Care for Women and Newborns* (2009b).

Early Discharge

Regardless of the patient's diagnosis, the time from admission to discharge is as short as possible to keep costs in check and to reduce chances for a hospital-acquired infection. Because birth is considered a normal event that does not require a long LOS, care of new mothers and infants requires teaching from the earliest encounters. In 1996, federal legislation was passed to require that insurance companies allow the option of a 48-hour hospital LOS after vaginal birth and a 4-day LOS after cesarean birth. Discharge may be earlier, if deemed appropriate, after discussion between the physician or midwife and the patient. Although it is not required by federal law, many states mandate prompt follow-up for early discharge in the patient's home, an office, or a clinic. Some third-party payers voluntarily cover home visits for mothers who opt for earlier discharge because of the lower total cost for the home visit plus a short hospital LOS. Procedures other than birth that often have a brief LOS include angiography, modified radical mastectomy, vaginal hysterectomy, or uterine artery embolization for fibroids. Technology such as robotic-assisted procedures have now turned many once-invasive surgeries into day or overnight surgeries.

Concerns about Early Discharge

Although advantages of early discharge include reduced risk for hospital-acquired infection and prompt ambulation, concerns also

exist for newly delivered women. Nurses and other health care providers should be concerned about the new mother's ability to care for herself and her baby so soon after birth. Women may be exhausted from a long labor or complicated birth and unable to absorb all the information nurses attempt to teach before discharge. Once home, many new mothers must also care for other children, often without the assistance of family members or friends.

Nurses may detect early signs of maternal or infant complications that may not be evident to parents while in the health care facility. Parents at home may not recognize the development of a serious maternal or neonatal infection or jaundice, and care may be delayed until the illness has become severe. The ethical and legal implications of sending a mother home before she is ready to adequately care for herself and her newborn are very real concerns for nurses who must balance cost constraints with patient needs.

Similar problems may occur in the older woman who must care for herself after an inpatient or outpatient procedure. Sedating drugs given for a procedure may have prolonged effects, especially on older adults. Although the older woman may appear to understand all instructions and sign papers that indicate her understanding, she may not remember what was taught after returning home. Therefore, it is ideal that a trusted friend or family member be taught with the patient and that printed or online instructions in simple language be provided. Follow-up phone calls or visits are often scheduled within 2 weeks to reevaluate the healing process after a procedure (Wilson, 2011).

Methods to Deal with Short Lengths of Stay

Teaching begins at admission. Self-care during pregnancy or in women's health begins at first encounter. More teaching must occur during pregnancy when the mother's physical needs do not interfere with her ability to comprehend the new knowledge. In the facility, careful documentation and notification of the primary care provider are essential so that patients are not discharged inappropriately if abnormal findings develop. Self-care and infant-care discharge instructions should be explained to the woman and her support person. A printed form, signed by both the patient and the nurse, is placed in the chart with a copy given to the woman for later reference in self-care and care of the baby. Other methods for follow-up such as home visits, phone calls, and return visits to the birth facility for nursing assessments after discharge may identify complications early when they can be addressed most effectively.

Nursing follow-up by phone calls, sometimes called *phone triage*, is the least expensive of postdischarge methods. However, the nurse does not see or physically examine the patient or her infant, and specific protocols and procedures should be in place for the triage call and for nursing actions that should be taken if a potential problem is identified during the call. Documentation should be kept on a form developed for follow-up phone calls. Any instructions given to the patient (recommended actions if problems arise, if a minor problem does not improve, or if a problem worsens) during phone triage must be documented.

SUMMARY CONCEPTS

- Ethical dilemmas are a difficult area of practice and are best solved by applying common ethical methods and principles and the steps of the nursing process.
- When ethical principles of beneficence, nonmaleficence, autonomy, and justice result in ethical dilemmas, the nursing process may be used to guide ethical decision making.
- Elective termination of pregnancy is a controversial issue that generates strong feelings in two opposing factions in the United States. Supreme Court decisions have limited or upheld the right of states to impose restrictions on abortion.
- Nurses must examine their beliefs and resolve personal decisions about abortion before they are faced with the situation in their own practices.
- When using online communications to transmit data about patients, colleagues, or facilities, nurses must be careful not to violate confidentiality and to maintain ethical conduct.
- Punitive approaches to ethical and social problems may prevent women from seeking adequate prenatal care.
- Issues in fetal therapy include weighing the risks and benefits for the mother versus those for the fetus and determination of whose rights should prevail.
- Issues in infertility concern the high cost and low success rate of some treatments, the fate of unused embryos and multiple fetuses, and the rights of surrogate parents.
- Poverty is a major social issue that underlies adequacy of health care resources, access to prenatal care, government programs to increase health care to indigent women and children, and health care rationing.
- Nurses are expected to perform in accordance with nurse practice acts, standards of care, and agency policies. Doing so provides the best prevention of, or defense against, malpractice claims.
- Nurses can help defend malpractice claims by following guidelines for informed consent, refusal of care, and documentation and by maintaining their levels of expertise.
- To give informed consent, the patient must be competent, receive full information, understand that information, and consent voluntarily.
- Complete and timely documentation is the best evidence that the standard of care received by a patient was met. Therefore, nurses must ensure their documentation accurately reflects the care given. Late entry documentation should be avoided, if possible.
- Continuing pressures on optimal nursing practice include use of unlicensed assistive personnel and short lengths of stay.

Reproductive Anatomy and Physiology

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain female and male sexual development from prenatal life through sexual maturity.
2. Describe the normal anatomy of the female and male reproductive systems.
3. Explain the normal function of the female and male reproductive systems.
4. Explain the normal structure and function of the female breast.

An understanding of the structure and function of the reproductive organs is necessary for the effective nursing care of women during and after their reproductive years and for couples that require family planning or infertility care. This chapter reviews basic prenatal development, sexual maturation, and the structure and function of the female and male reproductive systems. Because of its emphasis in this book, the female reproductive system is discussed most extensively.

SEXUAL DEVELOPMENT

Sexual development begins at conception when the **genetic sex** is determined by the union of an ovum and a sperm. During childhood, the sex organs are inactive. They become active during puberty as the person begins sexual maturation.

Prenatal Development

The mother's ovum carries a single X chromosome. Each of the father's spermatozoa carries either an X chromosome or a Y chromosome. If an X-bearing spermatozoon fertilizes the ovum, the offspring's genetic sex is female. If a Y-bearing spermatozoon fertilizes the ovum, a genetic male offspring results.

Although genetic sex is determined at conception, the reproductive systems of males and females are similar, or sexually undifferentiated, for the first 6 weeks of prenatal life. During the seventh week, differences between males and females appear in the internal structures. The external genitalia continue to look similar until the ninth week when these outer structures begin to change. Differentiation of the external sexual organs is complete at about 12 weeks of gestational age.

The basic trend for prenatal sexual development is to have female structures. The presence of only a small part of the Y chromosome (the short arm) changes this trend and directs the early (primitive) sex cells to become testes. The absence of the critical part of the Y chromosome allows the primitive sex cells to continue on their course of becoming ovaries (see [Chapter 6](#)).

During fetal life, both ovaries and testes secrete their primary hormones, which are estrogen and testosterone, respectively. Testosterone causes development of male sex organs and external genitalia, and its absence results in development of female sex characteristics. Although estrogen is secreted by the fetal ovary, the hormone is not required to initiate development of female sex structures.

Childhood

The sex glands of girls and boys are inactive during infancy and childhood. At sexual maturity the hypothalamus stimulates the anterior pituitary gland to produce hormones, which, in turn, stimulate sex hormone production by the **gonads**, reproductive (sex) glands.

Sexual Maturation

Puberty refers to the time during which the reproductive organs become fully functional. It is not a single event but a series of changes that occurs over several years during late childhood and early adolescence. Primary sex characteristics relate to the maturation of those organs directly responsible for reproduction. Examples of primary sex characteristics are maturation of ova in the ovaries and production of sperm in the testes. **Secondary sex characteristics** are changes in other

TABLE 4-1 COMPARISON OF SECONDARY SEX CHARACTERISTICS IN FEMALES AND MALES

FEMALES	MALES
Development of glandular and ductal systems in breast; deposition of fat selectively in breast, buttocks, and thighs, resulting in a rounded figure	Muscle mass 50% greater
Wide, round pelvis	Narrow, upright, and heavier pelvis
Pubic and axillary hair	Pubic and axillary hair; facial and chest hair; increased amount of hair on upper back in some males; male pattern baldness, beginning on top of head
Soft, smooth skin texture	Coarser skin
Higher-pitched voice	Deeper voice

systems that differentiate females and males but do not directly relate to reproduction (Table 4-1).

Initiation of Sexual Maturation

Changes of puberty occur in an orderly sequence in the **somatic sex cells** (body cells other than the gametes) of both genders. Not all factors that initiate sexual maturation are known. Secretions of the hypothalamus, anterior pituitary, and gonads all play a role. The hypothalamus can secrete **gonadotropin-releasing hormone** (GnRH) to initiate puberty during infancy and early childhood, but it does not do so in significant amounts until late childhood. Production of even tiny quantities of sex hormones by the young child's ovaries or testes inhibits secretions of the hypothalamus, preventing premature onset of puberty. Maturation of another brain area, as yet unknown, probably triggers the hypothalamus to initiate puberty (Hall, 2011).

The maturing child's hypothalamus gradually increases production of GnRH beginning at age 9 to 12 years (Blackburn, 2013; Hall, 2011; Jones, 2009a,c). The level of GnRH increases slowly until it reaches a level adequate to stimulate the anterior pituitary to increase its production of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The ovaries and testes increase production of sex hormones and begin maturing **gametes** (reproductive cells, an ovum in the female and a sperm in the male) in response to higher levels of FSH and LH. Sex hormones also induce development of secondary sex characteristics. Table 4-2 lists the major hormones that play a role in reproduction.

The age at which changes of puberty begin and the time required to complete these changes vary among individuals. Hormonal changes of puberty begin about 6 months to 1 year earlier in girls than in boys. The growth spurt that occurs with puberty also begins earlier for girls than for boys. The obvious changes of puberty in girls, such as breast development and height increase, begin an average of 2 years before changes in boys. Changes of puberty occur in an orderly sequence in both genders. Increases in height and weight are dramatic during puberty but slow after puberty until mature heights and weights are attained. The nutritional state can also influence the start of puberty, with earlier onset occurring in well-nourished children.

Female Puberty Changes

As girls mature, the anterior pituitary gland secretes increasing amounts of FSH and LH in response to the hypothalamic secretion of

GnRH. These two pituitary secretions stimulate secretion of estrogens and progesterone by the ovary, resulting in maturation of the reproductive organs and breasts and development of secondary sex characteristics. The first noticeable change of puberty in girls, development of the breasts, begins at about 8 to 13 years of age. Menstruation occurs about 2 to 2.5 years after breast development, with an average age range of 9 to 16 years.

Breast Changes. Initially, the nipple enlarges and protrudes. The areola surrounding the nipple enlarges and becomes somewhat protuberant, although less so than the nipple. These changes are followed by growth of the glandular and ductal tissue. Fat is deposited in the breasts to give them the characteristic rounded female appearance. During puberty, a girl's breasts often develop at different rates, resulting in a lopsided appearance until one breast catches up with the other.

Body Contours. The pelvis widens and assumes a rounded, basin-like shape that favors passage of the fetus during childbirth. Fat is deposited selectively in the hips, giving them a rounder appearance than those of the male.

Body Hair. Pubic hair first appears downy and becomes thicker as puberty progresses. Axillary hair appears near the time of menarche. The texture and quantity of pubic and axillary hair vary among women and ethnic groups. Women of African descent usually have body hair that is coarser and curlier than that of white women. Asian women often have sparser body hair compared with women of other racial groups.

Skeletal Growth. Girls grow taller for several years during early puberty in response to estrogen stimulation. The growth spurt begins about 1 year after breast development begins. Estrogen's other powerful effect on the skeleton is to cause the epiphyses (growth areas of the bone) to unite with the shafts of the bones, which eventually stops growth in height.

Reproductive Organs. The girl's external genitalia enlarge as fat is deposited in the mons pubis, labia majora, and labia minora. The vagina, uterus, fallopian tubes, and ovaries grow larger. In addition, the vaginal mucosa changes, becoming more resistant to trauma and infection in preparation for sexual activity. Cyclic changes in the reproductive organs occur during each female reproductive cycle.

Menarche. Approximately 2 to 2.5 years after the beginning of breast development, girls experience their **menarche**, or the first menstrual period. Early menstrual periods are often irregular and scant. These early menstrual cycles are not usually fertile because ovulation occurs inconsistently. Fertile reproductive cycles require preparation of the uterine lining precisely timed with ovulation. However, ovulation may occur during any female reproductive cycle, including the first. The sexually active girl can conceive even before her first menstrual period.

Delayed onset of menstruation is called **primary amenorrhea** if the girl's periods have not begun within 2 years after the onset of breast development or by age 16 years, or if the girl is more than 1 year older than her mother or sisters were when their menarche occurred. **Secondary amenorrhea** describes absence of menstruation for at least three cycles after regular cycles have been established or for 6 months. Both primary and secondary amenorrhea are more common in females who are thin. Women who are competitive athletes or ballet dancers or suffer from eating disorders (such as anorexia nervosa or bulimia) may have too little fat to produce enough sex hormones to stimulate ovulation and menstruation. Pregnancy is also a common cause of secondary amenorrhea. Both primary and secondary amenorrhea may result from inadequate pituitary stimulation of the ovary or failure of the ovary to respond to pituitary stimulation. Amenorrhea also may be caused by excessive androgenic hormones from the adrenal glands, which have a masculinizing effect.

TABLE 4-2 MAJOR HORMONES IN REPRODUCTION

PRODUCED BY	TARGET ORGANS	ACTION IN FEMALE	ACTION IN MALE
Gonadotropin-Releasing Hormone			
Hypothalamus	Anterior pituitary	Stimulates release of FSH and LH, initiating puberty and sustaining female reproductive cycles; release is pulsatile.	Stimulates release of FSH and LH, initiating puberty; release is pulsatile.
Follicle-Stimulating Hormone			
Anterior pituitary	Ovaries (female) Testes (male)	Stimulates final maturation of follicle. Stimulates growth and maturation of graafian follicles before ovulation.	Stimulates Leydig cells of testes to secrete testosterone.
Luteinizing Hormone			
Anterior pituitary	Ovaries (female) Testes (male)	Stimulates final maturation of follicle. Surge of LH about 14 days before next menstrual period causes ovulation. Stimulates transformation of graafian follicle into corpus luteum, which continues secretion of estrogens and progesterone for about 12 days if ovum is not fertilized. If fertilization occurs, placenta gradually assumes this function.	Stimulates Leydig cells of testes to secrete testosterone.
Estrogens			
Ovaries and corpus luteum (female) Placenta (pregnancy) Formed in small quantities from testosterone in Sertoli cells of testes (male); other tissues, especially liver, produce estrogen in male	Internal and external reproductive organs Breasts (female) Testes (male)	Reproductive organs: a. Maturation at puberty b. Stimulation of endometrium before ovulation Breasts: induce growth of glandular and ductal tissue; initiate deposition of fat at puberty. Stimulate growth of long bones but cause closure of epiphyses, limiting mature height. Pregnancy: stimulate growth of uterus, breast tissue; inhibit active milk production; relax pelvic ligaments.	Necessary for normal sperm formation.
Progesterone			
Ovary, corpus luteum, placenta	Uterus, female breasts	Stimulates secretion of endometrial glands; causes endometrial vessels to become dilated and tortuous in preparation for possible embryo implantation. Pregnancy: induces growth of cells of fallopian tubes and uterine lining to nourish embryo; decreases contractions of uterus; prepares breasts for lactation but inhibits prolactin secretion.	Not applicable
Prolactin			
Anterior pituitary	Female breasts	Stimulates secretion of milk (lactogenesis); estrogen and progesterone from placenta have an inhibiting effect on milk production until after placenta is expelled at birth; suckling of newborn stimulates prolactin secretion to maintain milk production.	Not applicable.
Oxytocin			
Posterior pituitary	Uterus, female breasts	Uterus: stimulates contractions during birth and stimulates postpartum contractions to compress uterine vessels and control bleeding. Stimulates let-down, or milk-ejection reflex, during breastfeeding.	Not applicable.
Testosterone			
Adrenal glands (female) Ovaries (female)	Sexual organs (male) Male body conformation after puberty	Small quantities of androgenic (masculinizing) hormones from adrenal glands cause growth of pubic and axillary hair at puberty; most androgens, such as testosterone, are converted to estrogen.	Induces development of male sex organs in fetus. Induces growth and division of cells that mature sperm. Induces development of male secondary sex characteristics.

FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Male Puberty Changes

Secretion of GnRH by the hypothalamus stimulates secretion of LH and FSH from the anterior pituitary. LH and FSH then stimulate secretion of testosterone and eventually cause **spermatogenesis**, or formation of male gametes, or sperm, in the maturing adolescent. Testosterone stimulates development of a boy's reproductive organs and secondary sex characteristics. The first outward sign of male puberty is growth of the testes, which may begin as early as 9.5 years of age. Penile growth begins about 1 year later as the circumference and length of the penis increase. Final male sexual maturation is complete at approximately 16.5 years of age (Blackburn, 2013; Hall, 2011). The skin of the scrotum thins and darkens as the sexual organs mature.

Nocturnal Emissions. Often called *wet dreams*, nocturnal emissions commonly occur during the teenage years. The boy experiences a spontaneous ejaculation of seminal fluid during sleep, often accompanied by dreams with sexual content. Boys should be prepared for this normal occurrence so that they do not feel abnormal or ashamed or fear that they have an infection or other problem.

Body Hair. Pubic hair growth begins at the base of the penis. Gradually, the hair coarsens and grows upward and in the midline of the abdomen. About 2 years later, axillary hair appears. Facial hair begins as a fine, downy mustache and progresses to the characteristic beard of the adult male. In most boys, chest hair develops, and some boys have hair on their upper backs. The amount and character of body hair vary among men of different racial groups, with Asian and Native American men often having less than white or African men. The quantity and character of body hair among men of the same racial group also vary.

Body Composition. Because of the influence of testosterone, men develop a greater average muscle mass compared with women. At maturity a man's muscle mass exceeds the woman's by an average of 50%, explaining the biologic advantage of men in tasks requiring muscle strength.

Skeletal Growth. Testosterone causes boys to undergo a rapid growth spurt, especially in height. A boy's linear growth begins about 1 year later than a girl's and may continue into his twenties. Testosterone eventually causes union of the epiphysis with the shaft of long bones, as estrogen does in girls. The height-limiting effect of testosterone is not as strong as that of estrogen in females, with the result that boys grow in stature for several years longer than girls do. The male's greater average height at maturity is the combined result of beginning the growth spurt at a slightly later age and continuing it for a longer time.

A boy's shoulders broaden as his height increases. His pelvis assumes a more upright shape, with narrower diameters and heavier composition than the female's. A man's pelvis is structurally suited for tasks requiring load bearing.

Voice Changes. Hypertrophy of the laryngeal mucosa and enlargement of the larynx cause the male's voice to deepen. Before reaching their lower tones at maturity, many boys experience embarrassing "cracking" or "squeaking" of their voices when they speak.

Decline in Fertility

The **climacteric** is a transitional period, which starts as female fertility declines and extends through menopause and the postmenopausal period. In most women, the climacteric occurs between ages 40 and 50 years. Maturation of ova and production of ovarian hormones gradually decline. The external and internal reproductive organs atrophy somewhat as well. **Menopause** is the term used to describe the final menstrual period. However, *menopause* (permanent cessation of menstruation) and *climacteric* are often used interchangeably to describe the entire gradual process of change. Perimenopause is the time from

the onset of changes associated with the climacteric, continuing for approximately 2 to 5 years after the last menstrual period (Blackburn, 2013; Hall, 2011). (See Chapters 33 and 34 for more information about the woman's needs during this phase of her life.)

Men do not experience a distinct marker event like menopause. Production of testosterone and sperm gradually declines, and sexual function decreases in the late forties and fifties.

FEMALE REPRODUCTIVE ANATOMY

The nurse needs a basic knowledge of the structure and function of the external and internal reproductive organs to understand their roles in pregnancy and childbirth (Table 4-3).

External Female Reproductive Organs

Collectively, the external female reproductive organs are called the *vulva*. These structures include the mons pubis, labia majora and minora, clitoris, structures of the vestibule, and perineum (Figure 4-1).

Mons Pubis

The mons pubis is the rounded, fleshy prominence over the symphysis pubis that forms the anterior border of the external reproductive organs. It is covered with varying amounts of pubic hair.

Labia Majora and Minora

The labia majora are two rounded, fleshy folds of tissue that extend from the mons pubis to the perineum. They have a slightly deeper

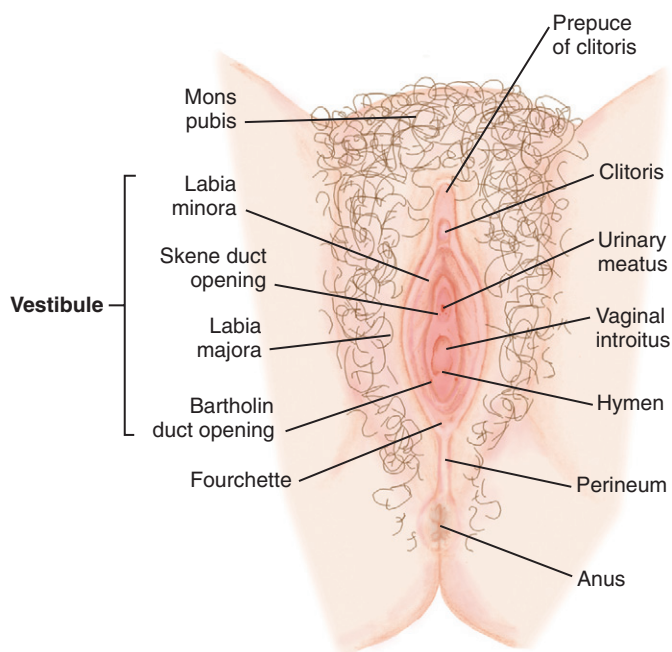

FIG 4-1 External female reproductive structures.

pigmentation than surrounding skin and are covered with pubic hair. The labia majora protect the more fragile tissues of the external genitalia.

The labia minora run parallel to and within the labia majora. The labia minora extend from the clitoris anteriorly and merge posteriorly to form the fourchette, which is the posterior rim of the vaginal introitus, or vaginal opening. The labia minora do not have pubic hair. They are highly vascular and respond to stimulation by becoming engorged with blood.

Clitoris

The clitoris is a small projection at the anterior junction of the two labia minora. This structure is composed of highly sensitive erectile tissue similar to that of the penis. The labia majora merge to form a prepuce over the clitoris.

Vestibule

The *vestibule* refers to structures enclosed by the labia minora. The urinary meatus, vaginal introitus, and ducts of Skene and Bartholin glands lie within the vestibule. Skene, or periurethral, glands provide lubrication for the urethra. Bartholin glands provide lubrication for the vaginal introitus, particularly during sexual arousal.

The vaginal introitus is surrounded by erectile tissue. During sexual stimulation, blood flows into the erectile tissue, allowing the introitus to tighten around the penis. This adds a massaging feeling that heightens the male's sexual sensations and encourages ejaculation.

The hymen is a thin fold of mucosa that partially separates the vagina and the vestibule. The intactness, or lack thereof, of the hymen is not a criterion of virginity. The hymen may be broken by injury, tampon use, intercourse, or childbirth.

Perineum

The perineum is the most posterior part of the external female reproductive organs. The perineum extends from the fourchette anteriorly to the anus posteriorly. It is composed of fibrous and muscular tissues that provide support for pelvic structures. The perineum may be

lacerated during childbirth, or it may be incised to enlarge the vaginal opening in a procedure called an *episiotomy*.

Internal Female Reproductive Organs

The internal reproductive structures are the vagina, the uterus, fallopian tubes, and ovaries (Figures 4-2 and 4-3). These organs are supported and contained within the bony pelvis.

Vagina

The vagina is a tube of muscular and membranous tissue about 8 to 10 cm long that lies between the bladder anteriorly and the rectum posteriorly. The vagina connects the uterus above with the vestibule below. The vaginal lining has multiple folds, or *rugae*, and a muscular layer capable of marked distention during childbirth. The vagina is lubricated by secretions of the cervix (the lowermost part of the uterus) and Bartholin glands.

The vagina does not end abruptly at the uterine opening but arches to form a pouchlike structure called the *vaginal fornix*. Each fornix is described by its location: anterior, posterior, and lateral.

The vagina has three major functions: (1) it allows discharge of the menstrual flow; (2) it is the female organ of *coitus* (male–female sexual union); and (3) it allows passage of the fetus from the uterus to outside the mother's body during childbirth.

Uterus

The uterus is a hollow, thick-walled, muscular organ, which is shaped like a flat, upside-down pear. The uterus houses and nourishes the fetus until birth and then contracts rhythmically during labor to expel the fetus. Each month the uterus is prepared for a pregnancy, whether or not conception occurs.

The uterus measures about $7.5 \times 5 \times 2.5$ cm and is larger in women who have borne children. It is suspended above the bladder and is anterior to the rectum. Its normal position is anteverted (rotated forward over the bladder) and slightly anteflexed (flexed forward).

Divisions of the Uterus. The uterus has three divisions: the corpus, the isthmus, and the cervix.

Corpus. The corpus, or body, is the upper division of the uterus. The uppermost part of the uterine corpus, above the area where the fallopian tubes enter the uterus, is the fundus of the uterus.

Isthmus. A narrower transition zone, the isthmus, is located between the corpus of the uterus and the cervix. During late pregnancy the isthmus elongates and is known as the *lower uterine segment*.

Cervix. The cervix is the tubular “neck” of the lower uterus and is about 2 to 3 cm in length. During labor, the cervix effaces (thins) and dilates (opens) to allow passage of the fetus. The os is the opening in the cervix between the uterus and vagina. The upper cervix and lower cervix are marked by the internal os and external os, respectively. The external os of a childless woman is round and smooth. After vaginal birth the external os has an irregular, slitlike shape and may have tags of scar tissue.

Layers of the Uterus. The uterus has three layers: the perimetrium, the myometrium, and the endometrium.

Perimetrium. The perimetrium is the outer peritoneal layer of serous membrane that covers most of the uterus. Laterally the perimetrium is continuous with the broad ligaments on both sides of the uterus.

Myometrium. The myometrium is the middle layer of thick muscle. Most muscle fibers are concentrated in the upper uterus, and their number diminishes progressively toward the cervix. The myometrium contains three types of smooth muscle fiber, each suited to specific functions in childbearing (Figure 4-4):

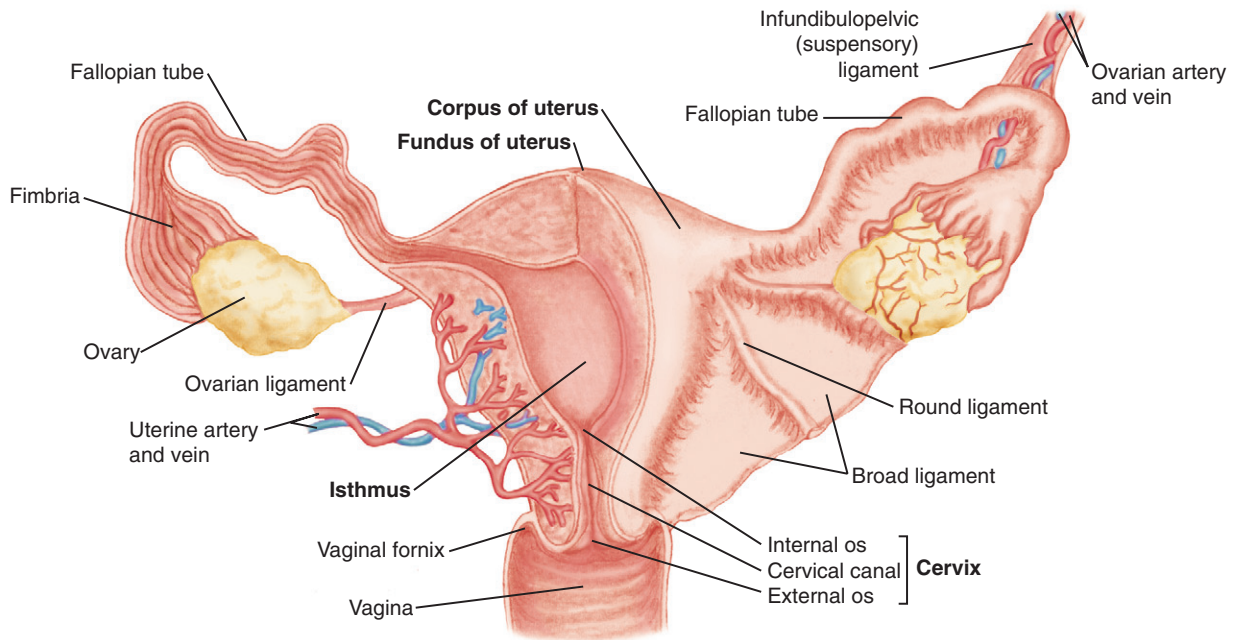

FIG 4-2 Internal female reproductive structures, anterior view.

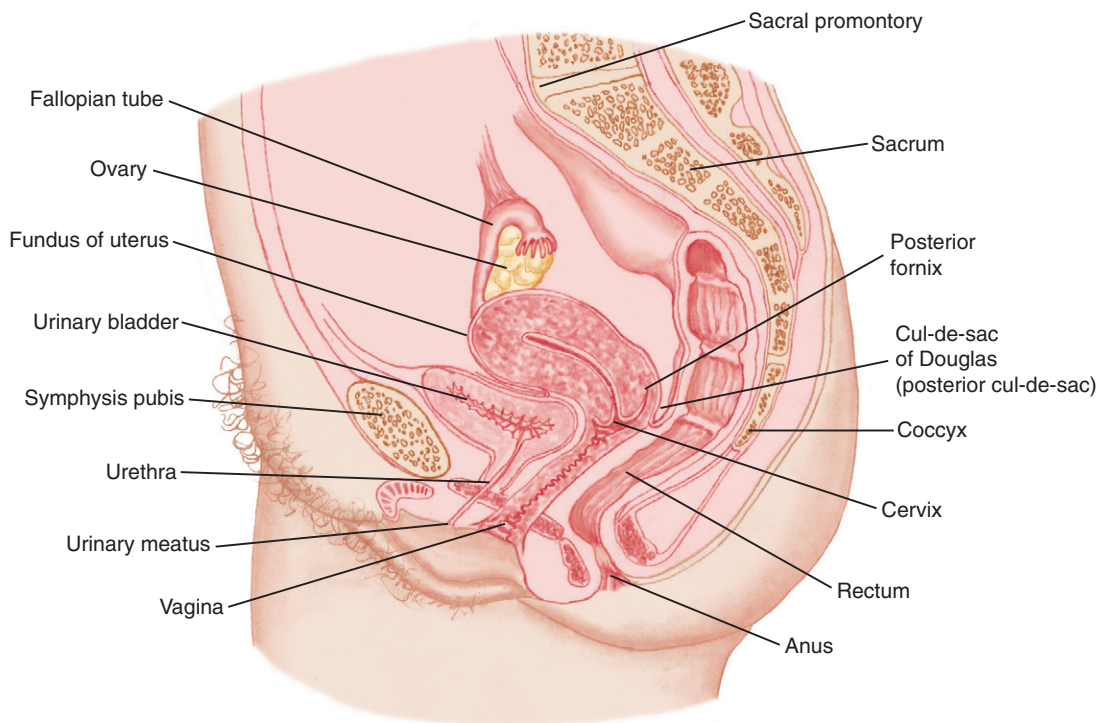

FIG 4-3 Internal female reproductive structures, midsagittal view.

1. Longitudinal fibers are found mostly in the fundus and are designed to expel the fetus efficiently toward the pelvic outlet during birth.
2. Interlacing figure-8 fibers constitute the middle layer. These fibers contract after birth to compress blood vessels that pass between them to limit blood loss.
3. Circular fibers form constrictions where the fallopian tubes enter the uterus and surround the internal cervical os. Circular fibers

prevent reflux of menstrual blood and tissue into the fallopian tubes, promote normal implantation of the fertilized ovum by controlling its entry into the uterus, and retain the fetus until the appropriate time of birth.

Endometrium. The endometrium is the inner layer of the uterus. It responds to the cyclic variations of estrogen and progesterone during the female reproductive cycle (see [Figure 4-7](#), p. 52). The endometrium has two layers:

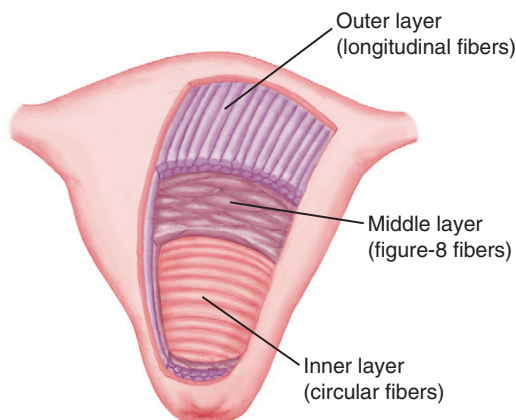

FIG 4-4 Layers of the myometrium showing the three types of smooth muscle fiber.

1. The basal layer is the area nearest the myometrium that regenerates the functional layer of the endometrium after each menstrual period and after childbirth.
2. The functional layer lies above the basal layer. Endometrial arteries, veins, and glands extend into the functional layer and are shed during each menstrual period and after childbirth in the lochia.

Fallopian Tubes

The fallopian tubes, also called *oviducts*, are 8 to 14 cm long and quite narrow (2 to 3 mm at their narrowest and 5 to 8 mm at their widest). They form a pathway for the ovum between the ovary and uterus. Fertilization occurs in the fallopian tubes. Each fallopian tube enters the upper uterus at the cornu, or horn, of the uterus.

The fallopian tubes are lined with folded epithelium containing hairlike processes called **cilia** that beat rhythmically toward the uterine cavity to propel the ovum through the tube. The rough, folded surface of its lining and small diameter make the fallopian tube vulnerable to blockage from infection or scar tissue. Tubal blockage may result in sterility or a tubal (ectopic) pregnancy because the fertilized ovum cannot enter the uterus for proper implantation.

The fallopian tubes have four divisions:

1. The interstitial portion runs into the uterine cavity and lies within the uterine wall.
2. The isthmus is the narrow part adjacent to the uterus.
3. The ampulla is the wider area of the tube lateral to the isthmus, where fertilization occurs.
4. The infundibulum is the wide, funnel-shaped terminal end of the tube. Fimbriae are fingerlike processes that surround the infundibulum.

The fallopian tubes are not directly connected to the ovary. The ovum is expelled into the abdominal cavity near the fimbriae at ovulation. Wavelike motions of the fimbriae draw the ovum into the tube. However, the tubal isthmus remains contracted until 3 days after conception to allow the fertilized ovum to develop within the tube. Initial growth of the fertilized ovum within the fallopian tube promotes its normal implantation in the upper uterus.

Ovaries

The ovaries are the female gonads, or sex glands. They have two functions: (1) sex hormone production and (2) maturation of an ovum during each reproductive cycle.

The ovaries secrete estrogen and progesterone in varying amounts during a woman's reproductive cycle to prepare the uterine lining for

pregnancy. Ovarian hormone secretion gradually declines to very low levels during the climacteric.

At birth, the ovary contains all the ova it will ever have. About two million immature ova are present at birth. Many of these degenerate during childhood, and at puberty about 200,000 to 400,000 viable ova remain. Many ova begin the maturation process during each reproductive cycle, but most never reach maturity. During a woman's reproductive life, only about 400 of the ova ever mature enough to be released and fertilized. By the time a woman reaches the climacteric, almost all her ova have been released during ovulation or have regressed. The few remaining ova are unresponsive to stimulating hormones and do not mature (Blackburn, 2013; Jones, 2009a,b; Moore & Persaud, 2013a,b).

Support Structures

The bony pelvis supports and protects the lower abdominal and internal reproductive organs. Muscles and ligaments provide added support for the internal organs of the pelvis against the downward force of gravity and increases in intraabdominal pressure.

Pelvis

The bony pelvis is a basin-shaped structure at the lower end of the spine (Figure 4-5). Its posterior wall is formed by the sacrum. The side and anterior pelvic walls are composed of three fused bones: the ilium, the ischium, and the pubis.

The linea terminalis, also called the *pelvic brim* or *ileopectineal line*, is an imaginary line that divides the upper, or false, pelvis from the lower, or true, pelvis. The false pelvis provides support for the internal organs and the upper part of the body. The true pelvis is most important during childbirth (see Chapter 12).

Muscles

Paired muscles enclose the lower pelvis and provide support for internal reproductive, urinary, and bowel structures (Figure 4-6). In addition, a fibromuscular sheet, the pelvic fascia, provides support for the pelvic organs. Vaginal and urethral openings are located in the pelvic fascia.

The levator ani is a collection of three pairs of muscles: the pubococcygeus, which is also called the *pubovaginal muscle* in the female; the puborectalis; and the iliococcygeus. These muscles support internal pelvic structures and resist increases in the intraabdominal pressure.

The ischiocavernosus muscle extends from the clitoris to the ischial tuberosities on each side of the lower bony pelvis. The two transverse perineal muscles extend from fibrous tissue of the perineum to the two ischial tuberosities, stabilizing the center of the perineum.

Ligaments

Seven pairs of ligaments maintain the internal reproductive organs and their nerve and blood supplies in their proper positions within the pelvis (see Figure 4-2).

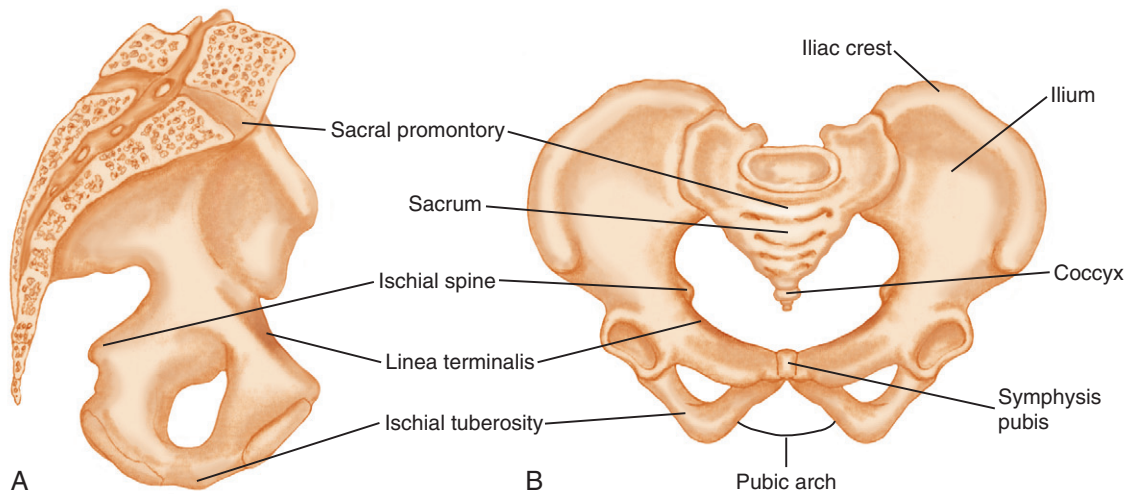

FIG 4-5 Structures of the bony pelvis, shown in lateral (A) and anterior (B) views.

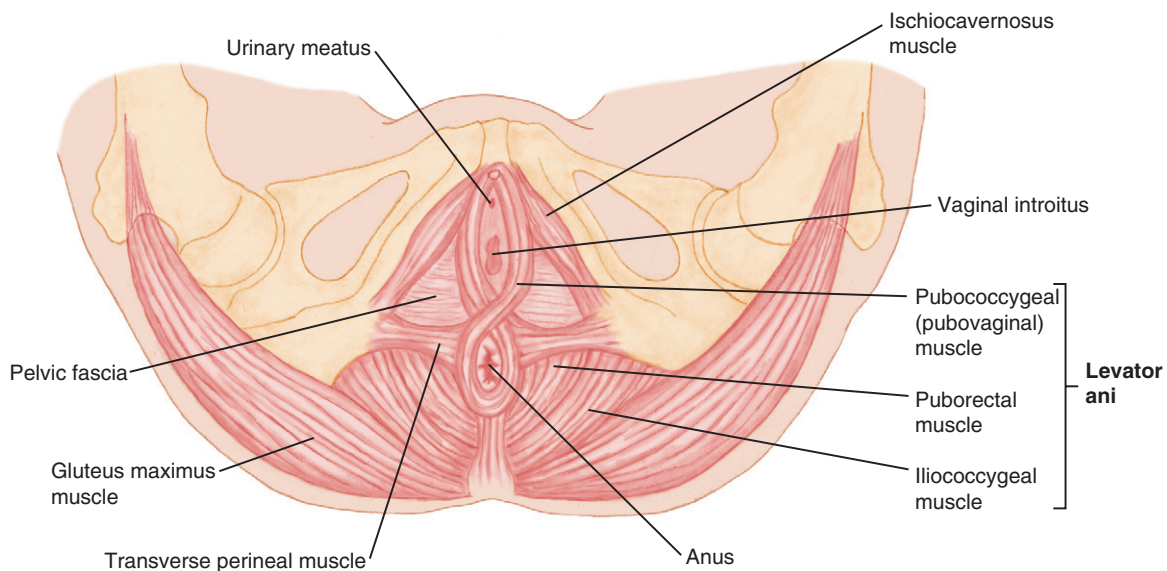

FIG 4-6 Muscles of the female pelvic floor.

Lateral Support. Paired ligaments stabilize the uterus and ovaries laterally and keep them in the midline of the pelvis. The broad ligament is a sheet of tissue extending from each side of the uterus to the lateral pelvic wall. The round ligament and fallopian tube mark the upper border of the broad ligament, and the lower edge is bounded by the uterine blood vessels. Within the two broad ligaments are the ovarian ligaments, blood vessels, and lymphatics.

The right and left cardinal ligaments provide support to the lower uterus and vagina. They extend from the lateral walls of the cervix and vagina to the side walls of the pelvis.

The two ovarian ligaments connect the ovaries to the lateral uterine walls. The infundibulopelvic (suspensory) ligaments connect the lateral ovary and distal fallopian tubes to the pelvic side walls. The infundibulopelvic ligament also carries the blood vessel and nerve supply for the ovary.

Anterior Support. Two pairs of ligaments provide anterior support for the internal reproductive organs. The round ligaments connect the upper uterus to the connective tissue of the labia majora. These ligaments maintain the uterus in its normal anteverted

position and help direct the fetal presenting part against the cervix during labor.

The pubocervical ligaments support the cervix anteriorly. They connect the cervix and anterior surface of the symphysis pubis.

Posterior Support. The uterosacral ligaments provide posterior support, extending from the lower posterior uterus to the sacrum. These ligaments also contain the sympathetic and parasympathetic nerves of the autonomic nervous system.

Blood Supply

The uterine blood supply is carried by the uterine arteries, which are branches of the internal iliac artery. These vessels enter the uterus at the lower border of the broad ligament near the isthmus of the uterus. The vessels branch downward to supply the cervix and vagina and upward to supply the uterus. The upper branch also supplies the ovaries and fallopian tubes. The vessels are coiled to allow for elongation as the uterus enlarges and rises from the pelvis during pregnancy. Blood drains into the uterine veins and from there into the internal iliac veins.

Additional ovarian and tubal blood supply is carried by the ovarian artery, which arises from the abdominal aorta. The ovarian blood supply drains into the two ovarian veins. The left ovarian vein drains into the left renal vein, and the right ovarian vein drains directly into the inferior vena cava.

Nerve Supply

Most functions of the reproductive system are under involuntary, or unconscious, control. Nerves of the autonomic nervous system from the uterovaginal plexus and inferior hypogastric plexus control automatic functions of the reproductive system.

Sensory and motor nerves that innervate the reproductive organs enter the spinal cord at the T12 through L2 levels. These nerves are important for pain management during childbearing (see Chapter 15).

FEMALE REPRODUCTIVE CYCLE

The term *female reproductive cycle* refers to the regular and recurrent changes in the anterior pituitary secretions, ovaries, and uterine endometrium that are designed to prepare the body for pregnancy (Figure 4-7). Associated changes in the cervical mucus promote fertilization during each cycle. The female reproductive cycle is often called the *menstrual cycle* because menstruation provides a marker for each cycle's beginning and end if pregnancy does not occur.

The female reproductive cycle is driven by a feedback loop between the anterior pituitary and ovaries. A feedback loop is a change in the level of one secretion in response to a change in the level of another secretion. The feedback loop may be positive, in which rising levels of one secretion cause another to rise, or negative, in which rising levels of one secretion cause another to fall.

The duration of the cycle is about 28 days, although it may range from 20 to 45 days (Hall, 2011). Significant deviations from the 28-day cycle are associated with reduced fertility. The first day of the menstrual period is counted as day 1 of the woman's cycle. The female reproductive cycle is further divided into two cycles that reflect changes in the ovaries and uterine endometrium.

Ovarian Cycle

In response to GnRH from the woman's hypothalamus, the anterior pituitary secretes FSH and LH. These secretions stimulate the ovaries to mature and release an ovum and secrete additional hormones that will prepare the endometrium for implantation of a fertilized ovum. The ovarian cycle consists of three phases: follicular, ovulatory, and luteal.

Follicular Phase

The follicular phase is the period during which an ovum matures. It begins with the first day of menstruation and ends about 14 days later in a 28-day cycle. The length of this phase varies more among different women than do the lengths of the other two phases. The fall in estrogen and progesterone secretion by the ovary just before menstruation stimulates secretion of FSH and LH by the anterior pituitary. As the FSH and LH levels rise slightly, 6 to 12 **graafian follicles** (sacs within the ovary), each containing an immature ovum, begin to grow. Each follicle secretes fluid containing high levels of estrogen, which accelerates maturation by making the follicle more sensitive to the effects of

FSH. Eventually, one follicle outgrows the others to reach maturity. The mature follicle secretes large amounts of estrogen, which depresses FSH secretion. The dip in FSH secretion just before ovulation blocks further maturation of the less-developed follicles. Occasionally, more than one follicle matures and releases its ovum, which can lead to a multifetal pregnancy. Women who take fertility drugs may release multiple mature ova that are used for assisted reproductive techniques (see Chapter 32).

Ovulatory Phase

Near the middle of a 28-day reproductive cycle and about 2 days before ovulation, LH secretion rises markedly. Secretion of FSH also rises but to a lesser extent than that of LH. These surges in LH and FSH levels cause a slight fall in follicular estrogen production and a rise in progesterone secretion, which stimulates final maturation of a single follicle and release of its ovum. Ovulation marks the beginning of the luteal phase of the female reproductive cycle and occurs about 14 days before the next menstrual period.

The mature follicle is a mass of cells with a fluid-filled chamber. A smaller mass of cells houses the ovum within this chamber. At ovulation a blisterlike projection called a *stigma* forms on the wall of the follicle, the follicle ruptures, and the ovum with its surrounding cells is released from the surface of the ovary, where it is picked up by the fimbriated end of the fallopian tube for transport to the uterus.

Luteal Phase

After ovulation and under the influence of LH, the remaining cells of the old follicle persist for about 12 days as a corpus luteum. The corpus luteum secretes estrogen and large amounts of progesterone to prepare the endometrium for a fertilized ovum. During this phase, levels of FSH and LH decrease in response to higher levels of estrogen and progesterone. If the ovum is fertilized, it secretes a hormone (chorionic gonadotropin) that causes persistence of the corpus luteum to maintain an early pregnancy. If the ovum is not fertilized, FSH and LH fall to low levels, and the corpus luteum regresses. Decline of estrogen and progesterone levels along with corpus luteum regression results in menstruation as the uterine lining breaks down.

The loss of estrogen and progesterone from the corpus luteum at the end of one cycle stimulates the anterior pituitary to again secrete more FSH and LH, initiating a new female reproductive cycle. The old corpus luteum is replaced by fibrous tissue called the *corpus albicans*.

Endometrial Cycle

The uterine endometrium responds to ovarian hormone stimulation with cyclic changes. Three phases mark the changes in the endometrium: proliferative, secretory, and menstrual.

Proliferative Phase

The proliferative phase occurs as the ovum matures and is released during the first half of the ovarian cycle. After completion of a menstrual period the endometrium is very thin. The basal layer of endometrial cells remains after menstruation. These cells multiply to form new endometrial epithelium and endometrial glands under the stimulation of estrogen secreted by the maturing ovarian follicles. Endometrial spiral arteries and endometrial veins elongate to accompany thickening of the functional endometrial layer and nourish the proliferating cells. As ovulation approaches, the endometrial glands secrete thin, stringy mucus that aids entry of sperm into the uterus.

Secretory Phase

The secretory phase occurs during the last half of the ovarian cycle as the uterus is prepared to receive a fertilized ovum. The endometrium

FIG 4-7 The Female Reproductive Cycle. This figure illustrates the changes in hormone secretion from the anterior pituitary and interrelated changes in the ovary and uterine endometrium.

continues to thicken under the influence of estrogen and progesterone from the corpus luteum, reaching its maximum thickness of 5 to 6 mm. The blood vessels and endometrial glands become twisted and dilated.

Progesterone from the corpus luteum causes the thick endometrium to secrete substances to nourish a fertilized ovum. Large quantities of glycogen, proteins, lipids, and minerals are stored within the endometrium, awaiting arrival of the ovum.

Menstrual Phase

If fertilization does not occur, the corpus luteum regresses, and its production of estrogen and progesterone falls. About 2 days before the onset of menstruation, vasospasm of the endometrial blood vessels causes the endometrium to become ischemic and necrotic. The necrotic areas of endometrium separate from the basal layers, resulting in the menstrual flow. The duration of the menstrual phase is about 5 days.

During a menstrual period, women lose about 40 mL of blood. Because of the recurrent loss of blood, many women are mildly anemic during their reproductive years, especially if their diets are low in iron.

Changes in Cervical Mucus

During most of the female reproductive cycle, the mucus of the cervix is scant, thick, and sticky. Just before ovulation, cervical mucus becomes thin, clear, and elastic to promote passage of sperm into the uterus and fallopian tube, where they can fertilize the ovum. *Spinnbarkeit* refers to the elasticity of cervical mucus. A woman may assess the elasticity of her cervical mucus to either avoid or promote conception (see Procedure 31-1).

THE FEMALE BREAST

Structure

The breasts, or mammary glands, are not directly functional in reproduction, but they secrete milk after childbirth to nourish the infant. The small, raised nipple is located at the center of each breast (Figure 4-8). The nipple is composed of sensitive erectile tissue and may respond to sexual stimulation. A larger circular areola surrounds the nipple. Both the nipple and areola are darker than surrounding skin. Montgomery's tubercles are sebaceous glands in the areola. They are inactive and not obvious except during pregnancy and lactation, when they enlarge and secrete a substance that keeps the nipple soft.

Within each breast are lobes of glandular tissue that secrete milk. These lobes are arranged in a pattern similar to spokes of a wheel around the hub. Between 15 and 20 of these lobes are arranged around

and behind the nipple and areola. Fibrous tissue and fat in the breast support the glandular tissue, blood vessels, lymphatics, and nerves.

Alveoli are small sacs that contain acinar cells to secrete milk. The acinar cells extract the necessary substances from the mammary blood supply to manufacture milk when the breasts are properly stimulated by the anterior pituitary gland. Myoepithelial cells surround the alveoli to contract and eject the milk into the ductal system when signaled by secretion of the hormone oxytocin from the posterior pituitary gland.

The alveoli drain into lactiferous ducts, which connect to drain milk from all areas of the breast. The lactiferous ducts become wider under the areola and are called *lactiferous sinuses* in this area. The lactiferous sinuses narrow again as they open to the outside in the nipple.

Function

The breasts are inactive until puberty, when rising estrogen levels stimulate growth of the glandular tissue. In addition, fat is deposited in the breasts, resulting in the mature female contour. The amount of fat is the major determinant of breast size; the amount of glandular tissue is similar for all mature women. Therefore, breast size is unrelated to the amount of milk a woman can produce during lactation.

During pregnancy, high levels of estrogen and progesterone produced by the placenta stimulate growth of the alveoli and ductal system to prepare them for lactation. Prolactin secretion by the anterior pituitary gland stimulates milk production during pregnancy, but this effect is inhibited by estrogen and progesterone produced by the placenta. Inhibiting effects of estrogen and progesterone stop when the placenta is expelled after birth, and active milk production occurs in response to the infant's suckling while breastfeeding.

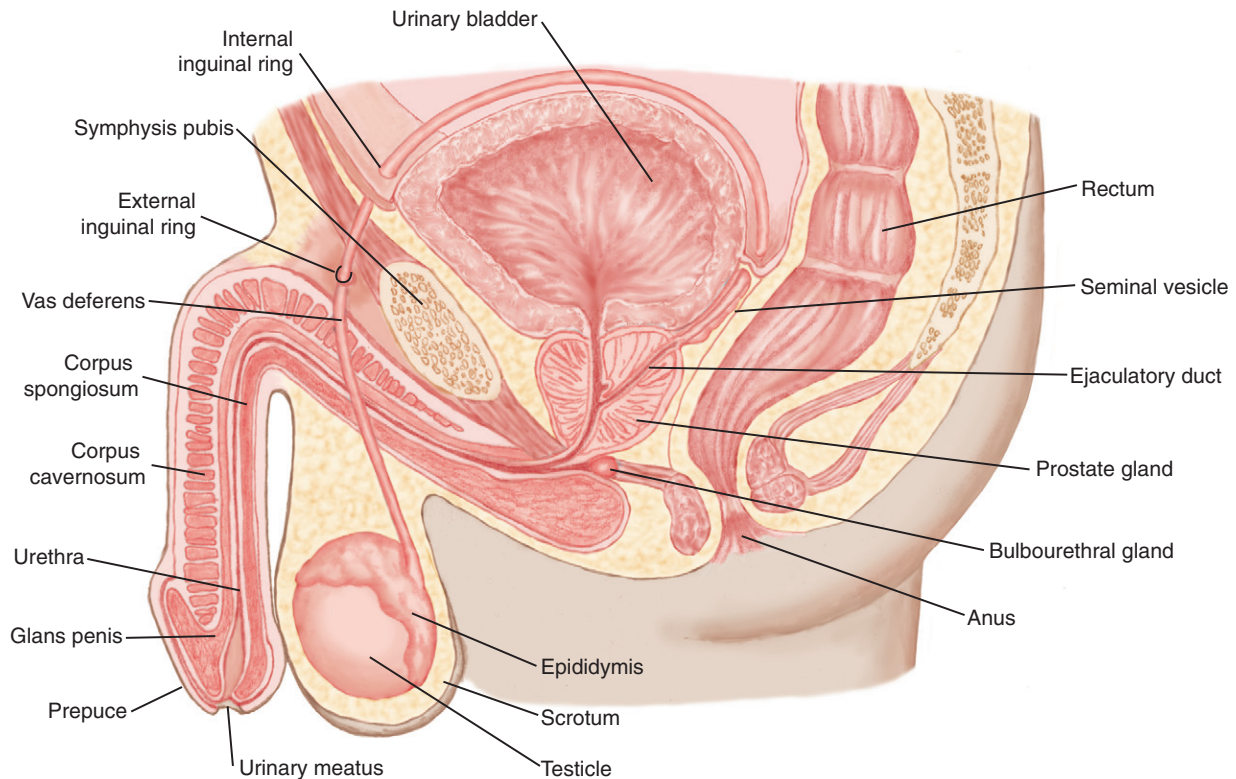

FIG 4-9 Structures of the male reproductive system, midsagittal view.

MALE REPRODUCTIVE ANATOMY AND PHYSIOLOGY

External Male Reproductive Organs

The male has two external organs of reproduction: penis and scrotum (Figure 4-9).

Penis

The penis has two functions. As part of the urinary tract, it carries urine from the bladder to the exterior during urination. As a reproductive organ, the penis deposits semen into the female vagina during coitus.

The penis is composed mostly of erectile tissue, which is spongy tissue with many small spaces inside. The three areas of erectile tissue are the corpus spongiosum, which surrounds the urethra, and two columns of the corpus cavernosum on each side of the penis.

The penis is flaccid most of the time because the small spaces within the erectile tissue are collapsed. During sexual stimulation, arteries within the penis dilate and veins are partly occluded, trapping blood in the spongy tissue. Entrapment of blood within the penis causes erection and enables penetration of the vagina during sexual intercourse.

The glans is the distal end of the penis. The urinary meatus is centered in the end of the glans. The loose skin of the prepuce, or foreskin, covers the glans. The prepuce may be removed during circumcision, a surgical procedure usually performed during the newborn period, although it may be performed later. The glans is very sensitive to tactile stimulation, which adds to the male's sensation during coitus.

Scrotum

The scrotum is a pouch of thin skin and muscle suspended behind the penis. The skin of the scrotum is somewhat darker than the

surrounding skin and is covered with small ridges called *rugae*. The scrotum is divided internally by a septum. One of the male gonads (testicle) is contained within each pocket of the scrotum.

The scrotum's main purpose is to keep the testes cooler than the core body temperature. Formation of normal male sperm requires that the testes not be too warm. A cremaster muscle is attached to each testicle. Contraction of the cremaster muscles draws the testicles closer to the body for warming while relaxation of these muscles allows the testicles to move away from the body for cooling.

Internal Male Reproductive Organs

The functions of the male external and internal reproductive organs are summarized in Table 4-4.

Testes

The male gonads, or testes, have two functions: (1) they serve as endocrine glands and (2) they produce male gametes, or sperm, also called *spermatozoa*. Androgens (male sex hormones) are the primary endocrine secretions of the testes. Androgens are produced by Leydig cells of the testes. The primary androgen produced by the testes is testosterone.

Unlike the female, who experiences a cyclic pattern of hormone secretion, the male secretes testosterone in a relatively even pattern. A feedback loop with the hypothalamus and anterior pituitary stabilizes testosterone levels. A small amount of testosterone is converted to estrogen in the male and is necessary for sperm formation.

Spermatogenesis occurs within tiny coiled tubes, the seminiferous tubules of the testes (Figure 4-10). Leydig cells are interstitial cells that support the seminiferous tubules and secrete testosterone, which is necessary to form new cells that will mature into sperm. Sertoli cells within the seminiferous tubules respond to FSH secretion by

nourishing and supporting sperm as they mature. Unlike the female, who has a lifetime supply of ova in her gonads at birth, the male does not begin producing sperm until puberty. The normal male produces new sperm throughout life, although production declines with age.

At ejaculation, about 35 to 200 million sperm are deposited in the vagina (Blackburn, 2013; Hall, 2011; Jones, 2009c). This large number is needed for normal fertility, although a single sperm fertilizes the ovum. Only a few sperm ever reach the fallopian tube, where an ovum may be available for fertilization. When the first sperm penetrates the ovum, changes within the ovum prevent other sperm from also fertilizing it (see Chapter 6).

Accessory Ducts and Glands

From the seminiferous tubules, sperm pass into the epididymis within the scrotum for storage and final maturation. In the epididymis, sperm

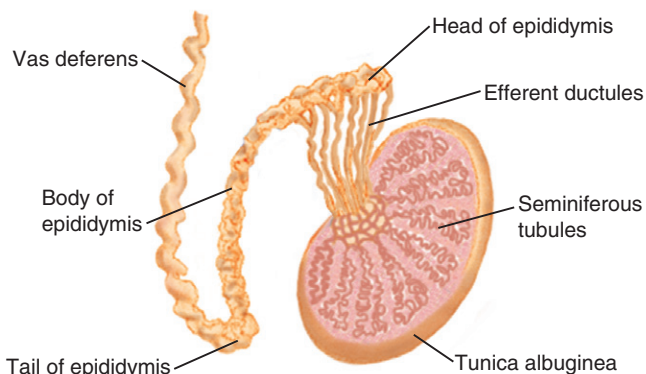

FIG 4-10 Internal Structures of the Testis. Initial production of sperm begins within the tiny, coiled seminiferous tubules. Immature sperm pass from the seminiferous tubules to the epididymis and then to the vas deferens. During their passage through these structures, sperm mature and acquire the ability to propel themselves after ejaculation.

develop the ability to be motile, although secretions within the epididymis inhibit actual motility until ejaculation occurs.

The epididymis empties into the vas deferens, where larger numbers of sperm are stored. The vas deferens then leads upward into the pelvis, then downward toward the penis through the internal and external inguinal rings. Within the pelvis the vas deferens joins the ejaculatory duct before connecting to the urethra.

Three glands—the seminal vesicles, the prostate, and the bulbourethral gland—secrete seminal fluids that carry sperm into the vagina during intercourse. The seminal fluid has four functions: (1) nourishing the sperm, (2) protecting the sperm from the hostile pH (acidic) environment of the vagina, (3) enhancing the motility of the sperm, and (4) washing the sperm from the urethra so that the maximum number are deposited in the vagina.

20. What are the two functions of the penis?
21. What two types of erectile tissue are in the penis? What is their function?
22. Why is it important for the testes to be contained within the scrotum?
23. What are the two functions of the testes?

SUMMARY CONCEPTS

- Initial prenatal development of the reproductive organs is similar for both males and females. If a critical part of the Y chromosome is not present at conception, female reproductive structures will develop.
- During puberty the reproductive organs become fully functional, and secondary sex characteristics develop.
- Puberty begins about 6 months to 1 year earlier in girls than in boys, although the early growth spurt in girls makes it seem that they begin puberty much earlier compared with boys.
- Females are generally shorter than males at the completion of puberty because they begin their growth spurt at an earlier age and complete it more quickly than boys.
- Girls often do not ovulate in early menstrual cycles, although they can ovulate even before the first cycle. Therefore, a girl can become pregnant before her first menstrual period if she is sexually active.
- The onset of puberty is more subtle in boys than in girls, beginning with growth of the testes and penis.
- Boys may have nocturnal emissions of seminal fluid, which may be distressing if the boy has not been educated that these events are normal and expected.
- At birth, a girl has all the ova she will ever have. New ova are not formed after birth; most are depleted when the woman reaches the climacteric.

Continued

SUMMARY CONCEPTS—cont'd

- The female reproductive cycle is often called the *menstrual cycle*. It includes changes in the anterior pituitary gland, ovaries, and uterine endometrium to prepare for a fertilized ovum. The character of cervical mucus also changes during the cycle to encourage fertilization.
- Breast size is unrelated to glandular tissue or the quantity or quality of milk a woman can produce for her infant after birth. Breast size is primarily related to the amount of fat present.
- For normal sperm formation, a man's testes must be cooler than his core body temperature.
- Seminal fluids secreted by the seminal vesicles, the prostate, and the bulbourethral glands nourish and protect the sperm, enhance their motility, and ensure that most sperm are deposited in the vagina during sexual intercourse.

Hereditary and Environmental Influences on Childbearing

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the structure and function of normal human genes and chromosomes.
2. Give examples of ways to study genes and chromosomes.
3. Explain some of the benefits and ethical implications of the Human Genome Project.
4. Describe the characteristics of single gene traits and their transmission from parent to child.
5. Relate chromosomal abnormalities to spontaneous abortion and birth defects in the infant.
6. Explain characteristics of multifactorial birth defects.
7. Identify environmental factors that can interfere with prenatal development and ways to prevent or reduce their negative effects.
8. Describe the process of genetic counseling.
9. Explain the role of the nurse in caring for individuals or families with concerns about birth defects.

Hereditary and environmental forces shape a person's development from before conception until death. As people learn more about genes and their influences on the body's function, they are discovering that genes have more influence on health, disease, and medication effectiveness than was previously thought. The nurse needs a basic knowledge of these forces to better understand disorders evident at birth (**congenital**) and those that develop later in life. This chapter reviews the basics of hereditary influences on development and the impact of environmental factors in causing **birth defects**. The nursing role in relation to genetic knowledge is also discussed.

HEREDITARY INFLUENCES

Hereditary, or **genetic**, influences pertain to development results that direct cellular functions provided by genes that constitute the 46 chromosomes in every somatic cell. Disorders can result if too much or too little genetic material is present in the cells and if one or more genes are abnormal and provide incorrect directions.

Structure of Genes and Chromosomes

A review of the structure of genes and chromosomes aids in understanding the reasons for the occurrence of disorders. Chromosomes

are composed of genes that in turn are composed of deoxyribonucleic acid (DNA) (**Figure 5-1**).

Deoxyribonucleic Acid

DNA is the building block of genes and chromosomes. Its three units are (1) a sugar (deoxyribose), (2) a phosphate group, and (3) one of four nitrogen bases (adenine, thymine, guanine, and cytosine).

DNA resembles a spiral ladder, with a sugar and a phosphate group forming each side of the ladder and a pair of nitrogen bases forming each rung. The four bases of the DNA molecule pair in a fixed way, allowing the DNA to be accurately duplicated during each cell division.

- Adenine pairs with thymine.
- Guanine pairs with cytosine.

The DNA also directs the manufacture of proteins needed for cell function. The sequence of bases within the DNA determines which amino acids will be assembled to form a protein and the order in which they will be assembled for cell processes. Some proteins form the structure of body cells, whereas others are enzymes that control metabolic processes within the cell. If the sequence of nitrogen bases in the DNA is incorrect or some bases are missing or added in critical places, a defect in body structure or function may result.

FIG 5-1 The deoxyribonucleic acid (DNA) helix is the building block of genes and chromosomes.

Bases are arranged in groups of three called *codons* for translation into a specific amino acid in the cell. For example, a triplet base codon may consist of the bases GCC (guanine, cytosine, cytosine), which tells the cell to produce the amino acid alanine. Other codons, known as *stop codons*, signal the end of a gene sequence.

Genes

A **gene** is a segment of DNA that directs the production of a specific product needed for body structure or function. Humans have 23,000 genes arranged on their chromosomes. Only a portion of the long strand of DNA that forms a chromosome makes a single gene. Some genes are active only during prenatal life and others become functional at various times after birth. Gene regulation is the process of turning genes on and off. During early development, cells begin to take on specific functions. Gene regulation ensures that the appropriate genes are expressed at the proper times. Gene regulation also helps an organism respond to its environment. Gene regulation is accomplished by a variety of mechanisms, including chemical modification of genes and the use of regulatory proteins to turn genes on or off (Hall, 2011; Jorde, Carey, & Bamshad, 2010; National Human Genome Research Institute [NHGRI], 2012a).

Genes that code for the same trait often have two or more alternate forms, or **alleles**. Familiar examples of alleles are the ABO blood types. Normal alleles provide genetic variation and sometimes a biologic advantage. If an allele occurs at least 1% of the time in the population, it is called a **polymorphism**.

Some changed gene forms, or **mutations**, may be harmless, but many such as those that cause the production of abnormal hemoglobin in sickle cell disease are harmful. Mutations may cause harm by the following actions:

- Substituting incorrect bases for the normal bases
- Interrupting the normal gene sequence or stopping it prematurely
- Duplicating some bases or entire gene sequences
- Adding or subtracting some bases within those making up a gene's sequence of bases, which will alter the amino acids it causes to be assembled

A mutation may occur in **gametes** (reproductive or germ cells) or **somatic cells** (other body cells). If the mutation occurs in a gamete, the mutation can be transmitted from one generation to the next. Mutations occurring in somatic cells are often associated with malignant change, but they are not transmitted from generation to generation.

Genes are too small to be seen under a microscope, but they can be studied in several ways:

- By measuring the products that they direct cells to produce, such as an enzyme or other substance
- By directly studying the gene's DNA
- By analyzing the gene's close association (linkage) with another gene that can be studied in one of the previous two ways

The tissue used for study of a gene depends on where the gene product is present in the body and the available technology. These tissues may include blood, skin cells, hair follicles, and fetal cells from the amniotic fluid or chorionic villi.

Genes that can be identified by direct analysis of DNA can be studied in any cells containing a nucleus, even if the gene product is not present in that tissue. Although not always used, DNA analysis of the blastomere (eight-cell stage of prenatal development) can be used to select embryos to be implanted in the uterus after in vitro fertilization. This prevents implantation of embryos with a specific gene defect or common chromosome defects.

The National Human Genome Research Institute is part of the National Institutes of Health. The Human Genome project is an international effort started in 1990 to identify all genes contained in the human body. Benefits of greater knowledge about specific human genes include the following:

- Performing genetic testing to determine the risk for a disorder or the actual or probable presence of the disorder
- Basing reproductive decisions on more accurate and specific information than has previously been available
- Identifying genetic susceptibility to a disorder so that interventions to reduce risk can be instituted
- Using gene therapy to modify a defective gene
- Modifying therapy such as medication based on an individual's genetic code or the genetic makeup of tumor cells
- Individualizing treatment or medications for a specific person

The explosion of knowledge about the genetic basis for many diseases raises many legal and ethical issues for which we do not yet have answers (Box 5-1). As our knowledge base grows, new issues are likely to emerge:

- Genetic information has implications for others in the person's family, raising privacy issues.
- Knowledge about a genetic disorder often precedes knowledge about treatment of the disorder.
- Identification of genetic problems could lead to poor self-esteem, guilt, and excessive caution, or, conversely, a reckless lifestyle.
- Presymptomatic identification of genetically influenced illness would be a source of long-term anxiety.
- Genetic knowledge could affect one's choice of a partner.

Concern about employment or insurance coverage related to genetic tests was addressed in the United States in 2008 with the enactment of the Genetic Information Nondiscrimination Act (GINA). Insurance companies and employers are prohibited from discriminating on the basis of information from genetic tests. Insurance companies are prohibited from discriminating in ways such as canceling, denying, refusing to renew, or changing the terms or premiums based solely on a genetic predisposition toward a specific disease. Employers are prohibited from using genetic information when making employment decisions. A genetic test cannot be demanded by an employer or insurance company (NHGRI, 2012c; White House Press Release, 2008).

Chromosomes

Genes are organized in 46 paired **chromosomes** in the nucleus of somatic cells. A gene can be likened to a single bead; a chromosome is like a string of beads. Each chromosome is composed of varying numbers of genes. A total of 22 chromosome pairs are **autosomes** (non-sex chromosomes), and the twenty-third pair is composed of the

BOX 5-1 ETHICAL ISSUES CREATED BY GREATER GENETIC KNOWLEDGE

- Should testing be offered for a genetic disease for which no treatment is available? What if the disease is fatal? Should testing be required if a person may carry a diagnosable disorder that might be passed on to his or her children, even if the person does not want the test?
- Huntington's disease is an example of a genetic disease that can be diagnosed. It has serious effects, with a fatal outcome during midlife. Should testing be offered? Should it be required before the person is allowed to reproduce?
- Who should own and control genetic information? Does an insurer have the right to a person's genetic information to assess risk and therefore set more accurate rates? Or is this information private? Should this information be disregarded for everyone when insurance rates are set?
Geneticists may have the ability to identify conditions that a person will develop in the future even if the problem is not present. Examples include hypertension, diabetes, and heart disease. If an insurance company knows that the person will develop this disorder, rates would be higher, or coverage would be denied. If an employer has this information, the person might not be hired to avoid raising insurance costs for the company. Yet, the reverse could be true. Genetic testing might prove that a person *would not* develop a disorder, thereby gaining them lower rates. If genetic testing before being insured is not permitted, is it right that all persons insured by a company subsidize those who develop disorders that could have been determined before being insured by paying higher rates?
- How should issues of racial or ethnic identification be handled? What if a person's parentage is not what he or she has always believed?
Discoveries in the process of genetic analysis may determine that a person is not of the racial identity previously thought, or a person might discover that a parent is not the biologic parent. What should be done if information of this nature is uncovered? What are possible implications for self-image and identity? How might other members of the family be involved in the unexpected discovery?

sex chromosomes, XX (female) or XY (male). Added, missing, and structurally abnormal chromosomes are usually harmful. **Homologous** chromosomes carry matching genetic information, that is, they have the same genes in the same sequence.

Mature gametes have half the chromosomes (23) of other body cells. One chromosome from each pair is distributed randomly in the gametes, allowing variation of genetic traits among people. When the ovum and sperm unite at conception, the total is restored to 46 paired chromosomes.

Cells for full chromosome analysis must have a nucleus and be living. Chromosomes can be studied by using any of several types of cells: white blood cells, skin fibroblasts, bone marrow cells, and fetal cells from the chorionic villi of the placenta or suspended in amniotic fluid.

Unlike genes, chromosomes can be seen under the microscope but only during cell division for a full chromosome analysis. Specimens must be obtained and preserved carefully to provide enough living cells for chromosomal analysis. Temperature extremes, blood clotting, and the addition of improper preservatives can kill the cells and render them useless for analysis.

Chromosomes look jumbled before they are arranged into a karyotype (Figure 5-2). Systematic study is possible using imaging of prepared chromosomes and then arranging them into a **karyotype** (Figure 5-3). In a karyotype, autosomal pairs are arranged from largest to smallest. Letters describe groups of similar size and appearance. Sex chromosomes may be arranged in a separate group.

A person's karyotype is abbreviated by a combination of numbers and letters. The number describes the total number of chromosomes, followed by either an XX to indicate that the sex chromosomes are female or an XY to indicate that they are male. Therefore, the chromosome complement is abbreviated as 46,XX for a normal female and as 46,XY for a normal male. If the chromosome number or structure is abnormal, as in Down syndrome (trisomy 21), which has an extra 21 chromosome, an added abbreviation indicates the abnormality: 47 (total number of chromosomes), XY (male), +21 (the number of the extra chromosome). Other abbreviations describe karyotypes with missing or structurally altered chromosomes.

FIG 5-2 Before arrangement in a karyotype, chromosomes appear jumbled. This photo is a spectral karyotype from a normal female. (From National Human Genome Research Institute. [2010]. *Digital media database: Spectral karyotype*. Retrieved from www.genome.gov.)

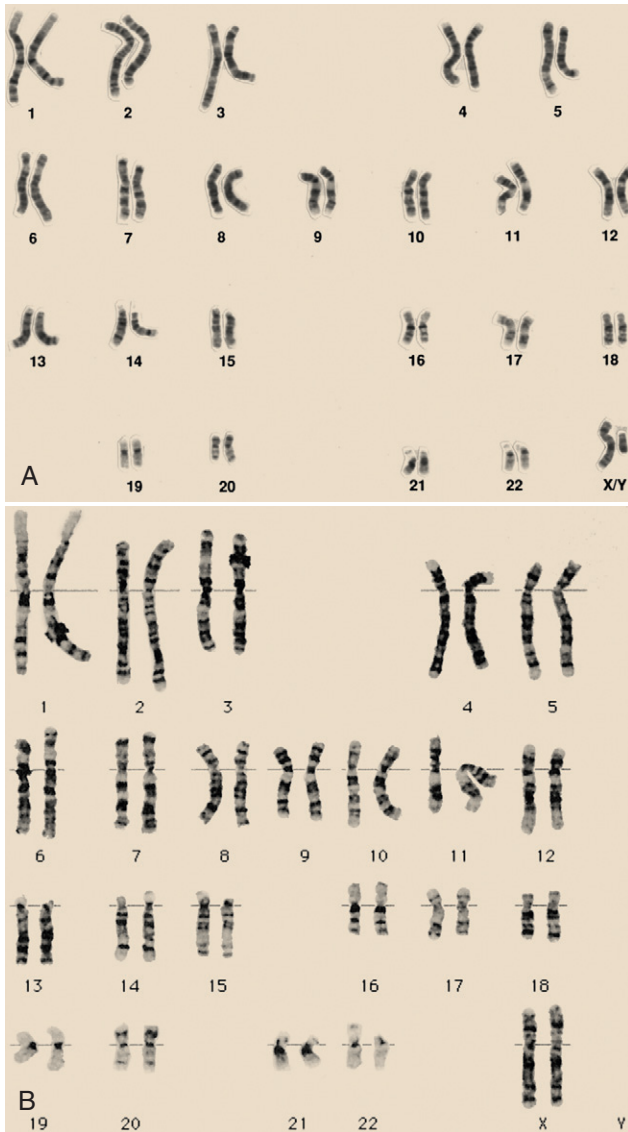

FIG 5-3 Karyotypes of chromosomes that were stained, creating bands to distinguish each chromosome and identify missing or duplicated chromosome material. **A**, Normal male karyotype: 46,XY. **B**, Normal female karyotype: 46,XX. (**A**, from National Human Genome Research Institute. [2010]. *Digital media database: Karyotype*. Retrieved from www.genome.gov; **B**, from Jorde, L. B., Carey, J. C., & Bamshad, M. J. [2010]. *Medical genetics* [4th ed., p. 101]. Philadelphia: Mosby.)

Finer chromosome analysis uses fluorescent-labeled DNA probes that attach to specific chromosomes. This technique is called fluorescent in-situ hybridization (FISH) and permits testing for added, missing, or rearranged chromosome material that otherwise may not be visible microscopically. FISH analysis can be done rapidly because stimulation of cells to divide is not required, as in other types of chromosome analysis. Another more specific chromosome analysis is the comparative genomic hybridization used to identify losses or duplications of specific chromosome regions, which often occur in tumor cells. Spectral karyotyping (SKY, see [Figure 5-2](#)) colors or “paints” each chromosome differently to identify rearrangements, losses, or gains of chromosome material ([Jorde et al., 2010](#); [NHGRI, 2012d](#)).

CHECK YOUR READING

1. What is the relationship among deoxyribonucleic acid (DNA), genes, and chromosomes?
2. Can genes be studied by examining them under a microscope? Why, or why not? What methods are used to study them?
3. Why do cell specimens for chromosomal analysis have to be alive, regardless of the tissue used?
4. What do each of these abbreviations mean: 46,XY and 46,XX? How are chromosome abnormalities described?

Transmission of Traits by Single Genes

Inherited characteristics are passed from parent to child by the genes in each chromosome. These traits are classified according to whether they are **dominant** (strong) or **recessive** (weak) and whether the gene is located on one of the autosome pairs or on the sex chromosomes. Both normal and abnormal hereditary characteristics are transmitted by these mechanisms.

Because humans have pairs of matched chromosomes, except for the sex chromosomes in the male, they have one allele for a gene at the same location on each member of the chromosome pair. The paired alleles may be identical (**homozygous**) or different (**heterozygous**).

Some genes, both normal and abnormal, occur more frequently in certain groups than in the population as a whole. For example, the gene that causes Tay-Sachs disease on chromosome 15 is carried by approximately 1 of every 30 (3.3%) U.S. Jews, a rate approximately 100 times its occurrence in the general population. Persons of French-Canadian ancestry and members of the Cajun population in Louisiana are similarly at risk ([American Congress of Obstetricians and Gynecologists \[ACOG\], 2009b](#); [March of Dimes, 2009](#); [National Tay-Sachs and Allied Diseases Association \[NTSAD\], 2012](#)). Because the abnormal gene occurs more frequently in these groups, their incidence of Tay-Sachs disease is also higher. Other disorders that are more common in certain ethnic groups are cystic fibrosis, which occurs primarily in whites of northern European descent, and sickle cell disease, which occurs more frequently in people of African descent. Guidelines for medical management of pregnant women who have some genetic risks are listed in the references.

Dominance

Dominance describes the way a person’s **genotype** (genetic composition) is translated into the **phenotype**, or observable characteristics. In the case of a dominant gene, one copy is enough to cause the trait to be expressed. For example, in the ABO blood system, genes for types A and B are dominant. Therefore, a single copy of either of these genes is enough for it to be expressed in the person’s blood type.

Two identical copies of a recessive gene are required for the trait to be expressed. The gene for blood type O is recessive. Laboratory testing identifies a person’s blood type as O only if that person receives a gene for blood type O from both parents. If the person receives a gene for type O from one parent and type A from the other parent, blood type A is expressed in laboratory blood typing.

On the basis of dominant and recessive forms of a gene, a person with type A blood can have one of two possible combinations of gene alleles:

- Two type A alleles
- One type A allele and one type O allele

Other alleles are equally dominant. The person who receives a gene for blood type A from one parent and type B from the other will have type AB blood, often called the *universal recipient*, because both alleles are equally dominant and expressed in blood typing.

Dominance and recessiveness are relative qualities for many genes. Some people with a single copy of an abnormal recessive gene (carriers) may have a lower than normal level of the gene product (e.g., an enzyme) that can be detected by biochemical methods. These people often do not have overt disease because the normal copy of the gene produces enough of the required product to allow normal or near-normal function.

Chromosome Location

Genes located on autosomes are either autosomal dominant or autosomal recessive, depending on the number of identical copies of the gene needed to produce the trait. However, genes located on the X chromosome are paired only in females because males have one X chromosome and one Y chromosome.

A female with an abnormal recessive gene on one of her X chromosomes usually has a normal gene on the other X chromosome that compensates and maintains relatively normal function. However, the male is at a disadvantage if his lone X chromosome has an abnormal gene. The male has no compensating normal gene because his other sex chromosome is a Y. The abnormal gene is expressed in the male because it is unopposed by a normal gene.

Patterns of Single Gene Inheritance

Three major patterns of single gene inheritance are (1) autosomal dominant, (2) autosomal recessive, and (3) X-linked (Box 5-2). Few genes are found on the Y chromosome, primarily the one that causes the embryo to differentiate into a male (Jorde et al., 2010; Nussbaum, McInnes, & Willard, 2007). Because few Y-linked traits have been identified, these will not be discussed.

Although the word pedigree is widely used among genetic professionals, the nurse may need to interpret it for the client. Be cautious when referring to the illustration of a family's genetic history as a *pedigree* because some associate the word only with animals. For example, when taking a genetic family history, the nurse might say, "I'm going to use several symbols to depict your family tree and its members' health histories. This diagram is called a *genogram*, but it's also often called a *pedigree*."

Single gene traits have mathematically predictable and fixed rates of occurrence. For example, if a couple has a child with an autosomal recessive disorder, the risk that future children will have the same disorder is 1 in 4 (25%) at every conception. The risk is the same at every conception, regardless of how many of a couple's children have been affected.

Autosomal Dominant Traits

An autosomal dominant trait is produced by a dominant gene on a non-sex chromosome. The expression of abnormal autosomal dominant genes may result in multiple and seemingly unrelated effects in the person. The gene's effects also may vary substantially in severity, leading a family to believe incorrectly that a trait skips a generation. A careful physical examination may reveal subtle evidence of the trait in each generation. In other cases, some people may carry the dominant gene but have no apparent expression of it in their physical makeup.

In some autosomal dominant disorders such as Huntington's disease, those with the gene will always have the disease if they live to the age at which the disorder becomes apparent. In other disorders, only a portion of those carrying the gene ever exhibit the disease.

New mutations account for the introduction of abnormal autosomal dominant traits into a family that has no history of the disorder. In this case, parents of the child are normal because their body cells do not have the altered gene (Jorde et al., 2010; Nussbaum et al., 2007).

The person who is affected by an autosomal dominant disorder is usually heterozygous for the gene; that is, the person has a normal gene on one chromosome and an abnormal gene on the other chromosome of the pair. Occasionally, a person receives two copies of the same abnormal autosomal dominant gene. Such an individual is usually much more severely affected than someone with only one copy.

Autosomal Recessive Traits

An autosomal recessive trait occurs if a person receives two copies of a recessive gene carried on an autosome. Everyone is estimated to carry abnormal autosomal recessive genes without manifesting the disorder because everyone has a compensating normal gene (Jorde et al., 2010). Because of the low probability that two unrelated people share even one of the same abnormal genes, the incidence of autosomal recessive diseases is relatively low in the general population.

Situations that increase the likelihood that two parents share the same abnormal autosomal recessive gene are as follows:

- Consanguinity (blood relationship of the parents)—Blood relatives have more genes in common, including abnormal ones.
- Groups that are isolated by culture, geography, religion, or other factors—The isolation allows abnormal genes to become concentrated over the years and occur at a greater frequency than in more diverse groups.

Many autosomal recessive disorders are severe, and affected persons may not live long enough to reproduce. Two notable exceptions are phenylketonuria (PKU) and cystic fibrosis. Improved care of people with these disorders has allowed them to live into their reproductive years. If one member of the couple has the autosomal recessive disorder, all their children will be carriers. Their child's risk for having similarly affected children is also higher, depending on the prevalence of the abnormal gene in the general population and the likelihood that their mate is a carrier.

CRITICAL TO REMEMBER

Single Gene Abnormalities

- A person affected with an autosomal dominant disorder has a 50% chance of transmitting the disorder to each biologic child.
- Two healthy parents who carry the same abnormal autosomal recessive gene have a 25% chance of having a child affected with the disorder caused by this gene.
- Parental consanguinity increases the risk for having a child with an autosomal recessive disorder.
- One copy of an abnormal X-linked recessive gene is enough to produce the disorder in a male.
- Abnormal genes can arise as new mutations. If these mutations are in the gametes, they are transmitted to future generations.

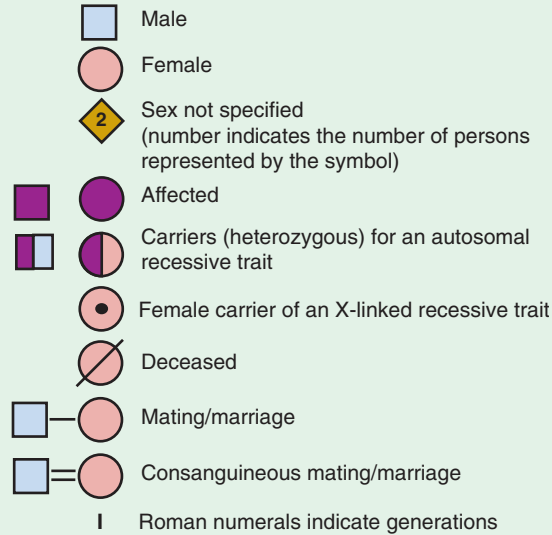

X-Linked Traits

X-linked recessive traits are more common than X-linked dominant traits and are the only X-linked pattern discussed in this chapter. Gender differences in the occurrence of X-linked recessive traits and the relationship of affected males to one another are important factors that distinguish these disorders from autosomal dominant and recessive disorders. In general, males are the only ones to show full effects of an X-linked recessive disorder because their only X chromosome has the abnormal gene on it. One of the two X chromosomes is inactivated randomly in a normal female embryo. The active X chromosome in cells usually provides adequate cell function, although one of the two X chromosomes is inactivated. Barr bodies seen in female cells indicate the inactive X, and they are not seen in normal male tissue

BOX 5-2 SINGLE GENE TRAITS

Genogram (Pedigree) Symbols

A genogram symbolically represents a family's medical history and the relationships of its members to one another. It helps identify patterns of inheritance that may help distinguish one type of disorder from another.

**Autosomal Recessive Characteristics**

Two autosomal recessive genes are required to produce the trait. Males and females are equally likely to have the trait. There is often no prior family history of the disorder before the first affected child. If more than one family member is affected, they are usually full siblings. Consanguinity (close blood relationship) of the parents increases the risk for the disorder. Disorders are more likely to occur in groups isolated by geography, culture, religion, or other factors. Some autosomal recessive disorders are more common in specific ethnic groups.

Transmission of Trait from Parent to Child

Unaffected parents are carriers of the abnormal autosomal recessive trait. Children of carriers have a 25% (1 in 4) chance for receiving both copies of the defective gene and thus having the disorder. Children of carriers have a 50% (1 in 2) chance of receiving one copy of the gene and being carriers like the parents. Children of carriers have a 25% (1 in 4) chance of receiving both copies of the normal gene. They are neither carriers nor affected.

Examples

Normal traits: Blood group O; Rh-negative blood factor.
 Abnormal traits: Tay-Sachs disease; sickle cell disease; cystic fibrosis.

Genogram**Autosomal Dominant****Characteristics**

A single copy of the gene is enough to produce the trait. Males and females are equally likely to have the trait. Often appears in every generation of a family, although family members having the trait may have widely varying manifestations of it. May have multiple and seemingly unrelated effects on body structure and function.

Transmission of Trait from Parent to Child

A parent with the trait has a 50% (1 in 2) chance of passing the trait to the child. The trait may arise as a new mutation from an unaffected parent. The child who receives the mutated gene can then transmit it to future generations.

Examples

Normal traits: Blood groups A and B; Rh-positive blood factor.
 Abnormal traits: Huntington's disease; neurofibromatosis.

Genogram**X-Linked Recessive Characteristics**

Although recessive, only one copy of the gene is needed to cause the disorder in the male, who does not have a compensating X without the trait. Males are affected, with rare exceptions. Females are carriers of the trait but not usually adversely affected. Affected males are related to one another through carrier females. Affected males do not transmit the trait to their sons.

Transmission of Trait from Parent to Child

Males who have the disorder transmit the gene to 100% of their daughters and none of their sons. Sons of carrier females have a 50% (1 in 2) chance of being affected. They also have a 50% chance of being unaffected. Daughters of carrier females have a 50% (1 in 2) chance of being carriers like their mothers. They also have a 50% chance of being neither affected nor carriers. A new X-linked recessive gene also may arise by mutation.

Examples

Colorblindness; Duchenne's muscular dystrophy; hemophilia A.

Genogram

samples. Females can show the full disorder in two uncommon circumstances:

- If a female has a single X chromosome (Turner syndrome)
 - If a female child is born to an affected father and a carrier mother
- X-linked recessive disorders can be relatively mild (e.g., colorblindness), or they may be severe (e.g., hemophilia). In addition, those having the disorder may be affected with varying degrees of severity.

CHECK YOUR READING

6. Why would parents who are first cousins be more likely to have a child with an autosomal recessive disorder?
7. If each member of a couple carries the gene for an autosomal recessive disorder, what are the chances that the children will have the disorder? What are the chances that the children will be carriers? What are the chances that the children will not receive the abnormal gene from either parent?
8. Why are males more often affected by X-linked recessive disorders? If a female carries an X-linked recessive disorder such as hemophilia, what are the chances that her sons will have the disorder? What are the chances that her daughters will be carriers?

Chromosomal Abnormalities

Chromosomal abnormalities can be numerical or structural. They are quite common ($\geq 50\%$) in the embryo or fetus that is spontaneously aborted (miscarried). Chromosomal abnormalities often cause major defects because they involve deletion or duplication of many genes. The normal number of chromosomes in body cells other than reproductive cells is 46, or **diploid**.

Numerical Abnormalities

Numerical chromosomal abnormalities involve added or missing single chromosomes or multiple sets of chromosomes. **Trisomy** and **monosomy** are numerical abnormalities of single chromosomes. The

term **polyploidy** refers to abnormalities involving full sets of chromosomes.

Trisomy. A trisomy exists when each body cell contains an extra copy of one chromosome, bringing the total number to 47 (Figure 5-4). Each chromosome is normal, but too many are present in each somatic cell. The most common trisomy is Down syndrome, or trisomy 21, in which three copies of chromosome 21 are in each somatic cell. Trisomies of chromosomes 13 and 18 are less common and have more severe effects. The incidence of bearing children with trisomies increases with maternal age, so most women who are 35 years or older and become pregnant are offered prenatal diagnosis to determine whether the fetus has Down syndrome or another trisomy. See Chapter 10 for more information related to prenatal tests.

Infants with Down syndrome have characteristic features that are usually noticed at birth (Figure 5-5). Chromosomal analysis is

FIG 5-4 Karyotype of a male with trisomy 21 (Down syndrome: 47,XY, +21). (From Jorde, L. B., Carey, J. C., & Bamshad, M. J. [2010]. *Medical genetics* [4th ed., p. 107]. Philadelphia: Mosby.)

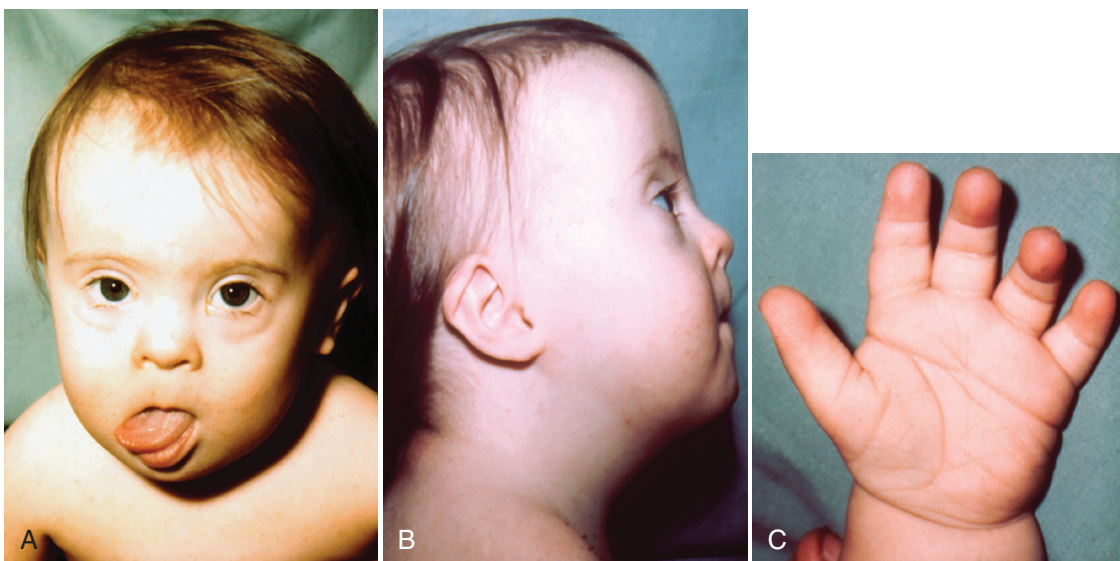

FIG 5-5 Newborn with several characteristic features of Down Syndrome, or Trisomy 21. Note that the infant has a flat face and occiput, low-set ears, and a protruding tongue. Also note the single transverse palm crease and a single crease on her fifth finger. (From Jones, K. L. [2006]. *Smith's recognizable patterns of human malformation* [6th ed., p. 10]. Philadelphia: Saunders.)

performed during the neonatal period to confirm the diagnosis and determine whether Down syndrome is caused by trisomy 21 or a rarer chromosomal anomaly that involves a structural rather than a numerical abnormality of chromosome 21.

Children with Down syndrome reach developmental milestones more slowly compared with normal children. Their intellectual development is delayed, although the severity varies, just as intelligence varies in the general population. Early intervention programs and regular medical care help these children reach their full ability and manage the physical problems associated with Down syndrome.

Klinefelter syndrome is a trisomy of the sex chromosomes. Males with Klinefelter syndrome (47, XYY) are taller than average, may have a lower intelligence and gynecomastia (larger breasts), and are usually sterile. Testosterone therapy and mastectomy for enlarged breasts may be done. Other sex chromosome trisomies possibly encountered include 47, X or 47- XYY (Jorde et al., 2010).

Monosomy. A monosomy exists when each body cell has a missing chromosome, with a total number of 45. The only monosomy compatible with postnatal life is Turner syndrome, or monosomy X (Figure 5-6). Over 99% of conceptions with the 45,XO karyotype are lost in spontaneous abortion (Carlson, 2009; Jorde et al., 2010; Moore, Persaud, & Torcheria, 2013a). The person with Turner syndrome has a single X chromosome and is always female.

Large cystic masses on either side of the neck (cystic hygromas) may be found on routine ultrasonography and lead to the diagnosis. Liveborn infants have excess skin around the neck left from the hygromas and edema that is most noticeable in the hands and feet during infancy. If Turner syndrome is not identified and treated during infancy or childhood, an affected girl will remain very short and will not have menstrual periods or develop secondary sex characteristics. Children with Turner syndrome usually have normal intelligence, although they may have difficulty with spatial relationships or with solving visual problems such as reading a map. The girl may have a broad, shieldlike chest with widely spaced nipples. Her kidneys may be joined at their upper poles (horseshoe kidney), and coarctation of the aorta may require corrective surgery. Treatment with estrogen at the age of puberty promotes development of secondary sexual characteristics. Continuing estrogen throughout life reduces development of osteoporosis (Jorde et al., 2010).

CRITICAL TO REMEMBER

Chromosome Abnormalities

Chromosome abnormalities are either numerical or structural.

NUMERICAL

Entire single chromosome added (trisomy)
Entire single chromosome missing (monosomy)
One or more added sets of chromosomes, resulting in cells containing 69 (triploidy) or 92 (tetraploidy) chromosomes

STRUCTURAL

Part of a chromosome missing or added
Rearrangements of material within chromosome(s)
Two chromosomes that adhere to each other
Fragility of a specific site, such as on the X chromosome ("fragile X syndrome")

Polyploidy. Polyploidy may occur when gametes do not halve their chromosome number during meiosis and retain both members of each pair or when two sperm fertilize an ovum simultaneously. The result is an embryo with one or more extra sets of chromosomes. The total number of chromosomes is a multiple of the **haploid** number of 23 (69 or 92 total chromosomes). Polyploidy usually results in an early spontaneous abortion but may occasionally be seen in a liveborn infant. This abnormality may be found in chorionic villus sampling (see Chapter 10) and may reflect an abnormality of the chorionic villi rather than of the fetus.

Structural Abnormalities

Chromosomal abnormalities may involve the structure of one or more chromosomes. Part of a chromosome may be missing or added, or DNA within the chromosome may be rearranged. Some of these rearrangements are common harmless variations. Others are harmful because important genetic material is lost or duplicated in the structural abnormality or the position of the genes in relation to other genes is altered so that their normal function is not possible.

Another structural abnormality occurs when all or part of a chromosome is attached to another (**translocation**) (Figure 5-7). Many people with a translocation chromosomal abnormality are clinically normal because the total of their genetic material is normal or balanced. If a parent has a balanced translocation, the offspring, like the parent, may have completely normal chromosomes or a balanced translocation. However, the offspring may receive too much or too little chromosomal material and be spontaneously aborted or have birth defects.

Balanced translocations are often discovered when amniocentesis reveals a translocation in the fetus or during infertility evaluations if a history of recurrent spontaneous abortions is reported. Either balanced or unbalanced chromosomal translocations may occur spontaneously in the offspring of parents who have no translocation.

Fragile X syndrome is an X-linked chromosomal abnormality. The syndrome was so named because a site on the X chromosome demonstrates breaks and gaps when the cells are grown in a medium deficient in folic acid. The syndrome is now usually diagnosed by molecular DNA studies. As in other X-linked traits, males are more severely affected compared with females, who have a compensating X chromosome that is usually normal. Fragile X syndrome is the most common inherited form of male mental retardation (Jorde et al., 2010; Moore et al., 2013a).

FIG 5-7 Illustration of a translocation of chromosome material between chromosomes 4 and 20. (National Institutes of Health, National Human Genome Research Institute [2012]: *Talking glossary of genetic terms*. Retrieved from <http://www.genome.gov/glossary/?id=201>)

MULTIFACTORIAL DISORDERS

Multifactorial disorders result from an interaction of genetic and environmental factors. The genetic tendency toward the disorder is modified by the environment. These interactions may either positively or negatively influence prenatal and postnatal development. For example, two embryos may have an equal genetic susceptibility for the development of a disorder such as spina bifida (open spine). However, the disorder will not occur unless an environment that favors its development, for example, deficient maternal intake of folic acid, also exists.

Characteristics

Multifactorial birth defects are typically (1) present and detectable at birth and (2) isolated defects rather than defects that occur with unrelated abnormalities. However, a multifactorial defect may cause a secondary defect. For example, infants with spina bifida often have hydrocephalus (abnormal collection of spinal fluid within the brain) as well. The hydrocephalus is not a separate defect but one that occurs because the primary defect—abnormal development of the spine and spinal cord—disrupts spinal fluid circulation, allowing the fluid to accumulate within the brain's ventricular system.

However, the infant who has defects other than those known to be associated with spina bifida probably does not have a multifactorial disorder. In this case, the spina bifida is more likely to be part of a syndrome such as a chromosome defect, which may pose a different risk for recurrence in a future child.

Multifactorial disorders are some of the most common birth defects that a maternal-child nurse encounters. Examples include the following:

- Many heart defects
- Neural tube defects such as anencephaly (absence of most of the brain and skull) and spina bifida
- Cleft lip and cleft palate
- Pyloric stenosis

Risk for Occurrence

Unlike single gene traits, multifactorial disorders are not associated with a fixed risk of occurrence or recurrence in a family. Presence of a trait in a family (**familial**) means that risks are an average rather than a constant percentage. Factors that may affect the risk are as follows:

1. Number of affected close relatives—Risk increases as the number of affected close relatives (parent, full sibling, or child) increases.
2. Severity of the disorder in affected family members—For example, bilateral cleft lip is associated with a higher risk for recurrence in a close relative than is a unilateral cleft lip on one side of the upper lip.
3. Gender of the affected person(s)—For example, pyloric stenosis occurs five times as often in males as in females. The couple who has a daughter with pyloric stenosis faces a higher risk for recurrence with future children because the genetic influence for development of the defect is greater if a female develops it.
4. Geographic location—The risk for some disorders, such as neural tube defects, is more prevalent in one population than another. Because a group at greater risk often lives near others with the same risk, occurrence of the disorder may be more frequent in that area. Neural tube disorders have shown greater prevalence in some areas such as the Rio Grande Valley in Texas, where many Hispanics live.
5. Seasonal variations—Seasonal variations are noted with some multifactorial disorders.

CRITICAL TO REMEMBER**Multifactorial Birth Defects**

- Multifactorial defects are some of the most common birth defects encountered in maternity and pediatric nursing practice.
- They are a result of interaction between a person's genetic susceptibility and environmental factors during prenatal development.
- These are usually single, isolated defects, although the primary defect may cause secondary defects.
- Some occur more often in certain geographic areas and among more closely related population groups.
- A greater risk of occurrence exists with the following:
 - Several close relatives have the defect, whether mild or severe.
 - One close relative has a severe form of the defect.
- The defect occurs in a child of the less frequently affected gender.
- Infants who have several major or minor defects that are not directly related probably do not have a multifactorial defect but have another syndrome such as a chromosomal abnormality.

If multifactorial disorders had no environmental component, the risk for occurrence and recurrence would be a precise percentage rather than a range. However, if no genetic component exists (if the disorder were totally related to environment), the ability to predict the risk for occurrence or recurrence would be minimal.

ENVIRONMENTAL INFLUENCES

Environment, for example, good nutrition that supplies all necessary raw materials for fetal growth and adequate folic acid intake before conception, may positively influence prenatal development. However, some environmental influences such as *teratogens* (environmental agents) or mechanical forces that can cause defects as the baby develops are harmful.

Environmental influences on childbearing are those that are not known to have a genetic component. At one time, the placenta was thought to be a shield against harmful agents within a pregnant woman's body. Now it is recognized that most agents can cross the placenta and affect the developing fetus.

Teratogens

Teratogens are agents in the fetal environment that either cause or increase the likelihood that a birth defect will occur. Some drugs have been definitely established as safe or harmful. With most agents, however, their potential for harming the fetus is not clear. Several factors make it difficult to establish the teratogenic potential of an agent:

1. Retrospective study—Investigators must rely on the mother's memory about substances she ingested or was exposed to during pregnancy. The conclusion that a specific agent is harmful and the ways in which it harms the fetus is possible only when many cases are collected in which the exposure history is similar and the birth defects are also similar.
2. Timing of exposure—Agents may be harmful at one stage of prenatal development but not at another. Exposure may be harmful but may vary with the prenatal development stage.
3. Different susceptibility of organ systems—Some agents affect only one fetal organ system, or they affect one system at one stage of development and another at a different stage of development.
4. Uncontrolled fetal exposure—Exposures cannot be controlled to eliminate extraneous agents or ensure a consistent dose. Interactions with other agents may reduce or compound the fetal effects.

BOX 5-3 SELECTED ENVIRONMENTAL SUBSTANCES KNOWN OR THOUGHT TO HARM THE FETUS*

- Alcohol
- Aminoglycosides
- Anticonvulsant agents
- Antihyperlipidemic agents (statins)
- Antineoplastic agents
- Antithyroid drugs
- Cocaine
- Diethylstilbestrol (DES)
- Folic acid antagonists
- Infections
 - Cytomegalovirus
 - Herpes simplex virus
 - Human immunodeficiency virus
 - Rubella
 - Syphilis
 - Toxoplasmosis
 - Varicella
- Lithium
- Mercury
- Retinoic acid
- Tetracycline
- Tobacco
- Warfarin

*Risks related to other drugs or additional substances are noted in [Appendix A](#). The nurse should observe for new information about adverse fetal effects from these or other drugs that may be given during pregnancy.

An agent that is toxic at one dose may have no apparent effect at another.

5. Placental transfer—Agents vary in their ability to cross the placenta.
6. Individual variations—Fetuses show varying susceptibility to harmful agents.
7. Nontransferability of animal studies—Results of animal studies cannot always be applied to humans. Agents that do not harm animal fetuses may damage the human embryo or fetus.
8. Risk for damage from an uncontrolled maternal disorder—Some maternal disorders, such as epilepsy or hypertension, may cause fetal damage if not controlled. A poorly controlled maternal disorder raises a question of whether the disorder itself or the medication used to control the disorder harms the fetus.

Teratogens typically cause more than one defect, which distinguishes teratogenic defects from multifactorial disorders. However, children affected by single gene and chromosome defects are also likely to have multiple defects. Therefore, clinicians consider single gene disorders, chromosomal abnormalities, and effects of teratogenic agents when trying to diagnose an infant born with multiple anomalies.

Hundreds of individual agents are either known or suspected teratogens ([Box 5-3](#)). Types of teratogens include the following:

- Maternal infectious agents (e.g., viruses, bacteria) that cross the placenta
- Drugs and other substances used by the woman (e.g., therapeutic agents, illicit drugs, tobacco, alcohol)

- Pollutants, chemicals, and other substances to which the mother is exposed in her daily life
- Ionizing radiation
- Maternal hyperthermia
- Effects of maternal disorders such as diabetes mellitus and PKU

Theoretically, all or some of the risk to the developing fetus can be eliminated by avoiding exposure to the agent or changing the fetal environment in some way.

Preventing Fetal Exposure

Ideally, prevention of exposure to harmful influences begins before conception because all major organ systems develop early in pregnancy, often before a woman realizes that she is pregnant. To avoid some agents such as alcohol and illicit drugs, some pregnant women must be committed to making substantial lifestyle changes. The Office of Teratology Information Specialists (OTIS) is a source of information about drug use (includes therapeutic, illicit, and herbal), infections and vaccines, and maternal medical conditions, as well as exposure to common things such as caffeine, suntan beds, or fish (www.otispregnancy.org).

Infections. Rubella immunization 28 days (1 month) before pregnancy virtually eliminates the risk that the mother will contract this infection, which may damage the fetus severely. If a woman becomes pregnant within 28 days after immunization, fetal risk is considered unlikely (American Academy of Pediatrics [AAP] & ACOG, 2012; March of Dimes, 2012b). For infections that cannot be prevented by immunization, the nurse may counsel the woman to avoid situations in which acquiring the disease is more likely (see Chapters 26 and 30).

Drugs and Other Substances. The U.S. Food and Drug Administration (FDA) has established pregnancy categories for therapeutic drugs based on their potential to harm the fetus. The categories range from A through D and X. Class A drugs have no demonstrated fetal risk in well-controlled studies. At the opposite end, pregnancy category X drugs are well established as being harmful. The physician must balance the woman's need for the drug's therapeutic effects against the fetal need to avoid exposure to it. A woman's use of botanical preparations must be considered because some are harmful during pregnancy. See Appendix A for information about drugs and botanical preparations during pregnancy and lactation.

Establishing whether an illicit drug can cause prenatal damage is difficult because women who use these substances often have other problems that complicate analysis of fetal effects. For example, these women may use multiple drugs and may have poor nutritional status, untreated sexually transmitted diseases (STDs), inadequate prenatal care, and stressful lives. In addition, illicit drugs are unlikely to be pure, and substances used to dilute them may themselves be harmful. Legal drugs may be combined with illegal drugs and users may abuse legal drugs.

Drugs are often metabolized and excreted in urine, including drugs in the fetal system. Fetal blood levels of drug often remain high because the fetus swallows amniotic fluid that contains excreted drug products, even after the drug has been eliminated by the mother's body.

The best action is for the woman to eliminate use of nontherapeutic drugs and substances such as alcohol. If she requires certain therapeutic drugs, the physician may be able to prescribe an alternative drug with a lower risk to the fetus or may eliminate nonessential therapeutic drugs such as acne medications.

The pregnant woman who abuses drugs presents a complex picture because maintenance of her drug habit usually takes priority over her health needs. She often has late or no prenatal care, increasing the likelihood that fetal damage occurred long before she encountered health care professionals.

Ionizing Radiation. Nonurgent radiologic procedures may be done during the first 2 weeks after the menstrual period begins, before ovulation occurs. For urgent procedures during pregnancy, the lower abdomen should be shielded with a lead apron, if possible. The radiation dose is kept as low as possible to reduce fetal exposure.

Maternal Hyperthermia. An important teratogen is maternal hyperthermia. The mother's temperature may rise unavoidably during illness. Nurses should caution pregnant women to avoid deliberate exposure to heat sources such as saunas and hot tubs. Temperatures vary widely among public hot tubs, and a specific guideline for duration of exposure is difficult. The important factor is how high the woman's body temperature rises and for how long, not just the sauna or hot tub temperature. She should remain in a sauna or hot tub no more than 10 minutes and should keep her head and chest out of the water. Exposure to temperatures of 37.8°C (100°F) or higher is not advised (AAP & ACOG, 2012; Cunningham, Leveno, Bloom et al., 2010).

Manipulating the Fetal Environment

Appropriate medical therapy can help a woman prevent fetal damage that could result from her illness. For example, a woman who has diabetes should try to keep her blood glucose levels normal and stable before and during pregnancy for the best possible fetal outcomes. A woman with PKU should return to her special phenylalanine-free diet before conception to prevent high levels of phenylalanine in her body that will damage the fetus.

All women of childbearing age should take at least 0.4 mg (400 mcg) of folic acid daily before conception because this has been found to reduce the incidence of neural tube defects by 50% to 70%. The recommended increase during later pregnancy is 0.6 mg (600 mcg). Women who have had a child with a neural tube defect need a higher amount of folic acid, 4 mg (4000 mcg), after consulting with their health care providers. In January 1999, the Centers for Disease Control and Prevention (CDC), the March of Dimes Birth Defects Foundation, and the National Council on Folic Acid began a national campaign to educate women about the importance of consuming adequate folic acid every day. A 2007 Gallup poll showed that more women of childbearing age now take a vitamin with folic acid but that the total remains low at 40% (March of Dimes, 2012a). The neural tube closes during the fourth week after conception, often before the woman knows she is pregnant. Nurses can help make women aware of their need for a supplement of folic acid before conception to help reduce this serious birth defect.

Mechanical Disruptions to Fetal Development

Mechanical forces that interfere with normal prenatal development include oligohydramnios and fibrous amniotic bands.

Oligohydramnios, an abnormally small volume of amniotic fluid, reduces the cushion surrounding the fetus and may result in deformations such as clubfoot. Prolonged oligohydramnios can interfere with fetal lung development by interfering with normal branching and development of the alveoli. Oligohydramnios may not be the primary fetal problem but related to other fetal anomalies. Oligohydramnios may also be a sign of reduced placental blood flow that may occur in certain complications of pregnancy.

Fibrous amniotic bands may result from tears in the inner sac (amnion) of the fetal membranes and can result in fetal deformations or intrauterine limb amputation. Fibrous bands are usually sporadic and unlikely to recur. Because these bands can cause multiple defects, they may be confused with birth defects from other causes such as chromosome and single gene abnormalities (Carlson, 2009).

GENETIC COUNSELING

Genetic counseling provides services to help people understand the genetic disorder they are concerned about and the risk of its occurrence in their family. Those concerned about multifactorial or environmental hazards can receive up-to-date information at most centers as well.

Availability

Genetic counseling is often available through facilities that provide maternal-fetal medicine services. State departments of mental health, mental retardation, and rehabilitation services also may provide counseling services. Local chapters of the March of Dimes are an important source of information about birth defects and counseling services. Fact sheets and other information about birth defects and their prevention are available at the March of Dimes website www.marchofdimes.com. Organizations that focus on specific birth defects provide valuable support and assistance in obtaining needed services for individuals and families affected by the disorder.

Focus on the Family

Genetic counseling focuses on the family, not merely on the affected individual. One family member may have a birth defect, but study of the entire family is often needed for accurate counseling. This may involve obtaining medical records and performing physical examinations and laboratory studies on numerous family members. Counseling is impaired if family members are unwilling to provide medical records and will not agree to examinations and laboratory studies. In addition, those who seek counseling may be unwilling to request cooperation from other family members or share newly acquired genetic information.

Process of Genetic Counseling

Genetic counseling may be a slow process that is not always straightforward. Several visits spread over months may be needed. Multiple family members may be part of the process. Tests for rare disorders may be performed at only one or a few laboratories in the world, and several weeks may be needed to complete them. Despite a comprehensive evaluation, a diagnosis may never be established. An accurate diagnosis is crucial to provide families with the best information about the risks for a specific birth defect, prognosis for the person affected, and options available to prevent or manage the disorder (Box 5-4). Even if the counseling does not provide clear information, expanding knowledge may allow a definitive diagnosis later, and families are encouraged to contact the center for updates.

Individuals or families may request genetic counseling before or during pregnancy or after a child has been born with a defect. A genetic evaluation may include many factors:

- A complete medical history of the affected person, including prenatal and perinatal history
- The medical history of other family members
- Laboratory, imaging, and other studies

BOX 5-4 DIAGNOSTIC METHODS THAT MAY BE USED IN GENETIC COUNSELING**Preconception Screening**

Family history to identify hereditary patterns of disease or birth defects
 Examination of family photographs
 Physical examination for obvious or subtle signs of birth defects
 Carrier testing
 Persons from ethnic groups with a higher incidence of some disorders
 Persons with a family history suggesting that they may carry a gene for a specific disorder
 Chromosomal analysis
 Deoxyribonucleic acid (DNA) analysis

Prenatal Diagnosis for Fetal Abnormalities

Maternal tests to screen for abnormalities
 Chorionic villus sampling
 Amniocentesis
 Ultrasonography
 Percutaneous umbilical blood sampling

Postnatal Diagnosis for an Infant with a Birth Defect

Physical examination and measurements
 Imaging procedures (such as ultrasonography, radiography, echocardiography)
 Chromosome analysis
 DNA analysis
 Tests for metabolic disorders (phenylketonuria, cystic fibrosis)
 Hemoglobin analysis for disorders such as sickle cell disease
 Immunologic testing for infections
 Autopsy

- Physical assessment of a child with the birth defect and other family members, as needed
- Examination of photographs, particularly for family members who are deceased or unavailable
- Construction of a genogram, or pedigree, to identify relationships among family members and their relevant medical history
 If a diagnosis is established, genetic counseling educates the family about the following:
 - What is known about the cause of the disorder
 - The natural course of the disorder
 - The likelihood that the disorder will occur or recur in other family members
 - Current availability of prenatal diagnosis for the disorder
 - The ways a couple may be able to avoid having an affected child
 - Availability of treatment and services for the person with the disorder

Genetic counseling is nondirective. The counselor does not tell the individual or parents what decision to make but educates them about options for dealing with the disorder. However, families often subjectively interpret the counseling. Some parents may regard a 50% risk of occurrence or recurrence as low, whereas others may think that a 1% risk is unacceptably high. Also, the family's values and beliefs influence whether they seek counseling and what they do with the information provided.

When risks and probabilities are discussed, these numbers must be stated in terms the individual or parents can understand, and their understanding must be verified. A 1-in-100 risk may sound higher to many people than a 1-in-5 risk. However, when the same numbers are framed in terms of percentages, the 1% risk is obviously much lower than the 20% risk.

Supplemental Services

Comprehensive genetic counseling includes services of professionals from many disciplines such as biology, medicine, nursing, social work, and education. These professionals provide family support and referrals to parent support groups, grief counseling, and intervention for problems that accompany the birth of a child with a birth defect, for example, socioeconomic and family dysfunction.

PARENTS WANT TO KNOW

About Birth Defects

1. *How can this birth defect be genetic? No one else in our family has ever had anything like it.*

Autosomal recessive disorders are carried by parents who themselves are unaffected. The abnormal gene may have been passed down through many generations, but the risk for an affected child is nonexistent until two carrier parents mate.

2. *Isn't the chance that this birth defect will happen to another of our children only one in a million?*

Autosomal recessive disorders have a 25% (1 in 4) chance of recurring in children of the same parents. Autosomal dominant disorders may pose a 50% risk for recurrence unless they resulted from a new mutation in the parental germ cells.

3. *Isn't this birth defect very likely to recur? We'd better not have any more children.*

Some birth defects are associated with a relatively high risk of recurrence; others have a low risk. Prenatal diagnosis may offer parents a way to avoid having an affected child, or some disorders may be treated before birth. New genetic knowledge may provide therapies not available just a short time ago. Parents' values and perceptions of risks of recurrence affect the final decision.

4. *Because we've already had a child with this birth defect (an autosomal recessive defect), will the next three be normal?*

If both parents are carriers for an autosomal recessive disorder, a 25% (1 in 4) risk exists for their child to be affected that is constant with each conception. The chance that their child will neither be affected nor be a carrier is constant with each conception. Each child has a 25% (1 in 4) chance of receiving both copies of the normal gene (unaffected and not a carrier) and a 50% (2 in 4) chance of receiving a single abnormal gene from one parent (a carrier but not affected with the disorder).

5. *If I undergo amniocentesis or another prenatal diagnostic test, can the test detect all birth defects?*

Although many disorders can be prenatally diagnosed, not all can be diagnosed in the same fetus. Testing is offered for one or more specific disorders after a careful family history is taken to determine appropriate tests.

6. *If the prenatal test results are normal, will my baby be normal?*

Normal results from prenatal testing exclude those specifically tested disorders. Every healthy couple has about a 5% risk of having a child with a birth defect, some of which are not obvious at birth. This baseline risk remains, even if all prenatal test results are normal.

7. *Will I have to have an abortion if my prenatal tests show that my baby is abnormal?*

Abortion may be an option for parents whose fetus is affected with a birth defect, but most parents are reassured by normal test results. If results are abnormal, some parents appreciate the time to prepare for a child with special needs. Better medical management can be planned for a newborn who is expected to have problems. Prenatal diagnosis gives many parents the confidence to have children despite their increased risk for having a child with a birth defect.

Nursing Care of Families Concerned about Birth Defects

Nurses have an important role in helping families that are concerned about birth defects. Some nurses work directly with family members who are undergoing genetic counseling. Many more nurses are generalists who bring their knowledge about birth defects and their prevention to those they encounter in everyday practice.

Nurses as Part of a Genetic Counseling Team

Many genetic counseling teams include nurses. Genetic nursing may include the following:

- Providing counseling after additional education in this area
- Guiding a woman or couple through prenatal diagnosis
- Supporting parents as they make decisions after receiving abnormal prenatal diagnostic results
- Helping the family deal with the emotional impact of a birth defect
- Assisting parents who have had a child with a birth defect to locate needed services and support
- Coordinating services of other professionals such as social workers, physical and occupational therapists, psychologists, and dietitians
- Helping families find appropriate support groups to help them cope with the daily stresses associated with a child who has a birth defect

Nurses in General Practice

Nurses who work in women's health care and those who work in antepartum, intrapartum, newborn, or pediatric settings often encounter families who are concerned about birth defects. These families may include a member with a birth defect. Other families may believe that they have an increased risk for having a child with a birth defect. Generalist nurses provide care and support that complements that given by nurses who work on a genetic counseling team.

Women's Health Nurses

The nurse who provides care in women's health may encounter families who should be referred for genetic counseling. The ideal time to provide counseling is before conception so that the childbearing couple has more options if risks are identified. Personal and family histories are taken and updated during primary care visits, and the nurse may identify factors that could affect a future child before conception. For example, the nurse may identify a woman who belongs to a group in which the sickle cell gene is more frequent, and subsequently arrange for testing to determine her carrier status. If testing reveals that she is a carrier for the gene, the woman can be advised that she could conceive a child with sickle cell disease if her partner is also a carrier. If her partner has not been tested, the nurse can arrange for his testing. The carrier may want to advise blood relatives of the need for testing.

Antepartum Nurses

Antepartum nurses often identify those who may benefit from genetic counseling. The antepartum nurse may also assist families with decision making, teaching about tests, management of abnormal results, and needed emotional support.

Identifying Families for Referral. Nurses in antepartum settings often identify a woman or family for whom referral for genetic counseling is appropriate at the first prenatal visit (Box 5-5). The personal and family history of the woman and her partner may disclose factors that increase their risks for having a child with a birth defect. In addition to the usual medical history about disorders such as hypertension and diabetes, the woman should be questioned about a family history

THERAPEUTIC COMMUNICATIONS

Assisting a Woman Who May Benefit from Genetic Counseling

Paula is a 41-year-old white woman who is 8-weeks pregnant with her first child after more than 10 years of infertility. Barbara is a nurse who works with Paula's obstetrician.

Paula: I know all about the risks at my age. I'm not so much worried about my own health as the baby's.

Barbara: You seem to be concerned that the baby might not be all right. *(Clarifying)*

Paula: Sure, what woman wouldn't be? I know I'm more likely to have a baby with Down syndrome at my age.

Barbara: Yes, the risks of having an infant with a chromosomal abnormality increase after the mother is 35 years old. Do you plan to have prenatal diagnosis to see if the fetus has this kind of problem? *(Paraphrasing and giving information. Barbara also uses a closed-ended question that tends to block communication because it is usually answered with a simple "yes" or "no.")*

Paula: Oh, yes. I know what's available from surfing the Internet and my doctor has asked me if I want that blood test. When we waited so long to have children, I just assumed that I'd have whatever tests were recommended. Now I just don't know.

Barbara: You're reconsidering prenatal testing now? *(Reflecting)*

Paula: Well, not exactly reconsidering. It's just that I've waited so long for a baby, and this may be our only one.

Barbara: [Waiting quietly but attentively because Paula seems to be thinking.] *(Using silence)*

Paula: I'm just worried about testing. I know blood tests aren't risky. I also know that most prenatal tests have a low risk, but what if I lose a normal baby? It took me so long to finally get pregnant, and I'm running out of time. I might not get another chance.

Barbara: It must be a very difficult decision. *(Reflecting)*

Paula: It is. Even if I have testing and the baby has Down syndrome, I'm not so sure I'd have an abortion. The outlook for people with Down syndrome is

much better than it used to be. Why have testing if I wouldn't do anything about an abnormal baby?

Barbara: You certainly have some valid concerns. How does your husband feel about testing? *(Questioning using an open-ended question)*

Paula: Oh, Bill is all for it. He keeps reminding me that the baby is probably normal and that I probably won't have a miscarriage if I have testing. His cousin had a child with Down syndrome, and Bill doesn't think we should knowingly bring a child with a serious birth defect into the world. What would you do if you were in my place?

Barbara: I can't answer that question because I'm not in your place. Let's review some of the issues so you can make the best decision for yourself and your family. First, you know you have an increased risk for having a baby with a chromosomal defect such as Down syndrome because of your age. Second, the odds that the baby will be normal are higher than the risk that the baby will be abnormal. Third, amniocentesis poses a small but real risk of causing a miscarriage. Fourth, you are undecided about whether you would end a pregnancy if the fetus were abnormal. Other issues to consider are time limitations and the option of screening with a sample of your blood. The blood test that the doctor told you about is done on your blood 8 to 10 weeks from now. The results of that test may reassure you but they may result in the need to make decisions about more complex testing such as amniocentesis. *(Summarizing)*

Paula: I know. I'm running out of time in more ways than one.

Barbara: If you like, I can set up an appointment with a genetic counselor. The counselor can provide you with the most accurate assessment of your risk for having a child with a birth defect and also the risks of any indicated prenatal diagnosis procedure. Then you can decide whether or not to have testing.

Paula: I think I'd like that, as long as I don't have to be committed to a particular decision before I go.

BOX 5-5 REASONS FOR REFERRAL TO A GENETIC COUNSELOR

Pregnant women who will be 35 years of age or older when the infant is born
 Men who father children after age 40 years
 Members of a group with an increased incidence of a specific disorder
 Carriers of autosomal recessive disorders
 Women who are carriers of X-linked disorders
 Couples related by blood (consanguineous relationship)
 Family history of birth defect or mental retardation
 Family history of unexplained stillbirth
 Women who experience multiple spontaneous abortions
 Pregnant women exposed to known or suspected teratogens or other harmful agents either before or during pregnancy
 Pregnant women with abnormal prenatal screening results such as multiple-marker screen or suspicious ultrasound findings

of birth defects, diseases that seem to "run in the family," mental retardation, and developmental delay.

Some people are reluctant to disclose that they have a family member with intellectual disability or a birth defect. The nurse can gently probe for sensitive information by asking questions about whether any family members have learning problems or are "slow." The use of words that are lay oriented and caring often elicits more information than clinical terms that may seem harsh, for example, "low IQ."

Helping the Family Decide about Genetic Counseling. If genetic counseling is appropriate, the physician or nurse-midwife discusses it with the woman and refers the family to an appropriate center. However, the final decision rests with the person affected. The nurse can help the woman and her family weigh issues that are important to them as they decide.

Genetic counseling can raise uncomfortable issues such as whether to undergo prenatal diagnosis, what to do if a condition cannot be prenatally diagnosed, and what options are acceptable if prenatal diagnosis shows abnormal results. Counseling may open family conflicts if information from other family members is needed or if family values differ on issues such as abortion of an abnormal fetus. In addition, the tests can show unexpected results (Box 5-6).

Teaching about Lifestyle. Nurses can teach a pregnant woman about harmful factors in her lifestyle that can be modified to reduce the risk of defects to offspring (see also Chapter 7). The nurse can support the woman in making difficult lifestyle changes such as stopping alcohol consumption, reducing or eliminating smoking, and improving the diet. Use of liberal praise can motivate a woman to continue her efforts to promote an optimal outcome. However, a negative attitude from nurses or other professionals may make the woman feel like a failure, and she may abandon her efforts to create a healthier lifestyle.

Providing Emotional Support. Until they know that prenatal test results are normal, possibly a period spanning several days or weeks, many women delay telling friends or family about their pregnancy or investing in it emotionally. When results are abnormal, women face

BOX 5-6 EXAMPLES OF PROBLEMS IN GENETIC COUNSELING AND PRENATAL DIAGNOSIS

Inadequate medical records
 Family members' refusal to share information
 Records that are incomplete, vague, or uninformative
 Inconclusive testing
 Too few family members available when family studies are needed
 Inadequate number of live fetal cells obtained during amniocentesis
 Failure of fetal cells to grow in culture if other testing techniques are not useful
 Ambiguous prenatal test results that are neither clearly normal nor clearly abnormal
 Unexpected results from prenatal diagnosis
 Finding an abnormality other than the one for which the person was tested
 Nonpaternity revealed with testing
 Inability to determine the severity of a prenatally diagnosed disorder
 Inability to rule out all birth defects
 Client misunderstanding of the mathematical risk as it is presented

more difficult decisions about whether to terminate or continue the pregnancy.

Helping the Family Deal with Abnormal Results. Because prenatal diagnostic tests are performed to detect disorders involving serious physical and often mental defects, the woman whose test results are abnormal must confront painful decisions. For many of these disorders, no effective prenatal or postnatal treatment exists. Only two choices may be available: continuing or terminating the pregnancy. In addition, the decision to terminate a pregnancy must be made in a short time. Making no decision is effectively a decision to continue the pregnancy. Although the physician or genetic counselor discusses abnormal results and available options, the nurse reinforces the information given to these anxious families and supports them.

When test results are abnormal, nurses should expect the couple to grieve. Even if a pregnancy was unplanned, the woman who undergoes prenatal diagnosis has already made the initial decision to continue the pregnancy. If results are abnormal, she must decide again if she will continue or end the pregnancy. Women who continue their pregnancies grieve over losing the expected normal infant (Weinhold, 2007).

Intrapartum and Neonatal Nurses

Nurses working in intrapartum and neonatal settings encounter families that have given birth to an infant with a birth defect that may have been unexpected. Stillborn infants sometimes have birth defects that contributed to their intrauterine death. In addition to the loss of their baby, these parents face pain because of the associated abnormality. An

autopsy may be performed to document all anomalies and to establish the most accurate diagnosis of the birth defect for future counseling. Nursing care for families that experience a perinatal loss, whether a result of the infant's death or the loss of the expected normal infant, is addressed in Chapter 24.

Nurses who care for these families in the intrapartum and neonatal settings will find the parents anxious, depressed, and sometimes hostile because of the unexpected event. The family's usual coping mechanisms may be inadequate for the situation, or new coping mechanisms may not have been developed. Diagnostic studies are often recommended soon after the birth of an infant with an abnormality to establish a diagnosis and to give parents accurate information about the abnormality and the options available to them. However, a high anxiety level reduces their ability to understand the often massive amount of information received. The nurse is in the best position to evaluate the family's perception of the problem, help them understand the diagnostic tests, reinforce correct information, and correct misunderstandings. In addition, the nurse is often most therapeutic by simply being an available, active listener, helping to ease the family's pain over the event.

Nurses should encourage families to contact lay support groups, which are significant sources of support because members fully understand the daily problems encountered in the care of a child with a birth defect. Such groups can help the parents manage the stress and chronic grief associated with prolonged care of these children. Support groups also can help the parents see the positive aspects and victories when caring for their child with special needs. Internet sites regarding specific birth defects are often available to offer parent education and support.

Pediatric Nurses

Children with birth defects typically have numerous recurrent medical problems. They usually are hospitalized more often and for longer periods compared with children without birth defects. Travel to specialized hospitals may be needed for their care, adding to the family's stress. These families often incur substantial expenses for medical care and equipment that are not covered by insurance or public assistance programs. Transportation costs to reach distant health care facilities may be difficult to pay. Household income may be lost because one parent, usually the mother, stops working to care for the child.

Family dysfunction is common, and the strain of caring for a child with a serious birth defect may lead to divorce. Siblings often feel left out of their parents' attention because the needs of this child demand so much of their parents' time.

The nurse case manager can reduce the family's stress by helping them locate appropriate support services. The nurse can contact social services departments to help the family find financial and other resources needed to care for the child. If parents have not connected with a lay support group, a nurse can encourage them to do so.

SUMMARY CONCEPTS

- The 46 human chromosomes are long strands of DNA, each containing up to several thousand individual genes.
- With the exception of those genes located on the X and Y chromosomes in males, genes are inherited in pairs that may be identical or different. Some genes are dominant, and some are recessive.
- Many genes can be analyzed by the products they produce, their DNA, or their close association with another gene that is more easily analyzed.
- Cells for chromosome analysis must be living cells. Specimens must be handled carefully to preserve viability if analysis of dividing cells in the metaphase of cell division is necessary. Other techniques such as FISH permit study of cells without requiring active cell division, allowing rapid test results.
- Chromosome abnormalities are either numerical, with the addition or deletion of an entire chromosome or chromosomes, or structural, with deletion, addition, rearrangement, or fragility of the chromosome material.

Continued

SUMMARY CONCEPTS—cont'd

- Single gene disorders are associated with a fixed risk of occurrence or recurrence. The type of single gene abnormality (autosomal dominant, autosomal recessive, or X-linked) determines the risk.
- Multifactorial disorders occur because of a genetic predisposition combined with environmental factors.
- The risk for occurrence or recurrence of multifactorial disorders is not fixed but varies according to the number of close relatives that are affected, severity of the defect in affected persons, gender of the affected person, and geographic location. Seasonal variations may affect the risk for some disorders.
- Relatively few agents that can enter the fetal environment are known to be definitely teratogenic or definitely safe.
- The risk for fetal damage from environmental agents can be decreased by reducing exposure to the agent or manipulating the fetal environment.
- The purpose of genetic counseling is to educate individuals or families with accurate information so that they can make informed decisions about reproduction and appropriate care for affected members.
- The nurse cares for people with concerns about birth defects by identifying those needing referral, teaching, coordinating services, and offering emotional support.

Conception and Prenatal Development

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe formation of the female and male gametes.
2. Relate ovulation and ejaculation to the process of human conception.
3. Explain implantation and nourishment of the embryo before development of the placenta.
4. Describe normal prenatal development from conception through birth.
5. Explain structure and function of the placenta, the umbilical cord, and fetal membranes with amniotic fluid.
6. Describe the occurrence of common deviations from normal conception and prenatal development.
7. Describe prenatal circulation and the circulatory changes after birth.
8. Explain the mechanisms and trends in multifetal pregnancies.

THE FAMILY BEFORE BIRTH

A basic understanding of conception and prenatal development helps the nurse provide care to parents during normal childbearing and better understand problems such as infertility and birth defects. This chapter addresses formation of the gametes and the process of conception, prenatal development, and important auxiliary structures that support normal prenatal development. The reason for the occurrence of multifetal pregnancy (e.g., twinning) is also discussed.

GAMETOGENESIS

Gametogenesis is the development of ova in the woman and sperm in the man (Table 6-1). Production of **gametes** (reproductive, or germ, cells), requires a process different from formation of **somatic cells** or other body cells. Somatic cells reproduce by a process called *mitosis*. Each somatic cell has 46 paired chromosomes: 22 pairs of **autosomes** (non-sex chromosomes) and 1 pair of **sex chromosomes** (X or Y chromosomes). During mitosis, the cell divides into two new cells, each having 46 chromosomes like the parent cell.

Gametogenesis requires a special reduction division called *meiosis*. Unlike **mitosis**, in which the **diploid** number (46) of chromosomes is retained in the new cells, **meiosis** halves the number of chromosomes to arrive at the **haploid** number of 23. Only 1 of each chromosome

pair (22 autosomes and 1 sex chromosome) is directed to the gamete. Also, with the exception of the X and Y chromosomes in the male, each chromosome exchanges some material with its mate so that the new chromosome in the gamete contains some material from the mother and some from the father. This process, which is called *crossing over*, allows variation in genetic material while keeping constant the total amount of chromosome material from generation to generation. When the sperm and ovum unite at conception, the “halves” form a new cell and restore the chromosome number to 46.

Oogenesis

Oogenesis is the formation of female gametes (Figure 6-1, A) within the ovary. Oogenesis begins during prenatal life when primitive ova (oogonia), like all other cells, multiply by mitosis. Each oogonium contains 46 chromosomes, as do other body cells. Before birth, these oogonia enlarge to form primary oocytes, each surrounded by a layer of follicular cells. These are called *primary follicles*. The primary oogonium begins its first meiotic division during fetal life but does not complete the process until puberty. The primary follicle and its oogonium, which still contains 46 chromosomes, remain dormant throughout childhood.

By the 30th week of gestation, the female fetus has all the ova she will ever have. Many of these ova regress during childhood. When a girl’s reproductive cycles begin at puberty, some of the primary follicles

TABLE 6-1 COMPARISON OF FEMALE AND MALE GAMETOGENESIS

	OOGENESIS	SPERMATOGENESIS
Time during which primary germ cells are produced	Fetal life; no others develop after about 30 weeks of gestation	Continuously after puberty
Hormones that control process	GnRH FSH LH Estrogen	GnRH FSH LH Testosterone Estrogen (small amounts converted from testosterone) Growth hormone
Number of mature germ cells that develop from each primary cell	One	Four
Quantity	One during each reproductive cycle of about 28 days	Approximately 35 to 200 million released with each ejaculation
Size	Large; visible to naked eye; abundant cytoplasm to nourish embryo until implantation	Tiny compared with ovum; little cytoplasm; head is almost all nuclear material (chromosomes)
Motility	Relatively nonmotile; transported by action of cilia and currents within fallopian tubes	Independently motile by means of whiplike tail; mitochondria in middle piece provide energy for motility
Chromosome complement	23 total: 22 autosomes plus 1 X sex chromosome	23 total: 22 autosomes, plus either an X or a Y sex chromosome

FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

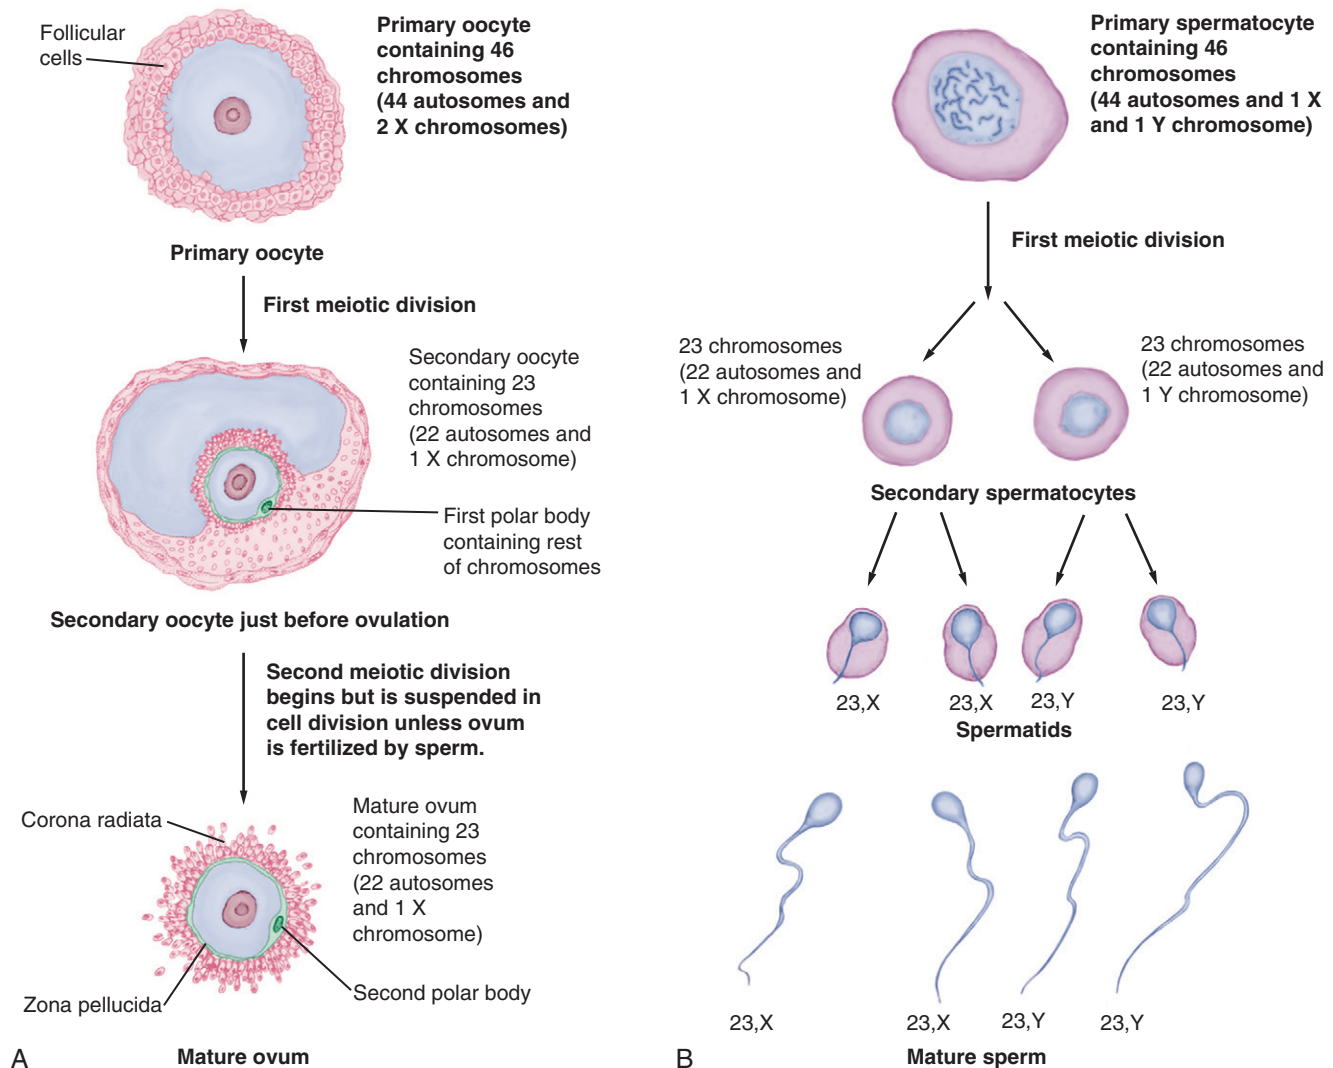

FIG 6-1 Gametogenesis. **A**, Formation of the mature ovum. **B**, Formation of mature sperm.

present at birth begin maturing. The process of gamete maturation continues throughout her reproductive years until the climacteric, which is sometimes called the *change of life*.

When the oocyte matures, two meiotic divisions reduce the chromosome number from 46 paired chromosomes to 23 unpaired chromosomes: 22 autosomes and 1 X chromosome. Shortly before **ovulation**, or release of the mature ovum from the ovary, the primary oocyte completes its first meiotic division, which began during fetal life. The result is a secondary oocyte that now contains 23 chromosomes. The primary cell's cytoplasm is divided unequally with this division, and most of it is retained by the secondary oocyte. The remainder of cytoplasm plus the other half of the chromosomes go into a tiny, nonfunctional polar body that soon degenerates.

At ovulation, the secondary oocyte begins to form a mature ovum (second meiotic division). Each of the 23 chromosomes divides without replication of the deoxyribonucleic acid (DNA). The second meiotic division is prolonged, and the mature ovum remains suspended in metaphase, the middle part of cell division. If fertilization occurs, the second meiotic division is completed, resulting in a mature ovum that also contains 23 chromosomes and a second tiny polar body containing the 23 discarded chromosomes that degenerate. If the ovum is not fertilized, it does not complete the second meiotic division and degenerates. In oogenesis, one primary oocyte results in a single mature ovum.

When the mature ovum is released from the ovary, it is surrounded by two layers: the zona pellucida and the cells of the corona radiata. These layers protect the ovum and prevent fertilization by more than one sperm. For fertilization to occur, the sperm must penetrate these two layers to reach the ovum's cell nucleus.

Spermatogenesis

Spermatogenesis (formation of sperm, or male gametes, in the testes) (see [Figure 6-1, B](#)) begins during puberty in the male and requires about 70 days to be completed. Primitive sperm cells, or spermatogonia, develop during the prenatal period and begin multiplying by mitosis during puberty. Unlike the female, the male continues to produce new spermatogonia that can mature into sperm throughout his lifetime. Although male fertility gradually declines with age, men can father children in their fifties, sixties, and beyond.

Each spermatogonium contains 46 paired chromosomes, like other body cells. In the mature male, a spermatogonium enlarges to become a primary spermatocyte that still contains all 46 chromosomes. The first meiotic division forms two secondary spermatocytes and reduces the number to 23 unpaired chromosomes in each gamete: 22 autosomes and 1 X or Y sex chromosome in each spermatocyte. Each chromosome of the secondary spermatocyte divides to retain 23 chromosomes in the second meiotic division, forming two spermatids. Therefore, 50% of the four spermatids that result from the two meiotic divisions of the spermatogonium carry an X chromosome, and 50% carry a Y chromosome. The spermatids gradually evolve into mature sperm.

The gamete from a male determines the gender of the new baby because the ovum carries only an X chromosome. Each mature sperm contains 23 chromosomes: 22 autosomes and either an X or a Y chromosome. If an X-bearing spermatozoon fertilizes the ovum, the baby is a girl. If a Y-bearing spermatozoon fertilizes the ovum, the baby is a boy.

The mature sperm has three major sections: a head, middle portion, and tail ([Figure 6-2](#)). The head is almost entirely a cell nucleus and contains the male chromosomes that join the chromosomes of the ovum. The middle portion supplies energy for the tail's whiplike action. The movement of the tail propels the sperm toward the ovum.

FIG 6-2 Mature sperm.

CHECK YOUR READING

1. What is the purpose of meiosis in the gametes?
2. How many mature ova can be produced by each oogonium? When does meiosis occur in the female?
3. How many mature spermatozoa can be produced by each spermatogonium? When does meiosis occur in the male?

CONCEPTION

Natural conception is the interaction of many factors, including correct timing between release of a mature ovum at ovulation and **ejaculation** (semen expulsion) of enough healthy, mature, motile sperm into the vagina. Although exact viability is unknown, the ovum may survive no longer than 24 hours after its release at ovulation. Most sperm survive no more than 24 hours in the female reproductive tract, although a few may remain fertile in the woman's reproductive tract up to 80 hours ([Blackburn, 2013](#); [Hall, 2011](#)).

Preparation for Conception in the Female

Before ovulation, several oocytes begin to mature under the influence of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the woman's anterior pituitary gland. Each maturing oocyte is contained within a sac called the **graafian follicle**, which produces estrogen and progesterone to prepare the **endometrium** (uterine lining) for a possible pregnancy. Eventually, one follicle outgrows the others. The less mature oocytes permanently regress.

Release of the Ovum

Ovulation occurs approximately 14 days before a woman's next menstrual period would begin. The follicle develops a weak spot on the surface of the ovary and ruptures, releasing the mature ovum with its surrounding cells onto the surface of the ovary. The collapsed follicle is transformed into the **corpus luteum**, which maintains high estrogen

FIG 6-3 Process of fertilization. **A**, A sperm enters the ovum. **B**, The 23 chromosomes from the sperm mingle with the 23 chromosomes from the ovum, restoring the diploid number to 46. **C**, The fertilized ovum is now called a *zygote* and is ready for the first mitotic cell division.

and progesterone secretion necessary to make final preparation of the uterine lining for a fertilized ovum.

Ovum Transport

The mature ovum is released on the surface of the ovary, where it is picked up by the fimbriated (fringed) ends of the fallopian tube. The ovum is transported through the tube by the muscular action of the tube and movement of cilia within the tube. Fertilization normally occurs in the distal third of the fallopian tube (ampulla) near the ovary. The ovum, fertilized or not, enters the uterus about 3 days after its release from the ovary.

Preparation for Conception in the Male

The male preparation for fertilizing the ovum consists of ejaculation, movement of the sperm in the female reproductive tract, and preparation of the sperm for actual fertilization.

Ejaculation

When a male ejaculates during sexual intercourse, 35 to 200 million sperm, 50% to 90% of which are morphologically normal, are deposited in the upper vagina and over the cervix. The sperm are suspended in 2 to 5 milliliters (mL) of seminal fluid, which nourishes and protects the sperm from the acidic environment of the vagina (Blackburn, 2013; Hall, 2011; Jones, 2009d). Many sperm are lost as the ejaculate drips from the vaginal introitus. Other sperm are inactivated by acidic vaginal secretions or digested by vaginal enzymes and phagocytes. The seminal fluid coagulates slightly after ejaculation to hold the semen deeply in the vagina. Many sperm are relatively immobile for approximately 15 to 30 minutes until other seminal enzymes dissolve the coagulated fluid and allow the sperm to begin moving upward through the cervix.

Transport of Sperm in the Female Reproductive Tract

The whiplike movement of the tails of spermatozoa propels them through the cervix, uterus, and fallopian tubes. Uterine contractions induced by prostaglandins in the seminal fluid enhance movement of the sperm toward the ovum. Only sperm cells enter the cervix. The seminal fluid remains in the vagina.

Many sperm are lost along the way. Some are digested by enzymes and phagocytes in the female reproductive tract, whereas others simply lose their direction, moving into the wrong tube or past the ovum and

out into the peritoneal cavity. Only 50 to 150 reach the fallopian tube where the ovum waits (Jones, 2009b).

Preparation of Sperm for Fertilization

Sperm are not immediately ready to fertilize the ovum when they are ejaculated. During the trip to the ovum, the sperm undergo changes that enable one of them to penetrate the protective layers surrounding the ovum, a process called *capacitation*. During capacitation, a glycoprotein coat and seminal proteins are removed from the acrosome, which is the tip of the sperm head. After capacitation, the sperm look the same but are more active and can better penetrate the corona radiata and zona pellucida surrounding the ovum.

Sperm must also undergo an acrosome reaction to further prepare them to fertilize the ovum. The sperm that reach the ovum release hyaluronidase and acrosin to digest a pathway through the corona radiata and zona pellucida. Their tails beat harder to propel them toward the center of the ovum. Eventually, one spermatozoon penetrates the ovum.

Fertilization

Fertilization occurs when one spermatozoon enters the ovum and the two nuclei containing the parents' chromosomes merge (Figure 6-3).

Entry of One Spermatozoon into the Ovum

Entry of a spermatozoon into the ovum has three results. First is the zona reaction, in which changes in the zona pellucida surrounding the ovum prevent other sperm from entering. Second, the cell membranes of the ovum and sperm fuse and break down, allowing the contents of the sperm head to enter the cytoplasm of the ovum. Third, the ovum, which has been suspended in the middle of its second meiotic division since just before ovulation, completes meiosis. This results in a nucleus with 23 chromosomes and the expulsion of a second nonfunctional polar body. The mature ovum now contains 23 unpaired chromosomes (22 autosomes and 1 X chromosome) in its nucleus.

Fusion of the Nuclei of Sperm and Ovum

Once a spermatozoon has penetrated the ovum, fusion of their nuclei begins. The sperm head enlarges, and the tail degenerates. The nuclei of the gametes move toward the center of the ovum, where the membranes surrounding their nuclei touch and dissolve. The 23 chromosomes from the sperm mingle with the 23 from the ovum, restoring

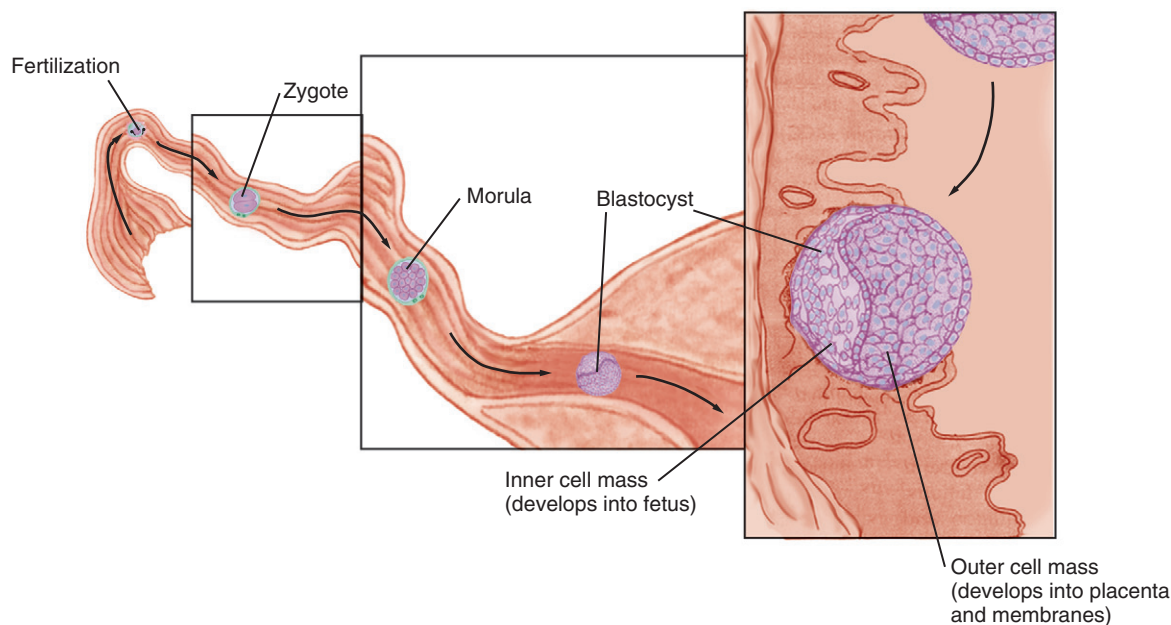

FIG 6-4 Prenatal development from fertilization through implantation of the blastocyst. Implantation gradually occurs from day 6 through day 10. Implantation is complete on day 10.

the diploid number to 46. Fertilization is complete, and cell division can begin when the nuclei of the sperm and ovum unite.

PREEMBRYONIC PERIOD

The preembryonic period is the first 2 weeks after conception (Figure 6-4). Around the fourth day after conception, the fertilized ovum, now called a **zygote**, enters the uterus.

Initiation of Cell Division

The zygote divides into 2, then 4, then 8 cells, and so on. Until the 16-cell stage, the cells become tightly compacted with each division so that they occupy about the same amount of space as the original zygote. When the **conceptus** (cells and membranes resulting from fertilization of the ovum) is a solid ball of 12 to 16 cells, it is called a **morula** because it resembles a mulberry.

The outer cells of the morula secrete fluid, forming a **blastocyst**, a sac of cells with an inner cell mass placed off center within the sac. The inner cell mass develops into the **fetus**. Part of the outer layer of cells develops as the fetal membranes and the **placenta**, or the fetal structure that provides nourishment, removes wastes, and secretes necessary hormones for continuation of the pregnancy.

Entry of the Zygote into the Uterus

When the blastocyst contains about 100 cells, it enters the uterus. It lingers in the uterus another 2 to 4 days before beginning implantation. The endometrium, now called the **decidua**, is in the secretory phase of the reproductive cycle, 1½ weeks before the woman would otherwise

begin her menstrual period. The endometrial glands are secreting at their maximum, providing rich fluids to nourish the conceptus before placental circulation is established. The endometrial spiral arteries are well developed in the secretory phase, providing easy access for the development of the placental blood supply.

Implantation in the Decidua

The conceptus carries a small supply of nutrients for early cell division. However, implantation at the proper time and location in the uterus is critical for continued development. Implantation, or **nidation**, is a gradual process that occurs between days 6 and 10 after conception. During the relatively long process of implantation, embryonic structures continue to develop.

Maintaining the Decidua

Implantation and survival of the conceptus require a continuing supply of estrogen and progesterone to maintain the decidua in the secretory phase. The zygote secretes human chorionic gonadotropin (hCG) to signal the woman's body that a pregnancy has begun. Production of hCG by the conceptus causes the corpus luteum to persist and continue secretion of estrogen and progesterone until the placenta takes over this function.

Location of Implantation

The conceptus must be in the right place at the right time for normal implantation to occur. The site of implantation is important because that is where the placenta develops. Normal implantation occurs in the upper uterus, slightly more often on the posterior wall than the anterior wall (Moore, Persaud, & Torchia, 2013, a, b). The upper uterus is the best area for implantation and placental development for three reasons:

1. The upper uterus is richly supplied with blood for optimal fetal gas exchange, nutrition, and waste elimination.
2. The uterine lining is thick in the upper uterus, preventing the placenta from attaching too deeply into the uterine muscle and facilitating easy expulsion of the placenta after full-term birth.

- Implantation in the upper uterus limits blood loss after birth because strong interlacing muscle fibers in this area compress open endometrial vessels after the placenta detaches.

Mechanism of Implantation

Enzymes produced by the conceptus erode the decidua, tapping maternal sources of nutrition. Primary chorionic villi are tiny projections on the surface of the conceptus extending into the endometrium, now called the *decidua basalis*, which lies between the conceptus and the wall of the uterus. The chorionic villi eventually form the fetal side of the placenta. The decidua basalis forms the maternal side of the placenta (see Figure 6-7, A).

At this early stage, nutritive fluid passes to the embryo by *diffusion* (the passive movement across a cell membrane from an area of higher concentration to one of lower concentration) because the circulatory system is not yet established. The conceptus is fully embedded within the mother's uterine decidua by 10 days, and the site of implantation is almost invisible.

As the conceptus implants, usually near the time of the next expected menstrual period, a small amount of bleeding ("spotting") may occur at the site. Implantation bleeding may be confused with a normal menstrual period, particularly if the woman's menstrual periods are usually light.

EMBRYONIC PERIOD

The embryonic period of development extends from the beginning of the third week through the eighth week after conception (Figure 6-5). Basic structures of all major body organs are completed during the embryonic period (Table 6-2).

Differentiation of Cells

The **embryo** (developing baby from the beginning of the third week through the eighth week after conception) progresses from undifferentiated cells with essentially identical functions to differentiated, or specialized, body cells. By the end of the eighth week, all major organ systems are in place, and many are functioning, although in a simple way.

Development of the specialized structures is controlled by three factors: (1) genetic information in the chromosomes received from the parents, (2) interaction between adjacent tissues, and (3) timing. Although basic instructions are carried within the chromosomes, one tissue may induce change toward greater specialization in another, but only if a signal between the two tissues occurs at a specific time during development. In this way, structures develop with appropriate sizes and relationships to each other.

During the embryonic period, structures are vulnerable to damage from **teratogens** because these structures are developing rapidly. Normal development of one structure often requires normal and properly timed development of another structure. Unfortunately, a woman may not realize she is pregnant during this sensitive time. For this reason, the possibility of pregnancy should be explored with her before the prescription of drugs or administration of diagnostic procedures

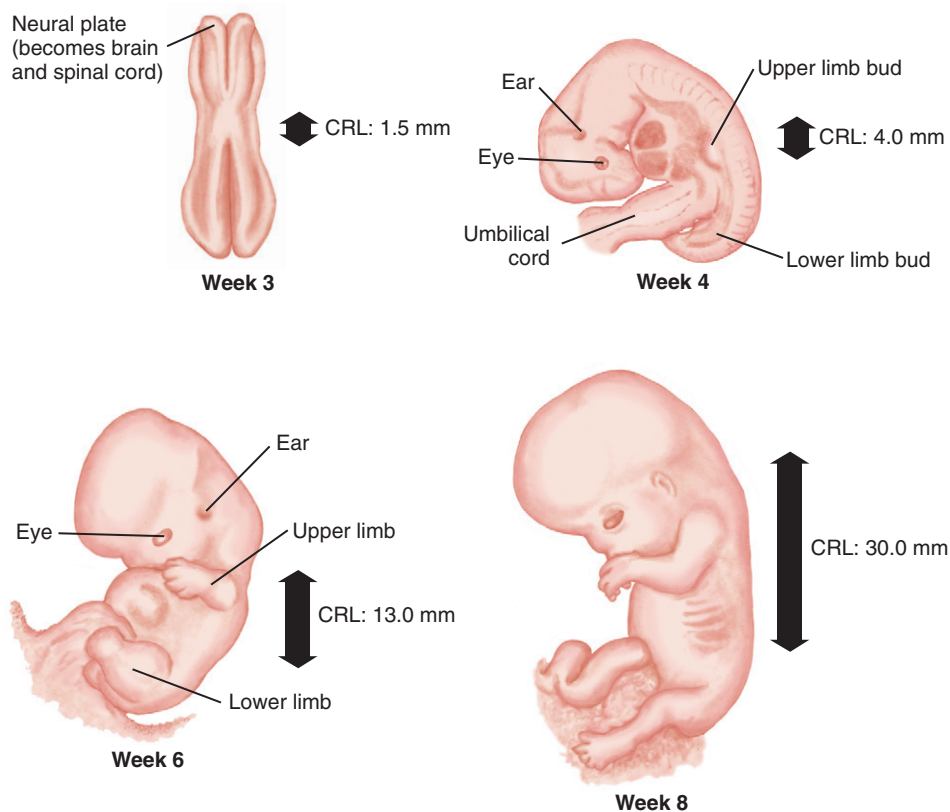

FIG 6-5 Embryonic development from week 3 through week 8 after fertilization. **A**, Week 3. **B**, Week 4. **C**, Week 6. **D**, Week 8. *CRL*, Crown-rump length.

TABLE 6-2 TIMETABLE OF PRENATAL DEVELOPMENT BASED ON FERTILIZATION AGE*

NERVOUS/ SENSORY SYSTEM	CARDIORESPIRATORY SYSTEM	DIGESTIVE SYSTEM	GENITOURINARY SYSTEM	MUSCULOSKELETAL SYSTEM	INTEGUMENTARY SYSTEM
3 Weeks: 1.5-mm CRL[†]					
Flat neural plate begins closing to form neural tube. Neural tube still open at each end.	Heart consists of two parallel tubes that fuse into a single tube. Contractions of heart tube begin. Chorionic villi of early placenta connect with heart.	Endoderm (inner germ layer) will become digestive tract.		Paired, cube-shaped swellings (somites) appear and will form most of head and trunk skeleton. Muscle, bone, and cartilage develop from mesoderm.	Epidermis (outer skin layer) will develop from ectoderm (outer germ layer). Dermis (deep skin layer) and connective tissue will develop from mesoderm (middle germ layer).
4 Weeks: 4-mm CRL					
Neural tube closed at each end. Cranial end of neural tube will form brain; caudal end will form spinal cord. Eye development begins as an outgrowth of forebrain. Nose development begins as two pits. Inner ear begins developing from hindbrain.	Heart begins partitioning into four chambers and begins beating. Blood circulating through embryonic vessels and chorionic villi. Tracheal development begins as a bud on upper gut and branches into two bronchial buds.	Development of primitive gut as embryo folds laterally. Stomach begins as a widening of tube-shaped primitive gut. Liver, gallbladder, and biliary ducts begin as a bud from primitive gut.	Primordial germ (reproductive) cells are present on embryonic yolk sac.	Upper limb buds are present and look like flippers. Lower limb buds appear.	Mammary ridges that will develop into mammary glands appear.
6 Weeks: 13-mm CRL					
Development of pituitary gland and cranial nerves. Head sharply flexed because of rapid brain growth. Eyelid development beginning. External ear development begins in neck region as six swellings.	Blood formation primarily in liver. Three right and two left lung lobes develop as outgrowths of right and left bronchi. Partitioning of heart into four chambers completed.	Most intestines are contained within umbilical cord because liver and kidneys occupy most of abdominal cavity. Stomach nearing final form. Development of upper and lower jaws.	Kidneys are near bladder in pelvis. Kidneys occupy much of abdominal cavity. Primordial germ cells incorporated into developing gonads. Male and female gonads are identical in appearance.	Arms are paddle shaped, and fingers webbed. Feet and toes develop similarly, but a few days later than arms and hands. Bones cartilaginous, but ossification of skull begins.	Mammary glands begin development. Tooth buds for primary (deciduous) teeth begin developing.
8 Weeks: 30-mm CRL					
Spinal cord stops at end of vertebral column. Taste buds begin developing. Eyelids fuse. Ears have final form but are low-set.	Heart partitioned into four chambers. Heartbeat detectable with ultrasound. Additional branching of bronchi.	Stomach has reached final form. Lips are fused. Intestines remain in umbilical cord.	Testes begin developing under influence of Y chromosome. Ovaries will develop if a Y chromosome is not present. External genitalia begin to differentiate but still appear quite similar.	Fingers and toes still webbed, but distinct by end of week 8. Bones begin to ossify. Joints resemble those of adults.	Auricles of ear low-set but beginning to assume final shape.

Continued

TABLE 6-2 TIMETABLE OF PRENATAL DEVELOPMENT BASED ON FERTILIZATION AGE—cont'd

NERVOUS/ SENSORY SYSTEM	CARDIORESPIRATORY SYSTEM	DIGESTIVE SYSTEM	GENITOURINARY SYSTEM	MUSCULOSKELETAL SYSTEM	INTEGUMENTARY SYSTEM
10 Weeks: 61-mm CRL; Weight, 14 g[†]					
Head flexion still present, but straighter. Eyelids closed and fused. Top of external ear slightly below eye level.	May be possible to detect heartbeat with Doppler transducer. Blood produced in spleen and lymphatic tissue.	Intestines contained within abdominal cavity as growth of this cavity catches up with digestive system development. Digestive tract patent from mouth to anus.	Kidneys in their adult position. Male and female external genitalia have different appearance but are still easily confused.	Toes distinct; soles face each other.	Fingernails begin developing. Tooth buds for permanent teeth begin developing below those for primary teeth.
12 Weeks: 87-mm CRL; Weight, 45 g					
Surface of brain is smooth, without sulci (grooves) or gyri (convolutions). Nasal septum and palate complete development.	Heartbeat should be detected with Doppler transducer.	Sucking reflex present. Bile formed by liver.	Kidneys begin producing urine. Male and female external genitalia can be distinguished by appearance.	Limbs are long and thin. Involuntary muscles of viscera develop.	Downy lanugo begins developing at end of this week.
16 Weeks: 140-mm CRL; Weight, 200 g					
Face is human-looking because eyes face forward rather than to side.	Pulmonary vascular system developing rapidly.	Fetus swallows amniotic fluid and produces meconium (bowel contents).	Urine excreted into amniotic fluid.	Lower limbs reach final relative length, longer than upper limbs. A woman who has been pregnant before may begin to feel fetal movements.	External ears have enough cartilage to stand away from head somewhat. Blood vessels easily visible through delicate skin. Fingerprints developing.
20 Weeks: 160-mm CRL; Weight, 460 g					
Myelination of nerves begins and continues through first year of postnatal life.	Heartbeat should be detectable with regular fetoscope.	Peristalsis well developed.	More than 40% of nephrons are mature and functioning. Testes contained in abdomen but begin descent toward scrotum. Primordial follicles of ovary reach peak of 5 to 7 million and then gradually decline.	Fetal movements felt by mother and may be palpable by an experienced examiner.	Skin is thin and covered with vernix caseosa. Brown fat production complete. Nipples begin development.
24 Weeks: 230-mm CRL; Weight, 820 g					
Spinal cord ends at level of first sacral vertebra because of more rapid growth of vertebral canal.	Primitive thin-walled alveoli (air sacs) have developed and are surrounded by capillary network. Surfactant production begins in lungs. Respiration possible, but many fetuses die or have disabilities if born at this time.		Testes descending toward inguinal rings.	Fetus is active. Fetal movements become progressively more noticeable to both mother and examiner.	Body appearance lean. Skin wrinkled and red. Fingerprints and footprints developed. Fingernails present. Eyebrows and lashes present.

TABLE 6-2 TIMETABLE OF PRENATAL DEVELOPMENT BASED ON FERTILIZATION AGE—cont'd

NERVOUS/ SENSORY SYSTEM	CARDIORESPIRATORY SYSTEM	DIGESTIVE SYSTEM	GENITOURINARY SYSTEM	MUSCULOSKELETAL SYSTEM	INTEGUMENTARY SYSTEM
28 Weeks: 270-mm CRL; Weight, 1300 g					
Major sulci and gyri are present.	Erythrocyte formation completely in bone marrow.		Testes descended through inguinal canal into scrotum by end of week 26.		Skin slightly wrinkled but smoothing out as subcutaneous fat is deposited under it.
Eyelids no longer fused after 26 weeks.	Sufficient alveoli, surfactant, and capillary network to allow respiratory function, although respiratory distress syndrome is common. Many infants born at this time survive with intensive care.				
Responds to bitter substances on tongue.					
32 Weeks: 300-mm CRL; Weight, 2100 g					
Maturation of parasympathetic nears that of sympathetic nervous system, resulting in fetal heart rate variability on electronic fetal monitor tracing.	Surfactant production nears mature levels. Respiratory distress still possible if born at 32 weeks. Fetal heart rate variability gradually increases toward full term.				Skin smooth and pigmented. Large vessels visible beneath skin. Fingernails reach fingertips. Lanugo disappearing.
38 Weeks: 360-mm CRL; Weight, 3400 g					
Sulci and gyri developed.	Newborn infant has about one eighth to one sixth number of alveoli of an adult. Well-developed ability to exchange gas.		Both testes usually palpable in scrotum at birth. The newborn girl's ovaries contain about one million follicles. No new ones are formed after birth; their numbers continue to decline after birth.		Fetus plump, and skin smooth. Vernix caseosa present in major body creases. Lanugo present on shoulders and upper back only. Fingernails extend beyond fingertips. Ear cartilage firm.
Visual acuity about 20/600 at birth.					

*Fertilization age is about 2 weeks less than gestational age.

†CRL, Crown-rump length; g, gram(s).

such as radiography. Some agents may be damaging at one time during pregnancy but not at another. Others may be damaging at any time during pregnancy (see [Appendix A](#)).

Weekly Developments

Development occurs simultaneously in all embryonic organ systems. Prenatal development proceeds in patterns that continue after birth:

- Cephalocaudal (head to toe)
- Central-to-peripheral direction (from center outward)
- Simple to complex (early cells may become any cell of the body before they become specialized into specific structures with specific functions)

- General to specific (upper extremities begin as limb buds before detailed development of bones, joints, muscles, ligaments, and fingers)

Full term ranges from 36 to 40 weeks of **fertilization age** calculated from date of conception, or 38 to 42 weeks of **gestational age** (after last menstrual period). Because conception occurs approximately 2 weeks after the first day of the last menstrual period in most women who have 4-week cycles, the fertilization age, used in this chapter, is approximately 2 weeks shorter than the gestational age. However, gestational age is most commonly used in practice because the last menstrual period provides a known marker, whereas most women do not know exactly when they conceived. Ultrasonography

provides added information to identify the most accurate fetal age (see Chapter 10).

Week 2

Implantation is complete by the end of the second week after fertilization. The most growth occurs in the outer cells, or trophoblast, which eventually becomes the fetal part of the placenta. The inner cell mass that will develop into the baby becomes flattened into the embryonic disc. Cells that eventually form part of the fetal membranes develop.

Week 3

Many women miss their first menstrual period during the third week after conception. The embryonic disc develops three layers, called *germ layers*, which, in turn, give rise to major organ systems of the body (Table 6-3). The three germ layers are the ectoderm, the mesoderm, and the endoderm.

The central nervous system (CNS) begins developing during the third week. A thickened, flat neural plate appears, extending toward the end of the embryonic disc that will become the head. The neural plate develops a longitudinal groove that folds to form the neural tube. At the end of the third week, the neural tube is fused in the middle but still open at each end.

Early heart development consists of a pair of parallel heart tubes that run and then fuse longitudinally. The primitive, or tubular, heart begins beating at 22 to 23 days, resulting in a wavelike flow of blood. By the end of the fourth week, coordinated contractions result in the unidirectional flow of blood that characterizes the mature heart. Vessels developing in the chorionic villi and membranes join the heart tube. Primitive blood cells arise from the endoderm lining the distal blood vessels.

Week 4

The shape of the embryo changes during the fourth week after conception. It folds at the head and tail end and laterally, resembling a C-shaped cylinder. A “tail” is apparent during the embryonic period because the brain and spinal cord develop more rapidly compared with other systems. The tail disappears as the rest of the body catches up with growth of the CNS. The neural tube closes during the fourth week. If the neural tube does not close, defects such as anencephaly and spina bifida result.

Formation of the face and upper respiratory tract begins. Beginnings of the internal ear and the eye are apparent. The upper extremities appear as buds on the lateral body walls. Because the embryo is sharply flexed anteriorly, the heart is near the embryo’s mouth. Partitioning of the heart into four chambers begins during the fourth week and is completed by the end of the sixth week.

The lower respiratory tract begins growth as a branch of the upper digestive tract, which is a simple tube at this time. Gradually, the esophagus and trachea complete separation. The trachea branches to form the right and left bronchi. These bronchi, in turn, branch to form the three lobes of the right lung and two lobes of the left lung. Continued branching of the bronchi eventually forms the terminal air sacs, or alveoli. The alveoli proliferate and become surrounded by a rich capillary network that enables oxygen and carbon dioxide exchange at birth.

Week 5

The head is very large because the brain grows rapidly during the fifth week after fertilization. The heart is beating and developing four chambers. Upper limb buds are paddle shaped with obvious notches between the fingers. Lower limbs form slightly later than upper ones. Lower limbs are also paddle shaped, but the area between the toes is not as well defined as is the division between the fingers.

Week 6

The rapidly developing head is bent over the chest. The heart reaches its final four-chambered form. Upper and lower extremities continue to become more defined.

The eyes continue to develop, and the beginnings of the external ears appear as six small bumps on each side of the neck. Facial development begins with eyes, ears, and nasal pits that are widely separated and aligned with the body walls. Gradually the embryo grows such that the face comes together in the midline and the external ears assume their proper position on the sides of the head.

Week 7

General growth and refinement of all systems occur 7 weeks after conception. The face becomes more human looking. The eyelids begin to grow, and the extremities become longer and better defined. The trunk elongates and straightens, although a C-shaped spinal curve remains in the newborn at birth.

TABLE 6-3 DERIVATIVES OF THE THREE GERM LAYERS

ECTODERM	MESODERM	ENDODERM
Brain and spinal cord	Cartilage	Lining of gastrointestinal and respiratory tracts
Peripheral nervous system	Bone	Tonsils
Pituitary gland	Connective tissue	Thyroid
Sensory epithelium of eye, ear, and nose	Muscle tissue	Parathyroid
Epidermis	Heart	Thymus
Hair	Blood vessels	Liver
Nails	Blood cells	Pancreas
Subcutaneous glands	Lymphatic system	Lining of urinary bladder and urethra
Mammary glands	Spleen	Lining of ear canal
Tooth enamel	Kidneys	
	Adrenal cortex	
	Ovaries	
	Testes	
	Reproductive system	
	Lining membranes (pericardial, pleural, and peritoneal)	

The intestines have been growing faster than the abdominal cavity during the embryonic period. The relatively large liver and kidneys also occupy much of the abdominal cavity. Therefore, most of the intestines are contained within the umbilical cord while the abdominal cavity grows to accommodate them. The abdomen is large enough to contain all its normal contents by 10 weeks.

Week 8

The embryo has a definite human form, and refinements to all systems continue. The ears are low-set but approaching their final location. The eyes are pigmented but not yet fully covered by eyelids. Fingers and toes are stubby but well-defined. The external genitalia begin to differentiate, but male and female characteristics are not distinct until 10 weeks after conception, or 12 weeks after the woman’s last menstrual period.

CHECK YOUR READING

11. Why is the embryo particularly susceptible to damage from teratogens?
12. How does the lower respiratory tract develop?
13. Why are the intestines mostly contained within the umbilical cord until the tenth week?

FETAL PERIOD

The fetal period is the longest part of prenatal development. It begins 9 weeks after conception and ends with birth. All major systems are present in their basic form. Dramatic growth and refinement in the structure and function of all organ systems occur during the fetal period (Figure 6-6). Teratogens may damage already formed structures but are less likely to cause major structural alterations. The CNS is vulnerable to damaging agents through the entire pregnancy. (In this discussion, *weeks of gestation* refers to weeks after conception. Add 2 weeks to obtain the approximate number of weeks from the woman’s last menstrual period.)

Weeks 9 through 12

The head is approximately half the total length of the fetus at the beginning of this period. The body begins growing faster than the head, changing the proportions. The extremities approach their final relative lengths, although the legs remain proportionately shorter than the arms. The first fetal movements begin but are too slight for the mother to detect.

The face is broad with a wide nose and widely spaced eyes. The eyes close at 9 weeks and reopen at 26 weeks after conception. The ears appear low-set because the mandible is still small.

FIG 6-6 Fetal development from week 9 through week 38 of fertilization age. The gestational age, measured from the first day of the last menstrual period, is approximately 2 weeks longer than the fertilization age.

The intestinal contents that were partly contained within the umbilical cord enter the abdomen by 11 weeks as the capacity of the abdominal cavity catches up with them in size. Blood formation occurs primarily in the liver during week 9 but shifts to the spleen by the end of week 12. The fetus begins producing urine during this period and excretes it into the amniotic fluid.

Internal differences in males and females begin to be apparent in the seventh week. External genitalia look similar until the end of the ninth week. By the end of week 12, the fetal gender can be determined by the appearance of the external genitalia.

Weeks 13 through 16

The fetus grows rapidly in length, so the head becomes smaller in proportion to the total length. Movements strengthen, and some women, particularly those who have been pregnant before, are able to detect them. This phenomenon is referred to as *quickening*. The face looks human because the eyes face fully forward. The ears approach their final position at the sides of the head and in line with the eyes.

Weeks 17 through 20

Fetal movements feel like fluttering or “butterflies.” Some women may not recognize these subtle sensations. The fetus is unlikely to survive at the age of 20 weeks.

Changes in the skin and hair are evident. *Vernix caseosa*, a fatty, cheeselike secretion of the fetal sebaceous glands, covers the skin to protect it from constant exposure to amniotic fluid. *Lanugo* is fine, downy hair that covers the fetal body and helps the vernix adhere to the skin. Both vernix and lanugo diminish as the fetus reaches term. Eyebrows and head hair appear.

Brown fat is a special heat-producing fat deposited during this period that helps the newborn maintain temperature stability after birth. It is located on the back of the neck, behind the sternum, and around the kidneys (see [Chapter 19](#), [Figure 19-4](#)).

Weeks 21 through 24

While continuing to grow and gain weight, the fetus still appears thin because of minimal subcutaneous fat. The skin is translucent and red because the capillaries are close to its fragile surface.

The lungs begin to produce surfactant, a surface-active lipid that makes it easier for the baby to breathe after birth. Surfactant reduces surface tension in the lung alveoli and prevents them from collapsing with each breath. Production of surfactant begins at approximately 20 weeks but does not reach levels that increase likelihood of survival outside the uterus until 26 to 28 weeks after conception. Surfactant production increases during late pregnancy, particularly during the last 2 weeks ([Hall, 2011](#); [Moore et al., 2013b](#)). To reduce respiratory distress of prematurity, artificial surfactant may be given to infants who are at risk for a deficiency because of their immaturity. Maternal corticosteroids such as betamethasone may be given before birth to accelerate surfactant production in the preterm fetus likely to be born before completion of 34 weeks of gestation (see [Chapter 27](#) for discussion of preterm labor care).

The capillary network surrounding the alveoli is increasing but still very immature, although some gas exchange is possible. A fetus born at this gestational age is less likely to survive because of inadequate gas exchange. Other systems are extremely immature as well, such as blood vessels in the brain that may bleed.

Weeks 25 through 28

The fetus is more likely to survive if born during this period because of maturation of the lungs, pulmonary capillaries, and CNS. The fetus becomes plumper with smoother skin as subcutaneous fat is deposited

under the skin. The skin gradually becomes less red. The eyes, which were closed during the ninth week, reopen. Head hair is abundant. Blood formation shifts from the spleen to the bone marrow.

During early pregnancy the fetus floats freely within the amniotic sac. However, the fetus usually assumes a head-down position during this time for two reasons:

1. The uterus is shaped like an inverted egg. The overall shape of the fetus in flexion is similar, with the head being the small pole of the egg shape and the buttocks, flexed legs, and feet being the larger pole.
2. The fetal head is heavier than the feet, and gravity causes the head to drift downward in the pool of amniotic fluid.

The head-down position is also most favorable for normal birth.

Weeks 29 through 32

The skin is pigmented according to race and is smooth. Larger vessels are visible over the abdomen, but small capillaries cannot be seen. Toenails are present, and fingernails extend to the fingertips. The fetus has more subcutaneous fat, which rounds the body contours. If the fetus is born during this period, chances of survival are good with specialized neonatal care.

Weeks 33 through 38

Growth of all body systems continues until birth, but the rate of growth slows as full term approaches. The fetus is mainly gaining weight. The pulmonary system matures to enable efficient and unlabored breathing after birth.

The well-nourished term fetus at 38 or more weeks is rotund with abundant subcutaneous fat. At birth, boys are slightly heavier than girls. The skin is pink to brownish pink, depending on race. Lanugo may be present over the forehead, upper back, and upper arms. Vernix often remains in major creases such as the groin and axillae.

The testes are in the scrotum. Breasts of both male and female infants are enlarged, and breast tissue is palpable beneath the areola and nipple because of maternal hormone effects.

CHECK YOUR READING

14. What is the difference between *fertilization age* and *gestational age*? Which term is more commonly used, and why?
15. Why does the fetus usually assume a head-down position in the uterus?
16. What is the purpose of each of the following fetal structures or substances: Vernix caseosa? Lanugo? Brown fat? Surfactant?

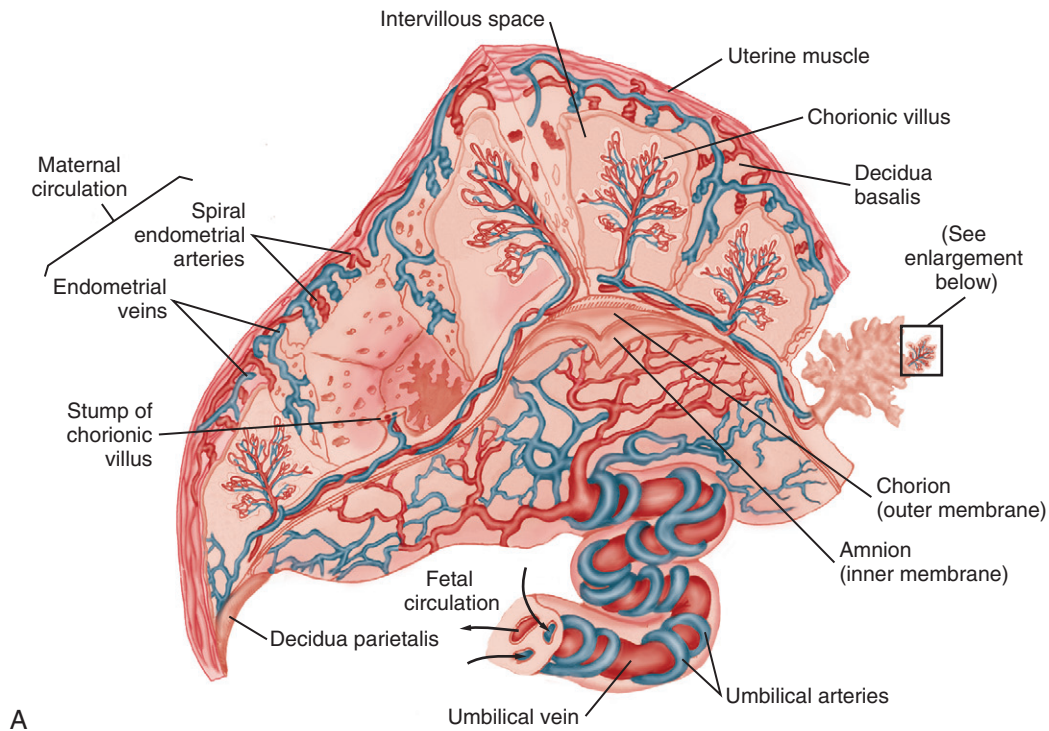

AUXILIARY STRUCTURES

Three auxiliary structures sustain the pregnancy and permit normal prenatal development: the placenta, the umbilical cord, and fetal membranes. These structures develop simultaneously with the baby's development.

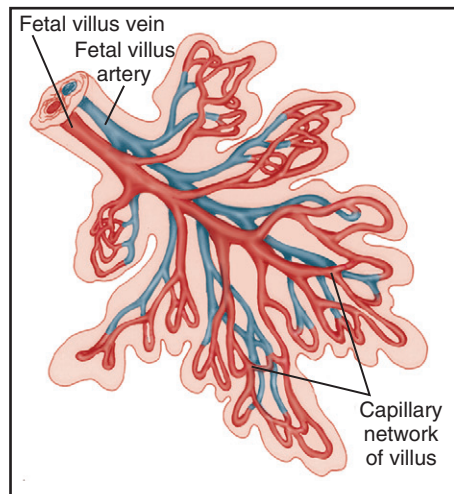

Placenta

The placenta is a thick, disc-shaped organ. The placenta has two components: maternal and fetal ([Figure 6-7](#)). It is involved in (1) metabolic functions, (2) transfer functions, and (3) endocrine functions. The fetal side is smooth, with branching vessels covering the membrane-covered surface. The maternal side is rough where it attaches to the uterus (see [Figure 12-14, A and B](#)).

The umbilical cord is normally inserted on the fetal side of the placenta, near the center. However, it may insert off center or even out on the fetal membranes ([Figure 6-8](#)).

A

B

FIG 6-7 **A**, Placental structure showing relationship of placenta, fetal membranes, and uterus. *Arrows* indicate the direction of blood flow between the fetus and placenta through the umbilical arteries and vein. Blood from the mother bathes the fetal chorionic villi within the intervillous spaces to allow exchange of oxygen, nutrients, and waste products without gross mixing of maternal and fetal blood. **B**, Structure of a chorionic villus; its fetal capillary network is illustrated.

During early pregnancy, the placenta is larger than the embryo or fetus. However, the fetus grows faster than the placenta, so the placenta is approximately one sixth the weight of the fetus at the end of a full-term pregnancy.

Maternal Component

Development. When conception occurs, cells of the endometrium undergo changes that promote early nutrition of the embryo and enable most of the uterine lining to be shed after birth. These changes convert endometrial cells into the decidua. In addition to

providing nourishment for the embryo, the decidua may protect the mother from uncontrolled invasion of fetal placental tissue into the uterine wall.

The three decidual layers are (1) the decidua basalis, which underlies the developing embryo and forms the maternal side of the placenta; (2) the decidua capsularis, which overlies the embryo and bulges into the uterine cavity as the embryo and fetus grow; and (3) the decidua parietalis, which lines the rest of the uterine cavity. By about 22 weeks of gestation, the decidua capsularis fuses with the decidua parietalis, filling the uterine cavity.

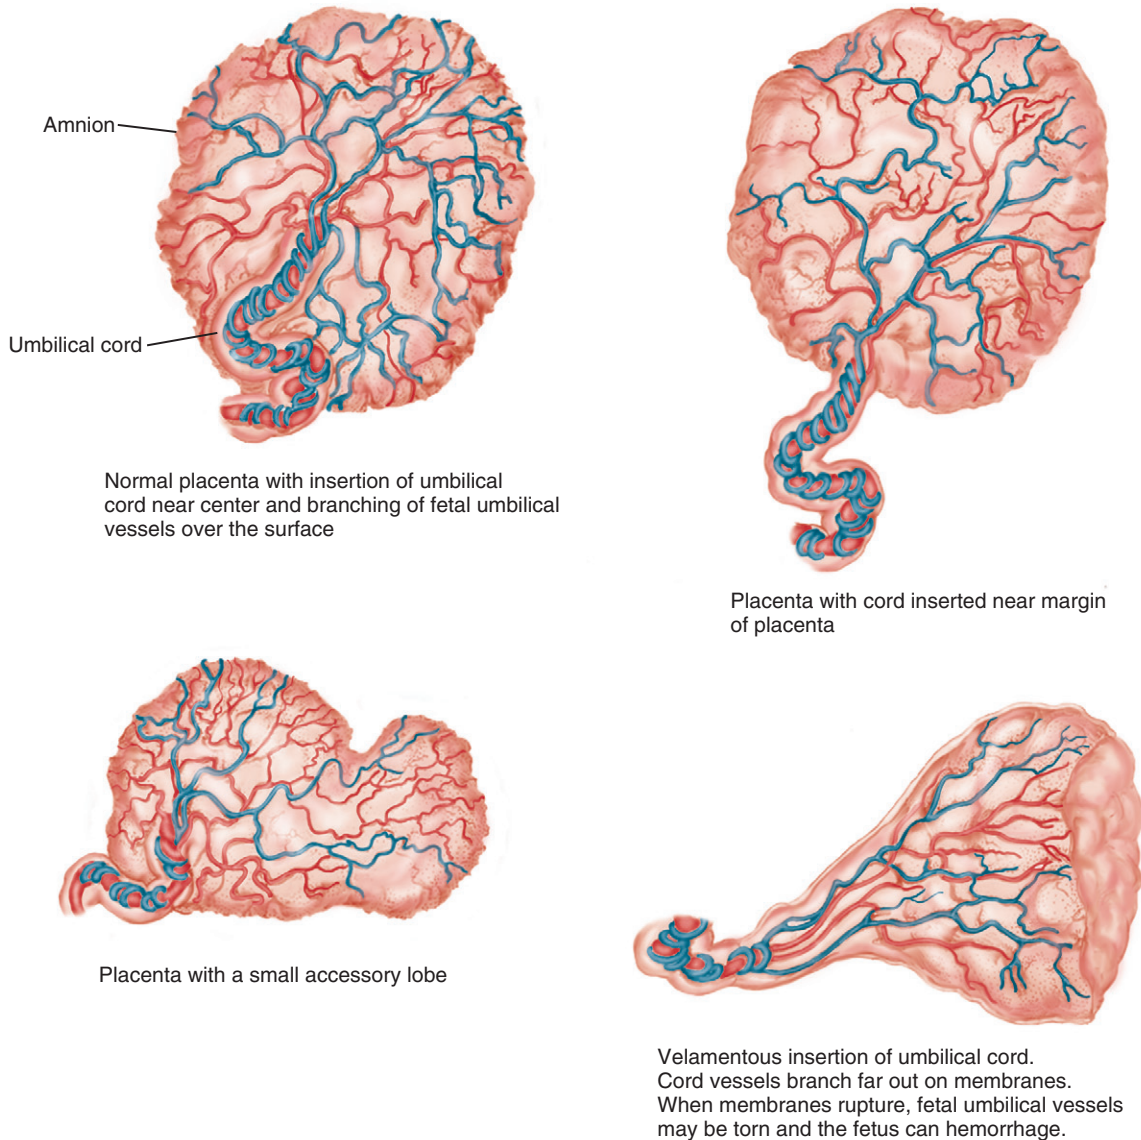

FIG 6-8 Placental variations.

Circulation on the Maternal Side. Maternal and fetal blood normally do not mix in the placenta, although they flow very close to each other. Exchange of substances between mother and fetus occurs within the intervillous spaces of the placenta. While in the intervillous space, the mother's blood is briefly outside her circulatory system. About 150 mL of maternal blood is contained within the intervillous space. Blood in the intervillous space is changed approximately three to four times per minute, requiring circulation of 450 to 750 mL per minute for placental perfusion.

Maternal blood spurts into the intervillous spaces through 80 to 100 spiral arteries in the decidua. After the oxygenated and nutrient-bearing maternal blood washes over the chorionic villi containing the fetal vessels, it returns to the maternal circulation through the endometrial veins for elimination of fetal waste products.

Fetal Component

Development. The fetal side of the placenta develops from the outer cell layer (trophoblast) of the blastocyst at the same time the inner cell mass develops into the embryo and fetus. The primary

chorionic villi are the initial structures that eventually form the fetal side of the placenta.

Circulation on the Fetal Side. The umbilical cord contains the umbilical arteries and vein to transport blood between the fetus and placenta. Chorionic villi are bathed by oxygen- and nutrient-rich maternal blood in the maternal intervillous spaces. Each chorionic villus is supplied by a tiny fetal artery carrying deoxygenated blood and waste products from the fetus. The vein of the chorionic villus returns oxygenated blood and nutrients to the embryo and fetus.

Capillaries in the chorionic villi are separated from actual contact with the mother's blood by the membranes of each villus. This arrangement allows contact close enough for exchange and prevents mixing of maternal and fetal blood. The closed fetal circulation is important because the blood types of mother and fetus may not be compatible.

The placental arteries and veins converge in the blood vessels of the umbilical cord. Two umbilical arteries and one umbilical vein transport blood between the fetus and the fetal side of the placenta. Blood is circulated to and from the fetal side of the placenta by the fetal heart.

TABLE 6-4 MECHANISMS OF PLACENTAL TRANSFER

MECHANISM	DESCRIPTION	EXAMPLES OF SUBSTANCES TRANSFERRED
Simple diffusion	Passive movement of substances across a cell membrane from an area of higher concentration to one of lower concentration	Oxygen and carbon dioxide Carbon monoxide Water Urea and uric acid Most drugs and their metabolites Glucose
Facilitated diffusion	Passage of substances across a cell membrane by binding with carrier proteins that assist transfer	
Active transport	Transfer of substances across a cell membrane against a pressure or electrical gradient, or from an area of lower concentration to one of higher concentration	Amino acids Water-soluble vitamins Minerals: calcium, iron, iodine
Pinocytosis	Movement of large molecules by ingestion within cells	Maternal IgG class antibodies Some passage of maternal IgA antibodies

IgA, Immunoglobulin A; IgG, immunoglobulin G.

Metabolic Functions

The placenta produces some nutrients needed by the embryo and for placental functions. Substances synthesized include glycogen, cholesterol, and fatty acids (Moore et al., 2013, a, b).

Transfer Functions

Exchange of oxygen, nutrients, and waste products across the chorionic villi occurs through several methods (Table 6-4). Placental transfer of harmful substances also may occur. Most substances that enter the mother's bloodstream can enter the fetal circulation, and many agents enter it almost immediately.

Gas Exchange. Respiration is a key function of the placenta. Oxygen and carbon dioxide pass through the placental membrane by simple diffusion. The average oxygen partial pressure (P_{O_2}) of maternal blood in the intervillous space is 50 mm Hg. The average blood P_{O_2} in the umbilical vein (after oxygenation) is approximately 30 mm Hg (Hall, 2011; Jones, 2009d).

The following three reasons explain how the fetus can thrive in this low-oxygen environment:

1. Fetal hemoglobin can carry 20% to 50% more oxygen than adult hemoglobin.
2. The fetus has a higher oxygen-carrying capacity because of a higher average hemoglobin level (14.5 to 22.5 g/dL) and hematocrit value (approximately 48% to 69%).
3. Hemoglobin can carry more oxygen at low carbon dioxide partial pressure (P_{CO_2}) levels than it can at high levels (Bohr effect). Blood entering the placenta from the fetus has a high P_{CO_2} , but carbon dioxide diffuses quickly to the mother's blood, where the P_{CO_2} is lower, reversing the levels of carbon dioxide in the maternal and the fetal blood. Therefore, the fetal blood becomes more alkaline, and the maternal blood becomes more acidic. This allows the mother's blood to release oxygen and the fetal blood to combine with oxygen readily.

The fetal P_{CO_2} is only about 2 to 3 mm Hg higher than the P_{CO_2} of maternal blood. However, carbon dioxide is very soluble, allowing it to pass across the placental membrane into maternal blood at this low-pressure gradient.

Nutrient Transfer. The growing fetus requires a constant supply of nutrients from the pregnant woman. Glucose, fatty acids, vitamins, and electrolytes pass readily across the placenta. Glucose is the major energy source for fetal growth and metabolic activities.

Waste Removal. In addition to carbon dioxide, urea, uric acid, and bilirubin are readily transferred from fetus to mother for disposal. Because the normal placenta removes wastes for the fetus, metabolic defects such as phenylketonuria (PKU) are usually not evident until after birth.

Antibody Transfer. Many of the immunoglobulin G (IgG) class of antibodies are passed from mother to fetus through the placenta. This confers passive (temporary) immunity to the fetus against diseases to which the mother is immune, for example, measles. Passage of antibodies against disease is beneficial because the newborn does not produce antibodies for several months after birth. The preterm or small-for-gestational age infant has little protection from maternal antibodies because they are transferred during late pregnancy and are poorly transferred if placental function is inadequate.

Passage of antibodies from mother to fetus is not always beneficial. If maternal and fetal blood types are not compatible, the mother may already have or may produce antibodies against fetal erythrocytes. The mother's antibodies may then destroy the fetal erythrocytes, causing fetal anemia or even death. This situation may occur if the mother is Rh-negative and the fetus is Rh-positive.

Transfer of Maternal Hormones. Most maternal protein hormones do not reach the fetus in significant amounts. The female fetus exposed to androgenic hormones may have masculinization of her genitalia, and her true gender may be difficult to visually determine at birth.

Endocrine Functions. The placenta produces several hormones necessary for normal pregnancy. hCG causes the corpus luteum to persist for the first 6 to 8 weeks of pregnancy and secrete estrogens and progesterone. As the placenta develops further, it takes over estrogen and progesterone production and the corpus luteum regresses. When a Y chromosome is present in the male fetus, hCG also causes the fetal testes to secrete testosterone, necessary for normal development of male reproductive structures.

Human placental lactogen, also called *human chorionic somatomammotropin*, promotes normal nutrition and growth of the fetus as well as maternal breast development for lactation. This placental hormone decreases maternal insulin sensitivity and glucose use, making more glucose available for fetal nutrition.

Steroid hormones secreted by the placenta include estrogens and progesterone. Estrogens cause enlargement of the woman's uterus, enlargement of the breasts, growth of the ductal system of the breasts,

and enlargement of the external genitalia. Estriol is the most plentiful estrogen produced during pregnancy.

Progesterone is essential for normal continuation of the pregnancy. Functions of progesterone include the following:

- Causes secretory changes in the endometrium, providing nourishment as the conceptus enters the uterus.
- Causes the changes in endometrial cells that convert them into the larger and thicker cells of the decidua, which characterize pregnancy.
- Reduces muscle contractions of the uterus to prevent spontaneous abortion.
- May induce some immune tolerance in the mother's body for the conceptus.
- Acts with estrogens and other hormones to cause growth of the breasts, budding of the alveoli that will secrete milk, and development of secretory characteristics in the alveolar cells.

Other hormones produced by the placenta include human chorionic thyrotropin and human chorionic adrenocorticotropic.

Fetal Membranes and Amniotic Fluid

The two fetal membranes are the *amnion* (inner membrane) and the *chorion* (outer membrane). The two membranes are so close they seem to be one membrane (the “bag of waters”), but they can be separated. If the membranes rupture in labor, amnion and chorion usually rupture together, releasing the amniotic fluid within the sac.

The amnion is continuous with the surface of the umbilical cord, joining the epithelium of the abdominal skin of the fetus. Chorionic villi proliferate over the entire surface of the gestational sac for the first 8 weeks after conception. A conceptus observed at this time looks like a shaggy sphere with the embryo suspended inside. As the embryo grows, it bulges into the uterine cavity. The villi on the outer surface gradually atrophy and form the smooth-surfaced chorion. The remaining villi continue to branch and enlarge to form the fetal side of the placenta.

Amniotic fluid protects the growing fetus and promotes normal prenatal development. Amniotic fluid protects the fetus by the following actions:

- Cushioning against impacts to the maternal abdomen
 - Maintaining a stable temperature
- Amniotic fluid promotes normal prenatal development by the following actions:
- Allowing symmetric development as the major body surfaces fold toward the midline
 - Preventing the membranes from adhering to developing fetal parts
 - Allowing room and buoyancy for fetal movement

Amniotic fluid is derived from two sources: (1) fetal urine and (2) fluid transported from the maternal blood across the amnion. Castoff fetal epithelial cells and vernix are suspended in the amniotic fluid. The water of the amniotic fluid changes by absorption across the amnion, returning to the mother. The fetus also swallows amniotic fluid and absorbs it in the digestive tract. Waste products are returned to the placenta through the umbilical arteries.

The volume of amniotic fluid increases during pregnancy and is approximately 700 to 800 mL at 40 weeks. An abnormally small quantity of fluid (less than 50% of the amount expected for gestation, or under 400 mL at term) is called oligohydramnios and may be associated with the following (Blackburn, 2013; Carlson, 2009; Hall, 2011):

- Poor placental blood flow
- Preterm membrane rupture
- Failure of fetal kidney development
- Blocked urinary excretion

Poor fetal lung development (pulmonary hypoplasia) and malformations such as skeletal abnormalities may result from compression of fetal parts.

Hydramnios (also called *polyhydramnios*) is the opposite situation, in which the quantity may exceed 2000 mL. Hydramnios may be associated with the following (Blackburn, 2013):

- Imbalanced water exchange among mother, fetus, and amniotic fluid that has no known cause
- Poorly controlled maternal diabetes mellitus that results in large quantities of fetal urine excretion having an elevated glucose level
- Malformations of the CNS, cardiovascular system, or gastrointestinal tract that interfere with normal fluid ingestion, metabolism, and excretion
- Chromosomal abnormalities
- Multifetal gestation

FETAL CIRCULATION

The course of fetal blood circulation is from the fetal heart; to the placenta for exchange of oxygen, nutrients, and waste products; and back to the fetus for delivery to fetal tissues (Figure 6-9, A).

Umbilical Cord

The fetal umbilical cord is the lifeline between the fetus and placenta. It has two arteries that carry deoxygenated blood and waste products away from the fetus to the placenta, where these substances are transferred to the mother's circulation. The umbilical vein carries freshly oxygenated and nutrient-laden blood from the placenta back to the fetus. The umbilical arteries and vein are coiled within the cord to allow them to stretch and prevent obstruction of blood flow through them. The entire cord is cushioned by a soft substance called *Wharton's jelly* to prevent obstruction resulting from pressure.

Fetal Circulatory Circuit

Because the fetus does not breathe air, several alterations of the postnatal circulatory route are needed (see Figure 6-9, A). Also, the fetal liver does not have the metabolic functions that it will have after birth because the mother's body performs these functions. Three shunts in the fetal circulatory system allow blood with the highest oxygen content to be sent to the fetal heart and brain: the ductus venosus, the foramen ovale, and the ductus arteriosus. At birth, the infant's lungs oxygenate the blood, the placenta is removed from the circulatory path, and the liver must perform its metabolic functions.

Oxygenated blood from the placenta enters the fetal body through the umbilical vein. About two thirds of the blood goes through the liver by term, and the rest bypasses the liver and enters the inferior vena cava through the first shunt, the ductus venosus. The blood then enters the right atrium and joins with deoxygenated blood from the lower body and head. Most of the blood passes directly into the left atrium through the second shunt, the foramen ovale, where it mixes with the small amount of blood returning from the lungs. Blood is pumped from the left ventricle into the aorta to nourish the body. A small amount of blood from the right ventricle is circulated to the lungs to

A Fetal circulation

B Circulation after birth

FIG 6-9 A, Fetal circulation. Three shunts allow most blood from the placenta to bypass the fetal lungs and liver; they are the ductus venosus, ductus arteriosus, and foramen ovale. **B**, Circulation after birth. Note that the fetal shunts have closed. The umbilical vessels (ductus venosus and ductus arteriosus) will be converted to ligaments.

nourish the lung tissue. The rest of the blood from the right ventricle joins oxygenated blood in the aorta through the third shunt, the ductus arteriosus. The head and upper body receive the greatest amount of oxygenated blood.

The wall of the right ventricle of the fetal heart is thicker than that of the left because resistance to blood flow through the uninflated lungs is high, similar to the resistance in other parts of the fetal body. When the infant begins breathing after birth, resistance to pulmonary blood flow from the right ventricle decreases, whereas resistance to systemic flow from the left ventricle increases. The thickness of the wall of the left ventricle increases to meet greater resistance to systemic outflow. The thickness of the right ventricle has little change. As cardiac growth progresses throughout childhood, the thickness of the left ventricle remains greater than that of the right ventricle (Blackburn, 2013; Moore et al., 2013, a, b).

Changes in Blood Circulation after Birth

Fetal circulatory shunts are not needed after birth because the infant oxygenates blood in the lungs and is not circulating blood to the placenta (see Figure 6-9, B). As the infant breathes and the lungs expand, blood flow to the lungs increases, pressure in the right side of the heart falls, and the foramen ovale closes. The ductus arteriosus constricts as the arterial oxygen level rises. Persistent hypoxia may cause the ductus arteriosus to remain open for a prolonged period. The ductus venosus constricts when flow of blood from the umbilical cord stops.

Transition to the postnatal circulatory pattern is gradual. Functional closure begins when the infant breathes and the cord is cut, removing the placenta from the circulation. The foramen ovale and ductus venosus are permanently closed as tissue proliferates in these structures. The ductus venosus becomes a ligament, as do the umbilical vein and arteries (see Table 19-1).

MULTIFETAL PREGNANCY

The incidence of multifetal pregnancy (multiple gestation) has increased in the United States. Much of the increase is a result of a rise in maternal age, when women naturally are more likely to have twins, and infertility treatments that induce multiple ovulation. Twin births in 2009 rose 2% from the previous year to 33.2 per 1000 live births. Triplet and higher-order multiple births rose 4% to 153.5 per 100,000 live births in 2009. After a peak of triplets and higher-order multiples in 2001, the rate declined slightly until the 2009 rise (Martin, Hamilton, Ventura et al., 2011). Twin births to non-Hispanic white women were 37.0 per 1000, whereas the rate for non-Hispanic black women rose to 38.0 per 1000 live births. The Hispanic or Latino twin birth rate remained about the same at 22.5 per 1000 live births in 2009. American Indian or Alaskan Native twinning was lower at 23.5 per 1000 and Asian or Pacific Islander twin births were 30.6 per 1000 in 2009 (Martin et al., 2011).

Twinning is the most common form of multifetal pregnancy. The same processes that occur in twin pregnancies also may occur in higher-order multiple gestations. Twins are often called *identical* or *fraternal* by lay people but are more accurately described by their

zygosity, or the number of ova and sperm involved. The two types of twins are *monozygotic* and *dizygotic* (Figure 6-10).

Monozygotic Twinning

Monozygotic twins are conceived by the union of a single ovum and spermatozoon, with later division of the conceptus into two. Monozygotic twins have identical genetic complements and are the same gender. However, they may not always look identical at birth because one twin may have grown much larger than the other or one may have a birth defect such as a cleft lip. Monozygotic twins have a higher rate of birth defects, preterm births and low birth weight. Monozygotic twinning occurs essentially at random (about 1 in 250 natural [non-assisted] pregnancies), and a hereditary or racial component is not well established (Newman & Unal, 2012).

Monozygotic twinning occurs when a single conceptus divides early in gestation. The blastocyst in most monozygotic twins is formed with two inner cell masses instead of one. If this occurs, usually in 70% of monozygotic twin pregnancies, the fetuses usually have two amnions (inner membranes) but a single chorion (outer membrane) (Blackburn, 2013; Cunningham, Leveno, Bloom et al., 2010; Newman & Unal, 2012).

If the conceptus divides earlier, two separate but identical morulas (and then blastocysts) develop and implant separately. These monozygotic twins have two amnions and two chorions. Although the placentas develop separately, they may fuse and appear as one at birth. The chorions also may fuse during prenatal development. Examination of the placenta and membranes after birth may not identify whether twins are monozygotic or dizygotic. Tests such as DNA analysis or detailed blood typing may be needed to determine whether twins are monozygotic or dizygotic.

Late separation of the inner cell mass may result in twins having a single amnion and a single chorion. These twins are more likely to die because their umbilical cords become entangled during pregnancy. Incomplete separation of the inner cell mass may result in conjoined (formerly called “Siamese”) twins.

Dizygotic Twinning

Dizygotic twins arise from two ova that are fertilized by different sperm. Dizygotic twins may be the same or different gender, and they may not have similar physical traits.

Dizygotic twinning may be hereditary in some families, presumably because of an inherited tendency of the females to release more than one ovum per cycle. Women of some races are more likely to have dizygotic twins. Infertility therapy increases the incidence of twins, usually dizygotic, because induction of ovulation often results in the release of multiple ova, with implantation of more than one zygote in the uterus. Women who conceive after age 40 years also have an increased incidence of spontaneous dizygotic twin births because multiple ova are more likely to be released near the climacteric.

Because dizygotic twins arise from two separate zygotes, their membranes and placentas are separate. The membranes, the placentas, or both may fuse during development if they implant closely. Dizygotic twins are not conjoined because they do not involve division of a single cell mass into two but arise from two separate conceptions.

High Multifetal Gestations

Pregnancies resulting in triplets or higher may arise from a single zygote or a combination of a single and multiple zygotes, or each may arise from a separate zygote. High multifetal pregnancies pose greater hazards to both the mother and her fetuses. The incidence of long-term handicaps is higher as the number of fetuses increases.

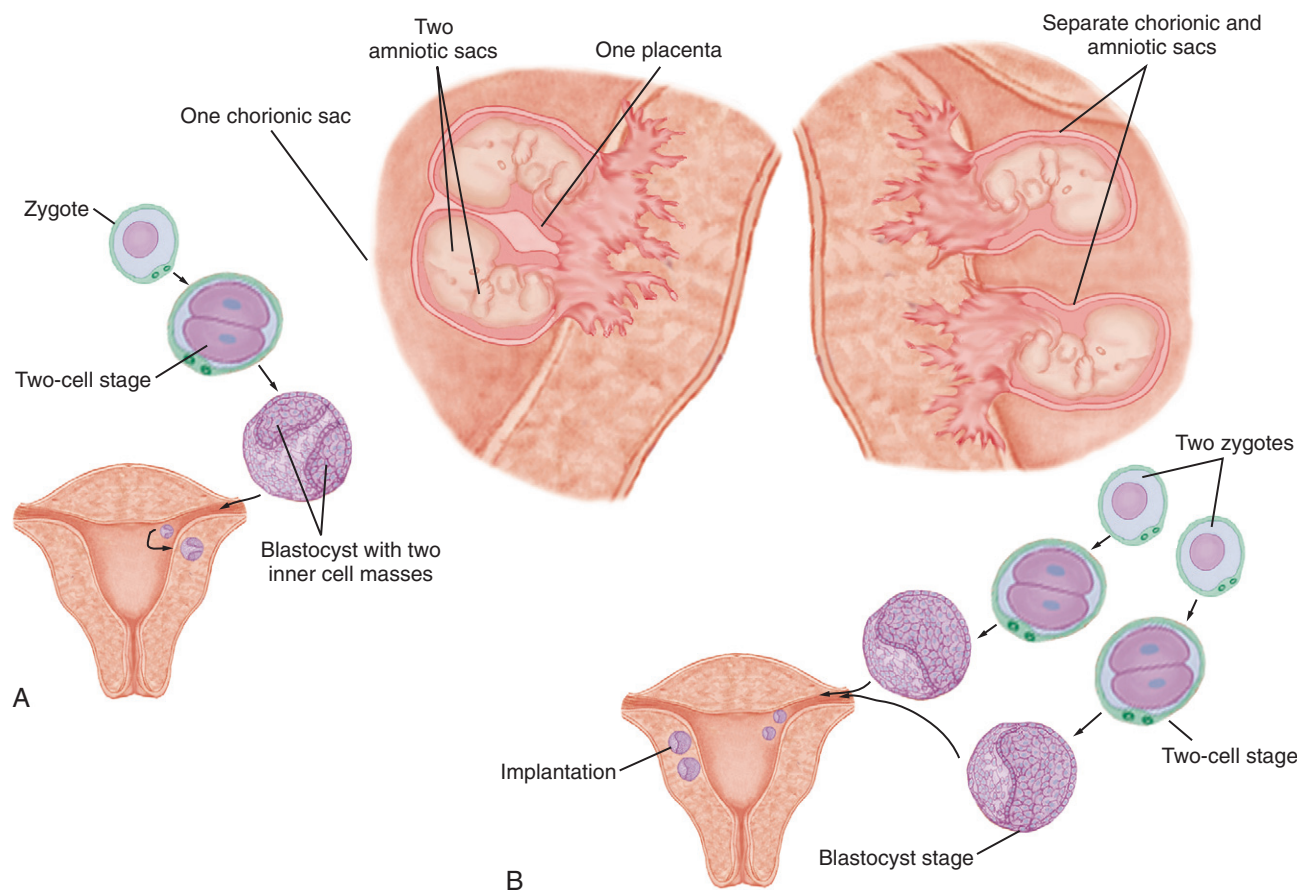

FIG 6-10 **A**, Monozygotic twinning. The single inner cell mass divides into two inner cell masses during the blastocyst stage. These twins have a single placenta and chorion, but each twin develops in its own amnion. **B**, Dizygotic twinning. Two ova are released during ovulation, and each is fertilized by a separate spermatozoon. The ova may implant near each other in the uterus, or they may be far apart.

CHECK YOUR READING

24. How do monozygotic twins occur?
25. Why can examination of the placenta and membranes in a multifetal pregnancy not always establish whether the newborns are monozygotic or dizygotic?
26. Why are dizygotic twins often of different genders?

SUMMARY CONCEPTS

- The purpose of gametogenesis is to produce ova and sperm that have half the full number of chromosomes, or 23 unpaired chromosomes. When an ovum and sperm unite at conception, the number is restored to 46 paired chromosomes.
- The female has all the ova she will ever have at 30 weeks of prenatal life. No other ova are formed after this time.
- One primary oocyte can mature into one mature ovum that contains 23 unpaired chromosomes (22 autosomes and 1 X chromosome).
- A male can continuously produce new sperm from puberty through the rest of his life, although fertility gradually declines after age 40 years.
- One primary spermatocyte can result in production of four mature sperm. Two of the mature sperm have 22 autosomes and 1 X sex chromosome. Two have 22 autosomes and 1 Y sex chromosome.
- The male determines the baby's gender because only sperm carry either an X or a Y sex chromosome. The female contributes only an X chromosome to the baby.
- The basic structures of all organ systems are established during the first 8 weeks of pregnancy. During this period, teratogens may cause major structural and functional damage to the developing organs.
- The fetal period is one of growth and refinement of already established organ systems. Teratogens are less likely to cause major structural damage to the fetus but may cause major functional damage.
- The placenta is an embryonic or a fetal organ with metabolic, respiratory, and endocrine functions.
- Transfer of substances between mother and embryo or fetus occurs by four mechanisms: simple diffusion, facilitated diffusion, active transport, and pinocytosis.

Continued

SUMMARY CONCEPTS—cont'd

- Most substances in the maternal blood can be transferred to the fetus.
- The fetal membranes contain the amniotic fluid, which cushions the fetus, allows normal prenatal development, and maintains a stable temperature.
- The umbilical cord is the lifeline between the fetus and the placenta. Two umbilical arteries carry deoxygenated blood and waste products to the placenta for transfer to the mother's blood. One umbilical vein carries oxygenated and nutrient-rich blood to the fetus. Coiling of the vessels and enclosure in Wharton's jelly reduce the risk of obstruction of the umbilical vessels.
- Three fetal circulatory shunts are needed to partially bypass the fetal liver and lungs: the ductus venosus, foramen ovale, and ductus arteriosus. These structures close functionally after birth but are not closed permanently until several weeks or months later.
- Multifetal pregnancy may be monozygotic or dizygotic. Twins are the most common form of multifetal pregnancy.
- Examination of the placenta and membranes alone cannot conclusively establish whether multiple fetuses are monozygotic or dizygotic.
- Dizygotic twins are more likely to occur in certain families and racial groups and especially in mothers older than 40 years and women who take fertility treatments to induce ovulation.

Physiologic Adaptations to Pregnancy

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the physiologic changes that occur during pregnancy.
2. Differentiate presumptive, probable, and positive signs of pregnancy.
3. Compute gravida, para, and estimated date of delivery.
4. Describe preconception and initial antepartum assessments in terms of history, physical examination, and risk assessment.
5. Identify subsequent antepartum assessments.
6. Discuss maternal adaptation to multifetal pregnancy.
7. Describe the common discomforts of pregnancy in terms of causes and measures to prevent or relieve them.
8. Use the nursing process and critical thinking skills to develop plans of nursing care for the most common problems and discomforts of pregnancy.

From the moment of conception, changes occur in the pregnant woman's body. These changes are necessary to support and nourish the fetus, prepare the woman for childbirth and lactation, and maintain the woman's health. Pregnant women are often puzzled by the physical changes and unprepared for associated discomforts. Many women rely on nurses to provide accurate information and compassionate guidance throughout their pregnancy. To respond effectively, nurses must understand not only the physiologic changes but also how these changes affect the daily lives of expectant mothers.

CHANGES IN BODY SYSTEMS

Although pregnancy challenges each body system to adapt to increasing demands of the fetus, the most obvious changes are in the reproductive system.

Reproductive System

Uterus

Growth. The most dramatic change during pregnancy occurs in the uterus, which before conception is a small, pear-shaped organ entirely contained in the pelvic cavity. The nonpregnant uterus weighs up to 70 g (2.5 oz) and has a capacity of about 10 mL (one third of an ounce). By **term** (38 to 42 weeks of gestation) the uterus weighs 1100

to 1200 g (2.4 to 2.6 lb) and has a capacity of 5 L (Norwitz & Lye, 2009).

Uterine growth occurs as the result of hyperplasia and hypertrophy. Growth can be predicted for each **trimester** (one of three 13-week periods of pregnancy). Early in pregnancy, growth results from hyperplasia caused by estrogen and growth factors. In the latter half of pregnancy, uterine growth results mainly from hypertrophy as the muscle fibers stretch in all directions to accommodate the growing fetus. In addition to muscle growth, fibrous tissue accumulates in the outer muscle layer of the uterus and the amount of elastic tissue increases. These changes greatly increase the strength of the muscle wall (Cunningham, Leveno, Bloom et al., 2010).

Muscle fibers in the myometrium increase in both length and width. Although the uterine wall thickens during early pregnancy, the wall of the uterus thins to about 0.5 to 1 cm (0.2 to 0.4 inch) and the fetus can be palpated easily through the abdominal wall by term (Blackburn, 2013). As the uterus expands into the abdominal cavity, it displaces the intestines upward and laterally. The uterus gradually rotates to the right as a result of pressure from the rectosigmoid colon on the left side of the pelvis.

Pattern of Uterine Growth. The uterus grows in a predictable pattern that provides information about fetal growth (Figure 7-1). This growth helps confirm the estimated date of delivery (EDD), sometimes

FIG 7-1 Uterine growth pattern during pregnancy.

called the *estimated date of birth (EDB)*. By 12 weeks of gestation, the fundus can be palpated above the symphysis pubis. At 16 weeks, the fundus reaches midway between the symphysis pubis and the umbilicus. It is located at the umbilicus at 20 weeks.

The fundus reaches its highest level at the xiphoid process at 36 weeks of gestation. It pushes against the diaphragm, and the expectant mother may experience shortness of breath, even during rest. By 40 weeks, the fetal head descends into the pelvic cavity, and the uterus sinks to a lower level. This descent of the fetal head is called **lightening** because it reduces pressure on the diaphragm and makes breathing easier. Lightening is more pronounced in first pregnancies.

Contractility. Throughout pregnancy, the uterus undergoes irregular contractions called **Braxton Hicks contractions**. During the contractions, the uterus temporarily tightens and then returns to its original relaxed state. During the first two trimesters, the contractions are infrequent and usually not felt by the woman. Contractions occur more frequently during the third trimester and may cause some discomfort. They are called *false labor* when they are mistaken for the onset of early labor.

Uterine Blood Flow. As the uterus enlarges, an increase in the size and number of blood vessels expands blood flow dramatically. As pregnancy progresses, the delivery of materials needed for fetal growth and the removal of metabolic wastes depends on adequate perfusion of the placental intervillous spaces. During late pregnancy, blood flow to the uterus and placenta reaches 1200 mL per minute and is 17% of maternal cardiac output (Koos, Kahn, & Equils, 2010). Almost 90% of the blood goes to the placenta (Ross, Ervin, & Novak, 2012). Maternal blood carried by the myometrial arteries enters the intervillous spaces, where oxygen and nutrients are transferred to the chorionic villi and hence to the fetus. Metabolic wastes from the fetus diffuse into venous structures of the mother (see Chapter 6).

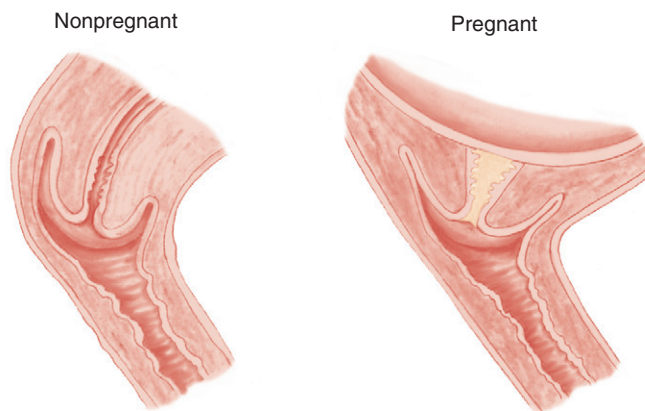

FIG 7-2 Cervical changes that occur during pregnancy. Note the thick mucous plug filling the cervical canal.

Cervix

The cervix also undergoes significant changes after conception. Water content and vascularity of the area increase. The most obvious changes occur in color and consistency. Increasing levels of estrogen cause **hyperemia** (congestion with blood) of the cervix, resulting in the characteristic bluish purple color that extends to include the vagina and the labia. This discoloration, referred to as the **Chadwick sign**, is one of the earliest signs of pregnancy.

The cervix is largely composed of connective tissue that softens when the collagen fibers decrease in concentration. Before pregnancy, the cervix has a consistency similar to that of the tip of the nose. After conception the cervix feels more like the lips or earlobe. The cervical softening is referred to as the **Goodell sign**.

A less obvious change occurs as the cervical glands proliferate during pregnancy, and the glandular walls become thin and widely separated. As a result, the endocervical tissue resembles a honeycomb that fills with mucus secreted by the cervical glands. The mucus, which is rich in immunoglobulins, forms a plug in the cervical canal (Figure 7-2). It blocks the ascent of bacteria from the vagina into the uterus during pregnancy to help protect the fetus and the uterine membranes from infection (Cunningham et al., 2010).

The mucous plug remains in place until term when the cervix begins to thin and dilate, allowing the mucous plug to be expelled. One of the earliest signs of labor may be “bloody show,” which consists of the mucous plug and a small amount of blood. Bleeding is produced by disruption of the cervical capillaries as the mucous plug is dislodged when the cervix begins to thin and dilate.

Vagina and Vulva

Increased vascularity causes the vaginal walls to appear bluish purple. Softening of the abundant connective tissue allows the vagina to distend during childbirth. The vaginal mucosa thickens, and vaginal rugae (folds) become very prominent.

Vaginal cells contain increasing amounts of glycogen, which causes rapid sloughing and increased thick, white, vaginal discharge. The pH of the vaginal discharge is acidic (3.5 to 6) because of the increased production of lactic acid that results from the action of *Lactobacillus acidophilus* on glycogen in the vaginal epithelium (Bond, 2011; Cunningham et al., 2010). The acidic condition helps prevent growth of harmful bacteria in the vagina. However, the glycogen-rich environment favors the growth of *Candida albicans*, and persistent yeast infections (candidiasis) are common during pregnancy.

Increased vascularity, edema, and connective tissue changes make the tissues of the vulva and perineum more pliable. Pelvic congestion

during pregnancy can lead to heightened sexual interest and increased orgasmic experiences.

Ovaries

Progesterone, called the “hormone of pregnancy,” must be present in adequate amounts from the earliest stages to maintain pregnancy. Progesterone helps suppress contractions of the uterus and may also help prevent tissue rejection of the fetus (Blackburn, 2013). After conception, the corpus luteum of the ovaries secretes progesterone, mainly during the first 6 to 7 weeks of pregnancy (Cunningham et al., 2010). Between 6 and 10 weeks of gestation, the corpus luteum produces a smaller amount of progesterone as the placenta takes over production (Blackburn, 2013). The corpus luteum then regresses because it is no longer needed.

Ovulation ceases during pregnancy because the high circulating levels of estrogen and progesterone inhibit the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which are necessary for ovulation.

Breasts

During pregnancy the breasts change in both size and appearance (Figure 7-3). Estrogen stimulates the growth of mammary ductal tissue, and progesterone promotes the growth of the lobes, lobules, and alveoli. The breasts become highly vascular, with a delicate network of veins often visible just beneath the surface of the skin. If the increase in breast size is extensive, striations (“stretch marks”) similar to those that occur on the abdomen may develop.

Characteristic changes in the nipples and areolae occur during pregnancy. The nipples increase in size and become darker and more erect, and the areolae become larger and more pigmented. The degree of pigmentation varies with the complexion of the expectant mother. Women with very light skin tones exhibit less change in pigmentation than those with darker skin.

Sebaceous glands called tubercles of Montgomery become more prominent during pregnancy and secrete a substance that lubricates the nipples. In addition, a thick, yellowish fluid—**colostrum**—is secreted as early as 16 weeks of gestation (Bond, 2011). Secretion of milk is suppressed during pregnancy by the high levels of estrogen and progesterone.

FIG 7-3 Breast changes that occur during pregnancy. The breasts increase in size and become more vascular, the areolae become darker, and the nipples become more erect.

Cardiovascular System

During pregnancy, alterations occur in heart size and position, blood volume, blood flow, and blood components.

Heart

Heart Size and Position. Cardiac changes are minor and reverse soon after childbirth. The muscles of the heart (myocardium) enlarge 10% to 15% during the first trimester (Blackburn, 2013). The heart is pushed upward and to the left as the uterus elevates the diaphragm during the third trimester. As a result of the change in position, the locations for auscultation of heart sounds may be shifted upward and laterally in late pregnancy.

Heart Sounds. Some heart sounds may be so altered during pregnancy that they would be considered abnormal in the nonpregnant state. The changes are first heard between 12 and 20 weeks and continue for 2 to 4 weeks after childbirth. The most common variations in heart sounds include splitting of the first heart sound and a systolic murmur that is found in more than 95% of pregnant women (Monga, 2009). The murmur is best heard at the left sternal border. Up to 90% of pregnant women have a third heart sound (Blackburn, 2013).

Blood Volume

Total blood volume is a combination of plasma and components such as red blood cells (RBCs, erythrocytes), white blood cells (WBCs, leukocytes), and platelets (thrombocytes). Total blood volume increase begins by 6 weeks of gestation and reaches an average of 30% to 45% during pregnancy (Blackburn, 2013).

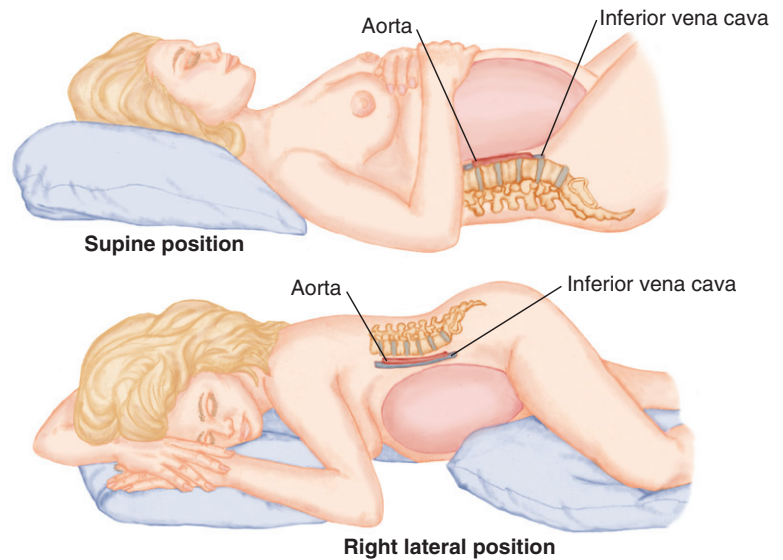

Plasma Volume

Plasma volume increases from 6 to 8 weeks until 32 weeks of gestation. The plasma volume is 40% to 60% (1200 to 1600 mL) greater than that in nonpregnant women (Blackburn, 2013). The increase is higher in multifetal pregnancies. The reason for the increase is unclear, but it may be related to vasodilation from nitric oxide, and estrogen, progesterone, and prostaglandin stimulation of the renin-angiotensin-aldosterone system, which causes sodium and water retention (Blackburn, 2013).

The increased volume is needed to (1) transport nutrients and oxygen to the placenta, where they become available for the growing fetus; (2) meet the demands of the expanded maternal tissue in the uterus and breasts; (3) provide a reserve to protect the pregnant woman from the adverse effects of blood loss that occurs during childbirth.

Red Blood Cell Volume. RBC volume increases by about 20% to 30% above prepregnancy values (Blackburn, 2013). Although both RBC volume and plasma volume expand, the increase in plasma volume is more pronounced and occurs earlier. The resulting dilution of RBC mass causes a decline in maternal hemoglobin and hematocrit. This condition is frequently called **physiologic anemia of pregnancy**, or **pseudoanemia of pregnancy**, because it reflects dilution of RBCs in the expanded plasma volume, rather than an actual decline in the number of RBCs, and does not indicate true anemia.

FIG 7-4 Supine Hypotensive Syndrome. When the pregnant woman is in the supine position, the weight of the uterus partially occludes the vena cava and the aorta. The side-lying position corrects supine hypotension.

Physiologic anemia should not be dismissed as unimportant, however. Frequent laboratory examinations may be needed to distinguish between physiologic and true anemia. Generally, iron deficiency anemia occurs when the hemoglobin is less than 11 grams per deciliter (g/dL) in the first and third trimesters or less than 10.5 g/dL in the second trimester (Cunningham et al., 2010; Centers for Disease Control and Prevention [CDC], 1998). Iron supplementation is often prescribed for all pregnant women by the second trimester to prevent anemia.

Dilution of RBCs by plasma may have a protective function. By decreasing blood viscosity, dilution may counter the tendency to form clots (thrombi) that could obstruct blood vessels and cause serious complications (see Chapter 28). Hemodilution may also increase placental perfusion (Monga, 2009).

Cardiac Output

The expanded blood volume of pregnancy results in an increase in cardiac output, the amount of blood ejected from the heart each minute. It is based on *stroke volume* (the amount of blood pumped from the heart with each contraction) and *heart rate* (the number of times the heart beats each minute). Cardiac output increases 30% to 50% with half of the rise occurring in the first 8 weeks of pregnancy and it remains elevated throughout pregnancy (Beckmann, Ling, & Barzanzski, 2010). The increase in cardiac output is the result of a gain in stroke volume and a heart rate acceleration that peaks at 15 to 20 beats per minute (bpm) by 32 weeks of gestation. Cardiac output is highest when the woman is lying on her side and is lower in the standing and supine positions (Gordon, 2012).

Systemic Vascular Resistance

Systemic vascular resistance falls during pregnancy. This change is likely because of (1) vasodilation resulting from the effects of progesterone and prostaglandins; (2) the addition of the uteroplacental unit, which provides a greater area for circulation and low resistance; (3) increased heat production from fetal, placental, and maternal metabolism, which produces vasodilation; (4) decreased sensitivity to angiotensin II; and (5) endothelial prostacyclin and endothelial-derived relaxant factors such as nitric oxide (Blackburn, 2013).

Blood Pressure

The effect of decreased systemic vascular resistance is that blood pressure (BP) changes little during pregnancy despite the increase in blood volume.

Effect of Position. Because BP is affected by position during pregnancy, the woman's position during measurements should be recorded so that the method of evaluation remains consistent. Systolic pressure remains largely unchanged or decreases slightly if it is measured when the woman is sitting or standing. Diastolic pressure shows a decrease (about 10 to 15 mm Hg) that is greatest at 24 to 32 weeks of gestation. BP returns to usual levels by term (Blackburn, 2013). Arterial pressures are about 10 mm Hg lower when the pregnant woman is in a side-lying or supine position than when she is sitting or standing (Monga, 2009).

Supine Hypotension. When the pregnant woman is in the supine position, particularly in late pregnancy, the weight of the gravid (pregnant) uterus partially occludes the vena cava and the aorta (Figure 7-4). The occlusion diminishes return of blood from the lower extremities and consequently reduces cardiac return. Cardiac output may be reduced 25% to 30% when the woman is in this position (Monga, 2009).

Collateral circulation developed in pregnancy generally allows blood flow from the legs and pelvis to return to the heart when the woman is in a supine position. As many as 5% to 10% of women develop a drop in BP known as *supine hypotensive syndrome*, with symptoms of lightheadedness, dizziness, nausea, or *syncope* (a brief lapse in consciousness) (Gordon, 2012). Blood flow through the placenta also decreases if the woman remains in the supine position for a prolonged time, which could result in fetal hypoxia.

Turning to a lateral recumbent position alleviates the pressure on the blood vessels and quickly corrects supine hypotension. Women should be advised to rest in the side-lying position to prevent or correct the occurrence of supine hypotension. If they must lie in the supine position for any reason, a wedge or pillow under one hip may be effective in decreasing supine hypotension.

Blood Flow

Five major changes in blood flow occur during pregnancy:

1. Blood flow is altered to include the uteroplacental unit.

2. Renal plasma flow increases up to 30% to remove the increased metabolic wastes generated by the mother and the fetus (Koos et al., 2010).
3. The woman's skin requires increased circulation to dissipate heat generated by increased metabolism during pregnancy.
4. Blood flow to the breasts increases, resulting in engorgement and dilated veins.
5. The weight of the expanding uterus on the inferior vena cava and iliac veins partially obstructs blood return from veins in the legs. Blood pools in the deep and superficial veins of the legs causing venous distention. Prolonged engorgement of the veins of the lower legs may lead to varicose veins of the legs, vulva, or rectum (hemorrhoids).

Blood Components

Although iron absorption is increased during pregnancy, sufficient iron is not always supplied by the diet. Iron supplementation is necessary to promote hemoglobin synthesis and ensure erythrocyte production adequate to prevent iron deficiency anemia (see Chapter 26).

Leukocytes increase during pregnancy ranging from 5000 cells/mm³ to 12,000 cells/mm³ or as high as 15,000 cells/mm³. Leukocytes increase further during labor and the early postpartum period, reaching levels of 25,000 cells/mm³ to 30,000 cells/mm³ (Blackburn, 2013).

Pregnancy is a hypercoagulable state because of an increase in factors that favor clotting and a decrease in factors that inhibit clotting. Fibrinogen (factor I), fibrin split products, and factors VII, VIII, IX, and X rise by 50% (Beckmann et al., 2010). These changes increase the ability to form clots. Fibrinolytic activity (to break down clots) decreases during pregnancy. The platelet count may decrease slightly but generally remains within the normal range (Blackburn, 2013). These changes offer some protection from hemorrhage during childbirth but also increase the risk of thrombus formation. The risk is a particular concern if the woman must stand or sit for prolonged periods with stasis of blood in the veins of the legs.

Respiratory System

The major respiratory changes in pregnancy are the result of three factors: increased oxygen consumption, hormonal factors, and the physical effects of the enlarging uterus.

Oxygen Consumption

Oxygen consumption rises by 20% in pregnancy. Half the increase is used by the uterus, the fetus, and the placenta, 30% by the heart and kidneys, and the rest by the respiratory muscles and breast tissues (Beckmann et al., 2010). The tidal volume (the volume of gas moved into or out of the respiratory tract with each breath) increases by 30% to 40%. Although residual volume decreases by 20%, total lung capacity decreases by only 4%. To compensate for the increased need, progesterone causes the woman to hyperventilate slightly by breathing more deeply, although her respiratory rate remains unchanged. The partial pressure of carbon dioxide (P_{CO₂}) decreases. Increased excretion of hydrogen ions from the kidneys partially compensates for the

resulting mild respiratory alkalosis. The hyperventilation and respiratory alkalosis facilitates transfer of carbon dioxide from the fetus to the mother (Monga, 2009).

Hormonal Factors

Progesterone. Progesterone is considered a major factor in the respiratory changes of pregnancy. Progesterone, along with prostaglandins, helps decrease airway resistance by up to 50% by relaxing the smooth muscle in the respiratory tract. Progesterone is also believed to increase the sensitivity of the respiratory center in the medulla oblongata to carbon dioxide, thus stimulating the increase in minute ventilation. These two factors are responsible for the heightened awareness of the need to breathe experienced by many women during pregnancy (Blackburn, 2013).

Estrogen. Estrogen causes increased vascularity of the mucous membranes of the upper respiratory tract. As the capillaries become engorged, edema and hyperemia develop within the nose, pharynx, larynx, and trachea. This congestion may cause nasal and sinus stuffiness, epistaxis (nosebleed), and deepening of the voice. Increased vascularity also causes edema of the eardrum and eustachian tubes and may result in a sense of fullness in the ears.

Physical Effects of the Enlarging Uterus

During pregnancy, the enlarging uterus lifts the diaphragm about 4 cm (1.6 inches). The elevation of the diaphragm does not impede its movement, however, which is increased by about 1 to 2 cm (0.4 to 0.8 inch) during respirations. The ribs flare, the substernal angle widens, and the transverse diameter of the chest expands by about 2 cm (0.8 inches) to compensate for the reduced space. These changes begin when the uterus is just beginning to enlarge. They result from the hormone relaxin, which causes relaxation of the ligaments around the ribs. Breathing becomes thoracic rather than abdominal, adding to the dyspnea that as many as 60% to 70% of women experience beginning in the first or second trimester (Blackburn, 2013).

Gastrointestinal System

The gastrointestinal system undergoes changes that are clinically significant because they may cause discomfort for the expectant mother.

Appetite

Unless the woman is nauseated, her appetite is often increased during pregnancy. This helps her consume the additional calories recommended. Food intake may increase by 15% to 20% beginning in early pregnancy (Blackburn, 2013).

Mouth

Elevated levels of estrogen cause hyperemia of the tissues of the mouth and gums and may lead to gingivitis and bleeding gums. Some women develop a highly vascular hypertrophy of the gums, called *epulis*. The condition regresses spontaneously after childbirth.

Although the amount of saliva does not usually change, some women experience *ptyalism*, or excessive salivation. The cause of ptyalism may be decreased swallowing associated with nausea or stimulation of the salivary glands by the ingestion of starch (Bond, 2011; Cunningham et al., 2010). Small, frequent meals and use of chewing gum and oral lozenges offer limited relief to some women.

Many women think that pregnancy causes loss of minerals from teeth to meet fetal needs. However, this is not true, and the tooth enamel is stable during pregnancy. Tooth decay may occur because of changes in saliva and the nausea and vomiting of pregnancy. Periodontal disease may result in infections that precipitate preterm labor (Blackburn, 2013).

Esophagus

The lower esophageal sphincter tone decreases during pregnancy, primarily because of the relaxant activity of progesterone on the smooth muscles. These changes, along with upward displacement of the stomach, allow gastroesophageal reflux of acidic stomach contents into the esophagus and produces heartburn (pyrosis).

Stomach

Elevated levels of progesterone relax all smooth muscle, decreasing tone and motility of the gastrointestinal tract. The effect on emptying time of the stomach is unclear, with some studies showing a decrease and others showing no change during pregnancy. Gastric acidity is decreased during the first two trimesters and increased during the third trimester. The risk of gastric ulcers decreases during pregnancy.

Large and Small Intestines

Emptying time of the intestines increases, allowing more time for nutrient absorption. It may also cause bloating and abdominal distention. Calcium, iron, some amino acids, glucose, sodium, and chloride are better absorbed during pregnancy, but absorption of some of the B vitamins is reduced (Blackburn, 2013). Decreased motility in the large intestine allows time for more water to be absorbed, leading to constipation. Constipation may cause or exacerbate hemorrhoids if the expectant mother must strain to have bowel movements. Flatulence may also be a problem.

Liver and Gallbladder

Although the size of the liver and gallbladder remains unchanged during pregnancy, estrogen and progesterone cause functional changes. The enlarging uterus pushes the liver upward and backward during the last trimester, and liver function is also altered. The serum alkaline phosphatase level rises to two to four times that in nonpregnant women. Serum albumin and total protein fall partly because of hemodilution (Williamson & Mackillop, 2009).

The gallbladder becomes hypotonic, and emptying time is prolonged. The bile becomes thicker predisposing to the development of gallstones. Reduced gallbladder tone also leads to a tendency to retain bile salts, which can cause itching (pruritus) (Bond, 2011).

Urinary System Bladder

The woman experiences frequency and urgency of urination throughout her pregnancy. Although uterine expansion within the pelvis is one cause of these urinary changes, frequency begins before the uterus is big enough to exert pressure on the bladder. Hormonal influences, increased blood volume, and changes in renal blood flow and *glomerular filtration rate* (GFR)—the rate at which water and dissolved substances are filtered in the glomerulus—may play a significant role in urinary frequency. Stress and urge incontinence that begins at any time during pregnancy and continues until after delivery is experienced by 30% to 50% of pregnant women (Blackburn, 2013) (see Chapter 34). Although frequency and urgency are normal during pregnancy, they are also signs of infection and, if accompanied by burning sensation or pain, may indicate urinary tract infection.

Bladder capacity doubles by term, and the tone is decreased in response to progesterone (Blackburn, 2013). Nocturia is common because sodium and water are retained during the day and excreted during the night when the woman is lying down. Pressure from the uterus pushes the base of the bladder forward and upward near the end of pregnancy. The bladder mucosa becomes congested with blood, and the bladder walls become hypertrophied as a result of stimulation from estrogen. Decreased drainage of blood from the base of the

bladder results in edema of its tissues and renders the area susceptible to trauma and infection during childbirth.

Kidneys and Ureters

Changes in Size and Shape. During pregnancy, the kidneys change in both size and shape because of dilation of the renal pelvis, calyces, and ureters above the pelvic brim. The dilation begins during the second month of pregnancy. The ureters become elongated and are compressed between the enlarging uterus and the bony pelvic brim.

The flow of urine through the ureters is partially obstructed, causing hydrostatic pressure against the renal pelvis. This occurs especially on the right side because the ureter turns toward the right during pregnancy and crosses the iliac and right ovarian veins. As much as 300 mL of urine may be present in the ureters (Blackburn, 2013). The resulting stasis of urine is important because it allows time for bacteria to multiply. The risk of bacteriuria, which may be asymptomatic, is increased and pyelonephritis results in 25% to 35% of these women (Vidaeff & Ramin, 2011).

Functional Changes of the Kidneys. Renal blood flow increases by 50% to 80% during pregnancy. This change results from increases in plasma volume and cardiac output. The flow is highest when the woman is in the left side-lying position. The GFR rises by as much as 50% because of the higher renal blood flow (Gilbert, 2011).

The increases in renal plasma flow and GFR are necessary for excretion of additional metabolic waste from the mother and the fetus. Glucose excretion increases, and glycosuria is common during pregnancy. Small quantities of amino acids, water-soluble vitamins, and electrolytes are also excreted because the filtered load of these substances exceeds the ability of the renal tubules to reabsorb them. Bacteria thrive in urine that is rich in nutrients, increasing the risk of urinary tract infections during pregnancy.

Urine output increases throughout pregnancy. Mild proteinuria is common and does not necessarily indicate abnormal kidney function or preeclampsia (Blackburn, 2013). Protein level may be monitored throughout pregnancy to identify increases that would indicate a problem. Tests of renal function may be misleading during pregnancy. As a result of increased GFR, serum creatinine and blood urea nitrogen decrease and creatinine clearance levels increase (Gordon, 2012).

10. Why do some women experience dyspnea during pregnancy?
11. How does the respiratory system compensate for upward pressure exerted on the diaphragm by the enlarging uterus?
12. How does pregnancy affect the gastrointestinal system?
13. Why are pregnant women at increased risk for urinary tract infection?

Integumentary System Skin

Circulation to the skin increases to help dissipate excess heat produced by increased metabolism. Pregnant women feel warmer and perspire more, particularly during the last trimester. Accelerated activity by the sebaceous glands fosters the development of acne. Additional changes include hyperpigmentation and vascular changes in the skin.

Hyperpigmentation. Increased pigmentation from elevated levels of estrogen, progesterone, and melanocyte-stimulating hormone occurs in 91% of pregnant women (Rapini, 2009). Women with dark hair or skin exhibit more hyperpigmentation compared with women with very light coloring.

Areas of pigmentation include brownish patches called **melasma**, chloasma, or the “mask of pregnancy.” Melasma involves the forehead, cheeks, and bridge of the nose and occurs in about 70% of pregnant

FIG 7-5 Linea Nigra. A dark pigmented line from the fundus to the symphysis pubis.

women. It may also occur in nonpregnant women taking oral contraceptives. Melasma increases with exposure to sunlight, but use of sunscreen may reduce the severity. Although melasma usually resolves after delivery when estrogen and progesterone levels decline, it continues for months or years in about 30% of women (Rapini, 2009).

The linea alba—the line that marks the longitudinal division of the midline of the abdomen—darkens to become the **linea nigra** (Figure 7-5). This dark line of pigmentation may extend from the symphysis pubis to as high as the top of the fundus. Preexisting moles (nevi), freckles, and the areolae become darker as pregnancy progresses. Hyperpigmentation usually disappears after childbirth.

Cutaneous Vascular Changes. During pregnancy, blood vessels dilate and proliferate, which is an effect of estrogen. Changes in surface blood vessels are obvious during pregnancy, especially in women with fair skin. These include angiomas (vascular spiders, telangiectasia) that appear as tiny red elevations branching in all directions and occur most often on areas exposed to the sun. Redness of the palms of the hands or soles of the feet, known as *palmar erythema*, also occurs in many white women and some African-American women. Vascular changes may be emotionally distressing for the expectant mother, but they are clinically insignificant and usually disappear shortly after childbirth.

Connective Tissue

Linear tears may occur in the connective tissue, most often on the abdomen, breasts, and buttocks, appearing as slightly depressed, pink to purple streaks called **striae gravidarum**, or “stretch marks” (Figure 7-6). They occur in 50% to 80% of pregnant women, and 10% have severe striae (Rapini, 2009). Women are concerned about striae because they do not disappear after childbirth, although the marks usually fade to silvery lines. Laser therapy is sometimes used after childbirth to reduce or eliminate severe striae. Many women believe that striae can be prevented by massaging with oil, vitamin E, or cocoa butter, but these substances have not been found to be effective. Antipruritic creams may be effective in controlling the itching that often occurs.

Hair and Nails

Because fewer follicles are in the resting phase, hair grows more rapidly and less hair falls out during pregnancy. After childbirth, hair follicles return to normal activity, and many women become concerned at the rate of hair loss that occurs 2 to 4 months following childbirth. They need reassurance that more follicles have returned to the normal resting phase and excessive hair loss will not continue. Hair growth returns to normal within 6 to 12 months after childbirth (Beckmann et al., 2010).

FIG 7-6 Striae Gravidarum. Linear tears that may occur in connective tissue.

The nails may become brittle or softer or may develop transverse grooves. Some women’s nails grow faster or split or break more easily during pregnancy. These changes end after childbirth and no treatment is needed.

Musculoskeletal System

Calcium Storage

During pregnancy, fetal demands for calcium increase, especially in the third trimester. Absorption of calcium from the intestine doubles during pregnancy. Calcium is stored for use during the third trimester when fetal needs peak. Although 28 to 30 g of calcium from maternal bone stores is transferred to the fetus, this amount is small in comparison with total maternal stores and does not deplete the maternal bone density (Blackburn, 2013).

Postural Changes

Musculoskeletal changes are progressive. They begin early in pregnancy when relaxin and progesterone initiate relaxation of the ligaments. At 28 to 30 weeks, the pelvic symphysis separates (Beckmann et al., 2010). The increased mobility of the pelvic joints causes the pregnant woman to assume a wide stance with the “waddling” gait of pregnancy.

During the third trimester, as the uterus increases in size, the expectant mother must lean backward to maintain her balance (Figure 7-7). This posture creates a progressive lordosis or curvature of the lower spine and often leads to backache. Obesity or previous back problems increase the problem.

Abdominal Wall

The abdominal muscles may be stretched beyond their capacity during the third trimester, causing **diastasis recti**, separation of the rectus abdominis muscles (see Chapter 17, Figure 17-4). The extent of the separation varies from slight and clinically insignificant to severe, when a large portion of the uterine wall is covered only by the peritoneum, fascia, and skin.

Endocrine System

Numerous changes in hormones occur in pregnancy (Table 7-1).

Pituitary Gland

The anterior pituitary gland increases in size during pregnancy. Serum prolactin levels increase tenfold by term to prepare the breasts for lactation (Blackburn, 2013). The hormones FSH and LH are not

needed to stimulate ovulation during pregnancy and are suppressed by high levels of estrogen and progesterone.

The posterior pituitary releases oxytocin, which stimulates contractions of the uterus. This action is inhibited by progesterone, produced mainly by the placenta during pregnancy. In the second half of pregnancy, estrogen causes a gradual rise of oxytocin receptors in the uterus

FIG 7-7 Lordosis increases by the third trimester as the uterus grows larger, and the woman must lean backward to maintain her balance.

increasing contractions near term (Boron & Boulpaep, 2009). After childbirth, oxytocin plays an important role in keeping the uterus contracted to prevent excessive bleeding. Oxytocin also stimulates the milk-ejection reflex after childbirth.

Thyroid Gland

Hyperplasia and increased vascularity cause the thyroid gland to enlarge moderately during pregnancy (Cunningham et al., 2010). It may show a greater increase in size if iodine intake is insufficient (Gordon, 2012). The availability of thyroid hormones increases by 40% to 100% (Blackburn, 2013).

Early in the first trimester, a rise in total thyroxine (T4) and thyroxine-binding globulin occurs. Levels of serum-unbound or free T4 rise early in pregnancy but return to normal nonpregnant levels by the end of the first trimester (Cunningham et al., 2010). Both T4 and triiodothyronine (T3) cross the placenta. Maternal thyroid hormones are important for fetal neurologic function because the fetus does not synthesize thyroid hormones until 12 weeks of gestation (Gordon, 2012).

Parathyroid Glands

Parathyroid hormone, which is important in calcium homeostasis, is decreased by 10% to 30% in the first trimester and increases by term. However, it remains in the normal range throughout pregnancy (Blackburn, 2013). Calcium supplies for transfer to the fetus are adequate.

Pancreas

Significant changes in the pancreas during pregnancy are the result of alterations in maternal blood glucose levels and fluctuations in insulin production. Blood glucose levels are 10% to 20% lower than before

TABLE 7-1 HORMONES RELATED TO PREGNANCY

HORMONE	SOURCE	MAJOR EFFECTS
Prolactin	Anterior pituitary	Primary hormone of milk production, insulin antagonist
Follicle-stimulating hormone (FSH)	Anterior pituitary	Initiates maturation of ovum, suppressed during pregnancy
Luteinizing hormone (LH)	Anterior pituitary	Stimulates ovulation of mature ovum in nonpregnant state, suppressed in pregnancy
Oxytocin	Posterior pituitary	Stimulates uterine contractions, stimulates milk-ejection reflex after birth, inhibited during pregnancy
Thyroxine (T4)	Thyroid	Increased during pregnancy to stimulate basal metabolic rate, used by fetus in early pregnancy
Cortisol	Adrenals	Increased during pregnancy, insulin antagonist, active in metabolism of glucose, protein, and fats
Aldosterone	Adrenals	Increased during pregnancy to conserve sodium and maintain fluid balance
Human chorionic gonadotropin (hCG)	Trophoblast	Prevents involution of corpus luteum to maintain production of estrogen and progesterone until placenta is formed
Estrogen	Corpus luteum of ovary, placenta	Suppresses FSH and LH, stimulates development of uterus and breasts, causes vascular changes in skin, uterus, respiratory tract and bladder, causes hyperpigmentation, insulin antagonist, increases fat stores
Progesterone	Corpus luteum of ovary, placenta	Maintains uterine lining for implantation, relaxes smooth muscles, decreases uterine contractions, develops breasts for lactation, increases carbon dioxide sensitivity, increases resistance to insulin, inhibits FSH and LH, prevents fetal tissue rejection, retains sodium
Human chorionic somatomammotropin (human placental lactogen)	Placenta	Stimulates metabolism of fat to provide maternal energy, antagonistic to insulin, promotes sodium retention, prepares breasts for lactation, acts as growth hormone
Relaxin	Corpus luteum, decidua, placenta	Inhibits uterine activity, softens connective tissue of cervix, relaxes cartilage and connective tissue

pregnancy, and hypoglycemia may develop between meals and at night as the fetus continuously draws glucose from the mother (Blackburn, 2013).

During the second half of pregnancy, maternal tissue sensitivity to insulin begins to decline because of the effects of human chorionic somatomammotropin (hCS), prolactin, estrogen, progesterone, and cortisol. The mother uses fatty acids to meet energy needs. Fasting blood glucose level is decreased as glucose passes to the fetus. Postprandial (after a meal) blood glucose level is higher than before pregnancy because of insulin resistance, making more glucose available for fetal energy needs. In healthy women, the pancreas produces additional insulin. In some women, however, insulin production cannot be increased and these women experience periodic hyperglycemia or gestational diabetes (see Chapter 26).

Adrenal Glands

Although the adrenal glands enlarge only slightly during pregnancy, significant changes occur in two adrenal hormones: cortisol and aldosterone. The concentrations of both serum cortisol and free (unbound) cortisol, the metabolically active form, are higher. The increase is the result of the elevated estrogen level and a decrease in metabolic clearance rate doubling the half-life of cortisol (Blackburn, 2013). Cortisol regulates carbohydrate and protein metabolism. It stimulates gluconeogenesis (formation of glycogen from noncarbohydrate sources such as amino and fatty acids) whenever the supply of glucose is inadequate to meet the body's needs for energy.

Aldosterone regulates the absorption of sodium from the distal tubules of the kidneys. It increases very early in pregnancy to overcome the salt-wasting effects of progesterone. This helps maintain the necessary level of sodium in the greatly expanded blood volume to meet the needs of the fetus. Aldosterone level is closely related to water metabolism.

Changes Caused by Placental Hormones

Human Chorionic Gonadotropin. In early pregnancy, human chorionic gonadotropin (hCG) is produced by the trophoblastic cells surrounding the developing embryo. The primary function of hCG in early pregnancy is to prevent deterioration of the corpus luteum so that it can continue producing estrogen and progesterone until the placenta is sufficiently developed to assume this function. The presence of this hormone produces a positive pregnancy test result.

Estrogen. Early in pregnancy, estrogen is produced by the corpus luteum. The placenta produces estrogen for the remainder of pregnancy. The effects of estrogen during pregnancy include:

- Suppression of FSH and LH
- Stimulation of uterine growth
- Increased blood supply to uterine vessels
- Added deposit of maternal fat stores to provide a reserve of energy
- Increased uterine contractions near term
- Development of the glands and ductal system in the breasts in preparation for lactation
- Hyperpigmentation
- Stimulation of vascular changes in the skin, breasts, upper respiratory tract, and bladder
- Antagonist to insulin

Progesterone. Progesterone is produced first by the corpus luteum and then by the fully developed placenta. Progesterone is the most important hormone of pregnancy. Its major effects include:

- Suppression of FSH and LH
- Maintenance of the endometrial layer for implantation of the fertilized ovum and prevention of menstruation

- Decreased uterine contractility to prevent spontaneous abortion
- Increased fat deposits
- Stimulation of development of the lobes, lobules, and ducts in the breast for lactation
- Relaxation of smooth muscles of the uterus, gastric sphincter, bowel, ureters, bladder
- Increased respiratory sensitivity to carbon dioxide, stimulating ventilation
- Suppression of the immunologic response, preventing rejection of the fetus
- Antagonist to insulin
- Retention of sodium

Human Chorionic Somatomammotropin. Also called *human placental lactogen (hPL)*, hCS is present early in pregnancy and increases steadily throughout pregnancy. Its primary function is to increase the availability of glucose for the fetus. A potent insulin antagonist, hCS reduces the sensitivity of maternal cells to insulin and decreases maternal metabolism of glucose. This frees glucose for transport to the fetus, who needs a constant supply. In addition, hCS encourages the quick metabolism of free fatty acids to provide energy for the pregnant woman. hCS also helps prepare the breasts for lactation and may act as a growth hormone.

Relaxin. Relaxin is produced by the corpus luteum, the decidua, and the placenta and is present by the first missed menstrual period. Relaxin inhibits uterine activity, softens connective tissue in the cervix, and relaxes cartilage and connective tissue to increase mobility of the pelvic joints (Blackburn, 2013).

Changes in Metabolism

During pregnancy, approximately 3.5 kg of fat and 30,000 kilocalories (kcal) are accumulated. In addition, the woman, fetus, and placenta synthesize 900 g of new protein (Blackburn, 2013). The basal metabolic rate increases 10% to 20% by the third trimester (Cunningham et al., 2010).

Weight Gain. A correlation exists between inadequate weight gain in pregnancy and small-for-gestational age infants, as well as between excessive weight gain and increased risk for large-for-gestational age infants. Therefore, women of normal prepregnancy weight are encouraged to gain an average of 11.5 to 16 kg (25 to 35 lb) during pregnancy (see Table 9-1) (Rasmussen & Yaktine, 2009). The fetus, placenta, and amniotic fluid make up less than half the recommended weight gain. The remainder is found in the increased size of the uterus and breasts, increased blood volume, increased interstitial fluid, and maternal stores of subcutaneous fat (see Figure 9-1).

Water Metabolism. The amount of water needed during pregnancy increases to meet the needs of the fetus, placenta, amniotic fluid, and increased blood volume. Total body water increases by 6.5 to 8.5 L by term (Gordon, 2012). The kidneys must compensate for the many factors that influence fluid balance. Increased GFR, prostaglandins, decreased concentrations of plasma proteins, and increased progesterone level all result in an increase in sodium excretion. However, increased concentrations of estrogen, deoxycorticosterone, hCS, and aldosterone all tend to promote the reabsorption of sodium. The net effect of the combined hormonal action is the maintenance of the sodium and water balance (Blackburn, 2013).

Edema. Because of hemodilution, colloid osmotic pressure decreases slightly, which favors the development of edema during pregnancy. Edema further increases toward term when the weight of the uterus compresses the veins of the pelvis. This process delays venous return, causing the veins of the legs to become distended, and increases venous pressure, resulting in additional fluid shifts from the vascular compartment to interstitial spaces.

Up to 70% of women have dependent edema during pregnancy. Accumulation of 2 L or more of fluid occurs with edema of the feet. The edema is obvious at the end of the day (particularly if a pregnant woman stands for prolonged periods), and the force of gravity contributes to the pooling of blood in the veins of the legs. Generalized edema occurs if women retain 4 to 5 L of water (Blackburn, 2013). Dependent edema is clinically insignificant if no other abnormal signs are present.

Carbohydrate Metabolism. Carbohydrate metabolism changes markedly during pregnancy when more insulin is needed as pregnancy progresses (see “Pancreas” above).

Sensory Organs

Eye

Corneal edema may cause women who wear contact lenses to have some discomfort. The problem resolves after childbirth, and women should not get new prescriptions for lenses for several weeks after delivery. Intraocular pressure decreases, which may cause improvement and a need for less medication in women with glaucoma (Blackburn, 2013).

Ear

Changes in the mucous membranes of the eustachian tube from increased levels of estrogen may cause women to have blocked ears and a mild, temporary hearing loss.

Immune System

Immune function is altered during pregnancy to allow the fetus, which is foreign tissue for the mother, to grow undisturbed without being rejected by the woman’s body. This may cause some autoimmune conditions such as rheumatoid arthritis and multiple sclerosis to improve during pregnancy (Cunningham et al., 2010). Resistance to some infections is decreased, however, and some viral and fungal infections occur more often during pregnancy (Blackburn, 2013; Koos et al., 2010).

CONFIRMATION OF PREGNANCY

Although many women undergo early ultrasonography to confirm the pregnancy, the diagnosis of pregnancy has traditionally been based on symptoms experienced by the woman as well as signs observed by a physician, nurse-midwife, or nurse practitioner. Figure 7-8 summarizes maternal changes that occur throughout pregnancy. (See Chapter 6 for a discussion on fetal growth and development.)

The signs and symptoms of pregnancy are grouped into three classifications: presumptive, probable, and positive indications. A diagnosis of pregnancy cannot be made solely on the presumptive or probable signs because they may have other causes, listed in Table 7-2. A definitive diagnosis of pregnancy can be based only on positive signs.

Presumptive Indications of Pregnancy

Most, but not all, presumptive indications are subjective changes that are experienced and reported by the woman. These changes are the least reliable indicators of pregnancy because they can be caused by conditions other than pregnancy.

Amenorrhea

Absence of menstruation (**amenorrhea**) in a sexually active woman who menstruates regularly is one of the first changes noted and strongly suggests that conception has occurred. Menses cease after conception because progesterone and estrogen, secreted by the corpus luteum, maintain the endometrial lining in preparation for implantation of the fertilized ovum. A small amount of bleeding from implantation of the blastocyst may cause the woman to think she is having a period. This occurs in 30% to 40% of pregnant women (Lu, Williams, & Hobel, 2010).

Nausea and Vomiting

Approximately 60% to 80% of women experience nausea and vomiting that begin at 4 to 8 weeks of pregnancy and resolve at 10 to 12 weeks, but some women experience it earlier and longer (Blackburn, 2013). Although the problem occurs most often in early pregnancy, a study of over 500 women found 45% experienced nausea and vomiting during the third trimester (Kramer, Bowen, Stewart et al., 2013). Nausea and vomiting are believed to be caused by the increased hormones (such as hCG and estrogen) and decreased gastric motility (an effect of progesterone).

Fatigue

Many pregnant women experience fatigue and drowsiness during the first trimester. The direct cause is unknown but it may be from changes in hormones such as progesterone.

Urinary Frequency

Urinary frequency begins in the first few weeks of pregnancy and results from hormonal and fluid volume changes. It continues later as the expanding uterus exerts pressure on the bladder. Late in the third trimester, the fetus settles into the pelvic cavity and causes more frequency and urgency of urination as the uterus presses against the bladder.

Breast and Skin Changes

Breast changes begin by the sixth week of pregnancy. The expectant mother experiences breast tenderness, tingling, feelings of fullness, and increased size and pigmentation of the areolae.

Many women observe increased pigmentation of the skin (such as melasma, linea nigra, darkening of the areolae of the breasts) during pregnancy. These skin changes are the result of estrogen and progesterone on melanocytes (Blackburn, 2013).

Vaginal and Cervical Color Change

The cervix, vagina, and labia change from pink to a dark bluish purple. This color change, called the *Chadwick sign*, is another presumptive sign of pregnancy (Blackburn, 2013; Bond, 2011; Cunningham et al., 2010; Gambone, 2010). It results from increased vascularity of the pelvic organs and is present by 8 weeks of pregnancy.

Fetal Movement

Unlike other presumptive indications of pregnancy, fetal movement (quickening) is not perceived until the second trimester. Although some women become aware of fetal movement sooner, most expectant

Gestational age 5-8 weeks

Woman misses menstrual period. Nausea; fatigue. Tingling of breasts. Uterus is size of a lemon; positive Chadwick, Goodell, and Hegar signs. Urinary frequency; increased vaginal discharge.

Gestational age 9-12 weeks

Nausea usually ends by 10 to 12 weeks. Uterus is size of an orange; palpable above symphysis pubis. Vulvar varicosities may appear. Fetal heartbeat may be heard with a Doppler.

Gestational age 13-16 weeks

Fetal movements may be felt at about 16 weeks. Uterus has risen into the abdomen; fundus midway between symphysis pubis and umbilicus. Colostrum present; blood volume increases.

Gestational age 17-20 weeks

Fetal movements felt. Heartbeat can be heard with fetoscope. Skin pigmentation increases: areolae darken; melasma and linea nigra may be obvious. Braxton Hicks contractions palpable. Fundus at level of umbilicus at about 20 weeks.

Gestational age 21-24 weeks

Relaxation of smooth muscles of veins and bladder increases the chance of varicose veins and urinary tract infections. Woman is more aware of fetal movements.

Gestational age 25-28 weeks

Period of greatest weight gain and lowest hemoglobin level begins. Lordosis may cause backache.

Gestational age 29-32 weeks

Heartburn common as uterus presses on diaphragm and displaces stomach. Braxton Hicks contractions more noticeable. Lordosis increases; waddling gait develops due to increased mobility of pelvic joints.

Gestational age 33-36 weeks

Shortness of breath caused by upward pressure on diaphragm; woman may have difficulty finding a comfortable position for sleep. Umbilicus protrudes. Varicosities more pronounced; pedal or ankle edema may be present. Urinary frequency noted following lightening when presenting part settles into pelvic cavity.

Gestational age 37-40 weeks

Woman is uncomfortable; looking forward to birth of baby. Cervix softens, begins to efface; mucous plug is often lost.

FIG 7-8 Maternal responses based on the date of the last menstrual period.

TABLE 7-2 INDICATIONS OF PREGNANCY AND OTHER POSSIBLE CAUSES

SIGN	OTHER POSSIBLE CAUSES
Presumptive Indications	
Amenorrhea	Emotional stress, strenuous physical exercise, endocrine problems, chronic disease, early menopause, anovulation, low body weight
Nausea and vomiting	Gastrointestinal virus, food poisoning, emotional stress
Fatigue	Illness, stress, sudden changes in lifestyle
Urinary frequency	Urinary tract infection
Breast and skin changes	Premenstrual changes, use of oral contraceptives
Chadwick sign	Infection or hormonal imbalance causing pelvic congestion
Quickening	Intestinal gas, peristalsis, or pseudocyesis (false pregnancy)
Probable Indications	
Abdominal enlargement	Abdominal or uterine tumors
Goodell sign	Hormonal contraceptives or imbalance
Hegar sign	Hormonal imbalance
Ballottement	Uterine or cervical polyps
Braxton Hicks contractions	Intestinal gas
Palpation of fetal outline	Large leiomyoma that feels like the fetal head, small soft leiomyoma that simulates fetal body parts
Uterine souffle	Confusion with the mother's pulse
Positive pregnancy test	Hematuria, proteinuria, some medications, tumors that produce human chorionic gonadotropin (hCG), some drugs
Positive Indications	
Auscultation of fetal heart sounds	
Fetal movements detected by an examiner	
Visualization of embryo or fetus	

mothers notice subtle fetal movements, which gradually increase in intensity between 16 and 20 weeks of gestation.

Probable Indications of Pregnancy

Probable indications of pregnancy are objective findings that can be documented by an examiner. They are primarily related to physical changes in the reproductive organs. Although these signs are stronger indicators of pregnancy, a positive diagnosis cannot be made because they may have other causes.

Abdominal Enlargement

Enlargement of the abdomen during the childbearing years is a fairly reliable indication of pregnancy, particularly if it corresponds with a slow, gradual increase in uterine growth. Pregnancy is even more likely when abdominal enlargement is accompanied by amenorrhea.

Cervical Softening

In the early weeks of pregnancy, the cervix softens as a result of pelvic vasocongestion (Goodell sign). Cervical softening is noted during pelvic examination.

Changes in Uterine Consistency

About 6 to 8 weeks after the last menses, the lower uterine segment is so soft that it can be compressed to the thinness of paper. This is called the **Hegar sign** (Figure 7-9). The body of the uterus can be easily flexed against the cervix.

Ballottement

Near midpregnancy, a sudden tap on the cervix during vaginal examination may cause the fetus to rise in the amniotic fluid and then rebound to its original position (Figure 7-10). This movement, called

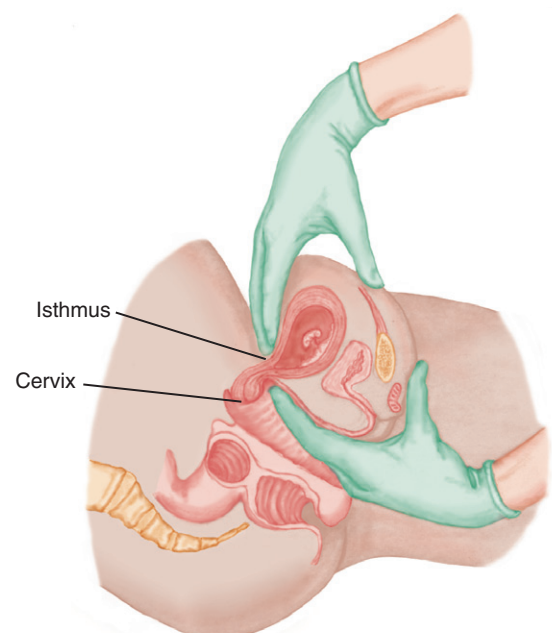

FIG 7-9 The Hegar sign demonstrates softening of the isthmus of the cervix.

ballottement, is a strong indication of pregnancy, but it may also be caused by other factors such as uterine or cervical polyps.

Braxton Hicks Contractions

Irregular, painless contractions occur throughout pregnancy, although many expectant mothers do not notice them until the third trimester.

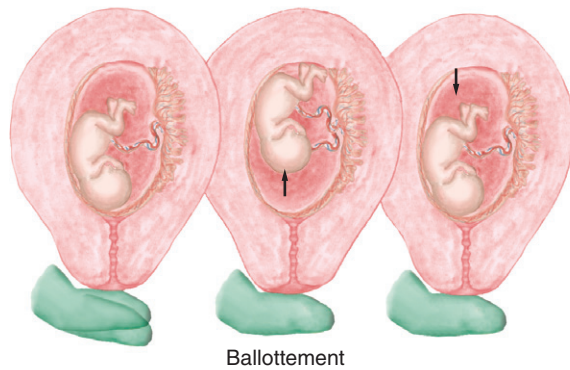

FIG 7-10 When the cervix is tapped, the fetus floats upward in the amniotic fluid. A rebound is felt by the examiner when the fetus falls back.

They increase in strength and frequency as the pregnancy nears term. It is important to differentiate Braxton Hicks contractions from the contractions of preterm labor. This is often difficult, and the woman should check with her health care provider if she is unsure, has more than five or six contractions in an hour, or has any other signs of early labor (Callahan & Caughey, 2009).

Palpation of the Fetal Outline

Unless the woman is very obese, an experienced practitioner is able to palpate the outlines of the fetal body by the middle of pregnancy. Outlining the fetus becomes easier as the pregnancy progresses and the uterine walls thin to accommodate the growing fetus.

Uterine Souffle

Late in pregnancy, the *uterine souffle*—a soft, blowing sound—may be auscultated over the uterus. This is the sound of blood circulating through the dilated uterine vessels and it corresponds to the maternal pulse. Therefore, to identify the uterine souffle, the rate of the maternal pulse must be checked simultaneously. Uterine souffle differs from *funic souffle*—the soft, whistling sound heard over the umbilical cord and corresponding to the fetal heart rate.

Pregnancy Tests

Pregnancy tests detect hCG or the beta subunit of hCG, which is secreted by the placenta and present in maternal blood and urine shortly after conception. Immunoassay tests are available to test blood or urine for pregnancy in a laboratory or home. They can detect hCG at very low concentrations and are positive as early as 3 to 7 days after conception (Pagana & Pagana, 2011). For home testing, the woman places her urine sample on a strip or wick and watches for a color or digital change. The first morning void is preferred because it is most concentrated. Instructions vary with different tests and the woman should read the directions carefully when testing at home.

Inaccurate Pregnancy Test Results. When pregnancy test results are reported as negative and the woman is in fact pregnant, the results are called *false-negative*. False-negative results may occur when the instructions are not followed properly, it is too early in the pregnancy, the urine is too dilute, or the woman is taking drugs such as diuretics. Hematuria, proteinuria, or some tumors may cause *false-positive* results, where the test indicates a pregnancy when the woman is not pregnant. Some anticonvulsants, antiparkinsonian drugs, tranquilizers, and hypnotics may also cause a false-positive result (Pagana & Pagana, 2011).

Positive Indications of Pregnancy

Only three signs are accepted as positive confirmation of pregnancy: auscultation of fetal heart sounds, fetal movement detected by an examiner, and visualization of the embryo or fetus.

Auscultation of Fetal Heart Sounds

Fetal heart sounds can be heard with a fetoscope by 18 to 20 weeks of gestation (Beckmann et al., 2010). The electronic Doppler, which is used more often, detects heart motion and makes an audible sound by 9 to 12 weeks of gestation (Gambone, 2010) (see Figure 14-1).

To distinguish the fetal heartbeat from the maternal pulse, the examiner palpates the maternal pulse while auscultating the fetal heartbeat. The normal fetal heart rate is 110 to 160 bpm in the third trimester. The fetal heart rate is muffled by the amniotic fluid, and the location changes because the fetus moves freely in the amniotic fluid.

Fetal Movements Detected by an Examiner

Fetal movements are considered a positive sign of pregnancy when felt or visualized by an experienced examiner who is not likely to be deceived by peristalsis in the large intestine.

Visualization of the Embryo or Fetus

Confirmation of pregnancy has become much simpler since the development of ultrasonography, which makes it possible to view the embryo or fetus and observe the fetal heartbeat very early in pregnancy. Positive confirmation of pregnancy is possible by transvaginal ultrasonography as early as 3 to 4 weeks of gestation (Beckmann et al., 2010). Ultrasonographic testing is discussed further in Chapter 10.

ANTEPARTUM ASSESSMENT AND CARE

The objective of antepartum care is to ensure that pregnancy ends in the birth of a healthy infant without impairing the health of the mother. Prenatal care involves early and continuing risk assessments, health education, counseling, and social support.

Good antepartum care begins before conception and continues on a regular basis thereafter. Inadequate antepartum care is associated with low birth weight and an increased incidence of prematurity in neonates. These two complications lead to increased infant morbidity and mortality.

In 2008, approximately 70.7% of women in the United States began antepartum care in the first trimester. Seven percent of pregnant women began care in the third trimester or had no prenatal care at all (National Center for Health Statistics, 2012). The *Healthy People 2020* goal is for at least 77.6% of women to begin antepartum care in the first trimester (U.S. Department of Health and Human Services, 2010). The amount of prenatal care varies among groups. American Indian, Alaska Native, most Hispanic, and African-American women are less likely than Asian, Pacific Islander, Cuban, or white women to begin care in the first trimester and more likely to begin care in the third trimester or to have no prenatal care at all (National Center for Health Statistics, 2012).

Preconception and Interconception Care

Ideally, the first visit takes place before conception. Preconception care (given before conception) and interconception care (given between pregnancies) are important to identify problems that might harm the mother or the infant once pregnancy occurs and to provide education to help ensure a healthy pregnancy. The early weeks of pregnancy are particularly important because during that time the fetal organs are forming and are especially sensitive to harm. Many women do not begin prenatal care until after this sensitive period, and injury may already have transpired. Interconception care is especially important for women who have had a previous pregnancy or birth with complications. It also identifies and treats risk factors that have occurred since the last pregnancy.

Because so many pregnancies are unintended, any visit to a health care provider by a woman of childbearing age should be seen as an opportunity for preconception or interconception care. This care can be part of developing a reproductive life plan that includes deciding the desired number and spacing of pregnancies. Such a plan helps women make changes that may improve birth outcomes (Malnory & Johnson, 2011; Sanders, 2009). Chronic conditions such as asthma, obesity, diabetes, or hypothyroidism should be addressed before pregnancy occurs. Previous reproductive problems and family history of possible genetic conditions are explored. Genetic testing may be indicated by the family history.

During a preconception visit, the health care provider obtains a complete history and performs a physical examination. The woman is assessed for health problems (such as diabetes, hypertension, or sexually transmitted diseases [STDs]), harmful habits (such as use of alcohol or drugs), or social problems (such as intimate partner violence) that might unfavorably affect pregnancy. If problems are discovered, intervention may be started immediately to avoid complications or worsening of the woman's condition or situation because of pregnancy. Screening for rubella, varicella, and hepatitis B is performed, and the vaccines are given, if indicated. The woman should be instructed to wait at least 1 month after receiving rubella and varicella vaccines before conceiving.

If the woman is taking prescription and over-the-counter drugs, vitamins, or other supplements, their effect on pregnancy is evaluated and changes made, if necessary. Approximately 50% of women report taking at least one medication during pregnancy (Mitchell, Gilboa, Werler et al., 2011). Medications that might be teratogenic can be changed to less harmful drugs.

Use of complementary or alternative therapies is also addressed because some that are safe at other times may be harmful during pregnancy. Avoidance of common teratogens or other harmful substances is discussed. Women who are obese can obtain help to lose weight before conceiving. Referral to smoking cessation programs may be indicated.

The woman is advised to consume 400 to 800 micrograms (mcg) (0.4 to 0.8 mg) of folic acid daily for at least 1 month before conception and 2 to 3 months after conception to decrease the risk of neural tube defects (U.S. Preventive Services Task Force, 2009). An intake of 600 mcg (0.6 mg) is recommended for the rest of pregnancy. Women who have given birth previously to an infant with a neural tube defect should take 4000 mg of folic acid daily during the 4 weeks before pregnancy and throughout the first trimester (Gregory, Niebyl, & Johnson, 2012).

Initial Prenatal Visit

If a preconception visit has occurred recently, many initial prenatal assessments will have been completed at that time. If not, the nurse practitioner, nurse-midwife, or physician will complete a thorough

history and physical examination. The following are the primary objectives of the first antepartum examination:

- Establish trust and rapport with the childbearing family.
- Verify or rule out pregnancy.
- Evaluate the pregnant woman's physical health relevant to childbearing.
- Assess the growth and health of the fetus.
- Establish baseline data for comparison with future observations.
- Evaluate the psychosocial needs of the woman and her family.
- Assess the need for counseling or teaching.
- Negotiate a plan of care to ensure a healthy mother and a healthy baby.

History

Obstetric History. The obstetric history provides essential information about previous pregnancies that may alert the health care provider to possible problems in the present pregnancy. Components of this history include the following:

- Gravida, para, **abortions** (spontaneous or elective termination of pregnancies before the twentieth week of gestation; spontaneous abortion is frequently called *miscarriage*), and living children
- Length of previous gestations
- Weight of infants at birth
- Labor experiences, type of deliveries, locations of births, and names of physicians or midwives
- Types of anesthesia and any difficulties with anesthesia during childbirths or previous surgeries
- Maternal complications such as hypertension, diabetes, infection, or bleeding
- Infant complications
- Methods of infant feeding used in the past and currently planned
- Special concerns

Gravida refers to a woman who is or has been pregnant, regardless of the length of the pregnancy. A **primigravida** is a woman pregnant for the first time. A **multigravida** has been pregnant more than once. **Para** refers to the number of pregnancies that have ended at 20 or more weeks, regardless of whether the infant was born alive or stillborn. A **nullipara** is a woman who has never been pregnant or has not completed a pregnancy of 20 weeks or more. A **primipara** has delivered one pregnancy of at least 20 weeks. A **multipara** has delivered two or more pregnancies of at least 20 weeks.

The number of fetuses in a pregnancy does not change the para. Therefore, a woman who gives birth to twins with her first pregnancy will be a gravida 1, para 1, if the birth occurs at 20 or more weeks of gestation.

Use of the acronym GTPAL is another way to describe pregnancy outcomes, where G = pregnancies or gravida, T = term pregnancies delivered, P = preterm pregnancies delivered, A = abortions, and L = living children. GTPAL is used by some authors to describe infants instead of pregnancies delivered. In this usage, T signifies term infants born, and P signifies preterm infants born (Box 7-1). Because the acronym is not used consistently, it can be confusing.

Nurses must use caution when discussing gravida and para with the expectant mother in the presence of her family or significant other. Although the antepartum record indicates a previous pregnancy or childbirth, she may not have shared this information with her family, and her right to privacy could be jeopardized by probing questions in their presence. The pregnancy may have terminated in elective or spontaneous abortion or in the birth of an infant who was placed for adoption. The confidentiality of the pregnant woman must always be protected. The nurse should wait until the woman is alone if it is necessary to clarify information about her gravida or para.

BOX 7-1 CALCULATION OF GRAVIDA AND PARA

A method for calculating gravida and para is to separate pregnancies and their outcome using the acronym GTPAL: G = gravida, T = term, P = preterm, A = abortions, and L = living children.

The following examples illustrate the use of this method:

- Jennie is 6 months pregnant. She had one spontaneous and one elective abortion in the first trimester. She has a son who was born at 40 weeks of gestation and a daughter who was born at 34 weeks of gestation. She is gravida 5, para 2, T = 1 (the son born at 40 weeks); P = 1 (the daughter born at 34 weeks), A = 2, L = 2. The two abortions are counted in the gravida but not included in the para because they occurred before 20 weeks of gestation. Therefore, Jennie's GTPAL would be 5-1-1-2-2.
- Lani gave birth to twins at 32 weeks' gestation and to a stillborn infant at 24 weeks of gestation. Approximately 2 years later, she experienced a spontaneous abortion at 12 weeks of gestation. If pregnant now, she is gravida 4, para 2 (the twins counting as 1 parous experience and the stillborn infant counting as 1 parous experience). If the GTPAL acronym is used to refer to pregnancies delivered, G = 4, T = 0 (no pregnancies went to term), P = 2 (the twins and the stillborn infant counting as 2 pregnancies ending in preterm birth), A = 1, L = 2. The GTPAL would be 4-0-2-1-2. If the GTPAL acronym is used to refer to infants born, G = 4, T = 0 (no infants were born at term), P = 3 (the twins and the stillborn infant born preterm), A = 1, L = 2. The GTPAL would be 4-0-3-1-2.

Menstrual History and Estimated Date of Delivery. A complete menstrual history is necessary to establish the estimated date of delivery (EDD). Common practice is to estimate the EDD on the basis of the first day of the last normal menstrual period (LNMP), although ovulation and conception occur about 2 weeks after the beginning of menstruation in a regular 28-day cycle. The average duration of pregnancy from the first day of the LNMP is 40 weeks, or 280 days.

Nägele's rule is often used to establish the EDD. This method involves subtracting 3 months from the date the LNMP began, adding 7 days and then correcting the year, if appropriate. For example:

- LNMP: August 30, 2014
- Subtract 3 months: May 30, 2014
- Add 7 days and change the year: June 6, 2015

Calculations of EDD may be inaccurate in some situations. For example, the Nägele rule is less accurate when the woman's menstrual cycle is very irregular. Many health care providers also use a gestational wheel to determine EDD quickly, although wheels are only accurate within plus or minus 5 days (Cunningham et al., 2010).

Ultrasound measurements taken early in pregnancy can more accurately determine the gestational age. The EDD is also important in deciding when to schedule certain tests commonly performed during pregnancy.

Gynecologic and Contraceptive History. Any previous gynecologic problems should be identified. STDs should be treated. Infertility problems with past or the present pregnancy should be discussed.

A detailed history of contraceptive methods is important. Although some concern exists about congenital malformations when pregnant women inadvertently use hormonal contraceptives, studies have shown the risk is no greater than that for the general population (Nelson & Cwiak, 2011). Of course, any woman who suspects she might be pregnant should stop taking hormonal contraceptives and use another contraceptive until she has confirmation from a health care provider.

Pregnancy with an intrauterine device (IUD) in place is unusual, but it can cause complications such as spontaneous abortion and

CASE STUDY 7-1 INTRODUCTION*

Sally, age 26 years, moved to this area 8 months ago with her husband and two children. They live in a four-room apartment, and she works as a secretary in a busy office. Her husband is a computer technician. Sally comes to the clinic because she thinks she may be pregnant. A full history and physical are performed, and the results are normal. She states she has always been healthy.

Sally gave birth to twin girls at 38 weeks gestation 3 years ago in another state. Last year, she had a spontaneous abortion at 7 weeks of gestation. She and her husband have been wanting to have another child and she stopped using birth control 3 months ago. Her last normal menstrual period began 6 weeks ago on November 16. She has begun to experience some nausea in the mornings.

Critical Thinking Exercise

1. If Sally is pregnant now, what would be her gravida and para?
2. Explain to Sally why amenorrhea and morning sickness are not positive indications of pregnancy.
3. Sally is examined and is pregnant. Use the Nägele rule to compute her EDD.

*Continues on p. 109.

preterm delivery. The IUD should be removed promptly and the woman advised to watch for influenza-like signs and symptoms, which may indicate a septic spontaneous abortion (Dean & Schwarz, 2011). A woman who shows signs of infection with an IUD in place should receive intensive antibiotic treatment and have her uterus evacuated (Cunningham et al., 2010).

Medical and Surgical History. Chronic conditions can affect the outcome of the pregnancy and must be investigated. Infections, surgical procedures, and trauma that may complicate the pregnancy or childbirth should be documented. The history includes the following:

- Age, race, and ethnic background (risk for specific genetic problems such as sickle cell disease, thalassemia, cystic fibrosis, and Tay-Sachs disease)
- Childhood diseases and immunizations
- Chronic illnesses such as asthma, heart disease, hypertension, diabetes, renal disease, lupus (onset and treatment)
- Previous illnesses, surgical procedures, and injuries (particularly of the pelvis and back)
- Previous infections such as hepatitis, STDs, tuberculosis, and presence of group B *Streptococcus*
- History of and treatment for anemia
- Bladder and bowel function (problems or changes)
- Amount of caffeine and alcohol consumed each day
- Tobacco use (number of years and number of packs per day)
- Prescription, over-the-counter, and illicit drugs (name, dose, frequency)
- Complementary or alternative therapies used
- Appetite, general nutrition, history of eating disorders
- Contact with pets, particularly cats (increased risk of infections such as toxoplasmosis; pregnant women should not empty litter boxes or eat uncooked meat)
- Allergies and drug sensitivities
- Occupation and related risk factors

Family History. A family history provides valuable information about the general health of the family, including chronic diseases such as diabetes and heart disease and infections such as tuberculosis and hepatitis. In addition, it may reveal information about patterns of genetic or congenital anomalies.

Partner's Health History. The partner's history may include significant health problems such as genetic abnormalities, chronic diseases, and infections. Use of drugs such as cocaine and alcohol may affect the family's ability to cope with pregnancy and childbirth. Tobacco use by the father increases the risk of upper respiratory tract infections for both the mother and the infant from exposure to passive smoke.

In addition, the father's blood type and Rh factor are important if the mother is Rh-negative or type O because blood incompatibility between the mother and fetus is possible.

Psychosocial History. The psychosocial history also should be elicited during the initial visit. It is discussed in [Chapter 8](#).

Physical Examination

Many women have not had a recent physical examination before becoming pregnant. Therefore, a thorough evaluation of all body systems is necessary to detect previously undiagnosed physical problems that may affect the pregnancy outcome. It also establishes baseline levels that will guide the treatment of the expectant mother and fetus throughout pregnancy.

Vital Signs

Blood Pressure. Position affects BP in the pregnant woman. BP should be obtained with the woman seated and her arm supported in a horizontal position at heart level. Documentation should include the position, arm used, pressures obtained, and type of sphygmomanometer used. Manual varieties are more accurate than automatic varieties.

All staff members should use the same Korotkoff phase to measure diastolic BP. Korotkoff fifth phase (disappearance of sound) is used most often because the fourth phase (muffling) is not always identifiable. Consistency helps identify gradual changes accurately. A BP of 140/90 mm Hg or higher may indicate preeclampsia and requires additional evaluation (see [Chapter 25](#)).

Pulse. The normal adult pulse rate is 60 to 90 bpm. Tachycardia is associated with anxiety, hyperthyroidism, and infection and should be investigated. Apical pulse should be assessed for at least 1 minute to determine the amplitude and regularity of the heartbeat and presence of murmurs. Pedal pulses are assessed to determine the presence of circulatory problems in the legs. Pedal pulses should be strong, equal, and regular.

Respirations. Respiratory rate during pregnancy is in the range of 16 to 24 breaths per minute. Tachypnea may indicate respiratory tract infection or cardiac disease. Breath sounds should be equal bilaterally, chest expansion should be symmetric, and lung fields should be free of abnormal breath sounds.

Temperature. Normal temperature during pregnancy is 36.6°C to 37.6°C (97.8°F to 99.6°F). Fever suggests infection and may require medical management.

Cardiovascular System

Venous Congestion. Additional assessment of the cardiovascular system includes observation for venous congestion, which can develop into varicosities. Venous congestion is most commonly noted in the legs, the vulva (as varicosities), or the rectum (as hemorrhoids).

Edema. Edema of the legs may be a benign condition that reflects pooling of blood in the extremities, which results in a shift of intravascular fluid into interstitial spaces. When pressure exerted by a finger leaves a persistent depression, pitting edema is present (see [Figure 17-8](#)).

Musculoskeletal System

Posture and Gait. Body mechanics and changes in posture and gait should be addressed. Poor body mechanics during pregnancy may place strain on the muscles of the lower back and legs.

Height and Weight. An initial weight is recorded to establish a baseline for evaluation of weight gain throughout pregnancy (see [Chapter 9](#)). The body mass index should be calculated (see [page 143](#)). Women who are underweight before pregnancy are at risk of having small-for-gestational age infants ([Wildschut, 2011](#)).

Obesity is a special concern during pregnancy (see [Chapter 9, page 143](#)). Obesity increases the incidence of hypertensive disorders, gestational diabetes, postpartum hemorrhage, poor labor progression, cesarean delivery, anesthesia complications, wound infection, and birth of large-for-gestational age infants ([Wildschut, 2011](#)). Obese women often need closer observation and careful management of complications during pregnancy. Tests of fetal well-being may be important during the third trimester ([Nodine & Hastings-Tolsma, 2012](#)).

Abdomen. The contour, size, and muscle tone of the abdomen should be assessed. The fundal height should be measured if the fundus is palpable above the symphysis pubis (see [page 111](#)). The fetal heart rate should be auscultated, counted, and recorded if the pregnancy is advanced enough that the fetal heart rate is audible.

Neurologic System

A complete neurologic assessment is not necessary for women who are free of signs or symptoms indicating a problem. However, deep tendon reflexes should be evaluated because hyperreflexia is associated with complications of pregnancy. (See [Chapter 25](#) "Assessing Deep Tendon Reflexes.")

Carpal Tunnel Syndrome. Carpal tunnel syndrome is believed to result when edema compresses the median nerve at the point where it passes through the carpal tunnel of the wrist. Symptoms include pain, burning, numbness, or tingling of the hand and wrist. Splinting of the wrist at night may provide improvement. It resolves by 3 months after childbirth for most women ([Blackburn, 2013](#)).

Integumentary System

Skin color should be consistent with racial background. Pallor may result from anemia. Jaundice may indicate hepatic disease. Lesions, bruising, rashes, areas of hyperpigmentation related to pregnancy (melasma, linea nigra), and stretch marks (striae) should be noted. Nail beds should be pink with instant capillary return.

Endocrine System

The thyroid enlarges moderately during the second trimester. However, gross enlargement or tenderness may indicate hyperthyroidism and requires further medical evaluation. Women with hypothyroidism should be treated during pregnancy to allow optimal development of the fetal central nervous system.

Gastrointestinal System

Mouth. Mucous membranes should be pink, smooth, glistening, and uniform. Lips should be free of ulcerations. Gums may be red, tender, and edematous and may bleed more easily. Teeth should be in good repair. Dental plaque may increase, and a temporary increase in tooth mobility may occur ([Blackburn, 2013](#)).

The woman should be referred for regular dental care. The second trimester may be the most comfortable time for dental care. However, if necessary, dental care can be performed during the third trimester if the woman is positioned to avoid supine hypotensive syndrome.

Intestine. A warm stethoscope for assessing bowel sounds is most comfortable for the pregnant woman. Bowel sounds may be diminished because of the effects of progesterone on smooth muscle. Bowel sounds are often increased if a meal is overdue or diarrhea is present. Problems with constipation can be discussed during abdominal examination.

Urinary System

A clean-catch midstream urine sample is tested for urinary tract infection and substances that may indicate a problem.

Protein. Although a trace amount of protein may be present in the urine, the amount should not increase. Its presence may indicate kidney disease, preeclampsia, or contamination by vaginal secretions.

Glucose. Small amounts of glucose may indicate physiologic “spilling” that occurs during normal pregnancy.

Ketones. Ketones may be found in the urine after heavy exercise or as a result of inadequate intake of food and fluid.

Bacteria. Increased bacteria in urine is associated with urinary tract infection, which is common during pregnancy.

Reproductive System

Breasts. Breast size and symmetry, condition of the nipples (erect, flat, inverted), and presence of colostrum should be noted. Any lumps, dimpling of the skin, or asymmetry of the nipples requires further evaluation.

External Reproductive Organs. The skin and mucous membranes of the perineum, vulva, and anus are inspected for excoriations, growths, ulcerations, lesions, varicosities, warts, chancres, and perineal scars. Enlargement, tenderness, redness, or discharge from the Bartholin or Skene gland may indicate gonorrheal or chlamydial infection. The examiner should obtain a specimen for culture from any discharge from lesions or inflamed glands to determine the causative organisms and to provide effective care.

Internal Reproductive Organs. A speculum inserted into the vagina permits the examiner to see the walls of the vagina and the cervix. The cervix should be pink in a nonpregnant woman and bluish purple in a pregnant woman (Chadwick sign). The external cervical os is closed in primigravidas, but one fingertip may be admitted in multiparas. The cervix feels relatively firm except during pregnancy, when marked softening is noted (Goodell sign). Routine cervical cultures for gonorrhea and chlamydial infection are generally obtained during the initial pregnancy examination. The examiner also collects a specimen for a Papanicolaou (Pap) test to screen for cervical cancer.

A bimanual examination involves the use of both hands, one on the abdomen and the other in the vagina, to palpate the internal genitalia. The examiner palpates the uterus for size, contour, tenderness, and position. The uterus should be movable between the two examining hands and should feel smooth. The ovaries, if palpable, should be about the size and shape of almonds and nontender.

Pelvic Measurements. Pelvic measurements may be assessed at this time to determine if the shape and size of the bony pelvis are adequate for a normal vaginal birth (see Figure 12-4).

Laboratory Data

Table 7-3 lists laboratory examinations commonly performed during pregnancy and describes the purpose and significance of each test. Table 7-4 shows laboratory values for pregnant and nonpregnant women.

Risk Assessment

Risk assessment begins at the initial visit when the health care provider identifies factors that put the expectant mother or fetus at risk for

complications and determines the need for specialized care. Many women identified as high risk give birth to healthy term infants. Furthermore, risk factors change as pregnancy progresses, and risk assessment must be updated throughout pregnancy. Table 7-5 lists major risk factors and their implications.

22. Why is it important for all caregivers to use the same techniques when measuring BP?
23. What are major risk factors during pregnancy?

Subsequent Assessments

Ongoing antepartum care is important to the successful outcome of pregnancy. Although the recommended number of visits can be reduced for women without complications, the usual schedule for prenatal assessment in normal pregnancy is:

- Conception to 28 weeks—every 4 weeks
- 29 to 36 weeks—every 2 weeks
- 37 weeks to birth—weekly (Cunningham et al., 2010; AAP & ACOG, 2012).

Although the preceding schedule is the traditional model of prenatal care, other options do exist. “CenteringPregnancy” is an example of an alternative method of care that is evidence based (Rotundo, 2011). The method involves ten 1.5- to 2-hour sessions with groups of 8 to 12 women, who meet with a nurse and a health care provider, beginning at 12 to 16 weeks of pregnancy and ending soon after childbirth. The women have an individual assessment before the first group session and during a small part of subsequent group sessions. Women assess their own blood pressure and weight and participate in educational sessions appropriate for that point of pregnancy. The social support provided by the group is an important benefit. Women participating in this form of care have been satisfied with their care and have had favorable pregnancy outcomes (Rotundo, 2011). Participants also receive more health promotion content and peer support than those receiving traditional care (Herman, Rogers, & Ehrenthal, 2012; Klima, Norr, Vonderheid et al., 2009). More information is available at www.centeringpregnancy.org.

CASE STUDY 7-1 CRITICAL THINKING EXERCISE

When she is 5 months pregnant, Sally says, “I don’t know why I have to come to see the doctor so often! I’m perfectly healthy now that I don’t have morning sickness any more, and it’s such a bother to go. I went through all this with my twins. It’s hard for me to get time off from work, and last time I had to wait in the office for ages before it was my turn. Then all that happens is that they check my weight, get a sample of urine, and take my blood pressure. The doctor comes in, asks me a few questions, listens to the baby’s heart, says come back in 4 weeks, and is out the door. And half the time I forget to ask the questions I have. This is a waste of time!”

Questions

1. How should the nurse respond to Sally?
2. What is the importance of the assessments made during Sally’s visit?
3. What suggestions might the nurse make to improve Sally’s experience?

*Continued from p. 107; continues on pp. 114 and 115.

TABLE 7-3 COMMON LABORATORY TESTS

TEST	PURPOSE	SIGNIFICANCE
Complete blood count (CBC)	To detect infection, anemia, or cell abnormalities	More than 15,000/mm ³ white blood cells or decreased platelets require follow-up.
Hemoglobin (Hgb) or hematocrit (Hct)	To detect anemia; often checked several times during pregnancy	Low hemoglobin (Hgb) or hematocrit (Hct) may indicate need for added iron supplementation.
Blood grouping, Rh factor, and antibody screen	To determine blood type to screen for maternal-fetal blood incompatibility	Identifies possible causes of incompatibility that may result in jaundice in neonate. If father is Rh-positive and mother is Rh-negative and unsensitized, Rh ₀ (D) immune globulin will be given to the mother at 28 weeks.
Venereal Disease Research Laboratory (VDRL) test or rapid plasma reagin (RPR)	To screen for syphilis	Treat, if results are positive. Retest, if indicated.
Rubella titer	To determine immunity	If titer is 1:8 or less, the woman is not immune. Immunize postpartum if not immune.
Tuberculin skin test	To screen for tuberculosis	If positive, refer for additional testing or therapy.
Genetic testing (for sickle cell anemia, cystic fibrosis, Tay-Sachs disease, and other genetic conditions)	Offered if an increased risk for certain genetic conditions exists	If mother is positive, check partner. Counsel as appropriate for test results.
Hepatitis B screen	To detect presence of antigens in maternal blood	If present, infants should be given hepatitis immune globulin and vaccine soon after birth.
Human immunodeficiency virus (HIV) screen	Voluntary test encouraged at first visit to detect HIV antibodies	Positive results require retesting, counseling, and treatment to lower risk of infant infection.
Urinalysis	To detect renal disease or infection	Requires further assessment if positive for more than trace protein (renal damage, preeclampsia, or normal), ketones (fasting or dehydration), or bacteria (infection).
Papanicolaou (Pap) test	To screen for cervical neoplasia	Refer for treatment if abnormal cells are present.
Vaginal-rectal culture	To detect chlamydia and gonorrhea (in early pregnancy) and group B streptococci (in late pregnancy)	Treat and retest as necessary; treat chlamydia and gonorrhea when discovered and group B streptococci during labor.
Multiple marker screen: maternal serum alpha-fetoprotein, human chorionic gonadotropin (hCG), and estriol. Inhibin A and nuchal lucency may also be measured	To screen for fetal anomalies	Abnormal results may indicate chromosomal abnormality (such as trisomy 13, 18, or 21) or structural defects (such as neural tube defects or gastroschisis).
Glucose challenge test	To screen for gestational diabetes	If elevated, 3-hour glucose tolerance test is recommended.

TABLE 7-4 LABORATORY VALUES IN NONPREGNANT AND PREGNANT WOMEN

VALUE	NONPREGNANT	PREGNANT
Red blood cell count	4.2–5.4 million/mm ³	3.8–4.4 million/mm ³ Decreases slightly because of hemodilution
Hemoglobin	12–16 g/dL	At least 11 g/dL during first and third trimesters and at least 10.5 g/dL during second trimester
Hematocrit, packed cell volume	37%–47%	33.8%–39%
White blood cell count	5000–10,000/mm ³	5000–15,000/mm ³
Platelets	150,000–400,000/mm ³	Slight decrease but within normal range
Prothrombin time	11–12.5 seconds	Slight decrease
Activated partial thromboplastin time	30–40 seconds	Slight decrease
D-dimer	Negative	Negative
Blood glucose, fasting	70–110 mg/dL	95 mg/dL or lower
Creatinine, serum (mg/dL)	0.65 ± 0.14 mg/dL	0.46 ± 0.13 mg/dL
Creatinine clearance, urine	85–120 mg/dL	110–180 mg/dL
Fibrinogen	200–400 mg/dL	300–600 mg/dL

(2010). *Williams' obstetrics* (23rd ed.). New York: McGraw-Hill; and Pagana, K. D., & Pagana, T. J. (2011). *Mosby's diagnostic and laboratory test reference* (19th ed.). St. Louis: Mosby.

TABLE 7-5 SUMMARY OF MAJOR RISK FACTORS IN PREGNANCY

FACTORS	ASSOCIATED PROBLEMS
Demographic Factors	
<16 years of age	Preterm birth, low birth weight, perinatal mortality, anemia, human immunodeficiency virus (HIV), sexually transmitted diseases (STDs)
>35 years of age	Gestational diabetes, hypertension, prolonged labor, cesarean birth, congenital anomalies, infant mortality, placenta previa
Low socioeconomic status or dependence on public assistance	Preterm labor, maternal perinatal mortality, low birth weight, chromosomal disorders, fetal growth disorders
Nonwhite race	Low birth weight, preterm birth, infant mortality for some groups
Multiparity	Abnormal fetal presentation, antepartum or postpartum hemorrhage, cesarean birth
Social and Personal Factors	
Low prepregnancy weight	Low birth weight
Obesity	Hypertension, gestational diabetes, failure to progress in labor, cesarean birth, anesthesia complications, high birth weight, wound infections, postpartum hemorrhage, thromboembolism
Height <152 cm (5 feet)	Cesarean birth because of cephalopelvic disproportion
Smoking	Spontaneous abortion, low birth weight, abruptio placentae, placenta previa, preterm birth, perinatal mortality, sudden infant death syndrome (SIDS)
Use of alcohol or unprescribed drugs	Congenital anomalies, neonatal withdrawal syndrome, fetal alcohol spectrum disorder
Obstetric Factors	
Birth of previous infant >4000 g (8.8 lb)	Maternal gestational diabetes, cesarean birth; birth injury, neonatal hypoglycemia
Previous fetal or neonatal death	Maternal psychological distress
Rh sensitization	Jaundice, fetal anemia, erythroblastosis fetalis, kernicterus
Previous preterm birth	Repeated preterm birth
Existing Medical Conditions	
Diabetes mellitus	Preeclampsia, cesarean birth, preterm birth, infant either small or large for gestational age, neonatal hypoglycemia, congenital anomalies
Thyroid disorder	
Hypothyroidism	Gestational hypertension, low birth weight, mental and motor developmental delay
Hyperthyroidism	Spontaneous abortion, heart failure, thyroid storm, preeclampsia, growth restriction, fetal or neonatal thyrotoxicosis
Cardiac disease	Congestive heart failure, arrhythmias, stroke, maternal mortality, growth restriction, preterm birth
Renal disease	Maternal renal failure, preeclampsia, preterm delivery, perinatal mortality, growth restriction
Concurrent infections	Severe fetal implications (heart disease, blindness, deafness, bone lesions) if maternal disease occurred in first trimester, increased incidence of spontaneous abortion or congenital anomalies associated with some infections

Vital Signs

Significant deviations from baseline values for vital signs indicate the need for further assessment. BP should be measured in the same arm, with the mother in the same position each time.

Weight

Weight should be recorded to document that weight gain is progressing as expected. Inadequate weight gain may indicate the pregnancy is not as advanced as was thought or the fetus is not growing as expected. A sudden, rapid weight gain may indicate excessive fluid retention.

Urine

Urine is tested at each visit for protein, glucose, and ketones. Urine is also checked for nitrates to identify urinary tract infection and the need for a urine culture.

Fundal Height

Measuring fundal height is an inexpensive and noninvasive method of evaluating fetal growth and confirming gestational age. It is performed at each visit once the fundus is high enough to be palpated in the abdomen. The bladder must be empty to avoid elevation of the uterus.

The woman lies on her back with her knees slightly flexed. The top of the fundus is palpated, and a tape measure is stretched from the top of the symphysis pubis, over the abdominal curve, to the top of the fundus (Figure 7-11).

From 16 weeks until 38 weeks, the fundal height, measured in centimeters, is approximately equal to the gestational age of the fetus in weeks within 3 cm in non-obese women (Gregory, et al., 2012). If a discrepancy between fundal height and weeks of gestation is present, additional assessment is necessary. The EDD may be incorrect and the pregnancy more or less advanced than thought. The number of fetuses present, fetal growth, the amount of amniotic fluid, presence of leiomyomata (fibroids), or gestational trophoblastic disease (hydatidiform mole) will affect the fundal height. Ultrasonography may be performed to obtain further information.

Leopold Maneuvers

Leopold maneuvers provide a systematic method for palpating the fetus through the abdominal wall during the later part of pregnancy. These maneuvers provide valuable information about the location and presentation of the fetus (see Chapter 13).

FIG 7-11 Uterine measurements include the distance between the upper border of the symphysis pubis and the top of the fundus.

Fetal Heart Rate

The fetal heart rate should be between 110 and 160 bpm. The location of the fetal heart sounds provides information that helps determine the position in which the fetus is entering the pelvis. For example, fetal heart sounds heard in an upper quadrant of the abdomen suggest that the fetus is in breech presentation.

Fetal Activity

Fetal movements (**quickening**) are usually first noticed by the expectant mother at 16 to 20 weeks of gestation and gradually increase in frequency and strength. In the last trimester, the woman may be asked to count fetal movements, commonly called *kick counts*. In general, fetal activity is a reassuring sign that indicates a physically healthy fetus.

Signs of Labor

The woman should be asked about signs of labor at each visit. A discussion of contractions, bleeding, and rupture of membranes will help the woman learn how to identify **preterm** labor. She should be cautioned to call the health care provider or go to the hospital if she thinks she might be in labor. During the third trimester, a discussion of the normal course of labor is important to prepare the woman.

Ultrasonographic Screening

Although an ultrasonographic examination is not necessary for all women, the test is often performed one or more times during pregnancy. Ultrasonography helps determine gestational age and may show some fetal anomalies and determine the gender of the baby (see [Chapter 10](#)).

Glucose Screening

The blood glucose level is screened at 24 to 28 weeks of gestation with a 1-hour oral glucose challenge test. If the result is 140 mg/dL or higher, the woman receives a 3-hour oral glucose tolerance test to determine if she has gestational diabetes (see [Chapter 26](#)).

Isoimmunization

Antibody tests may be repeated in the third trimester in women who are Rh-negative if the father of the baby is Rh-positive. If unsensitized, the woman should receive Rho (D) immune globulin (RhoGAM) prophylactically at 28 weeks of gestation (see [Chapter 25](#)).

Pelvic Examination

During the last month of pregnancy, the physician or nurse-midwife may perform a pelvic examination to determine cervical changes. The

descent of the fetus and the presenting part are also assessed at this time.

Multifetal Pregnancy

A multifetal pregnancy is a pregnancy in which two or more embryos or fetuses are present simultaneously (see [Chapter 6](#)).

Diagnosis

Multifetal pregnancies are more likely in women who are older, who are African-American, who have a personal or family history of multifetal pregnancies, or who have conceived as a result of infertility therapy.

Women with multifetal pregnancies are larger than expected for the weeks of gestation, have more fetal movements, and gain more weight. The fundal height is often 4 cm larger than that expected on the basis of gestational age computed from the last menstrual period ([Beckmann et al., 2010](#)). When more than one fetus is suspected, diagnosis should be confirmed with ultrasonography. Separate fetuses and heart activities may be seen as early as 6 weeks of gestation ([Tarsa & Moore, 2010](#)).

Maternal Adaptation to Multifetal Pregnancy

The degree of maternal physiologic changes is greater with multiple fetuses than with a single fetus. For example, with twins blood volume increases 500 mL more than the amount needed for a single fetus. This increases the workload of the heart and may contribute to fatigue and activity intolerance. The additional size of the uterus intensifies the mechanical effects of pregnancy. The uterus may achieve a volume of 10 L or more and weigh more than 9 kg (20 lb) ([Cunningham et al., 2010](#)). Respiratory difficulty increases because the overdistended uterus causes greater elevation of the diaphragm.

The uterus may also cause more compression of the large vessels, resulting in more pronounced and earlier supine hypotension. Greater compression of the ureters can occur, and maternal edema and slight proteinuria are common. Compression of the bowel makes constipation and hemorrhoids persistent problems. Nausea and vomiting occur three times as often as in single-fetus pregnancies because of the increased hormones ([Cunningham et al., 2010](#)). Fatigue and backache are also increased.

Antepartum Care in Multifetal Pregnancy

Early diagnosis of multifetal pregnancy allows time for the family to be educated about the many ways in which the pregnancy will differ from those involving a single fetus. Special antepartum classes can explain the need for increased nutrition, rest, and fetal monitoring. Instruction about signs of preterm labor, a common complication, should begin early. Discussions of the possible need to reduce activity and take frequent rest periods as well as the potential family stress caused by a high-risk pregnancy should also be included.

Women with multifetal pregnancies have more frequent antepartum visits to allow early detection of common complications. These include hypertension, preterm labor, placental abruption, placenta previa, gestational diabetes, congenital anomalies, low birth weight, and postpartum hemorrhage ([Beckmann et al., 2010](#); [Callahan & Caughey, 2009](#)). Ultrasound scanning may be performed every 4 to 6 weeks beginning at 24 weeks' gestation to assess the growth of each fetus. Frequent assessment of cervical changes is important in the third trimester ([Tarsa & Moore, 2010](#)). Other tests of fetal well-being may be performed twice weekly during the third trimester.

Nutritional education is essential. Adequate calories, iron, calcium, folic acid, and vitamins are important. ([Nichols-Richardson, 2011](#)). Women with a normal prepregnancy weight are advised to gain 17 to

25 kg (37 to 54 lb) during a twin pregnancy (Rasmussen & Yaktine, 2009).

The woman may have many concerns and may need more support than women with only one fetus. Discomforts of pregnancy, which are merely annoying to other women, are increased during multifetal pregnancies. Because preterm birth is the most frequent complication in multifetal pregnancies, teaching about signs of labor and how to respond should begin early in pregnancy.

In addition, the financial burden of medical and hospital care during and after pregnancy is increased. Concerns about the effect of more than one newborn on the family should also be discussed. The woman may need referral for assistance in these areas.

CHECK YOUR READING

24. What is the recommended schedule for antepartum visits?
25. How does fundal height relate to gestational age?
26. How does maternal adaptation differ in multifetal pregnancies?

Common Discomforts of Pregnancy

Many women experience discomforts of pregnancy that are not serious but detract from their feeling of comfort and well-being. (See [Case Study 7-1: Pregnant Women Want to Know](#).)

Nausea and Vomiting

The nausea and vomiting of pregnancy are frequently called *morning sickness* because these symptoms are more acute on arising. However, they may occur at any time and may continue throughout the day. Symptoms may be aggravated by odors (such as from cooking), fatigue, and emotional stress. Women need reassurance that although morning sickness is distressing, it is common, temporary, and will not harm the fetus. Morning sickness must be distinguished from *hyperemesis gravidarum*—severe vomiting accompanied by weight loss, dehydration, electrolyte imbalance, and ketosis (see [Chapter 25](#)).

Nausea and vomiting that significantly interfere with the woman's intake of nutrients may decrease the nutrients available to the fetus. Vitamin B₆ (pyridoxine), doxylamine, and phenothiazines may be prescribed by the health care provider, if necessary (Cunningham et al., 2010). Various nonpharmacologic alternative therapies may also be used for relief of nausea. The health care provider should be consulted before home remedies are used. Hypnosis and acupressure have also been found effective (Freeman, 2009).

Heartburn

Heartburn, an acute burning sensation in the epigastric and sternal regions, occurs in up to 80% of pregnant women (Blackburn, 2013). It is caused by reverse peristaltic waves that produce regurgitation of stomach contents into the esophagus. The underlying causes are diminished gastric motility, displacement of the stomach by the enlarging uterus, relaxation of the lower esophageal and gastric sphincters, and increased intraabdominal and intra gastric pressure as pregnancy progresses. If common remedies are not effective, the physician may prescribe histamine₂-receptor inhibitors (Blackburn, 2013).

Backache

Backache occurs in 45% to 59% of pregnant women (Blackburn, 2013). Backache is a common complaint during the third trimester. Increased joint mobility, lumbar lordosis, and relaxed ligaments contribute to the problem. Teaching correct posture and body mechanics can help prevent back pain (Figure 7-12). Stooping or bending puts a great deal of strain on the muscles of the lower back. Instruction should include correct and incorrect methods of lifting (Figure 7-13)

FIG 7-12 Posture during pregnancy may cause or alleviate backache. **A**, Incorrect posture. The neck is jutting forward, the shoulders are slumping, and the back is sharply curved, creating back pain and discomfort. **B**, Correct posture. The neck and shoulders are straight, the back is flattened, and the pelvis is tucked under and slightly upward.

FIG 7-13 Techniques for Lifting. Squatting places less strain on the back. **A**, Incorrect technique. Stooping or bending places a great deal of strain on muscles of the lower back. **B**, Correct technique. Squatting close to the object permits the stronger muscles of the legs to do the lifting.

and exercises to relax the shoulders and help prevent backache (Figure 7-14).

Round Ligament Pain

Round ligament pain is a sharp pain in the inguinal area or on the side, usually on the right. It results from softening and stretching of the ligament from hormones and uterine growth. The right round ligament is stretched more than the left because the uterus turns slightly to the right during pregnancy.

CASE STUDY 7-1 PREGNANT WOMEN WANT TO KNOW*

Sally has many questions about the common discomforts of pregnancy. Although this is her third pregnancy, she says she did not get her questions answered adequately previously. The nurse uses the following teaching plan to discuss Sally's concerns.

Nausea and Vomiting

- Eat crackers, dry toast, or dry cereal before arising in the morning; then get out of bed slowly.
- Eat small amounts of high-carbohydrate, low-fat foods every 2 hours and a total of five to six small meals per day to prevent an empty stomach.
- Eat a protein snack before bedtime.
- Suck on hard candy.
- Drink fluids frequently but separately from meals. Try small amounts of ice chips, water, and clear liquids like gelatin or frozen juice bars. Avoid coffee.
- Avoid fried, high-fat, greasy, or spicy foods and those with strong odors such as onion and cabbage. Instead, try bland foods that may be more easily tolerated.
- If cooking odors are bothersome, open a window to help disperse them.
- Experiment with different foods that may be helpful, such as ginger (tea, cookies, soda), peppermint (tea or candy), tart and salty combinations such as potato chips and lemonade or green apples, or sweet and salty combinations.
- Take prenatal vitamins at bedtime because they may increase nausea if taken in the morning.
- Use an acupressure band over a point approximately three fingerwidths above the wrist crease on the inner arm.
- Nap and rest more frequently, if possible, because fatigue may increase nausea.
- Check with your health care provider before taking any herbal remedies.
- Notify your health care provider for severe nausea and vomiting or signs of dehydration (dry, cracked lips, elevated pulse, fever, concentrated urine).

Heartburn

- Eat small meals every 2 to 3 hours and avoid fatty, acidic, or spicy foods.
- Eliminate or curtail smoking and drinking coffee and carbonated beverages, which stimulate acid formation in the stomach.
- Avoid citrus fruits and juices, tomato based products, chocolate, and peppermint if they increase symptoms.
- Try chewing gum.
- Avoid bending over or lying flat.
- Wear loose-fitting clothes.
- Take deep breaths and sip water to help relieve the burning sensation.
- Use antacids, but avoid those that are high in sodium and cause fluid retention (such as Alka-Seltzer, baking soda). Antacids high in calcium (such as Tums, Alka-Mints) are effective but may cause rebound hyperacidity. Take calcium-magnesium based antacids after meals and at bedtime. Avoid antacids containing phosphorus, sodium, or aluminum. Liquid antacids may be more effective, as they coat the esophagus.
- Remain upright for 1 to 2 hours after eating to reduce reflux and relieve symptoms.
- Avoid eating or drinking for 2 to 3 hours before bedtime and sleep with an extra pillow to elevate your head.

Backache

- Maintain correct posture with the head up and the shoulders back.
- Avoid high-heeled shoes because they increase lordosis and back strain.
- Do not gain excess weight.
- Do not lift heavy objects.
- To pick up objects, squat rather than bend from the waist.

- When sitting, use foot supports, arm rests, and pillows behind the back.
- Exercise: Tailor sitting, shoulder circling, and pelvic rocking strengthen the back and help prepare for labor.
- Application of heat or acupuncture may help.
- Standing with one foot in front of the other and rocking back and forth may help.
- A maternity back binder for use in pregnancy may be helpful.

Round Ligament Pain

- Use good body mechanics, and avoid very strenuous exercise.
- Do not make sudden movements or position changes.
- Do not stretch and twist at the same time. When getting out of bed, turn to the side first without twisting, and then get up slowly.
- Bend toward the pain, squat, or bring the knees up to the chest to relieve pain by relaxing the ligament.
- Apply heat and lie on the right side if discomfort persists.

Urinary Frequency and Loss of Urine

- Restrict fluids in the evening but take adequate amounts during the day.
- Limit intake of natural diuretics such as coffee, tea, and other sources of caffeine.
- Perform Kegel exercises to help maintain bladder control:
 - Identify the muscles to be exercised by stopping the flow of urine mid-stream. Do not routinely perform the exercise while urinating, however, because it might cause urinary retention and increase the risk of urinary tract infection.
 - Slowly contract the muscles around the vagina and hold for 10 seconds. Relax for at least 10 seconds.
 - Repeat the contraction-relaxation cycle 30 or more times each day.

Varicosities

- Avoid constricting clothing and crossing the legs at the knees, which impede blood return from the legs.
- Rest frequently with the legs elevated above the level of the hips and supported with pillows.
- Apply support hose or elastic stockings that reach above the varicosities before getting out of bed each morning. Putting them on later makes them less effective because pooling begins on rising.
- If working in one position for prolonged periods, walk around for a few minutes at least every 2 hours to stimulate blood flow and relieve discomfort.
- Walk frequently to stimulate circulation in the legs.
- Do foot circles and flex your feet toward your head frequently if sitting for long periods.

Constipation

- Self-care measures generally are as effective as laxatives but do not interfere with absorption of nutrients or lead to laxative dependency.
- Drink at least eight glasses of liquids including water, juice, or milk each day. These should not include coffee, tea, or carbonated drinks because of their diuretic effect. After drinking diuretic beverages, drink a glass of water to counteract its effect.
- Add foods high in fiber to help maintain bowel elimination. Include unpeeled fresh fruits and vegetables, whole-grain breads and cereals, bran muffins, oatmeal, potatoes with skins, dried beans, and fruit juices. Four pieces of fruit and a large salad provide enough fiber requirements for 1 day (see [Box 9-3](#)).
- Restrict consumption of cheese, which causes constipation.

CASE STUDY 7-1 PREGNANT WOMEN WANT TO KNOW*—cont'd

- Curtail the intake of sweets, which increases bacterial growth in the intestine and can lead to flatulence.
- Do not discontinue taking iron supplements if they have been prescribed. If constipation persists, consult your health care provider about use of stool softeners.
- Exercise stimulates peristalsis and improves muscle tone. Walking briskly for at least 1 mile per day, swimming, or riding a stationary bicycle may be helpful.
- Establish a regular pattern by allowing a consistent time each day for elimination. One hour after meals is ideal to take advantage of the gastrocolic reflex (the peristaltic wave in the colon that is induced by taking food into the fasting stomach).
- Use a footrest during elimination to provide comfort and decrease straining.

Hemorrhoids

- Avoid constipation to prevent straining that causes or worsens hemorrhoids. Drink plenty of water, eat foods rich in fiber, and exercise regularly.
- To relieve existing hemorrhoids, take frequent tepid baths. Apply cool witch hazel compresses or anesthetic ointments.
- Lie on your side with the hips elevated on a pillow.
- If pain or bleeding persists, call your health care provider.

Leg Cramps

- To prevent cramps, elevate the legs frequently to improve circulation.
- To relieve cramps, extend the affected leg, keeping the knee straight. Bend the foot toward the body, or ask someone to assist. If alone, stand and apply

pressure on the affected leg with the knee straight. These measures lengthen the affected muscles and relieve cramping.

(Courtesy Steve and Michelle Henry, Tustin, CA.)

- Avoid excessive foods high in phosphorus, such as soft drinks.
- Check with your health care provider regarding the need for supplemental calcium, magnesium, or sodium chloride.

Dependent Edema

- Apply support stockings before getting out of bed.
- Sit or lie with the legs elevated often.

*Continued from p. 109; continues on pp. 116 and 117.

Urinary Frequency

Although urinary frequency is a common complaint during pregnancy, the condition is temporary and is managed by most women without undue distress. Urinary incontinence, especially in the third trimester, may also occur. Kegel exercises may be helpful in maintaining bladder control.

Varicosities

Varicosities occur in 40% of pregnancies (Blackburn, 2013). They are seen more often in women who are obese, are multiparas, or have a family history of varicose veins. During pregnancy, the weight of the uterus partially compresses the veins returning blood from the legs, and estrogen causes elastic tissue to become more fragile. As blood pools, the vessels dilate and become engorged, inflamed, and painful. Varicose veins are exacerbated by prolonged standing, during which the force of gravity makes blood return more difficult.

Varicosities are usually confined to the legs but may involve the veins of the vulva or rectum (hemorrhoids). Varicosities may range from barely noticeable blemishes with minimal discomfort at the end of the day to large, tortuous veins that produce severe discomfort with any activity. They usually improve after childbirth but do not go away completely.

Constipation

Occasional constipation is not harmful, although it can cause feelings of abdominal fullness and flatulence and aggravate painful hemorrhoids. Intestinal motility is reduced during pregnancy as a result of progesterone, pressure from the enlarged uterus, and decreased activity. The result may be hard, dry stools and decreased frequency

of bowel movements. Iron supplementation often increases constipation.

Hemorrhoids

Hemorrhoids are varicosities of the rectum and may be external (outside the anus) or internal (above the sphincter). Some common causes are vascular engorgement of the pelvis, constipation, straining at stool, and prolonged sitting or standing. Pushing during the second stage of labor aggravates the problem, which may continue into the postpartum period. They often shrink and become less troublesome postpartum.

Leg Cramps

Painful contractions of the muscles of the legs occur in 25% to 50% of pregnant women (Blackburn, 2013). Cramps often occur during sleep when the muscles are relaxed or when the woman stretches and extends her feet with the toes pointed. Magnesium supplementation may be used (Erick, 2012). Venous congestion in the legs during the third trimester also contributes to leg cramps.

Cultural Considerations

Although the physical changes of pregnancy are fairly universal, culture often determines the health beliefs, values, and expectations of the family when a woman becomes pregnant (see Chapter 8).

27. What causes morning sickness?
28. How can backache be alleviated during pregnancy?

CASE STUDY 7-1 NURSING CARE PLAN*

ASSESSMENT: Sally returns to the clinic at 10 weeks of pregnancy. She has dry, cracked lips and a pulse rate of 90 bpm. She states that she is experiencing nausea with frequent vomiting throughout the day. She reports that the nausea is intensified by the odor of cooking food and she has little appetite. Although she is always thirsty, she restricts fluids because “they make me sicker.” Her urine sample is concentrated, with a specific gravity of 1.03 and a small amount of ketones.

NURSING DIAGNOSIS: Deficient Fluid Volume, related to inadequate intake of fluids and fluid loss through vomiting.

Critical Thinking: *Were all assessment data considered? Organize data and develop a second diagnosis. State outcomes for that diagnosis, and identify at least two interventions.*

Answer: *No. All data should be grouped and analyzed. Dry lips, tachycardia, thirst, and concentrated urine support the stated nursing diagnosis. Nausea throughout the day, occasional vomiting, and anorexia, however, suggest a second nursing diagnosis: Imbalanced Nutrition: Less than Body Requirements, related to nausea, vomiting, and anorexia.*

Outcome Criteria

- Maintain adequate intake of calories and nutrients to meet her needs, as evidenced by sufficient energy to carry on the activities of daily living, and a weight gain of 4.5 kg (10 lb) by 20 weeks.
- Report less nausea and a decrease in the episodes of vomiting within 2 weeks.

Interventions

1. Reassure her that nausea and vomiting usually disappear by the second trimester and do not indicate a problem with the pregnancy.
2. See “Nausea and Vomiting under Women Want to Know: How to Overcome the Common Discomforts of Pregnancy” for more interventions.

PLANNING: EXPECTED OUTCOMES: Sally will:

1. Increase intake of fluids to 2000 mL/day.
2. Maintain urine specific gravity within normal range (1.005–1.03).
3. Demonstrate no signs or symptoms of dehydration within 2 days (excessive thirst, fever, elevated pulse rate, decreased urine output, concentrated urine).

INTERVENTIONS AND RATIONALES

1. Suggest that Sally suck ice chips when she is most nauseated, followed by clear liquids such as small amounts of water, clear juices, or popsicles. *Clear liquids are most easily tolerated during nausea.*
2. Emphasize the importance of taking frequent small amounts of fluids. Suggest restricting intake of coffee and tea. *Small amounts of liquids are tolerated better compared with large amounts. Coffee and tea are diuretics.*
3. Suggest alternative sources of fluids, such as gelatin, frozen juice bars, ice cream, sherbet, pudding, and watermelon. *These foods are easily tolerated during nausea.*
4. Recommend that she experiment with soups, shakes, smoothies, and vegetable drinks when she is feeling better. *These liquids are high in nutrients.*
5. Discuss a variety of ways of coping with nausea to help increase fluid intake and prevent dehydration. *Offering multiple suggestions for helping nausea makes it more likely the woman will find one that helps.*
6. Teach Sally to keep a record of daily intake of food and fluids, episodes of vomiting, and measures that reduce her nausea. *Keeping a record helps her determine adequacy of intake and identify measures that are most helpful.*

7. Ask Sally to return within 2 days. *It is important to intervene quickly if the problem becomes worse.*

8. Instruct her to call by the next day if her nausea and vomiting or signs of dehydration become worse (fever, elevated pulse rate, or decreased urine output). *Serious dehydration and fluid and electrolyte imbalance must be treated promptly, and hospitalization may be necessary.*

EVALUATION: When Sally returns 2 days later, she reports the nausea continues but she has fewer episodes of vomiting. Her fluid intake is approximately 1900 mL. Her urine specific gravity is 1.01, and she denies excessive thirst. She has no other signs of dehydration.

ASSESSMENT: Sally says she is often very tired during the day, even though she is sleeping 8 to 10 hours at night. Fatigue concerns her because she is normally very energetic. Her job is demanding and requires that she concentrate and balance many factors at the same time.

NURSING DIAGNOSIS: Fatigue related to inadequate rest periods to accommodate the physiologic demands of pregnancy.

Critical Thinking: *What assumption has the nurse made? What other factors should be considered before this diagnosis is made?*

Answer: *Although extraordinary fatigue is common in early pregnancy, nurses must not assume that pregnancy is the only cause. Additional data such as hemoglobin and hematocrit levels should be obtained before this diagnosis is made.*

PLANNING: EXPECTED OUTCOMES: Sally will:

1. Identify methods to cope with fatigue at home and at work.
2. Report increased energy by the second trimester.

INTERVENTIONS AND RATIONALES

1. Acknowledge Sally’s fatigue and reassure her that it is self-limiting and a common experience during the first months because of hormonal changes. *Reassurance helps alleviate concern that fatigue indicates a problem with her pregnancy.*
2. Suggest she explore a flexible schedule or routine with her employer to allow rest periods at work. Advise a short nap after work before beginning other activities at home. *Short rest periods are often all that are needed to continue to function effectively.*
3. Recommend that she lie down or sit comfortably with her feet elevated for a few minutes every 2 hours and consciously relax the muscles of the legs, abdomen, and shoulders. *Relaxation renews energy even when sleep is not possible.*
4. Suggest that she try deep breathing and visualizing a favorite location or pastime whenever possible. Progressive relaxation—conscious tensing and relaxing of groups of muscles—may be helpful. *Relaxation exercises relieve physical tension that adds to fatigue and also provide mental distraction.*
5. Recommend that Sally get as much sleep as she feels she needs when possible. Adequate rest may involve curtailing social activities and tasks that can be postponed. *Although recreation is important, the need for sleep is overwhelming for some women during early pregnancy.*
6. Recommend that she enlist the assistance of family, significant others, and friends. *Assistance can free her of all but essential home responsibilities so that she can rest.*
7. Explain that during the second trimester Sally will probably have more energy, but that it is normal to be tired again near the end of pregnancy. *If she knows*

CASE STUDY 7-1 NURSING CARE PLAN*—cont'd

the normal course of fatigue during pregnancy she can plan ahead for ways to cope with it.

Critical Thinking: What additional interventions are necessary if the hemoglobin level and hematocrit are low?

Answer: If low levels of hemoglobin and hematocrit indicate that Sally is anemic, the physician or nurse-midwife should be

notified so that iron supplementation can be started. The nurse should provide education about iron-containing foods.

EVALUATION: Sally was able to negotiate two short rest periods each day at work and rests after work. She discusses techniques she uses to help renew her energy. At the third prenatal visit (14 weeks) Sally relates increased energy.

*Continued from p. 115.

APPLICATION OF THE NURSING PROCESS

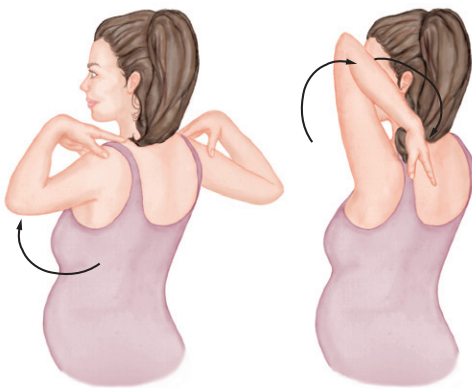

■ Family Responses to Physical Changes of Pregnancy

The nursing process focuses on identifying each family's unique responses to the physiologic changes of pregnancy, determining factors that might interfere with their ability to adapt to changes, and finding solutions to identified problems.

Assessment

Assess the woman's responses to the physiologic processes of pregnancy and explore the family's preparation for the birth. Use structured interviews and planned teaching sessions, as well as more informal discussions that occur spontaneously during assessments. Review the history and physical examination to obtain important data. Gather information from the expectant mother as well as from her partner and significant family members, if appropriate.

Shoulder circling

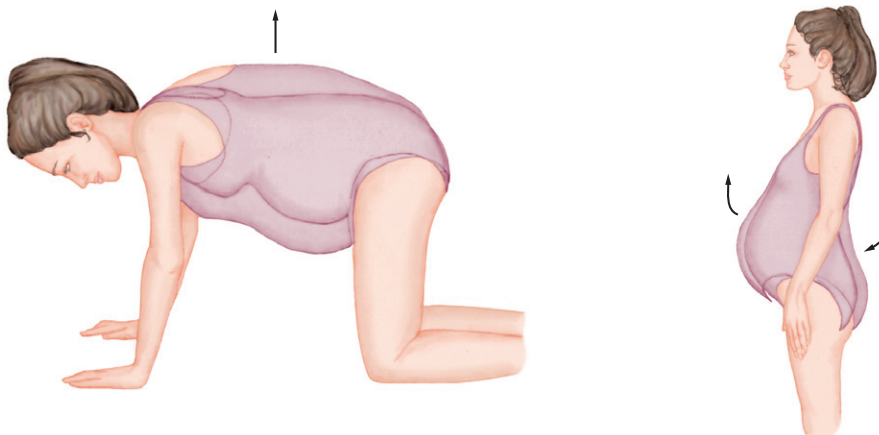

The fingertips are placed on the shoulders, then the elbows are brought forward and up during inhalation, back and down during exhalation. Repeat five times.

Tailor sitting

The woman uses her thigh muscles to press her knees to the floor. Keeping her back straight, she should remain in the position for 5 to 15 minutes.

Pelvic tilt or pelvic rocking

This exercise can be performed on hands and knees, with the hands directly under the shoulders and the knees under the hips. The back should be in a neutral position, not hollowed. The head and neck should be aligned with the straight back. The woman then presses up with the lower back and holds this position for a few seconds, then relaxes to a neutral position. Repeat 5 times. The exercise may also be performed in a standing position when the pelvis is rotated forward to flatten the lower back.

FIG 7-14 Exercises to prevent backache.

*Nursing diagnoses that are explored in this chapter.

Nursing Diagnosis

When analyzing data, nurses must use all their critical thinking skills before reaching a conclusion about the most significant nursing diagnoses (Box 7-2).

Many problem-oriented nursing diagnoses do not address the healthy family preparing for the birth of a child. Most families express an intense desire to protect the health of the unborn child and the well-being of the mother. Perhaps the most encompassing nursing diagnosis for the prenatal period is “Readiness for Enhanced Childbearing Process: prenatal health practices that provide optimal benefit to the fetus and mother.”

Planning: Expected Outcomes

Expected outcomes for this nursing diagnosis are that the woman will:

- Explain practices that promote the safety and well-being of the woman and fetus throughout pregnancy.
- Describe measures that provide relief from the common discomforts of pregnancy.
- Describe a realistic plan during the first visit to modify behaviors or habits that could adversely affect the health of the woman or fetus.

Interventions

Teaching Health Behaviors

Teaching should be addressed at each visit and should focus on the mother’s immediate questions and concerns. Common concerns are discussed here.

Bathing. Bathing protects pregnant women from infections and promotes comfort by dissipating heat produced by the increased metabolism. During the last trimester, when her balance is altered by a changing center of gravity, the woman is prone to falls. Advise her to use nonskid pads in the tub or shower.

Hot Tubs and Saunas. Although warm baths and showers help relax tense and tired muscles, pregnant women should avoid activities that may cause hyperthermia. Maternal hyperthermia, particularly during the first trimester, may be associated with fetal anomalies. Caution the woman not to be in a sauna for more than 15 minutes or a hot tub for more than 10 minutes and to keep her head, chest, shoulders, and arms out of the water (Beckmann et al., 2010).

Douching. Some women douche because they believe it increases cleanliness and prevents infection. However, despite increased vaginal discharge during pregnancy, douching is unnecessary at any time.

Douching increases the risk of ectopic pregnancy, cervical cancer, STDs, pelvic inflammatory disease, and endometritis (Cottrell, 2010). Bacterial vaginosis (BV) occurs more often in women who douche (McGregor & Lench, 2010). BV has been associated with spontaneous abortion, preterm birth, premature rupture of membranes, and chorioamnionitis (Cunningham et al., 2010). Discuss women’s reasons for douching and explain it is unnecessary.

Breast Care. Instruct the expectant mother to avoid using soap on her nipples because it removes the natural lubricant secreted by Montgomery glands in the areola. Advise her to wear a supportive bra that fits well to help prevent loss of muscle tone as the breasts become heavier during pregnancy. Wide bra straps distribute the weight evenly across the shoulders and provide greater comfort.

Inform the couple that breast stimulation increases oxytocin secretion and may cause uterine contractions. Therefore, it is unsafe if the woman has a history of preterm labor or existing signs of preterm labor such as rhythmic pelvic pressure or uterine contractions that assume a regular pattern or increase in frequency or intensity.

No breast or nipple preparation is necessary during pregnancy for breastfeeding (Riordan & Hoover, 2010). A discussion of breastfeeding should be included during prenatal visits and a referral to breastfeeding classes made if the woman is interested.

Clothing. Recommend practical, comfortable, and nonconstricting clothing. Tight jeans or pantyhose, which may impede venous circulation, should be avoided or worn only for short periods. Suggest the woman wear low heels because they do not interfere with balance. High heels increase the curvature of the lower spine (lordosis) that is prevalent during the last trimester, increasing backache and making her more likely to fall.

Exercise. Exercise during pregnancy is generally beneficial and can strengthen muscles, reduce backache and stress, and provide a feeling of well-being. The amount and type of exercise recommended depend on the physical condition of the woman and the stage of pregnancy. Exercise tolerance is often decreased, but mild to moderate exercise is generally not a problem.

Teach women who have no medical or obstetric complications to exercise in moderation for 30 minutes or more on most if not all days of the week (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012; Beckmann et al., 2010). Recreational sports can be continued if no risk of falling or abdominal trauma is present. Joint and ligament laxity and lumbar lordosis increase the risk of injury, especially in the third trimester. Contact sports and exercise such as rock climbing or skiing that requires balance or may cause injury are not safe. Exercise in the supine position should be discontinued after the first trimester to avoid supine hypotensive syndrome. Moderate aerobic exercise may be prescribed to women who are overweight or obese but have no other complications (Mottola, 2009).

Walking is an ideal exercise because it stimulates muscular activity, gently increases respiratory and cardiovascular effort, and does not result in fatigue or strain. Swimming and water exercises are excellent during pregnancy because the buoyancy of the water helps prevent injuries. Riding a stationary bike and yoga are also helpful. Exercise classes especially for pregnant women are often available and offer companionship with other women having similar experiences.

Instruct the woman not to begin strenuous exercise programs or intensify training during pregnancy. Those who have been exercising strenuously before pregnancy should consult the health care provider but may be able to continue some of their usual routine. As pregnancy progresses, the exercise program may need modification because the change in the woman’s center of gravity makes her more prone to falls.

FIG 7-15 During the third trimester, pillows supporting the abdomen and back provide a comfortable position for rest.

Therefore, an activity that is safe in the first trimester may not be safe in the third trimester.

Pregnant women must avoid becoming overheated during exercise because heat is transmitted to the fetus, causing an increase in fetal oxygen needs. Women should allow a cool-down period of mild activity after exercising. To prevent dehydration, it is important to take liquids frequently while exercising.

Exercise should be tailored to the way the woman feels to avoid overfatigue. The health care provider may suggest she take her pulse periodically and not exceed a certain heart rate range. Generally, if a woman cannot carry on a conversation while exercising, she is doing too much. The woman should stop exercising and seek medical advice if she has chest pain, dizziness, headache, vaginal bleeding, decreased fetal movement, or signs of labor while exercising.

Sleep and Rest. Problems sleeping may begin as early as the first trimester and continue throughout pregnancy (Gordon, 2012). Finding a comfortable position for rest may be difficult by the third trimester. Backache, abdominal discomfort and contractions, leg cramps, fetal movement, and urinary frequency may interfere with sleep.

Suggest the woman use pillows to support the abdomen and back to enhance sleep (Figure 7-15). Emphasize that frequent rest periods are beneficial, even if the woman does not fall asleep. Suggest relaxation exercises to use during the day and before bed. Avoiding caffeine and limiting fluids at night may also be helpful.

Sexual Activity. Sexual intercourse is generally safe for the healthy pregnant woman (see Chapter 8).

Nutrition. A discussion of nutrition should be part of each visit. The nurse should assess the woman's diet and use of prenatal vitamins and answer any questions she may have (see Chapter 9).

Employment. Most women of childbearing age in the United States are employed outside the home, and most continue to work during pregnancy. Women with uncomplicated pregnancies can usually continue working until they begin labor, if they wish (AAP & ACOG, 2012). However, the level of physical activity involved and the risk of exposure to environmental toxins and industrial hazards must be considered.

Maternal Safety. Work should not lead to undue fatigue. Frequent rest periods with the feet elevated are essential. Suggest that women in jobs that require constant standing or sitting should change positions often or walk briefly to stimulate circulation and reduce fatigue. Tasks that require balance may be hazardous as the center of gravity shifts. Heavy lifting should be avoided.

Working women often have many home responsibilities that, for some, do not decrease during pregnancy. The fatigue and stress of both the home and employment workloads may be difficult during

pregnancy. Recommend that, if possible, the expectant mother adapt her home and employment workloads during pregnancy to reduce fatigue and stress.

Exposure to Teratogens. Intrauterine exposure to toxic substances is of particular concern during the first trimester, the period of organogenesis. Advise women to investigate their own occupational hazards. For example, nurses and hospital personnel may be exposed to chemotherapy drugs, radiation, anesthetic gases, and infectious diseases such as cytomegalovirus; hair and nail salon workers may be exposed to hair spray and nail products; laundry and dry cleaning workers may be exposed to fetotoxic compounds; and farm workers may be exposed to pesticides. In addition, some women are exposed to passive smoking in the work place, which is harmful to both mother and fetus.

Travel. Car travel is safe during normal pregnancies. Generally, no more than 6 hours of car travel is recommended a day during pregnancy (Gregory, et al., 2012). Suggest the woman stop to walk every 1 to 2 hours so she can empty her bladder. Walking also helps decrease the risk of thrombosis that is elevated during pregnancy.

Instruct the woman to fasten the seat belt snugly with the lap belt under her abdomen and across her thighs and the shoulder belt in a diagonal position across her chest and above the bulge of her uterus. This position is uncomfortable for some women, and it causes concern about internal injuries if a collision occurs. However, it is safer to wear the belt than to leave it off and risk ejection from the vehicle during an accident.

Travel by plane is generally safe for up to 36 weeks in the absence of complications of pregnancy. Support stockings, periodic movement of the legs and ambulation, avoidance of restrictive clothing, and adequate hydration may help avoid venous thrombosis. The seat belt should be worn at all times because air turbulence is unpredictable (ACOG, 2009). The belt should be buckled below the abdomen (AAP & ACOG, 2012). Advise the woman to walk at least every hour to maintain adequate peripheral circulation and avoid thromboembolism. The woman should not travel to remote locations where medical care is unavailable. Suggest she take a copy of her medical records if traveling a long distance.

Immunizations. In general, immunizations with live virus vaccines (such as measles, mumps, rubella, and varicella) are contraindicated during pregnancy because they may have teratogenic effects on the fetus. Inactivated vaccines are safe and can be used in women who have a risk of developing diseases such as tetanus, hepatitis B, and influenza (Bruhn & Tillett, 2009). The woman should be advised to explain that she is pregnant before a vaccine is administered.

Inactivated influenza vaccine is especially important for women who are pregnant during flu season because they can have serious complications from the disease. It can be given at any point in pregnancy (ACOG, 2010a; AAP & ACOG, 2012; CDC, 2012). The CDC recommends that women who have not been previously vaccinated against pertussis receive the tetanus, diphtheria, and pertussis (Tdap) vaccine during each pregnancy. It is best given between 27 and 36 weeks of gestation, but can be given at any time during pregnancy (CDC, 2013). See the CDC website at <http://www.cdc.gov/vaccines> for current information.

Teaching Necessary Lifestyle Changes

Many expectant parents are willing to make changes in lifestyle to avoid adversely affecting the fetus.

Prescription and Over-the-Counter Drugs. Advise pregnant women to consult with their health care providers before taking any drugs. This applies to over-the-counter drugs as well as prescription drugs. Some nonsteroidal antiinflammatory drugs such as aspirin

should be avoided because they may increase bleeding. When prescription drugs are necessary, the health care provider weighs the risks against the benefits to decide if a drug can be used safely or if changes are necessary. Drugs taken during the first trimester are of particular concern because of the risk to developing fetal organs.

Complementary and Alternative Therapies. Some complementary and alternative therapies are very safe and helpful during pregnancy. Some, however, can be harmful. For example, herbs such as blue cohosh may cause contractions or harm the fetus if used in pregnancy (Skidmore-Roth, 2010). Ask about any complementary or alternative therapies used and advise the woman to discuss them with her health care provider.

Tobacco. An important aspect of prenatal care is assessment of and intervention for smoking. Approximately 16.4% of women in the United States smoke during pregnancy (Substance Abuse and Mental Health Services Administration, 2009). A Healthy People 2020 objective is that the number of women who stop smoking during the first trimester and do not restart for the entire pregnancy increase to 30% from a baseline of 11.3% (U.S. Department of Health and Human Services, 2010).

Identify women who smoke, and explain the effects of smoking during pregnancy (see Chapter 24). The Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN, 2010) advocates that every nurse screen for tobacco use and refer women to smoking cessation programs as needed. Make every effort to motivate expectant mothers to stop smoking and to avoid contact with others who smoke. Secondhand smoke increases the risk of preterm birth, respiratory distress syndrome, neonatal intensive care unit admission, and other complications (Ashford, Hahn, Hall et al., 2010).

The "5A" approach to smoking cessation is often effective (Barron, Petrilli, Strath et al., 2007):

1. **Ask** the woman at each visit if she smokes, if the amount of smoking has changed, and if she would like to quit. Pregnancy is a time when women are motivated to make changes that will benefit their health and that of the fetus.
2. **Advise** the woman about the importance of not smoking.
3. **Assess** the woman's willingness to try to stop smoking. Discuss motivational information if the woman is not willing to quit at this time. Refer the woman to a smoking cessation program if she is willing to try to stop smoking.
4. **Assist** the woman in making a plan to stop smoking, and provide practical counseling on how to solve the problems she may encounter—for example, avoiding others who smoke and being aware of activities she associates with smoking may be helpful. Advise her that total abstinence is essential to success.
5. **Arrange** follow-up visits or phone calls to discuss the woman's progress and any problems that may have occurred and to offer encouragement. Telephone support may be beneficial in preventing smoking relapse in women who have stopped smoking (Dennis & Kingston, 2008).

Include the woman's partner in discussions of smoking cessation and the effects of smoking on the fetus. The partner's support is especially important in helping the pregnant woman quit smoking. The partner who smokes may be interested in joining a cessation program, too. If so, the couple may be able to support each other in their efforts (Duckworth & Chertok, 2012).

Approximately 50% to 60% of women who stop smoking during pregnancy begin smoking again within 1 year after they give birth (ACOG, 2010b). Explain the effects of smoking on infants and provide continued support for smoking cessation during the postpartum period.

Although nonpharmacologic methods of smoking cessation are best, nicotine replacement therapy (NRT) may be used if other methods are unsuccessful (Cunningham et al., 2010). However, more research is needed about the use of NRT (Forest, 2010). Use of NRT during pregnancy should occur only under the close supervision of the health care provider (ACOG, 2010b; AAP & ACOG, 2012).

Alcohol. Alcohol is a known teratogen, and maternal alcohol use is a leading cause of intellectual disability in the United States. Alcohol may produce a characteristic cluster of developmental anomalies known as fetal alcohol spectrum disorders (see Chapter 24). Conclusive data about fetal effects of social or moderate drinking are not available, but no amount of alcohol consumed during pregnancy is known to be safe. Therefore, the best advice for women who are pregnant or who plan to become pregnant is to abstain from all alcohol.

Illicit Drugs. Use of so-called street or recreational drugs such as cocaine, heroin, and methamphetamines is harmful to the fetus. Advise the pregnant woman to seek help to discontinue all illicit drug use (see Chapters 24 and 30).

Teaching about Signs of Possible Complications

Instruct the pregnant woman and her family about signs and symptoms that should be reported immediately because they indicate a serious danger (see "Critical to Remember: Signs of Possible Pregnancy Complications"). The woman should be instructed to call her health care provider or go to the hospital immediately if she thinks she is experiencing complications.

Although making the expectant mother aware of signs of complications during pregnancy is crucial, the nurse must take care not to overly worry her. Avoid the term danger signs when talking to the woman and her family because it may be frightening. It is less alarming to say, "The signs I am about to explain to you are unusual, but if you notice them, notify your health care provider at once because they require immediate attention."

Providing Resources

Provide the woman with sources for more information. These may include Internet websites such as the March of Dimes at www.marchofdimes.com for information about pregnancy and infants. AWHONN and ACOG provide information websites for all women's health topics, including pregnancy, at www.health4women.org and www.acog.org/For_Patients.

A free service providing information about pregnancy and infants through 1 year is available by text to mobile phones. The service can be accessed by going to the website at www.text4baby.org or texting BABY to 511411 on a mobile phone. The service is supported by the National Healthy Mothers, Healthy Babies Coalition and provides three text messages weekly with health tips appropriate to the week of pregnancy or age of the infant.

Evaluation

Interventions can be considered to effectively meet the established outcomes if the mother and her family (1) discuss and practice self-care measures to promote safety and health of the mother and fetus, (2) explain methods to help relieve common discomforts of pregnancy, and (3) identify a plan early in pregnancy to modify habits or behaviors that could adversely affect health. If interventions are ineffective, the nurse collaborates with the family to define new plans and work out additional interventions.

CRITICAL TO REMEMBER**Signs of Possible Pregnancy Complications****SIGNS**

Vaginal bleeding with or without discomfort

Escape of fluid from the vagina

Swelling of the fingers (rings become tight) or puffiness of the face or around the eyes

Continuous pounding headache

Visual disturbances (such as blurred vision, dimness, flashing lights, spots before the eyes)

Convulsions

Persistent or severe abdominal or epigastric pain

Chills or fever

Painful urination

Persistent vomiting

Change in frequency or strength of fetal movements

Signs or symptoms of preterm labor: uterine contractions, cramps, constant or irregular low backache, pelvic pressure, watery vaginal discharge

POSSIBLE CAUSES

Spontaneous abortion, placenta previa, abruption placentae, lesions of the cervix or vagina, “bloody show”

Rupture of membranes

Excessive edema

Chronic hypertension or preeclampsia

Worsening preeclampsia

Eclampsia

Ectopic pregnancy (if early), worsening preeclampsia, abruption placentae

Infection

Urinary tract infection

Hyperemesis gravidarum

Fetal compromise or death

Labor onset

SUMMARY CONCEPTS

- Pregnancy causes a predictable pattern of uterine growth. In general, the uterus can be palpated halfway between the symphysis pubis and the umbilicus at 16 weeks of gestation, at the level of the umbilicus at 20 weeks, and at the xiphoid process by 36 weeks.
- Thick mucus fills the cervical canal and protects the fetus from infection caused by bacteria ascending from the vagina.
- Plasma volume expands faster and to a greater extent than red blood cells, resulting in a dilution of hemoglobin concentration. This physiologic anemia (pseud anemia) does not reflect an inadequate number of red blood cells.
- Although blood volume increases, blood pressure is not elevated during normal pregnancy.
- The gravid uterus partially occludes the vena cava and aorta when the mother is supine, causing supine hypotensive syndrome. This can be prevented or corrected if she assumes a lateral position.
- During the last trimester the uterus pushes the diaphragm upward. To compensate, the ribs flare, the substernal angle widens, and the circumference of the chest increases.
- Slight hyperventilation and decreased airway resistance allow increased oxygen needs to be met.
- Increased progesterone level is associated with relaxation of smooth muscles, resulting in stasis of urine and increasing the risk of urinary tract infections and constipation.
- Increased renal plasma flow causes increased GFR and effectively removes additional metabolic wastes produced by the mother and the fetus but often results in “spilling” of glucose and other nutrients into urine.
- Increased blood flow to the skin reduces heat generated by the increased metabolic rate.
- Forms of hyperpigmentation during pregnancy include melasma and linea nigra.
- Striae gravidarum occur from separation of connective tissue fibers.
- Increased estrogen and hCG and decreased gastric motility are associated with nausea in early pregnancy. Morning sickness will not harm the fetus and usually ends by 10 to 12 weeks.
- The expanding uterus causes progressive changes that can lead to muscle strain and backache during the last trimester.
- Progesterone maintains the uterine lining for implantation, prevents uterine contractions during pregnancy, and helps prepare the breasts for lactation.
- Presumptive and probable signs of pregnancy may be caused by conditions other than pregnancy and cannot be considered positive or diagnostic signs. Positive signs can have no other cause.
- The preconception, interconception, or initial prenatal visit includes a complete history and physical examination to determine potential risks to the mother and fetus and obtain baseline data for a plan of care.
- Assessment for risk of problems is performed at each prenatal visit because pregnancies considered low risk in early pregnancy may later become high risk.
- Multifetal pregnancies impose greater physiologic changes than a single-fetus pregnancy and require extra vigilance to detect possible complications.
- Families need information related to self-care, health promotion, and coping with the common discomforts of pregnancy.
- Nurses use the nursing process and critical thinking skills to assist the parents to make necessary changes in lifestyle.

Psychosocial Adaptations to Pregnancy

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the psychological responses of the expectant mother to pregnancy.
2. Identify the process of maternal role transition.
3. Explain the maternal tasks of pregnancy.
4. Describe the developmental processes of the transition to the role of father.
5. Describe the responses of prospective grandparents and siblings to pregnancy.
6. Discuss factors that influence psychosocial adaptation to pregnancy, such as age, parity, social support, absence of a partner, socioeconomic status, and abnormal situations.
7. Explain the ways in which these factors affect nursing practice.
8. Describe cultural influences on pregnancy and cultural assessment and negotiation.

Becoming a parent who is capable of loving and caring for a totally dependent infant is more than a biologic event. The process begins before conception and involves major changes in the woman, her partner, and the entire family. Although each couple adapts to pregnancy in a unique way, the psychological responses of prospective parents change as the pregnancy progresses. Although the initial reaction may be uncertainty, by the time the infant is born, the woman and her partner have completed **developmental tasks**, maturation steps that allow further development. These help them become parents in the true sense of the word. Both social and cultural factors influence their adjustment to the pregnancy.

MATERNAL PSYCHOLOGICAL RESPONSES

A woman's psychological response to pregnancy changes over time. Initially, she may be uncertain or ambivalent about the pregnancy, and her primary focus is on herself. Gradually, her focus shifts, and she becomes increasingly concerned about protecting and providing for the fetus.

First Trimester Uncertainty

During the early weeks, the woman is unsure if she is pregnant and tries to confirm it. She observes her body carefully for changes

indicating pregnancy. She may confer with family and friends about the probability and often uses an over-the-counter pregnancy test kit for validation.

Reaction to the uncertainty of pregnancy depends on the individual. A woman may be eager to find confirming signs, or she may dread the possibility and hope for signs indicating she is not pregnant. Usually, she seeks confirmation from a physician, nurse-midwife, or nurse practitioner during the first trimester of pregnancy.

Ambivalence

Because almost half of pregnancies are unintended, pregnancy is often unexpected. Once the pregnancy is confirmed, many women have conflicting feelings, or **ambivalence**, about being pregnant (Coverston, 2011). Some feel that this is not the right time, even if the pregnancy is wanted and planned. Women who had intended to become pregnant often say they thought it would take longer to occur and that they feel unprepared. Many pregnancies are desired but unplanned, and these women may wish they had completed some goal before becoming pregnant.

Pregnancy causes permanent life changes for the woman, and she often begins to examine expected changes and decide how she will cope with them. If it is her first pregnancy, the woman may worry about the added responsibility and feel unsure of her ability to be a good parent. A multipara may be apprehensive about how this pregnancy will affect

her relationship with her other children and her partner. Ambivalence has usually changed to acceptance by the second trimester.

The Self as Primary Focus

Throughout the first trimester, the woman's primary focus is on herself, not on the fetus. Early physical responses to pregnancy, such as nausea and fatigue, confirm something is happening to her, but the fetus seems vague and unreal. Because she has not gained weight to confirm a growing, developing fetus, she often thinks more about being pregnant than about the coming baby.

Physical changes and increased hormone levels may cause emotional lability (unstable moods). Her mood can change quickly from contentment to irritation or from optimistic planning to an overwhelming sleepiness. These changes may be confusing to her partner and her family, who are accustomed to more stability.

Nurses should concentrate on the mother's physical and psychological needs during this period of maternal self-focus. Teaching should be aimed at the common early changes of pregnancy and their normality. Ways of coping with morning sickness, sexuality, and mood swings are important subjects to explore with the couple. The nurse should assess how the couple is managing these changes and explain that such changes are normal and generally do not indicate problems.

Second Trimester

Physical Evidence of Pregnancy

During the second trimester, physical changes occur in the expectant mother that makes the fetus "real." The uterus grows rapidly and can be palpated in the abdomen, weight increases, and breast changes are obvious. Ultrasound examination allows the woman to see the fetus, and she may receive an ultrasound picture or video to share with her family. During this time, she feels the fetus move (quickening). This experience is important because it confirms the presence of the fetus with each movement. As a result, she no longer thinks of the fetus as simply a part of her body but now perceives it as separate, although entirely dependent on her (Figure 8-1).

The Fetus as Primary Focus

The fetus becomes the woman's major focus during the second trimester. The discomforts of the first trimester have usually decreased, and

FIG 8-1 Fetal movement, or quickening, confirms that a separate life is developing.

her size does not affect her activity. She is now concerned about producing a healthy infant. She is often interested in information about diet and fetal development. A feeling of creative energy and satisfaction is common.

Narcissism and Introversion

At this time, many women become increasingly concerned about their ability to protect and provide for the fetus. This concern is often manifested as **narcissism** (undue preoccupation with oneself) and **introversion** (concentration on the self and body). Selecting exactly the right foods to eat or the right clothes to wear may assume more importance than earlier in the pregnancy. Some women lose interest in their jobs, which may seem alien compared with the events taking place inside them. They may become less interested in current events as they focus on the pregnancy or may become fearful that world events threaten them and their fetus.

If this is her first pregnancy, the expectant mother wonders about the infant. She looks at baby pictures of herself and her partner and may want to hear stories about what they were like as infants. Although multiparas know more about infants in general, they are interested in this infant and concerned with this child's acceptance by siblings and grandparents. Expectant mothers may also examine their relationships with others and how these ties will change after the birth.

The woman often spends much time thinking about the fetus and daydreaming or fantasizing about what life will be like when it is born. She may call it by the name chosen and talk about the personality of the fetus. Some mothers enjoy reading about fetal development to see what changes are happening each week. This intense introspection may be confusing to her partner and family because it is so different from her usual behavior.

Body Image

Rapid and profound changes take place in the body during the second trimester. Changes in body size and contour are obvious with thickening of the waist, bulging of the abdomen, and enlargement of the breasts. Increasing breast size in a woman with previously small breasts may be a happy side effect of pregnancy. Other women with large breasts may be concerned about pregnancy changes causing their breasts to be too heavy or pendulous.

Changes may be welcomed because they signify growth of the fetus and give the woman and her partner a feeling of pride. They increase the woman's **body image** (subjective view of oneself). For some women, however, the change in body size and shape, coupled with hyperpigmentation of the skin and striae gravidarum, may contribute to a negative body image. Changes in body function such as altered balance, reduced physical endurance, and discomfort in the pelvis and lower back areas may also affect her body image (see Nursing Care Plan).

Changes in Sexuality

The sexual interest and activity of pregnant women and their partners are unpredictable and may increase, decline, or remain unchanged. The woman's physical comfort and sense of well-being are closely linked to her interest in sexual activity. The culture of the couple is also important. Intercourse during pregnancy is allowed and encouraged in some cultures but strictly forbidden in others.

During the first trimester, freedom from worry about becoming pregnant or the need for contraception may provide a sense of freedom and enhance sexual interest in both partners. However, nausea, fatigue, and breast tenderness may interfere with erotic feelings. Fear of miscarriage may cause couples to avoid intercourse, particularly if the woman has previously lost a pregnancy or has had infertility therapy. Nurses

☉ NURSING CARE PLAN

Body Image during Pregnancy

ASSESSMENT: Shannon is a 34-year-old primigravida in the 26th week of pregnancy. Both she and her husband have been runners for several years. With her physician's permission, she continued running until 6 weeks ago when she began to find it uncomfortable. Shannon says she now walks "like other old ladies." She expresses concern about the brown discoloration on her face and her increasing size and says she feels "fat, awkward, and ugly." She states, "I hate the way I look! I can't wait to get back into shape." She also has questions about what sexual activity is allowed during pregnancy.

NURSING DIAGNOSIS: Disturbed Body Image related to changes in body size, contour, and function secondary to pregnancy

EXPECTED OUTCOMES: By the end of her next prenatal visit Shannon will:

1. Make statements that indicate acceptance of expected body changes during her pregnancy.
2. Express her feelings about body changes to her husband and the health care team.
3. Set realistic goals for weight loss and the resumption of a running program after childbirth.
4. Report continued mutually satisfactory sexual activity during pregnancy.

INTERVENTIONS AND RATIONALES

1. Acknowledge Shannon's feelings. "I can see you're disappointed about not being able to run and concerned about how pregnancy has changed your body." *Feelings must be acknowledged, reflected, and dealt with before the underlying cause can be addressed.*
2. Clarify her concerns. "You've always been an athlete. Women often wonder if changes in pregnancy will affect them permanently." *An underlying unvoiced concern may be that pregnancy will change the woman so that she will be unable to continue athletics. This altered perception of herself may cause fear, grief, or both.*
3. Suggest that she share her feelings with her husband and seek his support. Model this interaction, if necessary: "I feel awkward and left out of a big part of our lives. I need some reassurance from you." *Although the woman may assume her partner recognizes and understands her negative feelings, this may not be true.*
4. Discuss types of low-impact, moderate exercise, such as walking or swimming, that would be beneficial for Shannon. *Moderate daily exercise is encouraged during uncomplicated pregnancy.*

5. Describe the expected pattern of weight gain for the rest of the pregnancy and correlate this with the growth and development of the fetus. Explain that adipose tissue provides needed energy for birth and lactation. *Knowledge of the expected weight gain and understanding that weight gain shows the fetus is growing may allay unexpressed fears of excessive weight gain.*
6. Help Shannon make realistic plans to lose weight and recover her strength and endurance after childbirth.
 - a. Explain the expected pattern of weight loss after childbirth.
 - b. Demonstrate graduated exercises that increase muscle tone and strength.
 - c. Discuss a diet that meets her needs for breastfeeding. *Many women are relieved to know that the added weight will be lost gradually. Breastfeeding requires additional calories and nutrients.*
7. Explain that the discoloration on her face (melasma) is normal and usually disappears after pregnancy. Suggest she limit exposure to the sun and use sunscreen. *Knowledge of what is normal is comforting. Limiting exposure to the sun and using sunscreen may help decrease the severity.*
8. Determine Shannon's specific concerns about sexuality and respond to those in particular. *Concerns vary among couples. Some couples worry about harming the fetus or causing discomfort for the mother.*
9. Reassure her that sexual activity poses no harm to either the mother or the fetus in a normal pregnancy. Explain the anatomy of the vagina, cervix, and uterus. Suggest she bring her partner to the next visit if he has concerns. *Knowledge of the separation between the vagina and the fetus may relieve concern about the safety of vaginal intercourse during pregnancy.*
10. Suggest that alternative positions such as side-lying, woman-superior, and vaginal entry from the back be used for intercourse during the third trimester. *The male-superior position becomes uncomfortable for the woman when the uterus is large and heavy, and it increases the risk of supine hypotension.*

EVALUATION: At the next prenatal visit, Shannon speaks with pride about how big the baby is growing and makes other statements showing more acceptance of body changes. She reports that her husband has shown increased concern about her feelings and has been very supportive since she shared her feelings with him. Shannon has explored other types of exercises and has found several she will use during the rest of her pregnancy. She begins to plan a realistic schedule of diet and exercise that she will follow after the birth. She relates mutually satisfying sexual experiences.

can reassure the couple that no evidence shows intercourse to be related to early pregnancy loss when no complications are present.

In the second trimester, women experience increased sensitivity of the labia and clitoris and increased vaginal lubrication from pelvic vasocongestion. Nausea is no longer a concern by this time for most women. Many have a general feeling of well-being and energy that may increase sexual responsiveness. Orgasm may occur more frequently and with greater intensity during pregnancy because of these changes. Although orgasm causes temporary uterine contractions, they are not harmful if the pregnancy has been normal.

During the third trimester, the "missionary position" (male on top) may cause discomfort because of abdominal pressure. Heartburn, indigestion, and supine hypotensive syndrome also increase in this position. The pressure of the fetus low in the pelvis may add to the discomfort. Moreover, fatigue, ligament pain, urinary frequency, and shortness of breath may be problems.

The nurse can suggest alternative positions such as female-superior, side-to-side, or vaginal rear-entry for intercourse. The side-lying position may be the most comfortable and require the least amount of energy during the third trimester. Hugging, cuddling, kissing, and mutual massage or masturbation are other ways to express affection without vaginal intercourse.

As they become larger, some women believe their bodies are ugly and worry about their partner's reaction to their increased size. Sexual response varies widely among men. Some men report heightened feelings of sexual interest, but others perceive the woman's body in late pregnancy as unattractive, and erotic feelings decrease. In addition, fear of harming the fetus or causing discomfort to the woman may interfere with sexual activity.

Despite the need for information, many women are reluctant to initiate a discussion about sexual activity. Unfortunately, most health care professionals do not introduce the topic. They may fear offending

the woman or may be uncomfortable with their own sexuality and embarrassed to begin a discussion. They often lack time for any but the most pressing assessments. The result may be that an important aspect of care is ignored.

A broad opening statement may help initiate discussion about sexual activity—for example, “Sometimes couples are concerned about having sex during pregnancy.” Such statements introduce the subject in a way that lets the woman feel comfortable either pursuing it or ignoring it.

The couple should be made aware of the normal changes in sexual desire that occur during pregnancy and the importance of communicating their feelings openly with each other to find solutions to problems. The nurse can reassure the couple that their feelings are normal.

Intercourse is safe throughout pregnancy if there are no complications. Bleeding, an incompetent cervix, placenta previa, rupture of membranes, and history of preterm labor in the present pregnancy are contraindications for intercourse. In addition, blowing into the vagina should be avoided at any time because it can cause an air embolus (Coverston, 2011; Cunningham, Leveno, Bloom et al., 2010).

Third Trimester Vulnerability

The sense of well-being and contentment that dominates the second trimester gives way to increasing feelings of vulnerability that peak in the third trimester during the seventh month (Coverston, 2011). The expectant mother may worry that the precious baby may be lost or harmed if not protected at all times (Figure 8-2). She often has fantasies or nightmares about having a deformed baby or harm coming to the infant and may become very cautious as a result. She may avoid crowds because she feels unable to protect the infant from infectious diseases or potential physical dangers. She needs reassurance that such dreams and fears are not unusual in pregnancy.

FIG 8-2 During the third trimester, the mother feels increasingly vulnerable. She cradles her fetus to signify her protectiveness.

Increasing Dependence

The expectant mother often becomes increasingly dependent on her partner in the last weeks of pregnancy. She may insist that he be easy to reach at all times and may call his cell phone or place of work several times during the day. She may rely on her partner and others more at this time and seek their help in making decisions. This may be frustrating if it is a marked change for her.

Women often have fears about the safety of the partner and that something will happen to him. Her need for love and attention from her partner is even more pronounced in late pregnancy. When she is assured of his concern and willingness to provide assistance, she feels more secure and able to cope.

Although the woman may not be able to explain the increasing dependence, she expects her partner to understand the feeling and may become angry if he is not sympathetic. Irritability may increase because of her fatigue at this time as well. The nurse can encourage couples to discuss fears and feelings openly so that misunderstandings can be avoided.

Some pregnant women have difficulty with tasks that require direct, sustained attention, particularly in the third trimester. Women may feel they have trouble concentrating or focusing on learning new material or skills at this time. Teaching should be clear and concise to help women learn most easily.

Preparation for Birth

Gradually, the feelings of vulnerability decrease as the woman comes to terms with her situation. The fetus continues to grow, and fetal movements are no longer gentle. Pokes, jabs, and kicks are intrusive expressions of the baby's crowded condition and increasing activity. The woman's relationship with the fetus changes as she acknowledges that although she and the fetus are interrelated, the baby is a pervasive presence and not a part of herself. Although she may not consciously acknowledge the increasing feelings of separateness, she longs to see the baby and become acquainted with her child.

Most pregnant women are concerned about their ability to determine when they are in labor. They review the signs of labor and question friends and family members who are parents. Many couples are anxious about getting to the birth facility in time for the birth, and they may be worried about coping with labor.

During the last few weeks, the woman becomes increasingly concerned about her due date and the experience of labor and delivery. Some women fear labor and dread the due date, whereas others are so uncomfortable that they look forward to that day, expecting it to be the exact day the birth will occur. They often say they are tired of being pregnant and want the pregnancy to be over.

Women pregnant for the first time are more likely to fear childbirth than multiparas. Many women fear the pain of childbirth or that something will go wrong during labor. Multiparas who had a previous negative pregnancy or birth experience have increased concerns during the current pregnancy. Worry may also increase if friends or relatives have had difficult pregnancies.

Women may seek help for their fears by talking to members of their support system or by seeking information from health care professionals, books, television, or the Internet. Women often watch TV programs that show pregnancy and childbirth to learn more about what their own experience might be like. However, information from websites or TV may not always be scientifically based, show practices that are evidence based, or depict experiences that are most common (Theroux, 2011).

During the third trimester an expectant mother prepares for the infant, if that is appropriate in her culture. “Nesting” behavior includes

TABLE 8-1 PROGRESSIVE CHANGES IN MATERNAL RESPONSES TO PREGNANCY

FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER
Emotional Responses		
Uncertainty, ambivalence, focus on self, emotional lability	Wonder, increased narcissism, introversion, concern about changes in her body and sexuality	Vulnerability, increased dependence, acceptance that fetus is separate but totally dependent
Physical Validation		
No obvious signs of fetal growth	Quickening, enlarging abdomen	Obvious fetal growth, discomfort, decreased maternal activity
Role		
May begin to seek safe passage for self and fetus	Seeks acceptance of fetus and her role as mother	Prepares for birth, sets up expectations of herself as a mother
“Self-Statement”		
“I am pregnant.”	“I am going to have a baby.”	“I am going to be a mother.”

obtaining clothing and furniture and arranging a place for the infant to sleep. Negotiation of how the couple will share household tasks is among the plans made at this time. In addition, many couples complete childbirth education classes (see [Chapter 11](#)). [Table 8-1](#) summarizes changes in maternal responses during pregnancy.

2. How might pregnancy affect the sexual responses of the mother and the father?

MATERNAL ROLE TRANSITION

Becoming a mother involves intense feelings of love, tenderness, and devotion that endure over a lifetime. How does a woman learn to be a mother?

Role transition is changing from one pattern of behavior and self-image into another. The transition into the mother role begins during pregnancy and increases with gestational age. The woman must accept the pregnancy and the changes that will result. She develops a relationship with the unborn child, first as part of herself and then as a separate individual. Near the end of pregnancy, she must prepare herself for the birth and for parenting the new baby.

Transitions Experienced throughout Pregnancy

The woman undergoes transitions in relationships that continue throughout the pregnancy. She becomes more aware of herself and the changes occurring in her life. Her relationship with the father changes as they both prepare for parenthood. Her relationship with her own mother is often examined and may change as the expectant mother develops a view of herself as a mother and what that role entails. The

woman needs mentors to help her understand that her feelings and experiences during pregnancy are normal. She also needs support from other new mothers ([Darvill, Skirton, & Farrand, 2010](#)).

Steps in Maternal Role Taking

[Rubin \(1984\)](#), in her classic work, observed specific steps that provide a framework for understanding the process of maternal role taking: mimicry, role play, fantasy, the search for a role fit, and grief work.

Mimicry

Mimicry involves observing and copying the behaviors of other women who are pregnant or mothers in an attempt to discover what the role is like. Mimicry often begins in the first trimester, when the woman may wear maternity clothes before they are needed to understand the feelings of women in more advanced pregnancy and see how others react to her. She may also mimic the waddling gait or posture of a woman who is close to delivery long before these changes occur for her.

Role Play

Role play consists of acting out some aspects of what mothers actually do. The pregnant woman searches for opportunities to hold or care for infants in the presence of another person. Role playing gives her an opportunity to “practice” the expected role and receive validation from an observer that she has functioned well. She is particularly sensitive to the responses of her partner and her own mother.

Fantasy

Fantasies (mental images formed to prepare for the birth of a child) allow the woman to consider a variety of possibilities and daydream or “try on” a variety of behaviors. Fantasies often revolve around how the infant will look and what characteristics he or she will have. The woman may daydream about taking her child to the park or reading or singing songs to the child. She may also have vivid dreams at night.

At times, fantasies are fearful. What if something is wrong with the infant? What if the baby cries and will not stop? Some women dream about a stranger entering their life. The stranger may represent the fetus ([Driscoll, 2008](#)). Fearful fantasies often provoke a pregnant woman to respond by seeking information or reassurance. For instance, she may ask her partner if he will love the baby even if he or she is not perfect, or she may strive to learn all she can about caring for a baby who is difficult to console.

Fantasies may change during each trimester and may be different for primigravidas and multigravidas. Fantasies are most frequent during the third trimester. The nurse shows acceptance and understanding by listening to women’s fantasies. In addition, listening helps the nurse identify concerns that may need further discussion.

The Search for a Role Fit

The search for a role fit occurs once the woman has established a set of role expectations for herself and internalized a view of a “good” mother’s behavior. She then observes the behaviors of various mothers and compares them with her own expectations of herself. She imagines herself acting in the same way and either rejects or accepts the behaviors, depending on how well they fit her idea of what is right. This process implies that the woman has explored the role of mother long enough to have developed a sense of herself in the role and to be able to select behaviors that reaffirm her view of how she will fulfill the role.

Grief Work

Although grief work seems incongruous with maternal role taking, women often experience a sense of sadness when they realize that they

must give up certain aspects of their previous selves and can never go back. A primigravida will never again be a carefree woman who has not had a child. She must relinquish some of her old patterns of behavior to take on the new identity as a mother. Even simple things such as going shopping or to the movies will require planning to include the infant or find alternative care. The multipara will have one more child claiming her attention. Changes may be particularly difficult for the adolescent mother, who is not used to planning ahead and may have to give up or change school plans as well (see Chapter 24).

Maternal Tasks of Pregnancy

To become mothers, pregnant women spend a great deal of time and energy learning new behaviors. As the woman works to establish a relationship with the infant, she must also reorder her relationship with her partner and family. This psychological work of pregnancy has been grouped into four maternal tasks of pregnancy (Rubin, 1984):

1. Seeking safe passage for herself and baby through pregnancy, labor, and childbirth
2. Gaining acceptance of the baby and herself from her partner and family
3. Learning to give of herself
4. Developing attachment and interconnection with the unknown child

Seeking Safe Passage

Seeking safe passage for herself and her baby is the woman's priority task. If she cannot be assured of that safety, she cannot move on to the other tasks. Behaviors that ensure safe passage include seeking the care of a physician or nurse-midwife and following recommendations about diet, vitamins, rest, and subsequent visits for care. In addition to following the advice of health care professionals, the pregnant woman must also adhere to cultural practices that ensure safety for herself and the infant.

Securing Acceptance

Securing acceptance is a process that continues throughout pregnancy. It involves reworking relationships so that the important persons in the family accept the woman in the role of mother and welcome the baby into the family constellation.

In her first pregnancy, the woman and the father of the baby must give up an exclusive relationship and make a place in their lives for a child. When her partner expresses pride and joy in each pregnancy, the woman feels valued and comforted. This feeling is so important that many women retain a memory of the partner's reaction to the announcement of pregnancy for many years.

Support and acceptance from her own mother are especially important. The pregnant woman gains energy and contentment when her mother freely offers acceptance and support. Many expectant mothers gain a sense of increased closeness with their mothers during pregnancy (Figure 8-3).

Problems may occur if the family strongly desires a child with particular characteristics and the woman believes that the family may reject an infant who does not meet the criteria. For example, if family members wish for a boy, will they accept a girl?

Learning to Give of Herself

Giving is one of the most idealized components of motherhood, but one that is essential. Learning to give to the coming infant begins in pregnancy when the woman allows her body to give space and nurturing to the fetus. She tests her ability to derive pleasure from giving by providing food, care, and acts of thoughtfulness for her family. The acceptance and enjoyment of the "gift" enhance her pleasure and

FIG 8-3 The bond between a pregnant woman and her own mother is particularly important to the young mother.

strengthen the role. She may also give small gifts to friends, especially those who are pregnant.

Pregnant women also learn to give by receiving. Gifts received at "baby showers" are more than needed items. They also confirm continued interest and commitment from friends and family and enhance the woman's ability to give. Intangible gifts from others, such as companionship, attention, and support, help increase her energy and affirm the importance of giving.

Committing Herself to the Unknown Child

The process of **attachment** (development of strong affectional ties) begins in early pregnancy when the woman accepts or "binds in" to the idea that she is pregnant, even though the baby is not yet real to her. During the second trimester the baby becomes real and feelings of love and attachment surge. This is especially true when quickening occurs or after an ultrasound shows recognizable parts of the baby.

Mothers report feedback from their unborn infants during the third trimester and describe unique characteristics of the fetus with regard to sleep-wake cycles, temperament, and communication. Love of the infant becomes possessive and leads to feelings of vulnerability. The woman integrates the role of mother into her image of herself. She becomes comfortable with the idea of herself as mother and finds pleasure in contemplating the new role (Mercer & Ferketich, 1994).

Some women delay attachment to the fetus until they feel sure the pregnancy is normal and will continue. This is especially true for women who have lost a pregnancy previously. They may begin to have feelings of attachment after they have passed a critical time that correlates to the time they lost a previous pregnancy (Driscoll, 2008).

PATERNAL ADAPTATION

Expectant fathers do not experience the biologic processes of pregnancy, but they also must make major psychosocial changes to adapt to a new role. These changes may be more difficult because the male partner is often neglected by the health care team and his peer group, as attention is focused on the woman. His concerns and anxieties may remain unknown because of the lack of focus on him.

Variations in Paternal Adaptation

Wide variations exist in paternal responses to pregnancy. Some men are emotionally invested and comfortable as full partners exploring every aspect of pregnancy, childbirth, and parenting. Others are more task oriented and view themselves as managers. They may direct the woman's diet and rest periods and act as coaches during childbirth but remain detached from the emotional aspects of the experience. Some men are more comfortable as observers and prefer not to participate. In some cultures, men are conditioned to see pregnancy and childbirth as "women's work" and may not be able to express their true feelings about pregnancy and fatherhood.

Readiness for fatherhood is more likely if a stable relationship between the partners, financial security, and a desire for parenthood are present. Additional factors include the man's relationship with his own father, his previous experience with children, and his confidence in his ability to care for the infant.

Fathers have many concerns during a pregnancy. Unplanned pregnancy is more likely to cause distress for fathers-to-be, as might be expected. In addition, coping with the expectant mother's emotional lability can be confusing and difficult. Common concerns include anxiety about the health of the mother and baby, financial concerns, and apprehension about his role during the birth and about the changes that will result when the baby arrives.

Financial concerns may be especially acute in a two-income family if the mother develops complications that prevent her from working as long as expected. A reduction in income coupled with an increase in expenses can result in added stress for both parents. Men may seek a second job or work overtime to prepare for the increased financial needs. Other concerns include the responsibility parenthood will bring and whether he and his partner will be good parents.

Developmental Processes

The responses of the expectant father are dynamic, progressing through phases that are subject to individual variation. *Jordan (1990)* describes three developmental processes that an expectant father must address:

- Grappling with the reality of pregnancy and the new child
- Struggling for recognition as a parent from his family and social network
- Making an effort to be seen as relevant to childbearing

The Reality of Pregnancy and the Child

The pregnancy and the child must become real before a man can assume the identity of father. The process requires time and may be incomplete until the birth. Initially, the pregnancy is a diagnosis only, and changes in the expectant woman's behavior, such as nausea and fatigue, are perceived as symptoms of illness that have little to do with having a baby.

A man's initial reaction to the announcement of pregnancy may be pride and joy, but he often experiences the same ambivalence as his partner, particularly if he is unprepared for the added responsibility or commitment. Various experiences act as catalysts or "reality boosters" that make the child more real (*Figure 8-4*). The most frequently

FIG 8-4 Reality boosters such as hearing the sounds of the fetal heart make the fetus more real for the father.

mentioned experiences are seeing the fetus on an ultrasound, hearing the baby's heartbeat, and feeling the infant move.

Preparing room for the baby and accumulating supplies also reinforce the reality of the coming child. These tasks often represent the first time that the expectant father has the opportunity to do something directly for the baby. The birth itself is the most powerful reality booster, and the infant becomes real to the father when he has an opportunity to see and hold the baby.

The Struggle for Recognition as a Parent

Men are often perceived by others as helpmates but not parents in their own right. Some men may be upset that their feelings are not validated and that they may not be recognized as parents as well as helpers. Many men accept that the focus should be on their partners, but others are frustrated by the lack of understanding of their own experiences.

Support groups or classes for expectant fathers are sometimes available. These groups allow them to talk with other men about changes resulting from the pregnancy and how these changes have affected them. Knowing his experiences and feelings are shared by other men in the same situation is very helpful.

Expectant mothers play an important role in helping their partners gain recognition as parents. Women who openly share their physical sensations and emotions help expectant fathers feel that they are part of the process. These women often say "we" are pregnant and include their partners in all discussions and decisions.

Nurses must learn to view the mother, the father, and the infant as one patient and not focus exclusively on the mother and the fetus. Men may be concerned about the physical symptoms experienced by expectant mothers. The nurse should encourage men to ask questions about their partners' pregnancies. These men are entitled to as much advice and reassurance as expectant women (*Figure 8-5*). Men who have sufficient information about pregnancy, birth, and newborn care are less likely to be psychologically stressed as men who do not feel they have enough information. Internet resources such as that of the American College of Obstetricians & Gynecologists also provide valuable information for fathers at www.acog.org.

The nurse can also guide the couple in discussion of the role the father will play during and after the birth. How actively will he participate during labor? Will he be involved in infant care from the start, or

FIG 8-5 The nurse who views the mother, father, and child as one patient provides parents with the greatest opportunity to learn infant care and parenting skills.

wait until the baby is older? Will he change diapers and help with nighttime care, or does he see those tasks as those of the mother? The expectant parents may be surprised to learn each other's views and will need to negotiate, taking the beliefs of each partner into consideration to determine the roles each will play.

Creating the Role of the Involved Father

Men use various means to create a parenting role that is comfortable for them. They may seek closer ties with their fathers to reminisce about their own childhoods. They may fantasize about their relationships with their children as they progress through the stages of childhood.

Expectant fathers also observe men who are already fathers and “try on” fathering behaviors to determine whether they are comfortable and fit their own concepts of the father role. Some men change their self-images and even their appearances to fit their new images (Coverson, 2011). In addition, many men assertively seek information about infant care and growth and development so that they will be prepared.

Parenting Information. Expectant fathers need information about infant care and parenting. Although adequate information may be given to them, fathers may not be ready to learn at the time it is provided. As a result, they may have unrealistic expectations and be unprepared to care for the newborn. Nurses must review information about infant care and growth and development after the infant is born when the knowledge is immediately relevant.

Couvade. The term **couvade** refers to pregnancy-related symptoms and behavior in expectant fathers. In primitive cultures, couvade took the form of rituals involving special dress, confinement, limitations of physical work, avoidance of certain foods, sexual restraint, and, in some instances, performance of “mock labor.”

In modern practice, expectant fathers sometimes experience physical symptoms similar to those of pregnant women, such as loss of appetite, nausea, headache, fatigue, and weight gain. Symptoms are more likely to occur in early pregnancy and lessen as the pregnancy progresses. They may be caused by stress, anxiety, or empathy for the pregnant partner. They are usually harmless but may persist and result in nervousness, insomnia, restlessness, and irritability. Although the symptoms are almost always unobserved by the health care team, anticipatory guidance is beneficial for both partners.

8. Why should information relating to newborn care presented in prenatal classes be repeated after the infant is born?

ADAPTATION OF GRANDPARENTS

The initial reaction of grandparents depends on factors such as their ages, the number and spacing of other grandchildren, and their perceptions of the role of grandparents.

Age

Age is a major determining factor in the emotional responses of prospective grandparents. Older grandparents have often already dealt with their feelings about aging and react with joy when they find they are to become grandparents. They look forward to being able to love grandchildren, who signify the continuity of life and family.

Younger grandparents may not be happy with the stereotype of grandparents as old persons. They may experience conflict when they must resolve their self-image with the stereotype. They often have career responsibilities and may not be accessible because of the continuing demands of their own lives.

Number and Spacing of Other Grandchildren

The number and spacing of other grandchildren also determine grandparents' reactions. A first grandchild may be an exciting event that creates great joy. If the grandparents have other grandchildren, another may be welcomed, but with less excitement. The subdued reaction may be disappointing to the couple, who may desire the same reaction as that expressed for the first grandchild.

Perceptions of the Role of Grandparents

Grandparents' beliefs about their importance to grandchildren vary widely. Many grandparents see their relationships with grandchildren as second in importance only to the parent-child relationship. They want to be involved in the pregnancy, and grandmothers often engage in rituals such as shopping and gift-giving showers that confirm their role as important participants. Many grandparents are intimately involved in child care and offer unconditional love to the child. They offer to care for older children while the mother gives birth, and they assist during the first weeks after childbirth.

In the past, grandparents were often asked for advice about child-bearing and child-rearing. Health care personnel have now become the “experts,” and many grandparents have difficulty adjusting to this change. Some grandparents may withdraw, sensing that their participation is no longer valued. Other grandparents worry about their lack of familiarity with modern ways of childbearing and parenting. Special classes are often available to teach them about current childbearing practices.

On the other hand, some contemporary grandparents plan little participation in pregnancy or child care. They may say, “I've raised my children, and I don't plan to do it again.” This attitude often results in conflict with the parents, who may feel hurt and wish for the grandparents' help during the third trimester and after the birth.

Nurses can assist families verbalize their feelings about the grandparents' responses to the pregnancy by statements such as, “It may seem that the grandparents aren't interested in the baby, but perhaps they are uneasy about what their role should be.” Parents and

grandparents may need to negotiate how the grandparents can be involved without feeling that they must assume more care of the child than they desire. For instance, the couple may need suggestions to help the grandparents participate in family gatherings that do not involve babysitting or child care. Letting grandparents know that the parents want them to share in the joy the child brings without other expectations may ease the situation.

ADAPTATION OF SIBLINGS

Sibling adaptation to the birth of an infant depends largely on age and developmental level.

Toddlers

Children 2 years old or younger are unaware of the maternal changes occurring during pregnancy and are unable to understand that a new brother or sister is going to be born. Because toddlers have little perception of time, many parents delay telling them that a baby is expected until shortly before the birth.

Although preparing very young children for the birth of a baby is difficult, the nurse can make suggestions that may prove helpful. Any changes in sleeping arrangements should be made several weeks before the birth so the child does not feel displaced by the new baby. Family members should be prepared that toddlers may show feelings of jealousy or resentment. Toddlers need frequent reassurance that they are loved.

Older Children

Children from 3 to 12 years are more aware of changes in the mother's body and may realize a baby is to be born. They may enjoy observing the mother's abdomen, feeling the fetus move, and listening to the heartbeat. They may have questions about how the fetus will develop, how it was created, and how it will get out of the abdomen. Although they look forward to the baby's arrival, preschool children may expect the infant to be a full-fledged playmate and may be shocked and disappointed when the infant is small and helpless. They also need preparation for the fact that the mother will go away for several days when the baby is born.

School-age children are often told about the pregnancy during the second trimester and benefit from being included in preparations for the new baby. They are interested in following the development of the fetus, preparing space for the infant to sleep, and helping to accumulate supplies the infant will need. They should be encouraged to feel the fetus move, and many come close to the mother's abdomen and talk to the fetus.

School-age children may wonder how the birth will affect their role in the family. Parents should address these concerns and reassure the children about their continued importance. Providing time alone with the parents may help them gain a sense of security (Figure 8-6). Reading books about other children's experiences after the birth of a sibling may be helpful.

Children as young as 3 years can benefit from sibling classes (see Chapter 11). The classes provide an opportunity for them to discuss what newborns are like and what changes the new baby will bring to the family. They are encouraged to bring a doll to these classes to simulate caring for the infant.

In some settings, siblings are permitted to be with the mother during childbirth. They should attend a class that prepares them for the event. During the birth, a familiar person who has no other role but to support and care for younger siblings should be available to explain what is taking place and to comfort or remove them if events become overwhelming.

FIG 8-6 A pregnant woman who spends time with an older child can provide affection and a sense of security.

Adolescents

The response of adolescents also depends on their developmental level. Some are embarrassed because the pregnancy confirms the continued sexuality of their parents. Many adolescents are immersed in their own developmental tasks involving loosening ties to their parents and coming to terms with their own sexuality. They may be indifferent to the pregnancy unless it directly affects them or their activities. Other adolescents become very involved and want to help with preparations for the baby.

FACTORS INFLUENCING PSYCHOSOCIAL ADAPTATIONS

Age

Pregnancy presents a challenge for teenagers, who must cope with the conflicting developmental tasks of pregnancy and adolescence at the same time. The major developmental task of adolescence is to form and become comfortable with a sense of self. On the other hand, one of the major tasks of pregnancy involves learning to “give of self,” a process that includes sacrificing personal desires for the benefit of the fetus.

Nurses who work with pregnant teenagers should help them adjust to their changing bodies and the increasing presence of the developing fetus. Adolescents also need prompting to follow a lifestyle that promotes the best outcomes for them and their infants.

The pregnant woman over age 35 years may also have some concerns. Pregnancy may mean a major change in her life. She may have medical conditions that impact the pregnancy, as well. Concerns

relating to the pregnant adolescent and the older woman are discussed further in [Chapter 24](#).

Multiparity

The assumption that a multipara needs less help than a first-time mother is inaccurate. Pregnancy tasks are often more complex for the multipara than for the primigravida. The multipara does not have as much time to take special care of herself as she did during the first pregnancy. She is more likely to experience fatigue and may have serious concerns about her other children accepting the infant. She may worry about finding time and energy for additional responsibilities. When seeking acceptance of the new baby, the multipara may find the family less excited than they were for the first child. The couple's celebration is also more subdued.

The woman spends a great deal of time developing a new relationship with the first child, who may become demanding. This behavior may foster feelings of guilt as the mother tries to expand her love to include the second child. Developing attachment for the coming baby is hampered by feelings of loss between herself and the first child. She senses that the child is growing up and away from her, and she may grieve for the loss of their special relationship.

Nurses cannot assume that the process is “old hat” and that information about labor, breastfeeding, and infant care is not needed. The parents may also need special assistance in integrating an additional infant into the family structure.

CRITICAL THINKING EXERCISE 8-1

Ruth, a 24-year-old gravida 2, para 1 at 32 weeks of gestation, appears apathetic and tired when she arrives at the prenatal clinic. She states she is worried about whether her 2-year-old son will accept the new baby and sometimes feels guilty that she is having this baby so soon.

Elisa, age 28 years, also has a prenatal visit. She is in her 28th week of pregnancy and has children who are 2, 4, and 6 years old.

Questions

1. How should the nurse respond to the concerns of these women?
2. How will the concerns of these multiparas likely differ from those of a primigravida?
3. How might the tasks of pregnancy differ between the two women?
4. What measures can each mother take to prepare other children before the new baby arrives?

Social Support

Social support has been found to be a significant predictor of health-related quality of life during the perinatal period ([Emmanuel, St. John, & Sun, 2012](#)). Social support comes from the woman's partner, family, friends, and co-workers. Generally, support from the woman's partner and her mother is particularly important. Women who have social support as well as those enrolled in Medicaid or the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) are more likely to receive prenatal care ([Potter, Pereyra, Lamp et al., 2009](#); [Sunil, Spears, Hook et al., 2010](#)).

Depression may occur in women who have little support during pregnancy, and they are more likely to begin prenatal care late. The nurse should assess for signs of depression in all women and refer them for help when necessary. (See [Chapter 28](#) for a discussion of postpartum depression that may have started during pregnancy.) When social support is inadequate the nurse can help the woman explore potential sources such as support groups, childbearing education classes, church, work, or school. Some community programs employ nurses or

paraprofessionals to visit expectant mothers to provide teaching and social support.

Absence of a Partner

Pregnant single women may have special concerns. Although some unmarried women have the financial and emotional support of a partner, others do not. They may experience more stress about telling their family and friends about the pregnancy. They may have to enlist more social support to substitute for that of a partner. Legal issues such as whom to list as the father on birth records and what arrangements must be made to allow paternal contact with the infant may be added concerns.

Many single women without partners live below the poverty level. They are more likely to delay prenatal care until the second or third trimester and are at increased risk for pregnancy complications and delivery of a low-birth-weight infant.

Nurses must recognize the single mother's needs for accessible and affordable prenatal care. In addition, nurses must be prepared to offer specialized supportive care for single mothers. Necessary social services may include Medicaid; the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) for food vouchers; and transportation to prenatal appointments.

Some women are single by choice. They may have been inseminated to achieve pregnancy or choose not to continue the relationship with the father. If the pregnancy was planned, these women may have fewer financial concerns.

Abnormal Situations

Other factors that influence psychosocial adaptation during pregnancy include abnormal situations such as intimate partner violence and substance abuse (see [Chapter 24](#)). The nurse should assess all women for both of these risk factors during pregnancy so that appropriate referrals for help can be given.

Socioeconomic Status

One of the greatest influences on childbearing practices is the socioeconomic status of the family. The term *socioeconomic status* refers to the resources available for the family to meet the needs for food, shelter, and health care. Socioeconomic status can be divided into the affluent, the middle class, the working poor, and the new poor ([Table 8-2](#)).

The Affluent

Affluent families have resources to provide for their needs and purchase health care. They have a good income, secure shelter in a safe neighborhood, and the education and reserves to protect themselves from economic fluctuations. They can pay for health care through either private means or insurance.

Affluent families believe they deserve the best in health care and respect from health care providers. They are future oriented and therefore value preventive care. In general, they seek early, regular antepartum care and comply with recommendations of the health care providers.

The Middle Class

The middle class constitutes the largest group of families in the United States. In fact, most health care workers fit into this class. They usually are able to rent or own homes in relatively safe neighborhoods. They have adequate food and either education or skills that assist them to obtain and keep jobs for long periods.

Middle-class families rely on group insurance, obtained as part of their salaries, to shield themselves from exorbitant health care costs. A

TABLE 8-2 IMPACT OF SOCIOECONOMIC FACTORS ON THE FAMILY'S RESPONSE TO PREGNANCY

AFFLUENT	MIDDLE CLASS	WORKING POOR AND UNEMPLOYED	NEW POOR
Resources Is confident of ability; has financial reserves to protect from economic fluctuations; owns or rents home in a safe neighborhood; has health insurance or can pay for health care; is able to provide enriched environment.	Has relative security but fewer reserves and more debt; owns or rents home in relatively safe neighborhood; depends on employment for health insurance.	Lacks skills and bargaining power; is most vulnerable to economic fluctuations; struggles to meet basic needs.	Was previously self-sufficient but has lost prior resources; may have recently lost job and insurance; unused to public assistance.
Value Placed on Health Care Values preventive care.	Values health care but must rely on health insurance related to employment.	May value health care but often does not see a way to improve situation.	Values health care but may no longer have finances to access it.
Time Orientation Is future oriented and seeks prenatal care early; expects best possible care and education for children.	Is future oriented and seeks early prenatal care; makes plans to provide best possible care and education for children.	Priority is to meet needs of present; often seeks prenatal care late; has an uncertain future.	Has middle-class time orientation but must meet present needs; may begin prenatal care late.

major concern is loss of a job that results in loss of health insurance. They are future oriented and seek health care early in pregnancy.

The Working Poor and Unemployed

The working poor and unemployed include unskilled or unemployed workers. They work for low wages and are often the last hired and the first fired. They frequently live below the poverty level and have barely enough to survive. Some have difficulty meeting their basic needs for food and shelter, and some become homeless.

Because of economic uncertainty, these families place more emphasis on meeting present needs and less value on preventive (future-oriented) care. This often causes them to postpone prenatal care until the second or even the third trimester (see Nursing Care Plan).

The New Poor

The new poor constitute a group of individuals and families who were previously self-sufficient but are now without resources because of circumstances such as loss of a job or health care insurance. They must find their way into a health care system that is unfamiliar and frightening.

The values of the new poor are those of the middle class: self-sufficiency, hard work, and pride in the ability to succeed. Seeking public assistance is very difficult for this group. These families are devastated when they encounter the lack of respect that may occur when some health care workers interact with families unable to pay for health care.

BARRIERS TO PRENATAL CARE

Women's access to prenatal care is limited by financial, systemic, and attitudinal barriers. Financial barriers are among the most important factors limiting prenatal care. Many women have no insurance or insufficient insurance to cover maternity care. Although Medicaid finances prenatal care for indigent women, the enrollment process is

burdensome and lengthy. Some women do not know how to access this resource or do not qualify.

Systemic barriers include institutional practices that interfere with consistent care. For example, women must often wait weeks for their first visit. In one study, a researcher called 239 obstetric offices in one state and asked when a newly pregnant woman with insurance could be seen for her first prenatal visit. First visits were available at between 4 weeks of gestation and 10.6 weeks of gestation. The average appointment offered was at 6.37 weeks, and 25% of the appointments were for later than 8 weeks' gestation (Nettleman, Brewer, & Stafford, 2010).

Prenatal visits are usually scheduled during daytime hours that conflict with working women's schedules. Taking time off from work often means loss of wages and may put the woman's job in jeopardy. In addition, child care is rarely available at sites of care, and some women are unable to find affordable care. Lack of transportation may keep women from getting prenatal care. In addition, interpreters may not be available for women who do not speak English well.

An important barrier to health care results from the unsympathetic attitude of some health care workers toward those who are unable to pay for prenatal care. Poor families may experience long delays, hurried examinations, rudeness, and arrogance from some members of the health care team. Staff may be overworked and frustrated with the workloads they carry. Women may wait hours for an examination that lasts only a few minutes. Many never see the same health care provider more than once. These women may not keep clinic appointments because they do not see the importance of the hurried examinations.

Nurses must treat each family with respect and consideration. They must insist that poor families who are unable to pay receive the same standard of care and respect received by families who can pay. Nurses can work to determine which barriers apply to the patients with whom they work and find ways to meet the needs of the specific population being served. Scheduling prenatal visits in the evening or on weekends, setting aside times for walk-in prenatal visits, and offering other services such as applications for Medicaid and WIC may increase use of

NURSING CARE PLAN

Socioeconomic Problems during Pregnancy

ASSESSMENT: Theresa, a 19-year-old primigravida, is seen for initial prenatal care at 24 weeks of gestation. She took the day off from work in a factory and rode the bus to the clinic. She is currently living with her sister and brother-in-law, who receive Temporary Assistance for Needy Families. During the interview, Theresa states that she will not be able to keep clinic appointments because she cannot afford to take more time off until the baby comes. She is unmarried and says the father of the baby is “gone.” Physical assessment shows Theresa and her fetus are healthy. She declares she does not need further prenatal care and only needs to find someone to deliver the baby.

NURSING DIAGNOSIS: Risk for Ineffective Health Maintenance related to lack of a plan to obtain regular prenatal care and lack of understanding of the importance of care

EXPECTED OUTCOMES: During the first prenatal visit, Theresa will:

1. Describe the benefits of prenatal care.
2. Verbalize a plan for obtaining regular prenatal care.

INTERVENTIONS AND RATIONALES

1. Use active listening to show concern and empathy with Theresa’s difficulties in obtaining prenatal care. *Expressing interest in Theresa’s situation may make her more likely to listen to health teaching.*
2. Emphasize why regular prenatal care is essential:
 - a. To monitor the growth and development of the baby
 - b. To evaluate Theresa’s health, which directly affects the health of the fetus
 - c. To detect problems and intervene before they become severe
Preventive care is often not a priority when the woman has conflicting needs for food and shelter. Many women are unaware that complications such as preeclampsia or gestational diabetes, which may be identified and treated with routine care, are serious hazards if they remain undetected.
3. Assist Theresa in devising a plan to obtain regular prenatal care.
 - a. Provide her with a list of prenatal clinics near her home or place of work and the hours they are open.
 - b. Discuss transportation services and determine whether family or friends can help her keep prenatal appointments.

- c. Explore dates, times, and alternatives until she finds a schedule that works for her.

- d. Obtain a list of phone numbers (e.g., friends, family, employer) where she can be reached for follow-up.

Some clinics are open on weekends and evenings to accommodate working women. Unreliable transportation is a major reason for failure to keep scheduled appointments, and clinic schedules that allow some flexibility are helpful. Interest in a patient’s individual situation is highly motivating for her to find a way to continue prenatal care.

EVALUATION: Theresa is attentive as the nurse talks about the importance of health care. She shows interest in finding a way to have regular prenatal care and makes an appointment for the next visit. If she misses scheduled appointments, follow-up phone calls to arrange alternative appointments may be necessary.

Critical Thinking: *Although this diagnosis addresses Theresa’s problem with managing prenatal care, what additional assessments should be made to determine how she is managing the psychosocial concerns of pregnancy? What additional nursing diagnosis might be relevant?*

Answer: *The nurse should assess Theresa’s progress with the tasks of pregnancy. She has made the first step in seeking safe passage, but other tasks may need attention, such as securing the acceptance of her family and learning to give of herself. It is important to assess for depression, which may begin in pregnancy and continue after birth. In addition, signs that she is developing attachment for the fetus are particularly important. An additional nursing diagnosis might be “Risk for Impaired Attachment related to lack of support from significant others or the presence of financial stress.” Interventions might include helping her explore sources of emotional support such as women’s groups, church members, or Internet websites related to pregnancy.*

prenatal services. Decreasing waiting time before appointments as much as possible is important. Cultural sensitivity is important for all caregivers.

Some women do not obtain early prenatal care because they do not realize they are pregnant, do not want the pregnancy confirmed, do not want anyone to know about the pregnancy, or are considering an abortion. A woman with an unintended pregnancy may be too depressed to begin prenatal care early. Many women rely on advice from family and friends during pregnancy, and some believe prenatal care is unimportant, especially when they are healthy and have no obvious problems with the pregnancy. A major motivator that brings most women to seek prenatal care at some point is concern for the health of the baby (Phillippi, 2009).

CHECK YOUR READING

12. Why do many low-income women delay seeking health care until the second or third trimester?
13. How do the attitudes of health care workers affect the care of poor families?

CULTURAL INFLUENCES ON CHILDBEARING

Many distinct cultural groups live in the United States. Each culture has its own health and healing belief system for major life events such as pregnancy and childbirth. The success of health care depends on how well it fits with the beliefs of those being served. Therefore, ignorance of culturally divergent beliefs may lead to failure in health care delivery.

Differences within Cultures

Wide variations of beliefs and practices exist within each culture, and nurses must recognize that people sharing a culture may not have identical beliefs. Those who have lived in Western societies for years or generations often do not exhibit behaviors prescribed by their culture of origin. Nurses must be careful not to stereotype people or expect a certain set of behaviors from every person in a particular cultural group. Individual differences are as important as cultural variations.

A woman who does not normally follow certain beliefs of her culture may adhere to them during pregnancy. She may do this to show respect for family members to whom these beliefs are especially important or to avoid offending them. She may fear that some part of the

belief may be true after all and that she will harm her baby if she does not follow it.

Cultural Differences Causing Conflict

Cultural differences that may cause conflict between health care workers and families during pregnancy are observed most often in the areas of health care beliefs, communication, and time orientation. It is important to understand these beliefs to give culturally sensitive nursing care. When health care professionals violate cultural norms, patients are less likely to follow their advice.

Health Beliefs

Health Maintenance. The predominant U.S. culture treats pregnancy like an illness, with frequent visits to a physician, laboratory tests, and hospitalization for delivery with various medical interventions. Many other cultures, however, view pregnancy as a natural condition with little or no need for medical care. Initial visits to a health care provider often occur later in pregnancy than expected by U.S. culture.

Different cultures have various requirements for maintaining health during pregnancy. For example, Mexican women may keep active to ensure a small baby and easy delivery and may continue sexual intercourse to lubricate the birth canal (Dumonteil & Leon, 2008). Puerto Rican women are often indulged by their families during pregnancy, and exercise is considered inappropriate at this time (Torres, 2013).

Women from India stay away from the sun and heat during pregnancy, avoid stress, and are pampered by their families (Chatterjee, 2008; Grewal, Bhagat, & Balneaves, 2008). Prenatal care may not begin for Indonesian women until the second trimester, when the soul is believed to enter the fetus (Albright, 2008). Cambodian women may begin prenatal care at 5 to 6 months' gestation (Spector, 2009). Korean women may practice Qi exercise which consists of physical postures, breathing techniques, and meditation. One study found women who practiced Qi exercise had less depression and physical discomfort and higher levels of interaction with the fetus (Ji & Han, 2010).

Native American women may not tie knots or make braids during pregnancy to prevent complications involving the umbilical cord. Some Japanese women believe that if they are happy during pregnancy, it will cause good fortune for the fetus who is learning from the mother. Cambodian women may avoid standing in doorways to prevent the baby from becoming stuck in the birth canal. Eastern European women may not cut or color their hair during pregnancy (Callister, 2008).

Some groups believe that unclean things and strong emotions such as anger cause harm to the fetus or a difficult childbirth. Chinese women may avoid frightening or negative emotional experiences because they might be stressful to the fetus (Callister, Eads, & Diehl, 2011). It is important to encourage positive health practices. Concentration, silence, prayer, and meditation to maintain mental and spiritual health are practiced by some. In many cultures, women must not have contact with illness or death and may not attend funerals during pregnancy.

Belief in Fate. Some cultures (such as Southeast Asian and Middle Eastern) promote a strong belief in fate. Women often think that the only way they can affect the outcome of pregnancy is by eating correctly and observing the taboos of their culture. Because of this belief, it may be difficult to convince women to seek early and regular prenatal care.

Advance preparation for the baby is also avoided in some cultures. Arabic Muslim women believe that preparing for the baby defies the will of Allah. Navajo families do not choose a name for the baby until after birth because they fear it will harm the infant (Callister, 2008).

Some Jewish families select items needed for the new baby but do not bring them home until after the birth (Kater, 2008). Russian women try not to be too optimistic about the pregnancy because it might bring bad luck. They also do not buy clothes or equipment until the baby is born well and healthy (Callister, Getmanenko, Garvrish et al., 2007).

Preventing Illness. Practices that prevent illness include the use of protective religious objects or charms such as amulets or talismans. Some women also believe that certain foods can prevent illness or provide a good pregnancy outcome. For instance, people in many cultures eat raw garlic or onion or adhere to food taboos and prescribed combinations of foods. Strict adherence to religious codes, morals, and practices is also believed to prevent illness.

To be certain that all essential information about folk medicine is obtained, nurses should inquire whether the patient is using folk remedies with questions such as "What do pregnant women take to protect themselves and the baby?" "How often and how much of this do you take?" "What special foods and drinks are important?"

Restoring Health. Traditional ways to restore health include natural folk medicine such as herbs and plants. Women may use charms, holy words, prescribed acts, and traditional healers before seeking other medical advice. Hispanics may consult *curanderas* for illness or a *partera* for care during pregnancy (Spector, 2009). Some Africans and Haitians may rely on folk medicine that includes witchcraft, voodoo, or magic (Cherry & Giger, 2013; Strickland, 2013).

Modesty. Fear, modesty, and a desire to avoid examination by men may keep some women from seeking health care during pregnancy. In many cultures (such as Muslim, Hindu, Hispanic), exposure of the genitals to men is considered demeaning. In these cultures, the reputations of women depend on their demonstrated modesty. If possible, female health care providers should perform examinations. If this is not possible, the woman should be carefully draped with all areas of the body covered except those that must be exposed for examination. A female nurse needs to remain with the woman at all times. Obtaining permission from the husband may be necessary before any examination or treatment can be performed. In addition, the woman's husband, a female friend, or a male relative should be allowed to be present during examinations.

Female Genital Cutting. Female genital cutting (FGC) is also called "female circumcision" or "female genital mutilation." The procedure is practiced in parts of Africa, Asia, and the Middle East and is usually performed at some time in childhood. Christian, Jewish, and Muslim women may have the procedure performed (Hess, Weinland, & Saalinger, 2010). Performing FGC is illegal in the United States (Callister, 2011).

FGC involves removal of part or all of the clitoris, labia minora, and labia majora (called "infibulation"). Urinary retention, incontinence, infections, and increased morbidity and mortality during childbirth may result from FGC (Association of Women's Health, Obstetric, and Neonatal Nurses, 2008). The practice has been associated with premarital chastity and is a prerequisite for marriage in some cultures.

Women who have had the procedure and now live in North America need nurses and physicians who are knowledgeable about the custom and prepared for the abnormal appearance of the woman's genitals. The nurse's own opinion of the practice should not cause the woman to be treated in a negative manner.

Nurses can assist the woman in locating a female health care provider with whom she is comfortable. The examinations should be made as comfortable as possible by maintaining utmost privacy and draping the woman to provide maximum coverage. Pelvic examination is very painful because the introitus is so small and inelastic scar tissue makes the area especially sensitive. A pediatric speculum may be

necessary because of the small vaginal opening. The woman may not give any verbal or nonverbal sign of pain, but this lack of response does not indicate an absence of pain.

Communication

Language. Language is a major barrier to health care. Numerous dialects within many languages can make it difficult to find competent interpreters. The ideal is to have trained interpreters, preferably women. Other persons may be used, if necessary, but considerations of confidentiality, the use of medical jargon, and the possible need to discuss sensitive issues indicate the need for professional interpreters.

Adults who came to the United States as children may speak English well and can interpret for their parents and grandparents. Other family

members or friends, as well as clinic or hospital staff, may be helpful but not fluent. They may misunderstand instructions, particularly if medical jargon is used (see Nursing Care Plan). Women may not want to discuss sensitive matters if the interpreter is a family member, and it is not appropriate to use the woman's children to interpret if the topics are likely to embarrass the parent or the child.

Telephone interpreter services are provided in many agencies. This is more awkward than having an interpreter at the bedside but ensures that both the nurse and the patient receive accurate information.

Communication Style. Styles in communication differ among cultures. For example, among Asians, nodding and smiling may mean "Yes, I hear you" but may not indicate agreement or even understanding. When presenting information, the nurse should validate

NURSING CARE PLAN

Language Barrier during Pregnancy

ASSESSMENT: Diep T., a young Vietnamese primigravida at 16 weeks' gestation, speaks very little English. She listens quietly to the nurse's health care instructions, and although she appears confused, she asks no questions. Her husband, Bao N., nods and smiles frequently and speaks more English than his wife but has difficulty responding to questions about his wife's health.

Critical Thinking: Why must additional assessments be made before a nursing diagnosis can be formulated?

Answer: Nodding and smiling do not always mean that persons from another culture understand health teaching. Instead, such actions may simply indicate that the information has been heard, or perhaps Mr. N. is being polite and does not want the nurse to feel inadequate as an instructor. Before assuming that Mr. N. can translate health care teaching for his wife, the nurse must validate his learning by asking Mr. N. to explain what he has learned.

NURSING DIAGNOSIS: Impaired Verbal Communication related to language barriers

EXPECTED OUTCOMES: Throughout the pregnancy the family will demonstrate adequate understanding of instructions by:

1. Keeping scheduled appointments.
2. Following health care instructions.
3. Verbalizing basic needs and concerns at each prenatal visit.

INTERVENTIONS AND RATIONALES

1. Assess the couple's ability to speak, read, and write in English and determine if they are fluent in other languages. *People who are not fluent in speaking a language may be more adept at reading it.*
2. Obtain the assistance of a fluent interpreter, preferably a woman.
 - a. Establish a list of bilingual staff members who are willing to interpret and understand the importance of confidentiality and exactness. Also, ensure that staff members are knowledgeable about the telephone interpreter service used by the agency.
 - b. Enlist the aid of adult family members or friends who can interpret for the couple, if a professional interpreter is not available. Be aware of confidentiality issues, however, and obtain the woman's permission first.
 - c. Use a translator to develop written material in languages most commonly encountered in the facility. Develop communication aids about common teaching topics in various languages. Use communication cards with questions and answers printed in Vietnamese with Diep and her husband.

- d. Use posters, pictures, and models (e.g., of the pelvis) to demonstrate anatomy, birth, or other concepts more clearly.

A fluent interpreter is essential because Asians do not always reveal that they do not understand instructions. This hinders follow-up questions. Printed materials help elicit basic information, reinforce information that was given verbally, and may answer unasked questions. Written materials and communication cards in the patient's language convey interest in communicating and provide a means of eliciting basic information. Pictures or models make information more understandable.

3. Face Diep and her husband rather than the interpreter when talking. Use quiet tones. Use the same interpreter whenever possible. Watch facial expressions for a clue to patients' understanding. *Talking directly to the patient while facing her shows respect and concern. Soft speech protects the patient's privacy and modesty. A natural response when people do not understand is to raise the voice. This may convey impatience or anger. A consistent interpreter enhances communication. Facial expressions may show confusion if the patient does not understand.*
4. Ask the interpreter to explain exactly what the nurse says as much as possible instead of paraphrasing. *If the interpreter paraphrases the nurse's words, important information may be lost.*
5. Consider nonverbal factors when communicating.
 - a. Speak slowly and smile when appropriate.
 - b. Keep an open posture. Do not cross the arms over the chest or turn away from the family.
 - c. Listen carefully to what the family says. Nod, lean forward, or encourage continued talk with frequent "uh-huhs."
 - d. Avoid fidgeting or watching a clock.
 - e. Determine Diep's response to a light touch on the arm, and use or avoid touch depending on her response.
 - f. Do not expect prolonged eye contact. *Even subtle body language can indicate interest and empathy or impatience, annoyance, or hurry. Touch and eye contact are sensitive cultural variables, and nurses must be aware that they are not always welcomed.*
6. Locate prenatal classes in which Vietnamese is spoken. Explain what is included in such classes and encourage the couple to attend. *Information is more easily learned in one's own language. Appropriate cultural concerns are likely to be discussed in classes taught in Vietnamese.*

EVALUATION: Diep keeps each prenatal appointment. She brings her husband or an English-speaking friend or family member with her to translate. She follows all recommendations and gradually asks appropriate questions more often at each visit.

understanding by asking the person to repeat the information: “Tell me what you understood” or “Show me what you learned.”

Knowing the “rules” of communication helps the nurse avoid making errors. Hispanics are traditionally diplomatic and tactful. They frequently engage in “small talk” before introducing questions about their care. Nurses must remember that small talk is a valuable use of time. It establishes rapport and helps accomplish the goals of care. American Indians often converse in a low tone that may be difficult to hear in a noisy setting. They may consider note-taking taboo and expect the caregiver to remember what is said (Spector, 2009).

Decision Making. It is important to determine who makes decisions for the family. In some cultures, it is the husband or another family member. In those situations, that person should be present when information is given or when the woman is asked to make decisions such as whether to have prenatal testing (Moore, Moos, & Callister, 2010).

Eye Contact. Many Americans and African-Americans consider eye contact important to communication. Eye-contact avoidance sometimes frustrates health care personnel, who believe that eye contact denotes honesty. However, in some cultures avoiding eye contact is a sign of respect (Spector, 2009). Eye-contact behavior is also important when nurses deal with Latino infants and children. *Mal ojo* (evil eye) is a sudden unexplained illness that may occur when an individual with special powers admires a child too openly. Eye contact between a woman and man may be considered seductive by those from Middle Eastern cultures.

Touch. Touch is also an important component of communication. In some cultures (Hindu, Muslim), touch by a woman other than the wife is offensive to men. Hispanics are more likely to appreciate touch, which may be viewed as a sign of sincerity. However, touch from a male nurse may not be appropriate when the patient is female (Darby, 2007). Nurses must remain sensitive to the response of the person being touched and should refrain from touching if the person indicates it is not welcomed.

Time Orientation

Time orientation can create conflict between health care professionals, who parcel out care in discrete units of time measured in minutes, and groups that keep time by the progress of the sun or seasons. American Indians, Middle Easterners, Hispanics, and American Eskimos tend to emphasize the moment rather than the future. This causes conflicts in a health care setting in which tests or appointments are scheduled at particular times. If a woman does not place the same importance on keeping appointments, she may encounter anger and frustration in the health care setting that leaves her bewildered and ashamed.

Culturally Competent Nursing Care

Culturally competent nursing care requires an awareness of, sensitivity to, and respect for the diversity of the patients served. It involves assessment of the family’s culture and cultural negotiation, when necessary.

Cultural Assessment

Although nurses cannot know all the precise details of every culture, they must be aware of the important aspects of the dominant cultures seen in their practice area and become adept at performing cultural assessment. Questions to help the nurse understand the family’s beliefs about appropriate care during pregnancy include:

- How will you and your family prepare for the baby?
- What concerns do you have about the pregnancy?
- What would provide the greatest assistance?
- Where do you obtain most health care information?

- What foods are encouraged or discouraged?
- Who will be with you during labor and birth of the baby?
- Who will help you at home during the pregnancy and after birth?

Cultural Negotiation

Cultural negotiation involves providing information while acknowledging that the family may hold views that are different from those of the nurse. If the family indicates that the information would be helpful, it can be incorporated into the teaching plan. A woman may not follow medical advice because of cultural beliefs.

If the family indicates that information is not helpful or is harmful in their opinion, the conflict must be acknowledged openly and clarified. “I sense that you are unsure about this. Tell me your concerns about it.” After allowing the family to express their beliefs, the nurse explains why the recommendation was made and works with the family to find a compromise satisfactory to all.

Cultural negotiation also involves sensitivity to specific concerns. For example, nurses must be aware of Islamic laws governing modesty when caring for Muslim women. Some Muslim women must cover their hair, body, arms to the wrist, and legs to the ankles at all times when in the presence of men. A Muslim woman may be prohibited from being alone in the presence of a man other than her husband or a male relative.

When talking to the woman’s significant others the nurse must be sure to call them by the correct name. For example, a Vietnamese or Korean woman usually keeps her maiden name when she marries (Quach, Nguyen, & Nguyen, 2008; Yi, 2008, a,b). Therefore, the husband and wife will have different last names.

APPLICATION OF THE NURSING PROCESS

Psychosocial Concerns

Assessment

The purpose of a psychosocial assessment is to monitor the adaptation of the family to pregnancy, which some consider a maturational “crisis” that requires a major transition in role function and relationships. For some families, pregnancy offers the potential for growth. For others, an alteration in family processes requires guidance and information. Specific needs can be discovered during a thorough psychosocial assessment. Some data such as age, gravida, para, and general health status are obtained during the physical assessment. Table 8-3 identifies areas for assessment, provides sample questions, and indicates nursing implications.

Nursing Diagnosis

Nursing diagnoses are based on data obtained during individual assessments and can vary among families (Box 8-1). Most families strive to maintain the health of the expectant mother and fetus and to complete developmental tasks that help the couple to take on the parent role. Perhaps the most encompassing nursing diagnosis is “Readiness for Enhanced Family Coping,” related to the desire to meet added family needs and assume parenting roles.

TABLE 8-3 PSYCHOSOCIAL ASSESSMENT

NORMAL FINDINGS (FINDINGS OF CONCERN)	SAMPLE QUESTIONS	NURSING IMPLICATIONS
<p>Psychological Response</p> <p>First trimester: uncertainty, ambivalence, mood changes, self as primary focus</p> <p>Second trimester: wonder, joy, focus on fetus</p> <p>Third trimester: vulnerability, preparing for birth (fear, anger, apathy, ambivalence, lack of preparation)</p>	<p>“How do you and your partner feel about being pregnant?”</p> <p>“How will the pregnancy change your lives?”</p> <p>“How do you feel about the changes in your body?”</p> <p>“How are you getting ready for the baby?”</p>	<p>Use active listening and reflection to establish a sense of trust. Reevaluate negative responses (fear, apathy, anger) in subsequent assessments.</p>
<p>Availability of Resources</p> <p>Financial concerns (lack of funds or insurance)</p> <p>Availability of grandparents, friends, family (family geographically or emotionally unavailable)</p>	<p>“What are your plans for prenatal care and birth?”</p> <p>“How do your parents feel about being grandparents?”</p> <p>“Who else can you depend on besides your family?”</p> <p>“Who helps you when there is a problem?”</p>	<p>Determine adequacy of financial means. Refer to resources such as a public clinic for care, Program for Women, Infants, and Children (WIC) for food. Help the couple discover alternative resources if family is unavailable. Identify family conflicts early to allow time for resolution.</p>
<p>Changes in Sexual Practices</p> <p>Mutual satisfaction with changes (excessive concern with comfort or safety, excessive conflict)</p>	<p>“How has your sexual relationship changed during this pregnancy?”</p> <p>“How do you cope with the changes?”</p> <p>“What concerns you most?”</p>	<p>Offer reassurance that intercourse is safe if pregnancy is normal. Suggest alternative positions and open communication.</p>
<p>Educational Needs</p> <p>Many questions about pregnancy, childbirth, and infant care (no questions, absence of interest in educational programs)</p>	<p>“How do you feel about caring for an infant?”</p> <p>“What are your major concerns?”</p> <p>“Where do you get information about pregnancy?”</p>	<p>Respond to needs that are expressed. Refer couple to appropriate child and parenting classes, reliable Internet sources of information.</p>
<p>Cultural Influences</p> <p>Ability of either the woman or her family to speak English or availability of fluent interpreters; cultural influences that support a healthy pregnancy and infant (harmful cultural beliefs or health practices)</p>	<p>“What foods and practices are recommended during pregnancy?”</p> <p>“What is forbidden?”</p> <p>“What is most important to you in your care?”</p> <p>“How do your religious beliefs affect pregnancy?”</p>	<p>Locate fluent interpreters, if needed. Avoid labeling beliefs as “superstition.” Reinforce beliefs that promote a good pregnancy outcome. Elicit help from accepted sources of information to overcome harmful practices.</p>

Planning: Expected Outcomes

Expected outcomes include:

- The expectant parents will verbalize emotional responses that are appropriate to each trimester.
- The family will describe methods to help the expectant parents complete the developmental processes of pregnancy.
- The family will identify cultural factors that may produce conflicts and collaborate to reduce those conflicts.

Interventions

Providing Information

Provide the prospective parents with information and anticipatory guidance to prepare them for the progressive changes that occur during pregnancy, and reassure them that their feelings and behaviors are normal. Guidance also gives them an opportunity to ask questions and explore their feelings. Common subjects include the following:

- The emotional changes that occur during pregnancy
- The developmental tasks of the mother
- Role transition
- The developmental processes of the prospective father

Adapting Nursing Care to Pregnancy Progress

Adapt nursing care to the changes that occur in each trimester of pregnancy. During the first trimester, focus on the woman's acceptance of the pregnancy. Tailor teaching to her feelings (physical and psychological), as this is a period of self-focus. The second trimester is a time to concentrate more on the fetus and how the woman and her family will adapt to the changes resulting from the birth. Ask about her fantasies about the baby and her relationships with significant others. The focus is on the woman's discomforts and readiness to give birth during the third trimester. Observe for signs the mother is having difficulty with any of the tasks or steps throughout pregnancy.

Discussing Resources

Initiate a discussion of the adequacy of the financial situation and support systems, and help couples without financial resources or insurance coverage find a convenient location to obtain prenatal care. This is particularly important for the new poor, who have little knowledge about how to gain access to government-sponsored care. Emotional resources include those that help the new family adjust to the demands of pregnancy and parenting.

BOX 8-1 COMMON NURSING DIAGNOSES USED IN PREGNANCY

Anxiety
 Risk for Impaired Attachment
 Disturbed Body Image*
 Ineffective Childbearing Process
 Readiness for Enhanced Childbearing Process
 Readiness for Enhanced Family Coping*
 Readiness for Enhanced Family Processes
 Interrupted Family Processes
 Risk for Ineffective Health Maintenance*
 Impaired Home Maintenance
 Deficient Knowledge
 Disturbed Personal Identity
 Ineffective Role Performance
 Situational Low Self-Esteem
 Ineffective Sexuality Pattern
 Impaired Verbal Communication*

*Nursing diagnoses explored in this chapter.

Discuss the responses and participation of the grandparents. Although emotional responses vary, the family unit is strengthened and the attachment of the grandparents to the child is enhanced when grandparents actively participate in the pregnancy.

If family members who traditionally offer help in times of stress are unavailable, refer the prospective parents to community resources such as support groups and childbirth education, sibling, breastfeeding, and new parenting classes.

Helping the Family Prepare for Birth

During the last trimester, discuss lifestyle changes that will occur when the infant is born. Unanticipated changes that accompany this dramatic life event may add stress and disrupt family processes. Help the prospective parents make practical plans for the infant, such as obtaining clothing and needed equipment and choosing the method of feeding.

Assist the parents in planning sibling preparation. Older siblings should be prepared several weeks or even months before the birth.

They often benefit from participating in planning for the baby. Younger children have a poor concept of time and can be prepared shortly before the birth.

Suggest the expectant parents consider how they will divide household, parenting tasks, and child care especially if the mother will return to work after childbirth. If these issues are not resolved, the couple can experience frustration and anger when one parent, usually the mother, assumes total care of the infant and attempts to complete all household tasks. Exhaustion and frustration can overwhelm the joys of parenting when one parent must provide all care.

Modeling Communication Technique

When disagreements are evident, discuss and model therapeutic communication techniques that include all significant family members. Techniques to clarify, summarize, and reflect feelings can defuse negative feelings that might result in family disruption (see Chapter 2).

Identifying Conflicting Cultural Factors

Explore possible areas of conflict related to cultural beliefs and health practices that affect pregnancy.

Expectant mothers are reassured when nurses support beneficial health beliefs before confronting them with concerns about health care practices. For example, “The foods you are choosing are very good for you and the baby. I am worried, though, because you missed your last appointment.”

If a conflict occurs because of differences in time orientation, acknowledge the problem, convey understanding of the differences, and emphasize the importance of calling when appointments cannot be kept. Many families do not realize that when they miss an appointment, another family misses the opportunity for health care.

Evaluation

When the family verbalizes concerns and emotions at each visit, the initial goal is met. Continued interest and involvement of the partner and significant family members are evidence that the family has completed the developmental tasks of pregnancy. Participation with health care workers to find a compromise if differing cultural beliefs cause conflict confirms that the family will identify and initiate measures to reduce conflicts.

SUMMARY CONCEPTS

- Maternal psychological responses progress during pregnancy from uncertainty and ambivalence to feelings of vulnerability and preparation for the birth of the infant.
- As the fetus becomes real, usually in the second trimester, maternal focus shifts from the self to the fetus and the woman turns inward to concentrate on the processes taking place in her body.
- Sexual activity varies among couples and may be culturally influenced. It is safe throughout pregnancy if no complications are present.
- Changes in the maternal body during pregnancy may result in a negative body image that affects sexual responses. This change may be especially troubling if the couple does not discuss emotions and concerns related to the changes in sexuality.
- Making the transition to the role of mother involves mimicking the behavior of other mothers, role play, fantasizing about the baby, developing a sense of self as mother, and grieving the loss of previous roles.
- To complete the maternal tasks of pregnancy the woman must seek safe passage for herself and the infant, gain acceptance from significant persons, and learn to be giving while forming an attachment to the unknown child.
- Paternal responses change throughout pregnancy and depend on the ability to perceive the fetus as real, gain recognition for the role of parent, and create a role as involved father.
- The most powerful reality boosters for the expectant father during pregnancy are hearing the fetal heartbeat, feeling the fetus move, and viewing the fetus on an ultrasound.
- In primitive cultures, *couvade* refers to pregnancy-related rituals performed by the man. Today, it refers to a cluster of pregnancy-related symptoms experienced by the man.

Continued

SUMMARY CONCEPTS—cont'd

- The response of grandparents to pregnancy depends on their ages and beliefs about the role of grandparents as well as the number and ages of other grandchildren.
- The response of siblings to pregnancy depends on their ages and developmental levels.
- Completing the developmental tasks of pregnancy is more difficult for multiparas because they have less time, experience more fatigue, and must negotiate a new relationship with the older child or children.
- Socioeconomic status is a major factor in determining health practices during pregnancy. Poor families have competing priorities for food and shelter and seek prenatal care late in pregnancy.
- Cultural differences in language, time orientation, and health beliefs can create conflicts between expectant families and health care workers.

Nutrition for Childbearing

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain the importance of adequate nutrition and weight gain during pregnancy.
2. Compare the nutrient needs of pregnant and nonpregnant women.
3. Describe common factors that influence a woman's nutritional status and choices.
4. Describe the effects of common nutritional risk factors in women on nutritional requirements during pregnancy.
5. Compare the nutritional needs of the postpartum woman who is breastfeeding with those of the woman who is not breastfeeding.
6. Apply the nursing process to nutrition during pregnancy, the postpartum period, and lactation.

At no other point in a woman's life is nutrition as important as during pregnancy and lactation. At this time, she must nourish not only her own body but also that of her baby. Nutrition may affect the size of the fetus and determine whether it has adequate stores of some nutrients after birth. If the woman fails to consume sufficient nutrients during pregnancy, her own stores of some nutrients may be depleted to meet the needs of the fetus, who also may be deprived of essential nutrients.

Nurses have ongoing contact with pregnant women and can provide education about nutrition on a continuing basis. This is especially important because many women do not adequately understand the nutritional needs of pregnancy. Nurses are often able to offer nutrition counseling before conception to women who are considering becoming pregnant. Such counseling increases the chances that a woman will be nutritionally healthy at the time of conception and will continue to practice good nutrition throughout pregnancy. It may also increase the level of nutrition the woman provides for her entire family. Therefore, nutritional education is an essential part of nursing care.

WEIGHT GAIN DURING PREGNANCY

Weight gain during pregnancy, especially after the first trimester, is an important determinant of fetal growth. Insufficient weight gain during pregnancy has been associated with low birth weight (less than 2500 g or 5.5 lb), small-for-gestational age (SGA) infants, preterm birth, and failure to initiate breastfeeding ([Agency for Healthcare Research and](#)

[Quality, 2008](#)). Low weight gain in the second trimester is especially associated with poor infant birth weight, even if overall gain is within the recommended range ([Grodner, Roth, & Walkingshaw, 2012](#)). Lower caloric intake and decreased intake of important nutrients are present when poor maternal weight gain occurs.

Excessive weight gain is also a problem. It is associated with increased birth weight of infants, gestational diabetes, prolonged labor, birth trauma, asphyxia, cesarean birth, low Apgar scores, hypoglycemia, overweight in children, and postpartum weight retention, ([American Dietetic Association \[ADA\], 2008](#); [Viswanathan, Siega-Riz, Moos et al., 2008](#)). Approximately 20% of women gain more than 18 kg (40 lb) during pregnancy ([Centers for Disease Control and Prevention \[CDC\], 2008a](#)). The nutrient intake is even more important than the weight gain itself. Weight gain from a diet lacking in essential nutrients is not as beneficial as weight gain from a balanced diet. It could be inadequate in nutrients such as protein, iron, or folic acid which could cause anemia, neural tube defects, or inadequate fetal nutrient stores.

Recommendations for Total Weight Gain

Recommendations for weight gain during pregnancy have changed considerably over the years. In the late nineteenth century, rickets, a disease of the bones resulting from deficiencies of calcium and vitamin D, caused some women to have small, distorted pelvises. Restricted weight gain kept the fetus small and facilitated delivery. Later, weight gain was limited because of the inaccurate belief that large gains caused preeclampsia.

CRITICAL THINKING EXERCISE 9-1

Cheryl, age 22 years, has gained 4.5 kg (10 lb) more than recommended at 31 weeks of pregnancy. She asks the nurse for help because she is very worried about her weight gain and thinking of starting a severe weight loss diet. She started pregnancy at the upper end of the normal body mass index (BMI) and should gain 25 to 35 lb during the pregnancy. She has no apparent edema and no complications of pregnancy.

Questions

1. Why is Cheryl's weight gain a problem?
2. What suggestions should the nurse make to help Cheryl with her diet?

Weight gain recommendations are based on the woman's prepregnancy body mass index (BMI). BMI is calculated by dividing the weight in kilograms by the height in meters squared. Another method is to divide the weight in pounds by the height in inches squared and multiply the result by 703 (CDC, 2011a). For example, if a woman weighs 56 kg (124 lb) before pregnancy and is 1.63 meters (64 inches) tall, her BMI is 21, which shows normal weight for height. A calculator to measure BMI is available at <http://www.nhlbisupport.com/bmi/>.

Recommended gains vary according to the woman's BMI before pregnancy (Table 9-1). The recommended weight gain during pregnancy is 11.5 to 16 kg (25 to 35 lb) for women who begin pregnancy at normal BMI. The range allows for individual differences because no precise weight gain is appropriate for every woman. It provides a target while allowing for variations in individual needs.

Low prepregnancy weight is associated with preterm labor, SGA, and increased perinatal mortality (Hark & Catalano, 2012). Women who are underweight should gain more to meet the needs of pregnancy as well as their own need to gain weight. They should gain 12.5 to 18 kg (28 to 40 lb).

Obesity is an increasing problem. When obese women become pregnant, they are at higher risk for spontaneous abortion, gestational diabetes, gestational hypertension, preeclampsia, prolonged labor, cesarean birth, congenital anomalies, macrosomia, postpartum hemorrhage, wound complications, thromboembolic disorders, and other postpartum complications (Bond, 2011; Cunningham, Leveno, Bloom, et al., 2010; Stotland, 2009; Yogev & Catalano, 2009). Their children

have an increased risk of childhood obesity (Josefson, 2011). Overweight and obese women should be advised to lose weight before conception to achieve the best pregnancy outcomes.

The current recommended gain for overweight women is 7 to 11.5 kg (15 to 25 lb) to provide sufficient nutrients for the fetus. The weight gain for obese women is 5 to 9 kg (11 to 20 lb). Lower weight gain or weight loss for obese women during pregnancy is not recommended at this time, as evidence about the effect on neurologic development of the infant is insufficient. More research is needed in this area (Rasmussen & Yaktine, 2009). Inadequate gain may cause catabolism of fat stores producing ketones, which may lead to preterm labor (Bond, 2011).

In the past, it was recommended that shorter women should gain only to the lower limits of the recommended range. However, evidence to support these guidelines has not been identified. These women should gain according to recommendations for their BMI (Rasmussen & Yaktine, 2009).

Adolescents should gain weight according to their prepregnancy BMI using adult rather than pediatric BMI categories. Using adult BMI categories may place adolescents in a lighter group who are advised to gain more weight, but additional weight gain in younger adolescents often improves birth outcomes (Rasmussen & Yaktine, 2009).

Another consideration is the woman who is pregnant with more than one fetus. Infants of a multifetal pregnancy are often born before term and tend to weigh less than those born of single pregnancies. A greater weight gain in the mother may help prevent low birth weight. The recommended gain for women of normal prepregnancy weight who are carrying twins is 17 to 25 kg (37 to 54 lb) (Rasmussen & Yaktine, 2009).

CASE STUDY 9-1 INTRODUCTION*

Holly, age 15 years, comes to the clinic for prenatal care at 6 weeks of pregnancy. She is accompanied by her mother, Mrs. H., who is worried about her daughter. Holly attends school and lives with her parents and four younger siblings. Her prenatal exam is normal, and information about nutrition is given along with other first-trimester information.

*Continues on p. 150.

Pattern of Weight Gain

The pattern of weight gain is as important as the total increase in weight. Early and adequate prenatal care allows assessment of weight gain on a regular basis throughout pregnancy. The general recommendation is an increment of about 0.5 to 2 kg (1.1 to 4.4 lb) during the first trimester, when the mother may be nauseated and the fetus needs few nutrients for growth. During the rest of the pregnancy, the weekly expected weight gain ranges and means for various prepregnancy weights are shown in Table 9-1.

Maternal and Fetal Weight Distribution

Women often wonder why they should gain so much weight when the fetus weighs only 3.2 to 3.6 kg (7 to 8 lb). The nurse should explain the distribution of weight to help them understand this need (Figure 9-1).

Factors that Influence Weight Gain

The nurse can positively influence the expectant mother's weight gain by teaching her the importance of her diet for fetal growth. A discussion of the effects of maternal intake on fetal growth and storage of nutrients often motivates women to improve their nutrition. Knowledge of factors that may negatively influence nutrient intake and weight gain helps the nurse devise plans for improving nutrition.

TABLE 9-1 RECOMMENDED WEIGHT GAIN DURING PREGNANCY

WEIGHT BEFORE PREGNANCY	TOTAL GAIN	RANGE AND MEAN OF WEEKLY GAIN (SECOND AND THIRD TRIMESTERS)
Underweight (BMI <18.5)	12.5-18 kg (28-40 lb)	Range: 0.44-0.58 kg (1-1.3 lb) Mean: 0.51 kg (1 lb)
Normal weight (BMI 18.5-24.9)	11.5-16 kg (25-35 lb)	Range: 0.35-0.5 kg (0.8-1 lb) Mean: 0.42 kg (1 lb)
Overweight (BMI 25-29.9)	7-11.5 kg (15-25 lb)	Range: 0.23-0.33 kg (0.5-0.7 lb) Mean: 0.28 kg (0.6 lb)
Obese (BMI ≥30)	5-9 kg (11-20 lb)	Range: 0.17-0.27 kg (0.4-0.6 lb) Mean: 0.22 kg (0.5 lb)

BMI, Body mass index.

NOTE: Weight gain during the first trimester should be 0.5 to 2 kg (1.1 to 4.4 lb).

Data from Rasmussen, K. M., & Yaktine, A. L. (Eds.), (2009). *Weight gain during pregnancy: Reexamining the guidelines*. Washington, DC: National Academies Press.

FIG 9-1 Distribution of Weight Gain in Pregnancy for Women of Normal Prepregnancy Weight. The numbers represent a general distribution because variation among women is great. The component with the greatest fluctuation is the weight increase attributed to extravascular fluids (edema) and maternal reserves of fat.

2. How much weight should the average woman gain during pregnancy? What factors might change this?
3. What pattern of weight gain is recommended for the average woman?

NUTRITIONAL REQUIREMENTS

Nutrient needs increase during pregnancy to meet the demands of the mother and fetus. The amount of increase for each nutrient varies. In most cases, the increases are not large and are relatively easy to obtain through the diet.

Dietary Reference Intakes

In the United States, **dietary reference intakes** (DRIs) are used to estimate nutrient needs. DRIs include the following four categories:

- **Recommended dietary allowance (RDA)**—The amount of a nutrient that is sufficient to meet the needs of almost all (97% to 98%) healthy people in an age group. The actual needs of individuals (particularly for calories and protein) may vary according to body size, previous nutritional status, and usual activity level.
- **Adequate intake (AI)**—The nutrient intake assumed to be adequate when an RDA cannot be determined.
- **Tolerable upper intake level (UL)**—The highest amount of a nutrient that can be taken without probable adverse health effects by most people.
- **Estimated average requirement (EAR)**—The amount of a nutrient estimated to meet the needs of half the healthy people in an age group.

Tables of recommendations are based on a reference individual, a hypothetical person of medium size. These tables are used to calculate nutrient needs based on age, gender, and size. Recommendations for energy, carbohydrate, and protein intakes are shown in [Table 9-2](#). Recommendations for vitamin and mineral intake and food sources are shown in [Table 9-4](#).

Energy

The energy provided by foods for body processes is calculated in kilocalories. **Kilocalories** (commonly called *calories* [the term used in this

TABLE 9-2 RECOMMENDATIONS FOR DAILY ENERGY, CARBOHYDRATE, AND PROTEIN INTAKES FOR WOMEN AGES 15 TO 50 YEARS

NONPREGNANT ADULT FEMALE	PREGNANCY	LACTATION
Energy		
Varies greatly according to body size, age, and physical activity level	First trimester: No change from nonpregnant needs	First 6 months: 330 kcal above nonpregnant needs (with an additional 170 kcal drawn from maternal stores)
<i>Example:</i> Woman, 30 years, active, height 1.65 m (65 inches), weight 50.4 kg (111 lb), body mass index (BMI) 18.5 needs 2267 kcal	Second trimester: 340 kcal above nonpregnant needs	Second 6 months: 400 kcal above nonpregnant needs
Same woman, weight 68 kg (150 lb), BMI 24.99 needs 2477 kcal	Third trimester: 452 kcal above nonpregnant needs	
Carbohydrate		
130 g	175 g	210 g
Protein		
46 g	71 g	71 g

Data from Institute of Medicine, Food and Nutrition Board. (2001). *Dietary reference intakes for energy, carbohydrates, fiber, protein and amino acids (macronutrients)*. Washington, DC: National Academy Press.

book]) refers to a unit of heat and is used to show the energy value in foods. Calories are obtained from carbohydrates and proteins, which provide 4 calories in each gram, and fats, which provide nine calories in each gram.

Carbohydrates

Carbohydrates may be simple or complex. The most common simple carbohydrate is sucrose (table sugar), which is a source of energy but provides no other nutrients. Fruits and vegetables contain simple sugars along with other nutrients. Complex carbohydrates are present in starches such as cereal, pasta, and potatoes. They supply vitamins, minerals, and fiber. They should be the major source of carbohydrates in the diet because of their value in providing other nutrients.

Another type of carbohydrate is fiber, the nondigestible product of plant foods and an important source of bulk in the diet. Fiber absorbs water and stimulates peristalsis, causing food to pass more quickly through the intestines. Fiber helps prevent constipation and also slows gastric emptying, causing a sensation of fullness.

Fats

Fats provide energy and fat-soluble vitamins. When decreasing calories is necessary, a reduction, but not elimination, of carbohydrates and fats is important. If carbohydrate and fat intake provides insufficient calories, the body uses protein to meet energy needs. This use decreases the amount of protein available for building and repairing tissue.

Women often restrict fat to prevent weight gain. However, essential fatty acids such as alpha-linolenic acid and linoleic acid, help in the fetal neurologic and visual development. Docosahexaenoic acid (DHA) is also important for fetal visual and cognitive development. These fatty acids are found in canola, soybean, and walnut oils, as well as some seafood such as bass or salmon (Nichols-Richardson, 2011a).

Calories

Approximately 80,000 additional calories are needed during pregnancy (Hark & Catalano, 2012). These extra calories furnish energy for production and maintenance of the fetus, placenta, added maternal tissues, and increased basal metabolic rate. Most pregnant women need a daily caloric intake of 2200 to 2900 calories, depending on their age, activity level, and prepregnancy BMI (ADA, 2008).

During the first trimester of pregnancy, no added calories are needed. However, the daily caloric intake for adolescent and adult pregnant women should increase by 340 calories during the second trimester and 452 calories during the third trimester (Institute of Medicine, Food and Nutrition Board, [IOM], 2002). This increase can be achieved relatively easily with a variety of foods and only a small increase in food (Table 9-3).

Nutrient Density. The quantity and quality of the various nutrients in each 100 calories of food is the **nutrient density**. Foods of high nutrient density have large amounts of quality nutrients per serving. During pregnancy, the increased need for most nutrients may not be met unless calories are selected carefully. The term *empty calories* refers to foods that are high in calories but low in other nutrients. Many snack foods contain excessive calories and low nutrient density and are high in fat and sodium. Increased calories should be “spent” on foods that provide the nutrients needed in increased amounts during pregnancy.

Women often use sugar substitutes to reduce their caloric intake. Saccharin (Sweet’N Low), sucralose (Splenda), and aspartame (Equal or NutraSweet) are considered safe for normal women during pregnancy. Use of aspartame by women with phenylketonuria can result in fetal brain damage because these women lack the enzyme to metabolize aspartame (Pronsky & Crowe, 2012).

Protein

Protein is necessary for metabolism, tissue synthesis, and tissue repair. The daily protein RDA is 46 g for females, depending on their age and size. A protein intake of approximately 71 g each day is recommended during the second half of pregnancy because of expansion of blood volume and growth of maternal and fetal tissues (Erick, 2012). This is an increase of 25 g of protein daily.

Protein is generally abundant in diets in most industrialized nations. Diets low in caloric intake may also be low in protein, however. If calories are low and protein is used to provide energy, fetal growth may be impaired.

The nurse should teach women at risk for poor protein diets how to determine intake and increase food sources of protein. When a woman needs to increase intake, she should eat more protein-rich foods rather than use high-protein powders or drinks. Protein substitutes increase protein intake but do not have the other nutrients provided by foods.

TABLE 9-3 EXTRA FOODS NEEDED TO MEET PREGNANCY REQUIREMENTS*

Energy (kcal)	1 carrot, 1 slice whole wheat bread, 1 T peanut butter, ½ banana, and 1 cup low-fat milk in 2nd trimester; add 1 oz cheddar cheese in third trimester
Protein	3 oz meat or poultry or 3 c milk or 3.5 oz cheddar cheese or 1 c cottage cheese or 3.75 oz peanuts or 1 c pinto or kidney beans
Iron	½ c raisin bran, or 1 c beef chuck, 1 c pinto beans, and 3 eggs
Thiamin	1.5 oz pork or 2.5 oz peanuts or 1 c brown rice or 1.5 c orange juice
Riboflavin	¾ c low-fat milk or ¾ c low-fat cottage cheese or 1.5 c broccoli or ¾ c cooked spinach or 1¼ egg or 2 chicken drumsticks or 4 oz lean beef
Niacin	2 T peanut butter or 3 oz ground beef or 1.5 oz pork chop or 1.5 oz salmon; also made by body from tryptophan
Vitamin C	2 T orange juice or 1.5 peaches or 1 banana or 1.5 pear or 1 c watermelon or ¼ c tomato juice

c, Cup; kcal, calories; T, tablespoon.

*Examples of foods that would meet the additional requirements of pregnancy for women between ages 19 and 50 years.

Data from U.S. Department of Agriculture, Agricultural Research Service. (2011). *USDA National Nutrient Database for Standard Reference, Release 24*. Nutrient Data Laboratory Home Page. Retrieved from <http://www.ars.usda.gov/ba/bhnrc/ndl>.

Vitamins

Although most people do not eat as much of every vitamin and mineral each day as recommended, true deficiency states for most nutrients are uncommon in North America.

Fat-Soluble Vitamins

Fat-soluble vitamins (A, D, E, and K) are stored in the liver. Deficiency states are not as likely to occur but excessive intake of these vitamins can be toxic. For example, too much vitamin A can cause fetal defects. The nurse should ask about vitamins and medications taken by pregnant women and counsel them about the dangers of excess vitamins (Table 9-4).

Water-Soluble Vitamins

Water-soluble vitamins (B₆, B₁₂, and C; folic acid; thiamin; riboflavin; and niacin) are not stored in the body as easily as fat-soluble vitamins. Therefore, they should be included in the daily diet. Because excess amounts are excreted in urine, the chances of toxicity from excessive intake are lower, but toxicity can occur with megadoses.

Water-soluble vitamins are easily transferred from food to water during cooking. Foods should be steamed, microwaved, or prepared in only small amounts of water. The remaining water can be used in other dishes such as soups.

Folic Acid

Folic acid (also called *folate*) can decrease the occurrence of neural tube defects such as spina bifida and anencephaly in newborns. It may also help prevent cleft lip, cleft palate, and some heart defects (CDC, 2011b; Nichols-Richardson, 2011a). Adequate intake of folic acid is especially important before conception and during the first trimester because the neural tube closes before many women realize they are pregnant. Because about half of pregnancies are unplanned, all women of childbearing age should consume at least 400 micrograms (mcg) (0.4 mg) of folic acid every day. Once pregnancy occurs, daily intake of 600 mcg (0.6 mg) of folic acid is recommended.

Although the CDC recommends a daily folic acid intake of 400 mcg (0.4 mg) for women capable of childbearing, the U.S. Preventive Services Task Force (USPSTF) recommends 400 to 800 mcg (0.4 to 0.8 mg) each day. The dose should be taken for at least 1 month before conception and for 2 to 3 months after conception (USPSTF, 2009). No change has been made in USPSTF's recommendation of 600 mcg (0.6 mg) of folic acid daily for the rest of pregnancy. For women who have previously had a child with a neural tube defect, the recommended dose is 4 mg (4000 mcg) daily during the months before conception (CDC, 2011b).

Women often do not realize the importance of folic acid in their diet before pregnancy begins, and many do not meet the recommended level in spite of a national campaign to make the public more aware of this problem. Inadequate intake of folic acid is the most prevalent vitamin deficiency during pregnancy (Hark & Catalano, 2012). One third of births occur to women ages 18 to 24 years, but women in this group have lower intake of supplements containing folic acid and less knowledge of the need for folic acid than older women (CDC, 2008b). More education is necessary to increase folic acid use in women of childbearing age. Fortunately, since food fortification with folic acid was begun, folic acid deficiency has decreased (CDC, 2012).

A Healthy People 2020 goal is for women of childbearing potential to take in at least 400 mcg of folic acid each day (U.S. Department of Health & Human Services [HHS], 2010). To help achieve adequate intake in the United States and Canada, folic acid is added to breads, cereals, and other products containing enriched flour.

- Why should all women of childbearing age consume 400 mcg of folic acid daily?

Minerals

Although most minerals are supplied in sufficient amounts in normal diets, the intake of iron and calcium may not be adequate before pregnancy (Grodner et al., 2012).

Iron

Iron helps form some enzymes necessary for metabolism and is important in the formation of hemoglobin. During pregnancy, approximately 1000 mg of absorbed iron above maternal iron stores are needed, especially in the second half of pregnancy. This includes 200 mg to compensate for daily losses during pregnancy, 300 mg that is transferred to the fetus, and 500 mg for increased maternal production of red blood cells (Monga, 2009). Maternal red blood cells increase 20% to 30% during pregnancy (Blackburn, 2013). Fetal stores of iron, which double during the last weeks of pregnancy, are important because the infant's intake of iron is low for the first 4 to 6 months after birth. Iron will be transferred to the fetus even if the mother is anemic, but infants will have less stored iron and an increased risk of anemia during the first year (Blackburn, 2013).

Even though iron is better absorbed during pregnancy, it is probably the only nutrient that cannot be supplied completely and easily by the diet. Iron is present in many foods but in small amounts (Table 9-5). The average woman's daily diet contains only about 6 mg of iron for each 1000 calories. In addition, some women restrict their intake of meats and grains in an effort to cut down on fat, carbohydrates, and calories. Menstrual bleeding causes loss of iron. Therefore, women frequently enter pregnancy with low iron stores (Kilpatrick, 2009). A Healthy People 2020 goal is to reduce iron deficiency in pregnant women to 14.5% from a baseline of 16.2% (HHS, 2010).

Approximately 25% of iron from animal sources (called **heme iron**) is absorbed. Only about 5% of **nonheme iron** (from plants and fortified foods) is absorbed (Gallagher, 2012). Absorption of iron is affected by intake of other substances. Calcium and phosphorus in milk and tannin in tea and red wine decrease iron absorption if they are consumed during the same meal. Coffee binds iron, preventing it from being fully absorbed. Antacids, phytates (in grains and vegetables), oxalic acid (in spinach), and ethylenediaminetetraacetic acid (EDTA; a food additive) also decrease absorption. Foods cooked in iron pans contain more iron. Foods containing ascorbic acid and meat, fish, or poultry eaten with nonheme iron-containing foods increase absorption (Gallagher, 2012).

Because of the difficulty of obtaining enough iron in the diet, health care providers often prescribe iron supplements of 30 mg/day. Women who are anemic, have more than one fetus, or begin supplementation late may need 60 to 100 mg daily (Cunningham et al., 2010). Supplementation may begin during the second trimester when the need increases and morning sickness has usually ended. Women who take high doses of iron also need zinc supplements because iron interferes with the absorption and use of this mineral (Nichols-Richardson, 2011a).

TABLE 9-4 RECOMMENDATIONS FOR VITAMINS AND MINERALS

ADULT FEMALES: NONPREGNANT	PREGNANCY AND LACTATION	SOURCES	IMPORTANCE IN PREGNANCY
Vitamins			
Vitamin A			
Ages 14-50: 700 mcg (RDA)*	<i>Pregnancy:</i> Ages 14-18: 750 mcg Ages 19-50: 770 mcg <i>Lactation:</i> Ages 14-18: 1200 mcg Ages 19-50: 1300 mcg	Dark green, yellow, or orange vegetables; whole or fortified low-fat or nonfat milk; egg yolk; butter and fortified margarine	Fetal growth and cell differentiation Excessive intake causes spontaneous abortions or serious fetal defects Isotretinoin (Accutane), a vitamin A derivative for acne, should not be taken during pregnancy because it causes fetal defects
Vitamin D			
Ages 14-50: 600 IU (15 mcg) (RDA)	<i>Pregnancy and lactation:</i> Ages 14-50: 600 IU (15 mcg) (RDA)	Fortified milk, margarine, and soy products; butter; egg yolks Synthesized in skin exposed to sunlight Vegans and those who are not exposed to sun and who do not eat fortified foods need supplements	Necessary for metabolism of calcium Inadequate amounts may cause neonatal hypocalcemia, and hypoplasia of tooth enamel Excessive intake causes hypercalcemia and possible fetal deformities Supplements should be taken with caution
Vitamin E			
Ages 14-50: 15 mg (RDA)	<i>Pregnancy:</i> Ages 14-50: 15 mg <i>Lactation:</i> Ages 14-50: 19 mg (RDA)	Vegetable oils, whole grains, nuts, dark green leafy vegetables	Rarely deficient in pregnant women but deficiency can cause anemia in mother and fetus
Vitamin K			
Ages 14-18: 75 mcg Ages 19-50: 90 mcg (AI)	<i>Pregnancy and lactation:</i> Ages 14-18: 75 mcg Ages 19-50: 90 mcg (AI)	Dark green leafy vegetables Also produced by normal bacterial flora in small intestine	Newborns are temporarily deficient and receive one dose by injection at birth to prevent hemorrhage
Vitamin B₆ (Pyridoxine)			
Ages 14-18: 1.2 mg Ages 19-50: 1.3 mg (RDA)	<i>Pregnancy:</i> Ages 14-50: 1.9 mg <i>Lactation:</i> Ages 14-50: 2 mg (RDA)	Chicken, fish, pork, eggs, peanuts, whole grains, cereals	Increased metabolism of amino acids during pregnancy
Vitamin B₁₂			
Ages 14-50: 2.4 mcg (RDA)	<i>Pregnancy:</i> Ages 14-50: 2.6 mcg <i>Lactation:</i> Ages 14-50: 2.8 mcg (RDA)	Meat, fish, eggs, milk, fortified soy and cereal products	Cell division, increased formation of red blood cells, and protein synthesis
Folic Acid			
Ages 14-50: 400 mcg (RDA)	<i>Pregnancy:</i> Ages 14-50: 600 mcg <i>Lactation:</i> Ages 14-50: 500 mcg (RDA)	Dark green leafy vegetables, legumes (beans, peanuts), orange juice, asparagus, spinach, and fortified cereal and pasta May be lost in cooking	Increased maternal red blood cell (RBC) formation, tissue growth Deficiency in first weeks of pregnancy may cause spontaneous abortion and neural tube defects
Thiamin			
Ages 14-18: 1 mg Ages 19-50: 1.1 mg (RDA)	<i>Pregnancy and lactation:</i> Ages 14-50: 1.4 mg (RDA)	Lean pork, whole or enriched grain products, legumes, organ meats, seeds, nuts	Forms coenzymes necessary to release energy, aids in nerve and muscle functioning Increased need because of greater intake of calories
Riboflavin			
Ages 14-18: 1 mg Ages 19-50: 1.1 mg (RDA)	<i>Pregnancy:</i> Ages 14-50: 1.4 mg <i>Lactation:</i> Ages 14-50: 1.6 mg (RDA)	Milk, meat, fish, poultry, eggs, enriched grain products, and dark green vegetables	Forms coenzymes necessary to release energy, aids in nerve and muscle functioning Increased need because of greater intake of calories

Continued

TABLE 9-4 RECOMMENDATIONS FOR VITAMINS AND MINERALS—cont'd

ADULT FEMALES: NONPREGNANT	PREGNANCY AND LACTATION	SOURCES	IMPORTANCE IN PREGNANCY
Niacin			
Ages 14-50: 14 mg (RDA)	<i>Pregnancy:</i> Ages 14-50: 18 mg <i>Lactation:</i> Ages 14-50: 17 mg (RDA)	Meats, fish, poultry, legumes, enriched grains, milk	Forms coenzymes necessary to release energy, aids in nerve and muscle functioning Increased need because of greater intake of calories
Vitamin C			
Ages 14-18: 65 mg Ages 19-50: 75 mg (RDA)	<i>Pregnancy:</i> Ages 14-18: 80 mg Ages 19-50: 85 mg <i>Lactation:</i> Ages 14-18: 115 mg Ages 19-50: 120 mg (RDA)	Citrus fruit, peppers, strawberries, cantaloupe, green leafy vegetables, tomatoes, potatoes Destroyed by heat and oxidation	Formation of fetal tissue, collagen formation, tissue integrity, healing, immune response, and metabolism
Minerals			
Iron			
Ages 14-18: 15 mg Ages 19-50: 18 mg (RDA)	<i>Pregnancy:</i> Ages 14-50: 27 mg <i>Lactation:</i> Ages 14-18: 10 mg Ages 19-50: 9 mg (RDA)	Meats, dark green leafy vegetables, enriched bread and cereal, dried fruits, tofu, legumes, nuts, blackstrap molasses	Expanded maternal blood volume, formation of fetal red blood cells, and storage in fetal liver for use after birth
Calcium			
Ages 14-18: 1300 mg Ages 19-50: 1000 mg (AI)	<i>Pregnancy and lactation:</i> Ages 14-18: 1300 mg Ages 19-50: 1000 mg (AI)	Dairy products, salmon, sardines with bones, legumes, fortified juice, tofu, broccoli	Mineralization of fetal bones and teeth
Phosphorus			
Ages 14-18: 1250 mg Ages 19-50: 700 mg (RDA)	<i>Pregnancy and lactation:</i> Ages 14-18: 1250 mg Ages 19-50: 700 mg	Dairy products, lean meat, fish, poultry, cereals; high in processed foods, snacks, carbonated drinks	Mineralization of fetal bones and teeth; excessive intake causes binding of calcium in intestines and prevents calcium absorption
Zinc			
Ages 14-18: 9 mg Ages 19-50: 8 mg (RDA)	<i>Pregnancy:</i> Ages 14-18: 12 mg Ages 19-50: 11 mg <i>Lactation:</i> Ages 14-18: 13 mg Ages 19-50: 12 mg (RDA)	Meat, poultry, seafood, eggs, nuts, seeds, legumes, wheat germ, whole grains, yogurt	Fetal and maternal tissue growth, cell differentiation and reproduction, DNA and RNA synthesis, metabolism, acid-base balance
Magnesium			
Ages 14-18: 360 mg Ages 19-30: 310 mg Ages 31-50: 320 mg (RDA)	<i>Pregnancy:</i> Ages 14-18: 400 mg Ages 19-30: 350 mg Ages 31-50: 360 mg <i>Lactation:</i> Ages 14-18: 360 mg Ages 19-30: 310 mg Ages 31-50: 320 mg (RDA)	Whole grains, nuts, legumes, dark green vegetables, small amounts in many foods	Cell growth and neuromuscular function; activates enzymes for metabolism of protein and energy
Iodine			
Ages 14-50: 150 mcg (RDA)	<i>Pregnancy:</i> Ages 14-50: 220 mcg <i>Lactation:</i> Ages 14-50: 290 mcg (RDA)	Seafood, iodized salt	Important in thyroid function Deficiency may cause abortion, stillbirth, congenital hypothyroidism, neurologic conditions

DNA, Deoxyribonucleic acid; RNA, ribonucleic acid.

TABLE 9-5 FOODS HIGH IN IRON CONTENT*

FOOD AND AMOUNT	AVERAGE AMOUNTS OF IRON SUPPLIED (mg)
Meats and Poultry (3 oz serving)	
Beef (average)	2
Chicken	1
Turkey	2
Legumes	
Kidney beans (1 cup [c])	5.2
Lentils (1 c)	6.6
Chickpeas (garbanzo beans) (1 c)	4.7
Lima beans (1 c)	4.5
Peas (1 c) (frozen)	2.4
Peanuts (4 oz)	2.6
Sunflower seeds (¼ c)	1.2
Grains	
Rice, white enriched cooked (1 c)	2.7
Bread, wheat (slice)	0.9
Bagel, plain enriched	4.3
Enriched cereals	7 to 18
Fruits	
Raisins (1 c)	2.7
Apricots, dried (10 halves)	0.9
Prune juice (1 c)	3
Vegetables (1 c)	
Broccoli	1
Collards	2.2
Tomatoes, stewed	3.4
Other	
Tofu, firm, ¼ block	1.3

*The recommended daily allowance for iron during pregnancy is 27 mg. Although many women take supplements because they do not eat enough iron-containing foods in their daily diet to meet this need, iron in foods is often better absorbed. Therefore, the nurse should suggest ways a woman can increase her dietary iron. Data from U.S. Department of Agriculture, Agricultural Research Service. (2011). *USDA National Nutrient Database for Standard Reference, Release 24*. Nutrient Data Laboratory Home Page, <http://www.ars.usda.gov/ba/bhnrc/ndl>.

Iron taken between meals is absorbed more completely, but many women find it difficult to tolerate iron without some food. Iron taken at bedtime may be easier to tolerate. For best results, it should be taken with water or a source of vitamin C such as orange juice, but not with coffee, tea, or milk. Side effects occur more often with higher doses and include nausea, vomiting, heartburn, epigastric pain, constipation, diarrhea, and black stools.

Women should be reminded to keep iron and all other medicines out of the reach of children. Accidental iron overdose is a leading cause of childhood poisoning.

Calcium

Calcium is necessary for bone formation, maintenance of cell membrane permeability, coagulation, and neuromuscular function. It is transferred to the fetus, especially in the last trimester, and is important

for mineralization of fetal bones and teeth. Calcium absorption and retention increase during pregnancy, and it is stored for use in the third trimester when fetal needs are highest.

Although a small amount of calcium is removed from the mother's bones, it is insignificant and mineralization of the woman's bones is usually not affected. A common myth is that calcium is removed from teeth during pregnancy. In reality, the calcium in teeth is stable and not affected by pregnancy.

Dairy products are the best source of calcium. Whole, low-fat, and non-fat milk all contain the same amount of calcium and may be used interchangeably to increase or reduce calorie intake. Women with **lactose intolerance** (lactase deficiency resulting in gastrointestinal problems when dairy products are consumed) need other sources of calcium (**Box 9-1**).

Calcium is also present in legumes, nuts, dried fruits, broccoli, and dark green leafy vegetables. Although spinach and chard contain calcium, they also contain oxalates that decrease calcium availability, making them poor sources. Caffeine increases excretion of calcium. Large amounts of fiber interfere with calcium absorption. More calcium is needed by women younger than 18 years because their bone density is incomplete. The recommendations for calcium intake during pregnancy and lactation are the same as those for nonpregnant women.

Women who do not eat dairy products because of lactose intolerance, to avoid eating animal products or for other reasons, should take supplements unless they can meet their needs with other calcium-rich foods. Calcium should be taken with vitamin D, which increases its absorption. It is better absorbed when taken with meals, separately from iron supplements.

BOX 9-1 CALCIUM SOURCES APPROXIMATELY EQUIVALENT TO 1 CUP OF MILK*

- ¾ cup (c) yogurt
- 1½ ounces (oz) hard cheese
- 1.5 c low-fat cottage cheese
- 1 c calcium fortified orange juice
- 1¾ c ice cream
- 3 c sherbet
- 3½ c pinto beans
- 1/2 block tofu
- 4½ c broccoli
- 1 c cooked collard greens (frozen)
- 6 oz canned salmon with bones
- 3 oz canned sardines with bones

*This list can be used to counsel women who are vegans or lactose intolerant. Lactose-intolerant women can often manage small amounts of yogurt and cheese without distress. Although the amounts of some foods listed are more than would be likely to be eaten within 1 day, they serve for comparison.

Data from U.S. Department of Agriculture, Agricultural Research Service. (2011). *USDA National Nutrient Database for Standard Reference, Release 24*. Nutrient Data Laboratory Home Page, <http://www.ars.usda.gov/ba/bhnrc/ndl>.

Sodium

Sodium needs are increased during pregnancy to provide for an expanded blood volume and the needs of the fetus. Although sodium is not restricted during pregnancy, excessive amounts should be avoided. Women are advised that a moderate intake of salt or the salting of foods to taste is acceptable, but that intake of high-sodium foods (**Box 9-2**) should be limited.

BOX 9-2 HIGH-SODIUM FOODS

- Products that contain the words *salt*, *soda*, or *sodium*, such as table salt, garlic salt, monosodium glutamate, bicarbonate of soda (baking soda)
- Foods that taste salty, including sauerkraut and snack foods such as popcorn, potato chips, pretzels, crackers
- Condiments and relishes such as catsup, chili sauce, horseradish, mustard, soy sauce, bouillon, pickles, green and black olives
- Smoked, dried, and processed foods such as ham, bacon, lunch meats, corned beef
- Canned soups, meats, and vegetables unless the label states the contents are low in sodium
- Canned tomato and vegetable juices
- Packaged mixes for sauces, gravies, cakes, and other baked foods

*During pregnancy, foods high in sodium should be consumed in moderation. Expectant mothers should be taught to read labels and avoid or limit products in which sodium is listed among the first ingredients.

Nutritional Supplementation Purpose

Food is the best source of nutrients. Health care providers usually prescribe prenatal vitamin-mineral supplements, and they are seen as an important part of pregnancy by many women. However, women with adequate diets may not need supplements except for iron and folic acid, which are often not obtained in adequate amounts through normal food intake. Expectant mothers who are vegetarians, lactose intolerant, or have special problems in obtaining nutrients through diet alone may need supplements. Assessment of each woman's individualized needs determines whether supplementation is appropriate.

Disadvantages and Dangers

Because they believe supplements are a harmless way to improve their diets, some women take large amounts without consulting a health care provider. No standardization or regulation of the amounts of ingredients contained in supplements is available at this time. Some supplements may not have the amount of an ingredient that is listed on the label and may not fulfill the health claims made for it.

The use of supplements may increase the intake of some nutrients to doses much higher than recommended. Excessive amounts of some vitamins and minerals may be toxic to the fetus. Vitamin A can cause fetal anomalies of the bones, urinary tract, and central nervous system when taken in high doses. Large amounts of vitamin A are taken by women using the drug isotretinoin (Accutane) for acne. High doses of some vitamins or minerals may interfere with the ability to use others. If women understand this, they are less likely to exceed recommended doses.

Some women believe their nutrient needs can be met by vitamin-mineral supplements and are less concerned about their food intake. Supplements do not generally contain protein and calories and may lack many necessary nutrients. Nurses must emphasize that supplements are not food substitutes and do not contain all the nutrients needed during pregnancy. In fact, some nutrients that are important to pregnancy and provided by foods may be unknown at this time.

CASE STUDY 9-1 PREGNANT WOMEN WANT TO KNOW*

At her next visit, Holly says she is taking extra prenatal vitamins to make up for any vitamins she does not get from her diet. The nurse includes the following in her teaching:

- Take only vitamin and mineral supplements prescribed by your health care provider. Over-the-counter supplements may not be formulated to meet your individual needs and could be harmful to you and your baby.
- Do not take more than the prescribed amount of supplements. Taking too much of some vitamins or minerals may interfere with the use of others, which could harm you or your baby.
- Take iron between meals, if possible. If you have nausea, heartburn, constipation, or diarrhea, try taking your iron at bedtime or with meals or a snack. To increase absorption, take iron with orange juice or another source of vitamin C. Do not take iron with calcium supplements, milk, tea, or coffee because these substances decrease absorption.
- Keep all vitamin and mineral supplements away from children because they may cause accidental poisoning.

*Continued from p. 143; continues on p. 155.

Water

Water is important during pregnancy for the expanded blood volume and as part of the increased maternal and fetal tissues. Women should drink approximately 8 to 10 cups (1920 to 2400 mL) of fluids that are mostly water each day (Erick, 2012). Fluids low in nutrients (such as carbonated beverages, coffee, tea, or juice drinks that contain high amounts of sugar and little real juice) should be limited because they are filling and replace other more nutritional foods and drinks.

Food Plan

The U.S. Department of Agriculture (USDA) MyPlate provides a guide for healthy eating for adults and children. Guidelines for pregnancy and lactation are discussed later and summarized in Table 9-6. Pregnant women can go to the website www.choosemyplate.gov to get an individualized diet plan specifically adapted for them and their needs during pregnancy.

Whole Grains

Breads, cereals, rice, and pastas provide complex carbohydrates, fiber, vitamins, and minerals. At least half of the daily servings should be whole grains because they provide more nutrients compared with processed grain products. Although foods can be enriched to replace some nutrients lost during processing, not all nutrients are restored by enrichment. MyPlate recommendations are for 6 oz each day for adult women. Pregnant women should have 7 to 9 oz, and lactating women should have 9 oz daily.

Vegetables and Fruits

Vegetables and fruits are important sources of vitamins, minerals, and fiber. The daily recommendation for vegetables for nonpregnant adult women is 2.5 cups, 3 to 3.5 cups for pregnancy, and 3 cups for lactation. Adult women should have 2 cups of fruit daily. Pregnant and lactating women should also have 2 cups of fruit daily. A wide range of vegetables and fruits provides the best nutrition. Dark green and orange or dark yellow vegetables are especially nutritious.

Dairy Group

The dairy group includes foods such as milk, yogurt, and cheese. They contain approximately the same nutrient values whether they are whole (4% fat), low fat (2% fat), or nonfat (skim), but calories and fat

TABLE 9-6 FOOD PLAN FOR PREGNANCY AND LACTATION

FOOD AND AMOUNTS PER SERVING	RECOMMENDED INTAKE FOR PREGNANCY*	RECOMMENDED INTAKE FOR LACTATION†
Whole grains (1 oz = 1 slice bread, ½ c rice or pasta)	7-9 oz	9 oz
Vegetables	3-3.5 c	3 c
Fruits	2 c	2 c
Dairy group (1 c milk or yogurt, 1.5 oz hard cheese, 2 c cottage cheese)	3 c	3 c
Protein group (1 oz meat/poultry/fish, 1 egg, ¼ c cooked beans, ¼ c tofu, 1 tbsp peanut butter)	6-6.5 oz	6 oz

c, Cup; oz, ounce; *tbsp*, tablespoon.

*Example for a woman 5 feet, 4 inches tall weighting 125 lb before pregnancy. Specific individualized food plans can be found at www.choosemyplate.gov.

†Amounts are for exclusive breastfeeding. If formula is also being used, 1 oz less grains, ½ c less vegetable, and ½ oz less of meat or beans is recommended.

Data from www.choosemyplate.gov. and U.S. Department of Human Services, Office of Women's Health. (2011). *Your guide to breastfeeding*. Washington DC: Author.

are less in the latter two. The dairy group has especially good sources of calcium. Adult women and those who are pregnant or lactating need 3 cups or the equivalent from this group.

Protein Group

Many adults think of meat, poultry, fish, and eggs as the only sources of protein. However, legumes (e.g., beans, peas, lentils), nuts, and soybean products such as tofu are also good sources. Adult women should consume 5 to 5.5 oz or the equivalent each day. Pregnant women need 6 to 6.5 oz and lactating women need 6 oz of protein foods daily. A typical portion of meat, fish, and poultry varies in size. A 3-oz portion is about the size of a deck of playing cards.

Other Elements

Concentrated sugars, fats, and oils should be eaten sparingly. They provide calories for energy but few other nutrients. An adequate allowance for oils for adult women is 5 to 6 teaspoons of unsaturated oils. Pregnant women need 6 to 8 teaspoons and lactating women need 6 teaspoons of unsaturated fats daily. Foods containing saturated fats and *trans* fatty acids should be avoided.

Food Precautions

Although fish are an excellent source of nutrients, certain precautions should be taken. Large fish often have high levels of mercury, which can damage the fetal central nervous system. Pregnant and lactating women should avoid those fish. Other types of fish have smaller amounts of mercury and can be eaten weekly (U.S. Food and Drug Administration [FDA], 2011). Raw fish may contain parasites or bacteria and should also be avoided.

SAFETY ALERT

Food Safety during Pregnancy and Lactation

- Do not eat shark, swordfish, king mackerel, and tilefish.
- Eat up to 12 oz shrimp, salmon, pollack, catfish, and canned light tuna, (but only 6 oz white albacore tuna) each week.
- Do not eat raw or undercooked fish, meat, poultry, or eggs.
- Avoid luncheon meats and hot dogs unless reheated until steaming hot.
- Avoid soft cheeses unless made with pasteurized milk.
- Do not consume refrigerated pâté, meat spreads, or smoked seafood.
- Do not consume raw (unpasteurized) milk or milk products.

Some foods may be contaminated with *Listeria monocytogenes*, which may cause listeriosis. If contracted during pregnancy, listeriosis may result in abortion, stillbirth, or severe illness of the newborn. More information about food safety during pregnancy can be obtained from the FDA website at www.fda.gov.

Eggs can be contaminated with harmful bacteria and should not be eaten unless fully cooked. Only eggs that have been pasteurized in the shell are safe to eat raw or partially cooked. Unpasteurized juices, cold deli salads, and raw sprouts should also be avoided. Eating meat that is raw or undercooked or unwashed fruits or vegetables may cause toxoplasmosis with severe consequences to the fetus. Toxoplasmosis can also be contracted by contact with cat feces.

FACTORS THAT INFLUENCE NUTRITION

Age, knowledge about nutrition, exercise, and cultural background influence the food choices women make and their nutritional status. The nurse must consider these factors when counseling women about their diets.

Age

Age is an important consideration. The adolescent who is not fully mature needs nutritional support for her own growth (see page 156). Older women who are in good health have the same nutritional requirements as younger pregnant women. They may have more knowledge about nutrition through life experiences or need as much teaching as younger women. Older women are more likely to be financially secure compared with very young women.

Nutritional Knowledge

Once pregnancy is confirmed, even women who have not previously been attentive to their diets often want to learn about the relationship between what they eat and the effect on the fetus. Although women know they should “eat well” during pregnancy, they may have little idea of what that means. Some lack basic understanding of nutrition and have misconceptions based on common food myths that interfere with good nutritional choices. They may seek information about nutrition

from books, magazine articles, TV, and the Internet. They benefit by receiving nutritional education from nurses.

Exercise

Moderate exercise during pregnancy is encouraged. Women who exercise more strenuously or are athletes may need modifications of their diet to meet additional nutritional needs. Extra calories may be needed to restore the energy used during exercise. A serving of fruit, yogurt, or pasta before and after exercise may be sufficient. Additional fluids should be taken during and after exercise as well.

Culture

Food is important in all cultures and often has special meaning during pregnancy and childbirth when certain foods may be favored or discouraged. Nurses need to know about the habits of a variety of cultures so that they can provide culturally appropriate nutritional counseling. Before making assumptions about the influence of a woman's culture on her diet, the nurse must assess each woman individually. Not all women follow food practices considered typical for their cultures.

The nurse should assess the woman's age, how long she has lived in North America, and whether she has adopted any common American eating habits. Greater exposure to North American diet may cause younger members of a group to make more dietary changes compared with their older relatives. Some women who usually follow an American diet may return to some aspects of their traditional cultural diet during pregnancy to "make sure" they do not harm the fetus.

Nurses often give women pamphlets in the appropriate language during nutritional teaching.

Before giving a woman printed materials, the nurse should determine if the woman can read English or her native language. People who cannot read may not readily admit it to others. In addition, the reading level may be too complicated for a woman with little education. Having an interpreter discuss the material with the woman helps determine how well she can read and aids in other teaching.

People of many cultures believe that certain foods, conditions, and medicines are "hot" or "cold" and must be balanced to preserve health. Foods considered hot in one culture may not fit in that category in another culture, and the designation does not necessarily match the temperature or spiciness of the food. In the Chinese culture, this belief is expressed with terms such as *yin* for cold and *yang* for hot and may influence what the mother eats during pregnancy and the postpartum period.

Food taboos may determine what some women eat during the childbearing period. For example, Samoan women avoid eating octopus or raw fish during pregnancy. Haitian women believe they should eat for two and eat a hearty diet with lots of red fruits and vegetables (Etienne & Pavlovich-Danis, 2010). They also believe eating white foods such as milk, white beans, and lobster after birth will increase the lochia. Some Asians believe that vitamin preparations that contain iron harden the bones, making birth more difficult (Callister, 2008). Chinese women may avoid spicy foods such as chili peppers but eat bird's nests, considered a delicacy (Callister, Eads, & Diehl, 2011).

Special foods may be customary during pregnancy or after birth. Punjabi women may drink milk to prevent melasma (Grewal, Bhagat, & Balneaves, 2008). A Korean family may bring the new mother a hot beef and seaweed soup to cleanse her body and increase breast milk production (Callister, 2008).

Cultural preferences for foods are extremely varied. For example, some African-Americans follow a diet similar to that of people living in the southeastern United States. Common foods include okra, collard greens, mustard greens, ham hocks, black-eyed peas, and hominy or grits. The diet of other African-Americans, however, varies according

to the geographic area in which they live. Lactose intolerance is common and results in a lack of calcium if other sources are not present in the diet. Intake of high-sodium and fried foods may present health problems.

Some Jewish women follow a strictly kosher diet. They avoid meat from animals that do not have cloven hooves or do not chew their cud, which excludes pork and pork products. The meat must be processed to remove all blood and cannot be eaten in the same meal as milk. Muslim women also do not eat pork and may fast on certain days. Although the religion exempts pregnant and nursing women from obligatory fasting, the woman must make up the fasting days at another time. Some choose to fast, regardless, for spiritual reasons, or so they do not have to make up the days later (Kridli, 2011).

The diet of Native American women may contain blue cornbread, potatoes, wild greens, legumes, nuts, tomatoes, and squash. Lactose intolerance is common, and milk and cheese are avoided. Meats may include wild game and poultry. Fried dough ("fry bread") is frequently served (Schlenker & Roth, 2011). Low-income Native Americans may receive food vouchers from the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC).

Food preferences for two cultures, Southeast Asian and Hispanic, are explored further here to show the influence of culture on diet. Immigrants from Southeast Asia are likely to follow diets similar to those in their homelands. Hispanics are a large minority group in the United States. Nurses throughout the United States need information about food preferences prevalent in these groups.

Southeast Asian Dietary Practices

Southeast Asians include those from Cambodia, Laos, and Vietnam. Traditional cooking methods in these countries include searing fresh vegetables quickly with small portions of meat, poultry, or fish in a little oil over high heat. Meals cooked in this manner are low in fat and retain vitamins. Most meals are accompanied by rice, which increases the intake of complex carbohydrates, and soup. White rice is usually preferred over brown rice. A salty fish sauce called *nuoc mam* is also part of most meals (Appel, 2013). Tofu and fresh fruits are frequent additions.

Many Southeast Asians eat American foods along with their traditional diet. Such foods as eggs, beef, pork, and bread add nutrients but also fat to the diet. Candy, soft drinks, coffee, butter or margarine, and fast foods have been less favorable influences because they are low in nutrients but high in sugar or fat.

Effect of Culture on Diet during Childbearing. In Southeast Asian cultures, pregnancy (especially the third trimester) is considered "hot," and women eat "cold" foods to maintain a balance. The diet includes sour foods, fruits, noodles, spinach, and mung beans and avoids fish, excessively salty or spicy foods, alcohol, and rice. Unfamiliar foods are avoided for fear they may harm the mother or her fetus.

The postpartum period is considered "cold," partly because of the loss of blood, which is "hot." Mothers avoid losing more heat, which would negatively affect their health. They stay warm physically and choose to eat "hot" foods, including rice with fish sauce, broth, salty meats, fish, chicken, and eggs. They may refuse cold drinks but welcome hot fluids, requesting tea or plain hot water. The family frequently brings food to the mother while she is in the hospital because hospital food may not meet her preferences.

Increasing Nutrients with Traditional Foods. Milk products are not part of the traditional Southeast Asian diet, and lactose intolerance is common. Soy milk may be used instead. Increasing the intake of commonly used dark green leafy vegetables such as mustard greens, bok choy, and broccoli increases calcium, iron, magnesium, and folic acid intake. Tofu is a good source of calcium and iron. A broth made

from pork or chicken bones soaked in vinegar, which removes calcium from the bones, is frequently served. If the mother avoids fortified milk, she may need vitamin D supplementation. Increasing the intake of meats and poultry elevates levels of protein, iron, vitamin B₆, and zinc.

Hispanic Dietary Practices

Spanish-speaking people such as Mexican-Americans, Puerto Ricans, and Cuban-Americans are often referred to as *Hispanics* or *Latinos*. Like Asians, many Hispanics follow the theories of “hot” and “cold” foods and conditions. They also consider pregnancy to be “hot” and the postpartum period to be “cold” and adjust the diet accordingly. During pregnancy, Hispanic women may not take prenatal vitamins or iron because they are considered “hot” or may take a “cold” food such as fruit juice to neutralize the effect (Callister, 2008).

Dried beans (especially pinto beans) are a staple of the Mexican-American diet and are part of most meals, served alone, as refried beans, or mixed with other foods such as rice. The major grain is corn, which is ground and made into a dough called *masa* to make corn tortillas. The corn is treated with lime and is a good source of calcium. Corn or flour tortillas are eaten with most meals. Rice is also an important grain. Many Hispanics are lactose intolerant, and milk is not commonly used. However, cheese is used in many dishes. Chili peppers and tomatoes are the most common vegetables. Green leafy and yellow vegetables are seldom included.

Hispanic foods are often hot, spicy, and fried. The diet is high in fiber and complex carbohydrates. However, it also tends to be high in calories and fat, leading many Mexican-Americans to become overweight.

Puerto Rican and Cuban diets are similar to that of Mexican-Americans, with the addition of tropical fruits and vegetables from the homeland, when available. *Viandas* (starchy fruits and vegetables such as plantains, green bananas, white and sweet potatoes, and chayote squash) are common. They may be cooked with codfish and onion. Guava, papaya, mango, and eggplant also are used when available.

NUTRITIONAL RISK FACTORS

The nurse must identify factors that may interfere with a woman’s ability to meet the nutritional needs of pregnancy.

Socioeconomic Status

Poverty

Low-income women may have deficient diets because of lack of financial resources and nutritional education. Carbohydrate foods are often less expensive than meats, dairy products, fresh fruits, and vegetables. Therefore, the diet may be high in calories but low in vitamins and minerals. A referral to Temporary Assistance for Needy Families (TANF) or WIC may be helpful if a woman’s food intake is inadequate because of lack of money. Vitamin-mineral supplementation may be important, especially if her diet is likely to be inconsistent. Low-income families may experience food shortages at the end of the month when resources are depleted or when food is shared with a large number of people (Barron, 2008).

Food Supplement Programs

The WIC program is administered by the USDA to provide nutritional assessment, counseling, and education to low-income women and children up to age 5 years who are at nutritional risk. The program also provides vouchers for foods such as milk, cheese, tofu, eggs, whole wheat bread, brown rice, tortillas, fruits and vegetables, iron-fortified cereal, juice, legumes, peanut butter, and formula to qualified women

and their children. Eligibility is based on an income at or below 185% of the federal poverty level. Women are eligible throughout pregnancy and for 6 months after birth if formula feeding or 1 year if breastfeeding. Children at risk for poor nutrition may be eligible until 5 years of age. Further information is available at www.fns.usda.gov/wic

CHECK YOUR READING

- When the nurse assesses cultural influences on nutrition during pregnancy, what factors must be considered?
- For what nutritional problems should the nurse assess when caring for low-income women?

Vegetarianism

A **vegetarian** is a person who eats only or mostly plant foods. It occurs in a variety of forms. **Vegans** avoid all animal products and may have the most difficulty meeting their nutrient needs. Their diet may be lacking in adequate calcium, iron, zinc, riboflavin, and vitamins D, B₆, and B₁₂ (Bond, 2011; Stotland, 2009). Vegans must pay particular attention to obtaining these nutrients in food or supplement form. It is easier for **lactovegetarians** (those whose diet includes milk products), **ovovegetarians** (those who include eggs), and **lacto-ovovegetarians** (those who include milk products and eggs) to meet their nutrient needs.

Although not true vegetarianism, a diet that eliminates red meats to decrease intake of saturated fats and cholesterol is a growing trend. Women who follow this type of diet usually eat small amounts of chicken, fish, and dairy products.

Although the knowledgeable vegetarian may eat a very nutritious diet, she is at higher risk during pregnancy. If she is new to vegetarian food practices, uninformed about pregnancy needs, or careless with her diet, she could fail to meet her nutrient needs.

Meeting the Nutritional Requirements of the Pregnant Vegetarian

Energy. Vegetarian diets may be low in calories and fat and some do not meet the energy needs of pregnancy. The diets are high in fiber and may cause a feeling of fullness before enough calories are eaten. A pregnant woman can increase caloric intake by eating snacks and higher calorie foods. If carbohydrate and fat intakes are too low, her body may use protein for energy, making it unavailable for other purposes.

Protein. Although most vegetarians get enough protein, this area needs consideration, especially in vegan diets. **Complete proteins** contain all the **essential amino acids** (amino acids the body cannot synthesize from other sources). Animal proteins are complete, but plant proteins (with the exception of soybeans) are **incomplete proteins**, lacking one or more of the essential amino acids.

However, even a diet with only plant proteins can meet the needs of pregnancy (Penny & Miller, 2008). Combining incomplete plant proteins with other plant foods that have complementary amino acids allows intake of all essential amino acids. Dishes that contain grains (e.g., wheat, rice, corn) and legumes (e.g., garbanzo, navy, kidney, or pinto beans; peas; peanuts) are combinations that provide complete proteins. Complementary proteins do not have to be eaten at the same meal if they are consumed in a single day.

Incomplete proteins can also be combined with small amounts of complete protein foods such as cheese or milk to provide all amino acids. Therefore, women who include even small amounts of animal products meet their protein needs more easily.

Many vegetarians use tofu, made from soybeans, which provides protein as well as calcium and iron. Meat analogs that have a texture similar to meat but are made from vegetable protein are available. Some look and taste like hamburgers, bacon, lunch meats, chicken patties, and other commonly eaten foods. Meat analogs may be fortified with nutrients that are often low in vegan diets.

Calcium. Vegetarians who include milk products in their diet may meet the pregnancy needs for calcium. Vegans obtain calcium from dark green vegetables and legumes, but their high-fiber diet may interfere with calcium absorption. Calcium-fortified juices or soy products such as soy milk or tofu may meet the requirements. Calcium supplements may be necessary. Vitamin D supplementation is especially important if the woman drinks no milk and has little exposure to sunlight. Soy milks may be enriched with vitamin D.

Iron. Iron from plants in the vegetarian diet is poorly absorbed. Absorption is enhanced by eating a source of vitamin C in the same meal in which nonheme iron is consumed or by preparing food in iron pans. Iron supplements are particularly important for vegetarian women during pregnancy.

Zinc. Because the best sources of zinc are meat and fish, vegetarians may be deficient in this mineral. Fortified cereals, nuts, and dried beans increase zinc intake. Vegans may need zinc supplements to meet their needs.

Vitamin B₁₂. Vitamin B₁₂ is obtained only from animal products. Because vegetarian diets contain large amounts of folic acid, anemia from inadequate intake of vitamin B₁₂ may not be apparent at first. Vegans may eat fortified foods such as cereal and soy products or take B₁₂ supplements.

Vitamin A. Vitamin A is generally abundant in vegetarian diets. If a pregnant vegetarian takes a multiple vitamin-mineral supplement, her intake of vitamin A may be excessive. Toxic effects include anorexia, irritability, hair loss, dry skin, and damage to the fetus. Supplementation should be individualized for each woman on the basis of her diet and needs.

Lactose Intolerance

Lactose intolerance is caused by a deficiency of the small intestine enzyme lactase necessary for absorption of lactose, a milk sugar. Some degree of lactose intolerance is normal for most of the world's population after early childhood. This includes many African-American, Hispanic, Asian, Pacific Islander, Native American, and Middle-Eastern people. Although those with lactose intolerance may tolerate cultured and fermented milk products such as aged cheese, buttermilk, and some brands of yogurt, symptoms may occur after drinking as little as one cup of milk. Symptoms include nausea, bloating, flatulence, diarrhea, and intestinal cramping.

Although the ability to tolerate lactose may increase during pregnancy, women who avoid dairy foods may not get the recommended amounts of calcium. Most women can tolerate small amounts (1/2 cup) of milk with meals, and they should increase their intake of other foods that provide calcium. Soy milk, low-lactose milk, and milk treated with lactase are available. The enzyme can be purchased to be added to milk or taken as a tablet. Nondairy sources of calcium should be increased (see [Box 9-1](#)). Calcium supplements may be necessary for some lactose-intolerant women.

Nausea and Vomiting of Pregnancy

Morning sickness usually disappears soon after the first trimester, although some women experience nausea at other times of the day and for a longer time. Most women can consume enough food to maintain nutrition sufficiently. They are often able to manage frequent small meals better than three large meals. Protein and complex

carbohydrates are often tolerated best, but fatty foods increase nausea. Drinking liquids between meals instead of with meals often helps. Eating a bedtime protein snack helps maintain glucose levels through the night. A carbohydrate food such as dry toast or crackers eaten before getting out of bed in the morning helps prevent nausea (see [Case Study 7-1, page 107](#)).

Anemia

Anemia is a common concern during pregnancy. Hemoglobin values decrease during the second trimester of pregnancy as a result of plasma increases diluting the blood. This physiologic anemia is normal (see [Chapter 7](#)). During the third trimester, hemoglobin levels generally rise to prepregnant levels because of increased absorption of iron from the gastrointestinal tract, even though iron is transferred to the fetus primarily during this time.

A woman may begin pregnancy with anemia or develop it during pregnancy. She is considered anemic if her hemoglobin is less than 11 grams per deciliter (g/dL) or her hematocrit is less than 33% during the first and third trimesters or the hemoglobin is less than 10.5 g/dL or hematocrit is less than 32% in the second trimester ([Cunningham et al., 2010](#)).

Iron stores may be measured by determining the serum ferritin level. A ferritin level less than 10 nanograms per 100 mL indicates that the anemia is caused by iron deficiency ([Pagana & Pagana, 2011](#)). If fetal iron stores during the third trimester are sufficient, anemia will not develop in the newborn for the first 4 to 6 months after birth. However, if the woman's intake of iron is insufficient, her hemoglobin levels may not rise during the third trimester, iron deficiency anemia may develop, and transfer of iron to the fetus may be decreased. Iron deficiency anemia occurs in as many as 47% of pregnant women ([Kilpatrick, 2009](#)). Anemic women need iron supplements and help choosing foods high in iron (see [Table 9-5](#)).

Abnormal Prepregnancy Weight

In addition to teaching about dietary changes, the nurse should be alert for problems associated with abnormal prepregnancy weight. The woman who is below normal weight may not have enough money for food or may have an eating disorder. Obese women may have other health problems such as hypertension that may affect the nurse's nutritional counseling plan.

Eating Disorders

Eating disorders include [anorexia nervosa](#) (refusal to eat because of a distorted body image and feelings of obesity) and [bulimia](#) (overeating followed by induced vomiting, fasting, or use of laxatives or diuretics). These conditions can be a threat to pregnancy and fetal development and require close supervision during pregnancy. They are associated with miscarriage, low birth weight, preterm birth, congenital anomalies, and postpartum depression ([Wisner, Sit, Altemus et al., 2012](#)). Women with anorexia often have amenorrhea and have difficulty conceiving. Women with bulimia or subclinical anorexia are more likely to become pregnant. All women should be asked about eating disorders, and nurses should assess for behaviors that may indicate disordered eating.

Some women with these disorders eat normally during pregnancy for the sake of the fetus. For others, the normal weight gain of pregnancy may be very stressful as old fears about obesity are reactivated. They may return to their previous eating patterns during pregnancy or in the early postpartum period when they do not lose weight immediately. Explaining that women often lose weight during breastfeeding may encourage them to breastfeed and eat a good diet during lactation ([Carwell & Spatz, 2011](#)). Women with eating disorders need a great deal of individual counseling to ensure that they meet the increased nutrient needs of pregnancy and understand normal postpartum weight

loss. Assessment of weight gain at each prenatal visit is especially important.

Food Cravings and Aversions

Women may have a strong preference or a strong dislike for certain foods that is present only in pregnancy. Cravings for pickles, ice cream (not necessarily together), pizza, chocolate, cake, candy, spicy foods, and dairy products are common. Food aversions often include those to coffee, alcoholic beverages, highly seasoned or fried foods, and meat. The cause of cravings and aversions is not known, but they may be a result of changes in the sense of taste and smell. They are generally not harmful, and some, like aversion to alcohol, may be beneficial.

Satisfying food cravings during pregnancy is thought important in many cultures. For example, women from India may believe cravings during pregnancy should be satisfied because they come from the fetus (Chatterjee, 2008). Ethiopian women may believe that unfulfilled food cravings during pregnancy may cause miscarriage (Spector, 2009).

Pica

Some women have cravings for nonnutritive substances. The practice of eating substances not usually considered part of a normal diet is called **pica**. Ice, clay or dirt, and laundry starch or cornstarch are the most common materials, but other items such as chalk, baking soda, antacid tablets, coffee grounds, freezer frost, toothpaste, burnt matches, or ashes may be included (Bond, 2011; Gordon, 2012; Nichols-Richardson, 2011a).

Pica is practiced by about 20% of pregnant women (Nichols-Richardson, 2011a). It is more common in women from inner cities, rural areas, and the southeastern United States; African-Americans; women who live in poverty and have poor nutrition; and those with a childhood or family history of the practice. However, pica is not limited to any one socioeconomic group or geographic area. Pica may be present before pregnancy occurs.

The cause of pica is unknown, although cultural values may make pica a common practice. Pica may be related to beliefs regarding the effects of the substance on labor or the baby. Some women believe it relieves nausea and vomiting (Erick, 2012). Iron deficiency is often associated with pica, and the woman should be tested to see if she needs additional iron supplementation (Hark & Catalano, 2012). Clay and dirt are not sources of iron and may decrease the absorption of iron and other minerals (Grodner et al., 2012).

Substances eaten may be contaminated with parasites, other organisms, or toxins such as lead. Clay and dirt may cause constipation or intestinal blockage. Eating large amounts of ice may cause dental problems. Another concern with pica is that it decreases the intake of foods and essential nutrients. Some women fear that their eating habits are harmful but are unable to ignore the cravings. They often keep their eating practices from caregivers who might disapprove.

CASE STUDY 9-1 CRITICAL THINKING EXERCISE*

At 16 weeks of pregnancy, Holly returns to the clinic. She very hesitantly confides to the nurse that she eats large amounts of ice. She buys bags of crushed ice each day. "I know I'm supposed to gain weight if I'm pregnant, but I'm just not hungry for anything besides ice. Her weight gain is slightly under what would be expected at this time.

Questions

1. What might happen if Holly believes the nurse disapproves of her actions?
2. How should the nurse handle this situation?

*Continued from p. 150; continues on p. 157.

Multiparity and Multifetal Pregnancy

The number and spacing of pregnancies and the presence of more than one fetus influence nutritional requirements. The woman who has had previous pregnancies may begin a pregnancy with a nutritional deficit. In addition, she may be too busy meeting the needs of her family to be attentive to her own nutritional needs.

Pregnancies spaced 18 to 23 months apart are healthier for the mother and the fetus. An interval of less than 6 months between pregnancies increases the risk of preterm and low birthweight infants as well as maternal morbidity and mortality (Reinold, Dalenius, Brindley et al., 2011).

Closely spaced pregnancies may not allow a woman to remedy any nutritional deficits originating during a previous pregnancy. If she has inadequate nutrient stores, she must meet nutritional needs from her daily diet and supplementation alone. Morning sickness from a new pregnancy soon after delivery may further interfere with an expectant mother's ability to eat an adequate diet.

The woman with a multifetal pregnancy must provide enough nutrients to meet the needs of each fetus without depleting her own stores. She needs more calories to meet her weight gain and energy needs. A woman of normal prepregnancy weight should gain 17 to 25 kg (37 to 54 lb) if she is pregnant with twins, a gain of 5.5 to 9 kg (12 to 19 lb) more than for women with a single fetus. When these women meet the recommended weight gain, they are less likely to deliver their twins before 32 weeks of gestation, and the infants are more likely to weigh more than 2500 g (5.5 lb) (Fox, Rebarber, Roman et al., 2010).

Women carrying triplets should gain a total of 23 to 27 kg (50 to 60 lb). Women pregnant with more than one fetus should consume an additional 300 calories per day for each fetus (Stotland, 2009). Additional vitamin-mineral supplementation may also be necessary.

Substance Abuse

Substance abuse often accompanies a lifestyle that is unlikely to promote healthy eating habits. The expense of supporting a substance abuse habit decreases money available to purchase food. Therefore, nutrition in pregnant women who abuse substances should be explored fully. Usually, more than one substance is involved, and the effects of various combinations of substances on nutrition are not fully understood. The damaging effects of smoking, alcohol, and illicit drug use on the fetus are discussed further in Chapter 24.

Smoking

Cigarette smoking increases maternal metabolic rate and decreases appetite, which may result in a lower weight gain. As the amount of smoking increases, infant birth weight decreases in spite of an adequate diet. Smoking decreases the availability of some vitamins and minerals, and vitamin-mineral supplements are important during pregnancy. Counseling to help the woman stop smoking or at least decrease the number of cigarettes smoked during pregnancy is essential (see Chapter 7).

Caffeine

The evidence regarding the effect of caffeine on nutrition during pregnancy is conflicting, and more research is needed. At this time, it appears that caffeine intake less than 200 mg/day is not a major contributing cause of miscarriage or preterm birth. Until more is known about its effects on nutrition and the fetus, caffeine intake should be limited during pregnancy to less than 200 mg/day (American College of Obstetricians and Gynecologists, 2010). A 6-oz cup of brewed coffee contains about 103 mg, tea contains 36 mg/6 oz, cola beverages contain

35 to 50 mg/12 oz, and cocoa contains 4 mg/6 oz (Mahan, Escott-Stump, & Raymond, 2012). The nurse should discuss other sources of caffeine, including some over-the-counter medications.

Alcohol

Because of the association between drinking and fetal alcohol spectrum disorders, women should avoid alcohol completely during pregnancy (see Chapter 24). Alcohol affects the absorption of vitamin B₁₂, folic acid, and magnesium, and often takes the place of food in the diet (Roth, 2011). Vitamin-mineral supplementation may be necessary for women who had large intakes of alcohol before pregnancy, even if they stop drinking after conception because their nutrient stores may be depleted.

Drugs

The use of drugs other than those prescribed during pregnancy increases danger to the fetus and may interfere with nutrition. Even some prescribed drugs have risks during pregnancy that must be weighed against their benefits. Abusers often use a combination of various drugs, and they may not be pure. The interaction of various drugs with nutrients is not fully understood.

Marijuana increases appetite, but women may not satisfy their hunger with foods of good nutrient quality. Heroin alters metabolism and may cause a woman to become malnourished. Cocaine acts as an appetite suppressant, interfering with nutrient intake. Vasoconstriction from cocaine use decreases nutrient flow to the fetus. Cocaine users also tend to drink more caffeine and alcoholic beverages. Amphetamines and methamphetamines depress appetite. Women who use amphetamines for dieting should be warned that these drugs should be discontinued during pregnancy.

Adolescence

Adolescent pregnancies are associated with higher risk for complications for both the expectant mother and the fetus (see Chapter 24). Pregnant adolescents who are less than 4 years **gynecologic age** (number of years since menarche) and those who are undernourished at the time of conception have the greatest nutritional needs (Stang & Larson, 2012). Maternal growth may interfere with placental blood flow and transfer of nutrients to the fetus. As a result, the adolescent mother may add weight and fat to her own body rather than use it for support of the fetus. This leads to a tendency to have smaller infants even with good weight gain in the mother.

Excessive weight gain during pregnancy should be avoided by adolescents as well as by adult women. Women who gain weight above the recommendations may have difficulty losing the weight gained and may become overweight or obese.

Nutrient Needs

The DRIs for nutrients needed by pregnant adolescents are the same as those for older women for most nutrients. Adolescents need more calcium, phosphorus, magnesium, and zinc to meet their own growth needs. Individualized assessment of gynecologic age, nutritional status, and daily diet may indicate the need for increases in other areas as well.

Common Problems

The diets of teenagers before pregnancy are often low in vitamin A, folic acid, calcium, iron, and zinc. Although they may get 3 or 4 servings of vegetables daily, 1 or 2 may be potatoes, often French fries. Girls average only 1.5 servings of fruits and dairy a day. Foods high in sugar and fat are common (Nichols-Richardson, 2011b). These habits often lead to inadequate stores of these nutrients for pregnancy. Supplements may be prescribed, but the adolescent may not take them

regularly. This combination of poor intake and unreliable supplementation may further deplete nutrient stores and general nutritional status.

Adolescents are often concerned about body image. If weight is a major focus for a teenager and her peers, she is more likely to restrict calories to prevent weight gain during pregnancy. Teenagers tend to skip meals, especially breakfast. The fetus requires a steady supply of nutrients, and the expectant mother's stores may be used if intake is not sufficient to meet fetal needs.

Teenagers are often in a hurry and want foods that are fast and convenient. Meals may be irregular and often eaten away from home. A significant part of the adolescent diet may consist of fast foods from restaurants or snack machines. These foods are often high in fat, sweeteners, and sodium and low in vitamins, minerals, and fiber. Peer pressure is an important influence on nutritional status. Choosing fast foods that do not make her appear different from her peers yet meet her added nutrient needs is important for the pregnant adolescent.

Teaching the Adolescent

Teaching the adolescent about nutrition can be a challenge for nurses. It is essential to establish an accepting, relaxed atmosphere and show willingness to listen to the teenager's concerns. Her lifestyle, pattern of eating, and food likes and dislikes should be explored to determine if changes are needed in her diet.

The adolescent's home life may affect her nutritional status. She may live at home with a mother who does the cooking, and the whole family may eat together. Or she may eat with the family only occasionally because she is often away at mealtimes. Some pregnant adolescents are homeless or in unstable situations. The number of other people in the home and the sufficiency of the food available also affect the dietary intake.

The nurse should keep suggestions to a minimum and focus only on those changes that are most important. If an adolescent believes she must eliminate all her favorite foods, she is likely to rebel. Asking for the adolescent's input increases the likelihood that she will follow suggestions. When changes are necessary the nurse should explain why they are important for both the fetus and the expectant mother. A teenager, like other pregnant women, often makes changes for the sake of her unborn baby that she would not consider for herself alone.

The teenager's likes and dislikes should be considered and snacks should be included in the meal plan. The need to be like her peers is of major importance to the adolescent, especially when she is going through the changes of pregnancy. With education about appropriate choices, she can eat fast foods with her friends and still maintain a nourishing diet. Giving her plenty of examples of alternatives from which she can choose should be very helpful (Table 9-7 and "Pregnant Adolescents Want to Know").

Other Risk Factors

Women who follow food fads may not meet the nutritional requirements for pregnancy. Those who have followed a severely restricted diet for a long time may have depleted nutrient stores. Nurses can help them understand the necessary changes to help ensure successful pregnancies.

Women with complications of pregnancy such as diabetes, heart disease, and preeclampsia may need dietary alterations. Those with other medical conditions such as extreme obesity, cystic fibrosis, and celiac disease may need nutritional counseling from a dietitian. Women with phenylketonuria should follow a low-phenylalanine diet before conception and during pregnancy to prevent cognitive impairment and other defects in the infant. This is true even if the woman has not usually followed the diet during adulthood (AAP & ACOG, 2012).

CASE STUDY 9-1 NURSING CARE PLAN*

ASSESSMENT: Holly is now 21 weeks pregnant and has gained 3.2 kg (7 lb). She reports she has decreased her ice intake a little and eats other crunchy foods in place of ice some of the time. She says she usually cooks for herself because “I don’t like the stuff Mom cooks.” She skips breakfast and eats from snack machines during breaks at school. She goes to fast food restaurants for lunch and after-school snacks. She states proudly that she has cut down on her ice intake considerably because she wants her baby to be healthy.

NURSING DIAGNOSIS: Imbalanced Nutrition: Less Than Body Requirements related to concern about weight gain and dietary choices inadequate to meet nutrient requirements of adolescent pregnancy

Critical Thinking: What other information does the nurse need to complete the assessment? Is Holly’s weight gain what is expected for this point in pregnancy?

Answer: A 24-hour diet history is necessary for a better understanding of Holly’s diet. The nurse should also ask about her likes and dislikes to make a meaningful diet plan for Holly. At 21 weeks of pregnancy, Holly would be expected to have gained about 0.5 to 2 kg (1.1 to 4 lb) during the first trimester and another 0.35 to 0.5 kg (0.8 to 1 lb) a week for the other 8 weeks, for a total of approximately 3.3 to 6 kg (7.5 to 12 lb) by the time of this assessment.

EXPECTED OUTCOMES: Holly will:

1. By the end of the current visit, explain the weight gain pattern and amount of food from each food group for pregnancy.
2. By the next visit, list foods she can choose at fast food restaurants that meet her nutrient needs and allow her to feel part of her peer group.
3. Continue to decrease the amount of ice she is eating throughout pregnancy.

INTERVENTIONS AND RATIONALES

1. Praise Holly for her interest in nutrition and her concern about gaining too much weight. Explain the expected weight gain for her during the pregnancy and show her that her weight gain thus far is slightly low. *Praise helps foster rapport and may focus attention on learning. Understanding of the expected pregnancy weight gain is essential.*
2. Discuss the reasons for appropriate weight gain during pregnancy and its effect on the fetus. Explain the needs of the adolescent who is not finished growing and the importance of preventing the problems associated with low birth weight in the infant. *Adolescents may not understand how diet affects the fetus and themselves during pregnancy. Explanation of the potential effects of her actions should increase the expectant mother’s interest in nutrition.*
3. Discuss the high caloric intake of fast foods in relation to her present diet, and explain the concept of nutrient density in terms of “spending calories” to “buy” nutrients needed during pregnancy. *Relating information to concepts already understood increases understanding.*
4. From her food preferences determine foods that meet her nutrient needs and are acceptable to her. Point out that fruits and vegetables are high in vitamins A and C, yet low in calories. *Individualizing the recommended diet to meet the woman’s likes and dislikes increases compliance.*
5. Suggest nutritional foods that Holly could choose at fast food restaurants, and ask which ones she would eat (see Pregnant Adolescents Want to Know: How Can I Eat Fast Foods and Still Maintain a Good Diet?). *The ability to eat nutritious fast foods with her friends helps the adolescent feel she is part of her peer group yet meet her nutritional needs.*

EVALUATION: Holly’s 24-hour diet histories show she is meeting the recommendations for each food group. She states her ice intake is only 2 to 3 cups a day. She gains 1.8 to 2.7 kg (4 to 6 lb) per month throughout the rest of her pregnancy for a total weight gain of 15 kg (33 lb). She offers ideas to the nurse about ways to eat fast foods healthfully and seems to enjoy educating the nurse about teenage diet preferences. Her hemoglobin level rises to 11 g/dL. A healthy 3.4-kg (7.5-lb) baby girl is born at term.

*Continued from p. 155.

TABLE 9-7 NUTRITIOUS CHOICES FROM SNACK MACHINES*

FOOD	NUTRIENTS PROVIDED
Yogurt, white or chocolate milk	Protein, calcium
Fruit juices, fresh fruits (usually apples or oranges), dried fruit	Vitamins, fiber
Vegetables such as baby carrots	Vitamins, fiber
Popcorn (best without butter or salt)	Fiber
Peanuts, almonds (roasted)	Protein, vitamins, calcium, iron
Granola or granola bars, trail mix, sunflower seeds	Fiber, protein
Crackers and cheese	Protein, calcium
Crackers and peanut butter	Protein

*Snack machines generally dispense foods high in calories, fats, and sodium and low in nutrients. Some of the foods listed here are somewhat high in calories, but all provide other worthwhile nutrients.

NUTRITION AFTER BIRTH

Nutritional requirements after birth depend on whether the mother breastfeeds her infant or gives formula. The nurse should review the woman’s nutritional knowledge as she returns to her prepregnancy diet and teach the breastfeeding mother how to adapt her diet to meet the needs of lactation.

PREGNANT ADOLESCENTS WANT TO KNOW

How Can I Eat Fast Foods and Still Maintain a Good Diet?

- Add cheese to hamburgers to increase calcium and protein. Include lettuce and tomato for vitamins A and C.
- Avoid dressings on hamburgers because they tend to be high in calories and fat.
- To reduce fat and calories, choose broiled, roasted, and barbecued foods (such as chicken breast, roast beef). Avoid fried foods (such as french fries, fried zucchini, onion rings, fried cheese) because they are high in fat and the high heat may destroy some vitamins. Breaded foods such as chicken nuggets and breaded clams are high in calories and absorb more oil if they are fried.
- Try wraps instead of sandwiches to decrease calories.
- Baked potatoes with broccoli, cheese, and meat fillings provide better nutrition compared with french fries or baked potatoes with sour cream and butter.
- Pizza is high in calories, but the cheese provides protein and calcium. Ask for vegetable toppings or add a salad to increase vitamins.
- Salad bars are often available at fast food restaurants and provide vitamins and minerals without adding too many calories. Use only a small amount of salad dressing, which is high in fat.
- Milk, milkshakes, and orange juice provide more nutrients than carbonated beverages, which are high in sodium and calories.
- Avoid pickles, olives, and other salty foods. Too much sodium may increase swelling of the ankles. Add only small amounts of salt to foods to prevent or decrease swelling.

Nutrition for the Lactating Mother

The lactating mother must nourish both herself and her baby as she did during pregnancy. Therefore, she continues to need a highly nutritious diet. Some DRIs for lactation are higher than those for nonpregnant adult women. Lactating women with poor diets may have reduced milk levels of fatty acids, selenium, iodine, vitamin A, and some B vitamins (Erick, 2012; Peckenpaugh, 2010).

Energy

During the first 6 months of lactation, the estimated energy requirement (EER) is 330 calories each day in addition to normal needs for women according to age, weight, and height. In addition to the calories consumed, it is estimated that 170 calories per day are drawn from the woman's fat stores. This provides a total of 500 calories each day above prepregnancy requirements to meet the needs of lactation. The use of calories from fat stores aids in postpartum weight loss.

The EER for the second 6 months of lactation is 400 calories more than prepregnancy needs. Although the infant takes solids after 6 months and decreases the milk intake, it is assumed that maternal energy stores have been used and the calories should come from the woman's daily intake (IOM, 2002). Milk volume is usually adequate even when a mother's diet is less than optimal, but volume may be reduced and maternal nutrient stores will be depleted with very low caloric intake.

Protein

The DRI for protein during lactation is 71 g each day. Although there is no change from the pregnancy DRI, it is important for the woman to maintain her protein intake throughout the breastfeeding period.

Fats

The long-chain polyunsaturated omega-3 and omega-6 fatty acids are present in human milk. Therefore, they should be included in the mother's diet during lactation.

Vitamins and Minerals

The DRIs for lactating women are higher than for pregnancy for vitamins A, B₆, B₁₂, C, and E and riboflavin, zinc, iodine, potassium, copper, and selenium. Lactating women who eat a well-balanced diet generally consume adequate amounts of essential nutrients to meet the infant's and their own needs. Although the quality of the milk is not affected by the mother's intake of most minerals, the vitamin content may be decreased if her diet is consistently low in vitamins.

Vitamin D is low in breast milk and supplements are recommended for infants (AAP & ACOG, 2012). Milk levels of some nutrients such as calcium remain constant because some nutrients are drawn from the mother's stores if her intake is poor. Many health providers recommend women continue to take their prenatal vitamin-mineral supplements during lactation.

Specific Nutritional Concerns

Some women have difficulty consuming all required nutrients and need special counseling. This group includes women who are dieting, adolescents, vegans, women who avoid dairy products, and those whose diet is inadequate for other reasons.

Dieting. Women who are concerned about losing weight after pregnancy need special consideration. After the initial losses in the first month, weight gradually decreases as maternal fat is used to meet a portion of the energy needs of lactation. However, breastfeeding does not necessarily result in weight loss, and some women maintain or even gain weight during lactation. This is more likely when weight gain during pregnancy was excessive.

Dieting should be postponed for at least 3 weeks after birth to allow the woman to recover fully from childbirth and establish her milk supply if she is breastfeeding. Gradual weight loss is preferable and should be accomplished by a combination of moderate exercise and a diet high in nutrients with at least 1800 calories per day (Grodner et al., 2012). Weight loss of approximately 0.45 to 0.68 kg (1 to 1.5 lb) a week is generally considered safe and will not compromise milk supply (Bronner, 2010). Nursing mothers should avoid appetite suppressants, which may pass into the milk and harm the infant. They should not use liquid diet drinks or diets that severely restrict any nutrient because they will not meet their needs.

Adolescence. The problems of the adolescent diet continue to be of concern during lactation. The adolescent may be deficient in the same nutrients as other mothers during lactation and may also have a low iron intake. If she dislikes or cannot afford fruits and vegetables, her intake of vitamins A and C may be inadequate.

Vegan Diet. The milk of the vegan mother may contain inadequate amounts of vitamin B₁₂, and they may need supplements. Vegans can meet their need for other nutrients during lactation by diet alone with careful planning. Those who are not knowledgeable about nutrition should take supplements.

Avoidance of Dairy Products. The recommendation for calcium is the same for pregnancy and lactation, and the calcium content of breast milk is not affected by maternal intake. Less calcium is excreted in urine during lactation. Although calcium is removed from the mother's bones during lactation, it is replaced when she is no longer breastfeeding (Bronner, 2010). Women who do not eat dairy products should obtain calcium from other sources or take a calcium supplement. Unless they consume foods fortified with vitamin D or are

exposed to sunlight, they may also require vitamin D supplementation, which is necessary for calcium absorption.

Inadequate Diet. Women with cultural or other food prohibitions may need help choosing a diet adequate for lactation. Low-income women may need referral to agencies such as WIC. If the mother must take medications that interfere with absorption of certain nutrients, her diet should be high in foods containing those nutrients.

Alcohol. Although the relaxing effect of alcohol was once thought to be helpful to the nursing mother, the deleterious effects of alcohol are too important to consider this suggestion appropriate today. An occasional single glass of an alcoholic beverage may not be harmful, but larger amounts may interfere with the milk-ejection reflex and may be harmful to the infant. Alcohol level in the milk peaks at 30 to 60 minutes after drinking if it is taken alone and 60 to 90 minutes if taken with food. When mothers drink alcohol they should not breastfeed for at least 2 hours (Lawrence & Lawrence, 2011).

Caffeine. Foods high in caffeine should also be limited. Infants of mothers who drink more than 2 to 3 cups of caffeinated coffee or the equivalent each day may be irritable or have trouble sleeping (March of Dimes, 2010).

Fluids. Nursing mothers should drink fluids sufficient to relieve thirst, which often increases in the early breastfeeding period. Eight to ten cups of fluids that do not contain caffeine are adequate. Drinking large quantities of fluids, as was once recommended, is not necessary.

Nutrition for the Nonlactating Mother

The postpartum woman who is not breastfeeding can return to her prepregnancy diet, provided it meets recommendations for adult women. Her diet should contain enough protein and vitamin C to promote healing. Many health care providers suggest that the woman continue to take her prenatal vitamin-mineral supplements until her supply is finished. This ensures adequate intake during the time of involution and helps renew nutrient stores.

The nurse should assess the mother's understanding of the amount of food she needs from each food group. A review of important nutrient sources for calcium and iron may be relevant. If the woman was anemic during pregnancy, she should continue to take an iron supplement until her hemoglobin level returns to normal.

Weight Loss

When her baby is born, a woman can expect to lose about 4.5 to 5.8 kg (10 to 13 lb) immediately. She loses approximately another 3.2 to 5 kg (7 to 11 lb) during the first week. Weight loss continues with the greatest loss during the first 3 months. If her weight gain during pregnancy has not been excessive, she will probably lose all but about 1 kg (2.2 lb) within a year if she follows a well-balanced diet (Blackburn, 2013). She should decrease her caloric intake to her normal nonpregnant levels to avoid retaining weight. Suggestions for sensible calorie reduction combined with exercise are appropriate.

Women who gain excess weight during pregnancy may have difficulty losing it after birth and may need help from a dietitian to plan a weight loss program. Those who do not lose the weight gained during pregnancy may begin the next pregnancy overweight and this may lead to further retention of weight after birth.

Mothers are sometimes so involved with the needs of the infant that they fail to eat properly. They may snack instead of planning meals for themselves, especially if they are home alone with the baby during the early weeks. The nurse should remind them that snacking often involves high caloric intake without meeting nutritional needs. During the postpartum period the mother needs to ensure her own good health so that she is able to care for her baby. Therefore, meals and snacks should be high in nutrient content.

EVIDENCE-BASED PRACTICE

Information for Postpartum Women about Weight Loss

Postpartum women are often very concerned about losing weight after giving birth. Women who retain gestational weight (GW) past a year after giving birth are at increased risk of becoming overweight or obese. They need information during and after giving birth about how to lose GW. Ohlendorf, Weiss, & Ryan (2012) conducted a study to determine women's plans to obtain weight loss information, what information they received by 4 months postpartum, what information they wished they had received, and electronic sources they preferred for obtaining the information.

A 22-item survey was given to 250 women during their postbirth hospitalization to ask about those topics. A follow-up telephone interview was completed by 179 (71.6%) of those women at 4 months postpartum. Results showed that 53.3% of the normal-weight women, 79% of the overweight women, and 81.4% of the obese women stated at the initial survey that they planned to seek weight loss information from health care providers. However, nearly 85% of women had received no GW loss information from providers by 4 months after giving birth. Other sources of information women most often planned to use included books or magazines, family, and the Internet.

By 4 months postpartum, the types of information women received were physical activity or exercise after childbirth, diet, and how to lose GW. Women stated they would have liked to receive information about those topics as well as referral to or information about exercise classes, how to lose more than GW, usual weight loss after childbirth, when to expect return to prepregnancy weight, specific information about weight loss while breastfeeding, and help with specific plans. The most frequent electronic sources the women said they would like to use to obtain information about GW loss were newsletters, hospital Web sites, and e-mail.

The postpartum hospitalization period and the follow-up visits are ideal times to help women obtain information about GW loss. Nurses and other health care providers can share their knowledge and provide referrals to other sources to help women improve their general health and future pregnancies.

19. What changes should the woman who is not breastfeeding make after the birth of her baby?

APPLICATION OF THE NURSING PROCESS

■ Nutrition for Childbearing

The nursing process focuses on determining any factors that might interfere with the woman's ability to meet the nutrient needs of pregnancy, the postpartum period, and lactation and finding solutions to any problems identified. This process primarily involves education of the woman.

Assessment Interview

The interview provides an opportunity to develop rapport and identify any specific problems affecting dietary intake.

Appetite. Begin the interview by discussing the woman's appetite. Has it changed during the pregnancy? How does it compare with her appetite before pregnancy? Morning sickness may decrease food intake during the first trimester. Determine the severity and duration of nausea and vomiting. Hyperemesis gravidarum is the most serious form of this problem and may require intravenous correction of fluid and electrolyte imbalance and parenteral nutrition (see [Chapter 25](#)).

Eating Habits. Assess the usual pattern of meals to discover poor food habits such as skipping breakfast, eating only snack foods for lunch, or eating fast foods for most meals. Determine who cooks for the family. If someone else does the cooking, discuss nutritional needs during pregnancy with that person. If the woman does the cooking herself, the likes and dislikes of other family members may influence what she serves, especially if she has little understanding of her own needs during pregnancy.

Food Preferences. Ask the woman about her food preferences and dislikes. Some women experience aversions to certain foods such as meats only during pregnancy. Careful counseling helps work around dislikes and aversions to find ways of obtaining the nutrients needed. For example, if she dislikes most vegetables, fruits may often be substituted.

Discussing likes and dislikes provides an opening to ask about food cravings and pica. Cravings may be for nutritional foods or foods low in nutrient density or eaten in amounts that interfere with intake of other foods. Ask about pica in a matter-of-fact manner to avoid giving an impression of disapproval. Food items such as ice are included in pica and the nurse should ask about it as well. Also determine if the mother eats large amounts of a particular food or group of foods.

When assessing for pica the nurse might say, "Have you had any cravings for special things to eat during your pregnancy?" This can be followed with, "Women sometimes eat things like ice, clay, and laundry starch during pregnancy. Have you tried these?"

Potential Problems. Identify any obvious areas of potential deficiency. For example, the woman might eat little meat, avoid vegetables, be lactose intolerant, or follow a fad diet. Assess the woman's knowledge about nutritional needs during pregnancy. Inquire how long the vegetarian has followed her diet, determine which foods she includes, and question her awareness of changes necessary during pregnancy.

Psychosocial Influences. Psychosocial factors should also be assessed because they can affect dietary intake. Women who are fatigued, stressed, and anxious during pregnancy may consume more high-calorie foods but have lower intake of some important nutrients. The diets of postpartum women are also affected by psychosocial factors. Those with stress, weight-related concerns, negative body image, and depressive symptoms are less likely to eat healthful diets.

Identify cultural or religious considerations that affect the diet. Do these apply only during pregnancy or at all times? Assess whether the woman follows all or only certain restrictions, and determine the effect on her nutrient intake.

Identify other factors that interfere with adequate nutrition. Women with low incomes may not know about sources of assistance. A woman's smoking habits, alcohol intake, and other substance abuse may become obvious during the interview. Determine if she takes medications that interfere with nutrient absorption. Other questions include the amount of time she has for food preparation and the frequency of fast food intake.

Provide an opportunity for the woman to ask about special concerns regarding her diet. This may bring out fears about weight gain, worry that specific foods could hurt the fetus, or other issues that have not yet been addressed.

Diet History

Diet histories provide information about a woman's usual intake of nutrients. Food intake records, 24-hour diet histories, and food frequency questionnaires can form a basis for counseling about any changes required to meet pregnancy needs. They also help the woman become more aware of her eating habits.

Food Intake Records. Food intake records are used to report foods eaten over 1 or more days. Instruct the woman to list everything she eats throughout the day. The list is more accurate if she writes down each food immediately after eating. Some women eat more nutritious foods during the recording period when they are concentrating on good diet, and then return to a less wholesome diet later.

24-Hour Diet History. Ask the woman to recall what she ate at each meal and snack during the previous 24 hours. Use specific questions about the size of portions, ingredients, and food preparation for each meal. Models of food items and measuring utensils may be helpful to determine portion sizes. Inquire about beverages and snacks between meals and at bedtime. Ask if this sample is typical of her usual daily food intake. If it is not, ask what foods are more representative of her usual intake. Analyze her diet to determine whether the woman has met the recommendations for specific food groups, calories, and protein. Detailed analysis for individual nutrients is unnecessary because it is time consuming and because daily variation in intake occurs.

The food history may be inaccurate if the woman cannot remember what she ate or is mistaken about amounts of food. The expectant mother may alter her reported intake to make it appear that she is eating better. She may be embarrassed about her inability to follow the diet prescribed because of lack of money or cooking facilities. The atmosphere created by the nurse is important in helping mothers feel free to be honest.

Food Frequency Questionnaires. Food frequency questionnaires, which contain lists of common foods, may provide information about diet over a longer period. Review the questionnaire with the woman, and ask her how often she eats each food. Foods consumed daily and weekly are her most common source of nutrients. Analyze the list to determine whether foods from each food group are eaten in adequate amounts to meet pregnancy needs, and determine whether any major groups are omitted.

Physical Assessment

Information about nutritional status can be obtained during the physical assessment. This assessment includes measurement of weight and examination for signs of nutritional deficiency.

Weight and Height at Initial Visit. Weigh the woman at the first prenatal visit to provide a baseline value for future comparison. Ask if she has gained or lost weight. Measure her height without shoes because she may not have had a recent accurate measurement. Determine her BMI from her prepregnancy weight and height to draw conclusions about her nutritional condition. If her weight is low for height, nutritional reserves are marginal.

Weight at Subsequent Visits. Assessment of weight gain at each prenatal visit provides an easy method of estimating whether nutrition is adequate and serves as a basis for counseling. Weigh the woman at each visit on the same scale with approximately the same amount of clothing.

Record the weight on a weight grid at each visit throughout the pregnancy ([Figure 9-2](#)). This grid allows examination of the pattern of weight gain as well as the total gain to date. It also helps keep track of the amount of gain between individual visits.

FIG 9-2 Weight Gain Grid for Pregnancy. The normal range for weight gain is 11.5 to 16 kg (25 to 35 lb).

Be careful not to overemphasize weight gain. In some instances, a woman may be afraid that caregivers will be disapproving if she gains weight and consequently may diet or fast a day or two before her prenatal visit.

Signs of Nutrient Deficiency. Observe for indications of nutritional status or any signs of deficiency. For example, bleeding gums may indicate inadequate intake of vitamin C. Actual deficiency states, however, are not likely to occur in women in most industrialized countries. The exception is iron deficiency anemia, which is common in a mild form. Signs and symptoms include pallor, low hemoglobin level, fatigue, and increased susceptibility to infection.

Laboratory Tests

Laboratory tests for in-depth analysis of nutrient intake are generally impractical. Analysis of specific nutrients is expensive and normal laboratory values during pregnancy have not been determined for all laboratory tests. Hemoglobin, hematocrit, and, in some cases, serum ferritin tests are most often used to determine anemia.

Ongoing Nutritional Status

At each prenatal visit (1) reassess the woman's dietary status, (2) ask if she has any questions about her diet or has had any difficulty, (3) check her weight gain to see whether she is within the expected pattern, (4) evaluate her hemoglobin and hematocrit levels to detect anemia, if appropriate, and (5) explain what assessments are being made and why.

Nursing Diagnosis

Although some women consume more calories than necessary during pregnancy and risk obesity as a result, other women are likely to eat fewer nutrients than recommended. The problem may be related to many factors, the most common of which is general lack of knowledge. Therefore, an important nursing diagnosis concerning nutrition is "Readiness for Enhanced Nutrition related to desire to learn about the nutrient needs of pregnancy."

Planning

The expected outcomes for this nursing diagnosis include the following:

FIG 9-3 Women often make changes in their diets for the sakes of their unborn children that they would not consider for themselves alone. (YanLev, Photographer. © 2012 Photos.com, a division of Getty Images. All rights reserved.)

- The woman will eat a daily diet that includes the recommended amount of food from each food group for pregnancy.
- The woman with a normal BMI before pregnancy will gain approximately 0.5 to 2 kg (1.1 to 4.4 lb) during the first trimester and 0.35 to 0.5 kg (0.8 to 1 lb) per week during the second and third trimesters for a total gain of 11.5 to 16 kg (25 to 35 lb).

Interventions

Identifying Problems

After analyzing food likes and dislikes and taking a 24-hour diet history, identify any obvious areas that are lacking and determine the woman's knowledge about the nutrient needs of pregnancy. If the woman is experiencing pica, try to find foods that will replace the substances she is eating. Crunchy foods may replace some ice ingestion. Some Hispanic women eat solid milk of magnesia, which tastes like clay to them (Spector, 2009). Other women are willing to make substitutions such as nonfat dry milk powder for laundry starch.

Explaining Nutrient Needs

Use the woman's diet history as a basis to introduce information about nutrition during pregnancy. Explain the recommended servings from each food group, help her analyze her own diet so she understands the process, and determine whether she meets the number of servings recommended for each food group. Explain which important nutrients are provided in each food group and why they are necessary for her and the fetus.

Calculate a rough estimate of calories, protein, iron, folic acid, and calcium in the diet to help her identify if she eats enough of these foods on a regular basis. Compare the usual sources of these nutrients with her diet history and favorite foods. Suggest ways she can increase nutrients lacking by increasing foods that are good sources. Advise the woman that adequate nutrition, especially intake of iron and folic acid, may help reduce fatigue during pregnancy and after birth.

Providing Reinforcement

Give frequent positive reinforcement when the woman is eating appropriately. Assist her in evaluating weaknesses in her diet and planning ways to remedy them (Figure 9-3). Ask her what problems she foresees in obtaining the nutrients she needs. Explore a variety of options to overcome expected problems, and ask about how these changes will affect the rest of her family. Perhaps the changes she needs to make for her own needs would be beneficial to the entire family.

If the woman can read, give her printed materials in her language on nutrition during pregnancy, and review them with her. If she can take the information home, she can review it to ensure that she is eating properly. A small pamphlet with pictures might be placed on the refrigerator to help her remember what foods she needs each day.

Demonstrate portion sizes by showing her plastic models of frequently eaten foods. These are available for various ethnic foods, as well, and help women understand how to incorporate cultural foods into the pregnancy food plan.

Evaluating Weight Gain

Compare the woman's weight with a weight gain chart to ascertain whether she has gained the appropriate amount of weight for this point in her pregnancy. Discuss the importance and expected pattern of weight gain and explain the need to eat foods high in nutrient density when she is increasing calories. If she is greatly outside of normal ranges, discuss necessary diet modifications with her primary health care provider. For example, an obese woman is expected to gain some weight, but the amount must be individualized according to her particular needs.

Although slight variations from the recommended weight gain have little significance, possible reasons for larger differences should be examined carefully. For women of normal weight, a monthly gain of less than 1 kg (2.2 lb) should lead to a discussion of diet and possible problems in food intake. A gain of more than 2.9 kg (6.5 lb) per month may signify edema. However, errors in calculation of gestation may also reflect a pattern of weight gain different from that expected.

Encouraging Supplement Intake

If vitamin-mineral supplements have been prescribed, determine whether she takes them regularly and, if not, explore reasons and possible solutions. Iron supplements often cause constipation, but dietary changes such as increased intake of fluids and fiber can help prevent this problem (Box 9-3). If she forgets, suggest that she take vitamin-mineral supplements with meals or iron tablets with orange juice at bedtime just before brushing her teeth. If she avoids iron supplements

BOX 9-3 COMMON SOURCES OF DIETARY FIBER

Fruits and vegetables (with skins, when possible): apples, strawberries, pears, carrots, corn, potatoes with skins, and broccoli
 Whole grains and whole grain products: whole wheat bread, bran muffins, bran cereals, oatmeal, brown rice, and whole wheat pasta
 Legumes: peas, lentils, kidney beans, lima beans, baked beans, and nuts

because of side effects such as nausea, she can take them with meals or snacks. Even though taking iron supplements with food decreases the absorption of the iron, it is preferred to not using the supplements at all. Let her know that black stools are a harmless side effect of iron supplements.

Making Referrals

The nurse can provide nutritional counseling that is more than adequate for most women, but some situations warrant referral to other sources. Refer women with health problems that affect nutrition (such as diabetes, celiac disease, extreme weight problems) to a dietician with follow-up by the nurse. Women with inadequate financial resources to buy food can be referred to public assistance programs such as WIC. At the next visit, determine whether the woman obtained the help needed and if other assistance is necessary.

Evaluation

Ongoing evaluation of diet and pattern of weight gain throughout the pregnancy determines whether the goals have been met. The woman should eat the recommended amount of foods from each food group daily. She should gain approximately 0.5 to 2 kg (1.1 to 4.4 lb) during the first trimester and 0.35 to 0.5 kg (0.8 to 1 lb) per week during the rest of her pregnancy. Total weight gain should be about 11.5 to 16 kg (25 to 35 lb).

SUMMARY CONCEPTS

- Nutritional education during the childbearing period may have long-term positive effects on the mother, the infant, and the entire family.
- Weight gain during pregnancy is an important determinant of fetal growth. Poor weight gain in pregnant women is associated with low-birth-weight and small-for-gestational age infants. Excessive weight gain may lead to increased birth weight, gestational diabetes, labor complications, and postpartum weight retention.
- The recommended weight gain during pregnancy for women of normal prepregnancy weight is 11.5 to 16 kg (25 to 35 lb). The amount is greater for women who are underweight or who carry more than one fetus, and it is less for overweight and obese women.
- The pattern of weight gain is also important. The woman should gain 0.5 to 2 kg (1.1 to 4.4 lb) during the first trimester and 0.35 to 0.5 kg (0.8 to 1 lb) per week thereafter.
- The recommended increase in daily energy intake during pregnancy is 340 calories in the second trimester and 452 calories in the third trimester. Calorie increases should be attained by choosing foods high in nutrient density to meet the other needs of pregnancy.
- Protein should be increased to 71 g daily during pregnancy, which is 25 g more than nonpregnancy needs.
- Women may not eat enough foods high in vitamins and minerals to meet recommendations.
- Fat-soluble vitamins (A, D, E, K) are stored in the liver. Excess consumption may result in toxic effects.
- Daily intake of water-soluble vitamins and folic acid is necessary because excesses are not stored but excreted.
- Minerals that may not be consumed at recommended amounts during pregnancy are iron and calcium. Iron is often added as a supplement and calcium is added for women with low intake.
- Vitamin-mineral supplements must be used carefully to prevent excessive intake and toxicity. Increased intake of some nutrients interferes with use of others.
- Pregnant women should drink approximately 8 to 10 cups of fluids each day. They should eat 7 to 9 oz of whole grains, 3 to 3.5 cups of vegetables, 2 cups of fruits, 3 cups of the dairy group, and 6 to 6.5 ounces of protein foods daily.
- Culture can influence diet during pregnancy. The nurse should learn whether a woman follows traditional dietary practices and whether her food practices are consistent with good nutrition.
- Both Asian and Hispanic dietary practices include the importance of *yin* and *yang* (cold and hot) foods. The nurse must know which foods are acceptable at what times.

Continued

SUMMARY CONCEPTS—cont'd

- Low-income women may not have enough money or knowledge to meet the nutrient needs of pregnancy. Nurses should refer them for financial assistance and nutritional counseling.
- Pregnant vegetarians may need help choosing an adequate diet that includes nonanimal sources of nutrients.
- Lactose-intolerant women should increase calcium intake from foods other than milk, such as calcium-rich vegetables.
- Abnormal prepregnancy weight, anemia, eating disorders, pica, multiparity, substance abuse, closely spaced pregnancies, and multifetal pregnancies are all nutritional risk factors that warrant adaptations of diet during pregnancy.
- Adolescents may skip meals and eat snacks and fast foods of low nutrient density. They are subject to peer pressure that may decrease their nutritional intake.
- Lactating women need an additional daily intake of 330 calories during the first 6 months, with the remaining 170 calories drawn from maternal stores. During the second 6 months of breastfeeding, an added daily intake of 400 calories is needed.
- Lactating women should avoid alcohol and excess caffeine.
- The postpartum woman who does not breastfeed should resume her prepregnant caloric intake and eat a well-balanced diet to enhance recovery from childbirth. Weight loss should be accomplished slowly and sensibly.

Antepartum Fetal Assessment

WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Identify indications for fetal diagnostic procedures.
2. Discuss the purpose, procedure, advantages, and risks of each diagnostic procedure discussed in this chapter.
3. Provide information for common questions that women may have about antepartum fetal assessment procedures.
4. Apply the nursing process to care of women undergoing antepartum fetal assessment procedures.

Until relatively recently, only nonspecific methods were available to assess the condition and physical development rate of the fetus. Fundal height was measured to estimate fetal growth, the fetal heart rate (FHR) was auscultated to verify life, and the mother's perception of fetal movements was noted. The development of additional methods has allowed the detection of physical abnormalities in the fetus and greater accuracy in the monitoring of the fetal condition, including growth rate.

Antepartum fetal assessments offer reassurance for most expectant parents. If no fetal anomalies are found and the fetus appears to be in good condition, relief and reduced anxiety are usually immediate. If fetal health is uncertain, the woman often faces decisions about further testing. She may experience anxiety throughout the pregnancy if tests continue to raise questions about the well-being of her baby. If tests identify fetal anomalies, the woman may face the choice of whether to continue the pregnancy. This decision can create emotional conflict as well as ethical dilemmas that are stressful for the entire family.

INDICATIONS FOR FETAL DIAGNOSTIC TESTS

Most fetal diagnostic procedures are reserved for pregnancies in which there is a reason to believe the fetus may experience developmental or physical problems while in utero or after birth. However, many health care providers believe that some screening tests such as ultrasound and maternal serum screening should be offered to all women.

Two broad reasons exist for antepartum fetal assessment testing: (1) to detect congenital anomalies and (2) to evaluate the condition of the fetus. Some procedures such as **amniocentesis** (transabdominal puncture of the amniotic sac) and ultrasound may be used for both purposes.

Many factors increase the risk for the fetus during pregnancy. These include maternal medical conditions such as diabetes and hypertension, demographic factors such as age and poverty, and obstetric factors such as previous birth of an infant who was preterm, was still-born, or had congenital anomalies (**Box 10-1**).

No antepartum testing or antepartum surveillance procedure can guarantee the birth of a perfect infant. The woman and her support person must be counseled that prenatal diagnostic tests cannot detect all congenital defects. A **baseline risk** (risk to the general population) remains for congenital defects in every pregnancy.

The woman has the right to refuse antepartum testing, even though she may have an increased risk for a baby with a birth defect that can be diagnosed with one of these tests. If a screening test suggests an abnormality that requires further testing to determine whether the abnormality is actually present, the woman has the right to accept or refuse further testing. Nurses must respect the woman's personal decisions.

ULTRASOUND

When high-frequency sound waves of an **ultrasound** beam are aimed at body tissues, they are deflected by tissues in their path and returned

BOX 10-1 INDICATIONS FOR FETAL DIAGNOSTIC PROCEDURES

Medical Conditions

Preexisting diabetes mellitus or gestational diabetes
 Hypertension (chronic or preeclampsia)
 Acute or nonacute infections (e.g., pyelonephritis)
 Sexually transmitted diseases
 Severe anemia
 Parents carry or express a genetic disorder (e.g., sickle cell anemia, cystic fibrosis)

Demographic Factors

Maternal age <16 or >35 years
 Poverty
 Nonwhite (greater risk for prematurity or neonatal or infant death)
 Inadequate prenatal care (initial visit after 20 weeks of gestation or fewer than five prenatal visits to physician or nurse-midwife)

Obstetric Factors

History of low-birth-weight (<2500 g [5 lb, 8 oz]) or preterm (<37 completed weeks of pregnancy) infant
 Multifetal pregnancy
 Malpresentation (breech, shoulder)
 Previous fetal loss or birth of infant with congenital anomaly
 Previous infant ≥ 4000 (8 lb, 13 oz) g at birth
 Hydramnios (≥ 2000 mL at term; amniotic fluid index ≥ 24 to 25 cm [Cunningham et al., 2010])
 Oligohydramnios (<500 mL at term; amniotic fluid index <5)
 Decrease in or absence of fetal movements
 Uncertainty about gestational age
 Suspected intrauterine growth restriction
 Discordant (unequal) fetal growth of twins
 Postmaturity (>42 weeks)
 Preterm labor (>20 weeks but <37 completed weeks of gestation)
 Grand multiparity (>5 pregnancies)

Concurrent Maternal Factors

Prepregnancy body mass index (BMI) less than 18.5 kg/m²
 Prepregnancy BMI 25 kg/m² or higher
 Inadequate weight gain or poor pattern of weight gain
 Excessive weight gain
 Use of drugs (legal, including prescribed, over-the-counter, and herbal; illegal), alcohol, tobacco

From Cunningham, F. G., Leveno, K. J., Bloom, S. L., et al. (2010). *Williams obstetrics* (23rd ed.). New York: McGraw-Hill.

as echoes. The amount of energy returned as an echo depends on the properties of the tissues in the path of the ultrasonic beam and the angle and strength of the beam. In obstetrics, the ultrasonic beam sent by a transducer is directed through tissues of the abdomen or vagina to provide two-dimensional images showing structures of different densities (Figure 10-1).

Technology and software advances have refined ultrasound data, producing a three-dimensional image with greater clarity and visual depth than the two-dimensional image. Three-dimensional ultrasound images have greater detail to confirm normal features and identify abnormalities, particularly those of surface features such as facial clefts. They provide more accurate identification of the extent and size of abnormalities. Ultrasound images in three dimensions are often easier to interpret because they are more realistic than two-dimensional flat

FIG 10-1 Two-dimensional sonogram showing the fetal body profile and details of the fetal arm, hand, and fingers. (Courtesy of Paul and Kerri Hamilton.)

FIG 10-2 Three-dimensional ultrasound image of a fetus in the third trimester, showing details of facial features. (From Benacerraf, B. R. [2008]. The role of three-dimensional ultrasound in the evaluation of the fetus. In P. W. Callen [Ed.], *Ultrasonography in obstetrics & gynecology* [5th ed.]. Philadelphia: Saunders.)

images (Figure 10-2). A four-dimensional image is becoming more available because it improves recognition of some anomalies (Manning, 2009). Methods that may be used to evaluate and store images include optical and magnetic media as well as thermal photographs. A simple written interpretation of the ultrasound image is done for each examination.

Today's procedures use real-time scanning, showing movement as it happens. Real-time ultrasound allows the observer to see fetal heart motion, fetal breathing activity, and fetal body movement. Real-time scanning also allows the observer to distinguish between moving tissues of the fetus and relatively fixed maternal tissues. Ultrasound may be used during any trimester, but the procedure and the reasons for its use vary. Ultrasound imaging is also used in gynecology and infertility care as well as many other medical and surgical procedures.

Emotional Responses

Most women in the United States have at least one ultrasound examination during pregnancy. The procedure is so common that many women expect and often look forward to an ultrasound at some time during pregnancy. Ultrasound is often done with the first prenatal visit to better date the pregnancy with the woman's last menstrual period (LMP) date and identify possible abnormalities. Although considered safe for a fetus based on long experience, ultrasound imaging should have a medical indication (*American College of Obstetricians and Gynecologists [ACOG], 2011b; Richards, 2012*).

Parents' responses to ultrasonography vary widely. Some expectant parents are excited and report feelings of love and protectiveness when they view the fetus. Others report more anxiety about the fetus and fear that something will be found wrong. Undoubtedly, parents breathe sighs of relief when scans show normal results. Sometimes, the presence of one or more "markers," findings that might indicate a problem, fails to give parents the expected reassurance and puts them on a path to other difficult choices they must make about their baby.

Both parents are usually fascinated by the quality of today's ultrasound images, which allows them to see their unborn baby with clarity. Many couples expect to know the gender of the fetus. Others do not want to know the gender, even if it is obvious, and prefer to wait and "be surprised." The sonographer often provides parents with still images and sometimes a short video of their fetus. Images made for parents are keepsakes and are not used for medical diagnostics but are incidental to the medical indication. Other views are archived for medical documentation purposes.

Levels of Obstetric Ultrasound

Ultrasound is a common tool for fetal imaging. Physicians or technologists with specific training are the only health care personnel who should perform examinations with medical indications. Three levels of obstetric ultrasound examination may be done for care of the pregnant woman (*American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012; ACOG, 2011b*):

- Standard (basic)—the standard scan includes a general survey of the fetus, placenta, and amniotic fluid volume.
- Specialized (comprehensive)—the specialized scan is done if abnormalities are found during the standard scan or with laboratory or other test results. To target the questionable finding for greater detail and information, the woman's primary care provider may request that the test be performed by a maternal-fetal medicine physician (perinatologist).
- Limited—limited ultrasound is done to address a specific question such as fetal presentation ([Box 10-2](#)).

BOX 10-2 INDICATIONS FOR LIMITED ULTRASOUND SCAN

Determine placental location.
 Detect presence or absence of fetal cardiac activity.
 Assess volume of amniotic fluid.
 Determine fetal presenting part.
 Guide delivery of the second twin in a vaginal birth.
 Assist with amniocentesis and external cephalic version.
 Assess fetal well-being (such as an amniotic fluid index [AFI]).
 Identify problems if mother uses unprescribed or illegal drugs, alcohol, or tobacco.

First-Trimester Ultrasonography

During the first trimester, transvaginal ultrasonography allows clear visualization of the uterus, gestational sac, embryo, and pelvic structures such as the ovaries and fallopian tubes.

Purposes

During the first trimester, ultrasonography is most frequently used to:

- Confirm pregnancy.
- Verify the location of the pregnancy (such as uterine, ectopic).
- Identify multifetal gestations.
- Determine gestational age with measures such as crown–rump length (CRL) and head measurements.
- Confirm number and viability of fetuses.
- Identify markers such as nuchal translucence, which suggests chromosome or other abnormalities.
- Determine the locations of the uterus, cervix, and placenta for procedures such as **chorionic villus sampling (CVS)**, a procedure to obtain a sample of chorionic villi for analysis of fetal cells.

An embryo can be seen about 5 to 6 weeks after the last menstrual period. At this time, the CRL of the embryo is the most reliable measure of gestational age. Fetal viability is confirmed by observation of fetal heartbeat, which is visible when the CRL of the embryo is 5 mm. Maternal structures and abnormalities such as uterine fibroids, ovarian cysts, and bicornuate uteri can be seen (*ACOG, 2011b; Richards, 2012*).

Procedure

The woman is placed in a lithotomy position for transvaginal ultrasound. A transvaginal probe encased in a disposable cover and coated with a gel that provides lubrication and promotes conductivity is inserted into the vagina. The woman may feel more comfortable if she inserts the probe herself. The procedure takes about 10 to 15 minutes to complete.

Second- and Third-Trimester Ultrasonography

Transabdominal ultrasonography is most often used during the second and third trimesters because the uterus extends out of the pelvis, allowing clear views of the fetus and placenta, which are no longer obstructed by pelvic bones.

Purposes

Ultrasonography is used throughout the second and third trimesters to:

- Confirm fetal viability.
- Evaluate fetal anatomy, including the umbilical cord, its vessels, and the insertion site.
- Determine gestational age.
- Assess serial fetal growth over several scans.
- Compare growth of fetuses in multifetal gestations and evaluate quantity of fluid in each amniotic sac.
- Evaluate four of five markers in a biophysical profile (see p. 178).
- Locate the placenta when **placenta previa** (abnormal implantation of placenta in the lower uterus) is suspected.
- Determine fetal presentation.
- Guide needle placement for amniocentesis or percutaneous umbilical blood sampling (PUBS).

Gestational age determination with ultrasonography is increasingly less accurate after the first trimester because the combination of individual growth potential and intrauterine environment causes greater variations among fetuses. Two methods improve the accuracy of gestational age determination in later pregnancy:

- Multiple measurements are calculated by computer software that uses measures such as fetal head biparietal diameter, head circumference, abdominal circumference, and length of bones in extremities.
- If the woman is between 24 and 32 weeks of gestation, two or three ultrasound measurements may be taken 2 weeks apart to compare against standard fetal growth curves.

Initial estimation of fetal age with ultrasonography after 32 weeks of gestation is subject to major error. The fetus is evaluated for other signs of well-being or compromise at this time (Manning, 2009; Richards, 2012). Evaluations such as biophysical profile provide added ultrasound information about fetal well-being.

Accurate gestational age is needed when testing the level of maternal serum **alpha-fetoprotein (MSAFP)** (plasma protein produced by the fetus) because the level of alpha-fetoprotein (AFP) is altered by fetal age and number of fetuses (see Box 10-3, p. 169). Accurate gestational age is also important if intrauterine growth restriction (IUGR) is suspected or the expected date of delivery is questioned.

A specialized ultrasound in the second trimester is used to evaluate the fetus when risk factors are present or the basic examination shows abnormal findings. Examples include prior birth of an infant with anomalies or abnormal clinical findings such as hydramnios (excessive amniotic fluid), oligohydramnios (insufficient amniotic fluid), or abnormal levels of MSAFP or other tests in **multiple-marker testing**. Fetal anatomy is carefully and systematically examined to identify major system and organ anomalies. Anomalies that can be detected with comprehensive ultrasonography include most **neural tube defects (NTDs)** (failure of the bony encasement of spinal cord or skull to close) such as myelomeningocele and anencephaly, abdominal wall defects such as gastroschisis and omphalocele, malformed kidneys, hydrocephalus, obstruction in fetal bowel and urinary systems, cleft lip and palate, and limb abnormalities.

Procedure

For transabdominal ultrasound, the woman is positioned on her back, with the head and knees supported. If she desires, a display panel can be positioned so that she (and her support person) can see the images on the screen. Her head should be elevated, and she should be turned slightly to one side to prevent supine hypotension, which may be caused by compression of the vena cava and aorta by the gravid uterus. A wedge or rolled blanket is placed under one hip to help her maintain this position comfortably. Warm mineral oil or transmission gel is spread over her abdomen, and the sonographer slowly moves a transducer over the abdomen to obtain a picture (Figure 10-3). The procedure takes 10 to 30 minutes.

During the second trimester, a full bladder may be needed to displace the gas-filled intestines and elevate the uterus for better image quality. If a full bladder is necessary, the woman should be instructed to drink several glasses of clear fluid about 1 hour before the examination and not void until after the examination. She may experience some discomfort as the transducer is moved over her distended bladder. Maternal intake of fruit juice is sometimes necessary to trigger the fetal movement needed to evaluate the biophysical profile.

Advantages

Ultrasound allows clear visibility of the fetus and surrounding structures and has been proven safe. Ultrasound is noninvasive and relatively comfortable. In addition, results are obtained immediately. It is widely available and portable.

FIG 10-3 The sonographer provides information while moving an ultrasound transducer over the mother's abdomen to obtain an image.

Disadvantages

Depending on their health care coverage, women may have a problem with the cost of ultrasonography. Women who do not have prenatal care in the first trimester of pregnancy, including those with uncertain gestation, will not obtain all potential benefits from an early ultrasound, when determination of gestational age is most accurate. Although accuracy continues to improve, ultrasound cannot identify all defects of fetal structures, fetal function, or both. Abnormal fetal function may affect the structure but ultrasound does not always find it.

The high quality of ultrasound images enables clinicians to identify several structural markers in the fetal anatomy that may predict a serious problem. For example, nuchal translucency, an area at the back of the fetal neck that does not return ultrasound echoes, has helped identify chromosome abnormalities and some heart defects early. Normal results are reassuring to parents, but suspicious or clearly abnormal images raise their anxiety levels. The physician must discuss with the woman all ultrasound findings and further testing that may be indicated by these results.

DOPPLER ULTRASOUND BLOOD FLOW ASSESSMENT

When an ultrasound wave is directed at an acute angle to a moving target, as with blood flowing through a vessel, the frequency of echoes changes as the cardiac cycle goes through systole and diastole. This change, referred to as the *Doppler shift*, indicates forward movement of blood within a vessel. The direction and velocity of the Doppler shift can be imaged in color, depending on the direction of the flow to or from the transducer (Figure 10-4) (ACOG, 2012).

Purpose

Pregnancies complicated by hypertension or fetal growth restriction may have Doppler ultrasound assessment of blood flow to identify abnormalities in the diastolic flow. Color imaging enhances detail about the degree of resistance to normal blood flow in the growth-restricted fetus. In severe cases, end-diastolic flow may be absent or even reversed. Such findings are not diagnostic in themselves but provide additional information in tests for fetal well-being (Baschat, Galan, & Gabbe, 2012; Harman, 2009).

FIG 10-4 Color Doppler Imaging of the Umbilical Vein and Two Arteries. Blood flow toward the transducer is typically shown as red while the flow away from the transducer is shown as blue. (Courtesy of Paul and Kerri Hamilton.)

ALPHA-FETOPROTEIN SCREENING

AFP is the predominant protein in fetal plasma and is synthesized by the embryonic yolk sac, developing fetal liver, and gastrointestinal tract. AFP diffuses from fetal plasma into fetal urine and is excreted into the amniotic fluid. Although a portion of the AFP in amniotic fluid is swallowed and digested by the fetus, the remainder crosses placental membranes into the maternal circulation. Therefore, AFP can be measured in maternal serum (MSAFP) and amniotic fluid (AFAFP). Abnormal concentrations of AFP are associated with serious fetal anomalies (Box 10-3).

Purpose

Low levels of MSAFP suggest chromosomal abnormalities such as trisomy 21. Elevated MSAFP levels are associated with open NTDs and body wall defects. These anomalies leave internal tissues exposed to amniotic fluid, allowing large quantities of AFP to seep into amniotic fluid and enter maternal serum.

The following are the most common open NTDs:

- Anencephaly—the cranial vault is absent, and most of the brain is undeveloped.
- Spina bifida, including meningocele and myelomeningocele—in meningocele, the meninges protrude from the spinal canal; in myelomeningocele, the spinal cord and meninges protrude through the defect, and extensive nerve damage may be expected.

Spina bifida occulta is not an open NTD and may cause no problems. Open NTDs are fairly common. Anencephaly occurred in 11.6 and spina bifida in 17.8 per 100,000 live births, respectively, in 2006. The rates for NTDs have declined since 1996, the year that folic acid supplementation and addition to food products was instituted; however, the rates for anencephaly have increased (Martin, Hamilton, Sutton, et al., 2009).

BOX 10-3 CONDITIONS ASSOCIATED WITH ABNORMAL MATERNAL SERUM ALPHA-FETOPROTEIN LEVELS

Elevated Levels of AFP*

- Open neural tube defects (anencephaly, spina bifida)
- Esophageal obstruction
- Abdominal wall defects (omphalocele, gastroschisis)
- Increased amount leaked by fetal kidney (hydronephrosis)
- Threatened abortion
- Fetal demise
- Normal fetus in conjunction with one or more of the following:
 - Amniotic fluid contaminated with fetal blood (e.g., during amniocentesis, percutaneous umbilical blood sampling)
 - Underestimation of fetal age
 - Maternal insulin-dependent diabetes (such as type 1)
 - Incorrect maternal weight (lower than the true weight)
 - Multifetal gestation

Low Levels of AFP

- Chromosomal trisomies (e.g., Down syndrome, or trisomy 21)
- Gestational trophoblastic disease
- Normal fetus in conjunction with:
 - Overestimation of gestational age
 - Increased maternal weight (higher than true weight)

*AFP, Alpha-fetoprotein.

Procedure

Initial screening is offered to all women between 16 and 18 weeks of gestation, when blood may be drawn to evaluate the concentration of MSAFP. Additional tests done at this time constitute a multiple-marker screening for defects (AAP & ACOG, 2012). Gestational age, maternal weight, multifetal pregnancy, race, maternal diabetes, and ethnicity can affect MSAFP and must be considered when evaluating the levels. Accurate maternal weight at the time of the blood sample is necessary because heavier women have greater dilution of their serum compared with thin women. The obese woman might have an inaccurate low MSAFP with serum dilution, whereas that of the thin woman might be inaccurately elevated. Women with type 1 diabetes have a greater risk for a fetus with an NTD yet may have a lower MSAFP level. Black women have a lower risk for a fetus with an NTD and yet may have higher MSAFP levels compared with other ethnic groups.

The mother is informed that MSAFP is a screening test rather than a diagnostic test and that further tests may be offered to explain abnormal concentrations. If MSAFP levels are elevated, ultrasound is offered to determine whether the abnormal concentration results from inaccurate gestational age, multifetal gestation, or fetal demise.

Advantages

Maternal serum AFP evaluation has several advantages:

- It is a simple procedure that requires only a sample of maternal blood.
- It is not invasive to the fetus and is the most economic procedure to screen for an open body wall defect such as an NTD or for a chromosome abnormality.
- Screening at about 16 weeks of gestation allows time for more comprehensive testing if results for MSAFP are abnormal. Parents may examine their options or prepare for the birth of an infant who will need special care.

Limitations

Some major limitations of MSAFP evaluation are the following:

- It is a screening test and must be viewed as the first step in a series of potential decisions about diagnostic procedures if abnormal concentrations are found. Parents must decide whether to proceed each time another diagnostic test is offered.
- Benign conditions such as inaccurate estimation of gestational age can result in apparently abnormal levels in a healthy fetus; the parents may experience a great deal of anxiety and expense if they choose to pursue follow-up testing.
- Timing also imposes some limits. Evaluation is performed between 16 and 18 weeks, but some women may not seek care until late in pregnancy, missing the opportunity for MSAFP evaluation and related screening.
- Because closed NTD and other closed defects do not produce elevated levels of AFP, normal levels of AFP do not guarantee that the baby is free of structural defects.

MULTIPLE-MARKER SCREENING

Although evaluation of MSAFP is a common noninvasive test for an open body wall defect such as an NTD, low levels of the protein are linked to chromosome defects. Trisomy 21, or Down syndrome, is a common birth defect that occurred in 49.5 per 100,000 births in 2006 (Martin et al., 2009). The risk for having an infant with a chromosome defect increases with maternal age, rising sharply after age 35 years. The birth rate among women older than 35 years is rising but remains lower than the birth rate among younger women. Therefore, tests to identify chromosome abnormalities noninvasively are useful for both younger and older pregnant women.

Two other markers, human chorionic gonadotropin (hCG) and unconjugated estriol, have been added to routine MSAFP evaluation to screen for chromosomal abnormalities. This package of three tests may be called a *triple-screen*. This multiple-marker screening increases detection of trisomy 18 and trisomy 21 (Gilbert, 2011; Simpson, Holzgreve, & Driscoll, 2012a). Maternal serum samples are taken between 16 and 18 weeks of gestation and results are considered positive if MSAFP and estriol levels are low and if hCG level is high. The woman should be offered additional testing such as amniocentesis for karyotyping or additional ultrasonography to look for physical characteristics if the results are positive.

A fourth marker, the placental hormone inhibin A, improves the accuracy of the triple-screen for identifying trisomy 21 in women younger than age 35 years, is becoming more common, and may be called the *quad-screen*. Added costs for multiple tests must be considered in terms of benefits to the woman and her fetus.

CHORIONIC VILLUS SAMPLING

Purpose

Chorionic villi are microscopic projections from the outer membrane (chorion) that develop and burrow into endometrial tissue as the placenta is formed. The villi are fetal tissues and reflect the chromosomal, metabolic, and genetic makeup of the fetus.

Indications

CVS is usually performed between 10 and 12 weeks of gestation to diagnose fetal chromosomal, metabolic, or deoxyribonucleic acid (DNA) abnormalities. CVS is not used to detect open body wall defects such as spina bifida, which require an amniotic fluid sample (AAP & ACOG, 2012; ACOG, 2009; Simpson, Richards, Otaño et al., 2012b).

Procedure

As with all diagnostic procedures, the woman should receive counseling about the procedure itself as well as genetic counseling about the specific defect for which CVS is being performed. The risks and benefits of the procedure should be carefully explained, and a signed informed consent should be obtained.

CVS can often be performed by either the transcervical or the transabdominal approach. The transcervical approach is usually more comfortable for the woman, but it often results in minor postprocedure bleeding. The approach providing the easiest, most direct access to the villi is usually chosen (Simpson et al., 2012b; Wapner, Jenkins, & Khalek, 2009).

For transcervical aspiration, the woman is placed in the lithotomy position. The vagina and cervix are washed with an antiseptic germicidal agent before the procedure, and strict aseptic technique is observed to decrease the chances of infection. Cultures for infections such as gonorrhea, chlamydia, and group B *Streptococcus* infection may be required before CVS. Under ultrasound guidance, a flexible catheter is inserted through the cervix, and a sample of chorionic villi is aspirated through the catheter into a syringe containing the culture medium (Figure 10-5).

Transabdominal CVS is performed with the woman in a supine position. Ultrasound helps identify the best entry position and angle of passage of the sampling needle. An area on the abdomen is cleansed with antiseptic solution. With ultrasound guidance, the physician inserts a needle through the abdominal wall and myometrium, and the tip is advanced to the placenta. A sample of chorionic villi is withdrawn for chromosome analysis.

After CVS, fetal heart activity is documented to confirm viability. Maternal vital signs are assessed, and the woman is allowed to void if needed. Rho(D) immunoglobulin (RhoGAM) is given to women who are Rh-negative because CVS increases the risk of Rh sensitization. A small amount of vaginal spotting may occur, but heavy bleeding or the passage of amniotic fluid, clots, and tissue should be reported. The woman needs to rest at home for several hours after the procedure. Sexual intercourse may be limited for a few days.

Advantages

CVS is performed between 10 and 12 weeks of gestation, so results are known earlier than early amniocentesis. As a result, CVS offers prenatal diagnosis to women who find later procedures unacceptable. Furthermore, if results are abnormal and the woman chooses abortion, she may consider the earlier abortion less physically and emotionally traumatic than a later procedure.

Risks

The rate of pregnancy loss after CVS is similar to that of amniocentesis. Fetal loss appears to be less frequent in centers that perform many CVS procedures. More than two attempts or bleeding during the week before the procedure increases the risk for fetal loss. Reports of limb reduction defects (LRDs) associated with CVS performed before 10 weeks of gestation appeared in the early 1990s. Current data appear to confirm the safety of CVS at the gestational age of 10 to 12 weeks, but the slight risk for LRDs must be shared with the parents (Simpson et al., 2012a; Wapner et al., 2009). Although not a risk, analysis of cells from

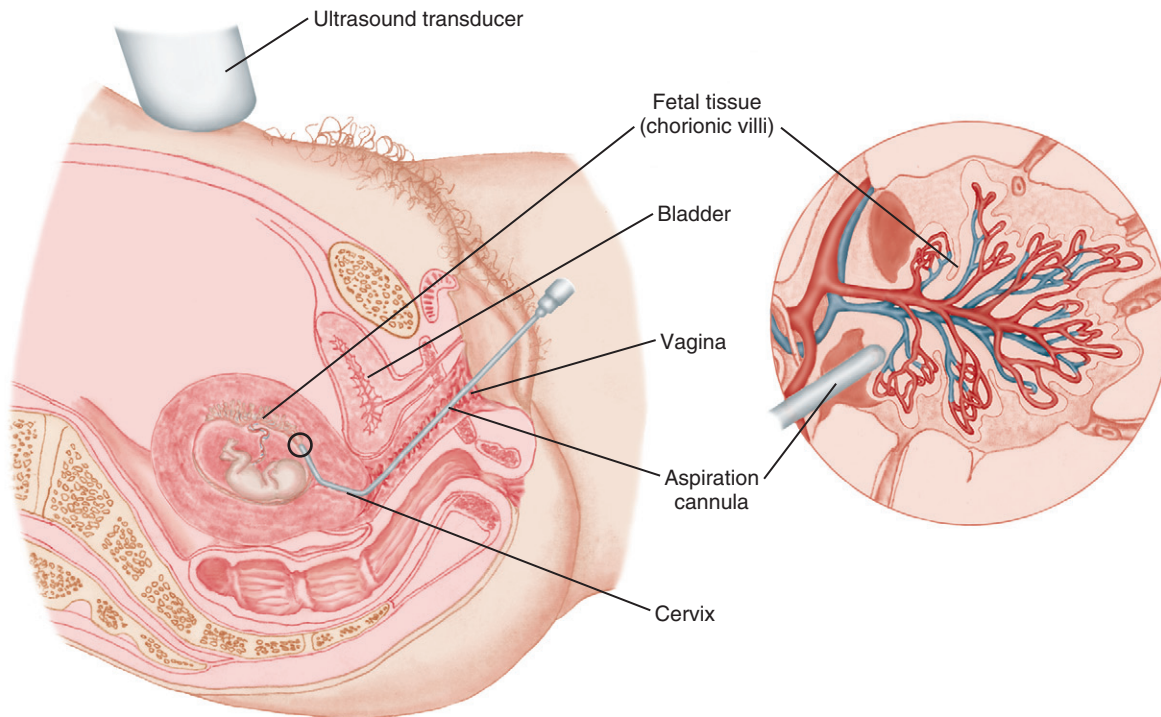

FIG 10-5 Transcervical Chorionic Villus Sampling. Tissue is aspirated to detect the presence of genetic defects in the fetus. Transabdominal aspiration is an alternative method.

CVS is labor intensive because maternal cells are mixed with fetal cells in the sample and must be removed.

Preliminary results from CVS are available within 2 to 3 hours because the villi cells rapidly divide. For added quality, villi cells are incubated for 2 to 4 days, with added cells placed in tissue culture for analysis within 7 days (Wapner et al., 2009). Tests other than karyotyping, such as those for metabolic disorders, may be available very quickly or may require a longer time for analysis. Clarifying questionable CVS results may require further testing with cells obtained by amniocentesis, adding expense, invasiveness, and anxiety to the prenatal diagnosis process.

9. What major risks are associated with CVS?

AMNIOCENTESIS

Amniocentesis is the aspiration of amniotic fluid from the amniotic sac for examination (Figure 10-6). The procedure is best performed at 15 to 20 weeks of gestation because adequate fluid volume and the quantity of viable fetal cells provide the best sample for evaluation. Early amniocentesis before 14 weeks can result in failure to obtain adequate amniotic fluid for sampling fetal cells. Because of disruption of the membranes and leaking of amniotic fluid, foot deformations such as talipes equinovarus (clubfoot) have occurred, although the exact risk is not known (see Chapter 20).

Purposes

Midtrimester

The most common purpose for midtrimester amniocentesis is to examine fetal cells present in amniotic fluid to identify chromosome abnormalities. Other methods of genetic analysis, such as those for

FIG 10-6 In amniocentesis, a needle is inserted through the woman's abdomen to aspirate fluid from the amniotic sac. The fluid can then be tested to determine fetal maturity, chromosome abnormalities, and other possible problems.

BOX 10-4 COMMON INDICATIONS FOR SECOND-TRIMESTER AMNIOCENTESIS

Maternal age ≥ 35 years
 Chromosomal abnormality in close family member
 Gender determination for maternal carrier of X-linked disorder (such as hemophilia, Duchenne muscular dystrophy)
 Birth of previous infant with chromosomal abnormalities or an open neural tube or body wall defect
 Pregnancy after three or more spontaneous abortions
 Elevated levels of maternal serum alpha-fetoprotein or multiple-marker screen that remain unexplained
 Maternal Rh sensitization of maternal Rh-negative blood to fetal Rh-positive blood

metabolic defects in the fetus, may be performed on the cells as well.

In addition to detecting chromosomal abnormalities, amniocentesis is used to evaluate the fetal condition when the woman is sensitized to Rh-positive blood, diagnose intrauterine infections, and investigate amniotic fluid AFP when the multiple-marker test done on maternal serum is not normal (Box 10-4).

Third Trimester

The most common indications for amniocentesis during the third trimester are to determine fetal lung maturity and evaluate the fetal condition when the woman has Rh isoimmunization. Although several types of maternal-fetal blood incompatibilities exist, Rh incompatibility is most severe (see Chapter 25).

Tests to Determine Fetal Lung Maturity. A test for fetal lung maturity is recommended when delivery is considered before 38 full weeks of gestation or if the actual gestation is uncertain. **Surfactant**, a surface-active substance composed primarily of phospholipids, reduces the surface tension on the inner walls of the alveoli, allowing them to stay open slightly when the infant exhales. Without adequate surfactant, the walls adhere to one another, making it difficult to inflate the alveoli with the next breath. Each breath requires greater effort to reopen collapsed alveoli, and the infant soon tires.

The **lecithin/sphingomyelin (L/S) ratio** is a test for estimating fetal lung maturity. Lecithin is a phospholipid component of fetal lung fluid and surfactant, and sphingomyelin is a general amniotic membrane lipid. Lecithin and sphingomyelin are present in approximately equal amounts until about 30 weeks of gestation. At this time, the level of sphingomyelin plateaus, whereas the level of lecithin continues to rise. An L/S ratio of at least 2:1 generally indicates adequate surfactant and mature fetal lungs. However, an L/S ratio of 2:1 may not indicate lung maturity in some conditions such as maternal diabetes. Therefore, amniotic fluid is usually tested for the presence of **phosphatidylglycerol (PG)** and **phosphatidylinositol (PI)**, two other components of surfactant, in addition to the L/S ratio. The presence of PG and PI phospholipids supports the likelihood that the fetal lungs are mature. The accuracy of the three tests may be affected by the presence of blood and meconium in the amniotic fluid. Additional tests include the TDx assay (surfactant-albumin ratio) to determine the surfactant content in amniotic fluid and the foam stability index (FSI), often called the “shake test” (Greenberg, Druzin & Gabbe, 2012; Mercer, 2009a).

Determining the PG level is also useful in evaluating the maturity of the fetal lungs from a sample of amniotic fluid taken from a vaginal pool when the membranes have ruptured prematurely. This test is

noninvasive, but the fluid sample will also be contaminated by substances such as mucus, blood, and bacteria, which may interfere with accuracy of other lung maturity tests (Mercer, 2009a).

Test for Fetal Hemolytic Disease. Amniocentesis may be used to determine fetal bilirubin concentration with a **Δ OD450 (delta OD450) test** to measure the optical density (OD) of the amniotic fluid stained by bilirubin if the mother is Rh-negative and was sensitized after being exposed to Rh-positive blood. Antibodies of the sensitized woman can destroy Rh-positive blood of the fetus, leaving the fetus vulnerable to erythroblastosis fetalis and hydrops fetalis (see Chapter 25).

Erythroblastosis is marked by excessive destruction of mature erythrocytes capable of carrying oxygen and the proliferation of immature erythroblasts incapable of carrying oxygen. The concentration of bilirubin, which is released from erythrocyte breakdown, increases. The fetus becomes anemic, jaundiced, and edematous (hydrops fetalis) as the heart fails. Because of possible errors in the amniotic fluid sample, fetal transfusion will not be done without sampling fetal blood to verify anemia (see PUBS).

Procedure

Before the examination, the woman is placed in the supine position and draped, with her abdomen exposed. A rolled towel is placed under one buttock to shift the weight of the uterus to the side and off the vena cava and aorta. Maternal blood pressure and FHR are assessed for baseline levels.

Ultrasonography is used to locate the fetus and placenta and identify the largest pockets of amniotic fluid that can safely be sampled. The skin is prepared with antiseptic solution. A small amount of local anesthetic may be injected into the skin. The woman may feel pressure as the needle is inserted and mild cramping as the needle enters the myometrium.

A 3- to 4-inch, 20- or 21-gauge spinal needle is inserted into the pocket of fluid. After discarding 1 to 2 mL of fluid, approximately 20 mL of fluid is removed for analysis. A smaller volume of fluid (about 1 mL per week of gestation) is available for early amniocentesis at 11 to 14 weeks. The woman rests quietly for observation while ultrasonography or electronic fetal monitoring (EFM) provides reassurance of the FHR and of the remaining fluid. She may then resume normal activities after 24 hours. Strenuous exercise such as jogging and other aerobic exercises should be deferred for 1 or 2 days. She should report persistent uterine contractions, vaginal bleeding, leakage of amniotic fluid, and fever (Cunningham, Leveno, Bloom et al., 2010).

As with CVS, RhoGAM is administered to prevent sensitization in nonsensitized Rh-negative women after amniocentesis.

Advantages

Amniocentesis has several advantages:

- It is a simple and reasonably safe procedure for diagnosis of many fetal abnormalities, maternal Rh-sensitization and its impact on the Rh-positive fetus, and fetal lung maturity.
- It is a relatively painless procedure that takes a short time.
- It has been performed for many years with few reported complications and is familiar to most obstetricians.

Disadvantages

Timing is a disadvantage of amniocentesis for genetic studies. About 15 to 16 weeks of gestation is when the uterus is readily accessible and the volume of amniotic fluid permits removal of at least 20 mL. Analysis of the fluid, requiring active division of cells for an adequate number to **karyotype** (display imaged chromosomes from largest pair to smallest pair), adds 3 to 7 days to the date of the amniocentesis, depending

on the test. Techniques that may be possible for more rapid results include DNA probes to identify specific genes in a chromosome, such as fluorescence in situ hybridization (FISH). Spectral karyotyping (SKY) can be used to “paint” each of the 23 pairs of chromosomes with a specific color to identify extra or missing chromosomes. Other tests done on the sample may include those for specific genetic defects or open body wall defects. (See also [Chapter 5](#).)

Test results from amniocentesis give a woman little time for decisions about additional tests or whether to terminate her pregnancy before 20 weeks. Her growing uterus makes pregnancy obvious, and she can feel fetal movements. Added tests—such as high-quality ultrasound imaging, biochemical screening through maternal serum, CVS, early amniocentesis, techniques for more rapid fetal chromosome analysis, and DNA analysis not requiring cell culture—have helped identify birth defects that previously were not known. Although the added techniques may seem simple at first, they can result in many additional choices to reach a final decision about whether a birth defect exists and what options are available.

Risks

The risks of amniocentesis include a pregnancy loss rate of less than 1%. A higher pregnancy loss rate of 2% to 5% has been noted after early amniocentesis between 11 and 13 weeks ([AAP & ACOG, 2012](#)). Ultrasound guidance of needle insertion reduces the incidence that the placenta or cord is pierced. Transfer of fetal blood to maternal circulation may occur, resulting in sensitization of the Rh-negative woman carrying an Rh-positive fetus. RhoGAM is administered to prevent sensitization in nonsensitized Rh-negative women after amniocentesis.

PERCUTANEOUS UMBILICAL BLOOD SAMPLING (PUBS)

PUBS, also called *cordocentesis*, involves the aspiration of fetal blood from the umbilical cord for prenatal diagnosis or therapy ([Figure 10-7](#)). Major indications for PUBS include diagnosis and management of Rh disease, diagnosis of abnormal blood clotting factors, and determination of the acid-base status of the fetus. Fetal blood may be used to clarify questionable results of genetic testing by methods previously discussed. The PUBS technique can be used to treat blood diseases and deliver therapeutic drugs that cannot be delivered to the fetus in another way. CVS has replaced PUBS for many fetal karyotyping tests.

Procedure

High-resolution ultrasound is used to locate the fetus, placenta, and umbilical cord and to guide needle insertion. The needle is inserted into the umbilical cord near the site at which the cord meets the placenta, which affords more cord stability. The umbilical vein is used more commonly than the umbilical arteries because it is larger and less likely to constrict during the procedure. Knowing which vessel (umbilical vein or artery) was sampled is important when testing fetal acid-base parameters. Blood returning to the fetus through the umbilical vein contains freshly oxygenated blood and lower carbon dioxide

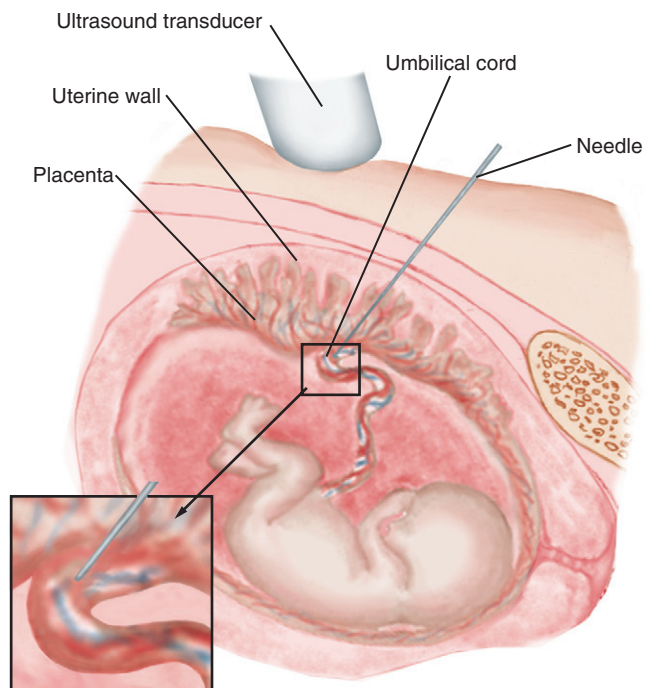

FIG 10-7 In percutaneous umbilical blood sampling (PUBS, or cordocentesis), a needle is inserted through the expectant mother’s abdomen and into an umbilical vessel (vein or artery) to withdraw a sample of fetal blood.

content compared with blood leaving the fetus and going to the placenta through the umbilical arteries.

After needle withdrawal, the duration of bleeding from the umbilical cord is usually short and can be monitored by ultrasound examination. The fetal heart is monitored electronically for 30 to 60 minutes ([Harman, 2009](#)). The Rh-negative woman is given RhoGAM to prevent sensitization by any Rh-positive fetal blood that may have entered her circulation.

Risks

PUBS can occasionally result in a variety of life-threatening complications for the fetus. Therefore, the perinatal team must be prepared for emergencies with a plan based on the indication for the sampling and fetal gestational age. This plan must be determined ahead of time and shared with the woman and her support person.

Fetal bradycardia is the most common complication and is usually brief and has no long-term consequence. More severe bradycardia is associated with puncture of the umbilical artery. Less common complications include prolonged bleeding from the cord, cord laceration, cord hematoma, thrombosis, thromboembolism, preterm labor, and preterm rupture of membranes. Maternal blood sensitization, usually to the Rh factor, may occur if a fetal-to-maternal bleed exceeds 10 mL and inadequate RhoGAM is given for prevention. Sensitization to other blood factors may also occur ([Harman, 2009](#); [Moise, 2012](#); [Weiner, 2010](#)). Premature rupture of membranes or preterm labor may also occur.

ANTEPARTUM FETAL SURVEILLANCE

Antepartum fetal surveillance has three goals: (1) to determine fetal health or compromise as accurately as possible, (2) to reduce perinatal morbidity and mortality, and (3) to guide intervention by the obstetric

THERAPEUTIC COMMUNICATIONS

Responding to Anxiety Related to Fetal Testing

Margaret is a 35-year-old primigravida. She had postponed pregnancy to complete her education and establish a law practice. She has now been referred for possible amniocentesis at 15 weeks of gestation because the risk for chromosomal abnormalities increases beginning at age 35 years. Counseling has already been provided by a specialist in genetics, and the risks and benefits of the amniocentesis have been discussed. The genetic counselor has also discussed with Margaret and her husband the option of multiple-marker screening and ultrasound rather than amniocentesis. Although ultrasound examination helps detect signs associated with chromosomal abnormalities or other birth defects possibly related to Margaret's age, multiple-marker screening helps identify other possible birth defects such as spina bifida.

Margaret: I'm here, but I'm not thrilled to be here.

Nurse: You wish you were somewhere else?

(Clarifying without attempting to lead.)

Margaret: The place isn't the problem really, but what about this test?

Nurse: What questions would you like to ask about the amniocentesis?

(Seeking information, staying with the woman's comments by paraphrasing.)

Margaret: Well, my mother believes that if one thinks bad thoughts, bad things will come to pass.

Nurse: Bad thoughts?

(Knowing that the intergenerational belief system is powerful, the nurse focuses and seeks clarification.)

Margaret: Yes, you know, if we think something could be wrong with the baby, it's more likely to be true.

Nurse: I'd like to hear more.

(“I” statement conveys interest and invites more discussion.)

Margaret: Well, my mother is not familiar with the tests, and she's just afraid that the test could hurt the baby.

Nurse: She must be very anxious about this test. How do you feel?

(The nurse notes that Margaret identifies her mother as the person who is concerned and avoids her own feelings. The nurse acknowledges her mother's feelings; and focuses on the Margaret's feelings by open-ended question.)

Margaret: She's anxious, and to tell you the truth, I'm anxious, too.

Nurse: You would rather not be having the test.

(This makes an assumption; she said only that she was anxious. Saying “Tell me more about that” might be more therapeutic.)

Margaret: No, I want the test. I'm glad there is an option to having an amniocentesis for those who want to go that way. But having more decisions from several kinds of prenatal tests also makes me worry even more about whether I'm making the right choices. I want this baby so much, and I've waited a long time.

Nurse: So, the anxiety is really about whether the decision you made is the right one.

(The nurse “hears” the anxiety that Margaret did not put into words; summarizes concerns; and helps the woman identify and focus on what seems unclear to her.)

Margaret: That's for sure. It will be so hard to wait for the final results, and I don't know what I would do if the news is bad or if I must decide about even more testing. I would also feel guilty if something happens to the baby because of the test.

Nurse: Waiting is difficult, but chances are that the news will be good.

(Acknowledging the difficulty is therapeutic, but offering reassurance blocks the interaction instead of focusing on the uncertainty expressed. The nurse might have said instead: “And it's very hard to imagine something is wrong with the baby.” This response would have kept the interaction going and focused on the client's feelings. Instead, the blocking comment ended the interaction without allowing a full expression of feelings.)

Margaret: You think so? I hope so.

team. The three most common methods of fetal surveillance are the following:

- **Nonstress test (NST)**, observing the fetal heart rate response to fetal movement
- **Contraction stress test (CST)**, observing the fetal heart rate response to contractions
- **Biophysical profile (BPP)**, evaluating fetal status with the five variables: fetal heart rate, breathing movements, gross body movements, muscle tone, and amniotic fluid volume

A fourth method, maternal assessment of fetal movement, provides a way for the pregnant woman to alert her health care provider to possible problems in her fetus. These methods are not expected to predict compromise caused by acute events such as abruptio placentae (premature separation of the placenta).

Nonstress Test**Purpose**

The NST identifies whether an increase in the FHR occurs when the fetus moves, indicating adequate oxygenation, a healthy neural pathway from the fetal central nervous system (CNS) to the fetal heart, and the ability of the fetal heart to respond to stimuli. FHR accelerations without fetal movement are also considered a reassuring sign of adequate fetal oxygenation. If the fetal heart does not accelerate with movement, however, fetal hypoxemia and acidosis are concerns. In those cases, an additional test such as the CST or BPP is necessary to evaluate the metabolic condition of the fetus. The test may help identify intraamniotic infection when the membranes have ruptured

prematurely (Greenberg, et al., 2012; Mercer, 2009b; 2012). The NST is often included as part of the BPP.

Procedure

The NST takes about 40 minutes, allowing for most fetal sleep–wake cycles, although the fetus may show a reassuring pattern more quickly or need more time to awaken and become active. A nurse with special preparation conducts the test in a hospital or an obstetrician's office. The physician makes the final interpretation of the fetal monitor strip. Before the test, the nurse discusses the test with the woman and explains why it is recommended. The test is termed *nonstress* because it consists of monitoring only. The fetus is not challenged or stressed by uterine contractions stimulated to obtain the necessary data.

Before the NST, the woman should void, and her baseline vital signs should be taken. The woman may be seated in a reclining chair or have her head elevated at least 45 degrees. Tilting her to one side to displace the uterus usually prevents supine hypotension.

The nurse applies external electronic monitoring equipment to the woman's abdomen to detect the fetal heart rate and any contractions. An ultrasound transducer to record fetal heart activity is secured on the woman's abdomen, where the fetal heart is heard most clearly. Next, a tocotransducer (“toco”), which detects uterine activity and fetal movement, is secured to the maternal abdomen (Figure 10-8). The woman may be given an event marker to press each time she senses movement, or the nurse may palpate the uterus to identify movements. Fetal heart activity and movements are recorded on a moving strip of paper or an electronic strip in computerized systems (see Chapter

14). Contractions may be identified during an NST. These are often irregular, reflecting normal functions of the uterus as pregnancy progresses. However, frequent contractions in the preterm pregnancy may indicate increased uterine irritability that should be reported.

Interpretation

Physicians must review and interpret NST results, although the nurse performs most NSTs. Results are classified as reactive (reassuring) or nonreactive (nonreassuring) (AAP & ACOG, 2012).

FIG 10-8 A nonstress test is a noninvasive test that measures the response of the fetal heart to fetal movements. Here, the nurse reassures the parents by pointing to fetal heart accelerations.

- Reactive (reassuring)—At least two fetal heart accelerations, with or without fetal movement, occur within a 20-minute period, peak at least 15 beats per minute (beats/min) above the baseline, and last 15 seconds (“15 by 15” from baseline to baseline) (Figure 10-9). Acoustic stimulation that elicits similar rate accelerations is also reassuring. Extending the testing time for an additional 40 minutes may be needed to allow for common fetal sleep–wake cycles.
- Nonreactive (nonreassuring)—Tracing does not demonstrate the required characteristics of a reactive tracing within a 40-minute period.

Fetal heart reactivity develops with maturation of the fetal autonomic nervous system and reactivity of 15 beats by 15 seconds should be present by 34 weeks, although it may appear earlier. Suggested criteria for a reassuring NST in the fetus younger than 32 weeks include two accelerations that peak 10 beats/min above the baseline with a duration of 10 seconds (“10 by 10”) within a 20-minute time window (AAP & ACOG, 2012; Greenberg et al., 2012; Treanor, 2009).

Advantages

The NST is noninvasive and painless and believed to be without risk to mother or fetus. Consequently, it is the primary means of fetal surveillance in pregnancies at increased risk for **uteroplacental insufficiency** (inability of placenta to exchange oxygen, carbon dioxide, nutrients, and waste products properly between maternal and fetal circulations) with consequent fetal hypoxia and acidosis. The NST is easy to administer and often is repeated one to two times per week and even daily if necessary. In addition, results are available immediately.

FIG 10-9 **A**, Several accelerations have a duration of at least 15 seconds, reaching a peak of 25 to 30 beats per minute in this example of a reactive nonstress test. Comparable accelerations without fetal movement are also reassuring. **B**, In this recording of a nonreactive nonstress test, accelerations are absent after fetal movement (FM). (Courtesy of Graphic Controls, Buffalo, New York.)

Disadvantages

A disadvantage is a false-positive test result that occurs in a well-oxygenated term fetus that does not have accelerations reaching a peak of 15 beats/min or that last less than 15 seconds from baseline to baseline. Because of the high false-positive rate, women may undergo additional testing even though her fetus is actually healthy. Additional testing related to a nonreactive NST is usually a BPP or a CST.

Sleep is the usual reason for lack of fetal movement. Fetal sleep cycles average 20 to 40 minutes but other sleep cycles are longer. Vibroacoustic stimulation (VAS) reduces many false-positive results. Various methods have been used to stimulate the fetus and elicit accelerations in the FHR. These include having the mother drink orange juice to raise her glucose level, manipulating her abdomen, and using sound stimulation such as speakers placed on the abdomen. Of these, only acoustic stimulation has been shown to be both safe and effective in reducing false-positive results. The fetus younger than 26 to 28 weeks may not yet have the startle response to sound and vibration.

Vibroacoustic (Acoustic) Stimulation

Purpose and Procedure

Vibroacoustic stimulation (VAS), also called *acoustic stimulation*, uses sound stimulation to elicit fetal movement. VAS may stimulate fetal movement that results in a reactive NST or may confirm nonreactive NST findings and may shorten the time required to obtain high-quality NST data during the last trimester of pregnancy. Reactive test results obtained with a vibroacoustic stimulator, similar to an electronic larynx, appear to predict fetal well-being without interfering with detection of the compromised fetus. Vibroacoustic stimulation can be used in intrapartum monitoring to verify questionable findings (see [Chapter 14](#)).

A vibroacoustic stimulator is applied to the maternal abdomen over the area of the fetal head, and stimulation with vibration and sound is given for up to 3 seconds. Vibroacoustic stimulation can be repeated at 1-minute intervals up to three times.

Fetal Responses

Brain responses to auditory stimulation appear between 26 and 28 weeks of gestation. The sound of vibroacoustic stimulation does not appear to damage hearing in the fetus. Temporary changes in fetal body movements, breathing movements, and heart rate have been described. Fetuses near term show an increase in the number of gross (large and easily visible or felt) body movements to vibroacoustic stimulation, whereas fetuses between 26 and 32 weeks of gestation show no response. This suggests maturational change in response to vibroacoustic stimulation. Likewise, near-term fetuses appear to have fewer and more irregular breathing movements after vibroacoustic stimulation ([Greenberg et al., 2012](#); [Harman, 2009](#); [Richardson & Gagnon, 2009](#)).

Risks

Vibroacoustic stimulation appears to be safe for the fetus in terms of hearing at 33 weeks' gestation or older ([Harman, 2009](#)). The amniotic fluid and maternal tissues surrounding the fetus soften the sound of the stimulator.

15. What is vibroacoustic stimulation and what is its expected result during the last trimester of pregnancy?

Contraction Stress Test

Purpose

A CST may be done if NST findings are nonreactive, or the test is sometimes the initial test of fetal well-being. Because a BPP often supplements both reassuring and nonreassuring NSTs, the CST is less often performed.

Uterine contractions compress the arteries that supply the placenta with oxygenated maternal blood, causing a recurrent decrease in fetal oxygen levels. The CST records the response of the FHR to stress induced by uterine contractions, identifying the fetus whose oxygen reserves are insufficient to tolerate the recurrent mild hypoxia of uterine contractions. Variability and accelerations of the FHR are expected as in the NST.

The fetus with adequate oxygen reserves tolerates the temporary hypoxia induced by uterine contractions, resulting in a reassuring FHR. However, if the fetus has inadequate reserves and substantial hypoxia has led to anaerobic metabolism, fetal acidosis results. This is likely to be manifested in nonreassuring fetal monitoring patterns.

Because contractions are induced, the CST is contraindicated in the following situations ([AAP & ACOG, 2012](#)):

- Preterm labor or women who have a high risk for preterm labor
- Preterm membrane rupture
- History of extensive uterine surgery or classical uterine incision for cesarean birth (see [Chapter 16](#))
- Placenta previa (see [Chapter 25](#))

Procedure

The nurse positions the woman in the supine position with her head comfortably elevated. Side-lying or uterine displacement reduces uterine pressure on her aorta and inferior vena cava. External EFM devices are applied to record uterine activity and FHR. An initial recording is taken to determine if the woman is having at least three spontaneous contractions within a 10-minute time period, each with a duration of 40 seconds or longer. If spontaneous uterine contractions are adequate to interpret the test, uterine stimulation is not needed. If adequate uterine contractions are not present, either of two methods is used to achieve three adequate contractions within a 10-minute period for interpretation of the test.

The nipple stimulation (breast self-stimulation) test is based on the knowledge that stimulation of the nipples causes release of oxytocin from the posterior pituitary, which can cause uterine contractions. The woman brushes her palm across one nipple through her clothing for 2 minutes, stopping if a contraction begins. The nipple stimulation continues after a 5-minute rest period until an adequate contraction pattern is attained.

If the breast self-stimulation test does not effectively stimulate contractions or if the health care provider does not prefer this method, the oxytocin challenge test may be performed. The oxytocin challenge test uses an intravenous infusion of dilute oxytocin to stimulate uterine contractions. The nurse inserts a primary intravenous line carrying plain fluid such as lactated Ringer solution and a long secondary (piggyback) line for administration of dilute oxytocin solution. The initial rate is low (0.5 to 1 milliunits per minute [mU/min]) and increased every 15 to 20 minutes until the desired contraction frequency is attained ([AAP & ACOG, 2012](#)).

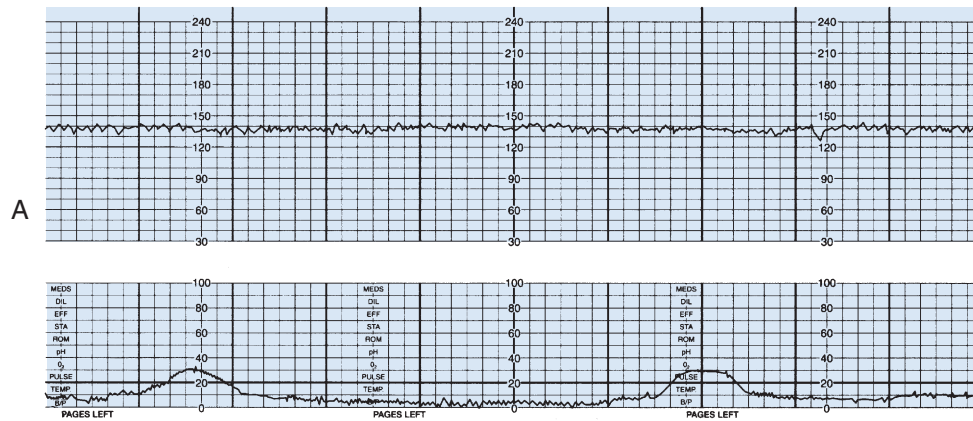

Interpretation

CST results may be interpreted as negative (normal, or reassuring of fetal well-being), positive (abnormal, or nonreassuring that the fetus is healthy), equivocal, or unsatisfactory ([AAP & ACOG, 2012](#); [ACOG, 2009](#)) ([Figure 10-10](#)).

Negative

No late decelerations

Reassuring that the fetus can tolerate labor

**Positive**Consistent late decelerations in $\geq 50\%$ of the contractions, even if contraction frequency is less than 3 in 10 minutes

Indicates UPI and fetal compromise during contractions

**Equivocal-suspicious**

Intermittent late or significant variable decelerations

A second CST should be repeated within 24 hours

Equivocal-hyperstimulation

Late decelerations with excessive uterine activity (contractions closer than every 2 minutes or lasting longer than 90 seconds)

Repeat CST within 24 hours with careful monitoring of the situation

Unsatisfactory

Test cannot be interpreted; either not enough data or unsatisfactory tracing; fewer than three contractions in 10 minutes

Repeat CST with careful attention to maternal position, oxytocin infusion, and placement of tocotransducer

FIG 10-10 Interpretation of Contraction Stress Test (CST). *UPI*, Uteroplacental insufficiency. (Courtesy of Graphic Controls, Buffalo, New York.)

- Negative (reassuring)—No **late decelerations** (decreases in the FHR persisting after the contraction ends), although the fetus was stressed by three contractions of at least 40 seconds' duration in a 10-minute period
- Positive (abnormal)—Late decelerations accompanying at least 50% of contractions, even when fewer than three contractions occur in 10 minutes
- Equivocal (suspicious)—Intermittent late decelerations and significant variable decelerations (sudden decreases in the FHR that quickly return to the baseline)
- Equivocal (hyperstimulation)—FHR decelerations occurring in the presence of contractions that are closer than every 2 minutes or last longer than 90 seconds
- Unsatisfactory—Fewer than three contractions in 10 minutes or a tracing that cannot be interpreted

Advantages

The CST has several advantages:

- The test provides a minimally invasive follow-up of a nonreactive NST result.
- If findings are negative, the CST offers more than 99% reassurance that the uteroplacental unit is likely to support life for at least 1 more week (ACOG, 2012).
- A positive CST result allows the physician to analyze available options for further testing and make plans for the birth of an infant who may be compromised because of decreased placental functioning during labor.

Disadvantages

The CST has three major disadvantages:

- The test is more time consuming than the NST.

- The CST requires precision, needing either the participation of the woman in breast self-stimulation or careful infusion of oxytocin by the nurse to obtain an adequate contraction pattern without causing hyperstimulation of the uterus.
- The cost is higher than that of the NST, particularly if the oxytocin challenge test is used. It is usually performed in a hospital setting with a per-hour charge. Equipment and supplies such as intravenous lines, oxytocin, and infusion pumps add to the cost.

CHECK YOUR READING

16. Why is initiating contractions usually necessary in a CST? Under what circumstances would the nurse not initiate contractions?
17. In a CST, what do late decelerations of FHR indicate?

Biophysical Profile

The condition of the fetus can be most accurately predicted if several parameters are evaluated. Unlike the NST and the CST, which assess only fetal heart activity, the BPP assesses five parameters of fetal status: FHR, fetal breathing movements, gross fetal movements, fetal muscle tone, and amniotic fluid volume. A modified BPP consisting of the NST and amniotic fluid volume likely evaluate the most critical elements to judge fetal well-being (ACOG, 2012; Cunningham, et al., 2010; Lau, 2011).

Purpose

The individual components of the examination are a combination of acute and chronic markers of fetal well-being. The acute or short-term markers are the FHR reactivity, fetal breathing movements, gross fetal movements, and fetal tone. The major chronic or long-term marker is the amount of amniotic fluid.

The acute markers are controlled by different CNS control centers that develop at different stages in gestation. Fetal tone is the earliest to develop, followed by fetal movements and then regular breathing movements. FHR reactivity develops last, at the end of the second trimester or beginning of the third trimester.

The fetal CNS centers that control each individual parameter of the BPP react differently to hypoxemia. The control centers that develop later require higher oxygen levels than those developing earlier. Therefore, FHR reactivity disappears first. Fetal breathing movements are affected next, and fetal movement and fetal tone are the last areas affected. Because of this, absence of fetal tone indicates advanced asphyxia and acidosis. This progression has been termed the *gradual hypoxia concept* (Figure 10-11).

The amount of amniotic fluid provides information about chronic hypoxia if loss of fluid is not the result of premature membrane rupture. During periods of hypoxemia, the fetus shunts blood from areas not critical to fetal life, such as the kidneys and lungs, to vital organs such as the heart, brain, and placenta. If hypoxemia is prolonged, blood flow to the fetal kidneys and lungs, which produce much of the amniotic fluid, may virtually cease. Therefore, oligohydramnios suggests prolonged fetal hypoxia and is a strong indication of fetal compromise. The amount of amniotic fluid is established by calculating the depth of the single maximum-sized pocket. A method that adds the depths of amniotic fluid in four uterine quadrants is the **amniotic fluid index (AFI)**. Established normal values for the AFI do not exist, but volume sums greater than 10 cm are considered reassuring, and volume sums less than 5 cm are considered oligohydramnios. An AFI higher than 18 to 20 cm suggests excess amniotic fluid volume, or hydramnios (Cunningham et al., 2010; Greenberg et al., 2012).

FIG 10-11 Effects of gradual hypoxemia and worsening of fetal acidosis.

Procedure and Interpretation

FHR reactivity is interpreted from an NST. The other four parameters are measured by real-time ultrasonography. A scoring technique is used to interpret the data, with each parameter contributing either 0 or 2 points. A score of 10 is perfect; a score of 0 is the worst score. A total score of 8 to 10 is considered normal unless oligohydramnios is present (Table 10-1). Oligohydramnios may indicate chronic fetal hypoxia and requires further evaluation (ACOG, 2012).

Modified Biophysical Profile

Some physicians now assess the fetus only by ultrasonography and omit the NST if other parameters are normal (ACOG, 2009; Cunningham et al., 2010; Greenberg et al., 2012). This shortens testing time without significantly compromising accuracy. In other medical facilities, the test is modified to include only two parameters—AFI and NST.

Advantages

The modified BPP is noninvasive and less costly than some tests because it can be performed on an outpatient basis. Results are immediately available and may decrease the number of false-positive NST findings. The BPP allows conservative treatment of high-risk clients such as women with diabetes because delivery can be delayed if fetal well-being is indicated. The BPP helps identify the presence and severity of hypoxia and acidemia because it measures multiple variables.

The BPP may be used when membranes rupture prematurely and the risk for fetal infection increases. BPP evaluation may accompany other fetal assessment methods to determine whether intrauterine infection has developed after the amniotic sac ruptures at an early gestation (Mercer, 2012, 2009b).

Disadvantages

Additional research is needed to refine interpretation of the test. For example, each variable is given equal weight, although some variables may be more important than others. The predictive accuracy of the BPP is best at the extremes, meaning that scores of 0 and 10 are highly predictive of the presence or absence of fetal acidosis, respectively. Scores toward the middle have less predictive accuracy.

Because perinatal asphyxia is a possible cause of cerebral palsy, antepartum surveillance techniques may allow fetal hypoxia to be identified and treated before it reaches critical levels. The BPP may be the primary test used to identify problems before they result in permanent fetal injury, but other methods must often enter the diagnostic picture to best clarify fetal condition.

TABLE 10-1 SCORING THE BIOPHYSICAL PROFILE FOR A TERM FETUS

CRITERION	POINTS	
	PRESENT (2 POINTS)	ABSENT (0 POINTS)
Nonstress test (NST) (if used)	Reactive NST (at least 2 fetal heart rate (FHR) accelerations peaking at least 15 beats per minute (beats/min) above baseline for 15 seconds within a 20-minute period)	Nonreactive NST (absence of required characteristics for reactive test after 40 minutes of testing)
Fetal breathing movements (FBMs)	≥1 episode(s) of rhythmic FBMs of 30 seconds or more within 30 minutes	Absent FBMs or none that meet criterion for “present”
Gross body movements	≥3 trunk movements in 30 minutes; limb and trunk movement is considered one movement	Up to 2 trunk movements in 30 minutes
Fetal tone	≥1 episode(s) of fetal extremity extension with return to flexion; opening or closing of hand within 30 minutes	Extension with return to partial flexion; absence of flexion
Amniotic fluid volume	At least one pocket of fluid that measures at least 2 cm in two planes perpendicular to each other	Amniotic fluid volume that does not meet this criterion

* *Interpretation:* Normal (reassuring) = 8 to 10 points; equivocal = 6 points; abnormal = 4 points or less and delivery may be considered. If oligohydramnios is present, more frequent testing is warranted, and delivery may be considered. If the NST is omitted from the biophysical profile (BPP), the maximum score of the four remaining ultrasound criteria is 8.

19. Why is amniotic fluid volume an important parameter in the BPP?

MATERNAL ASSESSMENT OF FETAL MOVEMENT

Movements by the fetus, as assessed by the mother, are often called “kick counts.” Fetal movement is associated with fetal condition, and daily evaluation of these movements provides a way of evaluating the fetus. Variations in fetal movement are affected by such factors as maternal activity, obesity, and medications. Most women perceive fetal movement best when lying on their left side. Maternal reporting of atypical changes in fetal activity has shown to be as valid as formal counting and documentation of fetal movement (Cunningham et al., 2010; Greenberg et al., 2012).

Procedure

Several protocols exist for assessing kick counts. The woman lies on her side, places her hands on the largest part of her abdomen, and concentrates on fetal movements. She uses a clock or timer and records the number of movements felt during that time. Protocols are not essential but may give the woman a more structured timetable for when to concentrate on fetal movements. Examples of kick count protocols include the following (ACOG, 2012; Greenberg et al., 2012):

- Count fetal movements for 30 minutes three times per day (Figure 10-12). Further evaluation is recommended if fewer than three movements occur in 1 hour or if the mother feels no movements in 12 hours.
- Count fetal movements daily for 1 hour. If fewer than 10 movements are felt, continue counting for another hour. Fewer than 10 movements in a 2-hour period should be reported to the health care provider.
- The count-to-10 method entails counting the first 10 movements and noting the starting time and the time of day when the tenth movement is felt. The health care provider should be notified if the tenth movement occurs progressively later or if fewer than 10 movements occur in 12 hours.

- Count fetal movements for 30 minutes in the morning and evening to establish a baseline. If a 50% decrease or no fetal movement occurs, extend the counting period for 30 minutes.

Advantages

Counting fetal movement has the following obvious advantages:

- It has no cost.
- It is noninvasive.
- It may identify fetal problems early in the client who has no known pregnancy risk factors.
- It is convenient for the woman and validates her perceptions of fetal status.

Disadvantages

Many variables make interpretation of fetal movement counts difficult, including the following:

- Fetal resting state decreases movements.
- Maternal perception of movement may vary. The ability of women to perceive fetal movement varies considerably, even in the same woman at different times.
- The time of day may affect fetal movement (lower in the morning, higher in the evening).
- Drugs taken by the mother (such as methadone, heroin, cocaine, alcohol, tobacco) may affect fetal activity.
- The mother may evaluate fetal movements erratically, making her counts less informative.

APPLICATION OF THE NURSING PROCESS

■ Diagnostic Testing

Perinatal nurses perform NSTs and CSTs. Asking the woman about fetal activity is a routine part of assessment at each office visit during the last half of pregnancy. Nurses explain testing procedures and the information that can be determined from the tests. Nurses also reduce anxiety by providing emotional support when decisions about repeated testing or a series of procedures become necessary.

FIG 10-12 Daily Fetal Movement Record in Use. The mother counts the number of fetal movements (kicks) within a specified period several times per day and indicates each movement on a chart. She reports any abnormality to her health care provider.

EVIDENCE-BASED PRACTICE

Mother's Perception of Fetal Monitoring

Does a pregnant woman's perception of her baby's movement make any difference in the outcome of the pregnancy? Saastad et al. (2008) conducted a study in Norway to identify whether providing pregnant women specific information about normal fetal activity (including maternal awareness of fetal movement and maternal concern about decreased fetal movement) affected the outcome of the pregnancy.

Decreased fetal activity is expected with fetal sleep-wake cycles. Fetuses are individuals and therefore are expected to have varied intensity and frequency of activity and sleep. Intensity of fetal activity is expected to increase as the fetus grows and becomes more crowded in the uterus. As the pregnancy progresses, the woman often becomes more aware of the activity of her baby as well as the time of day the baby is more active. The woman's own perception of her baby's movement patterns and any significant changes in that pattern is vital information for care providers.

Other studies have found that the mother's perception varies greatly among women. Factors that may affect maternal perception include maternal position, gestational age, maternal obesity, placenta location, amniotic fluid volume, maternal medication and glucose levels, maternal activity (such as exercise), and maternal cigarette smoking and caffeine consumption. Despite variations in maternal perception all studies have found that maternal awareness of gross body movements increases if the women are focusing on movements while lying in a quiet room.

Health care professionals have not reached agreement on a specific measure of "what is normal." Therefore, practitioners often set their own "normal" guidelines for expected fetal movements. In this study, 25% of the participants did not receive information from their providers about expected normal fetal

activity. Receiving information, even if inconsistent among providers, was associated with greater maternal perception of fetal activity but also greater concerns if their baby deviated from the guidelines.

The growth-restricted, or small-for-gestational-age (SGA), fetus exhibits less fetal activity on ultrasounds done at different gestational ages. Results of this study identified an association between low maternal awareness of fetal activity and a greater risk of having an SGA baby. Mothers who received information about fetal activity demonstrated greater maternal concern with decreased activity but their increased concern did not reduce the risk for an SGA baby or cesarean birth.

The research team suggested questions to ask mothers at prenatal visits that may increase their awareness: "What do you think your baby looks like now?" "What behaviors have you recognized?" "Do you know when your baby is asleep and awake?" "Who is living inside your womb?" "Have you recognized if the baby is responding if you stroke your womb?" Researchers believe that questions like these may increase the mother's curiosity about her baby and increase awareness about her baby's patterns of activity without undue concerns. Greater maternal awareness of activity may not reduce the risk for an SGA baby but may possibly result in earlier identification of fetal growth restriction.

If you have had a baby or are pregnant, can you describe how you would have answered some of these questions? Are there other questions you might ask if you provide care for women receiving regular prenatal care visits? How might you change these questions at various gestational ages? Does your postpartum mother have any descriptions of how she perceived fetal movements during pregnancy or times she was concerned? If she was concerned, what did she do about it?

Assessment

Collect as much information as possible about the woman and her reasons for having the tests. The information may be helpful when conducting the tests and interpreting the results. Necessary information includes the following:

- Gravida, para, living children, gestation (in weeks), problems in any previous pregnancies
- Maternal health problems (such as hypertension, diabetes, heart disease)
- Current obstetric problems (such as vaginal bleeding, decreased fetal movement, multifetal gestation, intrauterine growth restriction, malpresentation, hydramnios, oligohydramnios)

- Prior obstetric problems (such as birth of a stillborn infant or an infant with congenital anomalies, birth of a low-birth-weight infant or a large-for-gestational-age infant)
- History of substance abuse, including alcohol and tobacco
- Knowledge of reasons for the test and the procedure to be performed: "What questions can I answer before we start the test?" Identify whether the woman needs added information from the provider who ordered or will perform the test.
- Knowledge of surveillance regimen if additional testing is necessary: "Will you tell me what you understand about the need to repeat the test every week?" "What kinds of changes in your baby's movement are important to report?" "How soon should you report the changes?"

- Emotional response to the tests: “What are your major concerns?” “What can we do to make the tests easier for you?”
- The woman’s or couple’s expectations of the diagnostic tests. The risks and limitations of testing should be discussed, as well as the indications. It may also be necessary to remind the couple that results from one test may indicate that others are appropriate. They must decide at each step whether to continue.

Nursing Diagnosis

Women at increased risk for problems during pregnancy require fetal diagnostic procedures. Their responses vary, depending on their levels of knowledge and their usual responses to stressful situations. Many women are concerned with both the test and the condition of the fetus. The relevant nursing diagnosis is “Anxiety related to lack of knowledge of diagnostic procedures and the uncertain condition of the fetus.”

Planning

Expected outcomes for this nursing diagnosis are that the woman (and her support person) will do the following:

- Describe how, when, and why she is to be tested before testing procedures are initiated.
- Verbalize concerns about the condition of the fetus and seek information from her health care team at each appointment.

Interventions

Providing Information

The nurse may be the primary provider of information such as for an NST, or the nurse may reinforce physician explanations. Provide simple, clear explanations of what the test measures and its purpose and frequency. Tell the woman how long the test takes, and describe the testing procedure to reduce anxiety caused by lack of knowledge. Tell her about possible discomfort. Give the woman verbal and written information about follow-up care and what to report.

Parents often become concerned when screening test results are abnormal, such as an MSAFP or multiple-marker test. The nurse may need to remind them that other factors may cause abnormal results and that added tests help clarify the results. In addition, nurses often need to interpret technical information that parents receive from physicians because it may be confusing, adding to their anxiety. Awaiting results from follow-up testing, even if very brief, often adds to parents’ anxiety.

Providing Support

Identify and respond to feelings expressed by expectant parents when antepartum testing procedures are recommended or fetal problems are confirmed. The woman often experiences frustration with the discomfort, limitations, and time-consuming demands of pregnancy and the regimen of fetal testing. Skill in therapeutic communication is never more important than during counseling about fetal diagnostic tests.

- Active listening conveys interest and concern.
- Paraphrasing allows for interpretation because it expresses in different words what concerns the family.
- Reflecting what the family conveys about feelings helps them “hear” their feelings.
- Clarifying helps the woman “see” the issues and available options.
- Comforting measures such as touch, if culturally acceptable to the woman, convey empathic concern and are especially important during difficult procedures.

Although nurses offer caring concern and careful reflection of feelings, they do not offer advice. The woman, along with her primary support person and other chosen persons, must make decisions about antepartum assessment. Nurses frequently help the family contact persons (such as a clergy member or close relative) to whom they turn in troubled times such as when abnormal test results are verified.

Helping Women Set Realistic Goals

Women benefit from understanding how an antepartum surveillance regimen benefits the fetus. Although the repeated tests may seem tedious, they often offer the best chance for the fetus to be delivered at the best possible time. Explain to the woman that testing helps the perinatal team decide whether intervention is needed and choose the best possible intervention under the circumstances. The fetus has an improved chance of surviving and reaching maturity if test results remain reassuring.

If the woman is having testing to identify fetal abnormalities, help her understand that a baseline risk for abnormalities remains when tests show the fetus is normal. Even if performing all diagnostic tests for birth defects on a woman were possible, the background risk would remain.

Supporting the Woman’s Decision

Prenatal genetic diagnosis sometimes leads a woman to choose pregnancy termination, often during the second trimester. The woman also has the right to indicated prenatal genetic diagnostic procedures even if she would not terminate her pregnancy for a fetus with an abnormality. Nurses must examine their own ethical beliefs before becoming involved in fetal diagnostic testing. They must be prepared to support whatever decision a family makes, even if it is not one they would make. A woman who decides to continue or terminate a pregnancy is entitled to compassionate care regardless of the nurse’s personal views about her decision.

Evaluation

Expected outcomes are successful if the woman verbalizes knowledge of the reasons tests are recommended and how and when they will be performed. The second goal and expected outcome is met if the woman and family verbalize any concerns about the fetus and seek additional information from the perinatal team as needed.

SUMMARY CONCEPTS

- Ultrasound is widely used during pregnancy to determine a variety of fetal and placental conditions and aid in the performance of other tests such as amniocentesis. It is also used in gynecology and infertility care as well as medical and surgical conditions. Color Doppler ultrasound is a variation that allows estimation and direction of blood flow and vascular resistance in fetal structures.
- AFP assessment is performed on maternal serum or amniotic fluid with the primary goal of detecting open body wall defects such as NTDs. Additional tests are required if AFP levels are abnormal.

Other markers—hCG and estriol, and possibly inhibin A—may be assessed with MSAFP in a triple- or quad-screen for chromosomal anomalies such as trisomy 21.

- CVS is performed at 10 to 12 weeks of gestation to provide parents with information about chromosomal and other congenital defects in the first trimester of pregnancy. CVS does not provide a sample of amniotic fluid for AFP testing.
- Amniocentesis is usually performed in the second trimester to identify fetal genetic defects or open defects such as NTDs. It may be

Continued

SUMMARY CONCEPTS—cont'd

- used during the third trimester to evaluate fetal maturity or Rh incompatibility problems. Standard amniocentesis is performed at 15 to 20 weeks of gestation. Early amniocentesis (11 to 14 weeks) allows earlier diagnosis of genetic problems.
- PUBS involves aspiration of blood from umbilical vessels to detect blood disorders, acid-base balance, or fetal disease. Therapeutic medications and blood products can also be injected by the same route. Fetal bradycardia is the most common complication.
 - The NST determines whether the fetal heart rate accelerates when the fetus moves. Accelerations of the heart rate, regardless of fetal movement, are a reassuring sign because they are associated with adequate fetal oxygenation and an intact neural pathway from the fetal brain to the heart. The healthy fetus younger than 32 weeks of gestation may not have accelerations that meet the criteria for a reactive NST in the older fetus.
 - CSTs evaluate response of the fetal heart to recurrent short interruptions in placental blood flow and oxygen supply that occur with uterine contractions.
 - BPPs assess 5 fetal markers: fetal heart rate, breathing movements, gross fetal movements, muscle tone, and amniotic fluid volume. A modified BPP consists of a NST and amniotic fluid volume.
 - Maternal assessment of fetal movement (“kick counts”) is a non-invasive method of evaluating the fetus; another advantage of this test is that it has no cost. The poorly oxygenated fetus usually moves less than the well-oxygenated fetus. The woman may be advised to follow any of several protocols because no standard protocol exists.
 - All perinatal nurses must be prepared to offer clear explanations of diagnostic procedures and any problems the woman should report. Support for the family requiring fetal diagnostic tests can reduce their anxiety.

Perinatal Education

WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. List the goals of perinatal education.
2. Explain choices in childbearing and the effects of education on these choices.
3. Describe various types of education for childbearing families.
4. Identify techniques for pain relief taught in childbirth classes.
5. Describe the labor partner's role in helping the woman during labor and birth.
6. Explain the components frequently included in a birth plan.

Perinatal education is important to help couples learn about pregnancy, birth, and parenting. Many classes not only focus on preparation for childbirth but also include information formerly received during the birth facility stay.

GOALS OF PERINATAL EDUCATION

The goals of perinatal education are to help parents become knowledgeable consumers, take an active role in maintaining health during pregnancy and birth, and learn coping techniques for pregnancy, childbirth, and parenting. Meeting these goals helps reduce parents' fear of the unknown and increases their abilities to make informed decisions regarding childbirth and parenting with confidence and satisfaction.

Perinatal education classes are strongly recommended by the American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) because they can have a beneficial effect on patients' experience (AAP & ACOG, 2012). A *Healthy People 2020* goal is to increase the proportion of women who attend a series of prepared childbirth classes (U.S. Department of Health and Human Services, 2010).

PROVIDERS OF EDUCATION

Although most perinatal education classes are taught by registered nurses (RNs), physical therapists or others with special education also may become perinatal educators. Many instructors are certified by organizations such as the Lamaze International or the International

Childbirth Education Association (ICEA). Certification ensures that the instructors have received special preparation to provide sound education adhering to the certifying organization's general philosophy.

Teachers must be knowledgeable about adult education theory and techniques and skillful in handling groups of people of diverse ages and from diverse backgrounds. They should be familiar with the policies and daily routines of the agencies their students will use so that the information they present is current and accurate.

Education may be presented formally in classrooms in schools, health departments, civic organizations, medical groups, hospitals, or private homes. Teachers may be employed by a sponsoring agency or self-employed. Classes may also occur in less traditional sites such as places of employment. Teaching women ways to reduce risk factors for complications helps employers reduce costs associated with prematurity and low birth weight.

Teaching methods involve discussion, demonstration and return demonstration, written material, role play, and use of visual aids such as DVDs, models, posters, and equipment. Material used should be evaluated frequently to ensure it is up to date and correct.

Nurses in medical offices, clinics, and birth sites also educate women informally. Teaching may occur in waiting rooms of clinics before women are called for their appointments or as part of routine care. Waiting room teaching has disadvantages because women participate only when they are waiting for appointments and may not receive all the information they need. However, teaching in waiting rooms reaches women who might not attend any classes.

CLASS PARTICIPANTS

Participants in classes have traditionally been middle-income couples who are older and better educated than those who do not take classes. Low-income women may not have transportation or be able to pay for classes. Although inexpensive or free classes are available in some areas, women with little or no prenatal care may not know about them. Classes in languages other than English are often available in areas where they are needed.

People take classes for a variety of reasons. Many want to participate actively in all aspects of childbearing. For these people, making decisions about what happens to them is important, and they want the education to help them decide wisely. Others are looking for coping strategies to deal with their fears of childbirth or pain.

Some women develop a greater sense of control during labor and delivery when they have taken prepared childbirth classes. When women believe they are informed and have some control over what happens to them, they are more likely to expect birth to be satisfying and fulfilling and to experience it as such.

CHOICES FOR CHILDBEARING

One purpose of perinatal education is to help parents learn about available options so they can make appropriate choices. Parents learn that many ways of birthing are possible, none of which is the only “right” method. Knowledgeable parents can communicate assertively with their health care providers about their needs and desires.

Health Care Provider

Women contemplating pregnancy and birth may choose a certified nurse-midwife (CNM), nurse practitioner (NP), or obstetrician to be their health care providers. They need to know what to expect from each of these practitioners.

A CNM cares for women at low risk for complications and refers them to a back-up physician if problems develop. CNMs, NPs, and physicians treat women during pregnancy and the postpartum period, but NPs do not perform deliveries. NPs usually work in a physician’s office and see women for routine prenatal care, but the delivery is performed by the physician. A CNM, NP, or family practice physician may also care for the newborn. A physician generally arrives for the birth near the end of labor, whereas the CNM is often present through most of labor and birth. See [Chapter 2](#) for more information about the various provider roles.

Some couples visit several different care providers before choosing the one they feel is best for them. They may ask about the provider’s usual practices and the provider’s beliefs about areas that are important to them, such as medication, use of episiotomies, or aspects of infant care.

Setting

The woman and her partner must choose a birth setting and select a care provider who practices in that setting. Hospitals are the most common setting for birth in North America. They often have birthing suites that provide a homelike atmosphere. A freestanding birth center provides an atmosphere that is less institutional than that of the hospital. Home birth allows the woman to give birth in her own surroundings with delivery managed by a midwife (see “[Current Settings for Childbirth](#)” in [Chapter 1](#)). Couples may visit the birth setting before making a choice. Their insurance may limit their selection of a setting.

FIG 11-1 An expectant mother may ask a sister or close female friend to be her labor partner and attend classes with her.

Support Person

During labor, the woman needs someone with her to help her through the experience. The support person is most often the father of her baby, but a relative or friend may also take this role ([Figure 11-1](#)). Some women wish to share the birth experience with several relatives and close friends. If the birth setting is traditional, only one or two people may be permitted to be present. In less traditional settings, more support people are usually allowed.

Some women hire a **doula** to provide support during labor. A doula is a trained labor support person who provides physical and emotional support throughout labor and sometimes during the postpartum period. Some have national certification by specialty organizations such as the ICEA to perform the role.

Siblings

The presence of children at birth is controversial. Some believe that children become closer to their new siblings when they are present at birth. Others believe that the sights of the birth process, blood, and their mothers in pain may be too frightening for children. Some debate focuses on the age of the child attending the birth.

Children who participate in the birth of a sibling may attend all or part of the labor and birth or may join the parents just after the birth to participate in the immediate celebration. An adult support person is necessary to stay with the child throughout the experience. The support person should have no role other than attending to the child. This role includes gauging the child’s response, providing explanations and reassurance, and taking the child out of the room as needed.

Education

Expectant mothers must also decide on prenatal education classes. Their decisions are based on the classes available in the area, costs, and types of information they need. Small classes of a few women and their partners are ideal but may be too expensive or unavailable. The teacher is usually an RN who has experience in maternity nursing and is certified by a nationally known organization such as Lamaze International or the ICEA.

CHECK YOUR READING

1. What are the goals of perinatal education?
2. What major decisions must couples make in preparation for childbirth?

TYPES OF CLASSES AVAILABLE

Although most people think of perinatal education primarily as preparation for the birth experience, classes are available for all areas of pregnancy, childbirth, and parenting.

Preconception Classes

Classes for couples who are thinking about having a baby are designed to help them have a healthy pregnancy from the beginning. Information about nutrition before conception, healthy lifestyle, signs of pregnancy, and choosing a caregiver is presented. The effects of pregnancy and childbirth on a woman's relationships and career are discussed. Preconception classes emphasize early and regular prenatal care beginning before pregnancy and ways to reduce risk factors for poor pregnancy outcome.

Early Pregnancy Classes

Early pregnancy classes focus on the first two trimesters (Box 11-1). First-trimester classes are sometimes called *early bird* or *right start classes*. They cover information on adapting to pregnancy and understanding what to expect in the months ahead. Emphasis is placed on how to have a healthy pregnancy by obtaining prenatal care and avoiding hazards to the fetus.

Second-trimester classes focus on changes that occur during middle pregnancy and what to expect during the third trimester. Teachers discuss childbirth choices and information to help students become more knowledgeable consumers.

BOX 11-1 TOPICS COVERED IN EARLY PREGNANCY CLASSES

Pregnancy changes
Anatomy and physiology
Physiologic and psychological changes
Fetal development
Hazards to the mother and fetus (e.g., drugs, alcohol, smoking, environmental hazards)
Medical care (e.g., what to expect at each visit)
Communication with the provider
Prenatal screening tests
Self-care
Hygiene
Nutrition
Exercise and body mechanics
Discomforts of pregnancy
Warning signs and actions to take
Sexuality
Work and pregnancy
Infant care
Selection of a pediatrician
Infant development
Infant feeding
Birth
Birth options (such as birth plan, costs)
Preterm labor

FIG 11-2 The nurse teaching this class discusses movement of the fetus through the pelvis.

CASE STUDY 11-1 INTRODUCTION

Carmen, age 21 years, is 3 months pregnant with her first baby. She and her husband, Ramon, "are so excited about having a baby." Carmen works as a teacher's aide in a primary school. Ramon, age 26 years, manages a small restaurant. Both Carmen and Ramon are the youngest in their families and have little actual experience with infants. Carmen plans to have her baby at the local hospital. She asks her friend Maria about what classes she should take. Maria is a nurse at the hospital where Carmen will have her baby.

Critical Thinking Exercise

1. What classes should Maria recommend that Carmen take at this time?

*Continues on p. 192.

Exercise Classes

Exercise classes help women keep fit and healthy during pregnancy. Some classes also continue into the postpartum period. Written consent from the primary caregiver may be required to ensure that the woman can participate safely. The instructor should understand the special needs of pregnancy and teach low-impact exercises preceded by warm-up routines. Women should avoid excessive heart rate elevation to prevent diversion of blood away from the uterus. Prenatal yoga classes may also be available.

Childbirth Preparation Classes

In childbirth preparation classes during the third trimester, women and their support persons learn self-help measures and what to expect during labor and birth (Figure 11-2). Although once referred to as "natural childbirth classes," they are now called *prepared childbirth classes* to denote the woman's preparation for all aspects of childbirth, including complications.

Couples learn coping methods to help them approach childbirth in a positive manner. Teachers do not promise prevention of all pain in labor. However, the increased confidence and the techniques learned in prepared childbirth classes may help increase tolerance of pain during labor.

Prepared childbirth classes based in birth facilities include detailed information on what to expect in that particular setting but may not cover options that are unavailable at that agency. Hospital classes have sometimes been criticized for teaching women to be "good" or compliant patients. Class series range from a 1-day class to 3 to 12 meetings, depending on the content included. A disadvantage of short classes is that there is less time to absorb the information and for supervised practice.

FIG 11-3 The teacher helps each couple, individually and together, practice pushing during a labor rehearsal.

If the class is held in a birth setting, a tour of the maternity areas may be offered as part of the class or as a separate class. Supervised practice of relaxation, breathing techniques, and coping strategies in “labor rehearsals” is part of every class (Figure 11-3). DVDs assist women to develop a realistic picture of the birth process (Box 11-2).

The teacher describes advantages and disadvantages of various options in birthing. For example, couples may learn that epidural anesthesia, which is almost routine in many areas, usually removes most pain but may increase the length of labor, cause less effective pushing, and make catheterization and administration of oxytocin more likely. On the other hand, use of relaxation techniques avoids the disadvantages of analgesic drugs and anesthesia but does not remove all pain. When women have balanced views of their options, they are able to discuss them intelligently with caregivers and make better decisions. It is important to emphasize that the decision whether to use medications is an individual choice and there is no right or wrong decision.

Many women plan to have epidural anesthesia during childbirth (see Chapter 15). However, knowing how to use nonpharmacologic pain relief measures is very helpful until the woman can obtain pharmacologic pain relief.

Refresher Courses

Women who had classes within the last 3 years often take a refresher class for an update of current practices and a review of techniques. One class is usually held and supervised practice is a major focus. Courses may also include discussion of role changes in the family and sibling adjustment.

Cesarean Birth Preparation Classes

Although cesarean birth is discussed in general childbirth classes, women planning a cesarean birth may take a separate class (Box 11-3).

General Cesarean Classes

In 2011, 32.8% of births in the United States were by cesarean delivery (Hamilton, Hoyert, Martin et al., 2013). Therefore, women need preparation for this possibility. Cesarean birth is usually discussed briefly

BOX 11-2 TOPICS INCLUDED IN PREPARED CHILDBIRTH CLASSES

Some topics may be presented in separate classes.

Physical and psychological changes of the last trimester

- Common discomforts and concerns

- Nutrition

- Exercise and body mechanics

- Sexuality

- Danger signs and actions to take

Labor and birth

- Anatomy and physiology of labor

- Plans for the birth (e.g., options, birth plan)

- Signs of labor and when to go to the hospital

- Hospital admission, procedures, and policies

- Physical and emotional aspects of labor

- Labor variations (e.g., back labor)

- Medical procedures (e.g., induction, augmentation, amniotomy, episiotomy, vacuum extraction)

- Birthing process

- Recovery

- Tour of maternity unit

- Role of the labor partner

- Techniques for support

Coping techniques for labor

- Relaxation and breathing techniques

- Comfort measures

- Labor rehearsals

- Pain relief (pharmacologic and nonpharmacologic)

Complications

- Fetal testing

- Preterm labor

- Hypertension

- Cesarean birth

High-risk pregnancy

CRITICAL THINKING EXERCISE 11-1

Liz, gravida 2, para 1, tells you that she does not plan to attend prepared childbirth classes because she took classes before her son, Danny, was born 5 years ago.

Question

1. What should you discuss with her?

BOX 11-3 TOPICS INCLUDED IN CESAREAN BIRTH CLASSES

- Indications

- Prenatal tests

- Preparation (e.g., nothing by mouth, Foley catheter)

- Anesthesia

- Surgical procedure

- Role of support person during surgery

- Options

- Postsurgical care and pain relief

- Relaxation techniques

- Postpartum course

- Future birth options

during general prepared childbirth classes. Topics include indications, options, surgical procedure, and postoperative course. A discussion of the risks for elective cesarean birth before 39 weeks gestation should also be included. Written materials may be helpful for later review if the need for surgery develops.

Reasons for cesarean births should be discussed in detail. A woman might view the terms “failed induction” and “failure to progress” as casting blame on her. She may believe that if she had used relaxation techniques better or been more tolerant of pain, she might have avoided the need for surgery. Teachers often point out that the causes of cesarean births are conditions over which the woman has no control.

Couples are sometimes inattentive during discussions about cesarean birth because they think “It can’t happen to me.” Teachers can attract their attention by pointing out the number of couples in the class who may have cesarean births based on the 2011 rate. In a class of 9 couples, 3 women may have a cesarean birth.

Planned Cesarean Birth Classes

Women who know they will have a cesarean birth may attend planned cesarean birth classes. The class offers those who have had a previous cesarean birth an opportunity to share experiences and feelings and clarify misconceptions. These women may remember little about the preparation for an emergency because they were frightened and exhausted. Couples anticipating their first cesarean birth may appreciate hearing about recovery from others who have had the experience.

Vaginal Birth after Cesarean Birth

Women who wish to have a vaginal birth after cesarean (VBAC) or a trial of labor after cesarean may take a special class. Content includes explanations of the precautions taken, rationale, coping techniques, and statistics regarding complications. Situations that might necessitate another cesarean birth and the emotional aspects of a “failed VBAC” are also discussed.

Breastfeeding Classes

Prenatal breastfeeding education is important because of the short time available after birth to help breastfeeding mothers in the birth facility. Classes help increase a woman’s confidence in her ability to breastfeed successfully and provide her with resources if she encounters difficulties. Teachers are often certified lactation consultants who have special education and advanced knowledge about breastfeeding.

Breastfeeding classes include information about the various aspects of lactation and help support persons attending learn methods of providing assistance during breastfeeding (Box 11-4). Resources for additional help are provided in case the woman encounters difficulties. Some teachers hold additional sessions after the birth to provide ongoing counseling at a time when mothers may experience unexpected problems. These sessions allow discussion of problems as they occur.

Parenting and Infant Care Classes

Content for parenting classes typically includes information parents need during the early weeks after the birth (Box 11-5). Baby equipment such as infant car seats is often displayed. Practice with dolls may also be included. Classes may continue after the birth of the infant.

Postpartum Classes

Although the postpartum period is discussed briefly in prepared childbirth classes, the mother can also attend classes after birth.

Content includes the physiologic and psychological changes of the postpartum period, role transition, sexuality, and nutrition. Signs of postpartum depression are often discussed, with emphasis on when

BOX 11-4 TOPICS INCLUDED IN BREASTFEEDING CLASSES

- Anatomy and physiology
- Preparation for breastfeeding
- First feedings
- Positioning and latch-on
- Establishment of milk supply
- Prevention and solutions for problems: engorgement, sore nipples, nipple confusion, insufficient milk supply, mastitis
- Nutrition
- Use of bottles and storage of breast milk
- Breast pumps
- Role of support person(s)
- Work and breastfeeding
- Weaning

BOX 11-5 TOPICS INCLUDED IN PARENTING AND INFANT CARE CLASSES

- Normal newborn appearance: marks, rashes, normal behavior
- General care: diapering, cord care, circumcision care, bathing
- Behavior cues
- Feeding methods and problems, schedules, colic
- Other concerns: crying, comforting techniques, sleeping through the night
- Safety: car seats, positioning for sleep, “baby proofing” the home
- Baby equipment
- Early growth and development: expectations, infant stimulation, immunization
- Illness: signs of common conditions, taking a temperature, calling the physician
- Infant cardiopulmonary resuscitation (CPR)
- Family and relationship changes

the woman should seek help. Some classes are informal support groups led by a knowledgeable professional. Other classes focus primarily on exercise for the postpartum period. Because many women return to work soon after childbirth, sessions are often held at night and on weekends and include the concerns of working mothers.

Breastfeeding infants are usually welcome. Some classes focus on activities that mothers and babies can do together. They also deal with common questions mothers have during the early weeks after discharge.

Other Classes

A wide variety of other classes may also be available. Women pregnant with more than one fetus may attend a class that covers the differences in the pregnancy experience and care this entails. They may also receive information about caring for more than one newborn at a time. Classes for women at high risk for preterm delivery may include causes, prevention, and treatment of preterm labor. Discussion of preterm infant needs is also included.

Classes for Family Members Classes for Fathers

Classes for fathers often focus on the male perspective of pregnancy, birth, and parenting. They provide an opportunity for men to meet

FIG 11-4 During sibling classes, children learn about the new babies coming into their lives.

other expectant fathers and ask questions they might not ask in classes that include expectant mothers. Some classes are called “Boot Camp for Dads” or “Dad to Dad” and involve practicing infant care techniques with dolls. Classes are often taught by nurses who are experienced fathers or new fathers are invited to come and share their experiences.

Siblings

Sibling classes are usually for children aged 3 to 12 years. The classes teach them about newborn characteristics and help decrease anxiety about the approaching birth (Figure 11-4).

Many young children have never seen a newborn and are expecting a child near their own age who can be a playmate. A visit with a newborn infant allows them to see newborns at close range and learn to be safe helpers. DVDs and stories promote discussion about normal feelings of jealousy and anger. Emphasis is placed on the important role of big brothers and sisters and the fact that a baby could not replace them in their parents’ affection.

A separate parent discussion may provide suggestions for further preparation and ways to cope with the transition after birth. Concerns about sibling rivalry and meeting the needs of more than one child are common topics (see Chapter 18). Sibling visitation during hospitalization to help decrease the child’s anxiety is also discussed.

Special sibling classes may be held for children who will be present at the birth. These help prepare the child for the sights and sounds of birth. The child’s support person also attends the class.

Grandparents

Classes for grandparents provide updates about recent developments in childbirth and parenting practices. Grandparents compare parenting in the past and present in a supportive environment with others in similar situations. Topics generally focus on family-centered childbirth and infant care. Changes in infant care practices such as positioning the newborn on the back for sleep are emphasized. Discussions review current views of feeding, early growth and development, accident prevention, and current immunization against pertussis for all who are in contact with infants. Infant and child cardiopulmonary resuscitation (CPR) may also be offered. The art of grandparenting and the importance of grandparents are particularly emphasized.

5. Why are sibling and grandparent classes important?

EDUCATION FOR CHILDBIRTH

Studies to determine whether education for childbirth affects patient satisfaction, pain relief, length of labor, and frequency of complications have had conflicting results. Many studies agree that couples receiving prenatal preparation for childbirth are more satisfied with their birth experiences and have greater feelings of control, even when unexpected complications occur. Classes include information on the types of pain medication and their advantages and disadvantages, as well as non-pharmacologic methods of increasing comfort.

Methods of Pain Management

Education

One of the most important aspects of any childbirth preparation class is education to increase the woman’s confidence in her ability to cope with birth. Confidence may be increased by classes that provide detailed information about childbirth, DVDs that offer vicarious childbirth experiences, testimonials by others who have undergone the childbirth experience, and presentation of techniques to increase coping ability during labor.

By learning what to expect during labor and birth, women and their support persons are able to rehearse the experience in their minds in preparation for the actual event. They practice coping techniques during simulated contractions. Realistic, valid class information and discussion of possible variations are essential so that couples are adequately prepared.

Relaxation

Tension and anxiety during labor cause tightening of abdominal muscles, impeding contractions and increasing pain by stimulation of nerve endings that heighten awareness of pain. Prolonged muscle tension causes fatigue and increased pain perception. When anxiety and tension are high, uterine contractions are less effective, and the length of labor increases. A woman who is able to remain relaxed is likely to have a more efficient and less painful labor and an increased ability to use other techniques to help herself. Techniques taught for relaxation during labor can be used at other stressful times as well.

Conditioning

Many techniques for prepared childbirth are based partially on theories of conditioned response, in which certain responses to stimuli become automatic through frequent association. Women learn to associate uterine contractions with relaxation by practicing relaxation techniques with mental images of contractions. Because effective conditioning requires a great deal of practice, women are encouraged to practice their techniques daily. For some women, the intensity of real uterine contractions is surprisingly different from their experiences during practice sessions. They may have difficulty with relaxation as a result and may need to use other methods along with conditioning.

METHODS OF CHILDBIRTH EDUCATION

Although all methods of prepared childbirth education use some combination of pain management techniques, each method has unique aspects. Many classes have a holistic approach, providing a variety of techniques from which couples can choose those that work best for them.

Dick-Read Childbirth Education

Grantly Dick-Read was an English physician who was one of the first to use education and relaxation techniques to help women through

childbirth. His theory was that fear of childbirth results in tension and pain. To prevent the fear-tension-pain cycle, he developed a method of slow abdominal breathing in early labor and rapid chest breathing in advanced labor. His methods were the first to be called *natural childbirth*.

Bradley Childbirth Education

The Bradley method was the first to include the father as a support person for “husband-coached childbirth.” Abdominal breathing to increase relaxation and breath control is taught in these classes. The Bradley method also emphasizes avoidance of medications and other interventions. In addition, classes include general information included in most other childbirth preparation classes.

Lamaze Childbirth Education

The Lamaze method is often called **psychoprophylaxis** because it uses the mind to prevent pain. It involves concentration and conditioning to help the woman respond to contractions with relaxation and various techniques to decrease pain. The Lamaze method is the most popular method used today. A variety of techniques are taught, and women should feel free to choose among them. Women should not be taught that there is only one right way of responding to labor.

Class Content

The content of specific Lamaze classes may differ, but most follow a similar pattern. Although the focus is on the childbirth experience, other topics such as the postpartum period and infant care may be included. Techniques for coping with labor include education to prevent fear of the unknown and activities that increase coping ability during labor.

Lamaze teachers acknowledge that labor is painful and do not promise these techniques will produce a pain-free birth. Instead, the techniques are used to increase the woman’s ability to cope with pain by relieving some of the accompanying distress.

Exercises

Women learn toning and conditioning exercises to prepare for childbirth and help prevent discomfort in late pregnancy. Because the classes are taken during the third trimester of pregnancy, the instructor must consider the changes in the center of gravity and in joint stability that occur at that time when selecting exercises.

Relaxation Techniques

The ability to relax during labor is an important component of coping effectively with childbirth. Relaxation conserves energy, decreases oxygen use, and enhances other pain relief techniques. Women learn exercises to help them recognize and release tension. The labor partner assists the woman by providing feedback during exercise sessions and labor. The partner is alert to ways in which the woman shows tension. For example, she may tighten her shoulders, frown, or jiggle her foot when stressed. Her partner helps her focus on areas she finds difficult to relax. Positive feedback from the partner and teacher encourages women to increase relaxation.

Relaxation exercises must be practiced frequently to be useful during labor. Couples begin practice sessions in a quiet, comfortable setting. Later, they practice in other places that simulate the noise and unfamiliar setting of the hospital. Relaxation exercises may also be combined with other techniques such as imagery and massage (Figure 11-5).

Progressive Relaxation. Progressive relaxation involves contracting and then consciously releasing different muscle groups. The exercise is repeated throughout the body until all voluntary muscles are

FIG 11-5 As the woman practices relaxation techniques for labor, the partner massages her hand, and the nurse checks for muscle tension.

relaxed. The woman learns to differentiate between the feelings of tense and relaxed muscles. With this knowledge, she can systematically assess and then release muscle tension throughout her body.

Neuromuscular Disassociation. Neuromuscular disassociation helps the woman learn to relax her body even when one group of muscles is strongly contracted. This process helps prepare her to relax during the powerful uterine contractions of labor. The woman contracts an area such as an arm or a leg and then concentrates on releasing tension from the rest of her body. After a short time of contracting one area, she relaxes it and moves on to another area. Her partner checks for unrecognized tension by gently moving areas to see that they are limp.

Touch Relaxation. The purpose of touch relaxation is to help the woman learn to loosen taut muscles when they are touched by her partner. The woman tenses an area and then relaxes it as her partner strokes and massages the area. With frequent practice of this exercise, the woman becomes conditioned to respond to touch with relaxation. During labor, her partner’s touch is a signal for release of tension.

Relaxation against Pain. Because first-time mothers have difficulty imagining the pain and strength of labor contractions, they may occasionally practice use of relaxation against pain. The pain is caused by her partner, who exerts pressure against a tendon or large muscle of the arm or leg. The pressure is applied gradually to simulate the gradual increase, peak, and decrease of a uterine contraction. Sometimes ice is applied as another type of discomfort to simulate contractions.

Cutaneous Stimulation Techniques

Touch stimulates large-diameter sensory nerve fibers and interferes with transmission of pain impulses to the brain through small-diameter sensory nerve fibers. Massage and pressure on the palms and fingertips stimulate large-diameter nerve fibers. Relief is temporary because stimulation of these fibers results in **habituation**, a decreased response to stimuli. When habituation occurs, pain is more readily

FIG 11-6 The woman begins effleurage with the hands at the symphysis and then slowly moves around the sides and down the center toward the symphysis again. As an alternative, she can massage up the center of the abdomen and around the sides.

perceived. Periodically changing the type and area of stimulation increases effectiveness (Blackburn, 2013).

Effleurage. Effleurage is the slow massage of the abdomen or another body part during contractions (Figure 11-6). Women learn to perform effleurage using both hands in a circular motion. If fetal monitor belts are in place during labor, the woman can massage her abdomen between the belts. When she lies on her side, she uses only one hand to massage her abdomen. In the side-lying position, she may be more comfortable making smaller movements on her abdomen or massaging her thigh so that her arm and shoulder remain relaxed.

The woman and her partner may alternate effleurage to provide more variety in sensory input and decrease habituation. The woman can massage her thigh instead of her abdomen and use her fingertips to trace circles and figure-eight patterns on the bed. The use of specific patterns of effleurage provides sources of concentration and increased input to the brain. This may also interfere with transmission of pain impulses.

Sacral Pressure. Firm pressure against the sacral area may help relieve strain on the sacroiliac joint from a fetal occiput posterior position (often called “back labor”). It is also effective in women who do not have back labor. The partner begins to increase pressure on the sacrum as soon as the contraction begins. If a fetal monitor is in place, the partner can watch the line depicting the contraction to determine when to begin and end the pressure. The hand may be moved slowly over the area or remain positioned directly over the sacrum, but pressure should be continuous and firm throughout the contraction.

The partner should place the other hand over the woman’s hip to steady her during sacral pressure. Care should be taken not to jiggle the woman, which may be irritating. Between contractions the woman gives her partner feedback about hand placement. Often, moving the

hands a fraction of an inch increases effectiveness. This technique can be combined with thermal stimulation to increase effectiveness. Tennis balls may also be used to apply pressure to the back.

Other Massage. Massage of the temples and shoulders by the labor partner may help relax these areas. The palms and soles of the feet are particularly sensitive to touch, and firm massage of these areas may be helpful. Types of stimuli should be changed whenever they no longer seem effective, generally every 15 to 30 minutes.

Thermal Stimulation. Application of heat and cold stimulates thermoreceptors and may decrease pain sensation. Cool cloths used to wipe the woman’s face, ice chips eaten by the woman, and ice in a glove applied to the woman’s lower back may be effective. Alternating cold with heat over the back prevents habituation. In early labor, a whirlpool bath or shower with warm water directed against the back may be soothing.

A warm bath blanket, moist towel, or glove filled with warm water can be held against the sacrum for pressure and warmth. Cloth bags or socks filled with rice and warmed in a microwave may also be used. Any device for providing heat or cold should be covered with a washcloth or towel before being placed on the skin and should never be applied to any anesthetized area because injury could result.

Positioning. Position changes during labor also provide cutaneous stimulation. Women are taught to practice their techniques using a variety of positions and to change positions frequently during labor. Ambulation and an upright position make contractions more efficient and less painful. Position changes approximately every 30 to 60 minutes increase comfort and decrease muscle fatigue.

Mental Stimulation Techniques

Various methods of mental concentration help decrease pain. They may modify pain perception as a result of interference with pain impulses in the spinal cord or in the brain itself.

Focal Point. A focal point is an object on which the woman centers her attention during contractions. It helps her direct her thoughts away from the contractions. During the contraction, she looks at the focal point and thinks about its shape, size, and gradations of colors. Women often use pictures of infants or restful scenic landscapes as focal points. A DVD of scenery, perhaps combined with music, may increase interest in the focal point.

Women who do not bring focal points to the birth setting may use anything in their lines of vision, such as a pattern on the wallpaper or the support person’s face. Because the fetal monitor is directly next to the bed, many women focus on it. Watching the contraction pattern on the monitor usually is not soothing and tends to increase attention to the strength of the contraction. Focusing on a button or knob on the monitor may be more helpful.

Women who are familiar with meditation techniques may prefer closing their eyes and using an internal focal point during contractions. This allows them to shut out light and movement around them and focus on a mental picture.

Imagery. Another technique to enhance relaxation is imagery. During imagery exercises, childbirth educators often talk about a pleasant scene or experience while the woman imagines herself in that setting. A walk through a garden is portrayed by describing the flowers, the warmth of the sun, the sound of birds, and a feeling of peacefulness. Couples are encouraged to practice imagery with scenes of their own choosing. While practicing relaxation techniques, the woman can picture oxygen entering her body to nourish her baby as she inhales and tension leaving each time she exhales.

Other imagery suggestions are given for use during labor. The woman might picture a flower bud opening into full bloom to simulate the opening of the cervix. She can imagine the cervix pulling over the

infant's head and the infant moving lower in the pelvis with each contraction. Teachers usually advise women to save images of cervical dilation and childbirth until labor actually begins.

Music. Some women find that music and other sounds such as rainfall and waves at the seashore help them relax. They may use iPods or DVDs during practice and in the birth setting during labor. The rhythm of the music may assist the woman in pacing her breathing and help block out other noise. Music is often used with other techniques such as imagery to increase relaxation.

Special Techniques

Special techniques may be discussed briefly in classes. Some techniques require further preparation elsewhere. Acupressure or reflexology applies pressure over specific points on the body to raise endorphin levels to reduce pain. Biofeedback may lower pain by reducing tension of abdominal muscles. Some women find transcutaneous electrical nerve stimulation helpful. This process provides pain relief through the use of electrodes on the lower back to deliver low-intensity, high-frequency electrical stimulation of the nerves. Aromatherapy is sometimes used to cover hospital odors and promote relaxation. In hydrotherapy, the woman is immersed in a tub of water or a Jacuzzi. The water helps the woman relax, decreases muscle tension and pressure on the abdomen, and reduces the perception of pain.

Breathing Techniques

Although they were once the major focus of many classes, focused or controlled breathing techniques are now considered just one of many coping strategies used to enhance the woman's ability to work with her labor during birth (see the discussion on breathing techniques in Chapter 15, p. 284).

Classes may teach specific breathing techniques from which the mother can choose a pattern that is comfortable for her during labor. If they plan to use specific breathing patterns, the woman and her partner should practice the techniques frequently to gain comfort with them. If the woman has not practiced, these techniques may not be helpful during labor.

Focused breathing techniques should not be used in labor until they are actually needed, which is usually when the woman can no longer walk and talk during a contraction. If breathing techniques are used too early, the woman tends to move through the different techniques too quickly, and she may stop using them. In addition, use of the more complex breathing patterns in latent labor may increase fatigue. Women should be encouraged to adapt the techniques to their own comfort and needs.

7. How do cutaneous stimulation and imagery help reduce pain?
8. What is the purpose of breathing techniques in labor?

THE LABOR PARTNER

Almost all methods of childbirth preparation encourage the participation of someone who remains with the woman throughout labor. This person may be called a *labor partner*, *support person*, *coach*, or *labor companion*. The presence of a labor partner may help the woman cope more effectively, decrease her distress during labor, and result in greater satisfaction with the childbirth experience. This support person shares the experience and helps the woman remain focused and calm during labor.

The person who takes on this role may be the baby's father, a relative, or a friend. The labor partner generally attends classes with the mother to learn about labor, birth, and techniques to assist during labor. By practicing together, the woman and her partner learn to work smoothly as a team during labor. Classes may increase confidence for support persons, who learn specific techniques to use during labor. When the labor partner is the father, communication and a sense of closeness between the expectant parents may be enhanced.

The woman may wish to have a doula in addition to her support person. Doulas help the woman with physical support such as relaxation and massage and provide emotional support and advocacy throughout labor. Studies have shown the use of doulas to be very helpful. In one study, the use of a doula in addition to the woman's support person reduced the incidence of cesarean birth and use of anesthesia. The women and their support persons viewed doula support positively (McGrath & Kennell, 2008).

Role of the Labor Partner

Not all labor partners play identical roles during labor. Some take a major part in assisting the mother, but others provide support in less active ways. They may confine their support to giving verbal encouragement and some physical care such as back rubs, when requested. Others feel more comfortable with passive support by being present but not actively participating. Even with education, the support person may feel somewhat helpless and look to others to provide help to the laboring woman. Expectant fathers often have concerns about the health of the baby and safety of the mother during labor and may feel more comfortable when others provide support.

In some cultures, active involvement in labor is not an acceptable role for men. For example, some Hispanic couples may expect the partner to offer support by being present and encouraging the woman during labor rather than taking a more active role. Middle Eastern men also may not participate because of cultural reasons.

Encourage couples to think about the support person's labor role before labor begins and then encourage the partner in whatever role is chosen. Labor partners should not feel responsible for more than is included in the role. Teachers should discuss the duties of the labor nurse and encourage labor partners to seek assistance when they are uncertain. The labor nurse may have helpful suggestions and adaptations of techniques.

Class discussion of complications should include the role of the support person. For example, partners should understand circumstances that would allow or preclude their presence during a cesarean birth.

Support Techniques

Knowledge of specific, practical measures to assist the woman in labor often helps labor partners feel more comfortable in the birth setting. They learn ways to time contractions at home and to work with the fetal monitor in the birth setting. Telling the woman when the monitor shows the peak of the contraction is over can be particularly helpful. If the woman is sleeping between contractions, the monitor may show a contraction beginning before she feels it. The labor partner can alert her to begin her focused breathing before the contraction becomes strong.

Providing comfort measures is an important role of the support person. These include offering ice chips, wiping the woman's face with a cold cloth, using cold and warm packs, fanning the woman, and helping her change positions. Sacral pressure, back rubs, and other types of massage are also helpful. The partner suggests ways to make the environment less stressful, such as listening to music to obscure

CASE STUDY 11-1 NURSING CARE PLAN*

PLANNING FOR CHILDBIRTH: Carmen's pregnancy progresses normally. In her fifth month, she tells the nurse in the clinic that Ramon tends to favor the "old ways" and is unsure whether he should be involved during childbirth. She is most anxious for him to participate during her labor. Ramon seems embarrassed and says, "Having a baby is for women." He seems very loving toward Carmen and later says, "I want to help Carmen, but I don't know anything about these things. I'd just be in the way."

NURSING DIAGNOSIS: Decisional Conflict related to father's ambivalence toward his anticipated role in childbirth

Critical Thinking: *Is this an appropriate use of a nursing diagnosis? If Carmen is the patient, should the nurse make a nursing diagnosis that focuses on her husband?*

Answer: *Although Carmen is the primary patient, family-centered nursing involves care of all family members, especially when their needs affect those of the primary patient. If the nurse can help Carmen and Ramon resolve this problem, Carmen will be able to focus more positively on preparing for the birth of their baby.*

EXPECTED OUTCOMES: Ramon will:

1. Explore various options regarding his role during Carmen's labor and the birth of his baby.
2. Make a decision about his role during childbirth by 1 month before the baby is expected.

INTERVENTIONS AND RATIONALES

1. Explore Ramon's concerns before beginning discussion of educational opportunities for couples with Carmen. *In some cultures, the man is the head of the family and makes many of the decisions. Showing respect for his authority is important if health teaching is to be accepted.*
2. Use therapeutic communication techniques (such as reflection, paraphrasing) to help Ramon discuss his feelings about participating in childbirth. *Use of*

therapeutic communication shows the nurse is willing to listen and believes his feelings are important.

3. Ask Ramon how he views childbirth and the role of the support person during labor and birth. *Asking the partner about his perception of his role during birth helps the nurse adapt teaching to his needs.*
4. Explain various labor support roles. Include the options of actively participating by providing encouragement and comfort measures; merely being present for the labor or birth; or not participating at all in the birth experience. *The nurse must encourage and accept whatever role the support person chooses.*
5. Ask Ramon to consider the advantages and disadvantages of each role. Clarify any misinformation, and discuss additional advantages and disadvantages, if necessary. *Participation increases learning.*
6. Present all information in a nonjudgmental atmosphere. *If the nurse remains nonjudgmental, the person does not feel pressured to make a particular decision.*
7. Encourage Ramon to discuss this new information with Carmen, his friends, and family. If possible, refer him to other men who have played various roles during labor and birth. *Discussion with family and friends is important when making decisions and provides sources for other viewpoints.*
8. Suggest that Ramon think about his options and make a decision at a later date. Provide written information for Ramon and Carmen to review at home. *Processing new information and making decisions takes time. Written information provides a readily available source for review.*
9. Include Carmen in the discussion and ask for her input as well. *A couple may be unaware of each other's concerns and feelings. Hearing the partner talk about them helps each understand the other's point of view.*

EVALUATION: Ramon reports 2 months later that he has decided to go with Carmen to classes to learn more about childbirth. He is unsure about his degree of participation during labor and birth and says that he will decide when the time arrives. Carmen says she feels comfortable with Ramon's decision and is glad he will attend childbirth classes with her.

*Continued from p. 185; continues on p. 193.

surrounding noise and dimming the lights to promote rest between contractions.

Partners learn ways to provide feedback about breathing and relaxation and make suggestions during practice sessions and labor. They learn the importance of encouraging the woman and giving directions in a positive manner.

The woman and her support person may pack a bag of items that may help comfort the mother during labor (Box 11-6). As labor progresses, the couples use each article as it seems appropriate.

9. How is the woman in labor helped by having a labor partner?
10. What are the various roles that the support person might take?
11. What specific techniques do labor partners learn to help the woman in labor?

APPLICATION OF THE NURSING PROCESS

Education for Childbirth

The nursing process focuses on assisting the woman and her partner to obtain the knowledge necessary to plan for a birth experience that

is realistic, meets their individual needs, and allows them to progress through the childbearing experience as knowledgeable consumers and full participants in their own health care.

Assessment

Assess the educational needs of the woman and her partner. Some couples are quite knowledgeable about available prenatal classes and childbirth options, but others need direction in choosing classes that are right for them. The couple may come to the nurse with a **birth plan** (a description of the couple's preferences for their birth experience) already decided or may need help in exploring options.

Determine whether special factors require adaptation of the usual educational approaches. Examples are cultural factors, the pregnant adolescent, or the woman with a physical disability.

Next, assess the needs of support persons and the degree of participation they wish to have in the birth. They may have concerns about their role, especially during labor and birth. These must be addressed to decrease their anxiety and help them be more effective in supporting their partner.

Nursing Diagnosis

The nursing diagnosis pertaining to the couple who is not unusually anxious about childbirth but desires more information is "Readiness

BOX 11-6 WHAT TO TAKE TO THE HOSPITAL

Items to Be Included in the Labor Bag

Focal point
 Lotion, oil, or powder to make massage more comfortable
 Warm socks for cold feet
 Colored washcloths for washing face (white ones might be lost)
 Hand-held fan
 Rubber bands and clips for hair
 Tennis balls in a sock for sacral pressure
 Sugar-free sour lollipop for dry mouth
 Mouthwash
 Lip balm, unflavored
 Instruction sheets or reminder checklists
 Paper and pencil
 Playing cards or simple games for early labor
 Camera
 Snack for labor partner
 iPod, iPad, or CD player with headphones
 Cell phone and telephone numbers for calls after birth
 Pillows (use colored pillowcases to prevent loss)
 Rice bags (to warm in a microwave)

Items for After Birth

Robe and nightgown or pajamas that open in the front
 Nursing bras
 Slippers
 Shampoo, conditioner, comb, toothbrush, toothpaste
 Loose-fitting clothes to wear home
 Clothes for the baby to wear home
 Baby blankets
 Car seat

for Enhanced Childbearing Process related to desire for education about pregnancy, childbirth, and/or parenting.”

Planning

The expected outcomes for this nursing diagnosis are that the woman and her partner will:

- Make a birth plan that meets their needs and is realistic, based on available options.
- Verbalize a plan for obtaining education for pregnancy, childbirth, and parenting.
- Report feelings of increased confidence in their ability to cope with pregnancy, childbirth, and parenting before educational preparation is completed.

Interventions

Making a Birth Plan

Help couples prepare a plan for their birth experience if they wish. The birth plan, sometimes called a *family preference plan*, describes the couple's desires as they consider their choices in childbirth. The plan may be unwritten and very simple or a list of very specific items to be included in the childbirth experience. Cultural wishes can be incorporated into the birth plan.

The birth plan is a tool for expanding communication with health care professionals. It helps couples learn about their options and make informed choices and ensures that their wishes are known before labor begins. It may help the couple choose the provider, setting, and classes that are most conducive to meeting specific needs. The couple should

discuss the plan with the health care provider during pregnancy and with the nurse in the labor and delivery unit when they are admitted. This may result in a more satisfying birth experience even if not everything goes according to the expectations.

Help the couple learn about locally available choices and explain any restrictions. For example, insurance coverage may dictate which facility a woman must use. Those without insurance are concerned about the cost of various options. In addition, the health care provider or birth agency may have set policies on certain issues. Complications during labor and birth may necessitate changes in the plan.

If the couple has not chosen a health care provider, suggest that they interview several physicians or nurse-midwives to learn about the provider's usual practices and possible exceptions. If they have a provider, emphasize the importance of discussing their plan with him or her. With discussion, the couple and provider can create a plan that is satisfactory to all.

CASE STUDY 11-1 PARENTS WANT TO KNOW*

Carmen tells Maria that she has heard that some people make a birth plan but does not know what she should include in it. Although Maria works in the medical-surgical area of the hospital, she remembers what she learned as a nursing student about choices in childbirth. She also advises Carmen to talk to the nurse and the physician at the prenatal clinic. Maria discusses the following points for Carmen to consider in her birth plan.

- Use of intermittent or continuous fetal monitoring
- Intravenous fluids: use, avoidance, saline lock
- Food and oral fluids allowed in labor
- Position and activity for labor, position for delivery
- Use of tubs, showers, birthing balls
- Episiotomy
- Methods of pain relief
- Support persons present during labor
- Medical interventions (such as induction of labor)
- Breastfeeding immediately after birth, breastfeeding only, formula only, combination feeding
- Avoiding separation from the baby
- Cultural considerations
- Time of discharge

*Continued from p. 192.

Choosing Classes

Help the woman and her partner find classes suited to their educational needs. Give them a list and description of classes in the community and suggest that they talk with others who have taken various classes. They may wish to interview teachers to learn about their preparation and philosophies. Some couples want classes that consider avoidance of medication a primary goal of childbirth. Many prefer those that consider a variety of tools, including medication, for coping with pain.

Suggesting Classes for Special Needs

Refer women with special needs to appropriate courses. If none is available, suggest ways to adapt the information presented in regular classes to their own situations.

Adolescents. Although adolescents may attend regular prenatal classes, those designed especially to meet their needs are most effective. High schools with programs for school-aged mothers often offer such courses. Separate classes for their age group are more comfortable for

teens because of the presence of peers with similar problems and concerns. Fathers and other support persons may also attend.

Education for pregnant adolescents is similar to that for adults, but it focuses on the teenager's perceptions of childbearing. Clarification of misconceptions in a nonjudgmental manner makes classes more meaningful. Young women need information about the importance of prenatal care, nutrition, weight gain, body image, labor, birth, and contraception. The effects of substance abuse and sexually transmitted diseases on pregnancy and the fetus are other important topics for discussion.

Although the decision about whether to keep the infant is usually made before classes begin, options may be discussed. Because they may lack experience and have unrealistic expectations of infants, adolescents have a greater need for information about parenting and infant care than do older mothers. Provide an opportunity for discussion of ways in which the infant will affect the adolescent's life, future goals, and schooling.

Young teenagers with academic problems may have difficulty reading and understanding abstract concepts. Use of concrete terms and simple language helps to increase understanding. Models, DVDs, demonstrations, and presentations by those who have previously taken classes make the course more relevant. Classes should include interactive activities such as games and demonstrations because teenagers often are easily bored.

Women with High-Risk Pregnancies. The woman with a high-risk pregnancy has activity restrictions and may be unable to attend regular perinatal classes. If possible, help her arrange for individual instruction. CDs, DVDs, written materials, and phone or e-mail contact with an instructor are ways she can learn and practice techniques without attending classes. Downloading Internet classes are also a possibility.

Women Who Must Make Cultural Adaptations. Women from other cultures, especially those who do not speak English, are at a disadvantage when they enter birth settings in the United States.

Classes in other languages are often available in communities in which large groups with this need live. They contain the same basic information as the English versions, but the content and process are adapted to meet the cultural needs of the students. The teacher usually has the same cultural background as the students to ensure fluency in the language and understanding of their needs. This increases the likelihood the instructor and information presented are accepted.

The instructor discusses childbirth in the United States and compares it with that in the couples' countries of origin. Students learn the importance of prenatal care, which may not have been emphasized in their own cultures. They discuss expectations of health care providers and the birthing experience. Misconceptions about needs and care throughout the childbearing period are clarified. Many cultures focus on certain foods or actions that will help protect the mother and baby. To increase the woman's understanding and compliance with suggestions, nurses can explain how various practices help protect the woman and the infant.

Women with Other Needs. If necessary, refer the woman and her support person to classes that address other needs. Classes for adoptive couples may be available. Women who are concerned about continuing their careers after birth may enroll in courses for working mothers to help them choose child care and learn to balance the needs of family and work. A class for older mothers may discuss unique concerns of women over age 35 years. Classes for fathers may provide a comfortable environment for discussions of fathering, sexuality, and roles with other men with similar concerns.

Evaluation

If the expected outcomes have been achieved, the woman and her partner will:

- Prepare a realistic birth plan.
- Attend classes that are appropriate for their needs.
- Verbalize increased confidence in coping with pregnancy, childbirth, and parenting.

SUMMARY CONCEPTS

- Education for childbearing helps couples become knowledgeable consumers and active participants in pregnancy and childbirth.
- Women must make many decisions about childbirth, including choosing a birth attendant, a birth setting, a support person for labor, and the type of educational classes to attend.
- Many classes are available for pregnant women and their support persons. Early pregnancy classes emphasize ways to have a healthy pregnancy. Classes conducted in later pregnancy focus on preparation for childbirth, breastfeeding, and early parenting.
- Classes for fathers, siblings, and grandparents help all family members prepare for the birth.
- Education, relaxation, and conditioning are used to increase coping ability for childbirth.
- Exercises in relaxation help women recognize and learn methods to reduce tension during labor.
- Cutaneous and mental stimulation techniques help to reduce pain perception. Techniques need to be varied to prevent habituation.
- Having a labor partner or support person increases a woman's satisfaction with childbirth.
- The support person may participate in labor actively, minimally, or only by being present. The nurse should accept all roles taken by support persons.
- Specific support techniques include assisting with relaxation and breathing, encouraging the woman, and using sacral pressure, massage, and comfort measures.

Processes of Birth

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Describe the woman's physiologic and psychological responses to labor.
2. Describe fetal responses to labor.
3. Explain how each component of the birth process affects the course of labor and birth and the interrelation of these components.
4. Relate the mechanisms of labor to the process of vaginal birth.
5. Explain premonitory signs of labor.
6. Differentiate true and false labor.
7. Compare and contrast the labors of nulliparous and parous women.
8. Compare each stage of labor and the phases within the first stage.

Family roles and relationships are forever altered by birth, making nursing care related to this event rewarding. Understanding the physiologic and psychological components of the birth process helps the nurse provide safe, effective care for the childbearing family through evidence-based practice. Awareness of expected changes allows the nurse to support the laboring woman when these changes occur and provides a basis for identifying abnormal occurrences. This chapter focuses on the changes that occur during normal birth.

PHYSIOLOGIC EFFECTS OF THE BIRTH PROCESS

The birth process affects the physiologic systems of both the mother and fetus.

Maternal Response

The most obvious changes of pregnancy and birth occur in the woman's reproductive system, but significant changes also occur during labor in her cardiovascular, respiratory, gastrointestinal, urinary, and hematopoietic systems.

Reproductive System

Characteristics of Contractions. Normal labor contractions are coordinated, involuntary, and intermittent.

Coordinated. The uterus can contract and relax in a coordinated way, like the heart and other smooth muscles. Contractions during pregnancy are of low intensity and uncoordinated. As the woman approaches full term, contractions become organized and gradually assume a regular pattern of increasing **frequency** (*period from the beginning of one uterine contraction to the beginning of the next*), **duration** (*period from the beginning of a uterine contraction to the end of the same contraction*) and **intensity** (*strength of a contraction*) during labor. Coordinated labor contractions begin in the uterine fundus and spread downward toward the cervix to propel the fetus through the pelvis.

Involuntary. Uterine contractions are involuntary and are not under conscious control. The mother cannot cause labor to start and stop by conscious effort. However, walking and other activities may stimulate existing labor contractions. Anxiety and excessive stress can diminish contractions, whereas relaxation can facilitate the natural processes.

Intermittent. Labor contractions are intermittent rather than sustained, allowing relaxation of the uterine muscle and resumption of blood flow to and from the placenta.

Contraction Cycle. Each contraction consists of three phases (Figure 12-1). The **increment** (*period of increasing strength*) occurs as the contraction begins in the fundus and spreads throughout the uterus. The peak, or **acme**, is the *period during which the contraction is*

FIG 12-1 Contraction cycle.

most intense. The **decrement** is the period of decreasing intensity as the uterus relaxes.

The contraction cycle and pattern of contractions are also described in terms of frequency, duration, and intensity. Frequency may be expressed in minutes and fractions of minutes (such as “contractions are 3½ to 4 minutes apart”). The 2008 National Institute of Child Health and Human Development (NICHD) update (Macones, Hankins, Spong et al., 2008) recommends that frequency be assessed as the number of contractions in 10 minutes, averaged over 30 minutes. Duration is usually expressed in seconds. For example, “Her contractions last 55 to 65 seconds.” The terms *mild*, *moderate*, and *strong* describe contraction intensity as palpated by the nurse. Different descriptions of intensity apply when an internal fetal monitor is used to record contractions (see Chapter 14).

The **interval** is the period between the end of one contraction and the beginning of the next. Most fetal exchange of oxygen, nutrients, and waste products occurs in the placenta at this time.

Uterine Body. Uterine activity during labor is characterized by opposing features. The upper two thirds of the uterus contracts actively to push the fetus down. The lower third of the uterus remains less active, promoting downward passage of the fetus. The cervix is also passive. The net effect of labor contractions is enhanced because the downward push from the upper uterus is accompanied by reduced resistance to fetal descent in the lower uterus.

Myometrial (pertaining to the uterine muscle) cells in the upper uterus remain shorter at the end of each contraction rather than returning to their original length; myometrial cells in the lower uterus become longer with each contraction. These two characteristics enable the upper uterus to maintain tension between contractions to preserve the cervical changes and downward fetal progress made with each contraction.

The opposing characteristics of myometrial contraction in the upper and lower uterine segments cause changes in the thickness of the uterine wall during labor. The upper uterus becomes thicker while the lower uterus becomes thinner and is pulled upward during labor. The physiologic retraction ring marks the division between the upper and lower segments of the uterus (Figure 12-2).

Opposing characteristics of contractions in the upper and lower uterine segments change the shape of the uterine cavity, which becomes more elongated and narrow as labor progresses. This change in uterine shape straightens the fetal body and efficiently directs it downward in the pelvis.

Cervical Changes. **Effacement** (thinning and shortening) and **dilation** (opening) are the major cervical changes during labor. Effacement and dilation occur concurrently during labor but at different rates. The **nullipara** (a woman who has not completed a pregnancy to

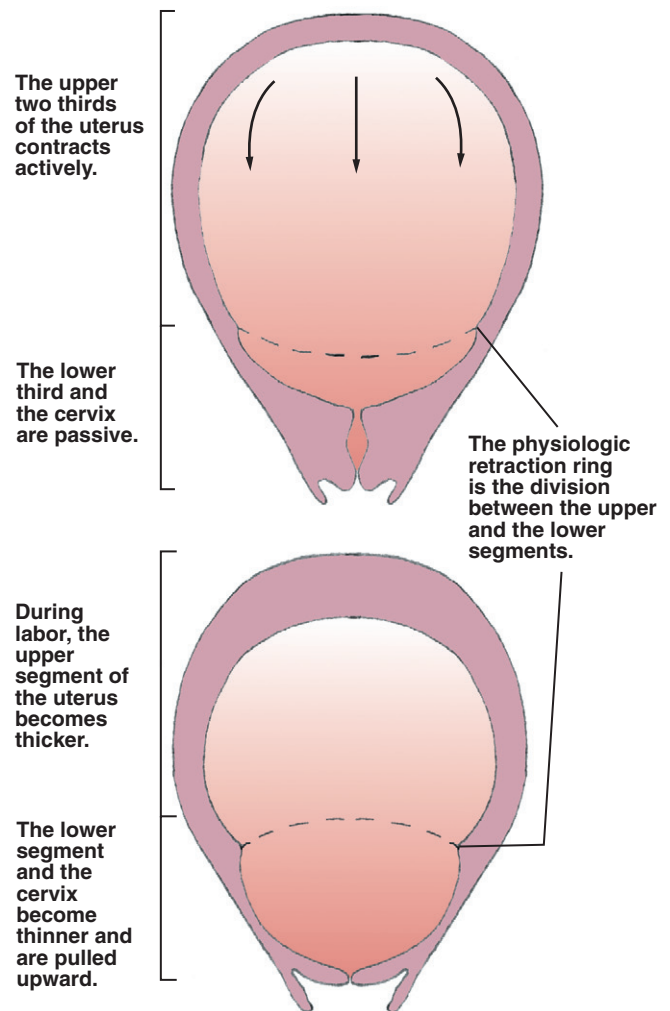

FIG 12-2 Opposing characteristics of uterine contraction in the upper and lower segments of the uterus.

at least 20 weeks of gestation) completes most cervical effacement early in the process of cervical dilation. In contrast, the cervix of a parous woman (a **para** is a woman who has given birth after a pregnancy of at least 20 weeks’ gestation; it also designates the number of pregnancies that end after at least 20 weeks of gestation) is usually thicker than that of a nullipara at any point during labor.

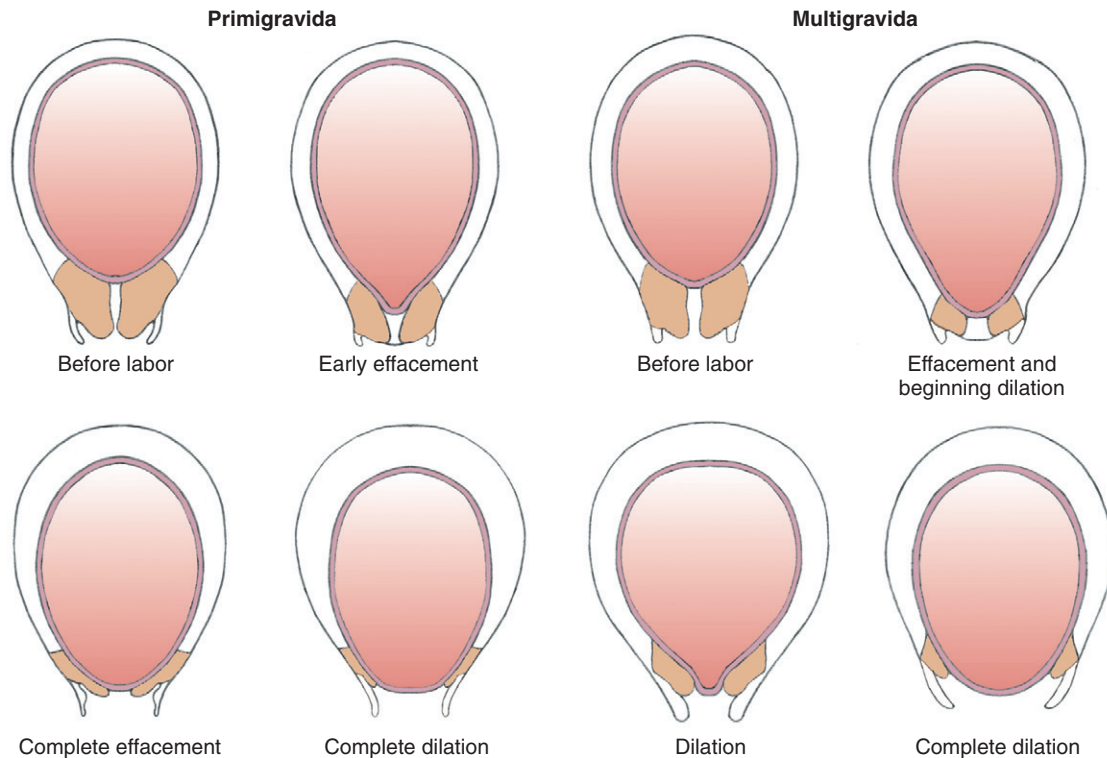

FIG 12-3 Cervical Dilatation and Effacement. During labor the multipara's cervix remains thicker than the nullipara's cervix.

Effacement. Before labor the cervix is a cylindrical structure about 2 cm long at the lower end of the uterus. Labor contractions push the fetus downward against the cervix while pulling the cervix upward. If the membranes are intact, hydrostatic (fluid) pressure of the amniotic sac adds to the force of the presenting part on the cervix. The cervix becomes shorter and thinner as it is drawn over the fetus and amniotic sac (Figure 12-3). The cervix merges with the thinning lower uterus rather than remaining a distinct structure. Effacement is estimated as a percentage of the original cervical length. A fully thinned cervix is 100% effaced. Effacement also may be documented as the cervical length estimated during vaginal examination.

Dilation. As the cervix is pulled upward and the fetus is pushed downward, the cervix dilates. Dilation is expressed in centimeters. Full dilation is approximately 10 cm, sufficient to allow passage of the average-sized full-term fetus. The action during effacement and dilation can be likened to pushing a ball out through the cuff of a sock.

Cardiovascular System

During each uterine contraction, the muscle fibers of the uterus constrict around the maternal spiral arteries that supply the placenta. This temporarily shunts 300 to 500 mL of blood back into maternal systemic circulation thereby causing a relative increase in the woman's blood volume. This temporary change increases her blood pressure slightly and slows her pulse rate. Therefore, the woman's vital signs are best assessed during the interval between contractions. Supine hypotension (see p. 76) may occur during labor if the woman lies on her back. The woman should be encouraged to rest in positions other than the supine to promote blood return to her heart and thus enhance blood flow to the placenta and promote fetal oxygenation.

Respiratory System

The depth and rate of respirations increase during labor, especially if the woman is anxious or in pain. A woman who breathes rapidly and

deeply may experience symptoms of hyperventilation if respiratory alkalosis occurs as she exhales too much carbon dioxide. She may feel tingling of her hands and feet, numbness, and dizziness. The nurse should help her slow her breathing and breathe into a paper bag or her cupped hands to restore normal blood levels of carbon dioxide and relieve these symptoms.

Gastrointestinal System

Gastric motility is reduced during labor to varying degrees, which can result in nausea and vomiting. Most women are not hungry but are thirsty and have dry mouths. Ice chips are commonly provided, and small amounts of other clear liquids and juices, popsicles, and hard nonsugar candy are often allowed. Solid food is usually withheld to prevent vomiting and aspiration of undigested food in the event that general anesthesia is required; however, research demonstrates maternal need for calories to perform the work of labor (Romano & Lothian, 2008). (See Chapters 13 and 15.)

Urinary System

The most common change in the urinary system during labor is a reduced sensation of a full bladder. Because of intense contractions and the effects of regional anesthesia, the woman may be unaware that her bladder is full, yet it may contribute to discomfort, especially that which persists after regional anesthesia. A full bladder can inhibit fetal descent because it occupies space in the pelvis.

Hematopoietic System

Most authorities recognize 500 mL as the maximum normal blood loss during vaginal birth. Women usually tolerate this loss well because the blood volume increases during pregnancy by 30% to 40% (1½ L) (Blackburn, 2013). A woman who is anemic at the beginning of labor has less reserve for normal blood loss and a poor tolerance for excess bleeding. A hemoglobin level of 10.5 grams per deciliter (g/dL) and a

hematocrit of 33% or higher give most women an adequate margin of safety for blood loss associated with normal birth. The leukocyte count may be 20,000 to 30,000/mm³ during active labor, with no other evidence of infection (Gordan, 2012).

Levels of several clotting factors, especially fibrinogen, are elevated during pregnancy and continue to be higher during labor and after delivery. This increase provides protection from hemorrhage but also increases the mother's risk for a venous thrombosis during pregnancy and after birth.

Fetal Response Placental Circulation

The exchange of oxygen, nutrients, and waste products between the mother and fetus occurs in the intervillous spaces without the mixing of maternal and fetal blood (see Chapter 6). During strong labor contractions, the maternal blood supply to the placenta decreases and eventually stops temporarily as the spiral arteries supplying the intervillous spaces are compressed by the uterine muscle. Therefore, most placental exchange occurs during the interval between contractions. The placental circulation usually has enough reserve compared with fetal basal needs to tolerate the periodic interruption of blood flow.

Fetal protective mechanisms include (Ross, Ervin, & Novak, 2012):

- Fetal hemoglobin (hemoglobin F), which more readily takes on oxygen and releases carbon dioxide
- High hemoglobin and hematocrit levels that can carry more oxygen than adult hemoglobin
- A high cardiac output

The fetus may not tolerate labor contractions well in conditions associated with reduced placental function, such as maternal diabetes and hypertension, and conditions associated with reduced fetal oxygen-carrying capacity, such as fetal anemia.

Cardiovascular System

The fetal cardiovascular system reacts quickly to events during labor. Alterations in the rate and rhythm of the fetal heart may result from normal labor effects or suggest fetal intolerance to the stress of labor. The fetal heart rate is rapid and ranges from 110 to 160 beats per minute (bpm) at term (Macones et al., 2008). The preterm fetus often has a rate in the higher end of this range.

Pulmonary System

The fetal lungs produce fluid to allow normal development of the airways. Lung fluid must be cleared to allow normal air breathing after birth. As term nears, production of fetal lung fluid decreases to about 65% of its maximum production and its absorption into the interstitium of the lungs increases. Labor speeds the absorption of lung fluid, so about 35% of the maximum amount remains in the airways at birth. Some fluid is expelled from the upper airways as the fetal head and thorax are compressed during passage through the birth canal. Most remaining lung fluid is absorbed into the interstitial spaces of the newborn's lungs and then into the circulatory system. A small amount is cleared by the lymphatic circulation (Blackburn, 2013).

Catecholamines (primarily epinephrine and norepinephrine) produced by the fetal adrenal glands in response to the stress of labor appear to contribute to the infant's adaptation to extrauterine life. They stimulate cardiac contraction and breathing, quicken the clearance of remaining lung fluid, and aid in temperature regulation. Infants born by cesarean birth not preceded by labor are more likely to have transient breathing difficulty (see Chapter 30, Transient Tachypnea of the Newborn [retained lung fluid]).

CHECK YOUR READING

1. How do labor contractions cause the cervix to efface and dilate? How do they cause fetal descent?
2. What differences in effacement are expected in the parous woman compared with the woman who has not previously given birth?
3. What changes occur in the maternal cardiovascular, respiratory, gastrointestinal, urinary, and hematopoietic systems during labor?
4. Why are intermittent rather than sustained uterine contractions important?
5. How does the normal process of vaginal birth benefit the newborn after birth?

COMPONENTS OF THE BIRTH PROCESS

Four major factors interact during normal childbirth. These factors are often called the *four Ps*: powers, passage, passenger, and psyche.

Powers

Uterine Contractions

During the first stage of labor (onset to full cervical dilation), uterine contractions are the primary force that moves the fetus through the maternal pelvis.

Maternal Pushing Efforts

During the second stage of labor (full cervical dilation to birth of the baby), uterine contractions continue to propel the fetus through the pelvis. In addition, the woman feels an urge to push and bear down as the fetus distends her vagina and puts pressure on her rectum. She adds her voluntary pushing efforts to the force of uterine contractions in second-stage labor.

Passage

The birth passage consists of the maternal pelvis and soft tissues. The bony pelvis is usually more important to the outcome of labor than the soft tissue because the bones and joints do not readily yield to the forces of labor. However, softening of the cartilage linking the pelvic bones occurs near term because of increased levels of the hormone relaxin.

The linea terminalis (pelvic brim) divides the bony pelvis into the false pelvis (top) and true pelvis (bottom) (see Chapter 4). The true pelvis is most important in childbirth. The true pelvis has three subdivisions: (1) the inlet, or upper pelvic opening; (2) the midpelvis, or pelvic cavity; and (3) the outlet, or lower pelvic opening. During birth, the true pelvis functions like a curved cylinder with different dimensions at different levels (Figure 12-4).

Passenger

The passenger is the fetus, membranes, and placenta. Several fetal anatomic and positional variables influence the course of labor.

Fetal Head

The fetus enters the birth canal in the cephalic **presentation** (*the fetal part that enters the pelvic inlet first*) 96% of the time. The fetal shoulders are also important because of their width, but they usually can be moved to adapt to the diameter of the pelvis.

Bones, Sutures, and Fontanelles. The bones of the fetal head involved in the birth process are the two frontal bones on the forehead, two parietal bones at the crown of the head, and occipital bone at the back of the head (Figure 12-5). The five major bones are not fused but are connected by **sutures** which are *narrow areas of flexible tissue that*

The boundaries of the inlet are the symphysis pubis anteriorly, the sacral promontory posteriorly, and the linea terminalis on the sides. The inlet is slightly wider in its transverse diameter (13.5 cm) than in its anteroposterior (diagonal conjugate) diameter (11.5 cm or greater).

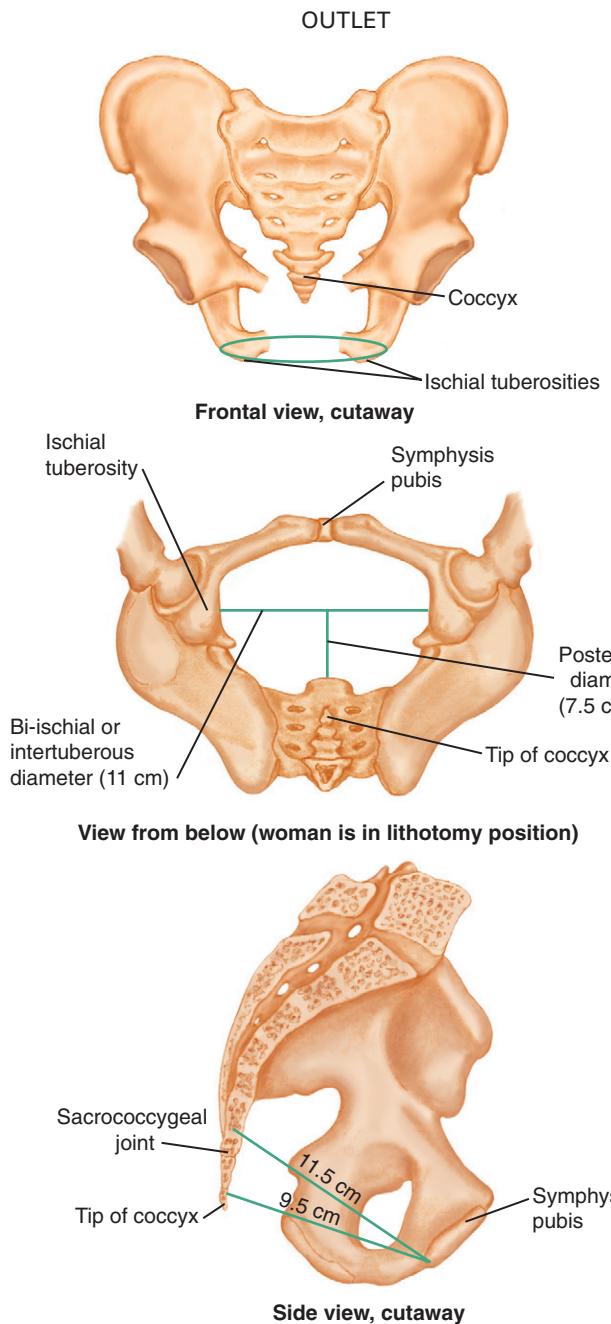

The diagonal conjugate is slightly larger than both the obstetric and true conjugates. The obstetric conjugate is the narrowest of the three conjugate diameters but cannot be measured directly. The obstetric conjugate is estimated by first measuring the diagonal conjugate and then subtracting 1.5 to 2 cm.

If the inlet is small, the fetal head may not be able to enter it. Because it is almost entirely surrounded by bone, except for cartilage at the sacroiliac joint and symphysis pubis, the inlet cannot enlarge much to accommodate the fetus. The bony measurements are essentially fixed.

The midpelvis, or pelvic cavity, is the narrowest part of the pelvis through which the fetus must pass during birth. Midpelvic diameters are measured at the level of the ischial spines. The anteroposterior diameter averages 12 cm.

The transverse diameter (bispinous or interspinous) averages 10.5 cm. Prominent ischial spines that project into the midpelvis can reduce the bispinous diameter.

FIG 12-4 Pelvic divisions and measurements.

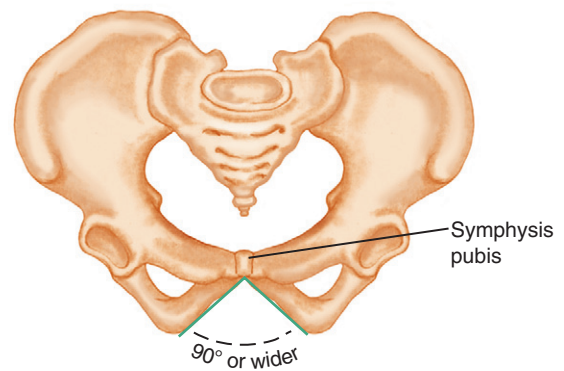

Three important diameters of the pelvic outlet are (1) the anteroposterior, (2) the transverse (bi-ischial or intertuberous), and (3) the posterior sagittal. The angle of the pubic arch also is an important pelvic outlet measure.

The anteroposterior diameter ranges from 9.5 to 11.5 cm, varying with the curve between the sacrococcygeal joint and the tip of the coccyx. The anteroposterior diameter can increase if the coccyx is easily movable.

The transverse diameter is the bi-ischial, or intertuberous, diameter. This is the distance between the ischial tuberosities ("sit bones"). It averages 11 cm.

The posterior sagittal diameter is normally at least 7.5 cm. It is a measure of the posterior pelvis. The posterior sagittal diameter measures the distance from the sacrococcygeal joint to the middle of the transverse (bi-ischial) diameter.

The angle of the pubic arch is important because it must be wide enough for the fetus to pass under it. The angle of the pubic arch should be at least 90 degrees. A narrow pubic arch displaces the fetus posteriorly toward the coccyx as it tries to pass under the arch.

FIG 12-4, cont'd

connect fetal skull bones, permitting slight movement during labor. The **fontanels** are wider spaces at the intersections of the sutures connecting fetal or infant skull bones.

The anterior fontanel has a diamond shape formed by the intersection of four sutures—the two coronal, frontal, and sagittal, which connect the two frontal and two parietal bones. The posterior fontanel has a triangular shape formed by the intersection of three sutures—one sagittal and two lambdoid, which connect the two parietal bones and occipital bone. The posterior fontanel is very small and often looks more like a slight indentation in the skull. The sutures and fontanels allow the bones to move slightly, changing the shape of the fetal head so that it can adapt to the size and shape of the pelvis by **molding** (shaping of the fetal head during movement through the birth canal). The

sutures and different shapes of the fontanels provide important landmarks to determine fetal **position** (relation of a fixed reference point on the fetus to the quadrants of the maternal pelvis) and head flexion during vaginal examination.

Fetal Head Diameters. Most fetuses enter the pelvis in the cephalic presentation, but several variations are possible. The major transverse diameter of the fetal head is the biparietal, measured between the two parietal bones. The biparietal diameter averages 9.5 cm in a term fetus.

The anteroposterior diameter of the head varies with the degree of flexion. In the most favorable situation, the head becomes fully flexed during labor and the anteroposterior diameter is suboccipitobregmatic, averaging 9.5 cm (see [Figure 12-5, B](#)).

FIG 12-5 **A**, Bones, sutures, and fontanels of the fetal head. Note that the anterior fontanel has a diamond shape, whereas the posterior fontanel is triangular. **B**, Lateral view of the fetal head demonstrating that anteroposterior diameters vary with the amount of flexion or extension.

Variations in the Passenger

Fetal Lie. The orientation of the long axis of the fetus to the long axis of the woman is called the **fetal lie** (Figure 12-6). In more than 99% of pregnancies, the lie is longitudinal and parallel to the long axis of the woman. In the longitudinal lie, either the head or the buttocks of the fetus enter the pelvis first. A transverse lie exists when the long axis of the fetus is at a right angle to the woman's long axis. This occurs in less than 1% of pregnancies. An oblique lie is at some angle between the longitudinal lie and the transverse lie.

Attitude. The relation of fetal body parts to one another is the **attitude** of the fetus (Figure 12-7). The normal fetal attitude is one of flexion, with the head flexed toward the chest and the arms and legs flexed over the thorax. The back is curved in a convex "C" shape. Flexion remains a characteristic feature of the term *newborn*.

Presentation. The fetal part that first enters the pelvis is termed the **presenting part**. Presentation falls into three categories: (1) cephalic, (2) breech, and (3) shoulder. The cephalic presentation with the fetal head flexed is the most common. Other presentations are associated with prolonged labor and other problems and are more likely to require cesarean birth.

Cephalic Presentation. The cephalic presentation is more favorable than others for several reasons:

- The fetal head is the largest single fetal part, although the breech (buttocks), with the legs and feet flexed on the abdomen, is collectively larger than the head. After the head is born, the smaller parts follow easily as the extremities unfold.
- During labor, the fetal head can gradually change shape, molding to adapt to the size and shape of the maternal pelvis.
- The fetal head is smooth, round, and hard, making it a more effective part to dilate the cervix, which is also round.

Cephalic presentation has four variations (Figure 12-8):

- **Vertex**—This is the most common type of cephalic presentation, in which the fetal head is fully flexed. It is called a *vertex* or *occiput presentation* and is the most favorable for normal progress of labor because the smallest suboccipitobregmatic diameter is presenting.

FIG 12-6 **Fetal Lie.** **A**, In a longitudinal lie, the long axis of the fetus is parallel to the long axis of the mother. **B**, In a transverse lie, the long axis of the fetus is at right angles to the long axis of the mother. The woman's abdomen has a wide, short appearance.

- **Military**—The head is in a neutral position, neither flexed nor extended. The longer occipitofrontal diameter is presenting.
- **Brow**—The fetal head is partly extended. The brow presentation is unstable, usually converting to a vertex presentation if the head flexes or to a face presentation if it extends. The longest supraoccipitomenal diameter is presenting.
- **Face**—The head is extended, and the fetal occiput is near the fetal spine. The submentobregmatic diameter is presenting.

Breech Presentation. A breech presentation occurs when the fetal buttocks enter the pelvis first, which happens in about 3% to 4%

of births (Cunningham, Leveno, Bloom et al., 2010). Breech presentation is more common in preterm births and when a fetal abnormality such as *hydrocephalus* (enlargement of the head with fluid) prevents the head from entering the pelvis during the later weeks of pregnancy or with abnormalities of the maternal uterus and pelvis and with *placenta previa* (placenta in the lower uterus).

Breech presentations are associated with several disadvantages:

- The buttocks are not smooth and firm like the head and are less effective at dilating the cervix.
- The fetal head is the last part to be born. By the time the fetal head is deep in the pelvis, the umbilical cord is outside the mother's body and is subject to compression between the fetal head and the maternal pelvis.

FIG 12-7 Attitude. **A**, The fetus is in the normal attitude of flexion, with the head, arms, and legs flexed tightly against the trunk. **B**, The fetus is in an abnormal attitude of extension. The head is extended, and the right arm is extended. A face presentation is illustrated.

- Because the umbilical cord can be compressed after the fetal chest is born, the head must be delivered quickly to allow the infant to breathe. This does not permit gradual molding of the fetal head as it passes through the pelvis.

The breech presentation has three variations, depending on the relationship of the legs to the body (Figure 12-9):

- Frank breech—This is the most common variation, occurring when the fetal legs are extended across the abdomen toward the shoulders.
- Full (complete) breech—This is a reversal of the usual cephalic presentation. The head, knees, and hips are flexed, but the buttocks are presenting.
- Footling breech—This occurs when one or both feet are presenting.

Shoulder Presentation. The shoulder presentation is a transverse lie and accounts for only 0.3% of births (Cunningham et al., 2010). It occurs more often with preterm birth, high parity, prematurely ruptured membranes, hydramnios, and placenta previa. A cesarean birth is necessary when the fetus is viable (one of a gestational age that might survive).

8. Why is the vertex presentation best during birth?

Position

Fetal position describes the location of a fixed reference point on the presenting part in relation to the four quadrants of the maternal pelvis (Figure 12-10). The four quadrants are the right and left anterior and right and left posterior. The fetal position is not fixed but changes during labor as the fetus moves downward and adapts to the pelvic

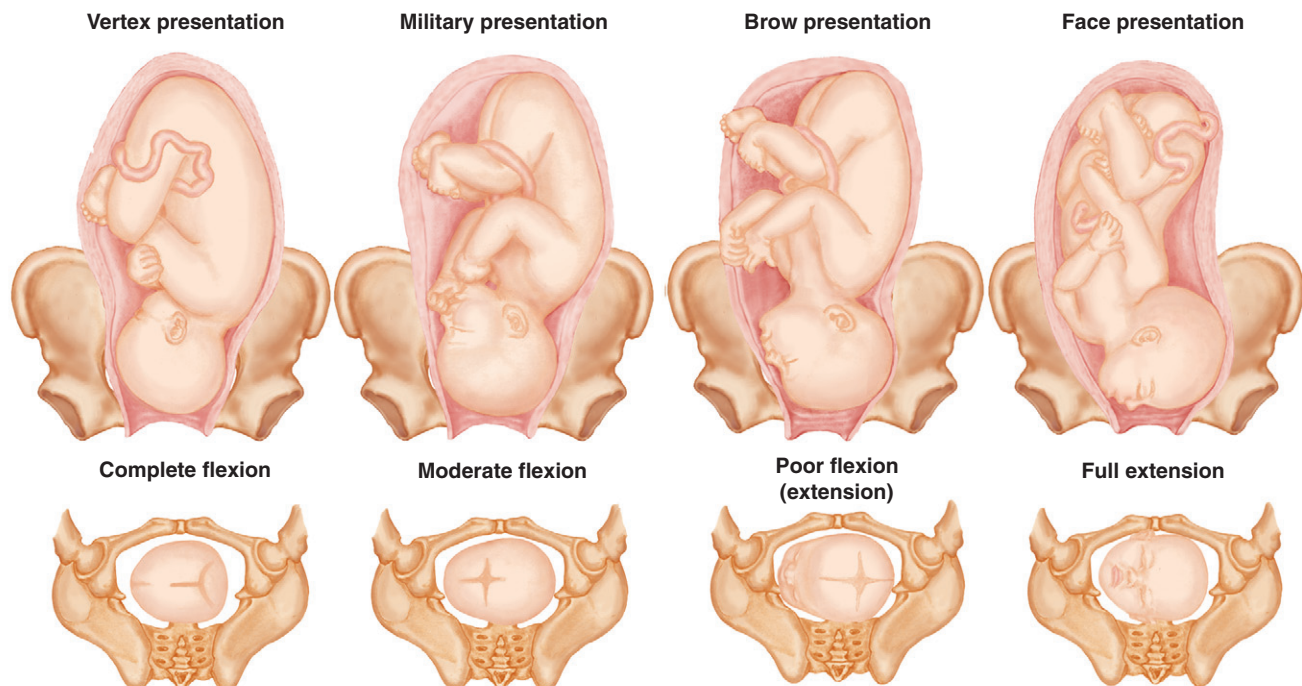

FIG 12-8 Four Types of Cephalic Presentation. The vertex presentation is normal. Note positional changes of the anterior and posterior fontanelles in relation to the maternal pelvis.

FIG 12-9 Three Variations of a Breech Presentation. Frank breech is the most common variation. Footling breeches may be single or double.

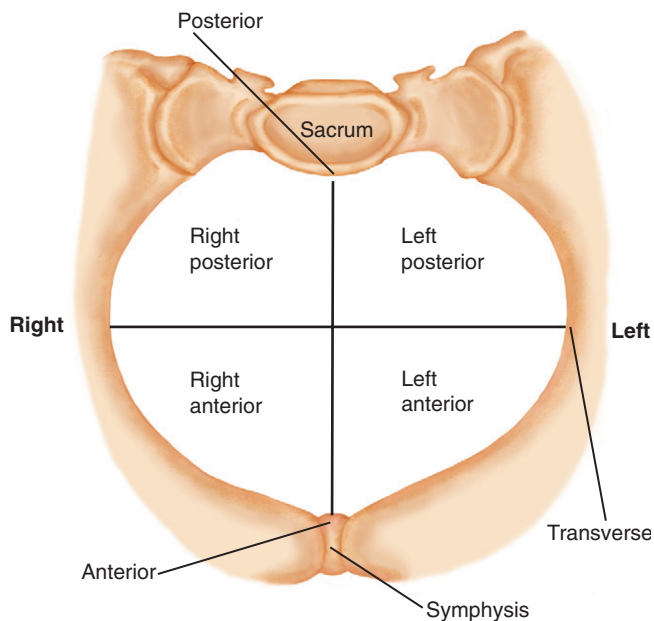

FIG 12-10 Four quadrants of the maternal pelvis from above, which are used to describe fetal position.

contours. Abbreviations indicate the relationship between the fetal presenting part and maternal pelvis.

Right (R) or Left (L). The first letter of the abbreviation describes whether the fetal reference point is to the right or left of the mother's pelvis. If the fetal reference point is neither to the right nor to the left of the pelvis, this letter is omitted.

Occiput (O), Mentum (M), or Sacrum (S). The second letter of the abbreviation refers to the fixed fetal reference point, which varies with the presentation. The occiput is used in a vertex presentation. The chin, or mentum, is the reference point in a face presentation. The sacrum

is used for breech presentations. Letters may also designate the less common brow (F for fronto) and shoulder (Sc for scapula) presentations.

Anterior (A), Posterior (P), or Transverse (T). These letters describe whether the fetal reference point is in the anterior or posterior quadrant of the mother's pelvis. If the fetal reference point is in neither an anterior nor a posterior quadrant, it is described as transverse. If the fetal occiput is located in the left anterior quadrant of the mother's pelvis, the position is described as left occiput anterior (LOA). If the occiput is in the mother's anterior pelvis, neither to the right nor to the left, it is described as occiput anterior (OA). If the fetal sacrum is located in the mother's right posterior pelvis, the abbreviation is R (right) S (sacrum) P (posterior) (Figure 12-11).

CHECK YOUR READING

- For each fetal position listed, describe the fetal landmark. Where is this landmark located in relation to the mother's pelvis: ROP? OA? RSA? LMA?
- If the fetus is in a face presentation, why is using the occiput to determine position within the pelvis not possible?

Psyche

A woman's psychological response to labor and birth are influenced by anxiety, culture, expectations, life experiences, and support.

Anxiety

Marked anxiety and fear decrease a woman's ability to cope with pain in labor. Maternal catecholamines secreted in response to anxiety and fear can inhibit uterine contractility and placental blood flow. In contrast, relaxation augments the natural process of labor. Preparation for childbirth can enhance a woman's ability to work with her body's efforts rather than resist the natural forces. Much of the nurse's care during labor involves promoting relaxation and reducing anxiety and fear. Information and a positive sense of control and mastery over the

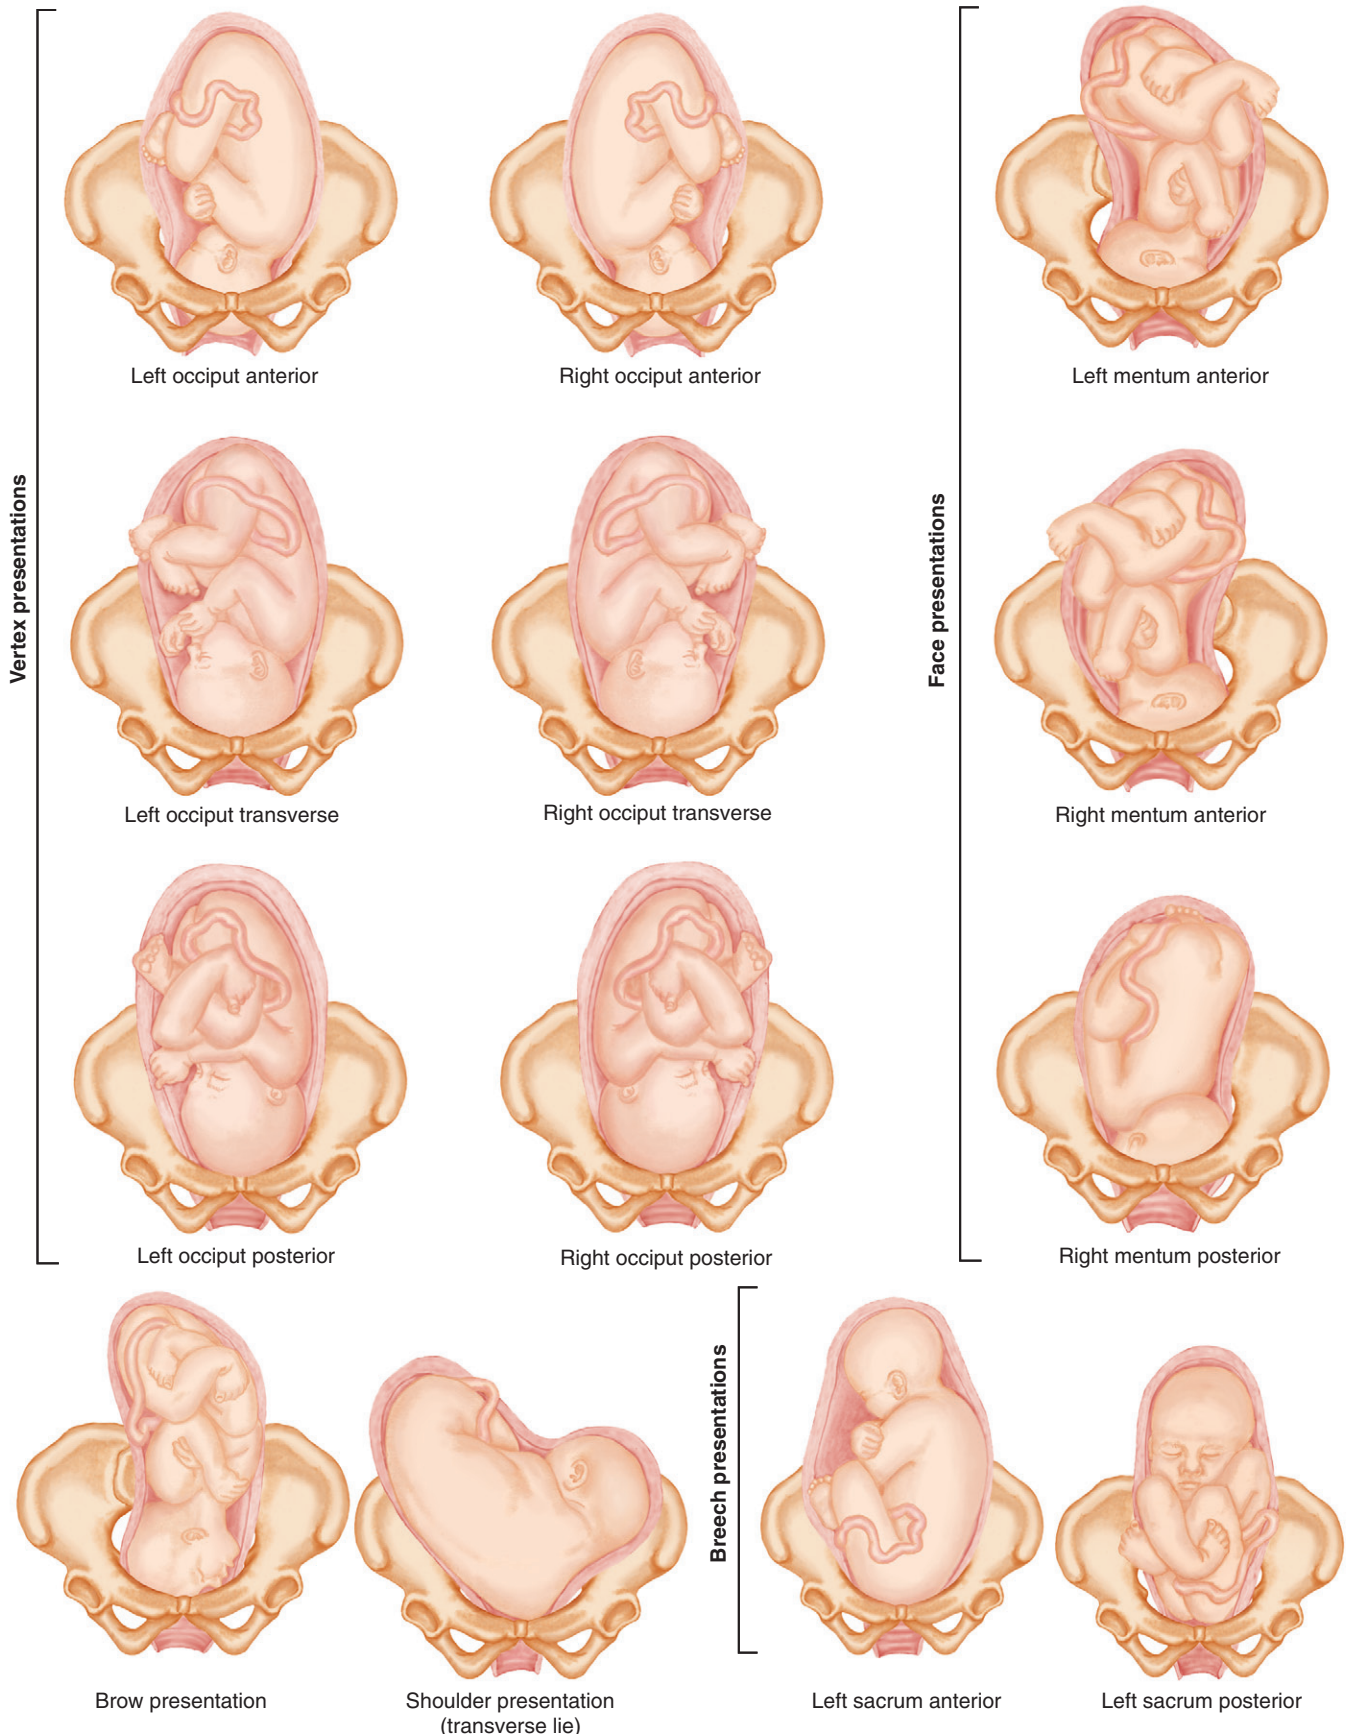

FIG 12-11 Fetal presentations and positions.

birth increase the woman's sense of satisfaction with her birth experience (Fair & Morrison, 2012).

Culture and Expectations. A woman's culture affects her values, expectations for and responses to birth and the practices surrounding it. The nurse's familiarity with a group's cultural values and practices provides a framework to care for the woman and her family as individuals. The nurse must assess the personal expectations and values of each woman and her support person related to birth within this general framework. Questions for the intrapartum period might include the following:

- How long have the woman and her family been in the area? Are they recent immigrants, or have their relatives and friends lived in the area for generations?
- What is the primary language used? Do the woman and her support person speak the same language? Does either or both of them speak the dominant language? Are they comfortable communicating in the nurse's language if that is not their usual language? How does a woman with hearing impairment communicate with people who can hear? If an interpreter is needed, what people would the woman or her family consider unacceptable interpreters (e.g., men or members of certain religious groups)?
- Who is the woman's primary support person for labor? What is that person's role? Will that person actively support the laboring woman (e.g., by coaching her breathing), or will he or she take a less active role? Who will be present at the birth?
- Who is the decision maker, or who must be consulted about important decisions?
- Will another relative (such as a grandmother) assume primary care for the infant?
- Is a professional caregiver (such as a nurse or physician) of the same gender and cultural group essential?
- What are the woman's feelings about touch? Is she comfortable telling the nurse when she does not welcome touch?
- Are specific symbols, practices, and ceremonies used during the birth period? Who will conduct any ceremonies?

Other cultural assessments are needed as labor progresses and birth occurs (see Chapters 15 and 18).

Birth as an Experience

Childbirth is a physical and an emotional experience. It is an irrevocable event that forever changes a woman and a family. Families describe the births of their children as they describe other pivotal events in life such as marriages, anniversaries, religious events, and even deaths. With smaller families, parents have greater expectations about the experience of childbirth than in the past. A woman who has more realistic expectations about the birth is more likely to have a positive experience. Nursing measures that increase the woman's sense of control and mastery during birth help her perceive the birth as a positive event. The woman's past experiences with childbirth, pain, personal success and failure will influence her expectations for this birth.

Support

The positive effects of continuous labor support are well documented (Gilliland, 2011; Hodnett, Gates, Hofmeyr et al., 2011; Kashanian, Javadi, & Haghghi, 2010; Khresheh, 2010). Support includes physical comfort measures, providing information, advocacy, praise and reassurance, presence, and the maintenance of a calm and comfortable environment.

Impact of Technology

The goal of maternity care is to protect the health of the mother, fetus, and newborn and to support and enrich the woman's birth experience.

Technology helps caregivers identify problems and intervene quickly to protect the health of the mother and the fetus. However, extensive use of sophisticated technology may make maternity care seem impersonal. Women may feel that their feelings are less important than the data from the monitors and infusion pumps attached to them. The nurse must guard against "nursing the machines" or internal feelings of being unnecessary to the woman's birth experience. If the nurse can keep the focus on the woman as the childbearer and the machine as a tool, frustration in all concerned is less likely.

Uncomplicated birth is a natural process that does not demand routine use of complex technology. Indeed, interventions during birth often lead to other interventions that may inhibit the natural process. For example, epidural analgesia is almost routine in births in the United States. Although epidural analgesia can provide dramatic pain relief, it also requires infusion of large amounts of intravenous fluids and usually confines the woman to bed. Because the bladder fills quickly, urinary catheterization may be another part of the process. Many upright positions such as walking and standing are not possible during epidural pain management.

Although normal labor and birth do not require routine use of sophisticated technology, many women subordinate their preferences for low-intervention birth experiences to their desires for what they believe offers maximal safety for their babies. Other women simply have not thought of a low-tech birth, possibly because many friends and relatives have had a high-tech birth. The intrapartum nurse can be the bridge between the technology and humanity of the birth experience. The nurse must continue to provide support and reassurance even if the woman has minimal pain because of an epidural block. The nature of nursing support is simply different in this case than if the woman were not using medication. The nurse must maintain the nursing focus on the woman, the fetus, and the support person rather than on the technology.

Interrelationships of Components

The four Ps have been described separately but are actually an interrelated whole. For instance, a woman with a small pelvis (passage) and a large fetus (passenger) can have a normal labor and birth if the fetus is ideally positioned and the uterine contractions and maternal bearing-down efforts (powers) are vigorous. The nurse's supportive attitude strengthens positive psychological elements (psyche) and enhances the processes of birth. The nurse can act as an advocate for the laboring woman and her support person to increase their sense of control and mastery of labor, which often reduces anxiety and fear and helps them achieve their desired birth experience.

NORMAL LABOR

Theories of Onset

Despite continuing research, the exact mechanisms that initiate labor remain unknown. Labor normally starts when the fetus is mature enough to adjust easily to extrauterine life but before it grows so large that vaginal birth is impossible. This stage (term gestation) occurs between 38 and 42 weeks after the first day of the woman's last menstrual period. One or more sonograms during pregnancy may have influenced the "due date," especially for the woman who often has irregular periods.

Natural labor begins when forces favoring continuation of pregnancy are offset by forces favoring its end. Research is ongoing in this area because this knowledge is essential to developing effective measures to treat preterm labor. Factors that appear to have a role in starting labor (Cunningham et al., 2010; Kilpatrick & Garrison, 2012) include:

EVIDENCE-BASED PRACTICE

Factors Associated with Labor Support Behaviors of Nurses

Support in labor benefits mothers and their babies. An important part of nursing care of the laboring woman and her family is the provision of support, but many nurses encounter barriers to labor support. Barrett and Stark (2010) studied data from 64 intrapartum nurses who had provided care to laboring women in the previous 24 months to determine factors associated with labor support behaviors. They found that older, more experienced intrapartum nurses were more likely to provide labor support compared with younger nurses. They also found that nurses who worked in facilities with higher rates of epidural analgesia and cesarean births were less likely to provide labor support.

The authors concluded that experienced intrapartum nurses should provide workshops and mentor younger nurses in labor support skills. They also suggested that medical interventions may negatively influence labor support behaviors of nurses. This may be because more interventions lead to increased responsibilities for the nurse to monitor and document the woman's responses to the interventions. It may also be due to the perception that the interventions limit the options for labor support or the perception that women with epidural analgesia do not need labor support.

What nursing interventions constitute labor support? What are the support needs of a woman and her family when epidural analgesia is used? How can an inexperienced intrapartum nurse develop labor support skills?

Reference: Barrett, S. J., & Stark, M. A. (2010). Factors associated with labor support behaviors of nurses. *The Journal of Perinatal Education, 19*(1), 12–18.

- Changes in the ratio of maternal estrogen to progesterone so that estrogen levels are higher than progesterone levels. Progesterone promotes smooth muscle relaxation of the uterus during most of pregnancy. Relatively higher estrogen levels as progesterone levels fall near the onset of labor enhance uterine sensitivity to substances that stimulate uterine contractions: prostaglandins from the fetal membranes and oxytocin from the maternal posterior pituitary gland. Estrogens increase the number of gap junctions—connections that allow the individual uterine muscle cells to contract as a coordinated unit.
- Prostaglandins produced by the decidua and membranes may have a role in preparing the uterus for oxytocin stimulation at term. Prostaglandins are secreted from the lower area of the fetal membranes (forebag) during labor and may reflect inflammation caused by contact with microorganisms from the woman's vagina.
- Increased secretion of natural oxytocin appears to maintain labor once it has begun. Oxytocin alone does not appear to start labor but may play a part in labor's initiation in conjunction with other substances. Evidence of fetal oxytocin secretion also exists.
- Oxytocin receptors in the uterus increase markedly as labor begins and the increase continues during labor and peaks at delivery. Oxytocin has little effect on the uterine muscle if the receptors have not developed.
- A fetal role in the initiation of labor appears likely. The fetal membranes release prostaglandin in high concentrations during labor. In addition to fetal oxytocin secretion, large quantities of cortisol are secreted by the fetal adrenal, possibly acting as a uterine stimulant.
- Stretching, pressure, and irritation of the uterus and cervix increase as the fetus reaches term size. During early pregnancy the uterus has not reacted to stretching by contracting as smooth muscle

normally does. A feedback loop is probably responsible for labor contractions at term: the fetal head stretches the cervix, causing the fundus of the uterus to contract, pushing the fetal head against the cervix, and causing more fundal contractions. Cervical stretching also causes secretion of oxytocin.

Premonitory Signs**Braxton Hicks Contractions**

Contractions occurring throughout pregnancy are irregular and mild. As term approaches, contractions become more noticeable and even painful. Parous women often describe more uterine activity preceding labor than do nulliparous women.

Increased perception of **Braxton Hicks contractions** (*irregular, mild uterine contractions that occur throughout pregnancy and become stronger in the last trimester*) often makes sleep difficult at the end of pregnancy. The contractions may become regular at times, only to decrease spontaneously. Because contractions are often uncomfortable but sometimes regular, the woman may be confused about whether labor has really begun.

Lightening

As the fetus descends toward the pelvic inlet (“dropping”), the woman notices that she breathes more easily because upward pressure on her diaphragm is reduced. However, increased pressure on her bladder causes her to urinate more frequently. Pressure of the fetal head in the pelvis also may cause leg cramps and edema. **Lightening** (*descent of the fetus toward the pelvic inlet before labor*) is most noticeable in nulliparas and occurs about 2 to 3 weeks before the natural onset of labor.

Increased Vaginal Mucous Secretions

An increase in clear and nonirritating vaginal secretions occurs as fetal pressure causes congestion of the vaginal mucosa. The woman may need to wear a perineal pad because of the quantity of mucus.

Cervical Ripening and Bloody Show

As full term nears, the cervix *softens because of the effects of the hormone relaxin and increased water content*. These changes (**ripening**) allow the cervix to yield more easily to the forces of labor contractions. As the fetal head descends with lightening, it puts pressure on the cervix, starting the process of effacement and dilation. Effacement and dilation cause expulsion of the mucus plug that sealed the cervix during pregnancy, rupturing small cervical capillaries in the process. **Bloody show** (*mixture of cervical mucus and pink or brown blood from ruptured capillaries in the cervix; often precedes labor and increases with cervical dilation*) may begin several days to a few weeks before the onset of labor, especially in the nulliparous woman, or it may not begin until labor starts.

A recent vaginal examination or sexual intercourse also may result in small amounts of bloody show because it disrupts these small vessels. Bloody show increases during labor as the cervix completes dilation and effacement. Women who have previously had a vaginal birth often have less bloody show than nulliparas.

Energy Spurt

Some women have a sudden increase in energy, which is called “nesting.” They should be cautioned to conserve their energy so that they are not exhausted when labor actually begins.

Weight Loss

A small weight loss of 2.2 to 6.6 kg (1 to 3 lb) may occur because the altered estrogen-to-progesterone ratio causes excretion of some of the extra fluid that accumulates during pregnancy.

True Labor and False Labor

False labor, also called *prodromal labor* or *prelabor*, is common because the exact time of labor's onset is rarely known and usually is gradual. False labor often causes women to go to the birth center, thinking that labor has started, only to be disappointed when it has not. The term *false labor* is discouraging to women because they do not realize that these "false" contractions are preparation for true labor.

Several characteristics distinguish true labor from false labor: contractions, discomfort, and cervical change. The best distinction between true and false labor is that contractions of true labor cause progressive change in the cervix. A more rapid increase in effacement and dilation occurs with true labor contractions.

Some women experience membrane rupture as the first sign of labor's onset. If this occurs, the woman should go to the birth center for evaluation. Infection and compression of the fetal umbilical cord are possible complications.

CRITICAL THINKING EXERCISE 12-1

Alan phones you when you are working in the birth unit of your hospital one night. He says, "My wife's baby is due. Heather has been having some contractions off and on all day, and they're keeping her awake now. Should we come to the hospital?"

Questions

1. Do you need any other information? If so, what information do you need? (Assume that your hospital has a protocol for telephone triage that allows nurses to answer and document similar phone inquiries.)
2. How should you explain these symptoms? What advice is appropriate?

PREGNANT WOMEN WANT TO KNOW

How to Know Whether Labor Is "Real"

True labor differs from false labor in three categories.

FALSE LABOR	TRUE LABOR
<p>Contractions</p> <p>Are inconsistent in frequency, duration, and intensity</p> <p>Do not change or may decrease with activity (such as walking)</p>	<p>Usually have a consistent pattern of increasing frequency, duration, and intensity</p> <p>Tend to increase with walking</p> <p>Begin in lower back and gradually sweep around to lower abdomen</p>
<p>Discomfort</p> <p>Is felt in the abdomen and groin</p> <p>May be more annoying than truly painful</p>	<p>May persist as back pain in some women</p> <p>Often resembles menstrual cramps during early labor</p>
<p>Cervix</p> <p>Does not significantly change in effacement or dilation</p>	<p>Includes progressive effacement and dilation (most important characteristic)</p>

Labor Mechanisms

The mechanisms (cardinal movements) of labor occur as the fetus is moved through the pelvis during birth. The fetus undergoes several positional changes to adapt to the size and shape of the mother's pelvis

at different levels (Figure 12-12). Although the mechanisms of labor are described separately in Figure 12-12, some occur concurrently. In a vertex presentation the mechanisms include the following:

- Descent of the fetal presenting part through the true pelvis
- **Engagement** of the fetal presenting part as its widest diameter reaches the level of the ischial spines of the mother's pelvis (0 station).
- Flexion of the fetal head, allowing the smallest head diameters to align with the smaller diameters of the midpelvis as the fetus descends
- Internal rotation to allow the largest fetal head diameters to align with the largest maternal pelvic diameters
- Extension of the fetal head as the neck pivots on the inner margin of the symphysis pubis, allowing the head to align with the curves of the pelvic outlet
- External rotation of the fetal head, aligning the head with the shoulders during expulsion
- Expulsion of the fetal shoulders and fetal body

The mechanisms of labor are different in presentations other than the vertex, but the reason is the same: to effectively use the available space in the maternal pelvis

14. Why does the fetal head turn during labor until the sagittal suture aligns with the anteroposterior diameter of the mother's pelvic outlet?

STAGES AND PHASES OF LABOR

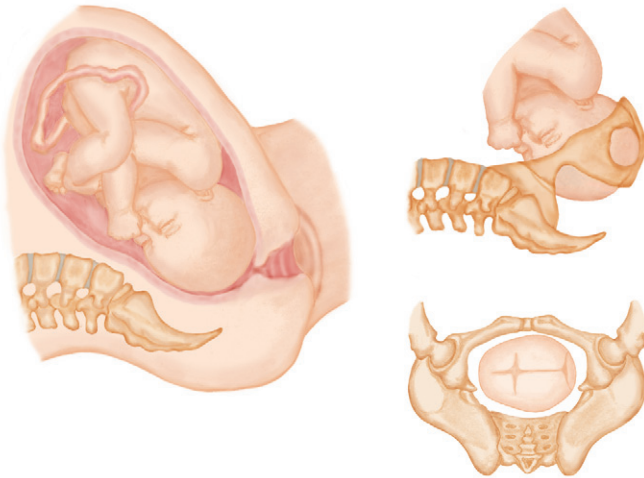

Labor is divided into four stages. Each stage has its unique qualities (Table 12-1). This chapter describes typical physiologic characteristics and maternal behaviors in the average woman. Individual women vary in their labor patterns and responses to labor. The woman who chooses an epidural block is likely to behave differently because of this method of pain management.

First Stage

Cervical effacement and dilation occur in the first stage, or the stage of dilation. It begins with the onset of true labor contractions and ends with complete dilation (10 cm) and effacement (100%) of the cervix. Three phases within the first stage are latent, active, and transition. The first stage of labor is the longest for both nulliparous and parous women. Each phase is characterized by changing maternal behaviors. These behaviors vary with the woman's preparation, use of coping skills, and use of medication.

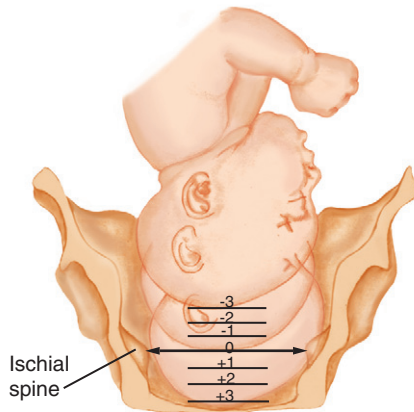

The rate of labor progress is important. When the active phase begins, the cervix of the nullipara usually dilates about 1.2 cm per hour and that of the **multipara** (a woman who has given birth after two or more pregnancies of at least 20 weeks of gestation; also informally used to describe a pregnant woman before the birth of her second child) dilates about 1.5 cm per hour (Cunningham et al., 2010; Kilpatrick & Garrison, 2012). Labor progress is often plotted on a labor progress graph called a *Friedman curve* (Figure 12-13). A later modification of the Friedman graph evaluates only the latent and active phases of cervical dilation.

DESCENT, ENGAGEMENT, AND FLEXION

Descent of the fetus is a mechanism of labor that accompanies all the others. Without descent, none of the mechanisms will occur.

Station

Station is a measurement of the descent of the fetal presenting part in relation to the level of the ischial spines of the maternal pelvis. The level of the ischial spines is a zero station. Other stations are described with numbers representing the approximate number of centimeters above (negative numbers) or below (positive numbers) the ischial spines. As the fetus descends through the pelvis, the station changes from higher negative numbers (-3, -2, -1) to zero to higher positive numbers (+1, +2, +3, etc.). Sometimes the terms *floating* or *ballotable* may describe a fetal presenting part that is so high that it is easily displaced upward during abdominal or vaginal examination, similar to tossing a ball upward.

FIG 12-12 Mechanisms (cardinal movements) of labor.

Engagement

Engagement occurs when the largest diameter of the fetal presenting part (normally the head) has passed the pelvic inlet and entered the pelvic cavity. Engagement is presumed to have occurred when the station of the presenting part is zero or lower. Engagement often takes place before onset of labor in nulliparous women. In many parous women and in some nulliparas, it does not occur until after labor begins.

Flexion

As the fetus descends, the fetal head is flexed farther as it meets resistance from the soft tissues of the pelvis. Head flexion presents the smallest anteroposterior diameter (suboccipitobregmatic) to the pelvis.

Internal Rotation

The fetus enters the pelvic inlet with the sagittal suture in a transverse or oblique orientation to the maternal pelvis because that is the widest inlet diameter. Internal rotation allows the longest fetal head diameter (the anteroposterior) to conform to the longest diameter of the maternal pelvis.

The longest pelvic outlet diameter is the anteroposterior. As the head descends to the level of the ischial spines, it gradually turns so that the fetal occiput is in the anterior of the pelvis (OA position, directly under the maternal symphysis pubis). When internal rotation is complete, the sagittal suture is oriented in the anteroposterior pelvic diameter (OA). Less commonly, the head may turn posteriorly so that the occiput is directed toward the mother's sacrum (OP).

Continued

EXTENSION

Extension beginning (internal rotation complete)

Extension complete

Because the true pelvis is shaped like a curved cylinder, the fetal face is directed posteriorly toward the rectum as it begins its rotation and descent. To negotiate the curve of the pelvis, the fetal head must change from an attitude of flexion to one of extension.

While still in flexion, the fetal head meets resistance from the tissues of the pelvic floor. At the same time, the fetal neck stops under the symphysis, which acts as a pivot. The combination of resistance from the pelvic floor and the pivoting action of the symphysis causes the fetal head to swing anteriorly, or extend, with each maternal pushing effort. The head is born in extension, with the occiput sliding under the symphysis and the face directed toward the rectum. The fetal brow, nose, and chin slide over the perineum as the head is born.

EXTERNAL ROTATION

When the head is born with the occiput directed anteriorly, the shoulders must rotate internally so that they align with the anteroposterior diameter of the pelvis.

After the head is born, it spontaneously turns to the same side as it was in utero as it realigns with the shoulders and back (through a process called *restitution*). The head then turns farther to that side in external rotation as the shoulders internally rotate and are positioned with their transverse diameter in the anteroposterior diameter of the pelvic outlet. External rotation of the head accompanies internal rotation of the shoulders.

EXPULSION

Expulsion occurs first as the anterior, then the posterior, shoulder passes under the symphysis. After the shoulders are born, the rest of body follows.

FIG 12-12, cont'd

TABLE 12-1 CHARACTERISTICS OF NORMAL LABOR

	FIRST STAGE	SECOND STAGE	THIRD STAGE	FOURTH STAGE
Work Accomplished	Effacement and dilation of cervix	Expulsion of fetus	Separation of placenta	Physical recovery and bonding with newborn
Forces	Uterine contractions	Uterine contractions and voluntary bearing-down efforts	Uterine contractions	Uterine contraction to control bleeding from placental site
Average Duration Nullipara	<i>Latent phase:</i> 7.3-8.6 hr <i>Active phase:</i> 8-10 hr (range, 6-18 hr); dilation averages 1.2 cm/hr <i>Transition phase:</i> 3.6 hr	Average, 50 min (range, 30 min-3 hr)	5-10 min; up to 30 min is normal for unassisted placental separation	1-4 hr after birth
Multipara	<i>Latent phase:</i> 4.1-5.3 hr <i>Active phase:</i> 6-7 hr (range, 2-10 hr); dilation averages 1.5 cm/hr <i>Transition phase:</i> 0-30 min	Average, 20 min (range 0-30 min)	Same as for nullipara	Same as for nullipara
Cervical Dilation	<i>Latent phase:</i> 0-3 cm <i>Active phase:</i> 4-7 cm <i>Transition phase:</i> 8-10 cm	10 cm (complete dilation)	Not applicable	Not applicable
Uterine Contractions	<i>Latent phase:</i> Initially mild and infrequent; progress to moderate strength, every 5 min with a regular pattern; duration increases to 30-40 sec by end of latent phase <i>Active phase:</i> Increase in frequency, duration, and intensity until every 2-3 min, 40-60 sec, and moderate to strong intensity <i>Transition phase:</i> Strong, every 1½-2 min, 60-90 sec	Strong, every 2-3 min, lasting 40-60 sec; may be slightly less intense than during transition phase of first stage; may pause briefly as second stage begins	Firmly contracted	Firmly contracted
Discomfort*	Often begins with a low backache and sensations similar to those of menstrual cramps; back discomfort gradually sweeps to lower abdomen in a girdlelike fashion; discomfort intensifies as labor progresses	Urge to push or bear down with contractions, which becomes stronger as fetus descends; distention of vagina and vulva may cause a stretching or splitting sensation	Little discomfort; sometimes slight cramp is felt as placenta is passed	Discomfort varies; some women have afterpains, more common in multigravidas or those who have had a large baby; as anesthesia wears off, perineal discomfort may become noticeable
Maternal Behaviors*	Sociable, excited, and somewhat anxious during early labor; becomes more inwardly focused as labor intensifies; may lose control during transition	Intense concentration on pushing with contractions; often oblivious to surroundings and appears to doze between contractions	Excited and relieved after baby's birth; usually very tired; often cries	Tired, but may find it difficult to rest because of excitement; eager to become acquainted with her newborn

*Maternal discomfort and behaviors often vary with pain-relief method chosen.

Data from Kilpatrick, S. J., & Laros, R. K. (1989). Characteristics of normal labor. *Obstetrics & Gynecology*, 74(1), 85-87; Kilpatrick, S., & Garrison, E. (2012). Normal labor and delivery. In S. G. Gabbe, J. R. Niebyl, & J. L. Simpson et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed., pp. 267-286). Philadelphia: Elsevier Saunders; and Simpson, K. R. (2008b). Labor and birth. In K. R. Simpson & P. A. Creehan (Eds.), *AWHONN's perinatal nursing* (3rd ed., pp. 300-388). Philadelphia: Lippincott.

FIG 12-13 A labor curve, often called a *Friedman curve*, may be used to identify whether a woman's cervical dilation is progressing at the expected rate. The symbol for station (X) may be added to the labor curve. Typical labor curves for a multiparous woman and a nulliparous woman are illustrated for comparison of patterns.

Latent Phase

The latent phase lasts through the first 3 cm of cervical dilation. Its length varies among women but is usually longer for the nullipara than for the multipara. Latent labor may be quite long, and much of it may pass unnoticed by the pregnant woman as latent labor gradually merges into active labor. Cervical effacement and fetal positional change occur during the latent phase, preparing for the more rapid changes of active labor. Duration of the latent phase of first stage averages 7.3 to 8.6 hours in nulliparas and averages 4.1 to 5.3 hours in multiparas (Kilpatrick & Garrison, 2012).

Contractions gradually increase in frequency, duration, and intensity. The interval between contractions shortens until contractions are about 5 minutes apart as the woman progresses to the active phase. Duration increases to 30 to 40 seconds by the end of the latent phase. With regard to intensity, labor begins with mild contractions, during which the contracting uterus can be easily indented with the fingertips, and progresses to moderate contractions, during which the uterine muscle is indented with more difficulty. The contractions gradually build to their peak intensity and remain at the peak briefly before diminishing.

During latent labor, the woman may notice discomfort in her back with each contraction. As labor progresses, back discomfort encircles the lower abdomen with each contraction. Many women describe the discomfort as similar to menstrual cramps, especially during early labor.

The woman is usually sociable, excited, and cooperative. She is anxious as she realizes that these contractions are not Braxton Hicks contractions but the "real thing," yet she is usually relieved that her pregnancy is finally about to end.

Active Phase

The active phase of labor is so named because the pace of natural labor increases. The cervix dilates from 4 to 7 cm and at a more rapid rate

than in the latent phase. Effacement of the cervix is completed. The fetus descends in the pelvis, and internal rotation begins. Active and transition phases are linked as one phase enters into the next and references may not distinguish the two.

Durations of active and transition phases usually vary with whether the woman had epidural analgesia. For nulliparas with no epidural the duration of these two phases within the first stage is about 7.7 to 13.3 hours and averages 10.2 hours with an epidural. For multiparas with no epidural the duration of these two phases within the first stage is about 5.7 to 7.5 hours and averages 7.4 hours with an epidural (Kilpatrick & Garrison, 2012; Kilpatrick & Laros, 1989).

Contractions are about 2 to 5 minutes apart, with a duration of about 40 to 60 seconds and an intensity that ranges from moderate to strong. Active labor contractions reach their peak intensity quickly and stay at the peak longer than during the latent phase.

As contractions intensify, discomfort also increases if the woman has not had analgesia such as an epidural block. The site of discomfort during the active phase is similar to that during the latent phase.

The woman's behavior changes. She becomes more anxious and may feel helpless as the contractions intensify. The sociability that characterized early labor is gone and is replaced by a serious, inward focus. She is unlikely to initiate interactions unless she has specific requests. Her behaviors are typical of a person concentrating intently on a demanding task. Women who choose to take pain medication and regional analgesia usually do so during this phase. The nurse helps the woman maintain her concentration, supports her coping techniques, and helps her find alternatives for methods that do not work for her.

Transition Phase

The cervix dilates from 8 to 10 cm in this phase of the first stage, and the fetus descends further into the pelvis. Bloody show often increases

with the completion of cervical dilation. Transition is a short but intense phase within the first stage, averaging 3.6 hours in the nullipara and having a variable length in the multipara (Simpson, 2008b).

Contractions are very strong. They may be as frequent as 1.5 to 2 minutes apart, and their duration is 60 to 90 seconds. Strong contractions combined with fetal descent may cause the woman to have an urge to push and bear down during contractions. Leg tremors, nausea, and vomiting are common.

The woman who does not choose epidural analgesia often finds the transition phase to be the most difficult part of her labor. She may be irritable and lose control. Her partner may be confused because actions that were helpful just a short time ago now bother her. The nurse can encourage the woman and her support person that the end of labor is near and help them use coping techniques most effectively. If premature bearing down is a problem, the nurse can help the woman blow outward with each breath until the urge passes.

CRITICAL THINKING EXERCISE 12-2

After examining a woman in labor with her first baby, the nurse-midwife gives you the following information: “Carmelita is 2 to 3 cm, 75%, and 0. The baby is vertex and ROP.”

Questions

1. What is the correct interpretation of this information? What behaviors would be expected for Carmelita at this time? What behaviors should suggest to you that she has begun making very rapid labor progress?

Second Stage

The second stage (expulsion) begins with complete (10 cm) dilation and full (100%) effacement of the cervix and ends with the birth of the baby. Duration of second stage labor also varies with whether the

woman has an epidural. Duration of the second stage for the nullipara with no epidural averages from 53 to 57 minutes while the average duration is 79 minutes with an epidural. Duration of the second stage for the multipara with no epidural ranges from 17 to 19 minutes while the average duration is 45 minutes with an epidural.

Contractions may diminish slightly or even pause briefly as the second stage begins. They are still strong, about 2 to 3 minutes apart, with a duration of 40 to 60 seconds.

As the fetus descends, pressure of the presenting part on the rectum and the pelvic floor causes an involuntary pushing response in the mother. She may say that she needs to have a bowel movement or say “the baby’s coming” or “I have to push.” Her voluntary pushing efforts augment involuntary uterine contractions. As the fetus descends low in the pelvis and the vulva distends with the crowning of the fetal head, she may feel a sensation of stretching or splitting even if no trauma occurs. The maternal urge to push does not always occur the moment the woman is fully dilated. Allowing the woman to “labor down” is most beneficial in most cases (see Chapter 13).

The woman often regains a feeling of control during the second stage of labor. Contractions are strong, but she may feel more in control and know that she is doing something to complete the process by pushing with the contractions. The word *labor* aptly describes the second stage. The woman exerts intense physical effort to push her baby out. Between contractions, she may be oblivious to her surroundings and appear to be asleep. She feels tremendous relief and excitement as the second stage ends with the birth of the baby.

Third Stage

The third (placental) stage begins with the birth of the baby and ends with the expulsion of the placenta (Figure 12-14). This stage is the shortest, with an average length of 6 minutes (Kilpatrick & Garrison, 2012). No difference in duration exists between nulliparas and parous women.

FIG 12-14 **A**, Fetal side of the placenta. **B**, Maternal side of the placenta. **C**, Separating membranes. **D**, Umbilical cord vessels: two arteries and one vein.

When the infant is born, the uterine cavity becomes much smaller. The reduced size decreases the size of the placenta site, causing it to separate from the uterine wall. Four signs suggest placenta separation:

- The uterus has a spherical shape.
- The uterus rises upward in the abdomen as the placenta descends into the vagina and pushes the fundus upward.
- The cord descends further from the vagina.
- A gush of blood appears as blood trapped behind the placenta is released.

The placenta may be expelled in one of two ways. In the more common Schultze mechanism, the placenta is expelled with the shiny fetal side presenting first (see [Figure 12-14, A](#)). In the less common Duncan mechanism the rough maternal side presents first (see [Figure 12-14, B](#)).

The uterus must contract firmly and remain contracted after the placenta is expelled to compress open vessels at the implantation site. Inadequate uterine contraction after birth may result in hemorrhage.

Pain during the third stage of labor results from uterine contractions and brief stretching of the cervix as the placenta passes through it.

Fourth Stage

The fourth stage of labor is the stage of physical recovery for the mother and infant. It lasts from the delivery of the placenta through the first 1 to 4 hours after birth.

Immediately after birth, the firmly contracted uterus can be palpated through the abdominal wall as a firm, rounded mass about 10 to 15 cm (4 to 6 inches) in diameter at or below the level of the umbilicus. Uterine size varies with the size of the infant and parity of the mother and is larger when the infant is large or the mother is a multipara. A full bladder or blood clot in the uterus interferes with uterine contraction, increasing blood loss. A soft (boggy) uterus and increasing uterine size are associated with postpartum hemorrhage because large blood vessels at the placenta site are not compressed (see [Chapter 28](#)).

The *vaginal drainage after childbirth* is called **lochia**. The three stages are lochia rubra, lochia serosa, and lochia alba (see [pp. 329-330](#)). Lochia rubra, consisting mostly of blood, is present in the fourth stage of labor.

Many women are chilled after birth. The cause of this reaction is unknown but probably relates to the sudden decrease in effort, loss of the heat produced by the fetus, decrease in intraabdominal pressure, and fetal blood cells entering the maternal circulation. The chill lasts for about 20 minutes and subsides spontaneously. A warm blanket, a hot drink, or soup may help shorten the chill and make the woman more comfortable.

Discomfort during the fourth stage usually results from birth trauma and afterpains. Localized discomfort from birth trauma such

as lacerations, an episiotomy, edema, or a hematoma is evident as the effects of local and regional anesthetics diminish. Ice packs on the perineum limit this edema and hematoma formation.

Afterpains are intermittent uterine contractions occurring after birth as the uterus begins to return to the prepregnancy state. The discomfort is similar to menstrual cramps. Afterpains are more common in multiparas, women who breastfeed, women who have large babies or other uterine overdistention during pregnancy, and cases involving interference with uterine contraction because of a full bladder or blood clot that remains in the uterus.

The mother is simultaneously excited and tired after birth. She may be exhausted but too excited to rest. The fourth stage of labor is an ideal time for bonding of the new family because the interest of both the parents and the newborn is high. It is the best time to initiate breastfeeding if maternal and infant problems are absent. The baby is alert and seeks eye contact with the new parents, giving powerful reinforcement for the parents' attachment to their newborn.

CHECK YOUR READING

15. How do maternal behaviors change during each phase of first-stage labor and the second stage?
16. What are typical characteristics of contractions during each phase of first-stage and second-stage labor?
17. What four signs may indicate that the placenta has separated?
18. What complications may occur if the uterus does not contract firmly and remain contracted after the placenta is expelled?

DURATION OF LABOR

The total duration of labor is significantly different for women who have never given birth and those who have previously given birth vaginally. The parous woman usually delivers more quickly than the nulliparous woman. However, women are individuals. Some nulliparas progress through labor quickly, whereas labor for some parous women resembles that of women who have never given birth. A woman who experienced a long labor with her first child may not have a long labor with every baby. If she has a history of rapid labor, however, later births are often rapid as well.

Because of the high cesarean birth rate and fewer *vaginal births after cesarean (VBAC)*, a parous woman may have had no vaginal births. In this situation, the woman is likely to have a labor more like that of the nullipara, particularly if she did not labor before her previous cesarean birth. Spontaneous and progressive labor can occur in the woman who had one or more cesarean births although most women do not expect that to happen.

SUMMARY CONCEPTS

- Labor contractions are intermittent, which allows oxygen, nutrients, and waste products to be exchanged between maternal and fetal circulations during the interval between contractions.
- The upper uterus contracts actively during labor, maintaining tension to pull the more passive lower uterus and cervix over the fetal presenting part. These actions result in cervical effacement and dilation.
- Maternal vital signs are best assessed between contractions because alterations in the woman's blood pressure and pulse rate may occur during a contraction.
- Hyperventilation may occur if the woman breathes deeply and rapidly. Its manifestations include tingling of the hands and feet, numbness, and dizziness.
- The fetal heart rate and rhythm respond rapidly to events occurring during labor.
- Several occurrences during late pregnancy and labor aid the newborn in making adaptations to extrauterine life: reduced production of fetal lung fluid and increased absorption of lung fluid into the interstitium of the fetal lungs; expulsion of fluid from upper airways during the compression forces of labor; and increased

Continued

SUMMARY CONCEPTS—cont'd

- catecholamine secretion by the fetal adrenals to stimulate cardiac contraction and breathing, speed clearance of remaining lung fluid, and aid in temperature regulation.
- Four interrelated components affecting the process of birth are the powers, passage, passenger, and psyche. Presentation and position further describe the relation of the fetus (passenger) to the maternal pelvis (passage).
- The mechanisms of labor favor the most efficient passage of the fetus through the mother's pelvis.
- The exact reasons for the beginning of labor are unknown, but several maternal and fetal factors seem to have a role. These include fetal adrenal gland production of cortisol; increase in the ratio of estrogen to progesterone effects; increased uterine oxytocin receptors and gap junctions; and stretching of the uterus and cervix.
- As labor approaches, the woman may notice one or more premonitory signs preceding its onset: increase in frequency and intensity of Braxton Hicks contractions, lightening, increased vaginal secretions, bloody show, a spurt of energy, and weight loss.
- The conclusive difference between true labor and false labor is that progressive effacement and dilation of the cervix occur with true labor.
- The four stages and phases of labor are characterized by different physiologic events and maternal behaviors: first stage, cervical dilation and effacement; second stage, expulsion of the fetus; third stage, expulsion of the placenta; and fourth stage, maternal physiologic stabilization and parent–infant bonding.
- Normal labor is characterized by consistent progression of uterine contractions, cervical dilation and effacement, and fetal descent.

THE CHILDBIRTH STORY

1. Shari, in early labor with her second child, spends time with her 5-year-old son Adam in the labor-delivery-recovery room.

2. The nurse frequently assesses the condition of both the mother and the fetus. Here, she listens to the fetal heart rate.

3. Although intravenous fluids are not always necessary, physicians often order them to prevent dehydration and for access to a vein in case an emergency develops.

4. The nurse establishes a relationship of trust by assisting Shari into a comfortable position and explaining information obtained by electronic fetal monitoring.

5. Shari plans a childbirth without anesthesia. Darren, the father, uses skills learned in childbirth education classes to help her cope with discomfort.

6. Maintaining control is more difficult for Shari as the contractions become stronger. The nurse praises the couple's efforts and reviews measures to reduce discomfort.

THE CHILDBIRTH STORY

7. During transition, often the most difficult phase of labor, the nurse remains in close contact with Shari and assists her through each contraction.

8. The nurse prepares the sterile instruments that will be used during the birth. A mask is not always needed when preparing the table for vaginal birth but should be used as needed for the birth.

9. As birth approaches, the nurse positions Shari and assists her to push with each contraction. Note that the nurse now wears protective glasses.

10. The nurse also encourages Darren to remain in close contact with the mother and continue to participate in the birth.

11. The physician suctions secretions from the nose and mouth of the infant when the head is delivered.

12. The physician holds the infant so that the parents can get their first look at their newborn son. The mask may not be needed by the physician.

THE CHILDBIRTH STORY

13. A nurse counts the apical pulse rate and observes the newborn's pink color, which makes the administration of oxygen unnecessary.

14. The father observes as the nurse suction secretions from the newborn's nose and mouth and completes identification procedures such as footprinting.

15. Darren is an interested observer as the nurse weighs and measures the newborn.

16. Nurses are aware of the importance of early contact, and as soon as possible after birth the mother, father, and newborn are brought together.

17. Although Adam was not present at the birth, within a short time he meets the wide-eyed baby, who gazes intently at his older brother.

18. Shari and the nurse demonstrate the mutual regard that developed as they shared the intense experience of labor and birth.

THE CHILDBIRTH STORY

19. The nurse palpates the fundus frequently during the first hour after childbirth to confirm that the uterus is firmly contracted, which prevents excessive bleeding.

20. Adam watches intently as his mother and grandmother put the baby to breast for the first time.

21. Nurses must teach mothers how to care for themselves and their infants within a very short time. Here, the nurse instructs Shari in cord care.

22. Shari gains confidence in circumcision care when the nurse allows a return demonstration.

23. Adam peeks at his baby brother while the family receives additional instructions.

24. Twenty-four hours after her admission, Shari and the infant are discharged from the postpartum unit.

Nursing Care during Labor and Birth

WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Analyze issues that may be faced by the new nurse who cares for women during the intrapartum period.
2. Provide patient and family teaching regarding when to go to the birth facility.
3. Describe admission and continuing intrapartum nursing assessments.
4. Describe common nursing procedures used when caring for women during the intrapartum period.
5. Prioritize nursing care of the intrapartum patient in emergent situations.
6. Communicate therapeutically with the intrapartum woman and her significant others.
7. Apply the nursing process to care of the woman experiencing false or early labor.
8. Apply the nursing process to care of the woman and her significant others during the intrapartum period.

Care of the woman and her family during labor and birth is a rewarding yet demanding specialty within nursing. The birth of a baby is more than a physical event. Every culture recognizes that birth has deep personal and social significance. Roles and relationships are forever altered by this event.

The nurse must support natural physical processes, promote a meaningful experience for the family, and be alert for complications. Additionally, the nurse cares for two clients, one of whom—the fetus—cannot be observed directly.

The intrapartum area is typically a happy place, and good outcomes for mothers and infants are usual. Most women have accepted their pregnancies and look forward to meeting their infants. Yet some women have had stressful lives and pregnancies and may enter the intrapartum period with preexisting or an increased risk for physical or psychosocial issues (see [Chapter 24](#)).

ISSUES FOR NEW NURSES

New nurses and nursing students often approach care of laboring women with apprehension. They may face several common issues when caring for families during birth.

Pain Associated with Birth

Working with people in pain is difficult, and most nurses feel compelled to relieve pain promptly. Yet pain is expected and has a purpose in labor. It cannot be eliminated. Some women choose to have unmedicated births. Mothers who want some form of analgesia during labor experience some pain before receiving the analgesia. Helping the woman manage the pain of birth is a critical part of nursing care, and many nurses find this to be the most creative aspect of their roles.

Inexperience and Negative Experiences

The nurse who has never given birth may feel inadequate to care for laboring women; however, the same nurse rarely believes that his or her previous experience of a fracture, for example, is necessary to provide care for a patient with a fracture. Nursing skills needed by the intrapartum nurse are basic: observation, critical thinking, problem solving, therapeutic communication, comfort promotion, empathy, and common sense.

Nurses also may be anxious because of their own difficult experiences during birth. They must be careful not to convey negative attitudes to the laboring woman and her significant other. Nurses should be aware of the negative image of birth portrayed by the media and be prepared to correct misperceptions ([Morris & McInerney, 2010](#)).

Unpredictability

Birth follows its own timetable, even with efforts to “manage” it. Some nurses find the uncertain nature of an intrapartum area troubling, whereas others find it exciting. Some occurrences cannot be predicted or explained. In addition, the number of women needing care and the levels of care they require can change quickly.

Intimacy

The intimate nature of intrapartum care and its sexual overtones make some nurses uncomfortable. They may feel that they are intruding on a private time.

The male nurse may be anxious about this aspect of intrapartum care. Although he may have cared for other female clients, his care rarely has been so focused on the reproductive system. He often wonders whether a woman’s male partner will accept him as a care provider.

Both male nurses and female nurses should maintain professional conduct and take cues from the couple. If the couple wants privacy, the nurse should intervene only as needed to assess the woman and fetus. In more advanced labor, both partners often welcome the presence of a competent, caring nurse of either gender. When in doubt, ask the couple for their preferences.

ADMISSION TO THE BIRTH FACILITY

The Decision to Go to the Birth Facility

During the last trimester, the woman needs to know when she should go to the hospital or birth center. Factors she should consider include the following:

- Number and duration of any previous labors
- Distance from the hospital
- Available transportation
- Child care needs
- Risk status

In their prenatal care, nurses teach women to distinguish between false (prodromal) and true labor. Nurses teach guidelines for going to the birth center and reinforce those given by the physician or nurse-midwife (see “Pregnant Women Want to Know: When to Go to the

PREGNANT WOMEN WANT TO KNOW

When to Go to the Hospital or Birth Center

These are guidelines for providing individualized instruction to women about when to enter the hospital or birth center.

- Contractions—A pattern of increasing regularity, frequency, duration, and intensity.
- Nullipara—Regular contractions, 5 minutes apart, for 1 hour
- Multipara—Regular contractions, 10 minutes apart, for 1 hour
- Ruptured membranes—A gush or trickle of fluid from the vagina should be evaluated, regardless of whether contractions are occurring.
- Bleeding—Bright-red bleeding should be evaluated promptly. Normal bloody show is thicker, pink or dark red, and mixed with mucus.
- Decreased fetal movement—If you notice a substantial decrease in the baby’s movement, notify your physician or nurse-midwife or come to the labor unit.
- Other concerns—These guidelines cannot cover all situations and do not replace specific instructions given to you by your birth attendant. Therefore, please go to the hospital for evaluation of any concerns and feelings that something may be wrong.

THERAPEUTIC COMMUNICATIONS

Establishing a Therapeutic Relationship

Sandra is a nursing student assigned to the intrapartum unit. A woman walks toward Sandra. The woman is leaning on a man and breathing rapidly. She says to Sandra, “I think I’m in labor, and my water broke on the way to the hospital.” The staff nurse greets the woman and asks Sandra to take the woman to a labor room.

Sandra: It sounds like today’s the day!

Sandra asks the woman’s name (Amy James) and that of her birth attendant (Donna, CNM, a nurse-midwife) as they walk slowly to a room.

Sandra: I’m Sandra, a nursing student. What names do you want us to call each of you? (*Questioning for information. Shows respect by not assuming how the couple wants to be addressed.*)

Amy: I’m Amy, and my husband is Jeff.

Sandra: Is this your first baby, Amy, or have you had others? (*Questioning in a way that avoids “yes” or “no” answers.*)

Amy: It’s my second, and the first took forever! I’ve been having contractions off and on since midnight, but they didn’t get regular till about 6:00 this morning. They are coming every 3 minutes now and starting to hurt a lot.

Sandra helps Amy put a gown on and prepares the external fetal monitor while they wait for the RN. She does not follow up on Amy’s implied concern about having a long labor, however.

Amy: Oh no . . . the monitor. . . .

Sandra: You have a problem about the monitor? (*Clarifying the nonspecific remark that Amy made about the monitor.*)

Amy: I hated having that thing on with my last baby. I had to lie the same way all the time or they couldn’t hear the baby. I know it’s best for the baby, though.

Sandra: You seem to have mixed feelings about the monitor. (*Reflecting what Amy seems to be feeling.*)

Amy: Yes, I didn’t like it, but I do feel better knowing the baby’s okay.

Sandra: We can often find ways so it doesn’t bother you so much. We don’t want you to feel tied down because that will make you more uncomfortable. (*Giving information without promising that Amy will be totally comfortable with the external fetal monitor.*)

Sandra observes that Amy’s contractions are every 3 minutes and strong. She seeks an experienced nurse to help evaluate Amy. Sandra uses critical thinking and wisely seeks help from an experienced nurse because Amy seems to be in active labor and this is her second baby. The fact that Amy’s first labor “took forever” does not necessarily mean that this labor will be long.

Hospital or Birth Center”). Not everyone has a typical labor, so a woman should be encouraged to go to the birth center if she is uncertain or has other concerns.

Nursing Responsibilities during Admission

The two nursing priorities when the woman arrives at the birth center are to (1) establish a therapeutic relationship and (2) assess the condition of the mother and fetus.

Establish a Therapeutic Relationship

The nurse must quickly establish a therapeutic relationship with the woman and her significant other. The woman’s first impression influences her perception of the quality of her entire birth experience.

Make the Family Feel Welcome. A warm greeting makes the woman and her significant other feel valued. Even if the unit is busy, the nurse should communicate interest, friendliness, caring, and competence.

Nurses often encounter women who speak a language other than English. Arranging for a culturally acceptable interpreter who is fluent

in the woman's language makes the woman and her family feel welcome and promotes safety because it enhances understanding. Telephone interpreters for several languages are now available in many hospitals. Interpreters for the hearing impaired may be needed.

When caring for a woman who has not had prenatal care or childbirth classes, which are behaviors that most nurses value, the nurse must not be judgmental in either words or actions. The woman's priorities and values may be different from those of the nurse, but she deserves the same respect, support, and care as the woman who made every preparation for her baby's birth.

Determine Family Expectations About Birth. Regardless of their number of children, women and their partners have expectations about the birth experience. The partners may have studied their options extensively and planned a birth that best fits their ideals. Those who have not made specific plans also have expectations shaped by contact with relatives, friends, previous birth experiences, and the media. A couple may want to repeat a previous satisfying experience or avoid repeating a poor experience. Sometimes, one part of a past birth has negatively influenced the couple's impression of the entire experience.

Convey Confidence. From the first encounter, the nurse should convey confidence and optimism in the woman's ability to give birth and the ability of her significant other to support her. Women having their first baby may be overwhelmed by the power of normal labor contractions. The nurse can reassure these women that intense contractions are normal in active labor while helping them manage contractions and watching for true problems.

Think about the different perspectives implied by the phrases *give birth* and *be delivered*. The woman who gives birth is an active and able participant; she is the principal action figure. However, the language of *be delivered* implies that the woman is passive. The nurse might ask "Who will attend you as you give birth?" rather than "Who will deliver your baby?"

Assign a Primary Nurse. Having one nurse give care during all of labor is ideal but often unrealistic. However, changes in caregivers should be as limited as possible. The woman should know the name and role of each caregiver. For example, the primary nurse might explain the role of a nursing student in the woman's care. Common roles of nursing students in the intrapartum area include promoting comfort, giving emotional support, and helping the primary nurse observe for maternal and fetal problems.

Use Touch for Comfort. Touch can communicate acceptance and reassurance and provide physical and emotional comfort to many laboring women. Women who usually do not welcome touch may appreciate it during labor. Cultural norms and personal history influence a woman's comfort with touch from an unrelated person. The nurse should not assume that the woman desires touch but instead ask her if she welcomes or benefits from touch. As labor progresses, the woman's desire for touch may change, and touch may become irritating rather than comforting.

Respect Cultural Values. Cultural beliefs and practices give structure, meaning, and richness to the birth experience. They influence the behavior of both the childbearing family and the professional staff. Most cultural groups have specific practices related to childbearing. The nurse should incorporate a family's cultural practices into care as much as is safe and possible.

People naturally believe that their own cultural values are best. The nurse should avoid using an attitude that is superior or diminishes the validity of another person's cultural beliefs. Trust in technology is a common value of many caregivers in the United States, but such reliance on technology is considered unnecessary, odd, and even harmful by many other cultures.

CHECK YOUR READING

1. What communication skills can the nurse use to establish a therapeutic relationship when the woman and her family enter the hospital or birth center?
2. How can the nurse incorporate a couple's cultural practices into intrapartum care?

Admission Assessments

A paper or computerized record of prenatal care is sent to the center where the woman plans to give birth and added to her chart when she is admitted. Admission information can be obtained from the prenatal record and verified or updated as needed. Women who have not had prenatal care or who have received care from a provider who practices at a different facility need more extensive assessment by the nurse and physician (Table 13-1). The prenatal record for the woman in preterm labor may not yet be available at the birth facility because these are usually sent near term. As computerized records become more secure, prenatal records may be transferred online between a physician or certified nurse-midwife who has privileges at the facility and the facility's authorized staff.

Focused Assessment

A focused assessment is performed before the broader database assessment in the intrapartum unit, opposite of the usual order. Assessment priorities are to determine the condition of the mother and fetus and whether birth is imminent.

Fetal Heart Rate. For assessment of a term fetus using intermittent auscultation, the following fetal heart rate (FHR) guidelines are considered reassuring (Feinstein, Sprague, & Trépanier, 2008; Simpson, 2008a):

- A baseline rate of 110 beats per minute (bpm) to 160 bpm
- Regular rhythm

If electronic fetal monitoring is used, additional reassuring characteristics include the following:

- Presence of accelerations in the FHR baseline
- Absence of decelerations from the baseline (see Chapter 14).

Maternal Vital Signs. Maternal vital signs are assessed to identify signs of hypertension and infection. Hypertension during pregnancy is defined as a sustained blood pressure increase to 140 mm Hg systolic or 90 mm Hg diastolic or higher. The hypertension may be a disorder that is specific to pregnancy or it may be chronic (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012; ACOG, 2012, 2010) (see Chapter 25 for more information). A temperature of 38°C (100.4°F) or higher suggests infection.

Impending Birth. Grunting sounds, bearing down, sitting on one buttock, and saying urgently, "The baby's coming" suggest imminent birth. The nurse abbreviates the initial assessment and collects other information after birth. While the nurse cares for the mother, minimal information can be quickly gathered if birth is imminent:

- Names of mother and support person(s)
- Name of her physician or nurse-midwife if she had prenatal care
- Number of pregnancies and prior births, including whether the birth was vaginal or cesarean
- Status of membranes
- Expected date of delivery
- Problems during this or other pregnancies
- Allergies to medications, foods, or other substances
- Time and type of last oral intake
- Maternal vital signs and FHR

TABLE 13-1 INTRAPARTUM ASSESSMENT GUIDE

ASSESSMENT, METHOD (SELECTED RATIONALES)	COMMON FINDINGS	SIGNIFICANT FINDINGS, NURSING ACTION
<p>Interview</p> <p><i>Purpose:</i> To obtain information about the woman's pregnancy, labor, and conditions that may affect her care. The interview is curtailed if she is in late labor.</p> <p><i>Introduction:</i> Introduce yourself, and ask the woman how she wants to be addressed. Ask her if she wants her partner and/or family to remain during the interview and assessment. (<i>Shows respect for the woman and gives her control over those she wants to remain with her.</i>)</p> <p><i>Culture and language:</i> If she is from another culture, ask what her preferred language is and what language(s) she speaks, reads, or verbally understands. (<i>Identifies the need for an interpreter and enables the most accurate data collection.</i>)</p> <p><i>Communication:</i> Ask the woman to tell you when she has a contraction, and pause during the interview and physical assessment. (<i>Shows sensitivity to her comfort and allows her to concentrate more fully on the information the nurse requests.</i>)</p> <p><i>Nonverbal cues:</i> Observe the woman's behaviors and interactions with her family and the nurse. (<i>Permits estimation of her level of anxiety. Identifies behaviors indicating that she should have a vaginal examination to determine whether birth is imminent.</i>)</p> <p><i>Reason for admission:</i> "What brings you to the hospital/birth center today?" (<i>Open-ended question promotes more complete answer.</i>)</p> <p><i>Prenatal care:</i> "Did you see a doctor or nurse-midwife during your pregnancy?" "Who is your doctor or nurse-midwife?" "How far along were you in your pregnancy when you saw the physician or nurse-midwife?" "Have you ever been admitted here before during this pregnancy?" (<i>Enables location of prenatal record and prior visit records.</i>)</p>	<p>Many women prefer to be addressed by their first names during labor.</p> <p>Common non-English languages of women in the United States are Spanish and some Asian dialects. The most common non-English language varies with location.</p> <p>Women in active labor have difficulty answering questions or cooperating with a physical examination while they are having a contraction.</p> <p><i>Latent phase:</i> Woman is sociable and mildly anxious.</p> <p><i>Active phase:</i> Woman concentrates intently during contractions; often uses prepared childbirth techniques.</p> <p>Labor contractions at term, induction of labor, or observation for false labor are common reasons for admission.</p> <p>Early and regular prenatal care promotes maternal and fetal health.</p>	<p>The surname (family name) precedes the given name in some cultures. Clarify which name is used to properly address the woman and to properly identify both mother and newborn. Have the woman verify accuracy of identification bands before placing them on her and baby.</p> <p>Secure an interpreter fluent in the woman's primary language. Ask her if there are people who are not acceptable to her as interpreters (e.g., males or members of a group in conflict with her culture). Family members may not be the best interpreters because they may interpret selectively, adding or subtracting information as they see fit. Phone interpreters are available in many facilities. Hearing-impaired women may read lips well, or they may need sign-language interpreters or other assistance.</p> <p>If contractions are very frequent, assess the woman's labor status promptly rather than continuing the interview. Ask only the most critical questions (see pp. 222, 228)</p> <p>The unprepared or extremely anxious woman may breathe deeply and rapidly, displaying a tense facial and body posture during and between contractions. These behaviors suggest that birth is imminent:</p> <ol style="list-style-type: none"> 1. Her statement that the baby is coming 2. Grunting sounds (low-pitched, guttural sounds) 3. Bearing down with abdominal muscles 4. Sitting on one buttock <p>Euphoria, combativeness, or sedation suggests recent illicit drug ingestion.</p> <p>Bleeding, preterm labor, pain other than labor contractions. Report these findings to the physician or nurse-midwife promptly.</p> <p>No prenatal care or care that was irregular or begun in late pregnancy means that complications may not have been identified.</p>

TABLE 13-1 INTRAPARTUM ASSESSMENT GUIDE—cont'd

ASSESSMENT, METHOD (SELECTED RATIONALES)	COMMON FINDINGS	SIGNIFICANT FINDINGS, NURSING ACTION
<i>Estimated date of delivery (EDD):</i> “When is your baby due?” (<i>Determines if gestation is term.</i>) “When did your last menstrual period begin?” (<i>For estimation of EDD if woman did not have prenatal care.</i>)	<i>Term gestation:</i> 38-42 weeks. The woman’s gestation may have been confirmed or adjusted during pregnancy with an ultrasound or other clinical examination.	Gestations earlier than the beginning of the 38th week (preterm) or later than the end of the 42nd week (postterm) are associated with more fetal or neonatal problems. The physician may try to stop labor that occurs earlier than 36 weeks if there are no contraindications for mother or fetus.
<i>Gravidity, parity, abortions:</i> “How many times have you been pregnant?” “How many babies have you had? Were they full term or premature?” “How many children are now living?” “Have you had any miscarriages or abortions?” “Were there any problems with your babies after they were born?” (<i>Helps estimate probable speed of labor and anticipate neonatal problems.</i>)	Labor may be faster for the woman who has given birth before than for the nullipara. Miscarriage is used to describe a spontaneous abortion because many lay people associate the term abortion with only induced abortions.	Parity of 5 or more (grand multiparity) is associated with placenta previa (see Chapter 25) and postpartum hemorrhage (see Chapter 28). Women who have had several spontaneous abortions or who have given birth to infants with abnormalities may face a higher risk for an infant with a birth defect.
<i>Pregnancy history</i> (<i>Identifies problems that may affect this birth.</i>)	Complications are not expected.	Women who have diabetes or hypertension may have poor placental blood flow, possibly resulting in fetal compromise. Some complications of past pregnancies, such as gestational diabetes, may recur in another pregnancy. The woman who plans a VBAC may need more support and reassurance to give birth vaginally.
<i>Present pregnancy:</i> “Have you had any problems during this pregnancy, such as high blood pressure, diabetes, infections, or bleeding?”	Complications are not expected.	Women who have diabetes or hypertension may have poor placental blood flow, possibly resulting in fetal compromise. Some complications of past pregnancies, such as gestational diabetes, may recur in another pregnancy. The woman who plans a VBAC may need more support and reassurance to give birth vaginally.
<i>Past pregnancies:</i> “Were there any problems with your other pregnancy(ies)?” “Were your other babies born vaginally or by cesarean birth?”	Women who had previous cesarean birth(s) may have a trial of labor and vaginal birth (VBAC). A woman who previously had a difficult labor or a cesarean birth may be more anxious than one who had an uncomplicated labor and birth.	Although the VBAC is less common, it may be chosen for a variety of reasons. The nurse should be aware of the need for support and for complications that may be more likely in the current pregnancy.
<i>Other:</i> “Is there anything else you think we should know so that we can better care for you?”	This open-ended question gives the woman a chance to share information that may not be elicited by other questions.	Women who say they have been “in labor” for an unusual length of time (e.g., “for 2 days”) have probably had false (prodromal) labor. These women may be very tired from the annoying and apparently nonproductive contractions.
<i>Labor status:</i> “When did your contractions become regular?” “What time did you begin to think you might really be in labor?” (<i>Facilitates a more accurate estimation of the time labor began.</i>)	Varies among women. Many women go to the birth facility when contractions first begin. Others wait until they are reasonably sure that they are really in labor.	Women who say they have been “in labor” for an unusual length of time (e.g., “for 2 days”) have probably had false (prodromal) labor. These women may be very tired from the annoying and apparently nonproductive contractions.
<i>Contractions:</i> “How often are your contractions coming?” “How long do they last?” “Are they getting stronger?” “Tell me if you have a contraction while we are talking.” (<i>Obtains the woman’s subjective evaluation of her contractions. Alerts the nurse to palpate contractions that occur during the interview.</i>)	Varies according to her stage and phase of labor. Labor contractions are usually regular and show a pattern of increasing frequency, duration, and intensity.	Irregular contractions or those that do not increase in frequency, duration, or intensity are more likely to represent false labor. Contractions that are too frequent or too long can reduce placental blood flow. Incomplete uterine relaxation between contractions also can reduce placental blood flow (see Chapter 14).
<i>Membrane status:</i> “Has your water broken?” “What time did it break?” “What did the fluid look like?” “About how much fluid did you lose—was it a big gush or a trickle?” (<i>Alerts the nurse of the need to verify whether the membranes have ruptured if it is not obvious. Identifies possible prolonged rupture of membranes or preterm rupture.</i>)	Most women go to the birth facility for evaluation soon after their membranes rupture. If a woman is not already in labor, contractions usually begin within a few hours after the membranes rupture at term.	If the woman’s membranes have ruptured and she is not in labor or if she is not at term, a vaginal examination is often deferred. A speculum examination may be done by the physician or nurse-midwife to identify the woman’s admission status. Labor may be induced if she is at term with ruptured membranes.

TABLE 13-1 INTRAPARTUM ASSESSMENT GUIDE—cont'd

ASSESSMENT, METHOD (SELECTED RATIONALES)	COMMON FINDINGS	SIGNIFICANT FINDINGS, NURSING ACTION
<p>Allergies: “Are you allergic to any foods, medicines, or other substances?” “Do you have an allergy to latex?” “What kind of reaction do you have?” “Have you ever had a problem with anesthesia when you have had dental work?” (<i>Determines possible sensitivity to drugs that may be used.</i>)</p>	<p>Record any known allergies to food, medication, or other substances. As needed, describe how they affected the woman.</p>	<p>Allergy to seafood, iodized salt, or imaging contrast media may indicate iodine allergy. Because iodine is used in many “prep” solutions, alternative ones should be used. Allergy to latex is more common. Allergy to dental anesthetics may indicate possible allergy to the drugs used for local or regional anesthetics. These drugs usually end in the suffix <i>-caine</i>.</p>
<p>Food intake: “When was the last time you had something to eat or drink?” “What did you have?” (<i>Provides information needed to most safely administer general anesthesia if required. Identifies possible fluid or energy deficit.</i>)</p>	<p>Record the time of the woman’s last food intake and what she ate. Include both liquids and solids.</p>	<p>If the woman says she has not had any intake for an unusual length of time, question her more closely: “Is there any food you may have forgotten, such as a snack or a drink of water or other liquid?”</p>
<p>Recent illness: “Have you been ill recently?” “What was the problem?” “What did you do for it?” “Have you been around anyone with a contagious illness recently?”</p>	<p>Most pregnant women are healthy. An occasional woman may have had a minor illness such as an upper respiratory tract infection.</p>	<p>Urinary tract infections are associated with preterm labor. The woman who has had contact with someone having a communicable disease may become ill and possibly infect others in the facility.</p>
<p>Medications: “What drugs do you take that your doctor or nurse-midwife has prescribed?” “Are there any over-the-counter or herbal drugs that you use?” “I know this may be uncomfortable to discuss, but we need to know about any illegal or abused substances that you use, to more safely care for you and your baby.” (<i>Permits evaluation of the woman’s drug intake and encourages her to disclose nonprescribed use.</i>)</p>	<p>Prenatal vitamins and iron are commonly prescribed. Record all drugs the woman takes, including time and amount of last ingestion. Women often do not consider botanical preparations as drugs. Women who use illegal substances often conceal or diminish the extent of their use because they fear reprisals.</p>	<p>Drugs may interact with other medications given during labor, especially analgesics and anesthetics. Substance abuse is associated with complications for the mother and infant (see Chapter 24). If the woman discloses that she uses illegal drugs, ask her what kind and the last time she ingested them (often referred to as “taking a hit”). A nonjudgmental approach in private is more likely to result in honest information.</p>
<p>Tobacco or alcohol: “Do you smoke or use tobacco in any other form? How many cigarettes a day?” “Do you use alcohol? How many drinks do you have each day (or week)?” (<i>Evaluates use of these legal substances.</i>)</p>	<p>As in substance abuse, women may underreport the extent of their use of tobacco or alcohol.</p>	<p>Infants of heavy smokers are often smaller and may have reduced placental blood flow during labor. Infants of women who use alcohol may show fetal alcohol effects at birth or later (see Chapter 30).</p>
<p>Birth plans (<i>Shows respect for the woman and her family as individuals and promotes achievement of their expectations; enables more culturally appropriate care</i>):</p>		
<p>Coach or primary support person: “Who is the main person you want to be with you during labor?” Ask that person how he or she wants to be addressed, such as “Mr. Ramos” or “Carlos.”</p>	<p>This is usually the woman’s husband or the baby’s father, but it may be her mother, her sister, or a friend, especially if she is single.</p>	<p>The woman who has little or no support from significant others probably needs more intense nursing support during labor and after the birth. These clients are more likely to have problems with parent–infant attachment.</p>
<p>Other support: “Is there anyone else you would like to be present during labor?”</p>	<p>Women often want another support person present.</p>	
<p>Preparation for childbirth: “Did you attend prepared childbirth classes?” “Did someone go with you?”</p>	<p>Ideally, the woman and a partner have had some preparation in classes or self-study. Women who attended classes during previous pregnancies do not always repeat the classes during subsequent pregnancies.</p>	<p>The unprepared woman may need more support with simple relaxation and breathing techniques during labor. Her partner may need to learn techniques to assist her.</p>
<p>Preferences: “Are there any special plans you have for this birth?” “Is there anything you want to avoid?” “Did you plan to record the birth with pictures or video?”</p>	<p>Some women or couples have strong feelings regarding certain interventions. Common ones are (1) analgesia or anesthesia; (2) intravenous lines; (3) fetal monitoring; (4) use of episiotomy or forceps.</p>	<p>Conflict may arise if the woman has not previously discussed her preferences with her physician or nurse-midwife or if she is unaware of what services are available where she gives birth.</p>

Continued

TABLE 13-1 INTRAPARTUM ASSESSMENT GUIDE—cont'd

ASSESSMENT, METHOD (SELECTED RATIONALES)	COMMON FINDINGS	SIGNIFICANT FINDINGS, NURSING ACTION
<p>Cultural needs: “Are there any special cultural practices that you plan when you have your baby?” “How can we best help you to fulfill these practices?”</p>	<p>Women from Asian and Hispanic cultures may subscribe to the “hot-and-cold” theory of illness and want specific foods after birth, such as soft-boiled eggs. They may not want their water or other fluids iced.</p>	<p>Try to incorporate all positive or neutral cultural practices. If a practice is harmful, explain why and try to find a way to work around it if the family does not want to give it up.</p>
Fetal Evaluation		
<p><i>Purpose:</i> To determine if the fetus seems to be healthy and tolerating labor well. <i>Fetal heart rate (FHR):</i> Assess by intermittent auscultation, or apply an external fetal monitor if that is the facility’s policy (most common in the United States). Document FHR according to the risk status and stage of labor (see Chapter 14).</p>	<p>Average rate at term is 110 to 160 bpm. Rate usually increases when the fetus moves and is reassuring.</p>	<p>These signs may indicate fetal stress and should be reported to the physician or nurse-midwife:</p> <ol style="list-style-type: none"> 1. Rate outside the normal limits 2. Slowing of the rate that persists after the contraction ends 3. No increase in rate when the fetus moves 4. Irregular rhythm <p>More frequent assessments should be made of the FHR and contractions if any finding is questionable.</p>
<i>Guidelines include:</i>		
<p>Low risk: every 1 hr (latent phase), every 30 min (active phase), every 15 min (2nd stage) High risk: every 30 min (latent phase), every 15 min (active phase), every 5 min (2nd stage)</p>		
Labor Status		
<p><i>Purpose:</i> To identify whether the woman is in labor and if birth is imminent. If she displays signs of imminent birth, this assessment is done as soon as she is admitted.</p>		
<p><i>Contractions (Yields objective information about labor status):</i> In addition to asking the woman about her contraction pattern, assess the contractions by palpation with the fingertips of one hand. Contractions should be assessed each time the FHR is assessed.</p>	<p>See Interview section earlier in table.</p>	<p>See Interview section earlier in table. Women who have intense contractions or who are making rapid progress should be assessed more frequently.</p>
<p><i>Vaginal examination (Determines cervical dilation and effacement; fetal presentation, position, and station; bloody show; and status of the membranes.)</i></p>	<p>Varies according to the stage and phase of labor. It may not be possible to determine the fetal position by vaginal examination when membranes are intact and bulging over the presenting part.</p>	<p>A vaginal examination is not performed if the woman reports or has evidence of active bleeding (heavier and redder than bloody show) and may not be done if her gestation is 36 weeks or less and she does not seem to be in active labor. Report reasons for omitting a vaginal examination to the physician or nurse-midwife.</p>
<p><i>Status of membranes:</i> During a vaginal examination, a flow of fluid suggests ruptured membranes. A pH test and/or fern test may be done, often using a sterile speculum exam. (Test is not needed if it is obvious that the membranes have ruptured.)</p>	<p>Amniotic fluid should be clear, possibly containing flecks of white vernix. Its odor is distinctive but not offensive. The test with a color change of blue-green to dark blue (pH > 6.5) suggests true rupture of the membranes but is not conclusive. The fern test is more diagnostic of true rupture of membranes because it is less likely to be affected by vaginal infections, recent intercourse, or other factors.</p>	<p>A greenish color indicates meconium staining, which may be associated with fetal compromise or postterm gestation. Thick meconium with heavy particulate matter (“pea soup”) is most significant (see Chapter 30). Thick green-black meconium may be passed by the fetus in a breech presentation and is not necessarily associated with fetal compromise. Cloudy, yellowish, strong-smelling, or foul-smelling fluid suggests infection. Bloody fluid may indicate partial placental separation (see Chapter 25).</p>

TABLE 13-1 INTRAPARTUM ASSESSMENT GUIDE—cont'd

ASSESSMENT, METHOD (SELECTED RATIONALES)	COMMON FINDINGS	SIGNIFICANT FINDINGS, NURSING ACTION
<i>Leopold's maneuvers:</i> Often done before assessing the FHR to locate the best place for assessment. (<i>Identifies fetal presentation and position. Most accurate when combined with information from vaginal examination.</i>)	A cephalic presentation with the head well flexed (vertex) is normal. The fetal head is often easily displaced upward ("floating") if the woman is not in labor. When the head is engaged, it cannot be displaced upward with Leopold's maneuvers.	A hard, round, freely movable object in the fundus suggests a fetal head, meaning the fetus is in a breech presentation. Less commonly, the fetus may be crosswise in the uterus: a transverse lie.
<i>Pain:</i> Note discomfort during and between contractions. Note tenderness when palpating contractions. (<i>Distinguishes between normal labor pain and abnormal pain that may be associated with a complication.</i>)	There may be verbal or nonverbal evidence of pain with contractions, but the woman should be relatively comfortable between contractions. The skin around the umbilicus is often sensitive.	Constant pain or a tender, rigid uterus suggests a complication, such as abruptio placentae (separated placenta) (see Chapter 25) or, less commonly, uterine rupture (see Chapter 27).
Physical Examination		
<i>Purpose:</i> To evaluate the woman's general health and identify conditions that may affect her intrapartum and postpartum care.		
<i>General appearance:</i> Observe skin color and texture, nutritional state, and appearance of rest or fatigue. Examine the woman's face, fingers, and lower extremities for edema. Ask her if she can take her rings off and put them on.	Women are often fatigued if their sleep has been interrupted by Braxton Hicks contractions, fetal activity, or frequent urination. Mild edema of the lower extremities is common in late pregnancy.	Pallor suggests anemia. Substantial edema of the face and fingers or extreme (pitting) edema of the lower extremities is associated with preeclampsia, although it may occur in the absence of this hypertensive disorder (see Chapter 25).
<i>Vital signs:</i> Take the woman's temperature, pulse rate, respirations, and blood pressure. Reassess the temperature every 4 hr (every 2 hr after membranes rupture or if temperature is elevated); reassess blood pressure, pulse, and respirations every hour.	<i>Temperature:</i> 35.8-37.3°C (96.4-99.1°F) <i>Pulse rate:</i> 60-100 bpm <i>Respirations:</i> 12-20/min, even and unlabored Blood pressure near baseline levels established during pregnancy. Transient elevations of blood pressure are common when the woman is first admitted, but they return to baseline levels within about ½ hr.	Report abnormalities to physician or nurse-midwife. Temperature of 38°C (100.4°F) or higher suggests infection. Pulse rate and respirations may also be elevated. Pulse rate and blood pressure may be elevated if the woman is extremely anxious or in pain. A blood pressure ≥ 140 mm Hg or ≥ 90 mm Hg diastolic or higher is considered hypertensive. For women who did not have prenatal care, there is no baseline for comparison.
<i>Heart and lung sounds:</i> Auscultate all areas with a stethoscope.	Heart sounds should be clear with a distinct S ₁ and S ₂ . A physiologic murmur is common because of the increased blood volume and cardiac output. Breath sounds should be clear, with respirations even and unlabored.	The woman who is breathing rapidly and deeply may have symptoms of hyperventilation: tingling and spasm of the fingers, numbness around the lips.
<i>Breasts:</i> Palpate for a dominant mass.	Breasts are full and nodular. Areola is darker, especially in dark-skinned women. Breasts may leak colostrum (clear, sticky, straw-colored fluid) during labor.	Report a dominant mass to the physician or nurse-midwife for later follow-up.
<i>Abdomen:</i> Observe for scars at the same time Leopold's maneuvers and the FHR are assessed. It is usually sufficient to assess the fundal height by observing its relation to the xiphoid process.	Striae (stretch marks) are common. If scars are noted, ask the woman what surgery she had and when. The fundus at term is usually slightly below the xiphoid process but varies with maternal height and fetal size and number.	Report a previous cesarean birth to the physician or nurse-midwife. Transverse uterine scars are least likely to rupture if the woman is in labor (see Chapter 27). Measure the fundal height (see pp. 91-92) if the fetus seems small or if the gestation is questionable.
<i>Deep tendon reflexes (DTRs):</i> Assess patellar reflex (see Chapter 25). Upper extremity DTRs should also be evaluated at admission if epidural block analgesia is planned because they are normally not as strong as the patellar reflex.	A brisk jerk without spasm or sustained muscle contraction is normal. Some women normally have hypoactive reflexes, but at least a slight twitch is expected. Obese women may appear to have diminished reflexes because of the fat tissue over the tendon.	Report absent (uncommon unless the woman is receiving magnesium sulfate) or hyperactive reflexes. Hyperactive reflexes and clonus (repeated tapping when the foot is dorsiflexed) are associated with pregnancy-induced hypertension and often precede a seizure (see Chapter 25).

Continued

TABLE 13-1 INTRAPARTUM ASSESSMENT GUIDE—cont'd

ASSESSMENT, METHOD (SELECTED RATIONALES)	COMMON FINDINGS	SIGNIFICANT FINDINGS, NURSING ACTION
<p><i>Midstream urine specimen:</i> Assess protein and glucose levels with a dipstick. Follow instructions on the package for waiting times. Check for ketones if the woman has not eaten for a prolonged period or has been vomiting. Send a separate specimen for urinalysis, if ordered.</p>	Negative or trace of protein; negative glucose and ketones.	Proteinuria is associated with pregnancy-induced hypertension but may also be associated with urinary tract infections or a specimen that is contaminated with vaginal secretions. Glycosuria is associated with diabetes. Ketonuria is common in poorly controlled diabetes or if the woman does not eat adequate carbohydrates to meet her energy needs.
<p><i>Laboratory tests:</i> Women who have had prenatal care may not need as many admission tests. Common tests include the following:</p> <ol style="list-style-type: none"> 1. Complete blood cell count (or hematocrit done on unit) 2. Blood type and Rh factor 3. Serum tests for syphilis. Other routine admission tests may include serum HIV, vaginal gonorrhea and chlamydia, or vaginal GBS tests. Routine drug screens are common for a woman who has not had prenatal care. 	<ol style="list-style-type: none"> 1. Hemoglobin at least 10.5 grams per deciliter (g/dL); hematocrit at least 33%. 2. The woman who is Rh-negative and has had regular prenatal care receives Rh immune globulin at 28 weeks of gestation to prevent formation of anti-Rh antibodies. 3. Negative on all. GBS screening may have been done recently during a prenatal visit late in pregnancy (see Chapter 26 for more information). 	<ol style="list-style-type: none"> 1. Values lower than these reduce maternal reserve for normal blood loss at birth. 2. Rh-negative mothers need Rh immune globulin after birth if the infant is Rh-positive. 3. A positive test indicates that the baby could be infected and needs treatment after birth. The mother should be treated if she has not been treated already. Maternal antibiotics are given for positive GBS to reduce newborn infection from organisms within the vagina.

*Women who have had prenatal care have much of this information available on their prenatal record. The nurse need only verify it or update it, as needed.

bpm, Beats per minute; GBS, group B *Streptococcus*; HIV, human immunodeficiency virus; VBAC, vaginal birth after cesarean.

- Pain: location, intensity, factors that intensify or relieve, duration, whether constant or intermittent, whether the pain is acceptable to the woman

If focused assessments of mother and fetus are normal and birth is not imminent, a more complete admission assessment is taken. If the initial assessments show that birth is near or another urgent condition is identified, the physician or nurse-midwife is notified promptly with essential assessment information.

CHECK YOUR READING

3. What are the three assessment priorities when a woman comes to the intrapartum unit?
4. What FHR characteristics (when auscultated) are reassuring?
5. What observations suggest that a woman is going to give birth very soon? What should the nurse do in that case?

Database Assessment

In addition to performing the focused assessment, the nurse should assess the mother, fetus, and available maternal support persons.

Basic Information. Intrapartum admission forms guide the nurse to obtain required information. Typical information includes:

- The woman's reason for coming to the hospital or birth center (such as contractions, rupture of membranes)
- Prenatal care: when it began, her most recent visit, and the name of her physician or nurse-midwife
- Estimated date of delivery (**EDD**, also may be abbreviated **EDB** [estimated date of birth]).

- Number of pregnancies, births, spontaneous and elective **abortions**.
- Allergies: medications, food, other substances such as latex
- Food intake: what food and when it was eaten
- Medical, surgical, and pregnancy histories
- Recent illness, including treatment
- Medications, including prescription and over-the-counter drugs, tobacco, alcohol, and other substances of abuse
- Complementary or alternative therapy; use of herbal and botanical preparations and their purposes
- Use of tobacco, alcohol, and illicit substances
- Her subjective evaluation of her labor
- Birth plans, including planned pain management methods
- Support persons: who they are and the role of each
- Potential domestic violence (ask only when the woman is alone)

Women often bring several people with them to the birthing room and want them to stay during admission. However, be careful about asking for sensitive information such as prior pregnancies and births and potential abuse when others are present. A woman may have had an abortion or relinquished a baby for adoption, and her family may not know about it. Even if her partner knows about previous pregnancies, her family or friends may not. Asking about domestic violence when the abuser is present will result in a quick denial and can be dangerous for the woman. Delay asking sensitive information until the woman is alone for confidentiality, safety, and accuracy.

Fetal Assessments. The fetal presentation and position are assessed using a combination of vaginal examination and Leopold's maneuvers ([Procedure 13-1](#)). The FHR is assessed by intermittent

CRITICAL THINKING EXERCISE 13-1

During a labor admission assessment, a woman quickly denies her use of drugs and herbal preparations other than her prenatal vitamins. She becomes quiet, answering the nurse's questions in a terse manner.

Questions

1. What might explain the woman's change in behavior?
2. Should the nurse alter the assessment interview?

auscultation, electronic monitoring or both (see [Chapter 14](#)). The nurse documents the color and odor of the amniotic fluid and the time of rupture if the membranes ruptured before admission.

Labor Status. The woman's labor status is determined by assessing her contraction pattern, performing vaginal examination and determining whether her membranes have ruptured. Contractions are assessed by palpation ([Procedure 13-2](#)), the electronic monitor, or both. Cervical dilation and effacement and the fetal station, presentation, and position are evaluated by vaginal examination. The vaginal examination may also reveal whether the membranes have ruptured if fluid is not obviously leaking from the vagina. Vaginal examination is not performed if the woman has active bleeding (other than bloody show) because the procedure can increase bleeding. Speculum rather than vaginal examination may be done if the gestation is preterm or with active bleeding.

Physical Examination. A brief physical examination evaluates the woman's overall health. Other important observations relating to birth include the presence and location of edema and abdominal scars and the height of the fundus.

CHECK YOUR READING

6. Which tests may be done if the nurse is not certain whether the woman's membranes have ruptured? (See [Table 13-1](#).)
7. Which characteristics of contractions may reduce blood flow to the placenta? (See [Procedure 13-2](#).)

Admission Procedures

Notify the Birth Attendant. After assessment the nurse notifies the woman's birth attendant to report the woman's status and obtain orders. The following data are provided:

- **Gravidity**, parity, abortions (spontaneous and elective), and term and preterm births
- EDB and fundal height if it conflicts with the EDB
- Contraction pattern
- Results of vaginal examination
 - Cervical dilation and effacement
 - Fetal presentation and position
 - Station of the presenting part
- FHR and pattern
- Maternal vital signs
- Any identified abnormalities and concerns about the maternal or fetal condition
- Pain, anxiety, or other reactions to labor

If the birth attendant admits the woman, any of several procedures may be performed.

Consent Forms. The woman signs consent for care during labor, such as anesthesia, vaginal birth and/or cesarean birth, blood transfusion, and testing for human immunodeficiency virus (HIV). A separate

consent for bilateral tubal ligation must be signed by the woman if she desires permanent sterilization at the time of birth. Consent to sterilization at delivery may be required before labor and verified at the time of birth with the emphasis that permanent sterility is expected after bilateral tubal ligation. Consent for newborn care and circumcision is often completed at admission.

Laboratory Tests. Women who had regular prenatal care need laboratory tests only for specific indications, whereas those who did not have prenatal care or a recent visit need more extensive tests. Simple tests that are often performed on the unit include the following:

- Hematocrit obtained by finger stick
- Midstream urine specimen to assess protein and glucose levels—usually obtained before notifying the birth attendant

Intravenous Access. If used, intravenous (IV) access is started with a large-bore catheter (18-gauge or larger). A saline lock may be used, or the woman may receive continuous infusion of fluids. The lock eases walking during early labor but provides quick access if fluids or drugs are needed. Continuous fluid infusion prevents and reduces dehydration and is necessary if epidural block analgesia is used. IV solutions containing electrolytes, such as lactated Ringer solution, are most common.

Assessments after Admission

If it is unclear following the initial assessment whether the woman is in true labor, the woman may be observed. After 1 or 2 hours, progressive cervical change (effacement, dilation, or both) strongly suggests true labor. The woman and fetus are assessed during the observation period as if in early labor.

After the admission assessment, the woman and fetus need regular assessments based on their risk status and whether they have interventions such as oxytocin stimulation or epidural analgesia. General guidelines for continuing assessments are listed here.

Fetal Assessments. Fetal assessments are performed to identify signs of well-being and those that suggest compromise. The principal fetal assessments include FHR and patterns and character of the amniotic fluid. Abnormalities revealed in these assessments may be associated with impaired fetal gas exchange and infection. See [Chapter 14](#).

Fetal Heart Rate. FHR is assessed using either intermittent auscultation or electronic fetal monitoring. Frequency of assessment and documentation depends on the risk status of the mother and fetus and the stage of labor.

A spontaneous rupture of membranes (SROM) may occur, or the birth attendant may perform an **amniotomy**. FHR is assessed for at least 1 minute when the membranes rupture. The umbilical cord could be displaced in a large fluid gush, resulting in compression and interruption of blood flow through it (prolapsed cord; see [p. 590](#)). Charting related to membrane rupture includes the time, FHR, and character and amount of the fluid.

Amniotic fluid should be clear and may include bits of *vernix*, the creamy white fetal skin lubricant. Cloudy, yellow, and foul-smelling amniotic fluid suggests infection. Green fluid indicates that the fetus passed meconium before birth. Meconium passage may have been in response to transient hypoxia, although the cause is often unknown. The newborn may need extra respiratory suctioning at birth if the fluid is heavily stained with meconium.

Quantity should be described in approximate terms; for example, at term, a "large" amount is more than 1000 mL, a "moderate" amount is about 500 to 1000 mL, and "scant" amniotic fluid is a trickle, barely enough to detect. If the fetus is well down into the pelvis when the membranes rupture, a small amount of fluid in front of the fetal head may be discharged (forewaters), with the rest lost at birth.

PROCEDURE 13-1 LEOPOLD'S MANEUVERS

PURPOSE: To determine presentation and position of the fetus and aid in location of fetal heart sounds

1. Explain the procedure to the woman and the rationale for each step as it is performed. Tell her what is found at each step. *Gives information, teaches the woman, and reassures her when the assessment findings are normal.*
2. Ask the woman to empty her bladder if she has not done so recently. Have her lie on her back with her knees flexed slightly. Place a small pillow or folded towel under one hip. *Decreases discomfort of a full bladder during palpation and improves ability to feel fetal parts in the suprapubic area. Knee flexion helps the woman relax her abdominal muscles to enhance palpation. Uterine displacement prevents aortocaval compression, which could reduce blood flow to the placenta.*
3. Wash your hands with warm water. Wear gloves if contact with secretions is likely. *Prevents transmission of microorganisms. Warm hands are more comfortable during palpation and prevent tensing of abdominal muscles.*
4. Stand beside the woman, facing her head, with your dominant hand nearest her. *The first three maneuvers are most easily performed in this position.*
5. Palpate the uterine fundus. The breech (buttocks) is softer and more irregular in shape than the head. Moving the breech also moves the fetal trunk. The head is harder and has a round, uniform shape. The head can be moved without moving the entire fetal trunk. *Distinguishes between a cephalic and breech presentation. If the fetus is in a cephalic presentation, the breech is felt in the fundus. If the presentation is breech, the head is felt in the fundus.*

6. Hold the left hand steady on one side of the uterus while palpating the opposite side of the uterus with the right hand. Then hold the right hand steady while palpating the opposite side of the uterus with the left hand. The fetal back is a smooth, convex surface. The fetal arms and legs feel nodular, and the fetus often moves them during palpation. *Determines on which side of the uterus is the back and on which side are the fetal arms and legs ("small parts").*

7. Palpate the suprapubic area. If a breech was palpated in the fundus, expect a hard, rounded head in this area. Attempt to grasp the presenting part gently between the thumb and fingers. If the presenting part is not engaged, the grasping movement of the fingers moves it upward in the uterus. *Confirms the presentation determined in the first maneuver. Determines whether the presenting part is engaged (widest diameter at or below a zero station) in the maternal pelvis.*
8. Omit the fourth maneuver if the fetus is in a breech presentation. *Is performed only in cephalic presentations to determine whether the fetal head is flexed.*

PROCEDURE 13-1 LEOPOLD'S MANEUVERS—cont'd

9. Turn so that you face the woman's feet. *Is most easily performed in this position.*
10. Place your hands on each side of the uterus with fingers pointed toward the pelvic inlet. Slide hands downward on each side of the uterus. On one side, your fingers easily slide to the upper edge of the symphysis. On the other side, your fingers meet an obstruction, the cephalic prominence. *Determines whether the head is flexed (vertex) or extended (face). The vertex presentation is normal. If the head is flexed, the cephalic prominence (the forehead in this case) is felt on the opposite side from the fetal back. If the head is extended, the cephalic prominence (the occiput in this case) is felt on the same side as the fetal back.*

PROCEDURE 13-2 PALPATING CONTRACTIONS

PURPOSE: To determine whether a contraction pattern is typical of true labor; to identify abnormal contractions that may jeopardize the health of the mother or fetus

1. Assess at least three contractions in a row at the time the fetal heart rate (FHR) is checked. Guidelines for minimal frequency of assessments for low-risk patients are, therefore, as follows:
 - a. Hourly during latent phase
 - b. Every 30 minutes during active phase and transition
 - c. Every 15 minutes during second stage

Assess more frequently if abnormalities are identified. Assessment of at least three sequential contractions permits better evaluation of the pattern. Palpate contractions periodically when an external fetal monitor is used because it is not accurate for intensity as a result of thickness of the abdominal fat pad, maternal position, and fetal position.
2. Place fingertips of one hand on the uterine fundus, using light pressure. Keep fingertips relatively still rather than moving them over the uterus. *The fingertips are more sensitive to the first tightening of the uterus. Contractions usually begin in the fundus, although the mother usually feels them in her lower abdomen and back. Constant moving of the hand over the uterus may stimulate contractions and give an inaccurate assessment of their true pattern.*
3. Note the time when each contraction begins and ends.
 - a. Determine frequency by noting the average time that elapses from the beginning of one contraction to the beginning of the next one.
 - b. Determine duration by noting the average time in seconds from the beginning to the end of each contraction.

- c. Determine interval by noting the average time between the end of one contraction and the beginning of the next one. *Contractions are expected to increase in frequency, duration, and intensity as labor progresses. False labor is usually characterized by contractions that are irregular and do not increase in frequency, duration, and intensity.*
4. Estimate the average intensity of contractions by noting how easily the uterus can be indented during the peak of the contraction:
 - a. With mild contractions, the uterus can be easily indented with the fingertips. The contractions feel similar to the tip of the nose.
 - b. With moderate contractions, the uterus can be indented with more difficulty. The contractions feel similar to the chin.
 - c. With firm contractions, the uterus feels “woody” and cannot be readily indented. The contractions feel similar to the forehead. Contractions during labor are expected to intensify progressively. If they do not the woman may not be in true labor or she may be experiencing dysfunctional labor (see Chapter 27).
5. Report hypertonic contractions:
 - a. Occurring less than 2 minutes apart or more than 5 contractions in 10 minutes
 - b. Durations longer than 90 to 120 seconds
 - c. Intervals shorter than 30 seconds
 - d. Incomplete relaxation of the uterus between contractions

Hypertonic contractions reduce placental blood flow by prolonged compression of the vessels that supply the intervillous spaces.

CRITICAL THINKING EXERCISE 13-2

Chloe is in labor at term with her second baby. The baby is in a left occiput anterior (LOA) position, and Chloe's cervix is 5 cm dilated and completely effaced. Her membranes rupture at the end of a strong contraction. You note that the fluid is green and watery.

Question

1. What nursing actions are most important at this time? Why?

Maternal Assessments. Several maternal assessments also relate to the health of the fetus, such as vital signs and contractions.

Vital Signs. Abnormalities should be reported and the assessment frequency increased (see Table 13-1).

Contractions. Contractions can be assessed by palpation or with the electronic fetal monitor. (See Chapter 14.)

Labor Progress. A vaginal examination is done periodically to determine cervical dilation and effacement and fetal descent (Figure 13-1). The frequency of vaginal examinations depends on the woman's parity, status of her membranes, and overall speed of her labor. Vaginal

PURPOSES

- To determine whether membranes have ruptured.
- To determine cervical effacement and dilation.
- To determine fetal presentation, position, and station.

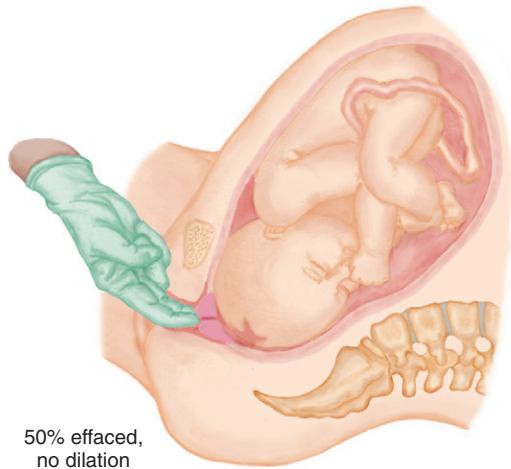

METHOD

Vaginal examination is not usually performed by the inexperienced nurse except when training for graduate nursing practice in the intrapartum area.

EQUIPMENT

Sterile gloves, sterile lubricant. If a pH swab or nitrazine paper is being used to test for ruptured membranes, lubricant is not used to avoid altering the test paper.

HAND POSITION

The nurse usually uses the index and middle fingers of the dominant hand for vaginal examination. The thumb and other fingers are kept out of the way to avoid carrying microorganisms into the vagina.

DETERMINING WHETHER MEMBRANES HAVE RUPTURED

Intact membranes feel like a slippery membrane over the fetal presenting part. No leakage of amniotic fluid can be detected.

Bulging membranes feel like a slippery, fluid-filled balloon over the presenting part. It may be difficult to feel the presenting part clearly if the membranes are bulging tensely.

Ruptured membranes show drainage of fluid from the vagina as the nurse manipulates the cervix and presenting part.

DETERMINING CERVICAL EFFACEMENT AND DILATION

The nurse determines *effacement* by estimating the thickness of the cervix. The uneffaced cervix is about 2 cm long. If it is 50% effaced, it is about 1 cm long. Effacement is expressed as a percentage (0% to 100%), or it may be described as the length in centimeters.

Dilation is determined by sweeping the fingertips across the cervical opening. The average woman's index finger is about 1.5 cm in diameter.

DETERMINING THE PRESENTING PART

The fetal skull feels smooth, hard, and rounded in a cephalic presentation. The fetal buttocks are softer and more irregular in a breech presentation. If the membranes are ruptured, the fetus in a breech presentation may expel thick, green-black meconium. (Presence of meconium in a breech presentation is *not* necessarily a sign of fetal compromise. The nurse must evaluate other signs of fetal condition.)

DETERMINING THE FETAL POSITION

In a cephalic presentation, the nurse feels for the distinctive features of the fetal skull. The posterior fontanel is usually felt in a vertex presentation and is triangular with three suture lines (two lambdoid and one sagittal) leading into it. The anterior fontanel is not felt unless the head is poorly flexed or is in the mechanism of extension in late labor. It feels like a diamond-shaped depression with four suture lines (one frontal, two coronal, and one sagittal) leading into it.

DETERMINING THE STATION

Findings of the vaginal examination may be recorded on a labor flow sheet, narrative, or a graph. The graph may be termed a *Friedman curve*, a *partogram*, or a *labor curve*.

FIG 13-1 Vaginal examination during labor.

examinations are limited to avoid the introduction of microorganisms from the perineal area into the uterus.

Intake and Output. Oral and IV intake and each voiding are recorded. Labor may reduce a woman's urge to void, so her suprapubic area should be checked every 2 hours or more frequently to identify bladder distention.

Pressure of the fetal head on the rectum in late labor makes many women feel the need to defecate. The nurse should look at the perineum for **crowning** of the fetal head if the woman suddenly expresses a strong need to defecate during a contraction.

Response to Labor. The woman's behavioral responses change as labor intensifies, especially if she has not had epidural analgesia. She withdraws from interactions but needs more nursing presence and reassurance. She may become more anxious because of pain and fear of bodily injury, unknown outcome, loss of control, unresolved psychological issues that influence her readiness to give birth (such as sexual abuse, previous birth experiences), and unexpected occurrences during labor.

Labor pains and the woman's ability to cope vary. The nurse constantly assesses whether additional pain control measures are needed. Behaviors that suggest the woman may want help with pain management include the following:

- Specific requests for medication and other pain control measures such as epidural analgesia (see [Chapter 15](#))
- Statements that current measures are ineffective
- Tension of her muscles and arching of her back during contractions
- Persistence of muscle tension between contractions
- A tense facial expression, rolling in the bed
- Expressions such as "I can't take it anymore"

Support Person's Response. Labor is stressful for the woman's support person, who often is the baby's father. He may become anxious, fearful, or tired. He feels a responsibility to protect and support the woman but may have limited resources for doing so. Watching the woman he loves in pain is difficult, even if the pain is normal. He may respond to stress in many ways, including being quiet, suffering silently, or reacting with pacing and anger. Some fathers respond by leaving the room frequently or for long periods, whereas others resist even short breaks.

Nurses encourage and value the father's presence during labor and birth. However, this may conflict with a couple's cultural norms dictating that birth is a strictly female activity. The father may be pulled in two directions, wanting to be included but hesitating because men in his culture are not customarily involved in birth. The nurse should respect the values of each couple and their wishes about father involvement.

The support person also may be the woman's parent or another relative, a friend of either gender, or a homosexual partner. The nurse must remember that anyone who assists the woman during labor may have feelings of anxiety and helplessness at times. Reassurance and care for the labor partner strengthen the person's ability to support the woman and enhance the likelihood that both will view the birth experience as positive.

CHECK YOUR READING

8. What is the routine frequency for FHR assessment in uncomplicated labor? Why should the FHR be assessed after the membranes rupture?
9. Describe the significance of each of the following types of amniotic fluid: greenish, cloudy, yellowish, foul-smelling.
10. Why are frequent vaginal examinations undesirable during labor?
11. What observations suggest that the woman may need additional help with pain management during labor?

APPLICATION OF THE NURSING PROCESS

False or Early Labor

Assessment

After observation, the nurse may realize that the woman is not in true active labor. If findings are normal and the woman's membranes are intact, she is usually discharged. The woman who is in very early latent labor may be discharged to await active labor, especially if she is a nullipara and lives nearby.

Analysis

A woman may be frustrated because she cannot tell whether labor is real. She may resist returning to the birth center, possibly causing needless delay of care. She often is tired of being pregnant and just wants it to be over. A nursing diagnosis applicable to many women with false labor contractions is "Deficient Knowledge: Characteristics of True Labor."

Planning

An expected outcome for this nursing diagnosis is that before discharge the woman and her support person will describe reasons for returning to the birth center for evaluation.

Interventions

Reassurance

A woman sent home after observation may feel foolish and frustrated. She may want to have labor induced simply to "get it over with." Reassure her that even professionals cannot always identify true labor and false labor. Also, tell her that important preparation for labor occurs during late pregnancy, such as softening of the cervix, even if obvious progress such as cervical dilation has not yet occurred. Early latent labor may gradually intensify as it merges into the active phase of first stage. Other women may notice a more abrupt intensity and frequency change as the latent phase becomes active labor.

Teaching

Review guidelines for returning to the birth center and explain that these are only guidelines and she should return if she has any concerns. Returning with false labor is better than entering in advanced labor or developing complications at home. Remind her that her body is often making the final preparations for birth.

Evaluation

The woman and her support person should describe guidelines for returning to the birth center. These include regular contractions, leaking of amniotic fluid, bleeding other than bloody show, and decreased fetal movement.

APPLICATION OF THE NURSING PROCESS

True Labor

The admission assessment may confirm that the woman is in true labor, or true labor may be evident after observation. Nursing diagnoses and collaborative problems change during labor because the intrapartum period is an active process. Problems covered in this chapter relate to fetal oxygenation, maternal discomfort, and maternal injury.

Nursing diagnoses often interact during labor. For example, high anxiety reduces effectiveness of pain-relief measures by interfering with relaxation. A maternal fluid volume deficit can alter fetal oxygenation because less blood is available to circulate to the placenta.

CASE STUDY 13-1 NURSING CARE PLAN*

ASSESSMENT: Cathy, 17 years old, is a gravida1, para 0, who is admitted in early labor. Her cervix is 3 cm dilated and completely effaced, and the fetus is at a 0 station. Her membranes are intact. Cathy's husband Tim is with her. They did not attend childbirth classes. Cathy is holding Tim's hand tightly and breathing rapidly with each contraction. She says in a shaky voice, "I'm so scared. I've never been in a hospital before. I just don't know if I can do this."

Critical Thinking: *Is there anything you read in the early introductions and assessment for which you question the validity? How would you handle your uncertainty about the validity?*

Answer: *Because most babies are born to unmarried parents, a nurse admitting a laboring 17-year-old woman is unlikely to think the couple is married despite the fact that a teen mother might truly be married to the baby's father. A nurse should not make assumptions too quickly. Did the fact that Cathy and Tim had not had childbirth classes fit with any personal assumptions?*

NURSING DIAGNOSIS: Anxiety related to unfamiliar environment and lack of birth preparation

EXPECTED OUTCOMES: Cathy will:

1. Express being less anxious after admission procedures are completed.
2. Have a relaxed facial expression and body posture between contractions.

INTERVENTIONS AND RATIONALES

1. Maintain a calm and confident manner when caring for Cathy. Express confidence in her ability to give birth. *Calm provides reassurance that labor is normal and that the mother has the resources within her to manage it.*
2. Use therapeutic communication when talking with Cathy. Adapt communication to the situation, simplifying explanations and directions as labor intensifies. *Clarity identifies dominant concerns so that they can be properly addressed. Intense physical sensations reduce the ability to comprehend complex information.*
3. Determine the couple's plans for birth, and work with them as much as possible. If an item in the plan cannot be met explain why. *Determining their plan enhances their sense of control and helps them have a satisfying birth experience.*
4. Stay with Cathy as much as possible during labor. Assure her that you are there to help her. *A nurse can provide reassurance through human contact and can reduce fears of abandonment.*
5. Orient Cathy to the labor room, and explain procedures and equipment she will encounter. *Information reduces fear of the unknown.*

EVALUATION: Cathy relaxes a bit after talking with the nurse and slows her breathing. Cathy says, "I feel a little better now. I hope I can have my baby before you go home." Tim also appears more relaxed.

*Continues on p. 235.

FETAL OXYGENATION

Assessment

The main assessments related to fetal well-being are the following (see Table 13-1 and Box 13-1):

- FHR evaluation
- Amount and character of amniotic fluid and time of rupture
- Maternal vital signs
- Contractions: frequency, duration, intensity, and resting interval

Nursing Diagnosis

Several factors such as maternal hypotension and hypertension, maternal fever, excessively strong and long contractions (tetanic), and compression of the umbilical cord can reduce fetal oxygen, nutrient, and waste exchange. The healthy fetus usually tolerates labor well, and the nurse simply needs to be alert for problems. Therefore, a valid collaborative problem is "Potential Complication: Fetal Compromise" (see **Critical to Remember** box). See Chapter 14 for other FHR characteristics associated with fetal compromise.

Planning

Patient-centered goals are not made for collaborative problems as they are for nursing diagnoses. Planning includes nursing responsibilities to (1) promote normal placental function and (2) observe for and report problems to the physician or nurse-midwife.

Interventions

Promote Placental Function

Maternal positioning is the primary measure to promote placental function during normal labor. The supine position should be avoided because it can cause the woman's uterus to compress her aorta and

BOX 13-1 ASSISTING WITH AN EMERGENCY BIRTH

The inexperienced nurse rarely must deliver a baby in the hospital or birth center but occasionally helps the more experienced nurse do so. Unplanned out-of-hospital births are not common, but they do occur.

Nursing Priorities for an Emergency Birth in Any Setting

Prevent or reduce injury to the mother and infant.

Maintain the infant's airway and temperature after birth.

Preparing for an Emergency Birth

Study the delivery sequence in Figures 13-7 and 13-8.

Locate the emergency delivery pack ("precip" tray) on the unit.

During the Birth

Remain with the woman to assist her in giving birth. Use the call bell, or ask her partner to call for help. Stay calm to reduce the couple's anxiety.

Put on gloves to prevent contact with blood and other secretions. Sterile gloves reduce transmission of environmental organisms to the mother and the infant. However, the nurse will be "catching" the infant in this situation. No invasive procedure is expected so clean gloves are adequate.

After the Birth

Observe the infant's color and respirations for distress. Suction excess secretions with a bulb syringe.

Dry the infant and place skin-to-skin with the mother. Cover mother and baby with warmed blankets to maintain warmth.

Put the infant to the mother's breast and encourage suckling to promote uterine contraction, which will facilitate placental expulsion, control bleeding, and initiate lactation.

inferior vena cava (aortocaval compression), reducing blood flow to the placenta. If she must be in the supine position for a procedure such as catheterization, a small pillow or folded blanket under one hip shifts her uterus to maintain good placental blood flow.

Observe for Conditions Associated with Fetal Compromise

If conditions associated with fetal compromise are identified, provide interventions directed at the most likely physiologic cause and notify the birth attendant.

CRITICAL TO REMEMBER

Conditions Associated with Fetal Compromise

- Fetal heart rate outside the normal range of 110 to 160 bpm for a term fetus or loss of fetal heart rate (FHR) variability with electronic FHR monitoring
- Meconium-stained (greenish) amniotic fluid
- Cloudy, yellowish, or foul-smelling amniotic fluid (suggests infection)
- Excessive frequency or duration of contractions (reduces placental blood flow)
- Incomplete uterine relaxation and intervals shorter than 30 seconds between contractions (reduces placental blood flow)
- Maternal hypotension (may divert blood flow away from the placenta to ensure adequate perfusion of the maternal brain and heart)
- Maternal hypertension (may be associated with vasospasm in spiral arteries, which supply the intervillous spaces of the placenta)
- Maternal fever (38°C [100.4°F] or higher)

Evaluation

Evaluation of client goals and expected outcomes does not apply to a collaborative problem. Throughout labor, compare actual data with the norms for mother and fetus.

DISCOMFORT

Assessment

See Table 13-1 for continuing assessments of the laboring woman.

Analysis

Women vary in their responses to labor's pain and the choices of pain management methods. The woman with choices for pain management and support for her choices has an increased sense of control over her birth experience. The woman who successfully masters the pain and other physical demands of labor is more likely to view her experience as positive. Her support person also is likely to feel more satisfaction with the experience. The nurse's role is to teach the patient and her significant other about various methods of pain management and then support her decisions and evaluate her responses.

Pain and anxiety are related nursing diagnoses. Excess anxiety reduces pain tolerance, and pain worsens anxiety. The nurse clusters assessment data to determine what the primary problem is. For example, several cues such as a previous poor experience during birth and expressions of worry and concern suggest that anxiety is primary. However, if contractions are intense and labor is progressing quickly, the primary nursing diagnosis would be pain. Of these two options,

CASE STUDY 13-1 NURSING CARE PLAN/NURSING CARE PLAN*

ASSESSMENT: Cathy's admission vital signs are all normal: temperature, 37.1°C (98.8°F); pulse rate, 88 bpm; respirations, 20/minute; and blood pressure, 112/70 mm Hg. The fetal heart rate averages 140 to 150 bpm. Her contractions occur every 4 minutes, last 50 seconds, and are of moderate intensity.

POTENTIAL COMPLICATION: Fetal compromise

EXPECTED OUTCOMES: Goals are not formulated for a potential complication because the nurse cannot independently manage fetal compromise. The nurse will:

1. Take actions to promote normal placental function.
2. Observe for and report signs associated with fetal compromise.

INTERVENTIONS AND RATIONALES

1. Encourage Cathy to use any position she desires except the supine. If she lies flat, a wedge should be placed under one hip to displace her uterus to one side. *The supine position can cause aortocaval compression, reducing blood flow to the placenta.*
2. Assess and document the fetal heart rate using the guidelines in Table 13-1. Report rates or patterns that are not reassuring. Assess the fetal heart rate more frequently if deviations from normal are identified. (Refer to Chapter 14 for detailed information.) *Observation allows prompt identification of changes in the rate or of abnormal rates. Fetal heart rate assessments that are outside expected limits need corrective action and should be reported for possible medical intervention.*
3. When the membranes rupture, observe the color, odor, and approximate amount of fluid, and note the time of rupture. Note the fetal heart rate after rupture. *Meconium-stained fluid may be associated with fetal compromise*

and should be reported. Cloudy, yellow, or foul-smelling fluid suggests infection. Prolonged rupture of membranes increases the risk of infection. A low fetal heart rate suggests significant cord compression.

4. Assess contractions when the fetal heart rate is assessed. Report incomplete uterine relaxation between contractions or excessively strong or long contractions (longer than 90 to 120 seconds or having ≤ 30 seconds of full relaxation). Keep in mind that the fetus with risk factors may not tolerate even less-than-normal labor contractions. *Most placental exchange occurs during the interval between contractions. Contractions that are too long or have an inadequate interval between them decrease the time available for the intervillous spaces of the placenta to eliminate wastes and refill with oxygenated blood and nutrients.*
5. Assess Cathy's blood pressure, pulse rate, and respirations every hour. Assess her temperature every 4 hours until her membranes rupture, then every 2 hours. If elevated, assess temperature every 2 hours or more frequently. *Maternal hypotension or hypertension can decrease blood flow to the placenta. Maternal fever increases the fetal temperature and metabolic rate, possibly raising fetal demand for oxygen beyond the mother's ability to supply it. A rising maternal pulse rate or fetal heart rate may precede the temperature elevation.*
6. See the nursing care plan in Chapter 14, p. 275, for additional interventions if signs of fetal compromise occur. This nursing care plan addresses basic actions to promote fetal oxygenation and identify possible problems.

EVALUATION: Because no client goal is established for a potential complication, evaluation is not done as in the nursing diagnosis. The fetal heart rate remains approximately the same, and there are no signs of fetal compromise. Cathy finds that sitting in a rocking chair is most comfortable.

*Continued from p. 234; continues on p. 241.

FIG 13-2 Cool, damp washcloths placed where the woman finds them most comforting help her relax during each contraction. Extra cool, damp washcloths should be available.

FIG 13-3 Most laboring women welcome ice chips to ease their dry mouths.

the nursing diagnosis selected for this discussion is “Pain related to effects of uterine contractions.”

Planning

The elimination of labor’s pain is not realistic. Therefore, appropriate goals and expected outcomes related to pain include the following:

1. During labor, the woman will state that her chosen method or methods of pain management are satisfactory and will tell the nurse if others are needed.
2. By discharge from the birth facility, the woman’s support person will express satisfaction with having provided labor support.
3. By discharge from the birth facility, the woman will describe her birth experience as positive.

Interventions

Labor pain management includes measures such as breathing techniques and medication to promote comfort and specific methods to relieve pain (see [Chapters 11](#) and [15](#)).

Provide Comfort Measures

Ordinary measures diminish irritating surroundings that reduce a woman’s ability to relax and use coping skills.

Lighting. Soft, indirect lighting is soothing, whereas a bright overhead light is irritating. Bright lights imply a hospital (“sick”) atmosphere rather than a normal event like birth. A bright, overhead light should be used only when needed. A small flashlight is handy if the woman wants her room kept dark.

Temperature. Labor is hard work, and the woman in labor is often hot and perspiring. Cool, damp washcloths on the woman’s face and neck promote comfort ([Figure 13-2](#)). Keep an ample supply of damp washcloths available, and change them often to keep them cool. The woman should wear socks if her feet are cold. An electric fan circulates air in the labor room and directs a breeze on the woman. Be sure that the fan does not blow on the infant after birth, which might cause hypothermia.

Cleanliness. Bloody show and amniotic fluid leak from the woman’s vagina during labor. The nurse should change the sheets and gown, as needed, to keep her dry and comfortable. Her preferences should be the guide because the woman may not want to be disturbed during late labor. Change the underpad regularly to reduce microorganisms that may ascend into the vagina. A folded towel or bath blanket absorbs larger quantities of amniotic fluid than the pad alone.

Mouth Care. Ice chips ([Figure 13-3](#)), frozen juice bars, and hard candy on a stick reduce the discomfort of a dry mouth. Brushing the

teeth and simply rinsing the mouth is helpful to the woman. Lip balm will provide needed moisture to her lips.

Bladder. A full bladder intensifies pain during labor and can delay fetal descent. It may cause pain that remains after an epidural is started. Remind the woman to empty her bladder, and check her suprapubic area at least every 2 hours.

Positioning. A specific maternal position may help reduce discomfort and assist the labor process. Encourage the woman to assume any position she finds comfortable (other than the supine) and change positions frequently ([Figure 13-4](#)). Movement and frequent position changes in labor decrease pain, improve maternal-fetal circulation, improve the strength and effectiveness of contractions, decrease the length of labor, facilitate fetal descent, and decrease perineal trauma and episiotomies ([Association of Women’s Health, Obstetric and Neonatal Nurses \[AWHONN\], 2008](#); [Zwelling, 2010](#)). [Zwelling \(2010\)](#) recommended that nurses follow six physiologic principles related to maternal positioning in labor proposed by [Fenwick and Simkin \(1987\)](#): promote spinal flexion, promote an increase in the uterospinal drive angle, facilitate stronger expulsive forces, promote a good fit, increase pelvic diameters, and facilitate occiput posterior rotation. By encouraging upright positions, frequent position changes, and a “C”-shaped spine with the mother leaning forward, the nurse can follow these principles.

“Back labor” is common when the back of the fetal head puts pressure on the woman’s sacral promontory (occiput posterior position). The discomfort of back labor is difficult to relieve with medication alone. Positions that encourage the fetus to move away from the sacral promontory, such as those in which the mother uses the hands-and-knees position or leans forward over a birthing ball (a sturdy ball similar to a beach ball), reduce back pain and enhance the internal rotation mechanism of labor. Smaller versions of the birthing ball are available for use when the mother is sitting and leaning forward.

Although ambulation and some positions may not be safe for the woman with an epidural, many options are available by utilizing the flexibility of modern birthing beds with leg supports, squatting bars and multiple positions of the head and foot sections. Nursing care of the woman with the epidural includes assisting the woman with position changes every 30 to 45 minutes ([Zwelling, 2010](#)).

Water. Water in the form of a shower, tub, or whirlpool is relaxing for many women (see [Chapter 15](#)). However, a bath may slow labor if used in latent labor. It should be used in active labor or if persistent, nonproductive contractions during early labor have caused the woman to become very fatigued. Breast stimulation by a shower or whirlpool often provokes contractions by secretion of natural oxytocin.

POSITIONS FOR FIRST STAGE

Standing**Advantages**

Adds gravity to force of contractions to promote fetal descent. Contractions are less uncomfortable and more efficient. Variation: standing, leaning forward with support reduces back pain because fetus falls forward, away from the sacral promontory.

Disadvantages

Tiring over long periods. Continuous electronic fetal monitoring is not possible without telemetry if woman is walking in the hall.

Nursing Implications

If the woman has intravenous fluid running, give her a rolling pole. Encourage her to alternate walking with other positions whenever she tires or desires to do so. Remind the woman and her partner when she should return to the labor area for evaluation of the fetal heart rate and her labor status.

Sitting Upright**Advantages**

Uses gravity to aid fetal descent. Can be done when sitting on side of bed, in a chair, or on the toilet. Can be used with continuous fetal monitoring. Avoids supine hypotension.

Disadvantages

May increase suprapubic discomfort. Contractions are the most efficient when the woman alternates sitting with other positions.

Nursing Implications

A rocking chair is soothing. Place a pillow on a chair with a disposable underpad over the pillow to absorb secretions. Use pillows or a footstool to keep a short woman's legs from dangling. Encourage the woman to alternate positions periodically. For example, she can alternate walking with sitting or sitting with side-lying.

FIG 13-4 Common Maternal Positions for Labor. Many maternal labor positions can be adapted for the first stage and second stage of labor.

Continued

Teaching

Teaching the woman in labor is a continuously changing task.

First Stage. Many women become discouraged because several hours are needed to reach 4 or 5 cm of cervical dilation. They believe that the last 5 cm will take as long as the first 5 cm. From a time standpoint, 5 cm is approximately two thirds of the way through first-stage labor rather than half of the way because the rate of dilation increases during the active phase.

A woman's urge to push usually occurs when her cervix is fully dilated and effaced and the fetus descends to about a +1 station or lower and internally rotates. However, as she nears the second stage, the fetus may descend enough to give her an urge to push before full cervical dilation. If her cervix, which is usually 8 or 9 cm dilated at this time, yields easily to downward pressure, pushing in response to her

spontaneous urge as the fetus descends rarely causes problems, especially if this is a second or later vaginal birth.

Pushing against a cervix that does not easily yield to pressure from the presenting part may result in cervical edema, which can block labor progress, or cervical lacerations. Teach the woman to exhale in short breaths if pushing is likely to injure her cervix or cause cervical edema.

Second Stage. The woman may need help to trust the sensations from her body and push most effectively during second-stage labor. Nursing research on labor support is increasing and has resulted in inclusion of care based on solid evidence. Nursing care based on "the way we've always done it" no longer has merit unless that care is supported by research evidence.

Laboring Down. Two hours was once accepted as the upper limit for the duration of the second stage, with little evidence of the benefits

POSITIONS FOR FIRST STAGE

Sitting, Leaning Forward with Support**Advantages**

Same as for sitting.
Reduces back pain because fetus falls forward, away from sacral promontory.
Partner or nurse can rub back or provide sacral pressure to relieve back pain.

Disadvantages

Same as for sitting.

Nursing Implications

Same as for sitting.

Semisitting**Advantages**

Same as for sitting.
Aligns long axis of uterus with pelvic inlet, which applies contraction force in the most efficient direction through pelvis.

Disadvantages

Same as for sitting.
Does not reduce pain as well as the forward-leaning positions.

Nursing Implications

Same as for sitting.
Raise bed to about a 30- to 45-degree angle.
Encourage the woman to use sitting (leaning forward) or side-lying position if she has back pain so that the caregiver can rub her back or apply sacral pressure.

FIG 13-4, cont'd

of restricting the duration of second stage or the accuracy of this time limit. A second stage longer than 2 hours is now recognized as safe as long as the mother and fetus show no signs of compromise.

Women push most effectively when they feel the reflex urge to do so as the fetus descends. Women having epidural analgesia with modern techniques usually detect an urge to push, although the urge may not be as strong as in women who did not have regional analgesia. Many women do not immediately feel the urge to push when the cervix is fully dilated, even if no regional analgesia such as an epidural is administered. A brief slowing of contractions often occurs at the beginning of the second stage. Pushing vigorously sooner than the onset of the reflexive urge may contribute to birth canal injury because her vaginal tissues are stretched more forcefully and rapidly than if she pushed spontaneously and in response to her body's signals. The mother may be frustrated and uncomfortable because she is asked to do something that does not feel right to her.

The technique of delaying pushing until the reflex urge to push occurs may be called any of several names, including *delayed pushing*, *laboring down*, *rest and descend*, and *passive pushing*. Delayed pushing has been shown to result in less maternal fatigue, decreased pushing

time, decreased risk of instrument-assisted and cesarean births, and Apgar scores equivalent to those of women who pushed immediately on full cervical dilation (Kelly, Johnson, Lee et al., 2010; Lai, Lin, Li et al., 2009).

Simply put, laboring down means allowing uterine contractions to cause most fetal internal rotation and descent after full dilation naturally. The woman rests before actively pushing her baby out. The nurse supports her as she pushes in response to her natural urge. If no fetal descent has occurred after 2 hours, the woman may be encouraged to use open-glottis pushing without holding her breath. Continued delay of descent requires evaluation by the midwife or physician.

Positions. Vertical maternal positions enhance fetal descent. Squatting is an ideal position for pushing because it enlarges the pelvic outlet slightly and adds the force of gravity to the mother's efforts, which is an advantage if she has a small pelvis or the fetus is large. Some women push effectively while sitting on the toilet because that is where they are accustomed to giving in to the sensation of rectal pressure. Pushing while sitting on a birthing ball, pulling against a squatting bar on the bed, or playing "tug of war" with another person provides a similar gravitational advantage. Women may find that

POSITIONS FOR FIRST STAGE

Side-Lying**Advantages**

It is a restful position.
Prevents supine hypotension and promotes placental blood flow.
Promotes efficient contractions, although they may be less frequent than with other positions.
Can be used with continuous fetal monitoring.

Disadvantages

Does not use gravity to aid fetal descent.

Nursing Implications

Teach the woman and her partner that although the contractions are less frequent, they are more effective.
This position offers a break from more tiring positions.
Use pillows for support and to prevent pressure: at her back, under her superior arm, and between her knees.
Use disposable underpads to protect the pillow between the woman's knees from secretions.
Some women like to put their superior leg on the bed rail. If the woman wants this variation, pad the bed rail with a blanket to prevent pressure.
If she wants to remain recumbent, she should use this position to promote placental blood flow.

Kneeling, Leaning Forward with Support**Advantages**

Reduces back pain because fetus falls forward, away from sacral promontory.
Adds gravity to force of contractions to promote fetal descent.
Can be used with continuous fetal monitoring.
Caregivers can rub her back or apply sacral pressure.
Promotes normal mechanisms of birth.

Disadvantages

Knees may become tired or uncomfortable.
Tiring if used for long periods.

Nursing Implications

Raise the head of the bed, and have the woman face the head of the bed while she is on her knees.
Another method is for the partner to sit in a chair, with the woman kneeling in front, facing her partner, and leaning forward on him or her for support.
Use pillow under the knees and in front of the woman's chest, as needed, for comfort.
Encourage her to change positions if she becomes tired.

FIG 13-4, cont'd

Continued

pulling on something from above is efficient. Her upper torso should be in front of her pelvis to allow her coccyx to move backward as the fetus descends deeply into her pelvis (Zwelling, 2010). Epidural analgesia may limit the positions a woman can assume for pushing; however with modern birthing beds, many modified positions are safe and effective with or without epidural analgesia.

If the mother pushes in the sitting or semi-sitting position, teach her to curve her body around her uterus in a "C" shape rather than arching her back. For greatest effectiveness, the woman should pull on her knees, handholds, or a squat bar while pushing. She should maintain a similar "C" shape to her upper body if she pushes on her side.

Method and Breathing Pattern. Support the woman's spontaneous pushing techniques if they are effective. The woman should push

with her abdominal muscles while relaxing her perineum. If she needs coaching, teach her to begin by taking a breath and exhaling and then to take another breath and exhale while pushing for 4 to 6 seconds at a time. Sustained pushing while holding a breath (Valsalva maneuver or "purple pushing") or pushing more than four times per contraction reduces blood flow to the placenta and is fatiguing. Another deep breath that is more like a sigh helps her relax after the contraction.

A woman who is modest or fears losing control may inhibit her best pushing efforts if she is instructed to push as if she were having a bowel movement, particularly if she is in a bed or chair. An anatomically correct image is to teach the woman to push down and out under her symphysis (pubic bone), following the pelvic curve. Seeing a diagram or model of the pelvis helps her to visualize the curve.

POSITIONS FOR PUSHING IN SECOND STAGE

Hands and Knees**Advantages**

Reduces back pain because the fetus falls forward, away from the sacral promontory.

Promotes normal mechanisms of birth.

The woman can use pelvic rocking to decrease back pain.

Caregivers can rub the woman's back or apply sacral pressure easily.

Disadvantages

The woman's hands (especially wrists) and knees can become uncomfortable.

Tiring when used for a long time.

Some women are embarrassed to use this position.

Nursing Implications

Encourage the woman to change to less tiring positions occasionally.

Ensure privacy when encouraging the reluctant woman to try this position if she has back pain.

A second hospital gown with the opening in front covers her back and hips but may be too warm.

A variation is for the mother to kneel and lean forward against a beanbag or the side of the bed. This variation reduces some of the strain of wrists and hands.

Standing

This position may be tiring, and access to the woman's perineum is difficult. Because the infant could fall to the ground if birth occurs rapidly, provide padding under the mother's feet. Gravity aids fetal descent.

Hands and Knees

Advantages and disadvantages are similar to those during first stage labor. In addition, caregivers must reorient themselves because the landmarks are upside down from their usual perspective.

Squatting**Advantages**

Adds gravity to force of contractions to promote fetal descent.

Straightens the pelvic curve slightly for more direct fetal descent.

Increases dimensions of pelvis slightly.

Promotes effective pushing efforts in the second stage.

Caregivers can rub back or provide sacral pressure.

Disadvantages

Knees and hips may become uncomfortable because of prolonged flexion.

Tiring over a long time.

Nursing Implications

Provide support with a squat bar attached to the bed or by two people standing on each side of the woman.

If she becomes tired, or between contractions, she can lean back into the sitting position.

Variation: Have the woman squat beside the bed as she pushes.

FIG 13-4, cont'd

Encouragement

Success breeds success. Tell the woman when her labor is progressing. If she can see that her efforts are effective, she has more courage to continue. Help her touch or see the baby's head with a mirror as crowning occurs.

Praise the woman and her support person when they use breathing and other coping techniques effectively. This reinforces their actions,

gives them a sense of control, and conveys the respect and support of the nurse. If one technique is not helpful after a reasonable trial (three to five contractions), encourage them to try other techniques.

Giving of Self

The importance of the nurse's caring presence cannot be overlooked as a component of labor support. Even independent women may

POSITIONS FOR PUSHING IN SECOND STAGE

Semisitting

Many women prefer this because they have the security of a back rest; it is also familiar to caregivers and allows easy observation of the perineum. Elevate the woman's back at least 30 to 45 degrees so that gravity aids fetal descent. The woman pulls on her flexed knees (behind or in front of them) as she pushes. She should keep her head flexed and her back in a "C" curve.

Side-Lying

The woman flexes her chin on her chest and curls around her uterus as she pushes. She pulls on her flexed knees or the knee of the superior leg as she pushes.

FIG 13-4, cont'd

CASE STUDY 13-1 NURSING CARE PLAN*

ASSESSMENT: In 1½ hours Cathy's cervical dilation progresses to 5 cm, and the fetus descends to a +1 station. Her contractions occur every 3 minutes, last 60 seconds, and are of strong intensity. The fetal heart rate remains near its admission level. Cathy is having difficulty relaxing between contractions and is complaining of back pain. She is relieved that her labor is progressing normally.

NURSING DIAGNOSIS: Pain related to effects of uterine contractions

EXPECTED OUTCOMES: Cathy will express assurance that she can manage labor pain satisfactorily.

INTERVENTIONS AND RATIONALES

1. Encourage Cathy to try positions such as standing or sitting and leaning forward, side-lying, leaning over the back of the bed, or on her hands and knees. Remind her to change positions about every half hour or when she feels the need for a change. *These positions shift the weight of the fetus away from the sacral promontory, reducing back pain. Alternating positions relieves strain and constant pressure and also helps the fetus adapt to the pelvis.*
2. Teach Tim to rub or apply firm pressure to Cathy's back. Ask Cathy where to rub and how hard to press. Apply powder to the area rubbed. *Back rubs or firm pressure counteract some of the back pain. Powder decreases friction and promotes skin comfort.*
3. Offer thermal pain management options:
 - a. A warm blanket or warm pack applied to her back
 - b. Cold packs applied to her back
 - c. Alternating warm and cold packs, or use of them for 20 minutes on and 20 minutes off

d. Warm water in a shower or whirlpool

Thermal stimulation interferes with transmission of pain impulses. Changing the thermal stimulation prevents habituation. Nipple stimulation in a shower or whirlpool causes release of oxytocin from the posterior pituitary and enhances contractions.

4. Teach Cathy simple breathing and relaxation techniques (see Chapters 11 and 15). *Breathing techniques provide distraction from pain and give her a sense of control. Relaxation enhances a woman's ability to manage pain and enhances normal labor processes.*
5. Observe Cathy's suprapubic area, and palpate for a full bladder at least every 2 hours. Remind her to void if she has not done so recently. *A full bladder contributes to discomfort and can prolong labor by obstructing fetal descent.*
6. Tell Cathy about her progress in labor. Explain that she will probably begin to dilate faster now that she has entered active labor. *Encouragement and the knowledge that her efforts are having the desired results increase a woman's willingness to continue.*
7. Tell Cathy what pharmacologic pain-relief measures are available to her. *Knowing available options gives the woman a sense of control because she can choose whether she wants these measures. (This action may be done during early labor to give a woman more time to consider her options.)*

EVALUATION: Cathy continues to have back pain that is 6 on a 0-to-10 scale but says that she is more comfortable sitting on the side of the bed with her head on a pillow on the overbed table. Tim rubs her back during contractions. She says she is able to manage the pain because there is less pain between contractions; she does not want medication yet.

*Continued from p. 235; continues on p. 243.

EVIDENCE-BASED PRACTICE

Technology and the Labor Nurse

Although the physiologic mechanisms of human birth are constant, practices surrounding birth change over time. There has been significant change in birthing practices in the United States during the last 50 years. To gain a patient's perspective of some of the changes, Fleming, Smart, and Eide (2011) interviewed 13 grand multiparous women (women who have experienced 5 or more births). The study inclusion criteria were that the woman had to: speak English, have given birth to 5 or more babies, have given birth in a hospital at least 4 times, and had not given birth in the last 12 months. Their birth experiences totaled 105 births, averaging 8.08 births each. Their mean age at the time of the study was 47.85 years old with a range of 36 to 63 years of age. The two research questions were, "What are grand multiparous women's perceptions and descriptions of nursing care during childbirth?" and "What are grand multiparous women's perceptions of nurses' use of technology during childbirth?"

The researchers identified eight themes from the data: (1) providing welcome care, (2) offering choices, (3) following birth plans, (4) establishing trust and rapport, (5) being an advocate, (6) providing reassurance and support, (7) relying on electronic fetal monitors and assessments versus nursing presence, and (8) having epidural coupled with loss of bodily cues.

Providing Welcome Care

The women wanted the care of a professional intrapartum nurse. Although they appreciated the care and support of their husbands and other family members, they wanted the care and support of the nurse. They believed the nurse was the one who "knew what to do" (p. 112). Previous birth experience did not affect this desire.

Offering Choices

The women expressed the desire to have a nurse who offered them choices. Offering choices was associated with having control. This is important because the woman's perception of control during labor has been correlated to her satisfaction with the birth experience. (Fair & Morrison, 2012). The choice may be as simple as offering ice chips during labor, but it is important.

Following Birth Plans

The women believed that the nurses valued and incorporated their birth plans into the care they provided. This was important to them.

Establishing Trust and Respect

The women wanted to establish a trusting relationship with their nurses so that they would have her personal care and expertise when they needed it. The women also reported that they looked to the nurses who they trusted for

nonverbal cues when other health care providers made suggestions. Some of the women reported distrust and displeasure in the nursing staff in one situation. Some of the women called the hospital birth units before coming in. They thought that the nurses should have called their provider so that he or she would be at the unit when they arrived.

Being an Advocate

The women appreciated when the nurse advocated for them, particularly regarding their birth plan.

Providing Reassurance and Support

Most of the women reported fear of pain and fear of being left alone during labor. This was not affected by the presence of family members. They wanted the nurses to be present to relieve family members and to provide support. The nurses' expressed belief in the woman's ability to birth her child was appreciated.

Relying on Electronic Fetal Monitors and Assessments versus Nursing Presence

The younger mothers were positive about fetal monitors. It was reassuring to be able to hear the baby's heartbeat. The older mothers, who had given birth without continuous monitoring, were annoyed by them. One mother, who had given birth in the 1970s, appreciated the fetal monitor at that time because she believed it brought the nurse into her room more often. However, this woman was present when her daughter gave birth. She commented that having a central fetal monitor prevented the nurses from coming into the room to personally monitor her daughter's progress and provide adequate care.

Having Epidurals Coupled with a Loss of Bodily Cues

The women valued epidurals for pain relief and for promoting relaxation. However, women who had one or more births without an epidural prior to having a birth with an epidural felt that the nurse attended to them less often when they had an epidural. They also reported a sense of loss of control and loss of the cues that their body gave them during childbirth without an epidural.

The results of this study are reaffirming to intrapartum nurses. Women in labor trust us to be knowledgeable, provide support beyond what can be provided by a husband or other coach, and advocate for them. They also want our presence and personal attention. They want a relationship with us. How can nurses use the technology of the twenty-first century as a tool to improve nursing care of laboring women?

References: Fleming, S. E., Smart, D., & Eide, P. (2011). Grand multiparous women's perceptions of birth, nursing care, and childbirth technology. *Journal of Perinatal Education, 20*(2), 108–117; Fair, C. D., & Morrison, T. E. (2012). The relationship between prenatal control, expectations, experienced control, and birth satisfaction among primiparous women. *Midwifery, 28*, 39–44.

become dependent during labor and need human contact. Many times the woman simply needs reassurance that all is going well and the nurse is there for her. The nurse's presence helps to allay her fears of abandonment and conveys safety, acceptance, support, and comfort.

Although the woman and her support person may have prepared for childbirth, they often welcome suggestions and affirmation from the nurse. They are more likely to use the techniques they learned if the nurse helps them. The nurse's presence, gentle coaching, and encouragement help the woman have confidence in her own body and fitness to give birth.

Labor nursing is a contact sport. Women who receive continuous support in labor have improved outcomes compared to women who do not have support (Hodnett, Gates, Hofmeyr et al., 2011;

Kashanian, Farahroos, & Haghighi, 2010). Laboring women need the human support of a skilled, empathic, and intuitive nurse at the bedside—coaching them, reassuring them, and, most of all, being there for them. This degree of support cannot be matched by the nurse who spends more time observing a fetal monitor at a central nurses' station than in the company of the laboring mother.

Offering Pharmacologic Measures

Childbirth is usually a normal process, and the prepared woman and labor partner can birth their infant without medication if they choose to do so. However, many do choose pharmacologic pain management. The nurse must be informative but neutral when explaining about available pain medication.

CASE STUDY 13-1 NURSING CARE PLAN*

ASSESSMENT: After another 2 hours Cathy is quite uncomfortable and requests pain medication. She is occasionally feeling an urge to push. Cathy cries and says she is “losing it” and “can’t take it anymore.” Tim asks anxiously, “What’s wrong? Is Cathy OK? Why is she acting this way?” The fetal heart rate remains near the admission range and shows no signs suggesting fetal compromise. Contractions occur every 2 minutes, last 70 seconds, and are strong.

Cathy’s cervix is now 8 cm dilated and the station is +1. She asks for pain relief but does not want an epidural. Butorphanol (Stadol), 1 mg slow IV push, helps her regain control and work with her contractions. She avoids pushing by blowing out at the peak of each contraction.

Cathy is fully dilated in 45 minutes, and the fetal station is +2. She pushes spontaneously several times with each contraction but tends to stiffen her back and push on the bed with her arms with each push. She pushes for about 10 to 15 seconds at a time, holding her breath each time. She prefers the semisitting position.

NURSING DIAGNOSIS: Deficient Knowledge: Effective pushing techniques

EXPECTED OUTCOMES: After instruction in more effective pushing techniques, Cathy will use the techniques until the birth occurs.

INTERVENTIONS AND RATIONALES

1. Observe Cathy’s perineum for fetal crowning with each push. A woman having her first baby can still give birth rapidly. *Observation permits the nurse to maintain the safety of both the mother and the baby should rapid birth occur.*

- Encourage Cathy to exhale as she spontaneously pushes strongly for about 4 to 6 seconds at a time. *Prolonged pushing against a closed glottis reduces blood return to the heart and maternal oxygen saturation and decreases placental blood flow, especially if it is done with every contraction.*
- Teach Cathy techniques to make each push more effective:
 - Instruct her to flex her head with each push. *Flexing her head directs each push downward into the pelvic cavity.*
 - Instruct her to pull against her flexed knees (or handholds on the bed) as she pushes, curving her body around her uterus. Encourage upright positions, including squatting. *Pulling provides leverage to gain a more effective push from the abdominal muscles. Upright positions take advantage of gravity, and squatting enlarges the pelvic outlet slightly.*
 - Have her push toward the vaginal outlet. *The vagina is the anatomically correct direction.*
 - Help her relax her perineum as she pushes down. *Relaxation reduces soft tissue resistance to fetal descent.*
 - Keep her sacrum flattened against the bed when she pushes in the semisitting position. *A flat sacrum straightens the pelvic curve somewhat (and is similar to squatting).*
- Do not talk to Cathy unnecessarily between contractions. *Silence allows her to conserve her energy for pushing efforts that are progressing well.*

EVALUATION: Cathy pushes more effectively with the nurse coaching her during each contraction. In another hour she gives birth to a 3346-g (7-lb, 6-oz) boy. The baby’s Apgar scores are 9 at both 1 and 5 minutes. Cathy has a small first-degree laceration that is sutured using a local anesthetic. The new family gets acquainted during the recovery period.

*Continued from p. 241.

Some women may have a firm goal to avoid pain medication during labor. A woman who planned an unmedicated birth may interpret the nurse’s information about available medication as pressure for her to take medication. If the woman takes the medication offered, she may later feel that she “gave in” at a “weak moment,” thus reducing her sense of mastery over her birth. She may feel disappointed and guilty because she took medication despite her planned unmedicated birth. Careful review of the woman’s birth plan and specific teaching or review of available options establish a therapeutic relationship with the woman, her coach, and the nurse. This should be done as early in the labor as possible while the woman is still in control and can think critically. The discussion should include the option for the woman to change her mind and how that will be communicated.

Other women may plan to use a specific method such as epidural analgesia. If something prevents use of a chosen method, the woman may be upset about this unexpected development in her birth experience. Although the event may not be what she wanted, encouraging the woman to express her feelings helps her put it into perspective.

Care for the Birth Partner

The woman’s support person is an integral part of her labor care. Her labor partner can provide care and comfort, which support the woman’s ability to give birth. However, do not expect too much of the support person or make assumptions about the type and amount of involvement desired.

Some partners are coaches in the true sense of the word, actively assisting the woman through labor. Others want the woman and nurse to lead them and tell them how to help. They are eager to do what they can but expect instructions about methods and timing. Many couples see the partner’s role as encouraging, offering moral support, and simply being there for the woman.

Imposing unrealistic expectations of leadership, care, and comfort on the partner makes the birth experience unnecessarily stressful. To ensure a positive experience for both the woman and her partner, accept whatever pattern of support the partner is able and willing to provide and is comfortable to the couple. Without taking over or diminishing this role, provide any support that the partner cannot.

Encourage the partner to conserve physical strength, eat, and drink liquids. The partner may have missed sleep during the hours of early labor and may need a break. Encouraging the partner to eat a meal or snack may be necessary. Some partners think that they should not eat because the laboring woman is not doing so. However, hypoglycemia has caused more than one support person to faint at the time of birth and miss the main event. The partner can step out of the room to eat a quick meal or snack while the nurse remains with the patient.

Evaluation

Achievement of the three goals or expected outcomes occurs if the following conditions are met:

- The woman indicates satisfaction with her method of pain management or requests nursing assistance to find other, more satisfactory methods.
- The woman’s support person expresses satisfaction with having provided labor support by the time of discharge.
- The woman describes her birth experience as positive by the time of discharge.

The first goal regarding pain management is continually reevaluated throughout labor. The ability of the woman’s support person is also continually evaluated. The last goal, describing the birth experience as positive, is evaluated after the woman and her significant other have had time to begin putting the birth experience into perspective.

FIG 13-5 The provider arranges instruments in final preparation for birth. Although the vagina is not sterile, a sterile table is prepared to limit introduction of outside organisms into the birth canal. Included on the sterile table are infant care materials (e.g., cord clamp, cord blood tube), instruments for repair of maternal injury or episiotomy, and anesthesia materials (if needed).

PREVENT INJURY

Assessment

Nursing assessments of the mother and fetus continue as the woman nears birth. During the second stage, observe the woman's perineum to determine when to make final birth preparations.

The exact time for final birth preparations varies according to the woman's parity, overall speed of labor, and fetal station. Preparations are usually completed when crowning in the nullipara reaches a diameter of about 3 to 4 cm. The multipara is prepared sooner, usually when her cervix is fully dilated and the fetal head is well down in the pelvis but before much crowning has occurred.

Nursing Diagnosis

The woman is vulnerable to injury immediately before and after birth for several reasons: (1) altered physical sensations such as intense pressure and effects of medication, (2) positional changes for birth, and (3) unexpectedly rapid progress. The nursing diagnosis selected for the laboring woman near the time of birth is "Risk for Injury (maternal) related to altered sensations and positional or physical changes."

Planning

The nurse's primary objective is to prevent and minimize injuries that can occur during final birth preparations and because of a sudden birth. The goal or expected outcome for this nursing diagnosis is that the woman does not have a preventable injury such as muscle strains, thrombosis, and lacerations during birth.

Interventions

Positioning the woman in the birthing bed is the first step in the sequence of events that culminates in the birth of the baby (Figures 13-5 to 13-7). During the period around birth, the nurse reduces factors that contribute to maternal injuries.

Transferring to a Delivery Room

Most vaginal births occur in a combination labor, delivery, and recovery room. Occasionally the woman must be transferred to a separate room for the birth. If so, she should be transferred early to avoid rushed, last-minute preparations that cause anxiety for everyone.

Positioning for Birth

Upright positions promote effective pushing and take advantage of gravity. Squatting is a good position for uncomplicated birth but limits accessibility to the woman's perineum and may not be an option for women having epidural analgesia. Maternal positions with the upper body leaning forward promotes expulsive efforts, directs the fetus efficiently toward the pelvic outlet, and increases the diameters of the pelvic outlet.

Other upright positions for the birth include standing and kneeling upright positions. The semirecumbent position limits movement of the coccyx as the fetus descends during birth but maintains some advantages of gravity. Sitting on a birthing bed with a cutout for the perineal area maintains many advantages of squatting and may be less tiring. The hands-and-knees position may be helpful if the fetus is in the occiput posterior position and to rotate wide fetal shoulders. Many women and birth attendants are more comfortable using stirrups and foot rests to support the woman's legs and feet and make her perineum more accessible. If she cannot move her legs because of motor block from anesthesia, raise and lower her legs together, and do not separate them too widely. Surfaces that contact the popliteal space behind the knee should be padded because pressure on veins near the surface could lead to thrombus formation. The woman's upper body should be in the semireclining or sitting position rather than the flat position.

Observe the Perineum

The exact time at which a woman is ready to give birth is an educated guess. A woman who has been having a slow labor may suddenly make rapid progress. Birth is near when the fetal head swings anteriorly in the mechanism of extension as the occiput slips under the symphysis pubis. Observe the woman's perineum, especially during late second-stage labor.

A classic sign of imminent birth is the mother's urgent cry, "The baby's coming!" Look at her perineum, and if the baby will be born before the physician or nurse-midwife arrives, remain calm, and support the infant's head and body with gloved hands as it emerges. The support person should push the call button to summon help.

Evaluation

The goal or expected outcome for this nursing diagnosis is evaluated throughout the postpartum period because injuries such as muscle strains or thrombus formation are not evident until later (see Chapter 17). The birth attendant notes lacerations after the baby's birth and makes necessary repairs.

NURSING CARE DURING THE LATE INTRAPARTUM PERIOD

Responsibilities during Birth

The nurse's responsibilities during birth may include the following:

- Preparation of a delivery table with sterile gowns, gloves, drapes, solutions, and instruments (see Figure 13-5)

Transfer and Positioning for Birth

Action: When the woman is almost ready to give birth, transfer her to the delivery room or position the birthing bed. The exact time varies with several factors (such as overall speed of labor and rate of fetal descent). **Rationale:** Rushed, last-moment preparations are anxiety-producing for the woman, her partner, and the nurse. Remaining in the birth position for a long time can be tiring.

Action: Continue observing her perineum while making final preparations for birth. **Rationale:** Birth may occur unexpectedly, and the nurse should be prepared to “catch” the infant if the attendant (physician or nurse-midwife) is not in the room.

Action: Continue observing the fetal heart rate (FHR) with continuous monitoring or intermittent auscultation. **Rationale:** Detects changes in fetal condition that may require interventions by the attendant to speed birth.

Action: Elevate the woman’s back, shoulders, and head with a wedge (on a delivery table) or by raising the head of the birthing bed. **Rationale:** Allows more effective maternal pushing and uses gravity to aid fetal descent.

Action: Stirrups or foot rests to support the woman’s legs and feet may be used on a birthing bed. Pad the surface. **Rationale:** Padding reduces pressure, preventing venous stasis and possible thrombus formation.

Action: When placing the woman’s legs in stirrups, elevate them and remove them simultaneously. Do not separate her legs widely. **Rationale:** Reduces strain on muscles and ligaments.

Prepping and Draping

Action: After the woman is in position, cleanse the perineal area with a sterile iodophor and water preparation unless she is allergic. Use warm water to dilute the iodophor scrub. **Rationale:** Removes secretions and feces from perineal area.

Action: After hand washing, apply sterile gloves for the prep procedure. Take a fresh sponge to begin each new area, and do not return to a clean area with a used sponge. Six sponges are needed. The proper order and motions are as follows:

1. Use a zig-zag motion from clitoris to lower abdomen just above the pubic hairline.

2, 3. Use a zig-zag motion on the inner thigh from the labia majora to about halfway between the hip and knee. Repeat for the other inner thigh.

4, 5. Apply a single stroke on one side from clitoris over labia, perineum, and anus. Repeat for the other side.

6. Use a single stroke in the middle from the clitoris over the vulva and perineum.

Rationale: Prevents cross-contamination or recontamination of an area that is already clean.

Action: The attendant may apply sterile drapes if desired. **Rationale:** A vaginal birth is a clean procedure rather than a sterile one because the vagina is not sterile. Sterile drapes are unnecessary, but some attendants may prefer to use them.

Birth of the Head

Action: If an episiotomy is needed, the attendant will perform it when the head is well crowned (see Chapter 20). **Rationale:** Minimizes blood loss from the episiotomy.

Action: As the vaginal orifice encircles the fetal head, the attendant applies gentle pressure to the woman’s perineum with one hand while applying counterpressure to the fetal head with the other hand (Ritgen’s maneuver). The attendant may ask the mother to blow so that she avoids pushing, or to push gently. **Rationale:** Controls the exit of the fetal head so that it is born gradually rather than popping out; this minimizes trauma to the maternal tissues.

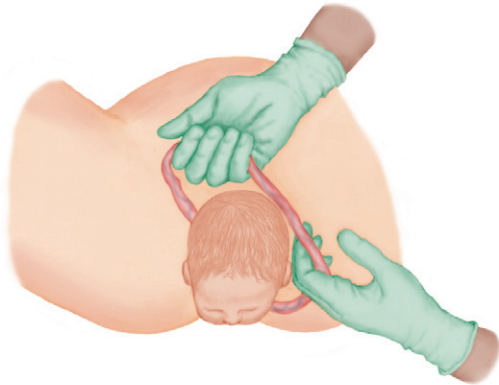

FIG 13-6 Sequence for Delivery.

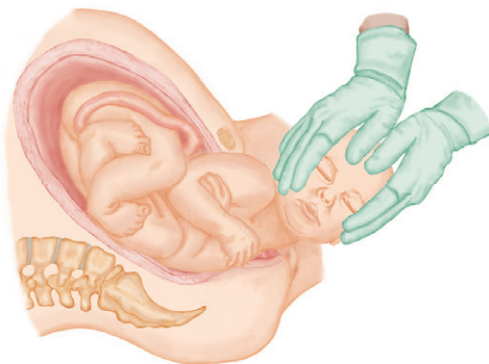

Continued

Action: The attendant wipes secretions from the infant's face and suction the nose and mouth with a bulb syringe. **Rationale:** Removes blood and secretions, preventing the infant from aspirating them with the first breaths.

Action: The attendant feels for a cord around the fetal neck (nuchal cord). If it is loose, it is slipped over the head. If tight, it is clamped and cut between two clamps before the rest of the baby is born. **Rationale:** Allows the rest of the birth to occur and prevents stretching or tearing the cord.

Birth of the Shoulders

Action: After external rotation, the attendant applies gentle traction on the fetal head in the direction of the mother's perineum. **Rationale:** External rotation allows the shoulders to rotate internally and aligns their transverse diameter with the anteroposterior diameter of the mother's pelvic outlet. Traction on the head in the direction of her perineum allows the anterior fetal shoulder to slip under the symphysis pubis.

Action: The attendant then lifts the head toward the mother's symphysis pubis. **Rationale:** Permits the posterior fetal shoulder to be eased over the perineum, minimizing trauma to the maternal tissues.

Clearing the Infant's Airway and Cutting the Cord

Action: The rest of the infant's body is born quickly after the shoulders are born. The attendant maintains the infant in a slightly head-dependent position while suctioning excess secretions with a bulb syringe. The infant is often placed on the mother's abdomen. **Rationale:** Gravity aids spontaneous drainage of secretions and prevents aspiration of oral mucus and secretions.

Action: The attendant clamps the cord. Either the father or the attendant cuts the cord above the clamp. **Rationale:** Allows parents to interact more freely with their infant. Prevents flow of blood between placenta and infant, which might result in anemia (if infant is higher than placenta) or polycythemia (if infant is below the placenta).

Delivery of the Placenta

Action: After the placenta separates, it can usually be delivered if the mother bears down. The attendant may pull gently on the cord. **Rationale:** Excess traction on the cord may cause it to break, making the placenta harder to deliver.

Action: The attendant inspects both sides of the placenta. **Rationale:** Ensures that no fragments remain inside the uterus that might cause hemorrhage and infection.

After the infant and placenta are born, the attendant inspects the birth canal for injuries. If needed, any injuries and the episiotomy (if one was done) are repaired.

FIG 13-6, cont'd

- Perineal cleansing preparation
- Supporting the woman and partner with final pushing efforts
- Initial care and assessment of the newborn
- Administration of medications (usually oxytocin) to contract the uterus and to control blood loss (see [Drug Guide](#) on p. 309). The anesthesiologist or nurse-anesthetist also may give maternal medications.

A nurse or resuscitation team from the nursery is usually present if the newborn is at risk for problems such as respiratory depression and if problems occurred during labor. A person certified to provide neonatal resuscitation must be present at all births (AAP & ACOG, 2012).

Personal protective equipment, including eye shields, should be worn as protection from fluid splashing and blood spurting as the cord

is cut. The newborn is covered with blood, amniotic fluid, vernix, and other body substances. The first bath usually occurs several hours after birth, so persons involved in infant care should wear gloves and other needed protective equipment to avoid contact with potentially infectious secretions.

Responsibilities after Birth

Intrapartum nursing care extends through the fourth stage of labor and includes care of the infant, the mother, and the family unit (for more information, see also [Chapters 17 through 23](#)).

Care of the Infant

Nursing care of the newborn includes supporting cardiopulmonary and thermoregulatory function and identifying the infant. In addition,

A, Crowning. The fetal head distends the labial and perineal tissues. The anus is stretched wide, and it is not unusual to see the woman's anterior rectal wall at this time. Any feces expelled are wiped posteriorly to avoid contaminating the vulva. The attendant (physician or nurse-midwife) is not holding the fetal head back but rather controlling its exit by using gentle pressure on the fetal occiput.

B, Ritgen Maneuver. Pressure is applied to the fetal chin through the perineum at the same time pressure is applied to the occiput of the fetal head. This action aids the mechanism of extension as the fetal head comes under the symphysis.

C, Birth of the Head. As the head emerges, the attendant prepares to suction the nose and mouth to avoid aspiration of secretions when the infant takes the first breath.

D, Restitution and External Rotation. After the head emerges, it realigns with the shoulders (restitution). External rotation occurs as the fetal shoulders internally rotate, aligning their transverse diameter with the anteroposterior diameter of the pelvic outlet.

E, Birth of the Anterior Shoulder. The attendant gently pushes the fetal head toward the woman's perineum to allow the anterior shoulder to slip under her symphysis. The bluish skin color of the fetus is normal at this point; it becomes pink as the infant begins air breathing.

F, Birth of the Posterior Shoulder. The attendant now pushes the fetal head upward toward the woman's symphysis to allow the posterior shoulder to slip over her perineum.

FIG 13-7 Vaginal Birth.

Continued

G, Completion of the Birth. The attendant supports the fetus during expulsion. Note that the fetus has excellent muscle tone, as evidenced by facial grimacing and flexion of the arms and hands.

H, Cord Clamping. While the infant is in skin-to-skin contact on the mother's abdomen, the attendant doubly clamps the umbilical cord. The cord is then cut between the two clamps. Samples of cord blood are collected after it is cut.

I, Birth of the Placenta. The attendant applies gentle traction on the cord to aid expulsion of the placenta. This placenta is expelled in the more common Schultze mechanism, with the shiny fetal surface and membranes emerging. Note the fetal membranes that surrounded the fetus and amniotic fluid during pregnancy. The chorionic vessels that branch from the umbilical cord are readily visible on the fetal surface of the placenta.

FIG 13-7, cont'd

assess the infant for approximate gestational age (see [Chapters 20 and 30](#)) and examine for obvious anomalies and birth injuries. A full neonatal assessment may be delayed for about 1 hour to give the family a chance to meet their new member and initiate breastfeeding. Much of the initial assessment can be done while new parents are bonding with their infant.

Maintain Cardiopulmonary Function. Assess the infant's Apgar score ([Table 13-2](#)) at 1 and 5 minutes (and at 10 minutes if response is poor) after birth for rapid evaluation of early cardiopulmonary adaptation. If the Apgar score is 8 or higher, no intervention is needed other than supporting thermoregulation and promoting normal respiratory efforts by positioning and bulb suction of the mouth and nose. If the infant is obviously in distress (no or low heart rate and respirations, limp muscle tone, lack of response to stimulation, blue or pale color), interventions to correct the problem are instituted immediately rather than waiting for the 1-minute Apgar score (American Academy of Pediatrics [AAP] & American Heart Association, 2011).

A baby with a vigorous cry and minimal secretions is usually sufficiently warmed by skin-to-skin contact with the parents, but a prewarmed warmer should be available. Avoid an extended time with the infant in a head-dependent position because upward pressure from the intestines limits diaphragmatic movement. An infant in a warmer should be placed in the flat position or turned to one side with the head flat or slightly elevated. Suction secretions from the infant's mouth and nose with a bulb syringe, as needed. Suctioning with a catheter may be necessary for more copious secretions.

Support Thermoregulation. Hypothermia raises the infant's metabolic rate and oxygen consumption, worsening any respiratory

problems. Place the infant on a prewarmed warmer, and quickly dry with warm towels to reduce evaporative heat loss. The head should be dried well because substantial heat loss can occur from the head, which is about one fourth of the neonate's body surface area. The stimulus of drying the skin promotes vigorous crying and lung expansion in most healthy infants.

Skin-to-skin contact with a parent also maintains the infant's temperature and promotes bonding between the infant and parent. Delaying the first bath for several hours allows the temperature to stabilize. Avoid positioning yourself between the infant and the radiant heat source in the warmer. The infant should be wrapped in dry, warm blankets when not in the warmer or making skin-to-skin contact. Remove wet linens, replacing them with warm and dry ones. A stockinette cap further reduces heat loss if it is placed on the baby's *dry* head. A cap is not worn while the infant is in the radiant warmer because the cap slows transfer of heat to the baby.

Identify the Infant. Bands with matching imprinted numbers and identifying information are the primary means to ensure that the right baby goes to the right mother after any separation ([Figure 13-8](#)). Check that the imprinted band number and mother's name are identical on each set of bands and have the parent(s) verify this information at the time of banding. Apply two bands on the infant, one on an arm and another on an ankle, or one on each ankle to prevent facial scratching. Infant bands are applied more snugly than those worn by an adult, with about one adult fingerwidth of slack in the bands. Trim the excess band ends and apply the longer band to the mother's wrist. The mother's primary support person usually wears a fourth band. The infant will not be released to any adult who

TABLE 13-2 APGAR SCORE

ASSESSMENT	POINTS										
	0	1	2	3	4	5	6	7	8	9	10
Heart rate	Absent	Below 100 beats per minute (bpm)	100 bpm or higher								
Respiratory effort	No spontaneous respirations	Slow respirations or weak cry	Spontaneous respirations with strong, lusty cry								
Muscle tone	Limp	Minimal flexion of extremities; sluggish movement	Flexed body posture; spontaneous and vigorous movement								
Reflex response	No response to suction or gentle slap on soles	Minimal response (grimace) to suction or gentle slap on soles	Responds promptly to suction or gentle slap to sole with cry or active movement								
Color	Pallor or cyanosis	Bluish hands and feet only	Pink (light skinned) or absence of cyanosis (dark skinned); pink mucous membranes								
	0	1	2	3	4	5	6	7	8	9	10
Infant needs resuscitation.†				Gently stimulate by rubbing infant's back while administering oxygen. Determine whether mother received narcotics, which may have depressed infant's respirations. Have naloxone (Narcan) available for administration.				Provide no action other than support of infant's spontaneous efforts and continued observation.			

*The Apgar score is a method for rapid evaluation of the infant's cardiorespiratory adaptation after birth. The nurse scores the infant at 1 minute and 5 minutes in each of five areas. The assessments are arranged from most important (heart rate) to least important (color). The infant is assigned a score of 0 to 2 in each of the five areas, and the scores are totaled. Resuscitation should not be delayed until the 1-minute score is obtained. However, general guidelines for the infant's care are based on three ranges of 1-minute scores: 0 to 2; 3 to 6; 7 to 10.

†NOTE: Neonatal resuscitation measures, if needed, do not await 1-minute Apgar scoring but are instituted at once.

FIG 13-8 When the birthing room nurse transfers care of the infant to the nurse who will provide ongoing newborn care, both nurses check the identification bands and record the same information.

is not wearing a band with a matching name and number. A set of bands is needed for each baby in a multiple birth. Some facilities take an early photo of the infant, when the infant is often alert, which serves two purposes: as a keepsake for the parents and identification in the event of abduction.

Care of the Mother

Nursing care of the mother during the fourth stage of labor focuses on observing for hemorrhage and relieving discomfort (Table 13-3).

Observe for Hemorrhage. Important assessments related to hemorrhage are the woman's vital signs, uterine fundus, bladder, lochia, and perineal and labial areas (see Chapter 17).

Vital Signs. Assess the woman's temperature when fourth-stage care begins. Blood pressure, pulse, and respirations should be assessed every 15 minutes during the first hour. A rising pulse rate is an early sign of excessive blood loss because the heart pumps faster to

compensate for reduced blood volume. The blood pressure falls as the blood volume diminishes, but this is a late sign of hypovolemia. A rising pulse rate may also reflect medications administered.

Fundus. The most common reason for excessive postpartum bleeding is that the uterus does not firmly contract and compress open vessels at the placental site. Assess the firmness, height, and positioning of the uterine fundus with each vital sign assessment. The fundus should be firm, in the midline, and below the umbilicus (about the size of a large grapefruit). If the fundus is firm, no massage is needed but if it is soft (boggy), it should be massaged until it is firm. Nipple stimulation from the infant's suckling releases oxytocin from the mother's posterior pituitary gland to maintain firm uterine contraction. Oxytocin in IV solution or administered intramuscularly has the same effect.

Bladder. A full bladder interferes with contraction of the uterus and may lead to hemorrhage. A full bladder is suspected if the fundus is above the umbilicus or displaced to one side, usually the right. The first two voidings are often measured until it is evident that the mother voids without difficulty and empties her bladder completely. Each voiding is usually at least 300 to 400 mL if she is emptying her bladder. If no contraindication such as altered sensation is present, the mother can walk to the bathroom (with assistance the first few times). She should sit on the side of the bed to make sure she is not lightheaded, move her legs back and forth, and raise her knees to be sure she has adequate strength and movement before ambulation.

Lochia. Assess for lochia with each vital sign and fundal assessment. The amount of lochia seems large to the inexperienced nurse and new mother. Perineal pads vary in their absorbency, but saturation of one standard pad (one that does not contain a cold pack) within the first hour is a guideline for the maximal normal lochia flow. Turn the mother to check for lochia pooling under her buttocks and back. Small clots may be present, but the presence of large clots is not normal, and the physician or nurse-midwife should be notified.

TABLE 13-3 MATERNAL PROBLEMS DURING THE FOURTH STAGE OF LABOR

SIGN	POTENTIAL PROBLEM	IMMEDIATE NURSING ACTION
Rising maternal pulse rate and/or falling blood pressure; possibly accompanied by low or no urine output	An early sign of hypovolemia caused by excessive blood loss (visible or concealed)	Identify probable cause of blood loss, usually a poorly contracted uterus. Take steps to correct it (see below). Indwelling catheter may be inserted to observe urine output.
Soft (boggy) uterus	A poorly contracted uterus does not adequately compress large open vessels at placental site, resulting in hemorrhage	With one hand securing uterus just above symphysis and other hand on fundus, massage uterus until firm. Push downward on <i>firm</i> uterus to expel any clots. Empty woman's bladder (by voiding or catheterization) if that is contributing to uterine atony.
High uterine fundus, often displaced to one side	Suggests a full bladder, which can interfere with uterine contraction and result in hemorrhage	Massage uterus if it is not firm. Help woman urinate in bathroom or on bedpan. If she cannot void, catheterize her (usually a routine postpartum order).
Lochia exceeding one saturated perineal pad per hour during fourth stage	Suggests hemorrhage; however, perineal pads vary in their absorbency, and this must be considered	Identify cause of hemorrhage, usually uterine atony, which is manifested by a soft uterus. Correct cause. If lacerations are suspected cause (excess bleeding with a firm fundus), notify birth attendant. Keep woman NPO* until birth attendant evaluates her.
Intense perineal or vaginal pain, poorly relieved with analgesics	Hematoma, usually of vaginal wall or perineum; signs of hypovolemia may occur with substantial blood loss into tissues	If hematoma is visible, apply cold packs to area to slow bleeding into tissues. Notify birth attendant, and anticipate possible surgical drainage. Keep woman NPO.

*NPO, Nothing by mouth.

Perineal and Labial Areas. Observe these areas for hematoma formation. Small hematomas usually are easily limited by ice packs that are also applied for comfort. Large and rapidly expanding hematomas may cause significant enlargement of the tissues involved, a bluish color, and pain.

Promote Comfort

Uterine contractions (afterpains) and perineal trauma are common causes of pain after birth. A postpartum chill often adds to discomfort. Pain usually is mild and readily relieved by simple measures. Notify the birth attendant if pain is intense or does not respond to common relief measures.

Ice Packs. Apply an ice pack to the perineum promptly after vaginal birth to reduce edema and limit hematoma formation. Some perineal pads include chemical cold packs. These pads absorb less lochia than ordinary pads, so this should be considered when estimating pad saturation. Ice packed into a glove is cheaper and colder than a chemical cold pack, although it melts quickly.

Analgesics. Afterpains and perineal pain respond well to mild oral analgesics. Regular urination reduces the severity of afterpains because the uterus contracts most effectively when the bladder is empty. The nurse should encourage the woman to take analgesics on a regular schedule to stay ahead of both perineal and afterpain discomfort.

Warmth. A warm blanket shortens the chill common after birth. A portable radiant warmer provides warmth to both the mother and infant. The mother may enjoy warm drinks initially.

Promote Early Family Attachment

The first hour after birth is ideal for parent–infant attachment because the healthy neonate is alert and responsive. Provide privacy while unobtrusively observing the parents and infant. The infant can remain in the parent's arms while the nurse takes vital signs and suction small amounts of secretions. Many newborn admission assessments can be

performed while the parent holds the baby. (See Box 13-2 for possible nursing diagnoses for the intrapartum family.)

Assist the mother to nurse during the recovery period if she plans to breastfeed. The infant is usually attentive and nurses briefly. Early nipple stimulation helps initiate milk production and contract the uterus.

When the parents are ready, siblings, other family members, and friends should be allowed to visit. Help siblings see and touch their new brother or sister by putting a stool at the bedside or letting them sit on the bed.

Toddlers are often upset by the separation from their mother and may not be interested in the new baby. With supervision, children of preschool age or older may sit in a chair and hold the baby. School-age children are often fascinated by the new baby and surroundings and ask many questions. Adolescents react in various ways. They may be excited and eager to be a substitute parent, or they may be embarrassed about their parents' obvious sexuality "at their age."

Observe for signs of early parent–infant attachment. Parent behaviors are tentative at first, progressing from fingertip touch to palm touch to enfolding of the infant. Parents usually make eye contact with the infant and talk to the baby in higher-pitched, affectionate tones.

Cultural variations should be considered when assessing early attachment (see [Chapters 18](#) and [21](#)). The nurse should be knowledgeable about the typical practices of the populations commonly served. In some cultures great attention to the newborn is considered unlucky (“evil eye”). (See [p. 118](#).)

SUMMARY CONCEPTS

- Some women do not have symptoms typical of true labor. They should enter the birth center for evaluation if they are uncertain and have concerns other than those listed in the guidelines.
- The childbearing family’s first impression on admission to the intrapartum unit is important to promote a therapeutic relationship with caregivers and a positive birth experience.
- Initial intrapartum assessments quickly evaluate maternal and fetal health and labor status.
- The fetus is the more vulnerable of the maternal–fetal pair because of complete dependence on the mother’s physiologic systems.
- The normal fetal heart rate at term averages 110 to 160 beats per minute (bpm). Other reassuring signs include regular rhythm, presence of accelerations, and absence of decelerations.
- A maternal supine position can reduce placental blood flow because the uterus compresses the aorta and inferior vena cava.
- General comfort measures promote the woman’s ability to relax and cope with labor.
- Regular changes in position during labor promote maternal comfort and help the fetus adapt to the pelvis.
- The nurse must be alert for signs of impending birth: The woman may state, “The baby’s coming,” make grunting sounds, and bear down.
- The priority nursing care of the newborn immediately after birth is to promote normal respirations, maintain normal body temperature, and promote attachment.
- The priority nursing care of the mother after birth is to assess for hemorrhage and promote firm uterine contraction, promote comfort, and promote parent–infant attachment.

Intrapartum Fetal Surveillance

 WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Identify the purposes of intrapartum fetal surveillance.
2. Explain the normal and pathologic mechanisms that influence fetal heart rate.
3. Identify the advantages and limitations of each method of intrapartum fetal surveillance: auscultation and electronic monitoring.
4. Explain the types of equipment used for auscultation and electronic fetal monitoring during labor and the advantages and limitations of each.
5. Describe the interpretation of intrapartum fetal assessment data.
6. Explain the methods that may be used in addition to electronic fetal monitoring to judge fetal well-being.
7. Describe appropriate responses to nonreassuring fetal heart rate patterns.
8. Use the nursing process to plan care for a woman undergoing intrapartum fetal assessment.

Intrapartum fetal assessment is the process of fetal surveillance to identify signs associated with well-being and with compromise. Accurate identification of these signs permits appropriate and timely care to reduce hazards to the fetus. At a minimum, intrapartum fetal assessment includes evaluation of the fetal heart rate (FHR) and the mother's uterine activity. More comprehensive monitoring includes assessment of fetal activity, fetal response to stimulation, and fetal pulse oximetry.

The purposes of intrapartum fetal assessment are to evaluate how the fetus tolerates labor and to identify hypoxic insult to the fetus during labor. However, no method of fetal assessment can identify every compromised fetus.

Malpractice claims related to fetal well-being and long-term outcomes may be brought many years, often decades, after the birth of a neurologically handicapped child. The nurse's documentation must prove that the standard of care was met *at the time of birth* for best defense. The nurse should detect signs associated with fetal **hypoxia** (reduced availability of oxygen to body tissues) and inform the physician or nurse-midwife in a timely manner. The nurse should contact administrators in the facility's chain of command if the birth attendant

does not respond promptly to the nurse's report of fetal problems. The perinatal nurse must obtain initial competency in fetal assessment that meets standards of care and facility policy and must maintain currency in fetal assessment. Documentation of data must be complete and clear to provide proper communication among professionals and to facilitate the best defense in any future lawsuit.

Two basic approaches to intrapartum fetal monitoring are taken: low technology and high technology. Each has advantages and limitations. The nurse may use either or both of these approaches to assess a fetus during labor, depending on the woman's wishes, risk status, and facility policy. Changes from one method to the other may also be done.

The low-technology approach uses intermittent auscultation (IA) of the FHR and palpation of uterine activity. In the United States, this type of fetal observation is more often used in home births and birth centers. It also may be used during hospital births.

Electronic fetal monitoring (EFM) is the high-technology approach to intrapartum fetal surveillance. Despite the almost universal use of electronic fetal monitoring in the United States, its benefits to the fetus over IA have not been established.

FETAL OXYGENATION

Adequate fetal oxygenation needs five related factors:

1. Normal maternal blood flow and volume to the placenta
2. Normal oxygen saturation in maternal blood
3. Adequate exchange of oxygen and carbon dioxide in the placenta
4. An open circulatory path between the placenta and the fetus through vessels in the umbilical cord
5. Normal fetal circulatory and oxygen-carrying functions

An understanding of the dynamics of uteroplacental exchange and fetal circulation is critical to the understanding of fetal responses to labor (see [Chapter 6](#)).

Uteroplacental Exchange

Oxygen-rich and nutrient-rich blood from the mother enters the intervillous spaces of the placenta via the spiral arteries (see [Figure 6-7](#)). Oxygen and nutrients in the maternal blood pass into the fetal blood that circulates within capillaries inside the chorionic villi in the intervillous spaces. Carbon dioxide and other waste products pass from the fetal blood into the maternal blood at the same time. Maternal blood carrying fetal waste products drains from the intervillous spaces through endometrial veins and returns to the mother's circulation for elimination by her body. Substances pass back and forth between mother and fetus without mixing of maternal and fetal blood.

During labor, contractions gradually compress the spiral arteries, temporarily stopping maternal blood flow into the intervillous spaces at the peak of strong contractions. During contractions the fetus depends on the oxygen supply already present in body cells, fetal erythrocytes, and the intervillous spaces. The oxygen supply in these areas is enough for about 1 to 2 minutes. As each contraction relaxes, fresh oxygenated maternal blood reenters the intervillous spaces, and blood containing carbon dioxide and other fetal waste products drains out.

Fetal Circulation

The fetal heart circulates oxygenated blood from the placenta throughout the body and returns deoxygenated blood to the placenta. The umbilical vein carries oxygenated blood to the fetus, and the two umbilical arteries carry deoxygenated blood from the fetus to the placenta (see [Figure 6-7](#)).

Regulation of Fetal Heart Rate

Mechanisms that regulate the heart rate are balanced to maintain cardiac output at a level that keeps the fetal heart and brain oxygenated. Fetal cardiac output increase is primarily accomplished by an increase in the heart rate. Conversely, a marked decrease in FHR decreases fetal cardiac output.

Five fetal factors interact to regulate the FHR:

1. Autonomic nervous system
2. **Baroreceptors**
3. **Chemoreceptors**
4. Central nervous system
5. Adrenal glands

The balance among forces that increase and those that slow the heart rate results in the characteristic fluctuations in FHR during the last trimester of pregnancy.

Autonomic Nervous System

The sympathetic and parasympathetic branches of the autonomic nervous system are balanced forces that regulate the FHR. Sympathetic stimulation increases the heart rate and strengthens myocardial contractions through release of epinephrine and norepinephrine. The net result of sympathetic stimulation is an increase in cardiac output.

The parasympathetic nervous system, through stimulation of the vagus nerve, reduces the FHR and maintains variability (see p. 263). The parasympathetic branch gradually exerts greater influence as the fetus matures, beginning between 28 and 32 weeks of gestation. Therefore, the average FHR in the term fetus is lower than that in the preterm fetus.

Baroreceptors

Cells in the carotid arch and major arteries respond to stretching when the fetal blood pressure increases. The baroreceptors stimulate the vagus nerve to slow the FHR and decrease the blood pressure, thus lowering cardiac output.

Chemoreceptors

Cells that respond to changes in oxygen, carbon dioxide, and acid-base levels, or pH, are found in the medulla oblongata and in the aortic and carotid bodies. Decreased oxygen concentration, increased carbon dioxide content, or a lower pH in blood or cerebrospinal fluid triggers an increase in the heart rate. However, prolonged hypoxia, **hypercapnia**, and **acidosis** (accumulation of acid [hydrogen ions] or depletion of base [bicarbonate]) depress the FHR.

Adrenal Glands

The adrenal medulla secretes epinephrine and norepinephrine in response to stress, causing a sympathetic response that accelerates the FHR. The adrenal cortex responds to a fall in the fetal blood pressure with release of aldosterone and retention of sodium and water, resulting in an increase in the circulating fetal blood volume.

Central Nervous System

The fetal cerebral cortex causes the heart rate to increase during fetal movement and decrease when the fetus is quiet. As the fetus becomes mature enough to have distinct wake and sleep states, the FHR responds with variations in rate. For example, the rate is slower and with little variability during deep fetal sleep, but faster and with greater variability and accelerations when the fetus is awake.

The hypothalamus coordinates the two branches of the autonomic nervous system, the sympathetic and parasympathetic systems. The medulla oblongata maintains the balance between stimuli that speed and slow the heart rate.

Pathologic Influences on Fetal Oxygenation

Compromise of fetal oxygenation may occur because of alterations in any of the placental or fetal factors or those of the pregnant woman.

Maternal Cardiopulmonary Alterations

Actual or relative reductions in the mother's circulating blood volume impair perfusion of the intervillous spaces with oxygenated maternal blood. Hemorrhage causes an actual decrease in the mother's blood volume. Relative reductions in maternal circulating volume involve altered distribution of the blood volume without blood loss. For example, epidural block analgesia may cause vasodilation, which increases the capacity of the maternal vascular bed. However, the amount of blood available to fill her vessels is unchanged. Hypotension results, with reduction of placental blood flow.

Aortocaval compression can occur when a pregnant woman lies in the supine position and the weight of the uterus compresses the aorta and the inferior vena cava. Aortocaval compression reduces blood return to her heart, lowers her cardiac output (supine hypotension), and can reduce placental perfusion.

Maternal hypertension may reduce blood flow to the placenta because of vasospasm and narrowing of the spiral arteries. Hypertension may be pregnancy induced or chronic or may result from ingestion of drugs such as cocaine.

EVIDENCE-BASED PRACTICE

“We’ve Always Done It That Way” Is Not Adequate

We learn about evidence-based practice in every nursing course, and students are often required to do an assignment related to research. “We’ve always done it this way” is not adequate support for nursing or medical actions. Health care facilities are increasing the creation of policies and procedures that do have adequate evidence of validity and that are changing as knowledge grows. But does real life nursing practice always use this evidence-based knowledge?

Simpson and Lyndon (2009) surveyed 133 experienced obstetric nurses via a secure website about five common situations that involve disagreement between a knowledgeable nurse and a physician on what is best for a patient. Each of the five situations described had two questions with multiple choice and free-text answers for the nurses’ response.

- What do you believe is the best action based on available evidence and national standards?
- What do you think would actually occur in practice (what would most nurses do)?

Two open-ended questions for participants were related to the following:

- How to promote communication and collaboration with physicians
- Barriers to communication and collaboration with physicians

The five situations that often result in conflict included the following physician actions:

- Order oxytocin infusion rate increased despite previous hyperstimulation at that rate and normal labor progress at the current rate
- Refuse to see a woman when FHR patterns are nonreassuring
- Deny permission for neonatal resuscitation team at delivery despite nonreassuring FHR patterns
- Tell the patient to continue pushing, although the nurse had the woman temporarily stop pushing because of nonreassuring FHR patterns
- Continue attempts to use vacuum extractor although the maximum number of attempts has exceeded facility and manufacturer guidelines (see Chapter 16).

Four classifications of participant responses are described with examples from the group of five situations.

- Best evidence/standard of care: Orders to increase oxytocin infusion rate despite adequate labor progression and previous uterine hyperstimulation at the rate ordered.

Remind the physician that the ordered rate had resulted in uterine hyperstimulation earlier. Reassure the physician that oxytocin will be increased if contractions or progress slows.

- Passive: The physician refuses to allow the neonatal resuscitation team to attend delivery when the EFM pattern suggests possible fetal compromise.
The nurse decides that the neonatal resuscitation team should not be called because the physician will yell at the team and the nurse and do so in

front of the patient. The nurse decides that it is better that the team be on standby.

- Passive-aggressive: The physician exceeds the number of attempts at successful vacuum extraction.
Responding to an emergency call for another vacuum extractor, the nurse asks the physician the number of attempts made in addition to the two she just witnessed. The nurse throws the new vacuum extractor to the floor, asks the physician if he wants to attempt forceps. The nurse also tells the physician that she would be glad to ask another OB doctor who was at the nurses’ station for assistance.
- Work-around: The physician refuses to come and see a woman who has a nonreassuring FHR pattern that remains unresponsive to the usual corrective interventions.
The nurse would notify the resident and have them call the attending physician.

Some barriers to communication and collegial relationships expressed by nurses in the survey were as follows:

- Physicians are higher in the hierarchy:
 - Doctors have the last word.
 - Hospitals cater to doctors.
- Greater power of the doctor:
 - Leads to intimidation or bullying.
 - Some doctors do not appreciate nurses’ suggestions. Hospitals promote a climate of conflict between doctors and nurses by not backing the nurse if a conflict occurs.
- Lack of respect felt by nurses. Nurses feared loss of their job if they stood their ground.

Suggestions for promoting effective communication and collaboration included the following:

- Basic courtesy
- A team approach with nurses and physicians working together builds rapport and trust and a sense of the abilities of all team members
- Equal support of hospitals for physicians and for nurses

Other participant communication about these issues, including a table of the results, can be found by reading this article critically.

While in clinical, ask experienced labor nurses about the most appropriate action for each of the five situations surveyed. Ask what usually occurs in these nurse-physician conflict situations in your clinical facility. How does real life compare to best practice for these situations and perhaps others?

What professional conflicts have you witnessed as you have progressed through your nursing clinicals? Can you identify a specific situation between a nurse and physician that you observed for each of the four response classifications listed earlier? How do you think you would have handled those conflicts?

Reference: Simpson, K.R. & Lyndon, A. (2009). Clinical disagreements during labor and birth: How does real life compare to best practice? *MCN: American Journal of Maternal-Child Nursing*, 34(1), 31–39.

A lowered oxygen level in the mother’s blood reduces the amount available to the fetus. Maternal acid-base alterations that accompany respiratory problems also can compromise exchange in the placenta. A lower maternal oxygen tension may result from respiratory disorders such as asthma or from smoking.

Uterine Activity

Hypertonic uterine activity reduces the time available for exchange of oxygen and waste products in the placenta. Contractions may be too long or too frequent or have too short an interval. The uterus may not fully relax between contractions, applying continuous compression to the spiral arteries and reducing maternal-fetal exchange in the

intervillous spaces. Hypertonic uterine activity may occur spontaneously or with uterine stimulants such as oxytocin (Pitocin), prostaglandins, or misoprostol (Cytotec).

Placental Disruptions

Conditions such as *abruptio placentae* (partial separation before birth) and infarcts reduce the placental surface area available for exchange. The amount and location of placental disruption relate to the degree of impairment in uteroplacental exchange. Large infarcts or separations cause greater impairment than smaller ones. Central infarcts or separations usually cause greater impairment than those on edges of the placenta.

Interruptions in Umbilical Flow

The usual cause of interrupted blood flow through the umbilical cord is compression. Blood flow through the umbilical cord may be reduced by compression between the fetal presenting part and the pelvis, by a **nuchal cord** (one that is wrapped around the fetal neck) or by a knot in the cord. It may occur with **oligohydramnios** because the amount of amniotic fluid is inadequate to cushion the cord, usually less than 500 mL at term. The umbilical cord also may become entangled between fetal body parts or it may have inadequate Wharton's jelly for cushioning.

The thin-walled umbilical vein is compressed initially, resulting in a reduced inflow of more highly oxygenated blood to the fetus. This results in initial hypoxia with hypotension. Baroreceptors and chemoreceptors respond by accelerating the FHR. Flow through the firmer-walled umbilical arteries that carry blood from the fetus to the placenta is reduced as cord compression continues, resulting in hypertension. Baroreceptors respond to hypertension by stimulating the vagus nerve, thus reducing blood pressure and slowing the fetal heart. The FHR again accelerates as pressure is relieved on the umbilical arteries and then on the umbilical vein.

Fetal Alterations

Fetal cells may be hypoxic despite adequate oxygen supply from the woman and adequate exchange within the placenta. A low circulating fetal blood volume, fetal hypotension, or fetal anemia may result in cellular hypoxia. Central nervous system (CNS) or cardiac abnormalities may cause an abnormal rate or rhythm. For example, a fetus with complete heart block may not respond to stimuli that would normally cause a rate increase.

Fetal cardiac output is presumed to fail at rates lower than 60 beats per minute (bpm) but all factors from the fetal monitor strip must be evaluated. Fetal tachycardia may reflect a recovery response from hypoxia or acidosis (Lyndon, O'Brien-Abel, & Simpson, 2009).

Risk Factors

When conditions associated with reduced fetal oxygenation exist (Box 14-1), assessments by either IA and palpation or EFM are done more often. No absolute indications, including the presence of risk factors, require the use of EFM during labor. Properly performed IA is equivalent to continuous electronic monitoring in assessing fetal condition (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2012).

CHECK YOUR READING

1. What five factors influence fetal oxygenation?
2. What changes in the FHR occur when the umbilical cord is compressed?
3. What risk factors indicate that fetal monitoring should be done more frequently? (See Box 14-1.)

AUSCULTATION AND PALPATION

IA of the FHR can be done using either the nonelectronic fetoscope or the Doppler ultrasound fetoscope (Figure 14-1). The nurse's expert fingertips palpate uterine activity (see Procedure 13-1).

Advantages

Mobility is a major advantage of auscultation and palpation for intrapartum fetal assessment. The woman is free to change position and walk around. Nothing restricts her freedom to move and she is likely to change positions more often, which promotes normal labor. The

BOX 14-1 POTENTIAL MATERNAL, FETAL, OR NEONATAL RISK FACTORS

Antepartum Period

Maternal History

Prior stillbirth (unexplained or potentially recurrent cause)
 Prior cesarean birth
 Poor nutrition, low prepregnancy weight, poor weight gain
 Multiple pregnancies, closely spaced
 Chronic diseases such as cardiac disease, anemia, hypertension, diabetes, asthma, and autoimmune diseases
 Acute infections such as urinary tract, pneumonia, gastrointestinal
 Hematologic problems such as anemia, deep vein thrombosis
 Drug use (includes prescription agents, over-the-counter drugs, herbal preparations, and illegal drugs)
 Psychosocial stress, domestic violence

Problems Identified during Pregnancy

Intrauterine growth restriction (IUGR)
 Gestation more than 42 weeks
 Marked decrease in fetal movement
 Multifetal gestation
 Preeclampsia, eclampsia
 Gestational diabetes
 Placental abnormalities (placenta previa, abruptio placentae)
 Severe maternal anemia
 Maternal infection
 Maternal trauma

Intrapartum Period

Maternal Problems

Hypotension or hypertension
 Hypertonic uterine contractions
 Abnormal labor: preterm or dysfunctional
 Prolonged rupture of membranes
 Chorioamnionitis
 Fever

Fetal or Placental Problems

Fetal anemia
 Abnormal fetal heart rate or pattern
 Meconium-stained amniotic fluid
 Abnormal presentation or position
 Prolapsed cord
 Abruptio placentae

Modified from Gauthier, D. (2009). Maternal-fetal assessment. In A. Lyndon & L. Usher (Eds.), *AWHONN: Fetal heart monitoring: Principles and practices* (4th ed., pp. 45–63). Dubuque, IA: Kendall Hunt; and Feinstein, N. F., Sprague, A., & Trépanier, M. J. (2008). *Fetal heart auscultation* (2nd ed.). Washington, D.C.: Association of Women's Health, Obstetric and Neonatal Nurses.

nurse must have regular, close, and frequent personal contact with the woman when performing IA and palpation. Water-based methods of pain management such as whirlpool baths or showers can be used more freely. The atmosphere is more natural than technologic and less invasive, which is important to some women during their birth experience. The equipment is less costly than EFM equipment, but staffing to achieve the needed 1:1 nurse-patient ratio may offset this cost advantage.

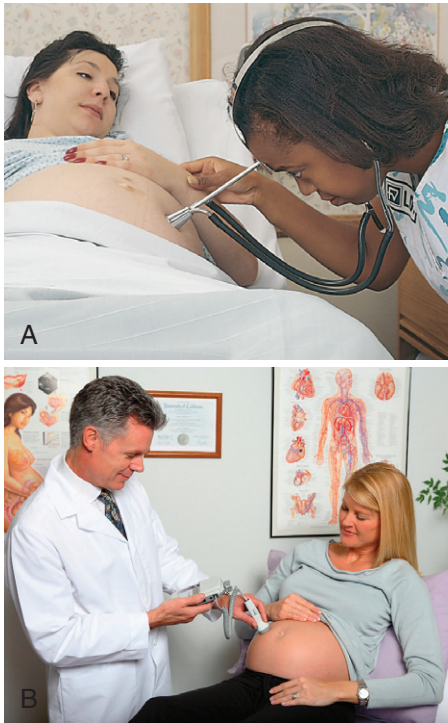

FIG 14-1 Low-Intervention Methods for Evaluating the Fetal Heart Rate during Labor. **A**, Fetoscope, showing the head attachment to enhance conduction of faint fetal heart sounds. Rarely used in U.S. hospital births. **B**, Transmission gel improves the clarity of the fetal heart movement sensed by the Doppler ultrasound transducer.

Limitations

A disadvantage of auscultation and palpation as the primary method of fetal assessment is that FHR and uterine activity are assessed for a small percentage of the total labor. The fetus is most stressed during contractions because of normal reduction of blood flow to the placenta at that time. The FHR is assessed during some contractions but is not recorded during every contraction. No continuous printed or computer-archived record exists to show the fetal response throughout labor or to identify subtle trends in the response.

Some women find that interruptions for auscultation are distracting. The pressure of the instrument on the abdomen is uncomfortable for some, and it may require several moves to locate the best place for auscultation. Maternal obesity or large amniotic fluid volume may make it difficult to hear the fetal heart sounds.

IA is more staff-intensive than electronic monitoring, with a 1:1 nurse-patient ratio recommended in clinical trials. When this nurse-patient ratio cannot be achieved, auscultation may not be a realistic option as the primary method of intrapartum fetal surveillance. The ACOG recommends continuous fetal monitoring if high-risk conditions exist in the woman or fetus, such as diabetes or fetal growth restriction (American College of Nurse-Midwives [ACNM], 2010; ACOG, 2009; Feinstein, Sprague, & Trépanier, 2008).

Auscultation Equipment

Two basic types of auscultation equipment are used: a fetoscope and a Doppler ultrasound **transducer** (device that translates fetal heart motion into an electrical signal). When listening with a fetoscope, the listener hears actual fetal heart sounds. The Doppler device senses motion and translates that motion into a sound that represents the

cardiac events. An external fetal monitor, which is the same technology as the Doppler transducer, can be used. However, automatic computer archiving may retain the data from the brief time, even if the recording is turned off while using the EFM for IA, and users must be aware of this fact (Feinstein et al., 2008).

Evaluation of Auscultated Fetal Heart Rate Data

Both the fetoscope and the Doppler transducer can be used to identify the FHR baseline, rhythm, and changes from the baseline. Because the fetoscope is detecting actual fetal heart sounds, it is reliable for detecting fetal dysrhythmias. The Doppler transducer (and external fetal monitor if it is being used for IA) also can be used to detect baseline, rhythm, and changes in the baseline. However, the Doppler transducer or external fetal monitor cannot be used to reliably detect dysrhythmias. (Procedure 14-1 explains auscultation of the FHR with the fetoscope and the Doppler transducer.) The fetoscope is rarely used in the United States despite its reliability in detection of fetal dysrhythmias.

ELECTRONIC FETAL MONITORING

EFM may be continuous, starting shortly after the woman is admitted; **intermittent**, with a short strip taken at regular intervals during labor; or intermittent during early labor and continuous during late labor.

Subjectivity of interpretation and use of varying descriptive terminology have made outcomes of research difficult to evaluate. Between 1995 and late 1996, a series of workshops was held to clarify and standardize definitions for electronic fetal monitoring data (National Institute of Child Health and Human Development [NICHD] Research Planning Workshop, 1997). A major purpose was to develop standard definitions to improve data collection and evaluation. Many health care facilities have adopted these definitions in their policies. Guidelines from AWHONN: *Fetal Heart Monitoring: Principles and Practices*, 4th edition (Lyndon & Usher [Eds.]) and terminology from the NICHD workshops are used in a simplified form here.

A 2008 workshop was held to review and update definitions to describe EFM patterns and to make recommendations about a classification system for use in the United States. The most recent definitions are for visual interpretation of patterns, but the 2008 group recognized that computer programs for interpretation are being developed. Three categories rather than the previous two categories describe the fetus at that point in time and are not predictive of disorders such as cerebral palsy. Interventions may result in a change of the interpretation category (Macones, Hankins, Spong et al., 2008). However, Murray, Huelsmann, & Mahlmeister (2009) expressed concerns about the new descriptors for EFM and uterine activity patterns and actions indicated, particularly for category II.

Advantages

The electronic monitor supplies more data about the fetus than auscultation and archives a permanent record on paper, computer media, or both (Figure 14-2). Continuous EFM shows how the fetus responds before, during, and after each contraction rather than occasional contractions. Gradual trends in FHR or contraction patterns are documented electronically.

Many women in the United States expect electronic monitoring and find the constant sound of the fetal heartbeat comforting. Their support person can use the tracing of contractions on the monitor strip to help the woman anticipate the beginning and end of each contraction. Nurses, physicians, and nurse-midwives are usually more comfortable with the electronic data generated and documented.

Electronic monitoring allows one nurse to observe two laboring women, primarily during uncomplicated early labor, while

PROCEDURE 14-1 AUSCULTATING THE FETAL HEART RATE

PURPOSE: To evaluate the fetal condition and tolerance of labor

1. Explain the procedure to give information to the woman and her partner. Wash your hands with warm water to reduce the transmission of microorganisms and to make your hands more comfortable when touching the woman's abdomen.
2. Use Leopold's maneuvers to identify the fetal back (see Procedure 13-1) because it usually is closest to the surface of the maternal abdomen, where fetal heart sounds are clearest. Illustrations show approximate locations of the fetal heart rate in different presentations and positions.
3. Assess the fetal heart rate with a fetoscope or Doppler transducer. The external fetal monitor may be used but is more often used for intermittent electronic fetal monitoring (short periods of electronic monitoring interspersed with periods of no fetal surveillance, such as maternal ambulation).
4. Fetoscope (see Figure 14-1, A): Place the bell of the fetoscope over the fetal back with the head plate pressed against your forehead to add bone conduction to the sound coming through the earpieces. (Not all models use bone conduction.) Move the fetoscope until you locate where the sound is loudest. Use your forehead to maintain pressure during auscultation to enhance the faint fetal heart sounds. Not frequently used in U.S. hospital births now, the procedure is, however, valid.
5. Doppler transducer (see Figure 14-1, B): Review the manufacturer's instructions for operating the Doppler device. Place water-soluble conducting gel over the transducer to make an interface for clear signal transmission, and turn it on. Place the transducer over the fetal back, and move it until you hear clear sounds that represent the fetal heart motion.
6. With one hand, palpate the mother's radial pulse to verify that the fetal heart rate is what is actually heard. If her pulse is synchronized with the sounds from the fetoscope or Doppler transducer, try another location for the fetal heart. Other sounds that may be represented by the Doppler are the funic souffle (blood flowing through the umbilical cord) or uterine souffle (blood flowing through the uterine vessels). The funic souffle is synchronized with the fetal heart and has the same rate; the uterine souffle is synchronized with the mother's pulse. Fetal movement sounds are common.

Auscultating the Fetal Heart Rate

1. Count the baseline fetal heart rate for a total of 30 to 60 seconds between contractions. Assessment during a contraction may clarify findings, but auscultation is difficult during contractions. Note accelerations or slowing of the rate. Counting at 6-second intervals and multiplying each result by 10 give a sequence of numbers that can be averaged. This method also provides a better picture of the depth and duration of a decrease in FHR while counting.
2. Note reassuring signs that suggest the fetus is tolerating labor well:
 - a. An average rate of 110 to 160 beats per minute
 - b. Regular rhythm
 - c. Accelerations from the baseline rate
 - d. No decrease in rate from the baseline rate
3. Note nonreassuring signs, and make more frequent assessments. Notify the physician or nurse-midwife for further evaluation:
 - a. Heart rate outside normal limits; unexplained tachycardia or bradycardia for 10 minutes or longer
 - b. Irregular rhythm
 - c. Gradual or abrupt decrease in rate

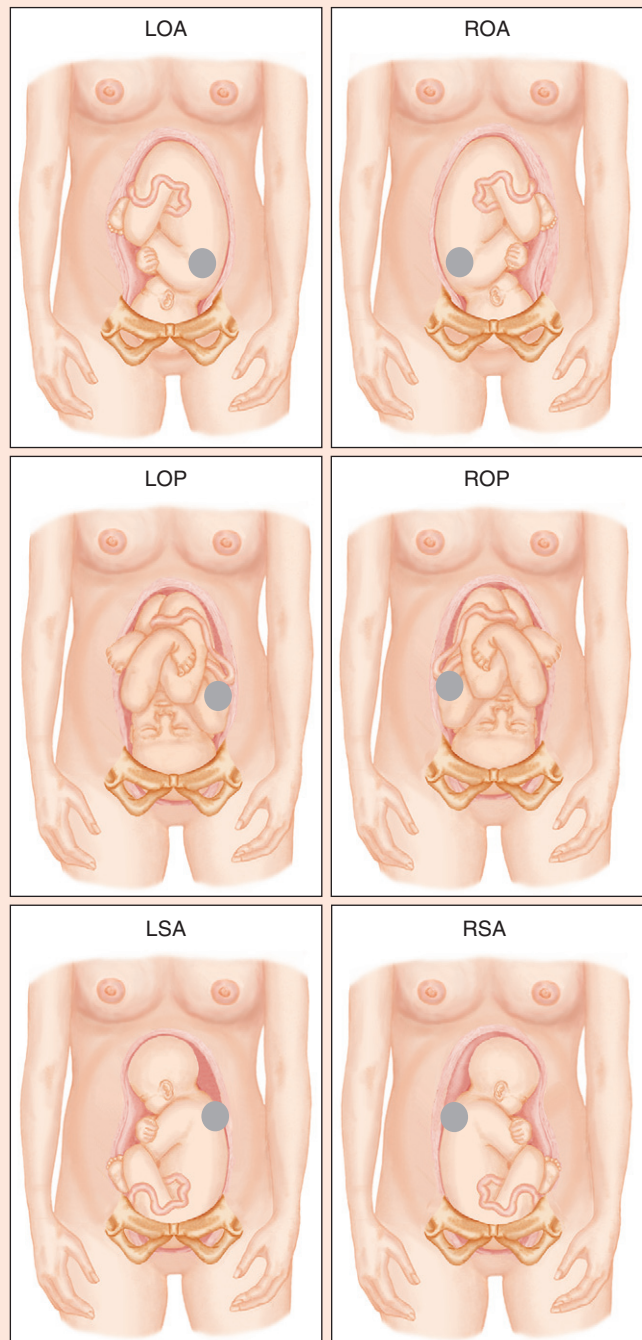

FIG 14-2 Bedside Unit for Electronic Fetal Monitoring. In addition to fetal heart rate and uterine activity, the unit can help the nurse evaluate the woman's pulse rate, blood pressure, and saturation of oxygen in her blood. Both fetuses in a twin gestation can be assessed. (Courtesy of Corometrics Medical Systems, Inc., Wallingford, CT.)

maintaining patient privacy. A 1 : 1 nurse-patient ratio is needed during the second stage, regardless of the monitoring method used. Pregnancy complications may require a 1 : 1 nurse-patient ratio, even if the woman is not in labor. Electronic monitoring can give the nurse more time for teaching and supporting the laboring woman with breathing and relaxation techniques if the nurse maintains the primary focus on the woman and not on the machine.

Limitations

Reduced mobility is a limitation of EFM. **Telemetry** (wireless transmission) or intermittent monitoring gives the woman more freedom of movement than continuous electronic monitoring without telemetry. Otherwise, the woman is limited to her bed or a nearby chair if EFM is continuous.

Frequent maternal position changes or an active fetus often requires constant adjustment of equipment. The belts or stockinette bands, used to keep sensors positioned properly for external monitoring, are uncomfortable for some women. A woman may concentrate on maintaining a good tracing rather than making herself comfortable or changing positions that might enhance fetal descent.

The high-tech atmosphere created by the electronic fetal monitor may be objectionable to a woman and her partner.

EFM, though used in more than 80% of births in the United States, has not proved to be consistently reliable at identifying the fetus who is truly in trouble. EFM best identifies the well-oxygenated fetus, but it does not as reliably identify the compromised fetus. Therefore, EFM must be considered a screening tool, rather than a diagnostic tool.

ELECTRONIC FETAL MONITORING EQUIPMENT

EFM equipment consists of the bedside monitor unit and sensors for FHR and uterine activity (see [Figure 14-2](#)). Sensors for each function may be either internal or external. Computer interfaces allow addition of chart annotations and admission and birth information and provide electronic storage of confidential information. Models with wireless transmission of data to the base, for observation and storage, allow ambulation while monitoring.

Fetal monitor clocks should be synchronized throughout the unit, often by connection to an atomic clock. Using the fetal monitor clock to determine the birth time allows the most accurate reconstruction

FIG 14-3 Electronic fetal monitoring can be continuous and provides nurses with monitor strips, either paper or computer based, on which uterine activity and fetal heart rate are permanently recorded.

of the events of labor. In legal proceedings, the amount of time required to accomplish corrective interventions can make a difference in the defense of a lawsuit.

Bedside Monitor Unit

The bedside fetal monitor unit uses information from the fetal heart rate and uterine activity sensors to provide a visual output in the form of a numeric display and a graphic strip ([Figure 14-3](#)). The strip may be printed by the monitor itself, similar to an electrocardiogram (ECG) strip, or viewed on a computer screen. The strip can be printed if electronic storage is not available in facilities that use a computer interface with the bedside monitor. Current units can record rates for both fetuses in a twin pregnancy and have inputs for maternal blood pressure, pulse rate, and blood oxygen saturation. (The maternal blood pressure may be signified on the strip by the acronym NIBP, which means noninvasive blood pressure.)

Paper Strip

Data about the FHR and uterine activity are printed on a paper strip having a horizontal grid for the FHR and another for the uterine activity ([Figure 14-4](#)). Segments of paper between perforations are numbered for identification and reassembly of a multipart strip. The FHR is recorded on the upper strip. The range of rates is from 30 to 240 bpm. Other countries may use a strip with a different configuration and paper speed.

Uterine activity is recorded on the lower grid as bell-shaped curves. Contraction intensity and **uterine resting tone** (uterine muscle tone before labor or during the contraction interval) from 0 to 100 mm Hg are recorded on the lower grid.

Vertical lines on both upper and lower grids are time divisions. At a paper speed of 3 centimeters per minute (cm/min), dark vertical lines are 1 minute apart. Lighter lines subdivide the 1-minute divisions into six 10-second segments. The vertical lines are used to time contraction frequency and duration and to identify the fetal response in relation to the contractions.

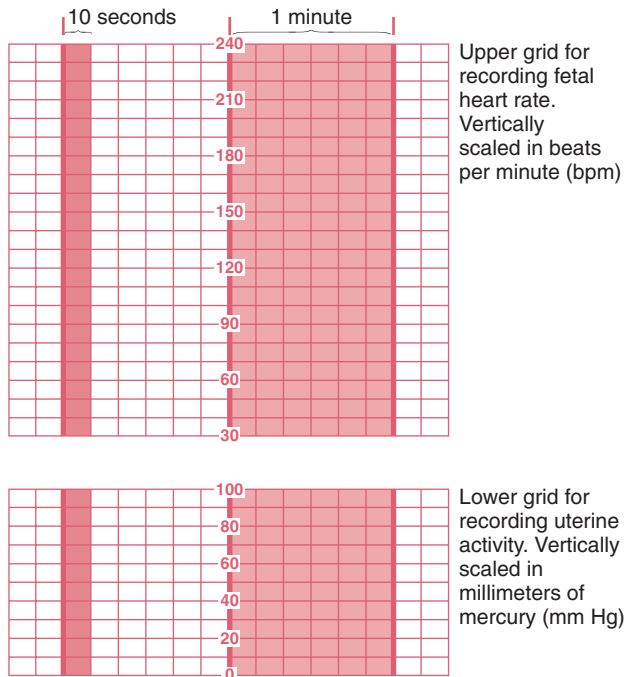

FIG 14-4 Paper Strip for Recording Electronic Fetal Monitoring Data. Each dark vertical line represents 1 minute, and each lighter vertical line represents 10 seconds. Paperless computer displays that depict the fetal heart rate and uterine activity patterns have a similar appearance.

The “paper” is often a computer’s monitor screen with the same appearance and scroll speed as a paper strip. The strip may not be routinely printed on paper at all. The nurse moves backward or forward through the strip on the screen using keyboard arrows or a pointing device such as a mouse or light pen or by setting a time and date to go to a specific location. Maintenance or malfunction in the computer system often requires printing of the records until function is restored.

Data Entry Devices and Computer Software

Monitors automatically print some notations such as the date, time, paper speed, and type of device being used to detect the FHR and uterine activity. Most also have data entry devices, allowing entry of data to be printed on the strip. Computer software is commonly used to archive fetal monitoring information plus other information relating to the care of mother and fetus. The software may extend beyond the intrapartum stay and be used for documentation in the postpartum and newborn periods.

Computer-assisted analysis of EFM data uses software to interpret visible patterns on the electronic fetal monitor. Automated analysis may become a common adjunct in the review of EFM data and in suggesting possible interventions for problems. The professional person—nurse, nurse-midwife, or physician—chooses whether to accept the software analysis.

Remote Surveillance

Most facilities have display units at the nursing station or other locations to allow surveillance when the nurse is not at the bedside. These units display the tracing on a screen and have settings for audible and visual alerts such as upper and lower limits for the FHR, decelerations, and end of the paper.

FIG 14-5 The nurse applies the uterine activity transducer to the woman’s upper abdomen, in the fundal area. The Doppler transducer for sensing the fetal heart rate is usually placed on her lower abdomen when the fetus is in the cephalic presentation.

Devices for External Fetal Monitoring

Both the FHR and uterine activity can be monitored by external sensors, or transducers. External devices are secured on the mother’s abdomen by elastic straps, a tube of wide stockinette, or an adhesive ring (Figure 14-5). External devices are slightly less accurate than internal ones but are noninvasive. They do not require ruptured membranes or cervical dilation, making them useful for women who should not have devices placed in the vagina or uterus, for example, the woman with preterm membrane rupture. (Procedure 14-2 contains instructions for using the external electronic fetal monitor.)

Fetal Heart Rate Monitoring with an Ultrasound Transducer

The Doppler ultrasound device detects movements other than fetal heart motion, for example, fetal or maternal activity or blood flow through the umbilical cord and the woman’s aorta. Today’s monitors filter these extraneous sounds to provide a clean tracing.

The Doppler transducer produces a two-part muffled sound that resembles the sound of galloping horses. The two closely linked sounds represent closure of the heart valves during systole (mitral and tricuspid valves) and diastole (aortic and pulmonic valves). Fetal or maternal activity produces a rough, erratic sound rather than the crisp, rhythmic sound characteristic of the fetal heart. Fetal hiccups have a distinct and rhythmic thumping sound that usually starts and stops abruptly.

Uterine Activity Monitoring with a Tocotransducer

A tocotransducer (also called a *tocodynamometer* or simply a “toco”) with a pressure-sensitive area detects changes in abdominal contour to measure uterine activity. The uterus pushes outward against the mother’s anterior abdominal wall with each contraction. The monitor calculates changes in this signal and prints them as bell shapes on the lower grid of the strip.

Movement other than uterine activity also registers on the monitor. For example, maternal respirations cause the uterine activity line to have a zigzag appearance. Other fetal or maternal movements such as fetal hiccups appear as spikes on the uterine activity tracing.

Uterine activity is sensed through the woman’s abdomen and is therefore useful for observing the frequency and duration of contractions. It does not reliably measure actual contraction intensity and uterine resting tone. Several factors affect apparent intensity as printed on the strip:

- Fetal size—The uterus will not push firmly against the abdominal wall with each contraction when the fetus is small, making contractions appear less intense.

PROCEDURE 14-2 EXTERNAL FETAL MONITOR

PURPOSE: To properly apply the external electronic fetal monitor; to perform a basic evaluation of the fetal heart rate and uterine activity patterns

1. Review agency policy for use of the electronic fetal monitor and how it interfaces with computer documentation. Verify that the date and time for the monitor are accurate and consistent with the computer document. Become familiar with proper operation of the monitor equipment and computer interface. Matching date and time are essential for correct documentation.
2. Perform a function test following manufacturer's instructions. Press "TEST" button and observe for result. Common correct test results are the following:
 - a. Fetal heart rate (FHR): The monitor prints a line at 120, 150, or 200 beats per minute (bpm), depending on the model.
 - b. Uterine activity: The monitor adds 50 to uterine activity display.
 - c. Maternal electrocardiogram (ECG): The monitor creates an artificial ECG waveform.

A correct function test ensures that the bedside monitor unit is calibrated properly so that caregivers are assured of accurate data to interpret. Each manufacturer sets standards for indicators of proper function. Knowledge of using connections with computer interfaces will be required if data are transmitted by these means.
3. Explain the basic procedure of electronic fetal monitoring to the woman and her partner or family. Vary instructions according to equipment being used and hospital protocols. The following are samples of instructions:
 - a. "Using the electronic fetal monitor is the way we normally assess the baby's response to labor contractions."
 - b. "Two belts go around your abdomen, one for the FHR sensor and one for contractions. Three belts are usually needed for twin pregnancies."
 - c. "Feel free to move with the monitor on. If the tracing is poor, we can adjust the sensors."

Knowledge decreases the woman's fear of the unknown. Teaching her that she can and should move with the monitor in place enhances her comfort and promotes normal labor.
4. Apply belts or stockinette if an adhesive ring is not used:
 - a. Slide both belts under the woman's back without the sensors attached. Be sure to keep the belts smooth under her back.
 - b. Cut a length of stockinette tubing about 15 to 18 inches long for the average-sized woman. Cut a longer length of wide stockinette for a heavier woman. Slide the stockinette up from her feet to her abdomen.

- c. An additional belt that is tied in a knot may apply pressure to the sensor to maintain ideal tilt against the woman's abdomen. A folded or rolled washcloth, roll of tape, or other simple techniques may be used to maintain the best tracing.

Smooth application of straps or stockinette enhances a woman's comfort and improves contact of external sensors with her abdomen. Good contact improves the quality of the tracing and may reduce the number of adjustments needed. "Tricks of the trade" may improve FHR tracings.
5. Use Leopold's maneuvers (see [Procedure 13-1](#)) to locate the fetal back as in intermittent auscultation (see [Procedure 14-1](#)).
6. Apply ultrasound gel to the Doppler ultrasound transducer, and place it on the woman's abdomen at the approximate location of the back of the fetus. Move the transducer until a clear signal is heard. Most bedside units have a green light or flashing heart shape to indicate a good signal. Gel eliminates air to improve sound transmission and reception of the ultrasound waves to provide more accurate data.
7. Place the uterine activity sensor in the fundal area or the area where contractions feel the strongest when palpated. This is often near the umbilicus for a term fetus. When the woman has a contraction, observe the tracing for the bell shape. The line for uterine activity is jagged because it also senses the rise and fall of the abdomen with breathing. Fetal or maternal movement, coughing, or sneezing causes a spike in the line. Observe through several contractions. The external uterine activity monitor senses the change in the abdominal contour as the uterus rotates forward with each contraction. Contractions are usually strongest in the fundus of the uterus. Observation of the uterine activity line (on the lower grid) through several contractions verifies correct placement and identifies needed changes in placement of the sensor.
8. Observe the strip for baseline FHR, presence of variability, periodic changes, and uterine activity (contraction duration and frequency). Palpate contractions for intensity and relaxation between contractions. Notify the physician or nurse-midwife of nonreassuring patterns or other concerns. Identify reassuring (normal) and nonreassuring (abnormal) FHR patterns (see [Table 14-1](#)). Contractions having a frequency greater than every 1½ minutes (or more than 5 contractions within 10 minutes), a duration longer than 90 to 120 seconds, a resting interval shorter than 30 seconds, or incomplete uterine relaxation between contractions may reduce maternal blood flow into the intervillous spaces and impair exchange of oxygen and waste products. The external uterine activity sensor is useful only for contraction frequency and duration. It is not accurate for actual intensity or uterine resting tone.

- Abdominal fat thickness—A thick layer of abdominal fat absorbs energy from uterine contractions, reducing their apparent intensity on the printed strip. The uterine activity recording of a thin woman whose uterus rotates sharply forward with each contraction may appear to be more intense than it actually is. Palpation with the nurse's fingertips may help clarify true intensity externally.
- Maternal position—Different maternal positions may increase or decrease the pressure against the transducer, changing the apparent intensity of contractions on the tracing.
- Location of the transducer—Uterine activity is best detected where it is strongest and where the fetus lies close to the uterine wall. This is usually over the fundus. Changes during contractions may not be detectable if the transducer is located elsewhere.

Devices for Internal Fetal Monitoring

Accuracy is the main advantage of using internal devices for EFM. However, their use requires ruptured membranes and about 2 cm of

cervical dilation. The devices are invasive, and the risk of infection is slightly increased.

Fetal Heart Rate Monitoring with a Scalp Electrode

The fetal scalp electrode (or spiral electrode) detects electric signals from the fetal heart ([Figure 14-6](#)). Fetal or maternal movement does not interfere with accuracy because the rate is calculated from electrical events in the fetal heart. The monitor unit generates a beeping sound with each fetal heartbeat, but this sound can be silenced, as can sounds from the Doppler transducer.

Although called a *fetal scalp electrode*, the device may be applied to the buttocks in a breech presentation. Areas to avoid for electrode application are the fetal face, fontanelles, and genitals. The electrode wire protrudes from the mother's vagina and is attached to a leg plate on her thigh. A cord from the leg plate connects to the bedside unit.

Because it barely penetrates the fetal skin (about 1 mm), the electrode is easily displaced. The tracing then becomes erratic or stops if

FIG 14-6 Internal Spiral Electrode and Intrauterine Pressure Catheter (IUPC). **A**, Parts of the fetal scalp electrode before it is applied. **B**, Fetal scalp electrode and IUPC in place and connected to the bedside monitor unit.

the electrode is fully detached. Secure attachment of the electrode is often difficult if the fetus has thick hair. The electrode is removed by turning it counterclockwise about one and one half turns until it detaches.

Uterine Activity Monitoring with an Intrauterine Pressure Catheter

Two kinds of intrauterine pressure catheters (IUPCs) can be used to measure uterine activity, including contraction intensity and resting tone:

- A solid catheter with a pressure transducer in its tip (Figure 14-7), which may have an additional lumen for **amnioinfusion**
- A hollow, fluid-filled catheter that connects to a pressure transducer on the bedside monitor unit

Both types sense intrauterine pressure and increases in intraabdominal pressure, as with coughing or vomiting.

The solid catheter is not affected by height because its transducer is in the catheter. However, the sensor in its tip measures hydrostatic pressure from the amniotic fluid above the fetal presenting part as well as the pressure from uterine activity. Therefore, recorded intrauterine pressures from the solid catheter are higher than those from the fluid-filled catheter, and the nurse must consider this fact when assessing

whether uterine activity is normal or hypertonic. Because it is simpler to use, the solid catheter is more commonly used.

The tip of the fluid-filled catheter in the uterus should be at the level of the transducer on the outside for best accuracy. If the tip is lower than the transducer, the recorded pressure is lower than the actual intrauterine pressure. If the tip is higher, the recorded pressure may be artificially high. Changes in the mother's position may alter the height of the catheter tip, requiring adjustment of the transducer's height.

EVALUATING INTERMITTENT AUSCULTATION AND PALPATION DATA

Data about FHR and uterine activity obtained by IA of the FHR and palpation of uterine activity should be evaluated in an orderly way to identify reassuring and nonreassuring signs. Some characteristics of FHR data obtained by IA are also evaluated when the data are obtained by EFM. However, characteristics unique to EFM strips, such as variability or deceleration patterns, should not be evaluated when IA is used (Feinstein et al., 2008; Harmon, 2009).

The baseline FHR is evaluated for the following:

- Rate, counting the FHR for at least 30 seconds between contractions
- Regularity of rhythm
- Absence of decrease from the baseline

A reassuring rate is between 110 and 160 bpm and regular. If the rate is within normal limits but has changed significantly from the

FIG 14-8 Electronic Fetal Monitor Strip Showing a Reassuring Pattern of Fetal Heart Rate (FHR) and Uterine Activity. The FHR baseline is 130 to 140 beats per minute (bpm); variability is about 10 bpm. There are no periodic changes in this strip. Contraction frequency is every 2 to 3 minutes, duration is about 50 to 60 seconds, intensity is 75 to 90 mm Hg with the internal spiral electrode, and uterine resting tone is approximately 10 mm Hg. (Courtesy of Corometrics Medical Systems, Inc., Wallingford, CT. Redrawn with permission.)

previous assessment, a longer listening period or more frequent assessments may clarify whether the rate is a change in the baseline or is a temporary increase or decrease. Accelerations in the rate may be heard and are a reassuring sign. An abrupt decrease in rate from the baseline rate is not reassuring and should be followed with other measures to clarify the fetal condition.

Contractions are palpated for frequency, duration, intensity, rest interval, and resting tone. If the fetus begins labor well oxygenated, then contractions that are no more frequent than every $1\frac{1}{2}$ minutes (or 5 within 10 minutes), are 90 to 120 seconds or less in duration, and have a resting interval of at least 30 seconds will allow adequate reoxygenation for the next contraction. Also, the uterus must fully relax for the intervillous spaces to refill with maternal oxygenated blood.

EVALUATION OF ELECTRONIC FETAL MONITORING STRIPS

The nurse evaluates the FHR tracing for baseline rate, variability, and presence of periodic changes. Uterine activity is evaluated by determining the frequency, duration, and intensity of contractions and by assessing uterine resting, or baseline, tone. FHR and uterine activity patterns must be evaluated together.

Other data are relevant to strip interpretation and interventions. Maternal vital signs, pulse oximeter data, maternal position and position changes, drug or oxygen administration, character of the amniotic fluid, labor status, and procedures performed are customarily recorded on the EFM strip.

Fetal Heart Rate Baseline

The FHR baseline is the average heart rate, rounded to 5 bpm, measured over 2 minutes of clear tracing within a 10-minute window. During this 2 or more minutes, the uterus must be at rest (Figure 14-8), and episodes of significant increases or decreases in rate must not occur. The baseline also excludes periodic and nonperiodic changes or segments of the baseline that differ by more than 25 bpm. The baseline rate is classified as follows (Cypher, 2009; Macones et al., 2008; NICHD, 1997):

- Normal—a rate that averages from 110 to 160 bpm. The preterm fetus at 26 to 28 weeks often averages a rate at the upper end of this range because the parasympathetic nervous system, which slows the rate, is immature. Some healthy full-term fetuses have a rate that averages 100 to 110 bpm.
- Bradycardia—less than 110 bpm, persisting for at least 10 minutes.
- Tachycardia—more than 160 bpm, persisting for at least 10 minutes. Some healthy term fetuses have bradycardia between 100 and 110 bpm with no other signs of compromise. A normal preterm fetus may have a baseline rate at the higher end of this range because the parasympathetic nervous system is immature.

Baseline Fetal Heart Rate Variability

Variability denotes the fluctuations in the baseline FHR within a 10-minute window that cause the printed line to have an irregular rather than a smooth appearance (Figure 14-9). Two types of variability, short-term and long-term, may be described in earlier research, but the NICHD consensus does not distinguish between the two types because they occur together (Macones et al., 2008; NICHD, 1997).

Variability occurs because multiple factors constantly speed and slow the fetal heart in a push-and-pull manner. Evaluation of variability helps to clarify how a fetus is tolerating the stress of labor, including factors that cause hypoxia. Variability is a significant component of the FHR tracing on the electronic monitor for two reasons:

- Adequate oxygenation promotes normal function of the autonomic nervous system and helps the fetus adapt to the stress of labor.
- Variability evaluates the function of the fetal autonomic nervous system, especially the parasympathetic branch.

Variability may be decreased by both nonpathologic and pathologic factors such as (Cunningham, Leveno, Bloom et al., 2010; Garite, 2012; Harman, 2009; Lyndon et al. 2009):

- Fetal sleep (usually lasting 40 minutes or less at term, but may last up to 2 hours)
- Narcotics or other sedative drugs such as magnesium sulfate given to the woman
- Alcohol, illicit drugs
- Fetal sepsis
- Fetal tachycardia

FIG 14-9 Contrasts in Fetal Heart Rate (FHR) Variability. A fetal scalp electrode is being used. **A**, Minimal variability (less than 3 beats per minute [bpm]). Note the smooth, flat line in the upper graph for the FHR. **B**, Moderate variability (average 20 bpm). Note the marked zigzag appearance of the FHR line compared with the flat appearance in **A**. (Courtesy of Corometrics Medical Systems, Inc., Wallingford, CT. Redrawn with permission.)

- Extreme prematurity
- Fetal anomalies that affect CNS regulation of the heart rate, such as anencephaly
- Hypoxia that is severe enough to affect the CNS
- Abnormalities of the CNS, heart, or both
- Maternal acidemia or **hypoxemia** (reduced blood oxygen, or low PO_2)
- The following descriptions classify variability in beats per minute:
 - Absent—undetectable
 - Minimal—undetectable to ≤ 5 bpm
 - Moderate—6 to 25 bpm
 - Marked— >25 bpm

Periodic Patterns in the Fetal Heart Rate

Periodic patterns are transient and recurrent changes from the baseline rate associated with uterine contractions. They include accelerations and decelerations. Periodic patterns are evaluated with baseline characteristics (rate and variability).

Accelerations

An acceleration is an abrupt, temporary increase in the FHR that peaks at least 15 bpm above the baseline and lasts at least 15 seconds (Figure 14-10). Accelerations often occur with fetal movement. They may be

nonperiodic (having no relation to contractions) as well as periodic. They may occur with vaginal examinations, uterine contractions, and mild cord compression and when the fetus is in a breech presentation. Accelerations are usually a reassuring sign, reflecting a responsive, nonacidotic fetus that is ≥ 32 weeks of gestation (Cunningham et al., 2010; Garite, 2012; Lyndon et al., 2009; Macones et al., 2008; NICHD, 1997).

The healthy preterm fetus may have accelerations that are less striking. Before 32 weeks of gestation, temporary increase in the FHR that peaks at least 10 bpm above the baseline and lasts at least 10 seconds is considered an acceleration. However, the younger preterm fetus may have the “15 bpm for 15 seconds” acceleration pattern that is expected at 32 weeks or more (Cunningham et al., 2010; Garite, 2012; Lyndon et al., 2009; Macones et al., 2008).

Accelerations lasting longer than 2 minutes but less than 10 minutes are prolonged accelerations. Accelerations that last longer than 10 minutes are a change in the baseline rate or may reflect a merging of several accelerations that later return to the previous baseline.

Decelerations

Periodic decelerations are classified into three types based on their shape and relationship to uterine contractions (Macones et al., 2008).

FIG 14-10 Acceleration of the Fetal Heart Rate. (Courtesy of Corometrics Medical Systems, Inc., Wallingford, CT. Redrawn with permission.)

CRITICAL TO REMEMBER

Differences between Early and Late Decelerations

Both Early and Late Decelerations

- Decrease from the baseline fetal heart rate and return to the baseline gradually (onset to nadir of at least 30 seconds).
- Occur with contractions.
- Rate decrease is rarely more than 30 to 40 beats per minute below the baseline.

Early Decelerations

- Are mirror images of the contraction (lowest point in the fetal heart rate occurs with the peak of the contraction).
- Return to the baseline fetal heart rate by the end of the contraction.
- Maternal position changes usually have no effect on pattern.
- Are associated with fetal head compression.
- Are not associated with fetal compromise and require no added interventions.

Late Decelerations

- Look similar to early decelerations but begin after the contraction begins (often near the peak).
- Nadir occurs after the peak of the contraction.
- Return to baseline after the end of the contraction.
- Reflect possible impaired placental exchange (uteroplacental insufficiency).
- Occasional late decelerations accompanied by moderate variability and accelerations are not ominous.
- Persistent late decelerations, especially with no accelerations and absent or minimal variability, should be addressed by nursing interventions to improve placental blood flow and fetal oxygen supply.
- The degree of fall in rate from baseline is unrelated to the amount of uteroplacental insufficiency.
- Should be addressed by nursing interventions to improve placental blood flow and fetal oxygen supply.

Early Decelerations. Fetal head compression briefly increases intracranial pressure, causing the vagus nerve to slow the heart rate. Early decelerations are not associated with fetal compromise and require no intervention. They occur during contractions as the fetal head is pressed against the woman's pelvis or soft tissue such as the cervix.

Early decelerations have a gradual, rather than abrupt, decrease from the baseline. They have a consistent appearance in that one early deceleration looks similar to others. The early decelerations mirror the contraction, beginning near its onset and returning to the baseline by the end of the contraction, with the low point (**nadir**) of the deceleration occurring near the contraction's peak (Figure 14-11). The rate at the lowest point of the deceleration is usually no lower than 30 to 40 bpm from the baseline.

Late Decelerations. Deficient exchange of oxygen and waste products in the placenta (uteroplacental insufficiency) may result in a pattern of late (delayed) decelerations. This nonreassuring pattern suggests that the fetus has reduced reserve to tolerate the recurrent reductions in oxygen supply that occur with contractions. The cause of uteroplacental insufficiency such as maternal hypotension may be acute. It may also occur with chronic conditions such as maternal hypertension and diabetes, which impair placental exchange.

Late decelerations are similar to early decelerations in the degree of FHR slowing and lowest rate (30 to 40 bpm) but are shifted to the right in relation to the contraction. They often begin after the peak of the contraction. The FHR returns to the baseline *after* the contraction ends (Figure 14-12). They have a consistent appearance. The FHR may remain in the normal range and may not fall much below its baseline level. The amount of rate decrease from the baseline is not related to the amount of uteroplacental insufficiency.

Variable Decelerations. Conditions that reduce flow through the umbilical cord may result in variable decelerations. These decelerations do not have the uniform appearance of early and late decelerations. Their shape, duration, and degree of fall below baseline rate vary. They fall and rise abruptly (within 30 seconds) with the onset and relief of cord compression, unlike the gradual fall and rise of early and late decelerations (Figure 14-13). Variable decelerations also may be non-periodic, occurring at times unrelated to contractions. The decrease in FHR is at least 15 bpm and lasts at least 15 seconds but less than 2 minutes (Cunningham et al., 2010; Garite, 2012; Macones et al., 2008).

Uterine Activity

Assessment of uterine activity involves four components: frequency, duration, and intensity of the contractions; and uterine resting tone (Macones et al., 2008). Contraction frequency may be measured with the electronic monitor as with palpation (beginning of one contraction to beginning of the next) or from peak to peak. Duration is calculated from the beginning to end of each contraction.

FIG 14-11 Early Decelerations. Note that the slowing of the fetal heart rate mirrors the contraction. It begins near the beginning of the contraction and returns to the baseline by the end of the contraction. Cause: fetal head compression. (Courtesy of Corometrics Medical Systems, Inc., Wallingford, CT.)

FIG 14-12 Late Decelerations. Note that the decelerations look similar to early decelerations but are offset to the right. They begin at about the peak of the contraction, and the nadir occurs well after the peak of the contraction, often during the interval. Cause: uteroplacental insufficiency. (Courtesy of Corometrics Medical Systems, Inc., Wallingford, CT. Redrawn with permission.)

FIG 14-13 Variable Decelerations. The decelerations are sharp in onset and offset. Note slight rate accelerations (shoulders) after each variable deceleration. Cause: umbilical cord compression. (Courtesy of Corometrics Medical Systems, Inc., Wallingford, CT. Redrawn with permission.)

CRITICAL THINKING EXERCISE 14-1

Nancy is having her labor induced with oxytocin and is having internal electronic fetal monitoring. Her contractions are, on average, 2 to 2.5 minutes apart, are 90 to 100 seconds in duration, and reach 75 mm Hg on the scale for the intrauterine pressure catheter. Uterine resting tone between contractions is about 20 mm Hg. The baseline fetal heart rate is 135 to 145 beats per minute (bpm) with about 7 bpm variability.

Nancy's nurse, Jackie, notes a pattern of uniform decelerations that begin at the peak of each contraction. The rate falls to 125 bpm before returning to the previous baseline about 30 seconds after the contraction ends.

Questions

1. What pattern does this describe?
2. What is the most appropriate nursing response? Why? If needed, are corrective actions urgent?

Palpation is used to estimate contraction intensity and uterine resting tone when an external uterine activity monitor is used (see [Procedure 13-2](#)). Contraction intensity is described as mild, moderate, or strong.

With either type of IUPC, the scale on the paper is used to describe intensity and resting tone. Intensity usually increases as labor progresses. Uterine contraction intensity with the IUPC is about 50 to 75 mm Hg during labor, although it may reach 110 mm Hg with pushing during the second stage. Average resting tone is 5 to 15 mm Hg.

Montevideo units (MVUs) may be used to describe contraction intensity in millimeters of mercury when an IUPC is used. The MVU is calculated by noting the contraction intensity in millimeters of mercury (mm Hg) above the resting tone and multiplying by the number of contractions in 10 minutes. For example, if a woman has three contractions in 10 minutes, each of which has an intensity of 110 mm Hg and a resting tone of 15 mm Hg, the result in MVUs is 285. Excess uterine activity during labor would be 400 MVUs ([Cunningham et al., 2010](#); [Harmon, 2009](#)).

CHECK YOUR READING

9. What is the significance of FHR accelerations?
10. What are the differences between early and late decelerations? Which pattern is nonreassuring?
11. Describe the appearance of variable decelerations. What is their cause?

SIGNIFICANCE OF FETAL HEART RATE PATTERNS

The 2008 NICHD conference report has divided interpretations into three categories to guide needed interventions. The previous two categories were reassuring and nonreassuring. The three categories of interpretation are as follows ([Macones et al., 2008](#)):

- Category I: Normal (reassuring)
- Category II: Indeterminate (often described as equivocal or ambiguous data)
- Category III: Abnormal (nonreassuring)

For category II patterns (equivocal or ambiguous patterns) or for questionable IA data, several methods may be used to further evaluate the fetal condition. [Table 14-1](#) summarizes reassuring and nonreassuring patterns.

Reassuring Patterns

Reassuring patterns such as normal rate and accelerations and absence of nonreassuring decelerations are associated with fetal well-being. No

intervention is required because the pattern suggests that the fetus has adequate reserves to tolerate intrapartum stressors.

Indeterminate Patterns

Indeterminate patterns, often referred to as *equivocal* or *ambiguous*, describe patterns that have elements of reassuring characteristics but also data that may be nonreassuring. Indeterminate patterns are termed *abnormal* in Canada at this time. Examples include the following ([Macones et al., 2008](#)):

- Tachycardia
- Bradycardia with presence of variability
- Minimal or marked baseline variability
- Absent variability with no recurrent decelerations
- Absence of accelerations after fetal stimulation
- Periodic or episodic variations such as the following:
 - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
 - Prolonged deceleration ≥ 2 minutes but < 10 minutes
 - Recurrent late decelerations with moderate baseline variability
 - Variable decelerations with other characteristics such as slow return to baseline and accelerations preceding or following (“overshoots,” or “shoulders”)

Nonreassuring Patterns

Nonreassuring, or abnormal, patterns occur if favorable signs are absent or if signs that are associated with fetal hypoxia or acidosis are

CRITICAL TO REMEMBER

Nursing Responses to Nonreassuring (Abnormal) Fetal Heart Rate Patterns

1. Identify the cause of the nonreassuring pattern to plan the best interventions:
 - Evaluate the pattern to determine its probable cause (late or variable decelerations, bradycardia or tachycardia, absent variability).
 - Evaluate maternal vital signs to identify hypotension, hypertension, or fever.
 - Perform vaginal examination to identify a prolapsed umbilical cord.
2. Stop oxytocin infusion if the drug is being administered.
3. Reposition the woman, avoiding the supine position, for FHR patterns associated with cord compression; repositioning may improve other nonreassuring patterns as well.
4. Increase the rate of a nonadditive intravenous fluid to expand the mother's blood volume and improve placental perfusion.
5. Administer oxygen by face mask at 8 to 10 liters per minute (L/min) to increase her blood oxygen saturation, making more oxygen available to the fetus.
6. Initiate electronic fetal monitoring if intermittent auscultation data are questionable.
7. Initiate continuous electronic fetal monitoring with internal devices if no contraindication exists.
8. Notify the physician or nurse-midwife as soon as possible. Report and document:
 - The pattern that was identified
 - Nursing interventions taken in response to the pattern
 - The fetal response after nursing interventions
 - The response of the physician or nurse-midwife (e.g., orders, other response)
9. If the nonreassuring pattern is severe, other staff members should begin preparing for immediate delivery (usually cesarean birth unless vaginal birth is imminent). Preparation for birth should include staff members for neonatal resuscitation.

TABLE 14-1 REASSURING (NORMAL) AND NONREASSURING (ABNORMAL) FETAL SURVEILLANCE ASSESSMENTS

Reassuring (Normal) Assessments

Baseline FHR: Stable, rate 110-160 beats per minute (bpm)

Moderate variability (6-25 bpm)

Accelerations: Peaking at least 15 bpm above the baseline with a duration of 15 seconds or more (10 bpm and 10 seconds if gestation 32 weeks or less)

Variable decelerations of less than 60 seconds with rapid return to baseline, accompanied by normal baseline rate and moderate variability

Uterine Activity:

Contraction frequency: No more frequent than every 1½ min (or 5 within 10 minutes)

Contraction duration: No longer than 90-120 seconds

Interval between contractions: At least 30 seconds

Uterine resting tone: Uterus relaxed between contractions (by palpation when intermittent auscultation or external fetal monitoring is used); uterine resting tone less than 20 mm Hg (with intrauterine pressure catheter)

Montevideo units: Less than 400

Nonreassuring (Abnormal) Assessments

PATTERN AND DESCRIPTION

POSSIBLE CAUSE OR CAUSES

Tachycardia

Baseline fetal heart rate (FHR) greater than 160 bpm for at least 10 min

Maternal fever (fetal tachycardia may precede fever or other signs of infection)
Maternal dehydration
Maternal or fetal hypoxia
Fetal acidosis
Maternal or fetal hypovolemia
Fetal cardiac dysrhythmias
Maternal severe anemia
Maternal hyperthyroidism
Drugs administered to mother (e.g., terbutaline, bronchodilators, decongestants, stimulant drugs)

Bradycardia

Baseline FHR less than 110 bpm for at least 10 minutes
Baseline rates between 100 and 110 bpm are usually not associated with fetal compromise if there are no nonreassuring patterns

Fetal head compression
Fetal hypoxia
Fetal acidosis
Fetal heart block
Umbilical cord compression
Late second-stage labor with maternal pushing

Decreased or Absent Variability

FHR baseline has a smooth, flat appearance

Fetal sleep episodes (usually 40 minutes or less; occasionally as long as 2 hours)
Fetal hypoxia with acidosis
Drug effects:
Central nervous system depressants
Local anesthetic agents

Late Decelerations

Gradual decelerations having a uniform appearance and a consistent relation to the contraction
Onset to nadir of 30 seconds or longer
Nadir occurs after the peak of the contraction

Uteroplacental insufficiency, which may be secondary to:
Maternal hypotension or hypertension
Excess uterine activity, spontaneous or stimulated
Placental interruption, such as abruptio placentae or placenta previa
Maternal diabetes
Maternal severe anemia
Maternal cardiac disease

Variable Decelerations

Sharp in onset and offset
May occur as a periodic or nonperiodic (random) pattern
Nonreassuring if:
Fall to less than 60 bpm for more than 60 seconds
Return to baseline prolonged
Overshoots (exceeding baseline after deceleration) are present
Accompanied by tachycardia, loss of variability, or both

Umbilical cord compression, which may be secondary to:
Prolapsed cord
Nuchal cord (around fetal neck)
Cord around fetal body parts
Oligohydramnios (abnormally small amount of amniotic fluid)
Cord between fetus and mother's uterus or pelvis, without obvious prolapse
Knot in cord

present. Nonreassuring patterns do not necessarily indicate that fetal hypoxia or acidosis has occurred. They indicate that steps should be taken to identify possible causes for the nonreassuring patterns and correct those causes.

Nonreassuring patterns are more significant if they occur together and are persistent. For example, bradycardia with variability of less than 3 bpm and late decelerations suggest greater fetal stress than bradycardia alone. Tachycardia is not typically persistent in the indeterminate category and may occur with other reassuring patterns. The healthy fetus may demonstrate occasional late decelerations, but a persistent pattern of late decelerations is more likely to represent compromise in a fetus, especially if it is combined with other nonreassuring patterns. Nonreassuring patterns include, but are not limited to, the following:

- Tachycardia
- Absent baseline variability
- Recurrent late decelerations
- Recurrent variable decelerations
- Bradycardia
- Hypertonic uterine activity, whether spontaneous or stimulated by drugs

Nonreassuring patterns do not always indicate that labor should end immediately. Several interventions may be used to clarify the fetal condition and to determine the best course of action. Other interventions can increase fetal oxygenation (Cunningham et al., 2010; Garite, 2012).

Clarification of Data

Two methods are used during the intrapartum period: vibroacoustic stimulation (VAS) and fetal scalp stimulation. Analysis of umbilical cord blood gases and pH is used immediately after birth.

Fetal scalp blood sampling for blood gases is less common. Fetal oxygen saturation monitoring had a brief trial with disappointing results and is no longer being done.

Vibroacoustic Stimulation. Vibroacoustic, or simply acoustic (or sound), stimulation may be used by the nurse, physician, or nurse-midwife as the initial method to stimulate the fetus or to supplement fetal scalp stimulation, or it may be used if scalp stimulation is contraindicated.

An artificial larynx or vibroacoustic stimulator is applied to the mother's lower abdomen, and it is turned on for up to 3 seconds. A reassuring response is an acceleration that peaks at 15 bpm for 15 seconds or more. An absent response, however, does not necessarily mean that the fetus is suffering from hypoxia or acidosis.

FIG 14-14 Fetal scalp stimulation helps identify whether the fetus responds to gentle massage. An acceleration in the fetal heart rate (FHR) peaking 15 beats per minute above the baseline suggests that the fetus is in normal oxygen and acid-base balance. Accelerations often occur with vaginal examination unrelated to a nonreassuring FHR pattern.

Fetal Scalp Stimulation. Scalp stimulation is used to evaluate the response of the fetus to tactile stimulation (Figure 14-14). The nurse, physician, or nurse-midwife may perform this procedure. The examiner applies pressure to the scalp (or other presenting part) with a gloved finger (or fingers) and sweeps the fingers in a circular motion. An FHR acceleration, as in VAS, is a reassuring response that suggests the fetus is in normal oxygen and acid-base balance. The acceleration may be delayed rather than immediate.

Fetal scalp stimulation is not done in some cases:

- Preterm fetus (may cause contractions)
- Prolonged rupture of membranes (higher risk of infection)
- Chorioamnionitis (intrauterine infection)
- Placenta previa (placenta overlies the cervix, and hemorrhage is likely)
- Maternal fever of unknown origin (possibility of introducing microorganisms into the uterus)

Fetal Scalp Blood Sample. Occasionally the physician may obtain a sample of fetal scalp blood to evaluate the pH. Normal scalp pH is 7.25 to 7.35. Scalp sampling is less common because it is invasive and the results are not available immediately.

Cord Blood Gases and pH. Umbilical cord blood analysis is used to assess the infant's oxygenation and acid-base balance immediately after birth. The samples are analyzed for pH; for partial pressure of carbon dioxide (PCO_2), partial pressure of oxygen (PO_2), and bicarbonate levels; and for base deficit. This information helps identify whether acidosis exists and whether it is respiratory (short-term), metabolic (prolonged), or mixed. Normal cord blood gases and pH can confirm that the fetus is adjusting normally to the stresses of labor, even though the fetal monitoring pattern may have been indeterminate or nonreassuring. Arterial cord blood best reflects fetal oxygenation because this blood is leaving the fetus on its way to the placenta.

The cord is promptly double-clamped (within 20 to 30 seconds of birth) and cut to isolate a 10- to 30-cm (4- to 12-inch) segment. Blood samples from an umbilical artery (deoxygenated) provide the most accurate information about the newborn's acid-base status. The sample can also be obtained from a fetal artery (oxygenated) on the surface of

CRITICAL THINKING EXERCISE 14-2

LaShonda is in active labor and is having external electronic fetal monitoring. LaShonda has not had medication, and her labor has been normal so far. Her membranes ruptured about 1 hour ago, and the amniotic fluid was clear. Contractions occur every 3 minutes, are 60 seconds in duration, and are of moderate intensity. Her uterus fully relaxes between each contraction.

The nursing student who is helping to care for LaShonda notes abrupt slowing of the fetal heart rate to about 90 beats per minute (bpm) during the next two contractions, each episode lasting about 30 seconds.

Questions

1. What pattern do these findings describe? What is the probable cause?
2. Are any nursing actions needed? Why? If nursing actions are needed, what are they, and in what order should they be done?

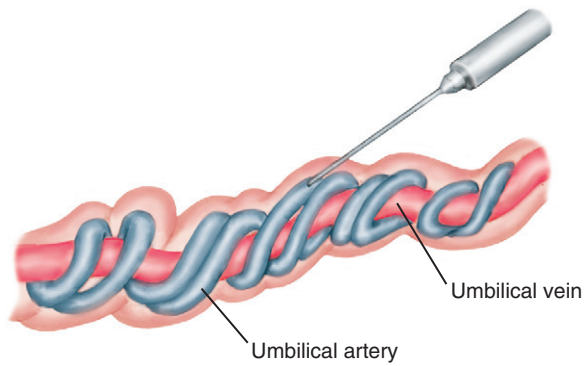

FIG 14-15 Obtaining a Blood Sample for Umbilical Cord Blood Gases and pH after Birth. Samples are drawn from the umbilical arteries, umbilical vein, or both. The samples in capped syringes may be kept for up to 60 minutes at room temperature and for 3 hours on ice.

the placenta. Blood is drawn into heparinized syringes to prevent coagulation, and the syringes are capped to avoid altering values by exposure to room air (Figure 14-15). Samples kept at room temperature are reliable for up to 60 minutes.

Interventions for Nonreassuring (Category III) Patterns

Any of several nursing or medical interventions, or both, may be indicated if a nonreassuring (abnormal) FHR pattern is present. All are directed toward identifying the cause of the nonreassuring pattern and improving fetal oxygenation with several possible interventions.

Identify the Cause. Careful examination of the strip may suggest a cause for the abnormal FHR pattern and direct the most appropriate interventions. For example, a pattern of late decelerations suggests uteroplacental insufficiency. However, uteroplacental insufficiency may be secondary to a variety of causes such as maternal hypotension or excessive uterine activity. Different causes require different corrective interventions. Checking the mother's vital signs identifies hypotension, hypertension, and fever. Maternal sedative medications may alter variability in a well-oxygenated fetus.

A vaginal examination may identify a prolapsed cord, which may cause variable decelerations, bradycardia, or both as the cord is compressed. A vaginal examination also evaluates the woman's labor status, which helps the birth attendant decide if labor should continue. For example, labor may be allowed to continue or it may be ended with forceps or a vacuum extractor if a nonreassuring pattern occurs during late labor. If the same nonreassuring pattern persisted during early labor despite interventions to correct it, a cesarean birth would be more likely.

Internal monitoring is often chosen for greater accuracy if a nonreassuring pattern develops when external devices are used. The fetal scalp electrode gives a clear picture of variability, and the IUPC allows the most precise determination of actual contraction intensity and resting tone.

Improve Fetal Oxygenation. Place the woman in the nonsupine position to eliminate aortocaval compression, which can reduce placental blood flow and add to maternal discomfort. Increasing infusion of nonadditive intravenous fluids such as lactated Ringer's solution increases the maternal blood volume to better perfuse the placenta if maternal hypotension is the problem.

Uterine activity reduces blood flow into the intervillous spaces, and a fetus with little reserve for stress may be unable to tolerate even normal contractions. Persistent hypertonic uterine activity may compromise a fetus with normal reserves. If a woman is receiving oxytocin,

it is discontinued or its rate may be slowed so that uterine activity is not stimulated. A **tocolytic** drug such as terbutaline (0.125 to 0.25 mg intravenously [IV] or 0.25 mg subcutaneously [SQ]), may be given to reduce uterine activity.

Increasing Maternal Blood Oxygen Saturation. Administration of 100% oxygen through a snug face mask makes more oxygen available for transfer to the fetus. A commonly suggested rate is 8 to 10 liters per minute (L/min).

Reducing Cord Compression. If cord compression is suspected, the woman is repositioned. She may be turned from side to side, or her hips may be elevated to shift the fetal presenting part toward her diaphragm. The hands-and-knees position may reduce cord compression on the cord that is entrapped behind the fetus. Several position changes may be required before the pattern improves or resolves.

Amnioinfusion increases the fluid around the fetus and cushions the cord. Lactated Ringer's solution or normal saline is infused into the uterus through an IUPC. The underpads must be changed regularly because fluid leaks out constantly. Possible complications include overdistention of the uterus and increased uterine resting tone. These complications are relieved by releasing some of the fluid. Amnioinfusion may be used to wash out and dilute fluid that contains thick meconium to reduce chances that the infant will aspirate it at birth, but research has not found amnioinfusion effective for this purpose.

APPLICATION OF THE NURSING PROCESS

■ Intermittent Auscultation and Electronic Fetal Monitoring

Assessment of the fetus using either IA or EFM requires additional education after entering the antepartum or intrapartum nursing specialty. The novice nurse or student usually provides care in the form of applying the external monitor, recording maternal vital signs, and assisting in position changes and ambulation. The experienced nurse should be notified promptly if questionable or nonreassuring findings such as bradycardia occur because they cannot always be anticipated.

The nurse may identify any of several nursing problems related to intrapartum fetal assessment. The woman or couple preferring a non-technical environment for birth may encounter a decisional conflict if EFM is routine in the birth facility. The woman may become anxious if she does not understand the data, if a change from IA is needed, or if complications develop. Pain may be increased and labor could be impeded by the reduced mobility that can occur with continuous EFM, even if the reduced mobility is self-imposed by the woman.

Two nursing care needs related to fetal assessment by either technique are the woman's (and support person's) learning needs and an expansion of nursing care related to fetal oxygenation. Care related to fetal monitoring by either auscultation or electronic means should be combined with that for normal or complicated intrapartum nursing, as needed.

FIG 14-16 The nurse teaches the woman and her partner about electronic fetal monitoring to limit her anxiety and promote her comfort during labor. The nurse should help the woman understand that the electronic fetal monitor is only one method used to evaluate the fetal well-being during labor.

LEARNING NEEDS

Assessment

Identify what the woman and her support person already know about auscultation and the electronic fetal monitor (Figure 14-16). Women who have attended prepared childbirth classes or have given birth before may have a basic understanding of the purpose and limitations of the fetal monitor. Identifying what patients already know allows you to build on their knowledge and correct any inaccurate information.

If the woman is not familiar with either technique of intrapartum fetal assessment, assess her perception of each. For example, does she believe that use of the electronic fetal monitor indicates the development of a complication, or does she expect its use? Is the woman comfortable with IA for fetal assessment or does she worry that something important will be missed?

Lack of knowledge contributes to anxiety. Note the anxiety level of the woman when the monitor is used. For example, is the woman afraid to move because the fetal heart sounds and tracing skip at that time? Does she place the monitor's data above her own comfort? Note questions about the monitor and its data, and then reassess after teaching to identify information that is still unclear or is causing anxiety.

Nursing Diagnosis

Many women expect to have continuous EFM during labor. They have often been introduced to it during prepared childbirth classes or have friends and family members who have had EFM. Most women have additional questions, however, and some women know little about this mode of fetal surveillance. Others may be quite surprised to learn that IA during birth is a valid choice.

Because of the prevalence of EFM for labor, the nursing diagnosis chosen for this discussion is "Deficient Knowledge: Fetal monitoring." A comparable nursing diagnosis could be made for the woman who has IA and palpation.

Planning

A goal for this nursing diagnosis is that, after being taught about intrapartum fetal surveillance, the woman and her partner will express understanding of the equipment, procedures, limitations, and expected data.

Interventions

Explain Fetal Heart Rate Auscultation with Uterine Palpation

Many women are surprised to know that auscultation and palpation are accepted modes of fetal surveillance during labor because they do not know anyone who had this "low-tech" approach. Explain that the frequency of assessment by either method varies with risk status and stage of labor. Also, explain that the physician or midwife may recommend EFM for several reasons and that this does not necessarily indicate a complication.

Explain the Electronic Fetal Monitor

Education continues as circumstances change. Explain the purposes of the monitor and the equipment to be used. For an uncomplicated birth, a simple explanation is to tell the parents that the monitor is a tool to assess how the fetus reacts to labor, especially during contractions. Reassure the woman that its use does not mean something is wrong with her baby. Explain why changes in the fetal assessment mode (e.g., from IA to EFM; from external to internal EFM) are made. Also helpful may be an explanation that the fetal monitor strip is only one of many factors evaluated during labor.

Address Parents' Safety Concerns

Explain how the equipment functions. Some women are afraid of being attached to an electrical device, especially because cords and electrodes are wet with amniotic fluid and vaginal secretions. Reassure the woman that the connections to her and those to the wall current are isolated from each other.

The woman may be concerned about attachment of the scalp electrode to the fetal presenting part. Show her that the electrode is a fine wire that penetrates the outer layer of skin only (about 1 mm, or the thickness of a dime). The IUPC lies beside the fetus, next to the inner wall of the uterus.

Coping with Misleading Data

Teach the woman that the monitor sometimes gives data that suggest a problem when no problem exists. For example, the FHR may suddenly fall to zero and the audible tone may stop if the sensor (external or scalp electrode) is displaced. The patient should call the nurse for adjustment or replacement of the sensor.

The woman may be discouraged because the curves representing contractions do not look as strong on the strip as they feel to her. This situation is common with use of an external transducer. Explain the factors that cause the contraction curves to appear stronger or weaker than they really are, for example, her position, the fetal position and size, or the amount of abdominal fat. Tell her the strip is used mainly to assess the timing of contractions and the reaction of the fetus to contractions when an external tocotransducer is used. Explain that an IUPC (internal fetal monitor) may be recommended if knowledge of true intrauterine pressure is crucial and if her membranes are ruptured.

Reassure the woman that her perception of her contractions and discomfort is important. Data from the woman are as important as the machine-generated data. Palpate contractions at intervals, and evaluate their appearance on the monitor strip.

Your attention is naturally drawn to the electronic fetal monitor when entering a woman's room. However, focus on the woman and her family, rather than devoting excessive attention to the monitoring equipment. The woman, not the monitor, is having the baby.

Include the Labor Partner

Tell the partner how to identify the onset and peak of contractions from the strip. During active labor, some women discover that

CASE STUDY 14-1 NURSING CARE PLAN*

Glenda is a 30-year-old African-American woman. She is a gravida 2, para 1, and has a 7-year-old son. Glenda had early and regular prenatal care. She had several biophysical profiles (BPP) during the last month of her pregnancy because of a slight blood pressure elevation.

ASSESSMENT: Glenda's labor is being induced with oxytocin (Pitocin) at 37 weeks of gestation because of preeclampsia. Her admission blood pressure was 148/94 mm Hg, and repeat assessments have been about the same level. Glenda's fetus will be monitored with electronic fetal monitoring. Glenda is accompanied by her husband, Paul. Glenda said they did not take classes because they felt that they remembered enough from their first birth. Chris is Glenda's intrapartum nurse.

Critical Thinking: *What nursing diagnosis is appropriate at this time? Should the nurse include Paul when considering the initial nursing diagnosis?*

Answer: *Although Glenda and Paul have had one successful pregnancy, the nurse should not assume that they know about current use of fetal monitoring in labor, because their son was born 7 years ago. The fact that they did not attend classes may mean they need teaching about electronic fetal monitors used in the labor unit if they are different from those used with her biophysical profiles.*

NURSING DIAGNOSIS: Deficient Knowledge: Electronic fetal monitoring

EXPECTED OUTCOMES: Glenda and Paul will state that they understand the reason for electronic monitoring, related equipment and procedures, and the data that are expected.

*Continues on p. 275.

contractions become intense before they can prepare for them. If this is the case, teach the support person to tell the woman when each contraction begins, to prepare her. This person can also encourage the mother by telling her when the peak has passed.

Enhance Comfort

Nursing care involves finding ways to make the mother comfortable and the monitor as nonintrusive as possible. Teach the woman ways to improve comfort while still allowing an adequate tracing to be obtained.

Explain that staying in one position not only is uncomfortable but also does not promote normal labor. The woman may assume any position except supine in most cases. She can sit in a chair, stand beside the bed, and assume most positions in the labor bed. She should find her most comfortable position; then the nurse can adjust the external devices to best detect contractions and the fetal heartbeat. Internal devices may be an option if external devices cannot be adjusted to provide useful data.

If the woman finds the sound produced by the electronic fetal monitor distracting or inconsistent with the atmosphere she wants, lower the sound or turn it off. The auditory cues for rate accelerations and decelerations are absent if the sound is muted, so the pattern on the strip must be noted.

If no other contraindications to walking exist, the woman may go to the bathroom to urinate or defecate. Unplug the sensors at the

INTERVENTIONS AND RATIONALES

1. Assess the parents' present knowledge and feelings about the common use of electronic fetal monitoring. *This builds on existing accurate knowledge and allows correction of misunderstandings. Therapeutic communication helps identify how the parents feel about use of this common technology in birth.*
2. Explain information about the monitor to Glenda and Paul. Reassure them that use of the fetal monitor does not mean something is wrong with Glenda or the baby.
 - a. Purpose: To record the fetal response to labor and guide interventions if nonreassuring patterns are identified. *This provides a realistic explanation of how the monitor is used.*
 - b. Safety: The monitoring sensors are electrically isolated from the wall current. The fetal scalp electrode (if used) penetrates the outer layer of skin, about a dime's thickness. The intrauterine pressure catheter lies between the baby and the wall of the uterus.
 - c. Encourage Glenda to call for assistance if she is concerned about anything related to the monitor, such as being unable to hear the fetal heartbeat. Tell her that a nurse will adjust her monitor as needed. *Sensors, especially external devices, are easily displaced. Preparing Glenda and Paul for this possibility reduces their fears if they should stop hearing the fetal heartbeat.*
 - d. Encourage Glenda to move about freely. Explain that she should urinate at least every 2 hours and that the nurse can help her roll the monitor to the bathroom door or temporarily disconnect the sensors. *Maternal movement and regular urination enhance normal labor processes. A woman is likely to become anxious and uncomfortable if she concentrates more on maintaining data from the monitor than on coping with labor.*

EVALUATION: Glenda and Paul say they expected electronic fetal monitoring during labor and are familiar with the external monitor because a similar model was used for the BPP. Glenda agrees to have internal monitoring if needed, saying that she understands that greater accuracy is important because of her higher risk status.

machine, let her walk to the bathroom, and reconnect and adjust the sensors when she returns. Alternatively, roll the machine to the door of the bathroom to keep the cords connected. Document ambulation and any interruption in monitoring on the strip. If the fetus has a nonreassuring pattern, it is preferable not to interrupt the recording. Computerized storage for EFM strips may result in setting off alarms when the monitor is disconnected, even for a short time.

Evaluation

The evaluation of knowledge is continuous because most women think of questions after initial explanations and as conditions change. Achievement of the goal or expected outcome is evident if the partners indicate their understanding after each explanation. Their understanding also may be accompanied by a decrease in signs of anxiety.

FETAL OXYGENATION

Assessment

Evaluate the fetal monitoring strip systematically for the elements noted previously. The following are recommended assessment and documentation intervals for both IA and EFM, although facility policies may be different:

- Low-risk women—every 30 minutes during the active phase and every 15 minutes during the second stage

PARENTS WANT TO KNOW

About Electronic Fetal Monitoring

When women have electronic fetal monitoring during labor, they often have questions that the nurse may answer. Here are some frequently asked questions and suggested answers.

Can I move around with the monitor?

You can move freely with the monitor. If you notice that you can't hear the fetal heart sounds or see the contractions as well, call me and I'll readjust it. Make yourself comfortable; then we'll adjust the machine, if necessary.

What if I need to go to the bathroom?

If you need to go to the bathroom, we'll unplug the cords from the machine, or we can roll the monitor to the door of the bathroom, and you can walk in there.

Will the monitor shock me? I don't know if I want to be hooked to an electrical outlet, especially because my water has broken and I have bloody show.

The part of the monitor that is attached to you and your baby transmits information only into the machine for processing. The sensors on your body are separated from electrical parts in the monitor.

Why is the baby's heart beating so fast?

A baby's heart normally beats faster than an adult's, both before and after birth. The normal rate for the baby is about 110 to 160 beats per minute. A rate outside these boundaries does not always mean that the baby has a problem, but we do look at the monitor strip closely to see if we need to check for other problems.

Why do those numbers for the baby's heart rate change so much?

The heart rate of a healthy baby near full term who is awake changes constantly. When the baby moves, the heart speeds up, just as yours does. When the baby sleeps the rate slows and is steadier.

What do those numbers for contractions (external monitor) mean? They change all the time.

The numbers reflect a change in the pressure that the monitor senses. The monitor senses many changes in pressure other than those from contractions, such as changes from breathing, coughing, laughing, or movement of you or the baby.

My contractions don't look very strong, but they sure feel strong to me! (External uterine activity monitor is being used.)

The external monitor senses contractions indirectly, rather than sensing the actual pressure within the uterus. Their appearance on the tracing varies because of many factors, such as your position, the position of the sensor on your abdomen, and the thickness of your abdominal wall. You may notice spikes on the line and the sound of a "bump" at regular intervals when the baby has hiccups, which is very common.

Will the internal monitor hurt my baby?

The spiral electrode attaches only to the outer layer of skin on the baby's head. We are careful to avoid sensitive areas on the head such as the fontanelles (soft spots) or the face. The uterine catheter slides up beside the baby.

TABLE 14-2 GUIDELINES FOR ASSESSMENT AND DOCUMENTATION OF FETAL HEART RATE USING AUSCULTATION

WOMEN WITHOUT RISK FACTORS	WOMEN WITH RISK FACTORS PRESENT ON ADMISSION OR THAT DEVELOP DURING LABOR
<p>Active First-Stage Labor</p> <p>At least every 30 minutes, just after a contraction</p>	At least every 15 minutes, just after a contraction
<p>Second-Stage Labor</p> <p>At least every 15 minutes</p>	At least every 5 minutes
<p>Other Times to Document Fetal Heart Rate</p> <ul style="list-style-type: none"> • Before artificial rupture of the membranes; after rupture of the membranes, either artificially or spontaneously • Before and after ambulation • If contractions become too frequent or last too long or if there is an inadequate interval between them • Before administration of oxytocin and when evaluating the dose for increase, maintenance, or decrease • Before administration of sedative medications or central nervous system depressants and at time of peak action • Before epidural analgesia is started and every 15 minutes for 1 hour after it is started 	

- High-risk women—every 15 minutes during the active phase and every 5 minutes during the second stage

Guidelines from the American College of Obstetricians & Gynecologists (AAP & ACOG, 2012; ACOG, 2009) specify a more frequent assessment of the FHR and do not distinguish between frequency for low- and high-risk women:

- Active first-stage labor—every 15 minutes
- Second-stage labor—every 5 minutes

See Table 14-2 for other times when the FHR should be evaluated and documented.

Take the woman's temperature every 4 hours (every 2 hours after membranes rupture). Maternal fever increases the fetal temperature

and fetal oxygen requirements. The nurse should assess the woman's pulse rate, respirations, and blood pressure hourly. Hypotension or hypertension may reduce maternal blood flow to the intervillous spaces.

Assessment of mother and fetus is continuous during the dynamic process of labor. Compare data about FHR patterns, uterine activity, and maternal vital signs with baseline data and normal ranges. Observe for subtle trends in the data, and distinguish between patterns that have similar appearances, for example, early and late decelerations.

Vaginal examination may be performed to evaluate specific FHR patterns, for example, to check for a prolapsed cord if a pattern of variable decelerations persists (see p. 591).

Nursing Diagnosis

The collaborative problem “Potential Complication: Fetal Compromise” is selected for nursing care related to fetal oxygenation when EFM is used.

Planning

Because the nurse does not manage fetal compromise independently, fetal goals are not made. The nurse’s responsibility includes planning to do the following:

- Promote adequate fetal oxygenation.
- Take corrective actions to increase fetal oxygenation if nonreassuring patterns are identified.
- Report nonreassuring patterns to the physician or nurse-midwife.
- Support the woman and her partner if a complication develops.
- Document assessments and care.

Interventions

Measures to promote fetal oxygenation are also discussed with the care of the woman in normal labor (see [Chapter 13](#)) and the woman having an epidural or subarachnoid block (see [Chapter 15](#)).

Take Corrective Actions

The priority of nursing care is to improve fetal oxygenation. If a nonreassuring pattern is noted, identify its cause and improve fetal oxygenation (see p. 254). Birth facilities have protocols to give nurses a framework for steps to take if nonreassuring patterns develop. Nursing interventions may include both independent nursing actions and delegated medical actions.

Reassure Parents

Parents understandably become anxious when a nonreassuring pattern occurs. Remain calm at the bedside to avoid increasing their anxiety. The call signal can be used to summon other nurses to help with corrective actions and to notify the physician or nurse-midwife if it is impossible to leave.

Explain any problems and the reason for corrective actions in simple, concise language. Severe anxiety reduces the parents’ ability to understand information. Inform them if the FHR returns to a reassuring pattern. Some corrective actions such as oxygen administration and positioning may continue after a reassuring pattern returns. Tell the woman she may talk while wearing the oxygen mask. Document parental response to teaching about care for nonreassuring patterns.

Notify Birth Attendant

Notify the birth attendant of nonreassuring patterns as soon as possible after taking corrective actions or have a co-worker notify the birth attendant. In addition, document the time and content of all consultations with the physician or nurse-midwife as well as the birth attendant’s response.

Document Assessments and Care

Record data related to fetal well-being according to facility policy. [Box 14-2](#) shows guidelines for documentation on the monitor and labor records. Documentation and charting may be done on computer media rather than paper. Recording data carefully can demonstrate good nursing care and show that the standard of care has been met.

Record the woman’s name, the date, and the time on the paper or electronic strip when electronic fetal monitoring begins. If a break in the paper strip occurs, for example, to change paper, label the new strip with the woman’s name, the date, and the time. Record the last panel number of the previous strip on the new strip so that the entire record can be reassembled sequentially.

BOX 14-2 DOCUMENTING ELECTRONIC FETAL MONITORING

Documentation When Monitoring is Initiated

Monitor Strip

Woman’s name and hospital or other permanent identifying number
 Physician’s or nurse-midwife’s name
 Date and time of admission
 Date and time monitoring begins (verify accuracy of electronic monitor date and time)
 Gravidity, parity, abortions, living children
 Gestation in weeks
 Presence of identified risk factors
 Character of amniotic fluid (when membranes rupture)
 Function test of monitor accuracy
 Initial mode of monitoring (external or internal devices)

Labor Record (if Paper-Only Documentation)

Same information as on monitor strip
 First panel number when a printed paper strip begins

Continuing Documentation

Monitor Strip

Maternal vital signs at appropriate intervals for stage of labor, membrane status, and interventions such as labor stimulation or pain management measures
 Notations of strip review at intervals appropriate for risk factors and labor status (see [Table 14-2](#))
 Vaginal examinations, including cervical dilation and effacement and fetal station
 Rupture of membranes (spontaneously or artificially)
 Color, quantity, and character (such as foul odor, cloudiness) of amniotic fluid
 Maternal position changes
 Maternal or fetal movement that affects tracing
 Maternal vomiting, coughing, or other movement that affects tracing
 Summaries while pushing in second stage
 Equipment adjustments, problems maintaining continuous tracing (such as an active fetus)
 Medication and anesthesia, including related interventions
 Changes of equipment mode, such as external to internal device
 Interventions for nonreassuring patterns and maternal-fetal response
 Interruptions such as the woman walking

Labor Record

Same information as on monitor strip
 Periodic summary of maternal vital signs, baseline rate, variability, periodic changes, and uterine activity (frequency, duration, and intensity of contractions and uterine resting tone)
 Nonreassuring maternal or fetal assessments, interventions, responses, provider notification, provider response
 Actions taken in chain of command if the physician or nurse-midwife does not respond appropriately to the nurse’s report of a problem

Note: Some of these actions may be entered automatically with electronic fetal monitor and computer interfaces.

Continue documenting the heart rate and maternal observations until vaginal birth occurs. If a cesarean birth is needed, continue monitoring by auscultation or electronic means as long as practical while preparing the woman for surgery. Remove internal devices before securing her legs to the operating table with a strap. Document the time at which monitoring is stopped and the time of abdominal incision. (See [Case Study 14-1](#), beginning on p. 272.)

CASE STUDY 14-1 NURSING CARE PLAN*

ASSESSMENT: Chris applies the external fetal monitor, which shows irregular spontaneous contractions. The fetal heart rate (FHR) baseline averages 125 to 135 beats per minute (bpm) with accelerations. The nurse begins an oxytocin infusion to induce labor. Glenda's blood pressure is 160/96 mm Hg, pulse rate is 76 bpm, and respirations are 18 per minute.

Critical Thinking: Does the nurse need other data at this point?

Answer: Added information would help clarify whether the elevation in Glenda's blood pressure is in response to anxiety or pain or is a part of her preeclampsia. Rechecking her blood pressure, possibly manually for greater accuracy, after she has had a few minutes to rest after the oxytocin is started would provide more information for Glenda's clinical picture. The nurse should assess Glenda for hyperactive reflexes and edema, particularly of her face and fingers (see Chapters 13 and 25).

POTENTIAL COMPLICATION: Fetal compromise

EXPECTED OUTCOMES: Expected outcomes for the fetus are inappropriate because nurses cannot independently manage fetal compromise. The nurse's planning for Glenda should reflect the need to do the following:

1. Compare FHR and uterine activity data with baseline levels before oxytocin induction.
2. Promote normal fetal oxygenation.
3. Take corrective actions for nonreassuring patterns.
4. Notify Glenda's physician if nonreassuring patterns develop.

INTERVENTIONS AND RATIONALES

1. Identify relevant risk factors for fetal compromise. *Development of preeclampsia is a risk factor that means Glenda should have increased frequency of maternal and fetal assessments.*
2. Encourage Glenda to assume any comfortable position other than the supine position. Teach her that vertical positions promote descent of her baby. Encourage her to change positions regularly, about every half hour. *The supine position can reduce blood return to the heart by compressing the inferior vena cava. Compression of the aorta and reduced cardiac output reduce placental perfusion. Regular changes of position promote normal labor progress and comfort.*
3. Evaluate the tracing at the following times, signing or initialing the paper strip or using computer documentation each time. Document a summary of the evaluation on the labor record.
 - a. Every 15 minutes during the first stage and every 5 minutes during the second stage. *Glenda's situation involves a high-risk pregnancy, and the fetus should be evaluated by those guidelines.*
 - b. Before and after procedures such as amniotomy, medications, epidural anesthesia because *rupture of membranes (spontaneously or by amniotomy) may result in cord compression. Medications may alter the rate or variability of the fetal heartbeat. Epidural anesthesia may cause hypotension, which can decrease uteroplacental perfusion.*

- c. With changes of activity such as urination and repositioning because *such changes could alter the uterine or umbilical cord blood flow. Sensors may slip and need adjustment with activity.*
4. Document(s) stating that assessment was done. *Documenting on both strip and labor record allows each to stand alone (if that is facility policy).* Use a four-step approach to evaluate the strip to make a systematic framework that allows evaluation of the fetal response to labor.
 - a. Baseline FHR: *Tachycardia may be an early response to hypoxia. Bradycardia may occur in response to vagal stimulation or prolonged hypoxia.*
 - b. Variability: *Normal variability suggests that the fetus is well oxygenated and not in acidosis.*
 - c. Periodic changes: Accelerations, decelerations. (Note the relationship of periodic changes to fetal movement, contractions, and the woman's status and activity. Note nonperiodic [random] accelerations or variable decelerations.) *Accelerations are a reassuring sign of fetal well-being. Early decelerations are a response to head compression. Late (uteroplacental insufficiency) and variable (umbilical cord compression) decelerations are nonreassuring. The nurse should attempt to identify their cause, correct it if possible, and take steps to improve fetal oxygenation.*
 - d. Uterine activity: Evaluate frequency and duration using either external or internal devices. When external uterine activity monitoring is done, palpate three or more contractions. Note whether the uterus relaxes between contractions for at least 60 seconds. If an intrauterine pressure catheter is used, read contraction intensity and uterine resting tone from scale on strip. Calculate Montevideo units (MVUs) if that is the policy in the facility. *The presence of contractions that are too long (more than 90 to 120 seconds in duration) or too frequent (closer than every 2 minutes), a resting interval of less than 30 seconds, or a baseline (resting) intrauterine pressure of more than 20 mm Hg reduces the time available for normal uteroplacental exchange. Because of diabetes and pregnancy-induced hypertension, uteroplacental exchange may be reduced before labor begins. Oxytocin stimulates uterine activity and adds to risk.*
5. If nonreassuring patterns develop, take appropriate corrective actions such as discontinuing the oxytocin, increasing the rate of the nonadditive intravenous solution, repositioning Glenda, and administering oxygen. Notify the physician of nonreassuring patterns, corrective actions taken, and the fetal response. Document assessments, interventions, and physician response. Implement new orders. *The first priority is to identify the cause of the nonreassuring pattern and improve fetal oxygenation. The physician should be notified of the maternal-fetal status for needed medical orders or additional interventions as soon as possible.*

EVALUATION: Goals are not established for collaborative problems. Chris compared data from the fetal monitor and other nursing evaluations with the baseline data before Glenda started receiving oxytocin to start contractions. For the first 4 hours of the oxytocin induction, the FHR continued near its baseline of 125 to 135 bpm, with variability averaging 10 bpm. FHR accelerations continued. No nonreassuring patterns were noted.

*Continued from p. 272; continues on p. 276.

CASE STUDY 14-1 NURSING CARE PLAN*

ASSESSMENT: The physician ruptures Glenda's membranes and inserts internal devices for the fetal heart rate (FHR) and uterine activity. Glenda's blood pressure is 145/90 mm Hg, and her oxytocin infusion continues. She is having contractions every 4 minutes; they are of 50 seconds' duration and 50 mm Hg intensity, and she has a uterine resting tone of 10 mm Hg. One hour after Glenda's membranes are ruptured, Chris notes that the baseline FHR has risen to approximately 150 beats per minute (bpm) with variability averaging 5 bpm or greater. A pattern of repeated late decelerations develops. Chris stops the oxytocin infusion and increases the rate of lactated Ringer's intravenous fluid, positions Glenda on her left side, and administers 100% oxygen at 10 liters per minute (L/min) with a snug face mask. The physician is notified. Baseline variability improves to 10 bpm, but repeated late decelerations continue. Glenda is holding Paul's hand tightly and breathing rapidly. Her vital signs are blood pressure, 158/96 mm Hg; pulse rate, 90 bpm; respirations, 32 per minute. Uterine activity is unchanged.

Critical Thinking: What new nursing diagnosis or collaborative problem seems apparent based on the latest assessment data? Why?

Answer: Glenda displays several behaviors typical of anxiety: rapid pulse and respiratory rates and gripping her husband's hand. The rise in her blood pressure could be due to anxiety, the disease process, or pain. Because of added complications and the minimal improvement in fetal status superimposed on Glenda's higher-risk status, anxiety seems appropriate. Helping her control her anxiety can promote a more normal labor as well as make her more comfortable.

NURSING DIAGNOSIS: Anxiety related to unexpected development of complications

EXPECTED OUTCOMES

1. Glenda will have a reduced respiratory rate (12-20/min) after interventions.
2. Glenda will have a more relaxed face and body posture after interventions.

INTERVENTIONS AND RATIONALES

1. Maintain calm behavior while performing corrective actions and notifying the physician. *Calm behavior nonverbally communicates competence to parents.*

Anxious behavior on the part of caregivers tends to increase the parents' anxiety.

2. Use simple, concise language for all explanations. *High anxiety or intense physical sensations impair a person's ability to comprehend explanations.*
3. Explain the problem to Glenda and Paul to help them understand what is happening and why the corrective actions are taken so that they are more likely to comply with the care.
 - a. The problem that was identified
 - b. The usual cause of the problem
 - c. Reasons for corrective actions
 - d. Expected results*Knowledge decreases fear of the unknown.*
 - e. Tell Glenda that she can talk while wearing the oxygen mask. *Assuring Glenda that she can talk while wearing the oxygen mask allows her to ask questions and express feelings to reduce anxiety and fear.*
4. Inform Glenda and Paul if the pattern improves or is resolved. For example, tell them when baseline variability improves and that the fetal pulse oximetry readings remain normal. *This decreases anxiety about the condition of the fetus.*
5. Ask Glenda if another position might be more comfortable or if she needs an analgesic drug. *Pain can increase anxiety and raise blood pressure, possibly reducing placental perfusion.*
6. Allow Glenda and Paul to express their feelings about the labor and birth during the postpartum period. Explain any gaps in their understanding about what happened. *This helps the couple accept and put unexpected occurrences in perspective. It decreases the possibility that one or both parents feel like "a failure" if emergency intervention (cesarean birth) became necessary.*

EVALUATION: Glenda requested an epidural and quickly became more comfortable. Over the next hour, the FHR pattern gradually improves. Her contraction pattern is unchanged. The baseline FHR slows (130 to 140 bpm), and late decelerations are sporadic. Accelerations are frequent. Baseline variability improves to 15 bpm, and fetal pulse oximetry readings remain in the normal range. Glenda gradually relaxes her grip on Paul's hand, and her body relaxes. Her respiratory rate slows to 20 breaths per minute. Glenda requires a cesarean birth because her cervix does not dilate to greater than 7 cm, despite adequate contractions and frequent position changes.

*Continued from p. 275.

SUMMARY CONCEPTS

- The purpose of intrapartum fetal assessment is to identify fetal well-being and to identify the fetus who may be having hypoxic stress beyond the ability to compensate for it.
- The two approaches to intrapartum fetal assessment are intermittent auscultation with palpation of uterine activity and electronic fetal monitoring. Each type has advantages and limitations. Electronic fetal monitoring has not been shown to be superior to auscultation with palpation, but more staff may be needed to achieve safe, intermittent auscultation with palpation.
- Fetal oxygenation depends on a normal flow of oxygenated maternal blood into the placenta, normal exchange within the placenta, patent umbilical cord vessels, and normal fetal circulatory and oxygen-carrying function.
- Stimulation of the sympathetic nervous system increases the FHR and strengthens the heart contraction. Stimulation of the parasympathetic nervous system slows the heart rate and maintains short-term variability. The parasympathetic nervous system matures later than the sympathetic, beginning at about 28 to 32 weeks of gestation.
- An advantage of the fetoscope over Doppler ultrasound devices is that the fetoscope assesses actual fetal heart sounds and therefore can be used to reliably identify fetal cardiac dysrhythmias. Doppler devices sense cardiac motion and convert the motion into sound that represents the cardiac activity.
- External electronic fetal monitoring is less accurate for fetal heart rate and uterine activity patterns than internal monitoring, but it is noninvasive.
- Greater accuracy is the main advantage of internal electronic fetal monitoring devices.
- Nursing responsibilities related to intrapartum fetal monitoring include promoting fetal oxygenation, identifying and reporting nonreassuring findings, supporting parents, communicating with the physician or nurse-midwife, and documenting all care.

Pain Management during Childbirth

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Compare childbirth pain with other types of pain.
2. Describe the way excessive pain can affect the laboring woman and her fetus.
3. Examine how physical and psychological forces interact in the laboring woman's pain experience.
4. Describe use of nonpharmacologic pain management techniques in labor.
5. Describe the way medications may affect a pregnant woman and the fetus or neonate.
6. Identify benefits and risks of specific pharmacologic pain control methods.
7. Explain nursing care related to different types of intrapartum pain management, both nonpharmacologic and pharmacologic.

Each woman has unique expectations about birth, including expectations about pain and her ability to manage it. The woman who successfully deals with the pain of labor is more likely to view her experience as a positive life event. A woman's experience with labor pain varies with several physical and psychological elements, and each woman responds differently. Nonpharmacologic and pharmacologic methods offer a selection of pain management techniques from which the laboring woman may choose.

UNIQUE NATURE OF PAIN DURING BIRTH

Pain is a universal experience but is difficult to define. It is an unpleasant sensation of distress resulting from stimulation of sensory nerves. Pain involves two components:

- A physiologic component, which includes reception by sensory nerves and transmission to the central nervous system
- A psychological component, which involves recognizing the sensation, interpreting it as painful, and reacting to the interpretation

Pain is subjective and personal. No one can feel another's pain. Evidence of pain is a person's reaction to it. Childbirth pain, however, differs from other types of pain in several important respects:

- It is part of a normal process. Childbirth pain is part of a normal process, whereas other types of pain are connected with injury or illness. Pain may lead a woman to assume different positions in labor, favoring descent of the fetus through her pelvis.
- Preparation time exists. The pregnant woman has several months to prepare for labor, including acquiring skills to help manage pain. Realistic preparation and knowledge about the birth process help her develop skills to cope with labor pain.
- It is self-limiting. Labor pain has a foreseeable end. Although it is intense, a woman can expect her labor to end in hours, rather than days, weeks, or months. Other kinds of pain may also be brief, but the baby's birth brings a rapid decrease in pain.
- Labor pain is not constant, but intermittent. A woman may describe little discomfort with contractions during early labor. Even during late labor, a woman may be relatively comfortable between contractions.
- Labor ends with the birth of a baby. The emotional significance of the child's birth cannot be ignored when trying to understand a woman's response to pain. Care about her fetus often motivates a woman to tolerate more pain during labor than she otherwise might be willing to endure.

ADVERSE EFFECTS OF EXCESSIVE PAIN

Although expected during labor, pain that exceeds a woman's tolerance can have harmful effects on her and the fetus.

Physiologic Effects

Excessive pain can heighten a woman's fear and anxiety, which stimulates sympathetic nervous system activity and results in increased secretion of catecholamines (epinephrine and norepinephrine). Catecholamines stimulate alpha and beta receptors, causing effects on the blood vessels and uterine muscles. Epinephrine stimulates both alpha and beta receptors, whereas norepinephrine stimulates primarily alpha receptors.

Stimulation of the alpha receptors causes uterine and generalized vasoconstriction and an increase in the uterine muscle tone. These effects reduce uterine blood flow as they raise the maternal blood pressure.

Stimulation of the beta receptors relaxes the uterine muscle and causes vasodilation. However, uterine vessels are already dilated in pregnancy, so dilation of other maternal vessels allows the woman's blood to pool in them. The pooling of blood reduces the amount of blood available to perfuse the placenta.

The combined effects of excessive catecholamine secretion are as follows:

- Reduced blood flow to and from the placenta, restricting fetal oxygen supply and waste removal
- Reduced effectiveness of uterine contractions, slowing labor progress

Labor increases a woman's metabolic rate and her demand for oxygen. Pain and anxiety increase her already high metabolic rate. She breathes fast to obtain more oxygen, exhaling too much carbon dioxide in the process. Significant changes, more than those expected during labor, can occur in the woman's partial pressure of oxygen (P_{aO_2}) and partial pressure of carbon dioxide (P_{aCO_2}) levels and in her arterial pH. These maternal respiratory and metabolic changes alter placental exchange significantly if they are persistent. The fetus may have less oxygen available for uptake and have less ability to unload carbon dioxide to the mother. The net result is that the fetus shifts to anaerobic metabolism, with buildup of hydrogen ions (acidosis). This type of acidosis is metabolic and does not resolve as quickly after birth as respiratory acidosis, which results from shorter periods of hypoxia.

Psychological Effects

Women have a surprising tolerance for labor pain. However, poorly relieved pain lessens the pleasure of this extraordinary life event for both partners. The mother may find it difficult to interact with her infant because she is depleted from a painful labor. Unpleasant memories of the birth may affect her response to sexual activity or another labor. Her support person may feel inadequate during birth. The woman's partner may feel helpless and frustrated when her pain is unrelieved.

VARIABLES IN CHILDBIRTH PAIN

A variety of physical and psychosocial factors contribute to a woman's pain response during labor. These factors provide possibilities for nursing interventions for pain relief.

Physical Factors

Childbirth pain is of two types—visceral and somatic. Visceral pain is a slow, deep, poorly localized pain that is often described as dull or aching. Visceral pain dominates during first-stage labor as the uterus contracts and the cervix dilates.

Somatic pain is a quick, sharp pain that can be precisely localized. Somatic pain is most prominent during late first-stage labor and during second-stage labor as the descending fetus puts direct pressure on maternal tissues.

Sources of Pain

Four sources of labor pain exist in most labors. Other physical factors may modify labor pain, increasing or decreasing it.

Tissue Ischemia. The blood supply to the uterus decreases during contractions, leading to tissue hypoxia and anaerobic metabolism. Ischemic uterine pain has been likened to ischemic heart pain.

Cervical Dilation. Dilation and stretching of the cervix and lower uterus are a major source of pain. Pain stimuli from cervical dilation travel through the hypogastric plexus, entering the spinal cord at the T10, T11, T12, and L1 levels (Figure 15-1).

Pressure and Pulling on Pelvic Structures. Some pain results from pressure and pulling on pelvic structures such as ligaments, fallopian tubes, ovaries, bladder, and peritoneum. The pain is a visceral pain; a woman may feel it as referred pain in her back and legs.

Distention of the Vagina and Perineum. Marked distention of the vagina and perineum occurs with fetal descent, especially during the second stage. The woman may describe a sensation of burning, tearing, or splitting (somatic pain). Pain from vaginal and perineal distention and pressure and pulling on adjacent structures enters the spinal cord at the S2, S3, and S4 levels (see Figure 15-1).

Factors Influencing Perception or Tolerance of Pain

Although physiologic processes cause labor pain, a woman's tolerance of pain is affected by other physical influences.

Labor Intensity. The woman who has a short, intense labor may complain of severe pain because each contraction does so much work

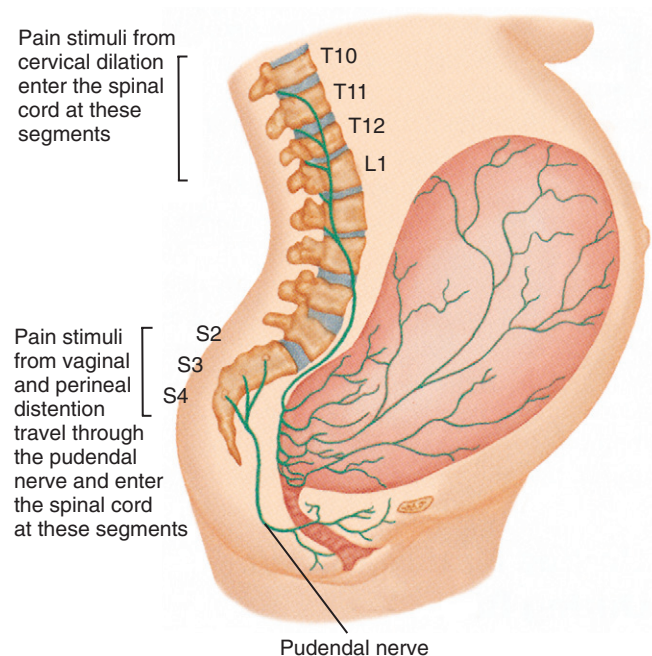

FIG 15-1 Pathways of Pain Transmission during Labor.

(effacement, dilation, and fetal descent). A rapid labor may limit her options for adequate pharmacologic pain relief as well.

Cervical Readiness. If prelabor cervical changes (softening, with some dilation and effacement) are incomplete, the cervix does not open as easily as it does when it is soft and dilation and effacement have begun. More contractions are needed to achieve dilation and effacement, resulting in a longer labor and greater fatigue in the laboring woman.

Fetal Position. Labor is likely to be longer and more uncomfortable when the fetus is in an unfavorable position. An occiput posterior position is a common variant seen in otherwise normal labors. In this position, each contraction pushes the fetal occiput against the woman's sacrum. She experiences intense back discomfort (back labor) that persists between contractions. A woman may not be able to deliver her baby until it rotates to the occiput anterior position. The fetal head must therefore rotate a wider arc before the mechanisms of extension and expulsion occur, so labor is often longer (see Figure 12-12). Back pain may decrease dramatically when a fetus rotates into the more favorable position. The rate of labor progress usually increases as well. However, back pain may persist in any labor.

Pelvic Readiness. The size and shape of a woman's pelvis influence the course and length of her labor. Abnormalities may contribute to fetal malpresentation or malposition, resulting in a difficult and longer labor.

Fatigue and Hunger. Fatigue reduces a woman's ability to tolerate pain and to use coping skills she has learned. She may be unable to focus on techniques that would otherwise help her tolerate labor. An extremely fatigued woman may have an exaggerated response to contractions, or she may be unable to respond to sensations of labor such as the urge to push. Because oral intake is often limited, her energy reserves are also likely to be depleted in a long labor.

Many women find that sleep is difficult during the last weeks of pregnancy. A woman's shortness of breath when lying down, frequent urination, and fetal activity interrupt sleep so that she often begins labor with a sleep deficit. If labor begins late in the evening, she may have been awake more than 24 hours by the time she gives birth. Even if a woman begins labor well rested, slow progress may exhaust her.

Caregiver Interventions. Although they may be appropriate for the well-being of a woman and fetus, common interventions often add discomfort to the natural pain of labor.

Intravenous (IV) lines cause pain when inserted and remain noticeable to many women during labor. Fetal monitoring equipment is uncomfortable to some women, but others want to hear the sounds. Both may hamper a woman's mobility, which she might use to assume a more comfortable position. A woman may expect routine electronic fetal monitoring (EFM) and subordinates her own comfort for reassurance of her baby's well-being with technology.

A woman whose labor is induced or augmented often reports more pain and increased difficulty coping with it because contractions reach peak intensity quickly. Labor is more interventional with induction or augmentation (see Chapter 16). Vaginal examinations, amniotomy, and insertion of internal fetal monitoring devices also increase a woman's discomfort briefly because of vaginal and cervical stretching. Vaginal manipulation often stimulates a contraction because of a reflex known as *Ferguson's reflex*.

Psychosocial Factors

Several psychosocial variables influence a woman's experience of pain.

Culture

A woman's sociocultural roots influence how she perceives, interprets, and responds to pain during childbirth. Some cultures encourage loud

CRITICAL THINKING EXERCISE 15-1

Truc is a Vietnamese-American in labor with her first baby. Her cervix is dilated 6 cm, effacement is 100%, and the fetus is at a +1 station. Truc's contractions occur every 3 minutes, last 50 to 60 seconds, and are of strong intensity. She smiles at the nurse each time the nurse talks to her but does not talk much herself. Truc stiffens her body during contractions and interacts little with her husband or the nurse at those times.

Questions

1. How should the nurse interpret Truc's assessment and behavior?
2. Does the nurse need additional data?
3. What nursing actions are appropriate?

and vigorous expression of pain, whereas others value self-control. However, women are individuals within their cultural groups. The experience of pain is personal, and caregivers should not make assumptions about how a woman will behave during labor.

Women should be encouraged to express themselves in any way they find comforting, and the diversity of their expressions must be respected. Loud and vigorous expression may be a woman's personal pain coping mechanism, whereas a quiet woman may need medication relief but feels the need to remain stoic. Accepting a woman's individual response to labor and pain promotes a therapeutic relationship. The nurse should avoid praising behaviors (such as stoicism) while belittling others (such as noisy expression). This restraint is difficult because noisy women are challenging to work with and may disturb others.

The unique nature of childbirth pain and women's diverse responses to it make nursing management complex. The nurse can miss important cues if the woman is either stoic or outspoken about her pain. With either extreme the nurse may not readily identify critical information such as impending birth or symptoms of a complication.

Anxiety and Fear

Mild or moderate anxiety can enhance attention and learning. However, high anxiety and fear magnify sensitivity to pain and impair a woman's ability to tolerate pain. Anxiety and fear consume energy the woman needs to cope with the birth process, including its painful aspects.

Anxiety and fear increase muscle tension, diverting oxygenated blood to the brain and skeletal muscles. Tension in pelvic muscles counters the expulsive forces of uterine contractions and the laboring woman's pushing. Prolonged tension results in general fatigue, increased **pain perception** or **threshold** (lowest stimulus level perceived as painful), and reduced ability to use skills to cope with pain.

If a previous pregnancy had a poor outcome such as a stillborn infant or one with abnormalities, a woman is probably more anxious during labor and for a time after birth. She is likely to examine and reexamine her infant to assure herself that this baby is normal.

Previous Experiences with Pain

Early in life a child learns that pain means bodily injury. Consequently, fear and withdrawal are natural reactions to pain during labor. Learning about the normal sensations of labor, including pain, helps a woman suppress her natural reactions of fear and withdrawal, allowing her body to do the work of birth.

A woman who has given birth previously has a different perspective. If she has had a vaginal delivery, she is probably aware of normal labor sensations and is less likely to associate them with injury or abnormality. Also, time has a way of blunting the memory of painful

experiences. A woman who had a previous long and difficult labor may be anxious about the outcome of the present one. She may be surprised that her second labor moves more quickly than her first. The woman having a second (or higher) vaginal birth may find late first stage and second stage labor to be more painful because the fetus descends faster. All women are different and yet similar.

Fewer women today have the option of choosing vaginal birth after cesarean (VBAC). However, a woman who plans a VBAC but has never experienced labor because her first baby was breech may be particularly anxious. The experience of cesarean birth is known to her, even if she does not want to repeat it, whereas labor is unknown. A repeat cesarean birth may seem to be the quicker and less painful option at times, yet she strongly prefers to have a “normal” vaginal birth, if possible. She may have difficulty yielding to the normal forces of birth.

Previous experiences may positively affect a woman’s ability to deal with pain. She may have learned ways to cope with pain during other episodes of pain or during other births and may use these skills adaptively during labor.

Preparation for Childbirth

Preparation for childbirth does not ensure a pain-free labor. A woman should be prepared for pain realistically, including reasonable expectations about analgesia and **anesthesia** (loss of sensation). She may feel that unexpected events during labor may invalidate her childbirth preparation.

Preparation reduces anxiety and fear of the unknown. It allows a woman to rehearse for labor and learn a variety of skills to master pain as labor progresses. She and her partner learn about expected behavioral changes during labor, and their knowledge decreases their anxiety when those changes occur.

Support System

An anxious partner is less able to provide the support and reassurance that the woman needs during labor. In addition, anxiety in others can be contagious, increasing the woman’s anxiety. She may assume that if others are worried, something is wrong.

The birth experiences of a woman’s family and friends cannot be ignored. Those individuals can be an important source of support if they express realistic information about labor pain and its control. If they describe labor as intolerable, however, she may have needless distress. Hearing that labor is painless is equally detrimental. No two labors are alike, even in the same woman.

STANDARDS FOR PAIN MANAGEMENT

The Joint Commission (TJC) (www.jointcommission.org) has recognized that pain management is an essential part of the care of all people in health care settings. The organization has added a number of explicit pain management standards related to the following:

- The rights of all patients to pain management
- Staff competency in pain assessment and management
- Establishment of policies and procedures that support prescription of appropriate pain medications
- Education of patients and families about effective pain management
- Discharge planning related to pain management

NONPHARMACOLOGIC PAIN MANAGEMENT

The nurse who cares for women in labor and birth can offer many nonpharmacologic and pharmacologic pain management methods. Education about nonpharmacologic pain management is the foundation of prepared childbirth classes, although today’s classes contain significant content on pharmacological pain management, particularly epidural analgesia. Most women use these methods to complement pharmacologic methods, although some use them as their only pain management techniques.

To be most helpful to women and their labor partners, the intrapartum nurse should know methods that are taught in local childbirth classes. Childbirth classes are often associated with medical rather than nursing interventions (Simkin & Bolding, 2004). Teaching techniques during labor that conflict with what a woman learned and practiced may confuse her. Other techniques can be reserved for use if a woman finds learned techniques ineffective.

Advantages

Nonpharmacologic methods have several advantages over pharmacologic methods if pain control is adequate. They do not slow labor and have no side effects or risk of allergy.

The woman who chooses analgesia needs alternative pain management until she receives it, usually after labor is established. Also, some pharmacologic methods may not eliminate labor pain, and a woman needs these techniques to control the pain that remains, even if it is greatly reduced.

Nonpharmacologic methods may be the only realistic option for a woman who enters the hospital in advanced, rapid labor. Drugs might not have enough time to take effect, or there may not be time needed to administer an effective epidural block before birth. The time of peak drug action in terms of newborn respiratory effort must be considered if an **analgesic** (systemic agent to relieve pain) drug is given.

Limitations

Nonpharmacologic methods also have limitations, especially as the sole method of pain control. Women do not always achieve their desired level of pain control using these methods alone. Because of the many variables in labor, even a well-prepared and highly motivated woman may have a difficult labor and need analgesia or anesthesia.

Gate-Control Theory

A discussion of nonpharmacologic pain management techniques would not be complete without discussion of the **gate-control theory** of pain. According to this theory, transmission of nerve impulses is controlled by a neural mechanism in the dorsal horn of the spinal cord that acts like a gate to control impulses transmitted to the brain. Transmission is affected by stimulation of large- or small-diameter sensory nerve fibers and descending impulses from the brain. This mechanism opens or closes the “gate” to pain sensation by allowing or preventing some impulses from reaching the brain, where they are recognized as pain.

Pain is transmitted through small-diameter sensory nerve fibers. Stimulation of large-diameter fibers in the skin blocks conduction of

pain through small-diameter fibers thereby “closing the gate” and decreasing the amount of pain felt. Examples of this stimulation include tactile stimulation such as massage, thermal stimulation, or hydrotherapy.

Impulses from the brain have a similar ability to impede transmission through the dorsal horn using visual and auditory stimulation techniques. Examples of visual or auditory stimulation include use of a focal point or breathing techniques.

Memory and cognitive processes affect the perception of stimuli as painful. Education and support during labor are used to increase the woman’s relaxation, confidence, and feeling of control. Although these methods may not completely prevent pain, they may decrease the severity of perceived pain (Creehan, 2008).

Preparation for Pain Management

The ideal time to prepare for nonpharmacologic pain control is before labor. During the last few weeks of pregnancy, the woman learns about labor, including its painful aspects, in childbirth classes. She can prepare to confront the pain, learning a variety of skills to use during labor. Her support person learns specific methods to encourage and support her. After admission, the nurse can review and reinforce what the partners learned in class.

The nurse can teach the unprepared woman and her support person nonpharmacologic techniques. The latent phase of labor is the best time for intrapartum teaching because the woman is usually anxious enough to be attentive and interested and yet comfortable enough to understand. The nurse must usually teach one contraction at a time during late labor because the woman’s focus is very narrow.

No one method or combination of methods helps every woman. Most methods may become less effective (habituation) after prolonged use, and changing techniques counters this problem. Knowing a variety of methods gives the nurse a selection.

Application of Nonpharmacologic Techniques

Techniques that can be applied during labor include relaxation, cutaneous stimulation, hydrotherapy, mental stimulation, and breathing techniques.

Relaxation

Promoting relaxation is a basis for all other methods, both nonpharmacologic and pharmacologic, because it achieves the following (Creehan, 2008; Freeman, 2009a; Rodgers & Micozzi, 2011):

- Promotes uterine blood flow, improving fetal oxygenation
- Promotes efficient uterine contractions
- Reduces tension that increases pain perception and decreases **pain tolerance** (maximum pain one is willing to endure)
- Reduces tension that can inhibit fetal descent

Environmental Comfort. Comfortable surroundings support relaxation. The nurse can reduce irritants such as bright lights and uncomfortable temperature and can change soiled underpads.

Music masks outside noise and provides a background for use of imagery and breathing techniques. This distraction shifts the woman’s attention from pain perception. Television has a similar effect for some women.

General Comfort. Promoting the woman’s personal comfort helps her focus on using pain management techniques during labor (Figure 15-2). This includes actions to increase comfort and reduce the effects of irritants.

Reducing Anxiety and Fear. The nurse may reduce a woman’s anxiety and increase her self-control by providing accurate information and focusing on the normality of her labor. Hospitals are typically associated with illness or injury, situations that are anxiety provoking.

FIG 15-2 General comfort measures such as the nurse’s reassuring presence or a cool cloth applied to the face supplement other methods of nonpharmacologic and pharmacologic pain control.

Yet, in North America, hospitals are the most common site for the normal event of birth.

Simple nursing actions keep the focus on the normality of childbirth regardless of the setting. For example, referring to a woman as a *client* or *patient* reinforces the atmosphere of illness associated with being in a hospital, whereas calling her by name helps her to see birth as a normal process. Empowerment of the woman and her partner by giving them choices, whenever possible, helps them see themselves as competent people who can accomplish the task of giving birth.

Specific Relaxation Techniques. Relaxation techniques work best if they are practiced before labor. During practice sessions at home, couples may practice *progressive relaxation*, in which the woman contracts and then releases specific muscle groups until all muscles are relaxed. *Neuromuscular dissociation* helps the woman learn to relax all muscles except those that are working (e.g., the uterus or the abdominal muscles when pushing). The woman can learn *touch relaxation* in response to her partner’s touch, and *relaxation against pain* as the partner deliberately causes mild pain and the woman learns to relax despite the pain.

Even if the woman did not practice these relaxation techniques at home, the nurse can teach her how to consciously relax as labor progresses. The partner can learn to watch for signs of tension, touch that area, and direct the woman to relax.

Cutaneous Stimulation

Cutaneous stimulation has several variations that are often combined with each other or with other techniques (Minnich, 2009).

Self-Massage. The woman may rub her abdomen, legs, or back during labor (effleurage) to counteract discomfort. Some women find abdominal touch irritating, especially near the umbilicus. Women in labor may find firm stroking more helpful than light stroking (see Figure 11-6).

Some women benefit from firm palm or sole stimulation during labor. They may like someone to rub their palms vigorously; independently to rub their hands or feet together; or to bang their palms on or grip a cool surface. They may hold another person’s hand tightly during a contraction. The nurse should determine if these actions indicate excess pain or if they are a woman’s way of countering pain and therefore useful.

Massage by Others. Massage increases circulation and reduces muscle tension. The support person or nurse can rub the woman’s back, shoulders, legs, or any area where she finds massage helpful. Body powder on the skin reduces friction during massage. Powder should be kept away from the nose and mouth of the newborn.

FIG 15-3 The coach applies sacral pressure to counter back pain, common during labor.

Counterpressure. Sacral pressure may help when the woman has back pain, usually most intense when her fetus is in an occiput posterior position. Sacral pressure may be applied using the palm of the hand, the fist or fists, or a firm object such as two tennis balls in a sock (Figure 15-3). A variation of sacral pressure is a double hip squeeze, in which the palms are placed on the woman's hips and pressed down and inward toward the symphysis (Adams & Bianchi, 2008; Simkin & Bolding, 2004). When pressure is used, the woman should guide the support person as to the exact location and amount of pressure. An upright maternal position enhances counterpressure with the fists to the lower back.

Touch. Nonclinical touch by the nurse is a powerful tool if the woman does not object to it. Holding her hand, stroking her hair, or similar actions convey caring, comfort, affirmation, and reassurance at this vulnerable time.

Thermal Stimulation. Many women appreciate warmth applied to the back, abdomen, or perineum during labor. Warmth increases local blood flow, relaxes muscles, and raises the pain threshold. Massage is often more comfortable to a tense woman after her skin is warmed. A warm shower, tub bath, or whirlpool bath is relaxing and provides thermal stimulation. A sock filled with dry rice and microwaved provides gentle warmth and can be used to apply warm pressure to the sacral area (Adams & Bianchi, 2008; Minnich, 2009; Simkin & Bolding, 2004).

Cool, damp washcloths provide comforting coolness if the woman feels hot. She may put them on her head, throat, abdomen, or any place she wants. She also may want to put them in her mouth to relieve dryness. Ice chips cool the mouth and provide hydration.

Acupressure. Acupressure is a directed form of massage in which the support person applies pressure to specific pressure points using hands, rollers, balls, or other equipment. It is related to its invasive counterpart, acupuncture, in which tiny needles are inserted into similar points. Acupuncture and acupressure have data to support effectiveness to relieve nausea and vomiting, including morning sickness of pregnancy. Few controlled studies exist on acupressure's usefulness during birth. For updated objective information on acupressure and other complementary and alternative medicine (CAM) techniques, visit the website for the National Center for

Complementary and Alternative Medicine (NCCAM), which is part of the National Institutes of Health (NIH; www.nccam.nih.gov).

Hydrotherapy

Water therapy can supplement any relaxation technique. The buoyancy afforded by immersion supports the body, equalizes pressure on the body, and aids muscle relaxation. In addition, fluid shifts from the extravascular space to the intravascular space, reducing edema as the excess fluid is excreted by the kidneys. Women who have used water therapy effectively in one pregnancy often want to have it in a subsequent pregnancy (Simkin & Bolding, 2004).

A shower, tub bath, or whirlpool bath is relaxing and provides thermal stimulation. Several studies have shown benefits of water therapy during labor, including immersion in a tub or whirlpool (jet hydrotherapy, or Jacuzzi). The major concern about immersion therapy has been newborn and postpartum maternal infections caused by microorganisms in the water. Infections can be caused by the woman's own ascending vaginal bacteria or by preexisting organisms in an improperly cleaned tub. However, several studies have not found a significant association between newborn or postpartum maternal infections and use of immersion hydrotherapy with proper cleaning (Creehan, 2008; Simkin & Bolding, 2004; Stark, Rudell, & Haus, 2008). More research is needed to clarify both the benefits and the concerns about hydrotherapy (Box 15-1). Facility policies should be written to outline specific guidelines based on most recent evidence for use of hydrotherapy.

Mental Stimulation

Mental techniques occupy the woman's mind and compete with pain stimuli. They also aid relaxation by providing a tranquil imaginary atmosphere.

Imagery. If the woman has not practiced a specific imagery technique, the nurse can help her create a relaxing mental scene. Most women find images of warmth, softness, security, and total relaxation most comforting.

Imagery can help the woman dissociate herself from the painful aspects of labor. For example, the nurse can help her visualize the work of labor: the cervix opening with each contraction or the fetus moving down toward the outlet each time she pushes. This technique is like visualizing success or movement toward a goal with each contraction. The nurse can help the woman visualize being in a pleasant and relaxing place.

Focal Point. When using nonpharmacologic techniques, a woman may prefer to close her eyes or may want to concentrate on an external focal point. Childbirth classes may emphasize that keeping the eyes open on a focal point helps her concentrate on something outside her body and thus away from the pain of contractions. She may bring a picture of a relaxing scene or an object to use as a focal point and to aid in the use of imagery. She can use any point in her room as a focal point.

10. How might each of these cutaneous stimulation techniques be used to aid relaxation during labor: Self-massage? Massage by others? Counterpressure? Warmth or cold?
11. When hydrotherapy is used during labor, why are these cautions required? Adequate maternal hydration? Control of water temperature?

BOX 15-1 USE OF WATER THERAPY DURING LABOR

Use of water therapy has accompanied trends toward a low-intervention approach to intrapartum care. Water therapy can be delivered in several ways:

- Shower
- Standard tub
- Whirlpool

Benefits

- Associated with a more natural, homelike atmosphere.
- Gives a woman greater control over her labor.
- Upright position facilitates progress of labor.
- Faster labor progress if contractions are frequent when woman enters the tub.
- Buoyancy relieves tired muscles and reduces pressure.
- Facilitates fetal rotation from occiput posterior or transverse positions to the occiput anterior position. The woman can also assume different positions to aid rotation.
- Many women report a perception of less pain.
- Reduction in the mean arterial pressure, reduced edema, and increased diuresis. This is especially helpful if the woman has pregnancy-induced hypertension.

Disadvantages

- May reduce frequency of contractions and dilation if used during the latent phase of labor.
- Fetus must be assessed with intermittent auscultation rather than electronic fetal monitoring.

Contraindications and Precautions

- No specific contraindications if the woman can safely be out of bed.
- Thick meconium in the amniotic fluid is an indication for continuous electronic fetal monitoring in most birth facilities and would preclude use of water therapy.
- Bleeding.
- Oxytocin induction or augmentation. The use of both oxytocin and water therapy could cause excess uterine activity.
- Maintain water temperature at 36° C to 37° C (96.8° F to 98.6° F) to avoid maternal and fetal hyperthermia that increases demand for oxygen.
- Encourage maternal fluids to prevent dehydration related to greater maternal fluid excretion by the kidneys.

FIG 15-4 A woman and her partner who are prepared for labor have learned a variety of skills to master pain as labor progresses. The coach uses hand signals to tell the woman how to change her pattern of paced breathing.

Breathing Techniques

Breathing techniques give a woman a different focus during contractions, interfering with pain sensory transmission (Figure 15-4). They begin with simple patterns and progress to more complex ones as greater distraction is needed. No universal right time exists to change patterns during labor. However, complex patterns are fatiguing if used for a long time.

For best results, the woman and her partner must practice the techniques frequently. If patterns are too complicated or if the woman has not practiced, they may not be helpful during labor. Breathing techniques should be used only when needed, usually when the woman can no longer walk or talk during a contraction. The woman should not change from a simpler technique to the next, more complex technique until necessary so that use of the most complex techniques is limited to the shortest time possible.

First-Stage Breathing. Breathing in the first stage of labor consists of a cleansing breath and progressively more complex techniques of paced breathing, if needed.

Taking a Cleansing Breath. Each contraction begins and ends with a deep inspiration and expiration known as the *cleansing breath*. Like a sigh, a cleansing breath helps the woman release tension. It

FIG 15-5 Slow-Paced Breathing. Although a specific rate may or may not be used, slow-paced breathing should be no slower than half the woman's usual respiratory rate to ensure adequate oxygenation. This pace is generally about six to nine breaths per minute.

provides oxygen to help reduce myometrial hypoxia, one cause of pain in labor. The cleansing breath also helps the woman clear her mind to focus on relaxing and signals her labor partner that the contraction is beginning or ending. The woman may inhale through the nose and exhale through the mouth or take her cleansing breath in any way comfortable for her. When electronic monitors are used, a partner may help ease the discomfort of rapid contractions by watching for the rise in the lower part of the strip that signals the beginning of the contraction and telling the woman to take a cleansing breath.

Slow-Paced Breathing. The first breathing is slow-paced breathing, a slow, deep breathing that increases relaxation (Figure 15-5). The woman should concentrate on relaxing her body rather than on regulating the rate of her breathing. Relaxation naturally triggers slower breathing, similar to that during sleep. The woman can use nose, mouth, or a combination, depending on which is most comfortable.

Slow-paced breathing should be used as long as possible during labor because it promotes relaxation and oxygenation. Labor nurses often teach the technique to women who enter labor unprepared. It is easy to learn between contractions and, with the support of the nurse, helps even a frightened woman become calm and able to work with her contractions.

FIG 15-6 Modified-Paced Breathing. The pattern for modified-paced breathing should be comfortable to the woman and no faster than twice her normal respiratory rate to prevent hyperventilation or interference with relaxation.

FIG 15-7 Combining Techniques. Slow and modified-paced breathing can be combined by using the slower breathing at the beginning and end of the contraction and the more rapid breathing over the peak of the contraction.

As with all techniques, variety prevents habituation. Adding other pain-relief approaches such as effleurage may help prolong the effectiveness of slow-paced breathing. Using another type of breathing for a short time may allow the woman to return to slower breathing again later.

Modified-Paced Breathing. When slow-paced breathing is no longer effective, the woman begins modified-paced breathing (Figure 15-6). This chest breathing at a faster rate matches the natural tendency to use more rapid breathing during stress or physical work such as labor. Although modified-paced breathing is shallower than slow-paced breathing, the faster rate allows oxygen intake to remain about the same. As with slow-paced breathing, the focus is on release of tension rather than on the actual number of breaths taken.

Women sometimes learn to combine slow and modified-paced breathing during a contraction (Figure 15-7). They begin slowly and use shallow, faster breathing over the peak of the contraction. During labor, women often do this naturally. The most important concern is ensuring that the breathing does not interfere with relaxation but enhances it.

Patterned-Paced Breathing. Patterned-paced breathing (sometimes called *pant-blow breathing*) involves focusing on the pattern of breathing (Figure 15-8). It is similar to modified-paced breathing. After a certain number of breaths, however, the woman exhales with a slight emphasis or blow and then begins the modified-paced breathing again. This addition causes her to focus more on her breathing and reduces habituation. The mouth should remain relaxed, and the woman should not try to make specific sounds that would tighten her vocal cords. Relaxation of her entire body is the goal.

The number of breaths before the blow may remain constant (usually between two and six) or may change in a pattern. Variations include a set pattern such as “3-1, 5-1, 3-1” or a decreasing, “stair-step,” pattern such as “6-1, 5-1, 4-1, 3-1.” Some couples use a random pattern determined by the coach, who uses hand signals to show the number of breaths the woman should take before each blow. The coach holds up fingers to show the total breaths to be taken or a single finger for each breath. Use of the random pattern, however, may be ineffective without sufficient practice to enable the coach and woman to work together well.

FIG 15-8 Patterned-Paced Breathing. Patterned-paced breathing adds a slight emphasis or “blow” on the exhalation in a pattern. The diagram shows the emphasis after every third inhalation.

Breathing to Prevent Pushing. If a woman pushes strenuously before the cervix is completely dilated, she risks injury to her cervix and the fetal head. Blowing prevents closure of the glottis and breath-holding, helping to overcome the urge to push strenuously. The woman blows repeatedly using short puffs when the urge to push is strong. The support person may learn to blow along with her to help the woman concentrate. Some women vary the blowing by using one short breath and one blow.

Overcoming Common Problems. Hyperventilation and mouth dryness are common when breathing techniques are used. Hyperventilation results from rapid deep breathing that causes excessive loss of carbon dioxide and therefore respiratory alkalosis. The woman may feel dizzy or lightheaded and may have impaired thinking. Vasoconstriction leads to tingling and numbness in the fingers and lips. If hyperventilation continues, tetany occurring from decreased levels of calcium in tissues and blood may result in stiffness of the face and lips and carpopedal spasm.

Women are taught to blow into a paper bag or their own cupped hands if they begin to feel dizzy. This kind of blowing increases the carbon dioxide levels by making the woman rebreathe her exhaled air. The woman should slow her rate of breathing to reduce the loss of carbon dioxide.

The woman’s mouth becomes dry with prolonged mouth breathing. To avoid dryness, she can place her tongue gently against the roof of her mouth to moisturize entering air. The support person can offer ice, mouthwash, sugarless suckers, or liquids, as allowed.

Second-Stage Breathing. Care in the second stage of labor encourages a physiologic completion of labor, assisting the mother to respond to her urge to push rather than directing her to push as soon as her cervix is completely dilated even if she does not feel the urge. Lengthy pushing in second stage has been shown to result in greater maternal fatigue, more operative births, and nonreassuring fetal heart rate (FHR) patterns and does not significantly shorten second stage (Association of Women’s Health, Obstetric and Neonatal Nurses [AWHONN], 2008).

Research has shown that strenuous directed pushing increases risk for structural and neurogenic injury to a woman’s pelvic floor. Closed-glottis pushing causes recurrent increases in intrathoracic pressure with a resulting fall in cardiac output and maternal blood pressure. The woman’s lower blood pressure then causes less blood to be delivered to the placenta, resulting in fetal hypoxia that is reflected in nonreassuring fetal heart patterns.

Promoting a physiologic second stage uses nondirected pushing. The woman makes her decision with the nurse about when it is time to start pushing. She may grunt, groan, sigh, or moan as she pushes, and the nurse should validate that these sounds are normal. Pushing three to four times for 6 to 8 seconds is likely to be effective in aiding descent and safe for the baby. Adjust the pushing process depending

on fetal status (AWHONN, 2008). See Chapter 13 for more discussion of second-stage nursing care.

With newer techniques of epidural analgesia, women who choose this method of labor pain control often feel the urge to push, although not as strongly as the urge felt by women who have not had this type of medication. Using their natural urge to push, even if reduced, helps them push with contractions most effectively. Delaying pushing for up to 1 to 2 hours after complete dilation has shown benefits similar to those in women who do not have epidural analgesia.

CASE STUDY 15-1 NURSING CARE PLAN*

ASSESSMENT: Beth is a 28-year-old gravida 1, para 0, who was admitted 1 hour ago. Beth's cervix is 3 cm dilated and 100% effaced, the station is -2, and her membranes are intact. Contractions occur every 3 minutes, last 40 to 50 seconds, and are of moderate intensity. The fetal heart rate averages 135 to 145 beats per minute (bpm) and has no nonreassuring patterns. Beth says that back pain is annoying but she feels that she can cope with it at this time. Beth and her husband Sam attended prepared childbirth classes and are using breathing techniques they learned.

NURSING DIAGNOSIS: Acute Pain related to effects of uterine contractions and pressure on pelvic structures

EXPECTED OUTCOMES: During labor, Beth will:

1. Continue to use techniques learned in prepared childbirth classes.
2. Have a relaxed facial and body posture between contractions.

Critical Thinking: *At this time, what methods for pain management are most appropriate to suggest, nonpharmacologic or pharmacologic?*

Answer: *If no one has already done so, the nurse should explore Beth's preferences for pain relief with her before labor becomes more intense. Nonpharmacologic methods are ideal in early labor if they provide adequate pain management. Walking or other upright positions often ease back discomfort and aid fetal descent. However, Beth's ability to use these nonpharmacologic methods would be reduced if she were to receive some pharmacologic methods of pain control, such as systemic analgesics. Her labor pattern is normal, membranes are intact, and the fetal heart rate is stable and within normal limits, so walking is not contraindicated.*

INTERVENTIONS AND RATIONALES

1. Adjust the environment for comfort to make it conducive to relaxation. *Relaxation underlies all other interventions because it increases a woman's ability to use her coping skills to tolerate discomfort.* Methods to make the environment more comfortable may include the following:
 - a. Adjust room thermostat.
 - b. Add warm blankets and socks for warmth.
 - c. Offer small electric fan or hand-held fan if Beth is hot.
2. Reduce distractions that *interfere with use of the skills for pain management taught in prepared childbirth classes.*
 - a. Close door to reduce outside noise.
 - b. Play music of Beth's choice to mask external noise.
 - c. Do not stand in front of her focal point.
 - d. Try to delay assessments or questions until after a contraction is over.

3. Reduce irritating stimulants that are *distractions that decrease the woman's ability to use learned childbirth skills and add to her discomfort.*
 - a. Keep sheets and underpads dry.
 - b. Dim the lights as Beth desires. Use bright lights only when necessary.
 - c. Perform all procedures and nursing interventions as gently as possible.
 - d. Avoid bumping the bed.
 - e. Limit visitors as the couple wishes.
4. Encourage Beth to assume the most comfortable positions and to change positions regularly (about every 30 to 60 minutes). If there is no contraindication, she may walk or sit in a chair or on a birth ball at the bedside. A rolled pillow or blanket provides a wedge in a side-tilt position. *Frequent position changes favor fetal descent by encouraging the fetal head to adapt to the pelvic diameters most efficiently.* Position changes also reduce muscle tension and unrelieved pressure:
 - a. Upright positions *enhance descent with gravity.*
 - b. If lying down, a side-lying or side-tilt position is more comfortable and *reduces aortocaval compression with decreased placental perfusion.*
5. Check for bladder distention hourly or more often if she has had large quantities of intravenous (IV) or oral fluids. Encourage voiding at least every 2 hours. With an order, catheterize her if her bladder is full and she cannot void. *The sensation to void may be decreased during labor. A full bladder contributes to overall discomfort and may impede fetal descent and prolong labor.*
6. Give Beth clear fluids such as ice chips or juice. If she should not have or does not want fluids to drink, moisten her mouth with a damp washcloth or have her rinse her mouth with water. *Women often use rapid mouth breathing during labor, resulting in a dry mouth. These methods may relieve some of the discomfort associated with a dry mouth. Clear liquids may be ordered to limit the risk of aspiration if general anesthesia is needed.*
7. Offer a back rub or firm, constant sacral pressure. Ask Beth where and how firm pressure should be applied. Use baby powder when rubbing her back. Have Beth tell caregivers if this technique becomes uncomfortable or if the location on her back needs to be changed. If Sam is rubbing her back, offer to relieve him occasionally and encourage him to take a break. *Back rubs may somewhat reduce discomfort associated with back labor by stimulating large-diameter fibers and interfering with transmission of the pain impulse to the brain. As labor continues, back rubs may become less effective or even uncomfortable. Powder reduces friction, which could be another source of discomfort. The partner needs a break to conserve energy and better help the woman in later labor.*
8. Keep Beth and Sam informed about the progress of labor and their baby's condition *to reduce their anxiety and fear of the unknown. Anxiety and fear increase pain perception and reduce pain tolerance.*

EVALUATION: Beth concentrates on her breathing techniques with each contraction but has a relaxed body posture between them. She continues to use learned skills effectively for about 2 hours, when she begins to have more difficulty coping with her contractions.

*Continues on p. 292.

PHARMACOLOGIC PAIN MANAGEMENT

Most women want pharmacologic pain relief at some point in their labor, even if they also use nonpharmacologic methods. Pharmacologic methods for pain management include systemic drugs, **regional** pain management techniques (block of pain in localized area with consciousness), and general anesthesia. Decisions for any method must be made on a risk-benefit process.

Special Considerations for Medicating a Pregnant Woman

Medicating a woman when she is pregnant is not as simple as before pregnancy, for the following reasons:

- Any drug taken by the woman is likely to affect her fetus.
- Drugs may have effects in pregnancy that they do not have in the nonpregnant person.
- Drugs can affect the course and length of labor.
- Pregnancy complications may limit the choice of pharmacologic pain management methods.
- Women who require other therapeutic drugs, use herbal or botanical preparations, or practice substance abuse may have fewer safe choices for labor pain relief.

Effects on the Fetus

Effects on the fetus of drugs given to the mother may be direct, resulting from passage of the drug or its metabolites across the placenta to the fetus. An example of a direct effect on the fetus is decreased FHR variability after administration of an analgesic to the woman.

Effects on the fetus may be indirect, or secondary to drug effects in the mother. For example, if a drug causes maternal hypotension, blood flow to the placenta is reduced. Fetal hypoxia and acidosis may result.

Maternal Physiologic Alterations

Normal pregnancy changes in four body systems have the greatest implications for pharmacologic pain management methods.

Cardiovascular Changes. Compression of the aorta and inferior vena cava by the uterus can occur when a woman lies in the supine position (aortocaval compression). If the woman must be in the supine position temporarily, the uterus is displaced to one side with the hands or with a small wedge or towel roll under one hip. Displacement is often to the left (left uterine displacement, or LUD), although either side may be used. Operating room tables are often tilted slightly to one side for a cesarean birth to provide the uterine displacement.

Respiratory Changes. A pregnant woman's full uterus reduces her respiratory capacity. To compensate, she breathes more rapidly and deeply. As a result, she is more vulnerable to reduced arterial oxygenation during induction of **general anesthesia** (systemic loss of sensation and consciousness) and is more sensitive to inhalational anesthetic agents. The normal edema of pregnancy is also present in her upper airways and may present difficulty if she must be intubated for general anesthesia.

Gastrointestinal Changes. A pregnant woman's stomach is displaced upward by her large uterus and has a higher internal pressure. Progesterone slows peristalsis and reduces the tone of the sphincter at the junction of the stomach and esophagus. These changes make a pregnant woman vulnerable to regurgitation and aspiration (inhalation) of gastric contents during general anesthesia.

Nervous System Changes. During pregnancy and labor, circulating levels of **endorphins** and **enkephalins**, natural substances with analgesic properties, are high. These substances modify pain perception and reduce requirements for analgesia and anesthesia.

The epidural and **subarachnoid spaces** between the arachnoid mater and pia mater are smaller during pregnancy, enhancing the spread of anesthetic agents used for epidural blocks or subarachnoid blocks (SABs). Cerebrospinal fluid (CSF) pressure is higher during a contraction and when the woman is pushing. Nerve fibers are more sensitive to local anesthetic agents. High intraabdominal pressure causes engorgement of the epidural veins, increasing the risk for intravascular injection of anesthetic agents. The net result of these changes is that a reduced volume of local anesthetic is needed to achieve satisfactory epidural block or SAB.

Effects on the Course of Labor

Ideally, analgesics are given when labor is well established to avoid slowing progress. However, caregivers must consider the adverse effects of excessive pain on labor progress, regardless of the cervical dilation. Regional analgesia, primarily the epidural block, can slow progress during the second stage by reducing a woman's spontaneous urge to push.

Effects of Complications

Complications during pregnancy may limit the choices of analgesia or anesthesia. For example, large volumes of IV fluids are infused to prevent hypotension with regional analgesia and anesthesia. If a pregnant woman has heart disease, this fluid load could be detrimental. Yet without it, she is vulnerable to hypotension.

Interactions with Other Substances

A woman who ingests drugs (therapeutic, over-the-counter, or illicit), herbal or botanical preparations, or other substances may have fewer options because of interactions between these substances and analgesics or anesthetics. For example, recent alcohol use increases the depressant effects of opioid analgesics, making both the mother and the newborn susceptible to respiratory depression.

17. Why is it important to know about a woman's intake of drugs, botanical medicines, legal substances (such as alcohol), and illegal drugs?

Regional Pain Management Techniques

Regional pain control methods may be used for intrapartum analgesia, surgical anesthesia, or both. These methods provide pain relief without loss of consciousness. Depending on the specific technique, it may be used for only labor, for only birth, or for both labor and birth.

Epidural block provides pain control during much of labor and for the birth itself. Intrathecal opioids are used for pain control during labor; additional measures are needed during late labor and for the birth. Another regional block, the SAB, is used only at birth. A combined spinal-epidural (CSE) analgesia allows subarachnoid injection of opioids via a spinal needle followed by ongoing pain relief from anesthetics injected through the epidural catheter. Regional anesthetics with a small area of anesthesia are used only for birth and include the local and pudendal blocks.

The major advantage of regional pain management methods is that the woman can participate in birth and yet have good pain control. The woman usually feels some pressure and discomfort, although these sensations are greatly reduced. Protective airway reflexes remain.

Disadvantages depend on the specific technique. The effects on the fetus depend primarily on how the woman responds rather than on direct drug effects.

Epidural Block

The lumbar epidural block is a popular regional block that provides analgesia and anesthesia for labor and birth without sedation of the woman and fetus. It is used for both vaginal and cesarean births. Epidural blocks are started and maintained by an **anesthesiologist** (physician specialized in administration of anesthesia) or **nurse-anesthetist** (registered nurse with advanced education and certification in anesthetic administration). The obstetrician may do this, but this is becoming less common.

The **epidural space** is outside the dura mater, between the dura and the spinal canal. It is loosely filled with fat, connective tissue, and epidural veins that are dilated during pregnancy (Figure 15-9).

An epidural block is performed by injecting a local anesthetic agent, often combined with an opioid, into the tiny epidural space. It provides substantial relief of pain from contractions and birth canal distention. The level of the epidural block can be extended upward to provide anesthesia for a cesarean birth or tubal ligation after birth. Analgesia, rather than full anesthesia that results in complete loss of movement and sensation, is preferred for labor. Lower concentrations of the anesthetic agent and an epidural opioid provide adequate pain relief without complete **motor block** (loss of voluntary movement) for most women. Higher concentrations of the anesthetic agent used for abdominal surgery result in greater loss of both motor and sensory functions.

Technique. The exact time to begin an epidural block is individualized. It is started just before a scheduled cesarean birth. For labor, the best time to start the block is when the woman is in active

labor, to avoid slowing progress. A number of ways are available to customize the epidural block for different pain management needs, however. If she is in early labor and needs pain relief, the woman may be given parenteral opioids until her labor is more active. Or she may be given a preservative-free epidural opioid via the epidural catheter, supplemented with a stronger epidural anesthetic agent when labor becomes more active. In this way, she obtains pain relief and relaxation in early labor with less likelihood that labor progress will be slowed.

The epidural space is entered at about the L3-L4 interspace (below the end of the spinal cord), and a catheter is passed through the needle into the epidural space (Figure 15-10). The catheter allows continuous infusion or intermittent injection of medication to maintain pain relief during labor and vaginal or cesarean birth. The infusion of epidural medication may also be regulated by a patient-controlled epidural analgesia (PCEA) pump (Hawkins & Bucklin, 2012; Tsen, 2009; Wong, 2009; Wong, Nathan, & Brown, 2009).

Epidural block requires a larger volume of anesthetic agent than the SAB because it is outside the meninges. Before the full epidural dose is given, a small (3-mL) test dose of anesthetic is injected by the anesthesia provider to determine if the epidural catheter has inadvertently punctured a blood vessel or the dura. If a large dose of anesthetic reaches the subarachnoid space instead of the epidural space, the woman experiences rapid, intense motor and **sensory block** (loss of sensation). Numbness of the tongue and lips, lightheadedness, dizziness, and tinnitus may occur with intravascular injection. Epinephrine in the test dose produces tachycardia if injected intravascularly, although the tachycardia can have other causes, such as pain (Hawkins & Bucklin, 2012; Wong, 2009).

Epidural opioids that may be used during labor include fentanyl (Sublimaze), sufentanil (Sufenta), ropivacaine (Naropin), and

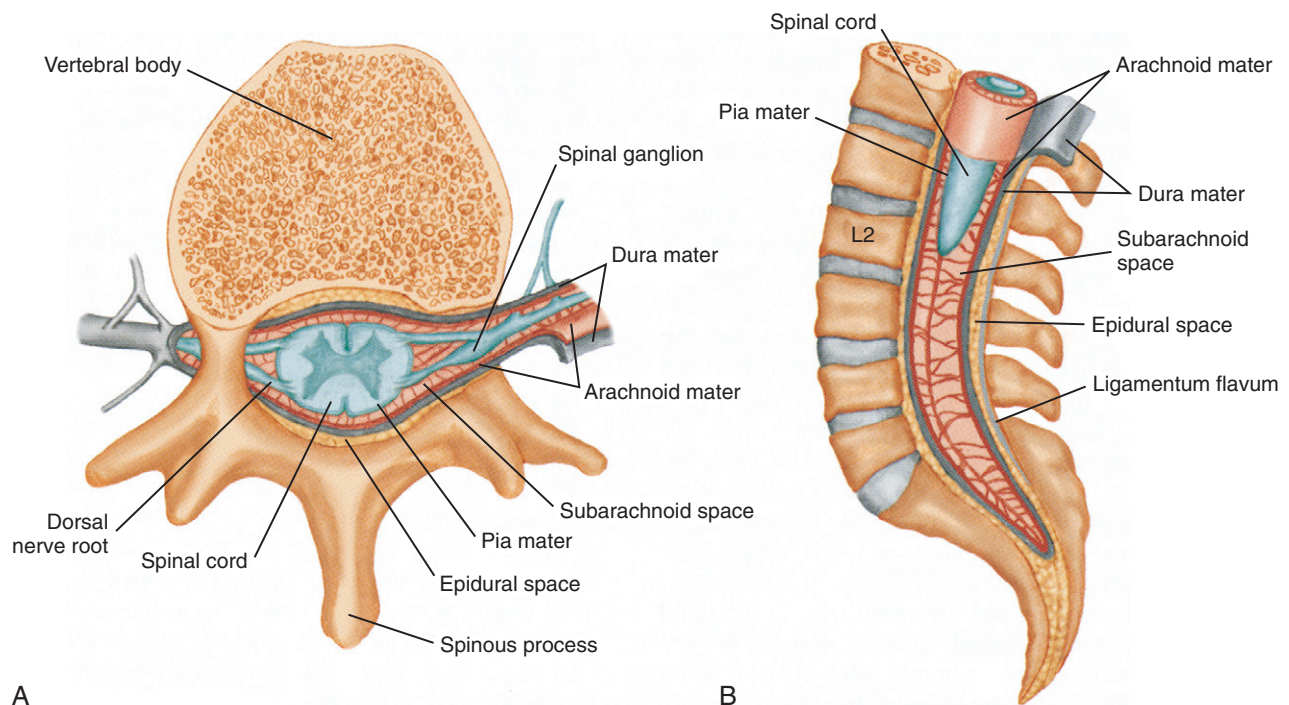

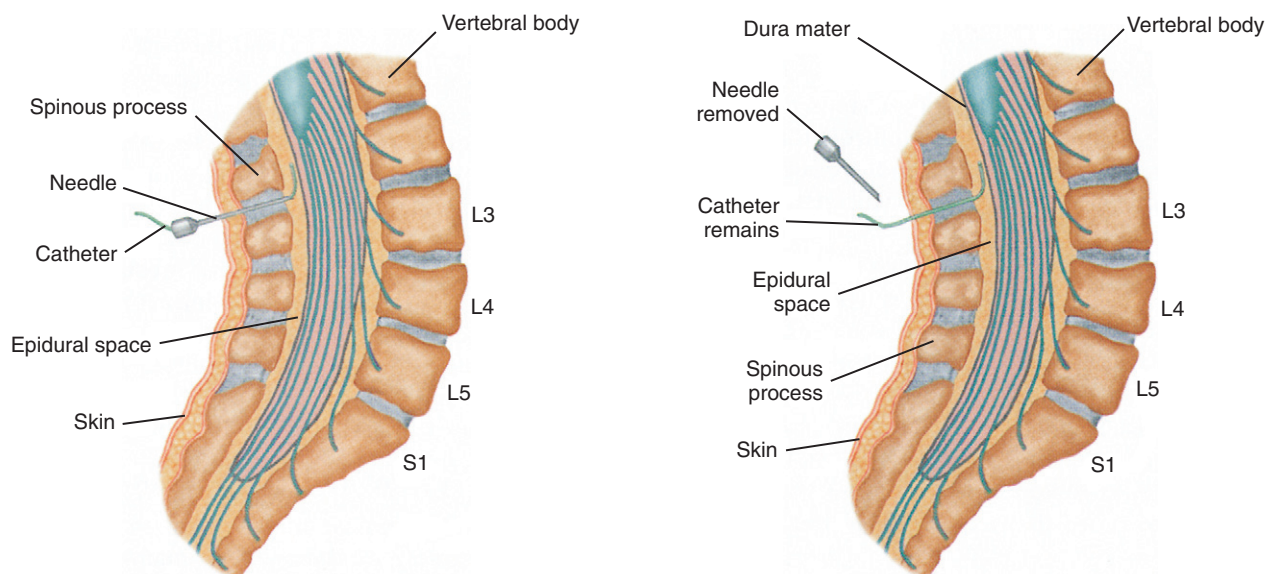

FIG 15-9 **A**, Cross-section of spinal cord, meninges, and protective vertebrae. The dura mater and arachnoid mater lie close together. The pia mater is the innermost of the meninges and covers the brain and spinal cord. The subarachnoid space is between the arachnoid mater and pia mater. **B**, Sagittal section of spinal cord, meninges, and vertebrae. The epidural and subarachnoid spaces are illustrated. Note that the spinal cord ends at the L2 vertebra.

The epidural space is entered with a needle below where the spinal cord ends. A fine catheter is threaded through the needle.

After the catheter is threaded into the epidural space, the needle is removed. Medication can then be injected into the epidural space intermittently or by continuous infusion for pain relief during labor and birth.

FIG 15-10 Technique for Epidural Block.

morphine (Duramorph, Astramorph). *All drugs injected into the epidural or subarachnoid spaces must be preservative free.*

A single dose of a long-acting epidural analgesic such as morphine is often given after cesarean birth before removal of the epidural catheter to provide long-acting pain relief with a low dose of opiate. The mother may require no added analgesics for almost 24 hours, or oral ones may be sufficient. The mother's respiratory status must be monitored for an extended time after the long-acting epidural analgesic, up to 24 hours based on the duration of action for the specific drug.

Dural Puncture. Because the tough dura and the fragile weblike arachnoid membranes lie close together, dural puncture also punctures the arachnoid. If the dura is unintentionally punctured with the needle used to introduce the epidural catheter, leakage of CSF can occur, which may result in a postdural puncture ("spinal") headache (see p. 292). Dural puncture and headache also can occur without obvious CSF leakage.

Contraindications and Precautions. Epidural block is not suitable for all laboring women, and some refuse the block. Contraindications include coagulation defects, uncorrected hypovolemia, an infection in the area of insertion or a severe systemic infection, allergy, or a fetal condition that demands immediate birth. Women who have had spinal surgery, such as for scoliosis (spinal curvature), are evaluated individually.

Adverse Effects of Epidural Block. Epidural block can have several adverse effects.

Maternal Hypotension. Sympathetic nerves are blocked along with pain nerves, which may result in vasodilation and hypotension. Maternal hypotension with possible reduction in placental perfusion is most likely to occur within the first 15 minutes of an epidural's initiation or injection of intermittent bolus doses to maintain pain relief. However, a significant percentage of women may have hypotension that occurs within 1 hour of initiation or repeat bolus doses (AWHONN, 2008; AWHONN, 2011; Hawkins & Bucklin, 2012; Wong,

2009). In addition, the fetus is more likely to have nonreassuring signs on an electronic fetal monitor strip, for example, a rising baseline, tachycardia, or late decelerations, if the mother has hypotension. Nonreassuring fetal signs may also have other etiologies, however (see Chapter 14).

Rapid infusion of a non-dextrose IV solution, often warmed, such as lactated Ringer's or normal saline, before initiation of the block fills the vascular system to offset vasodilation. Preload IV quantities are at least 500 to 1000 mL infused rapidly (Hawkins & Bucklin, 2012; Wong, 2009). If hypotension occurs and techniques such as rapid non-dextrose IV fluid bolus, maternal repositioning, and oxygen administration are ineffective, IV ephedrine in 5- to 10-mg increments promotes vasoconstriction to raise the blood pressure.

Bladder Distention. A woman's bladder fills quickly because of the large quantity of IV solution, but her sensation to void is reduced. Bladder distention may cause pain that remains after initiation of the block.

Prolonged Second Stage. Delayed pushing is often intentional for second stage labor and the urge to push may be less intense for the woman who has an epidural block, particularly if she has an intense motor block. The pelvic muscles may be relaxed, which can interfere with the mechanism of internal rotation (see Figure 12-12). These factors increase the chance for vacuum extractor-assisted births or forceps-assisted births.

Catheter Migration. After accurate placement, the epidural catheter may move. A woman may then have symptoms of intravascular injection, an intense block or one that is too high, absence of anesthesia, or a unilateral block. The anesthesia professional should be notified of any question about catheter placement.

Cesarean Births. Early research on whether cesarean births were more likely for women who had epidural blocks did show a risk but the epidural block was much more intense than current epidurals. More recent research has not shown epidurals to increase the risk for cesarean, although the length of second stage is likely to be longer than

for the woman who did not have an epidural (Cunningham, Leveno, Bloom et al., 2010; Hawkins & Bucklin, 2012; Wong, 2009).

Maternal Fever. For reasons that are not completely clear, fever after epidural analgesia during labor is common. The fever associated with epidural analgesia is usually not caused by infection but may result from the reduced hyperventilation and decreased heat dissipation, for example, reduced sweating, which occur when the woman's pain is relieved. Also, women who are having prolonged labors may be more likely to have epidural block analgesia. However, maternal fever increases the fetal temperature and the fetal demand for oxygen, which can lead to fetal hypoxia and acidosis.

Fever is also a marker for infection. To avoid needless administration of antibiotics and sepsis evaluations in the newborn, other indicators for infection, for example, fetal tachycardia or amniotic fluid with a cloudy or yellow color and a foul or strong odor, should be sought as well. The nurse must remember that maternal fever elevates fetal temperature, resulting in tachycardia and oxygen demand for both. One study found that a maternal temperature of more than 101°F (38.3°C) was associated with the need for infant resuscitation at birth and 1-minute Apgar scores less than 7. Medical and nursing personnel should try to lower the mother's temperature to a normal level and to identify and treat a suspected infection. Possible signals to the hypothalamus that may result in maternal fever after epidural block include the following (AWHONN, 2011; Cunningham et al., 2010; Hawkins & Bucklin, 2012; Segal, 2009; Wong, 2009):

1. Decreased hyperventilation, sweating, and activity after onset of pain relief reduce maternal heat production and signal the hypothalamus to raise the woman's temperature.
2. Vasodilation redistributes heat from the core to the periphery of the body, where it is lost to the environment. The lower core temperature then signals the hypothalamus to increase heat production.
3. Shivering often occurs with sympathetic blockade accompanied by a dissociation between warm and cold sensations. In effect, the body believes that the temperature is lower than the true temperature and raises the "thermostat" to produce heat by shivering, thus increasing the core temperature.

Adverse Effects of Epidural Opioids. Adverse effects associated with epidural opioids may include nausea and vomiting, pruritus itching, and delayed maternal respiratory depression.

Nausea and Vomiting. Adjunctive drugs such as promethazine (Phenergan) reduce nausea and vomiting that can occur with epidural opioids.

Pruritus. Itching of the face and neck is an annoying side effect that may occur with epidural opioids. Although she may not specifically complain of itching, a woman may rub or scratch her face and neck. Diphenhydramine (Benadryl), naloxone (Narcan), nalbuphine (Nubain), or naltrexone (Trexan) may relieve pruritus (Table 15-1) (Carvalho & Butwick, 2009; Santos & Bucklin, 2009).

Delayed Respiratory Depression. The possibility of late respiratory depression in the woman exists for up to 12 hours after the administration of an epidural opioid, depending on the duration of action of the drug used (Wong, 2009).

Nursing Care. The nurse should record baseline maternal vital signs and FHR patterns for comparison with prenatal levels and those after the block. Intravenous access is ensured, and the prescribed preload of fluid is given. The nurse supports the woman in the correct position and tells the anesthesia provider when the woman is having a contraction. The woman may feel a brief "electric shock" sensation as the catheter is passed. The nurse should assist her in remaining still while the block is completed. After the medication is injected, the

nurse observes for signs of subarachnoid puncture or intravascular injection.

Evidence-based practice guidelines from AWHONN (2011) suggest assessing the maternal blood pressure and fetal heart rate every 5 minutes during the first 15 minutes after initiation of the epidural or any additional bolus doses of epidural medication. Repeat at 30 minutes and at 1 hour after the procedure. Individual facilities may use these guidelines or develop their own guidelines. As in any labor, maternal and fetal assessments are done more frequently, if needed in the situation such as maternal bleeding or a nonreassuring FHR pattern.

The woman's bladder must be assessed frequently because of the large IV fluid load and her reduced sensation to void. Indwelling catheterization is common but intermittent catheterization if a woman is unable to void is recommended by AWHONN (2011). Nurses with proper education who have demonstrated current competence should be able to participate in management of pain relief during labor (American College of Obstetricians and Gynecologists [ACOG] and American Society of Anesthesiologists [ASA], 2008). Based on results from varied researchers that support a woman's ability to void or need few, if any, intermittent catheterizations, DeSevo & Semerano (2010) concluded that the goal of labor caregivers should be to support normal urination rather than catheterizing all women with epidural analgesia.

The nurse should observe for signs associated with catheter migration from the epidural space and for adverse effects from epidural opioids, such as nausea and vomiting and pruritus. Reassurance about the harmless and temporary nature of pruritus is often sufficient.

Intrathecal Opioid Analgesics

Intrathecal injection of an opioid analgesic provides another option for pain management without sedation. The drug is injected into the subarachnoid space, where it binds to opiate receptors, allowing much smaller doses than would be adequate if given systemically. The woman can feel her contractions but not the pain they would otherwise cause.

Advantages of intrathecal analgesics include the following:

- Rapid onset of pain relief without sedation
 - No motor block, enabling the woman to ambulate during labor
 - No sympathetic block, with its hypotensive effects
- Disadvantages may include the following:
- Limited duration of action, possibly requiring another procedure for continued pain relief
 - Inadequate pain relief for late labor and the birth, requiring added measures to manage pain at these times

Combining intrathecal opioids with epidural block in a CSE provides rapid pain control at the time an epidural catheter is placed. Epidural drugs are then given to provide a long-acting block for labor.

Technique. The subarachnoid space is entered with a spinal needle, as in the SAB. A preservative-free opioid analgesic is then injected. The drug chosen depends on the expected duration of labor at the time it is given. Drugs that may be used by this route include fentanyl, sufentanil, and morphine.

One technique for performing the CSE is to insert the epidural needle into the epidural space. The much thinner spinal needle is then inserted through the larger epidural needle to reach the subarachnoid space for injection of the intrathecal opioid. The smaller needle is then withdrawn and an epidural catheter placed for injection of epidural medication.

Adverse Effects of Intrathecal Opioids. As with epidural opioids, nausea, vomiting, and pruritus may occur. Delayed maternal respiratory depression may occur, depending on the drug used.

TABLE 15-1 DRUGS COMMONLY USED FOR INTRAPARTUM PAIN MANAGEMENT

DRUG/DOSE	COMMENTS
Opioid Analgesics	
Meperidine (Demerol) 12.5-50 mg every 2-4 hours IV; may be given by PCA*	Respiratory depression (primarily in the neonate) is the main side effect.
Fentanyl (Sublimaze) 50-100 mcg; may be repeated every hour; may be given by PCA Adjunct to epidural analgesia during labor (dose individualized)	Onset is quick (5 minutes for IV administration), but duration of action is short. Less nausea, vomiting, and respiratory depression occurs than with meperidine. Epidural use may cause pruritus.
Butorphanol (Stadol) 1 mg every 3-4 hours; range 0.5-2 mg IV; may be given by PCA	Has some narcotic antagonist effects; should not be given to the opiate-dependent woman (may precipitate withdrawal) or after other narcotics such as meperidine (may reverse their analgesic effects); also a respiratory depressant.
Nalbuphine (Nubain) 10 mg every 3-6 hours IV; may be given by PCA	Same as butorphanol. 5-10 mg may be given to relieve pruritus associated with epidural narcotics.
Adjunctive Drugs	
Promethazine (Phenergan) 12.5-25 mg every 4-6 hours IV; dilute in 10-20 mL of 0.9% normal saline or 50 mL of normal saline; administer over 10-20 minutes	Prevent and relieve nausea often associated with opioids. Duration of action is longer than most narcotics; may enhance respiratory depressant effects of narcotics. Dilution and slow infusion into a large vein reduce risk for tissue necrosis. Given to relieve pruritus from epidural narcotics.
Diphenhydramine (Benadryl) 10-50 mg every 4-6 hours IV Hydroxyzine (Atarax, Vistaril) 25-100 mg IM Z-track only	See promethazine.
Narcotic Antagonists	
Naloxone (Narcan)	Action shorter than most narcotics it reverses; must observe for recurrent respiratory depression and be prepared to give additional doses.
<i>Adult:</i> To reduce respiratory depression induced by opioids: 0.4-2 mg IV To reverse pruritus from epidural opioids: 0.04-0.2 mg IV or IV infusion 5-10 mcg/kg/hr	Small doses (0.04-0.08 mg) may be given to reduce pruritus from epidural opioids.
<i>Neonatal resuscitation:</i> 0.1 mg/kg IV (umbilical vein) or intratracheal	Neonatal resuscitation dose (see Chapter 30). Preferred method to correct neonatal respiratory depression is bag-and-mask ventilation.
Naltrexone (Trexan) 3-6 mg PO × 1 dose	Unlabeled use as a long-acting drug to relieve pruritus from epidural narcotics. May reduce some analgesic effect when given for pruritus.
Vasopressor	
Ephedrine 5-10 mg IV; up to 25 mg IV	Corrects hypotension related to epidural or subarachnoid block.

*IM, Intramuscularly; IV, intravenously; PCA, patient-controlled analgesia; PO, orally.

Nursing Care. Vital signs and FHR are taken at the usual intervals for the woman's stage of labor. Side effects, such as nausea and vomiting or pruritus, are reported and managed similarly to those occurring with the epidural block. Reduced effectiveness suggests that the drug's duration of action is ending or that the woman is in late labor. Other pain management methods may be needed for the remainder of labor and for birth.

Care for the woman undergoing a CSE block is the same as that for one receiving a noncombined block.

Subarachnoid (Spinal) Block

An SAB is a simpler procedure than the epidural block and may be performed when a quick cesarean birth is necessary and an epidural catheter is not in place. It is similar to local infiltration and pudendal block. SAB is performed just before birth, providing no pain relief during most of labor.

The physician or nurse-anesthetist injects local anesthetic into the subarachnoid space in a single dose. The woman loses both sensory and motor function below the level of the SAB, with relief of pain from contractions.

Technique. A 25- to 27-gauge spinal needle is placed in the subarachnoid space. Appearance of CSF at the needle hub ensures correct placement, and the local anesthetic is injected (Figure 15-11).

The level of anesthesia for both epidural blocks and SABs is determined by the volume, concentration, and density of the drug (Figure 15-12).

Contraindications and Precautions. Contraindications and precautions are similar to those for epidural block: the woman's refusal, coagulation defects, uncorrected hypovolemia, infection in the area of insertion, systemic infection, and allergy. SAB can be performed more quickly than an epidural block if prompt birth is necessary.

CASE STUDY 15-1 NURSING CARE PLAN*

ASSESSMENT: Three hours after admission, Beth's cervix is 4 cm dilated and 100% effaced and the fetal station is -1. Membranes have ruptured, and the amniotic fluid is clear. Contractions occur every 2 to 3 minutes, last 50 seconds, and are firm. Fetal heart rate and monitor patterns are reassuring. Back discomfort persists despite walking, leaning forward, and other position changes. She is having difficulty relaxing between contractions and is discouraged that labor is not progressing as quickly as she expected. She is no longer using prepared childbirth techniques effectively and rates her labor pain as 8 on a 0-to-10 scale. Beth reluctantly requests an epidural block, which will be given by continuous infusion.

Critical Thinking: At this time, what are some advantages and disadvantages of having an epidural? Are added measures needed to safeguard the fetus because of an epidural block?

Answer: An epidural may slow labor if performed earlier than this, but labor progress may benefit from the relief of pain and tension if done at this point or later. A disadvantage of the epidural block is that Beth's activity is limited, reducing her options for positions that might improve fetal descent and rotation through the pelvis.

To safeguard the fetus, the nurse gives Beth an IV preload of at least 500 mL of lactated Ringer's before the block is started, offsetting the hypotensive effects of the epidural. Fetal monitoring, usually by continuous electronic means, helps identify non-reassuring patterns that may occur. Beth may assume several positions but she should avoid a supine position that can cause aortocaval compression.

NURSING DIAGNOSIS: Risk for Injury related to altered sensation in her lower extremities

EXPECTED OUTCOMES: Beth will not fall or suffer other injury while experiencing the effects of epidural block. The fetus will not be born in an uncontrolled manner.

INTERVENTIONS AND RATIONALES

1. Assist Beth to change positions regularly. Ambulation after birth should be delayed until normal movement and strength return, and assistance should

be available until her legs have normal strength. *Changing positions reduces constant pressure on one area and helps prevent muscle strain. The epidural block causes a varying degree of motor block and weakness in different women. Assistance helps prevent falls when Beth first ambulates.*

2. Observe for signs of labor progress:
 - a. Contractions increasing in frequency, duration, and intensity
 - b. Fetal heart rate changes such as early or variable decelerations that reflect head or cord compression
 - c. Increase in bloody show
 - d. Statement reflecting urge to push (not always present)

Delayed pushing encourages natural fetal descent and rotation although epidural block may limit normal rotation. Rectal pressure associated with fetal descent may be reduced. To prevent the fetus from being born unattended, the nurse must observe for other signs that birth is near.
3. Support Beth's spontaneous pushing efforts. Teach her to avoid holding her breath while pushing longer than 6 to 8 seconds at a time. Explain to Beth and Sam that she may make grunting, moaning, or other sounds when pushing to avoid excessive breath-holding. *The urge to push may not be as strong but it is usually felt when the fetus descends low in the pelvis. Prolonged breath-holding or multiple long pushing efforts (see also Chapter 13) can cause fetal hypoxia and nonreassuring fetal heart rate patterns. Women may make a variety of sounds when they push.*

EVALUATION: Beth is satisfied with her pain relief after the epidural block, rating her pain as "0 out of 10." She has little motor block. Her blood pressure and the fetal heart rate remain within expected limits. Cervical dilation progresses to 10 cm (complete) without injury to Beth or her fetus. However, despite her vigorous pushing efforts, the fetal station remains at 0. Beth has a cesarean birth, delivering a 3912-g (8-lb, 10-oz) girl.

ADDITIONAL NURSING DIAGNOSES AND COLLABORATIVE PROBLEMS TO CONSIDER

Anxiety
 Risk for Aspiration
 Powerlessness
 Situational Low Self-Esteem
 Urinary Retention
 Potential Complication: Fetal Compromise

*Continued from p. 286.

Adverse Effects. Three adverse effects of an SAB are maternal hypotension, bladder distention, and postdural puncture headache. Hypotension is more likely with the SAB than with the epidural block and is treated in the same manner, often with a larger volume of preload IV fluid.

Postdural Puncture Headache. Postdural puncture headache may occur after SAB in some women because of CSF leakage at the site of dural puncture. A spinal headache is postural. It is worse when a woman is upright and may disappear when she is lying flat. Headache is less likely if a small-gauge needle is used.

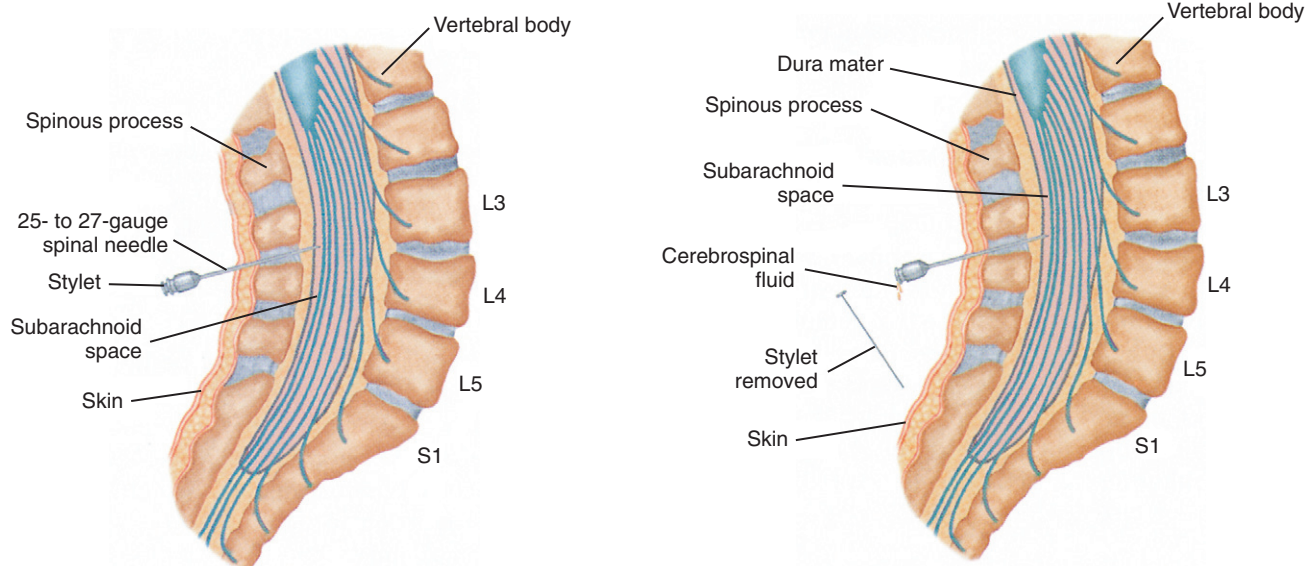

Bed rest with oral or IV hydration helps relieve the postdural puncture headache. Caffeine is another oral therapy. A blood patch may provide definitive relief. The blood patch involves injection of 10 to 15 mL of the woman's blood (obtained with sterile technique) into the epidural space. The blood forms a gelatinous seal over the hole in the dura, stopping spinal fluid leakage (Figure 15-13). The blood patch can be repeated, if needed. Epidural injection of dextran, sterile saline, or fibrin glue created from pooled human plasma also has resulted in some success (Hawkins & Bucklin, 2012).

Systemic Drugs for Labor

Systemic drugs have effects on multiple systems because they are distributed throughout the body. These intrapartum drugs include opioid analgesics and adjunctive drugs. Although general anesthesia is also systemic, it is discussed separately because it is used only at birth and causes loss of consciousness.

Nitrous Oxide

Older nurses may remember the use of nitrous oxide for labor pain. In Europe today, nitrous oxide may be used for pain relief during labor or for painful procedures in childbirth. However, use of nitrous oxide (also called "laughing gas") is being looked at again for relief of labor pain or painful procedures, such as laceration repair. Nausea, vomiting, and dizziness are some of the possible side effects to consider. For labor pain, the gas is delivered as 50 percent nitrous oxide and 50 percent oxygen. The woman controls when she takes breaths of the 50-50 combination. At this writing, nitrous oxide is available at only a few medical centers in the United States (Stewart & Collins, 2012).

A 25- to 27-gauge spinal needle with a stylet occluding its lumen is passed into the subarachnoid space below where the spinal cord ends.

The stylet is removed, and one or more drops of clear cerebrospinal fluid at needle hub confirm correct needle placement. Medication is then injected, and the needle is removed.

FIG 15-11 Technique for Subarachnoid Block.

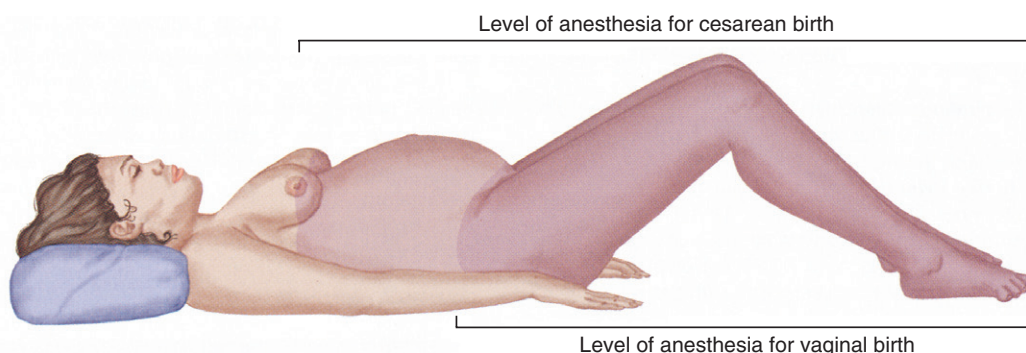

FIG 15-12 Levels of Anesthesia for Epidural and Subarachnoid Blocks. A level of T10 through S5 is adequate for vaginal birth. A higher level of T4 to T6 is needed for cesarean birth.

Parenteral Analgesia

Opioid analgesics are the most common parenteral medications given to reduce perception of pain without loss of consciousness. Analgesics that may be used for labor are meperidine (Demerol), fentanyl (Sublimaze), butorphanol (Stadol) (see [Drug Guide](#)), and nalbuphine (Nubain) (see [Table 15-1](#)) (Hawkins & Bucklin, 2012).

Although the drug may be prescribed for labor analgesia, meperidine often produces a dysphoric rather than an analgesic effect in the woman. She may be restless or irritable and have twitching, jerking, shaking, tremors, or even delirium. Of more concern is that meperidine produces a long-lasting active metabolite, normeperidine, which has a half-life of 3 to 6 hours in the woman but 3 days or longer in the newborn. For this reason meperidine is infrequently used for labor (Hawkins & Bucklin, 2012).

Meperidine and fentanyl are pure opioid **agonists**, or substances that cause a physiologic effect, but butorphanol and nalbuphine have mixed opioid agonist and **antagonist** (substance that blocks another substance or body secretion) effects. A woman who is dependent on opiates (such as heroin) should avoid agonist-antagonist drugs because

they may cause withdrawal effects in her and the newborn. They should not be given if the woman has already received a pure opioid because some analgesic effect of the first drug will be reversed. Agonist-antagonist drugs have a “ceiling effect” on the amount of analgesia they provide and are unsuitable for the increasing pain of the entire labor for many women.

The primary side effect of opioids is respiratory depression, which is more likely to affect the newborn. Timing of administration is important to reduce neonatal respiratory depression. An infant who is born at the peak of the drug’s action is more likely to have respiratory depression than if born earlier or later. Normeperidine can cause delayed respiratory depression in the newborn because of its lengthy duration of action in the newborn.

Opioid analgesics are given in small, frequent doses by the IV route during labor to provide a rapid onset of analgesia and a predictable duration of action. The woman will benefit from rapid pain control, with less likelihood of neonatal respiratory depression. Starting the injection at the beginning of the contraction, when blood flow to the placenta is normally reduced, limits transfer to the fetus. When

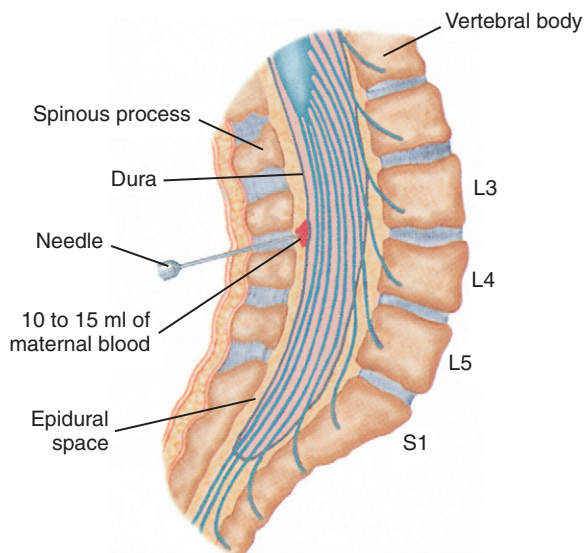

FIG 15-13 Blood patch for relief of spinal headache. To seal a dural puncture, 10 to 15 mL of the woman's blood is injected into the epidural space. Other fluids such as normal saline or dextran may be injected using a similar technique.

placental blood flow resumes, more of the drug is in maternal tissues. The drugs also may be delivered by patient-controlled analgesia (PCA) pump.

Opioid Antagonists

Naloxone (Narcan) reverses opioid-induced respiratory depression, although it is seldom used in obstetrics. Naloxone does not reverse respiratory depression from other causes such as barbiturates, anesthetics, nonopioid drugs, or pathologic conditions. Naloxone has a shorter duration of action than most of the opioids it reverses, and respiratory depression may recur. In an opiate-dependent woman or newborn, naloxone can induce withdrawal symptoms.

Airway management (i.e., bag-and-mask ventilation) takes precedence over use of naloxone for the newborn, and the drug is not routinely given to the baby for respiratory depression. See [Chapter 30](#) for additional information related to newborn resuscitation (American Academy of Pediatrics [AAP] & [American College of Obstetricians and Gynecologists \[ACOG\], 2012](#)). Small doses of naloxone may be given to the woman postpartum to relieve the pruritus that occurs with intrathecal or epidural narcotics. Naltrexone (Trexan), another opioid antagonist, and diphenhydramine (Benadryl), an antihistamine, may also be given for pruritus relief.

Adjunctive Drugs

Adjunctive drugs during the intrapartum period include those with antiemetic and tranquilizing effects and sedatives. These drugs are given to reduce nausea and anxiety and to promote rest (see [Table 15-1](#)).

Promethazine (Phenergan) relieves nausea and vomiting, which may occur when opioid drugs are given. Parenteral promethazine administration may be either the intramuscular (preferred but painful) or the IV route. Promethazine does not potentiate the opioid's analgesic effects but can add to the opioid's respiratory depressant effects. Because of the vesicant (blistering) effects of promethazine on tissue, IV administration should be done in a highly-diluted form, usually in a 50-mL bag of normal saline (NS) or according to facility protocols.

DRUG GUIDE

BUTORPHANOL (STADOL)

Classification: Opioid analgesic.

Action: Opioid analgesic with some agonist-antagonist effects; exact mechanism of action unknown; produces respiratory depression that does not increase markedly with larger doses.

Indications: Systemic pain relief during labor.

Dosage and Route

Intravenous

1 mg every 3-4 hours; range 0.5-2 mg; may be given undiluted.

Absorption: Onset of analgesia almost immediate with intravenous administration, peaks after about 30 minutes, and lasts about 3 hours; faster onset and shorter duration of action than meperidine or morphine.

Excretion: Excreted in urine; crosses placental barrier; secreted in breast milk.

Contraindications and Precautions: Contraindicated in persons who are hypersensitive; not used in opiate-dependent persons because antagonist activity of the drug may cause withdrawal symptoms in the woman or newborn; cautiously used during birth of preterm infant; drug actions potentiated (enhanced) by barbiturates, phenothiazines, cimetidine, and other tranquilizers.

Adverse Reactions: Respiratory depression or apnea (woman or newborn), anaphylaxis; dizziness, lightheadedness, sedation, lethargy, headache, euphoria, mental clouding, fainting, restlessness, excitement, tremors, delirium, insomnia; nausea, vomiting, constipation, increased biliary pressure, dry mouth, anorexia; flushing, altered heart rate and blood pressure, circulatory collapse; urinary retention; sensitivity to cold.

Nursing Considerations: Assess for allergies and opiate dependence. Observe vital signs and respiratory function in woman (respiratory rate of at least 12 breaths per minute) and newborn (respiratory rate of at least 30 breaths per minute). Have naloxone and resuscitation equipment available for treatment of respiratory depression in woman and neonate. Report nausea or vomiting to the birth attendant for a possible order for an antiemetic. Antiemetics or other central nervous system depressants may enhance the respiratory depressant effects of butorphanol.

Hydroxyzine (Atarax, Vistaril) is also an antihistamine with antiemetic effects. Parenteral hydroxyzine can be given only intramuscularly, by injection into a large muscle with the deep Z-track technique. *Hydroxyzine is not given by the IV route.*

Sedatives

Sedatives such as barbiturates are not routinely given because they have prolonged depressant effects on the neonate. However, a small dose of a short-acting barbiturate may be given to promote rest if a woman is fatigued from false labor or a prolonged latent phase.

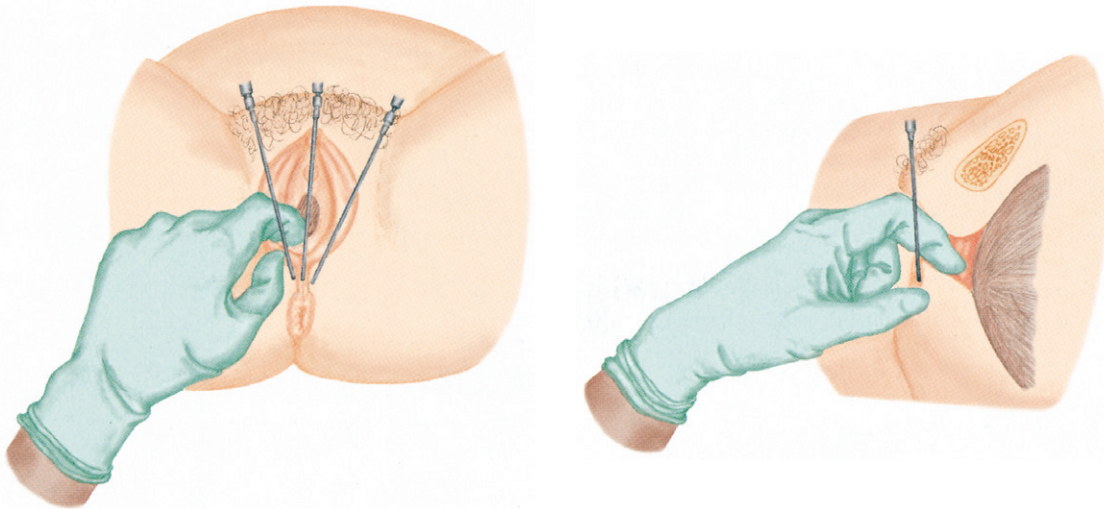

FIG 15-14 Local infiltration anesthesia numbs the perineum just before birth for an episiotomy or after birth for suturing of a laceration. The birth attendant protects the fetal head by placing a finger inside the vagina while injecting the perineum in a fanlike pattern or as needed.

Vaginal Birth Anesthesia

Local Infiltration Anesthesia

Infiltration of the perineum with a local anesthetic is done by the physician or nurse-midwife just before he or she performs an episiotomy or sutures a laceration (Figure 15-14). Local infiltration does not alter pain from uterine contractions or distention of the vagina. The local agent provides anesthesia in the immediate area of the episiotomy or laceration. A short delay occurs between anesthetic injection and onset of numbness, and the drug burns before its anesthetic action begins. Local infiltration rarely has adverse effects on either mother or infant.

Pudendal Block

A pudendal block anesthetizes the lower vagina and part of the perineum to provide anesthesia for an episiotomy and vaginal birth, using low forceps, if needed. A pudendal block does not block pain from uterine contractions, and the mother feels pressure. The pudendal block is a highly localized type of regional block, similar to a dental anesthetic that provides numbness for dental procedures.

The physician or nurse-midwife injects the pudendal nerves near each ischial spine with a local anesthetic (Figure 15-15). The perineum is infiltrated with local anesthetic because the pudendal block does not fully anesthetize this area. As in local infiltration, a brief delay occurs between injection and onset of numbness. Possible maternal complications include a toxic reaction to the anesthetic, rectal puncture, hematoma, and sciatic nerve block. If maternal toxicity is avoided, the fetus is usually not affected.

General Anesthesia

General anesthesia is systemic pain control that involves loss of consciousness. It is rarely used for vaginal births, but it still has a place in cesarean birth. Some women either refuse or are not good candidates for epidural block or SAB for cesarean birth. Occasionally, a planned epidural block or SAB proves to be inadequate for surgical anesthesia. General anesthesia may be needed unexpectedly and quickly for emergency procedures at any stage of pregnancy, such as to repair injury that results from an accident or domestic violence or to perform an appendectomy.

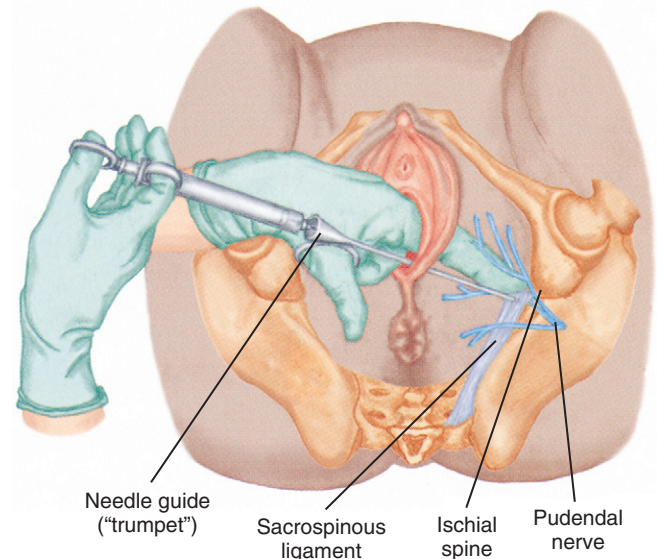

FIG 15-15 Pudendal block provides anesthesia for an episiotomy and use of low forceps. A needle guide ("trumpet") protects the maternal and fetal tissues from the long needle needed to reach the pudendal nerve. Only about 1.25 cm ($\frac{1}{2}$ inch) of the long needle protrudes from the guide.

Technique. Before induction of anesthesia, a woman breathes oxygen for 3 to 5 minutes, or at least four deep breaths, to increase her oxygen stores and those of her fetus for the short period of apnea during rapid anesthesia induction. The woman has a wedge under one side, usually her right (or the operating table is tilted), to reduce aortocaval compression and increase placental blood flow.

Adverse Effects. Major adverse effects are possible with the use of general anesthesia.

Maternal Aspiration of Gastric Contents. Regurgitation with aspiration of acidic gastric contents is a potentially fatal complication of general anesthesia. Aspiration of food particles may result in airway obstruction. Aspiration of acidic secretions results in a chemical injury

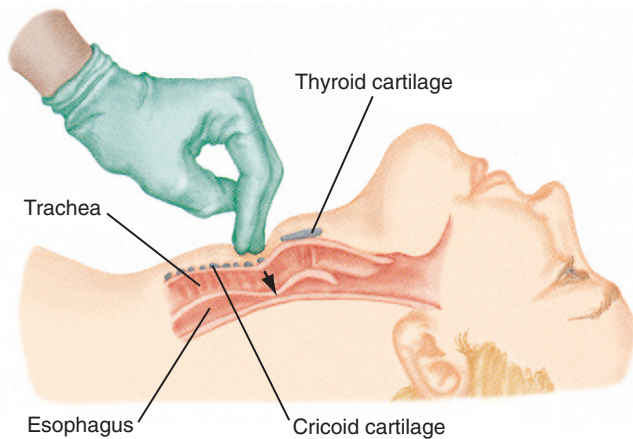

FIG 15-16 Cricoid pressure, or Sellick's maneuver, is used to prevent vomitus from entering the woman's trachea while she is being intubated for general anesthesia. An assistant applies pressure to the cricoid cartilage to obstruct the esophagus. Once the woman is successfully intubated with a cuffed endotracheal tube, gastric secretions cannot enter the trachea.

to the airways—**aspiration pneumonitis**. Infection often occurs after the initial lung injury.

Respiratory Depression. Respiratory depression may occur in either the mother or the infant but is more likely in the baby. This is more likely to occur if the interval between induction of anesthesia and cord clamping is long.

Uterine Relaxation. Some inhalational anesthetics may cause uterine relaxation. This characteristic is desirable for treating some complications, for example, replacing an inverted uterus. However, postpartum hemorrhage may occur if the uterus relaxes after birth.

Methods to Minimize Adverse Effects. Measures to reduce the risk of maternal aspiration or to limit lung injury if aspiration occurs include the following:

- Restricting intake to clear fluids or maintaining nothing-by-mouth (NPO) status if surgery is expected, such as with a scheduled cesarean birth
- Administering drugs to raise the gastric pH and make secretions less acidic, for example, sodium citrate and citric acid (Bicitra), ranitidine (Zantac), cimetidine (Tagamet), or famotidine (Pepcid)
- Administering drugs to reduce secretions, for example, glycopyrrolate (Robinul)
- Administering drugs to speed gastric emptying, for example, metoclopramide (Reglan)
- Using cricoid pressure (Sellick maneuver) to block the esophagus by pressing the rigid trachea against it (Figure 15-16)

Neonatal respiratory depression may be prevented by doing the following:

- Reducing the time from induction of anesthesia to clamping of the umbilical cord
- Keeping use of sedating drugs and anesthetics to a minimum until the cord is clamped

To reduce the time from induction of anesthesia to cord clamping, the woman is prepared and draped and the physicians are ready before anesthesia is induced. The anesthesia is kept light until the infant is born and the woman may move slightly on the table, although she usually has no memory of the experience. The anesthesia level is deepened as soon as the cord is clamped.

APPLICATION OF THE NURSING PROCESS

■ Pain Management

Nursing care related to pain management should be combined with support for normal labor and any complications that arise. Care of the fetus remains important (see Chapter 14). Two problems that affect many women are pain and care related to epidural analgesia (see Case Study 15-1).

PAIN

Assessment

Pain assessment begins at admission and continues throughout labor and postpartum (see Table 13-1). Pain-related assessments include the following:

- Preferences for pain management
- Previous surgeries, type of anesthesia, and any anesthesia-associated problems
- Maternal vital signs
- FHR and electronic fetal monitor patterns
- Allergies, focusing especially on allergy to opioid analgesics, dental anesthetics, and iodine (used in some skin preparation solutions)
- Oral intake—time and type of last intake
- Evidence of pain—verbal statement, requests for pain-relief measures, crying, moaning; and nonverbal evidence such as tense, guarded posture or facial expression

Labor Status

In addition to these routine assessments, ask the woman if she needs help with pain management. A stoic woman may give little evidence of pain yet may say she wants medication or other pain control, if asked.

When assessing pain, clarify the words a woman uses. When asked if she has “pain,” the woman may deny it. Yet changing the word used to “discomfort,” “cramping,” “aching,” “pressure,” or other words that may describe labor pain may elicit a different response. Do not assume that everyone uses the same words to describe his or her pain. Pain is an individual experience, and so is the expression of pain.

Asking a woman to rate her pain on a scale of 0 to 10 (or your facility's standard scale) helps clarify her pain's intensity. A zero represents no pain, whereas 10 is the worst possible pain. Ask the woman to rate her pain on this scale before and after pain-relief measures to evaluate their effectiveness. Multilingual and picture scales are available for those who do not speak the dominant language.

A surprising number of women have difficulty using a pain scale because they have little experience with pain. They may underestimate current pain, expecting an increase in the amount of pain (and therefore pain number) later in labor, or they may say that they have no idea what the “worst pain imaginable” is and therefore cannot guess how a

pain rating of 10 feels. A scale or description by the woman does, however, provide one measure of how pain feels before and after relief measures. Gulliver, Fisher, and Roberts (2008a, b) describe a Coping with Labor Algorithm developed at the University of Utah Hospital and Clinics. The algorithm provides examples of questions the nurse might ask, examples of behavior cues if the woman is or is not coping, and appropriate nursing actions.

Body language gives a clue to comfort level. Moaning, crying, thrashing, and an inability to use nonpharmacologic techniques are likely indicators that a woman needs help with pain control, including pharmacologic pain relief. However, more subtle clues such as remaining tense between contractions also suggest difficulty coping with pain.

Evaluate the woman's labor status to help her choose the most appropriate method of pain control. Inform her if she has reached a decision point in labor to use or not use a specific pharmacologic method. No standard time or amount of cervical dilation serves as a guideline for this critical point. This is estimated on the basis of projected time of birth, amount of time needed to establish a specific method, and the pharmacology of the drug or drugs.

Avoid making assumptions about a woman's pain based on her rate of labor progress, cervical dilation, or apparent intensity of contractions. Do not assume that a woman whose cervix is 2 cm dilated has little pain and that a woman whose cervix is dilated 8 cm has intense pain. An obese woman's contractions may be strong, but they may seem mild if they are assessed by palpation or an external monitor because of her thick abdominal fat pad. *Labor progress or contraction intensity cannot be equated with a woman's pain perception or tolerance.*

A woman's need for pain relief should not be based only on her outward expression. A quiet woman may need medication but may be reluctant to ask, whereas an expressive woman may be satisfied with only nonpharmacologic measures. Because women who do not speak the prevailing language may not know what is available, seek an interpreter not related to the laboring woman to communicate most effectively.

Observe for and report pain that is not typical of normal labor. Although labor pain is often intense, it should come and go with each contraction. The uterus should not be tender or boardlike between contractions and should not cause constant intense pain.

Nursing Diagnosis

Pain is expected in normal childbirth, and most laboring women have nursing needs that relate to its management. The nursing diagnosis is "Acute Pain related to effects of uterine contractions and fetal descent."

Planning

Because pain is a subjective experience and expected in labor, two expected outcomes are realistic. The woman will do the following:

1. Describe pain-relief measures, both nonpharmacologic and pharmacologic, as satisfactory during labor.
2. Effectively use breathing and relaxation techniques learned in childbirth class or from the nurse during labor.

Interventions

Nursing care related to intrapartum pain management focuses on reducing factors that hinder the woman's pain control and enhancing those that benefit it (see Chapter 13). Although epidurals are very common in North American hospitals, do not make the assumption that every woman will want one for birth. Caring contact with a nurse enhances pain management and the overall experience of giving birth.

Promoting Relaxation

Simple attention to details promotes relaxation. Make the environment more comfortable. If noise is a problem, suggest music or television to mask it. A warm blanket, a cool cloth, or a warm pack provides tangible comfort and conveys the nurse's caring attitude. Change linens and underpads, as needed, to keep the woman reasonably clean and dry.

Offer the woman a warm shower or bath, especially if she is tense and if no contraindications exist (see Box 15-1). In general, walking is good during early labor, and water therapy is better during active labor. The mild nipple stimulation that occurs in a whirlpool or shower may intensify contractions in a woman whose labor has slowed, causing her posterior pituitary gland to secrete oxytocin.

Reduce intrusions as much as possible. For example, wait until a contraction is over before asking questions or performing a procedure. Longer assessments and procedures may span several contractions, but try to stop during each contraction, if possible.

Reducing Outside Sources of Discomfort

Anesthetize the IV site with lidocaine (Xylocaine) before inserting the line if the woman is not allergic and if policy permits. Normal saline infiltration of the site has a similar effect. Remind her to change position regularly to reduce tension and discomfort from constant pressure. Support her with pillows.

Observe the woman's bladder for distention hourly, and encourage her to void every 2 hours or more often if she has received a large quantity of IV fluids. Most intrapartum orders include one for catheterization if the woman cannot void and her bladder is full. An indwelling catheter may be inserted for women who have an epidural to reduce repeated catheterizations.

Reducing Anxiety and Fear

Accurate information reduces the negative psychological impact of the unknown. Tell the woman about her labor and its progress. You cannot predict when she will give birth, but tell her if labor progress is or is not on course. Sometimes, she needs only the reassurance from an experienced nurse that her intense contractions are, indeed, normal. The woman may be willing to endure more discomfort than she otherwise would if she is making progress.

Be honest if problems do occur. A woman usually knows if a problem exists and is more anxious if she does not know what it is. Explain all measures taken to correct the problem, and inform her of the results.

Helping the Woman Use Nonpharmacologic Techniques

If the nonpharmacologic method is safe for the woman and fetus and if it is effective, do not interfere with its use. Try not to distract the woman from whatever technique she is using.

Massage. Fetal monitor belts hinder abdominal effleurage. Encourage the woman to do effleurage on uncovered areas of her abdomen or to stroke her thighs. Consider using intermittent auscultation or intermittent EFM (see Chapter 14).

Use powder to avoid friction, and seek feedback from the woman about the best location and amount of pressure to use for sacral pressure or other massage. Because this information may change during labor or massage may become uncomfortable rather than helpful, seek the woman's feedback regularly.

Mental Stimulation. Use a low, soothing voice when helping a woman use imagery. Speaking close to her ear is often helpful when trying to create a tranquil imaginary scene or to calm her. Use of a low, soothing voice during an emergency has a calming effect as well. Music can enhance mental stimulation techniques.

Breathing. Women often modify the techniques they learn in class or invent some of their own during labor. Encourage the woman to change techniques when she feels it is necessary but to save the complex ones for later labor. If she has trouble maintaining her concentration, the nurse or her support person may try to make eye contact (if culturally appropriate) and breathe the pattern with her.

Symptoms of hyperventilation (dizziness, tingling and numbness of the fingers and lips, carpopedal spasm) are likely if a woman breathes fast and deep. If she hyperventilates, she should breathe into her cupped hands, a paper bag, or a washcloth placed over her nose and mouth. Talk to her gently to slow her breathing.

Teach breathing techniques to the unprepared woman and her coach when she is admitted. Review them when she seems to need a different method. If she makes up a breathing technique that works, leave it alone.

When teaching pain management techniques to the unprepared woman who is in advanced labor, follow these guidelines:

- Teach one method at a time.
- Demonstrate the method between contractions.
- Use breathing techniques with the woman while maintaining eye contact.
- Give her control over her labor (for example, who is present or what technique she will use).
- Speak in a soft, calm tone of voice.

Incorporating Pharmacologic Methods

All pharmacologic methods require collaboration with medical personnel for orders. Tell the woman soon after admission what medication is available if she needs it. This is intended not to undermine her self-confidence but to allow her to make an informed choice about medication, when necessary. Analgesia is most effective if it is given before pain is severe.

Tell the woman that her preferences about pain-relief methods will be honored if possible, but predicting the course of her labor is impossible. Her preferred method of pain management may be inappropriate if labor has unexpected developments. Assure her that no

PARENTS WANT TO KNOW

How Will This Medicine Affect Our Baby?

Women and their partners often ask whether pain medication or anesthesia will harm their baby. The nurse can help parents choose wisely from available options by providing honest information:

- Pain that you cannot tolerate is not good for you or your baby, and it reduces the joy of this special event.
- Some risk is associated with every type of pain medication or anesthesia, but careful selection and the use of preventive measures minimize this risk. If complications occur, corrective measures can reduce the risk to you and your baby.
- Some pain relievers can cause your baby to be slow to breathe at birth, but carefully controlling the timing and dose of the medication reduces the likelihood that this will occur. We can use another medication to reverse this effect, if needed.
- Epidural or spinal anesthesia can cause your blood pressure to fall, which can reduce the blood flow to your baby. However, we give you lots of intravenous fluids to reduce this effect. We have other medications to increase your blood pressure if the fluids are not enough.
- General anesthesia can cause your baby to be slow to breathe at birth. To reduce this risk, the anesthesia will not be started until everything is ready for the surgery, and the doctors will clamp the baby's umbilical cord as quickly as possible.

pharmacologic method will be used without her understanding and consent (see [Parents Want to Know: How Will This Medicine Affect Our Baby?](#)).

If a woman finds nonpharmacologic methods inadequate, help her try other ones or offer her available medication. When contacting the birth attendant for medication orders, report the fetal and maternal status and vital signs, labor status, and her request for medication. If she has a continuous epidural block, contact the person who inserted it if problems occur. Observe special nursing considerations associated with the method used ([Table 15-2](#)).

Evaluation

Labor is not expected to be painless, even with the most effective pharmacologic methods. The first goal or expected outcome is achieved if the woman is satisfied with her ability to manage her pain. Many women have occasional difficulty using breathing or other techniques, even if they have practiced faithfully. The nurse may ask the following questions: How did the woman's pain scale rating change before and after the pain-relief method, whether nonpharmacologic or pharmacologic, was used? Is she satisfied with her level of pain relief?

EPIDURAL ANALGESIA

Many women choose epidural analgesia for pain relief during labor because of its effectiveness without sedation. Epidural block analgesia requires a number of specific nursing assessments and interventions.

Assessment

The admission assessment focuses on possible allergies to local anesthetics or opioid drugs that might be used in the block. Determine baseline maternal vital signs and the FHR and pattern. Assess for any skin infection in the area of the back where the epidural will be inserted.

Nursing Diagnosis

The primary risks associated with epidural analgesia are maternal hypotension and injury. These result in a collaborative problem and a nursing diagnosis:

- Potential complication—maternal hypotension with secondary fetal hypoxia
- Risk for Injury related to reduced sensation and movement secondary to varying epidural effects

Planning

Goals or expected outcomes are not appropriate for collaborative problems such as the potential complication of hypotension. The nurse's responsibilities include the following:

- Provide ordered preload of IV fluid.
- Observe for hypotension and report its occurrence to the professional who is in charge of the anesthetic for definitive treatment.

However, the following expected outcome is appropriate for the "Risk for Injury" nursing diagnosis: The woman has achieved the outcome if she does not have a treatment-related injury while her sensation and mobility are reduced.

Interventions

Maternal Hypotension

Maternal hypotension reduces blood supply to the placenta, decreasing fetal oxygen and nutrient supply and waste removal. Birth facilities will have policies that provide specific guidelines for care when women receive epidural block. Infuse the prescribed IV solution, at least 500 to 1000 mL, before the block's initiation. If the woman has not received

Assess the woman for drug use at admission. <ul style="list-style-type: none"> Women who are opiate-dependent should not receive analgesics having mixed agonist and antagonist actions (butorphanol and nalbuphine). 2. Observe neonate for respiratory depression, especially if mother had opioid narcotics within 4 hours of birth or at time of drug's peak action, or if mother received multiple opioid doses during labor: <ul style="list-style-type: none"> • Delay in initiating or sustaining normal depth and rate of respirations • Respiratory rate <30/min • Poor muscle tone: limp, floppy 3. Use of adjunctive drugs for nausea, such as promethazine, enhances respiratory depressant effects. 4. Have naloxone available for infants exposed to opioids during labor. Respiratory (bag-and-mask) and cardiac support precede drug administration in neonatal resuscitation. Observe for recurrent respiratory depression after administration of naloxone.
<p>Epidural Opioids</p> <p><i>Labor:</i> Mixed with a local anesthetic agent to give better pain relief with less motor block.</p> <p><i>Postoperatively:</i> Gives long-acting analgesia without sedation, allowing mother and infant to interact more easily.</p>	<ol style="list-style-type: none"> 1. Monitor for same nursing implications as with epidural block. 2. Do not give additional opioids or other CNS depressants except as ordered by anesthesia provider. Nonsteroidal antiinflammatory drugs or oral analgesics are often prescribed in routine orders. 3. Maternal respiratory depression may be delayed for up to 24 hours and varies with drug given. Observe respiratory rate and depth, oxygen saturation, and arousability hourly for 24 hours or as ordered. Notify the anesthesia provider for respiratory rate of <12/min, persistent oxygen saturation of <95% on pulse oximetry, reduced respiratory effort, difficulty arousing, or as ordered by provider. Cyanosis is a late sign of respiratory depression. 4. Have naloxone 0.4 mg, an oral airway, and an Ambu bag and mask immediately available, such as on a "crash cart." 5. Observe for pruritus or rubbing of face and neck. Routine postoperative orders to relieve pruritus are usually provided. Notify the anesthesia provider if these are inadequate. 6. Urinary retention may occur after indwelling catheter removal. Observe for adequacy of voiding, as in all postpartum women. 7. Notify the anesthesia provider for relief of nausea or vomiting. 8. Assess sensation and mobility before allowing ambulation.
<p>Intrathecal Opioid Analgesics</p> <p>Provides analgesia for most of first-stage labor without maternal sedation. A very small dose of the drug is needed because it is injected very near spinal cord where sensory fibers enter. Usually not adequate for late labor or birth itself. Often combined with epidural block for combined spinal-epidural (CSE) technique for labor.</p>	<ol style="list-style-type: none"> 1. Observe for common side effects of nausea, vomiting, and pruritus. Notify the anesthesia provider if these effects occur, and have an antagonist such as naloxone or naltrexone available. 2. Observe for delayed respiratory depression, depending on drug given. Use a pulse oximeter, as indicated. 3. Observe for nonreassuring fetal heart rate patterns that may be associated with reduced maternal oxygenation.
<p>Local Infiltration Anesthesia</p> <p>Numbs perineum for episiotomy or repair of laceration at vaginal birth. No relief of labor pain. Not adequate for instrument-assisted birth. (See Chapter 16.)</p>	<ol style="list-style-type: none"> 1. Assess for drug allergies, especially to dental anesthetics because they are related to those used in maternity care. 2. Apply ice to perineum after birth to reduce edema and hematoma formation and to increase comfort.
<p>Pudendal Block</p> <p>Numbs lower vagina and perineum for vaginal birth. No relief of labor pain because it is done just before birth. Provides adequate anesthesia for many instrument-assisted births. (See Chapter 16.)</p>	<ol style="list-style-type: none"> 1. Use same interventions as for local infiltration. A woman or her partner may be alarmed if the long needle is noticed (about 15 cm [6 inches]). Teach her that it must be long to reach the pudendal nerve through the vagina and that it will be inserted only about 1.25 cm (½ inch) near the location of the nerve. Tell her that a guide ("trumpet") will be used to avoid injuring her vaginal tissue or that of her baby.

Continued

TABLE 15-2 PHARMACOLOGIC METHODS OF INTRAPARTUM PAIN MANAGEMENT—cont'd

METHOD AND USES	NURSING CONSIDERATIONS
<p>Epidural Block</p> <p><i>Labor:</i> Insertion of catheter provides pain relief for labor and vaginal birth (T10-S5 levels).</p> <p><i>Cesarean birth:</i> If epidural was used during labor, level of block can be extended upward (T4-T6 level). Also used for cesarean birth that is not preceded by labor.</p>	<ol style="list-style-type: none"> 1. Prehydrate woman with warmed nonglucose crystalloid solution such as Ringer's lactate or normal saline solution. Common minimum amounts: 500-1000 mL for labor and vaginal birth; 1500-2000 mL for planned cesarean birth and postbirth tubal ligation. 2. Displace uterus manually or with a wedge placed under woman's side to enhance placental perfusion. 3. Assess for hypotension at least every 5 minutes for 15 minutes after block is begun and with each new dose until vital signs are stable. Report following to anesthesia provider: systolic blood pressure (BP) of <100 mm Hg or a fall of 20% or more from baseline levels, pallor, or diaphoresis. Facility procedures give further guidance. 4. Assess fetal heart rate for signs of impaired placental perfusion, and report following to anesthesia provider and nurse-midwife: tachycardia (>160 bpm for 10 minutes), bradycardia (<110 bpm for 10 minutes), late decelerations (see Table 14-1, p. 268). 5. If hypotension or signs of impaired placental perfusion occur, increase rate of infusion of nonadditive IV fluid, reposition woman to her side, and administer oxygen by face mask (8-10 L/min). Have ephedrine available (usually included in epidural tray). 6. Observe for a full bladder, and catheterize if the woman is unable to void. 7. Leg movement and strength vary after an epidural block. Transfer with help to avoid muscle strains to the nurse or the woman. 8. Have the woman ambulate only if adequate sensation and movement are present and with another person's assistance with first ambulation.
<p>Subarachnoid Block (SAB)</p> <p><i>Cesarean birth:</i> Can be established slightly faster than epidural block.</p> <p>Rarely used for complicated vaginal birth.</p> <p>Does not provide pain relief for labor because it is done just before birth.</p> <p>May be combined with an epidural block in a CSE. See "Intrathecal Opioid Analgesics" for more information.</p>	<ol style="list-style-type: none"> 1. See "Epidural Block" for these interventions: <ul style="list-style-type: none"> • IV prehydration • Uterine displacement • Observation of blood pressure and fetal heart rate • Care for hypotension or signs of impaired placental perfusion • Observation and intervention for bladder distention • Transfer and ambulation precautions 2. Observe for postspinal headache—a headache that is worse when woman is upright and that may disappear when she is lying flat. Notify the anesthesia provider if it occurs (a blood patch may be done). 3. Nursing interventions for postspinal headache: encourage bed rest, increase oral fluids if not contraindicated, give oral caffeine, and give analgesics, as ordered.
<p>General Anesthesia</p> <p>Cesarean birth if epidural or spinal block is not possible or if woman refuses regional anesthesia. May be required for emergency procedures such as replacement of inverted uterus.</p>	<ol style="list-style-type: none"> 1. Determine type and time of last food intake on admission. 2. Restrict oral intake to clear liquids or as ordered. Consult with the physician or nurse-midwife if surgical intervention is likely. 3. Report to anesthesia provider: oral intake before and during labor, vomiting. 4. Displace uterus (see "Epidural Block"). 5. Give ordered drugs such as sodium citrate and citric acid (Bicitra). 6. Maintain cricoid pressure (Sellick maneuver) during intubation. 7. Woman will remain intubated until protective (gag) reflexes have returned. Have oral airway and suction immediately available. Oxygen by face tent or face mask should be given after extubation. 8. Interventions for postoperative respiratory depression: give positive-pressure oxygen by face mask; observe oxygen saturation with pulse oximetry until woman is awake and alert; have woman take several deep breaths if oxygen saturation falls below 95%. Notify the anesthesia provider.

*CNS, Central nervous system; IV, intravenous; PCA, patient-controlled analgesia.

the full amount when the block is begun, notify the anesthesia professional.

The epidural may be placed, with the woman in the sitting or side-lying position, based on the decision of the anesthesia provider. If she is in a sitting position, hugging a pillow or a small birth ball helps her hold the correct position. Tell the anesthesia clinician when the woman is having a contraction. She may feel a brief “electric shock” sensation as the catheter is passed. After the epidural is initiated, maintain her position so that aortocaval compression is avoided, for example, by placing a pillow under one hip.

Measure the woman’s blood pressure and pulse rate (often an automatic cuff is used) every 2 to 3 minutes, or according to the facility’s protocol, for 15 to 20 minutes after the initial injection of medication, comparing the values with her baseline blood pressure and pulse rate. Maintain continuous EFM. A significant blood pressure decrease is a 20% fall from her baseline or a drop to 100 mm Hg or lower systolic. Hypotension of any degree accompanied by FHR decelerations is significant. If hypotension occurs, increase the rate of her IV fluid infusion, keeping her positioned to avoid aortocaval compression. Ephedrine, usually 5 to 10 mg, is ordered if hypotension is significant and a fluid increase does not quickly improve it. When the blood pressure is stable, assess it every 15 minutes. Pulse oximetry identifies a decrease in maternal oxygenation status to below 95%. Most electronic fetal monitors have the options of automatic blood pressure and pulse oximetry.

Continue observing the FHR. Signs of reduced placental perfusion may be evident before the woman shows signs of hypotension. These include fetal tachycardia (more than 160 bpm) or bradycardia (less than 110 bpm) and late decelerations (see [Chapter 14](#)). Take the mother’s temperature to identify elevations that may also contribute to fetal tachycardia.

Avoidance of Injury

Epidural block reduces lower extremity sensation and movement to varying degrees. Some women have such a light motor block that their epidural is called a “walking epidural.” However, to prevent falls, these women should not walk alone. Most women must remain in bed or sit in a nearby chair after their epidural is begun because of reduced sensation.

Assess the degree of motor block and sensation hourly. If a distinct increase or change is noted, report it to the anesthesia clinician because this may indicate catheter migration or another complication.

A woman who has reduced mobility and sensation should be moved so that she maintains an anatomic position. Avoid prolonged pressure on one area. Remember that changing position often improves labor progress, even if the woman does not need to change positions for comfort. If surgery is needed, pad bony prominences to reduce pressure on those areas.

Before any ambulation, such as for urination after birth, test the woman’s ability to raise and move her legs. Have her push her legs against your hands to determine her leg strength. When she ambulates, accompany her and monitor her ability to move and her strength the entire time the epidural is in effect. The woman should sit before standing to evaluate for postural (orthostatic) hypotension, which may occur in any postpartum woman regardless of her pain management methods during labor.

Evaluation

The collaborative problem is not evaluated, but the nurse compares the woman’s baseline blood pressure and FHR to those after the block is begun to identify any significant changes. The goal or expected outcome related to injury is achieved if the woman does not have an

injury related to her altered sensation and mobility while the epidural block is exerting its effects.

RESPIRATORY COMPROMISE

Assessment

General anesthesia may be needed any time during birth, most often for cesarean birth. Document the type (solids or liquids) and time of the woman’s last food intake. Question her closely if she reports an unusually long interval since her last oral intake. Anesthesia providers can anticipate and prevent problems better if they know the actual oral intake, although most assume that every woman has food in her stomach and induce general anesthesia accordingly.

Nursing Diagnosis

The nursing diagnosis appropriate to minimize respiratory compromise that may affect both the woman and her fetus is “Risk for Aspiration related to impaired protective laryngeal reflexes.”

The expected outcome is that the woman will not aspirate gastric contents during the perioperative period.

Planning

Nursing care of pregnant women who may require general anesthesia includes monitoring for the short-term risk for aspiration. It is impossible to predict every laboring woman who will require general anesthesia. In addition, surgery that requires general anesthesia may be required at any point during pregnancy such as for appendectomy or injury.

Interventions

Nursing interventions relate to identifying factors that increase a woman’s risk for aspiration and collaborative and nursing measures to reduce the risk of aspiration or lung injury.

Identifying Risk Factors

Report oral intake both before and after admission to the anesthesia provider. Oral intake during labor may be restricted to medications, clear liquids such as water and ice, clear fruit juices, carbonated drinks, clear tea and coffee, sports drinks, and Popsicles, or hard sugar-free candies ([ACOG, 2011](#)).

Vomiting is a common occurrence during normal labor, regardless of the mother’s oral intake. If vomiting occurs, chart the time, quantity, and character (amount, color, presence of undigested food).

Reducing Risk for Aspiration or Lung Injury

Nursing and medical personnel collaborate to reduce a woman’s risk for pulmonary complications.

Perioperative Care

Restrict oral intake, as ordered, if surgery is expected. Give ordered medications such as sodium citrate and citric acid (Bicitra). Depending on when the medications are needed, either the nurse or the anesthesia provider may administer parenteral drugs such as glycopyrrolate (Robinul).

An experienced nurse or a trained anesthesia assistant provides cricoid pressure (Sellick maneuver) to block the esophagus until the woman is intubated and the cuff of the endotracheal tube is inflated. Successful intubation with the cuffed endotracheal tube blocks passage of any gastric contents into the trachea. The value of cricoid pressure has not been thoroughly researched ([O’Sullivan and Hari, 2009](#)).

Postoperative Care

Birth facility protocols guide postoperative care, including preextubation and postextubation care for the woman who has had general anesthesia. The woman is extubated when her protective laryngeal reflexes have returned, often before transfer from the operating table. Suction equipment and an Ambu bag with appropriate-size mask should be immediately available not only in the operating room and postanesthesia care unit but also in standard patient care rooms on the nursing unit. Administer oxygen by mask or face tent for 2 to 5 minutes until the woman is awake and alert because the agents used for general anesthesia are respiratory depressants. Monitor oxygen saturation with a pulse oximeter. If her oxygen saturation falls below 95%, have her

take several deep breaths. Deep breathing also helps her eliminate inhalational anesthetics and reduces stasis of pulmonary secretions.

Assess the woman's pulse rate, respiration, and blood pressure every 15 minutes for 1 hour or until stable; then continue according to policy. In addition to using pulse oximetry, observe her color for pallor or cyanosis, which respectively suggest shock or hypoventilation.

Evaluation

Interventions for this nursing diagnosis are preventive and short term because it is a temporary high-risk situation. The goal is met if the woman does not aspirate gastric contents during the perioperative period.

SUMMARY CONCEPTS

- Childbirth pain is unique because it is normal and self-limiting, the woman has time to prepare for the pain, and the pain ends with a baby's birth.
- Excess or poorly relieved pain may be harmful to the mother and fetus.
- Pain is a complex physical and psychological experience. It is subjective and personal.
- Four sources of pain are present in most labors, but other physical and psychological factors may increase or decrease the pain felt from these sources. These sources are cervical dilation, uterine ischemia, pressure and pulling on pelvic structures, and distention of the vagina and perineum.
- Relaxation enhances all other pain management techniques.
- Several nonpharmacologic pain management techniques supplement relaxation—cutaneous stimulation, hydrotherapy, mental stimulation, and breathing techniques.
- Physiologic alterations of pregnancy may affect a woman's response to medications.
- Any drug that the expectant mother takes, whether therapeutic or abused, including herbal or botanical preparations, also may affect

the fetus. Fetal effects may be direct or indirect and their durations of action may be different from those in an adult.

- The nurse should observe for respiratory depression, primarily in the newborn, if the mother has received opioid analgesics during labor.
- The major advantages of regional pain management methods are that the woman can participate in the birth and that she retains her protective airway reflexes.
- The nurse should monitor and take actions to prevent maternal hypotension that may result from an epidural or subarachnoid block.
- If the woman receives a regional pain management technique that carries the risk for maternal hypotension, the nurse should observe for fetal heart rate changes associated with impaired placental perfusion.
- The primary adverse effects that should be monitored in the woman who receives epidural or intrathecal opioids are nausea and vomiting, pruritus, and delayed respiratory depression.
- Regurgitation with aspiration of acidic gastric contents is the greatest risk for a woman who receives general anesthesia.

Nursing Care during Obstetric Procedures

WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Identify clinical situations in which specific obstetric procedures are appropriate.
2. Explain risks, precautions, and contraindications for each procedure.
3. Identify nursing considerations for each procedure.
4. Identify methods to provide effective emotional support to the woman undergoing an obstetric procedure.
5. Apply the nursing process to care for the woman having a cesarean birth.

Although labor is a normal process, some women require special procedures to help them and their fetuses. A physician or nurse-midwife performs these procedures. Nursing considerations for each procedure are addressed in this chapter.

AMNIOTOMY

Indications

Amniotomy (artificial rupture of the amniotic sac) is usually performed in conjunction with **induction** (artificial initiation) and **augmentation** of labor (artificial stimulation of ineffective uterine contractions) and to allow internal electronic fetal monitoring (see Chapter 14). Amniotomy is not often used as the sole means to induce and augment labor, and more data are needed to determine its effectiveness when used in this way (Simpson, 2008c). Amniotomy also is associated with risks that must be considered by the birth attendant before performing the procedure.

Risks

Amniotomy is performed by the physician or nurse-midwife. The nurse must observe for three risks associated with amniotomy—prolapse of the umbilical cord, infection, and abruptio placentae—and must assist in emergency procedures. Spontaneous rupture of membranes has the same three risks.

Prolapse of the Umbilical Cord

The primary risk is that the umbilical cord will slip down in the gush of fluid. The cord can be compressed between the fetal presenting part and the woman's pelvis, obstructing blood flow to and from the placenta and reducing fetal gas exchange.

Infection

With interruption of the membrane barrier, vaginal organisms have free access to the uterine cavity and may cause **chorioamnionitis** (inflammation of the amniotic sac, usually caused by bacterial and viral infections). The risk is low at first but increases as the interval between membrane rupture and birth increases. Birth within 24 hours of membrane rupture is desirable, although infection does not occur at any absolute time.

Abruptio Placentae

Abruptio placentae can occur if the uterus is distended with excessive amniotic fluid when the membranes rupture. As the uterus collapses with discharge of the amniotic fluid, the area of placental attachment shrinks. The placenta then no longer fits its implantation site and partially separates. A large area of placental disruption can significantly reduce fetal oxygenation, nutrition, and waste disposal.

FIG 16-1 **A**, Disposable plastic membrane perforator. **B**, Close-up of hook end of plastic membrane perforator. **C**, Correct method to open the package. **D**, Technique for artificial rupture of membranes.

Technique

A disposable plastic hook (such as AmniHook) is commonly used to perforate the amniotic sac (Figure 16-1). The birth attendant performs a vaginal examination to determine cervical dilation and effacement, fetal station, and fetal presenting part. Amniotomy is often deferred if the fetal presenting part is high or the presentation is not cephalic. The risk of a prolapsed cord is higher in these situations because more room is available for the cord to slip down. The fetus in a noncephalic presentation is more likely to be born by **cesarean birth** (surgical birth of the fetus) and an amniotomy is done at the time of surgery through the abdominal and uterine incisions.

The hook is passed through the cervical opening, snagging the membranes. The opening in the membranes is enlarged with the finger, allowing fluid to drain.

Nursing Considerations

Obtaining Baseline Information

The fetal heart rate (FHR) is assessed with electronic monitoring or auscultation to verify a reassuring rate and pattern before amniotomy is performed. The initial fetal assessment provides a baseline to compare with later assessments. A minimum of 20 to 30 minutes is needed for adequate baseline fetal evaluation.

Assisting with Amniotomy

Before amniotomy, two or three underpads should be placed under the woman's buttocks to absorb the fluid; the underpads should be overlapped to extend from her waist to her knees. A folded bath towel under the buttocks absorbs more amniotic fluid. Explain to the woman that amniotomy is no more painful than a vaginal examination because there are no sensory nerves in the amniotic sac. Also, the amniotic sac is fetal tissue rather than maternal tissue.

Other supplies needed are a disposable plastic hook, sterile glove for the birth attendant, and a packet of sterile lubricant. The nurse should partly open the package containing the plastic hook at the handle end and hold back the package until the birth attendant takes the hook with a sterile, gloved hand.

Providing Care after Amniotomy

Nursing care after amniotomy is the same as that after spontaneous membrane rupture.

Identifying Complications. The FHR is assessed for at least 1 full minute after amniotomy. Nonreassuring monitor patterns or significant changes from previous assessments are reported promptly to the birth attendant and assessment continues. Cord compression is usually accompanied by a rate less than 100 beats per minute (bpm), which further falls during contractions.

The quantity, color, and odor of the amniotic fluid are charted. The fluid should be clear (often with bits of vernix) and have a mild odor. A large amount of vernix in the fluid suggests that the fetus may be preterm. Greenish, meconium-stained fluid may be seen in postterm gestation or placental insufficiency. Fluid with a foul or strong odor, cloudy appearance, or yellow color suggests chorioamnionitis. **Hydramnios** (excessive volume of amniotic fluid) is associated with some fetal abnormalities. **Oligohydramnios** (abnormally small quantity of amniotic fluid) may be associated with placental insufficiency or fetal urinary tract abnormalities.

CRITICAL THINKING EXERCISE 16-1

A physician performs an amniotomy on a laboring woman whose cervix is dilated to 5 cm. The amniotic fluid is pale yellow and moderate in amount, and it has a strong odor. The baseline fetal heart rate ranges from 155 to 165 beats per minute (bpm), accelerating when the fetus moves. Maternal vital signs are as follows: temperature, 99.7°F (37.6°C); pulse rate, 92 bpm; respirations, 22/min; blood pressure, 116/80 mm Hg. Contractions are of moderate to firm intensity, every 3 to 4 minutes, with a duration of 50 to 60 seconds and complete uterine relaxation between contractions.

Questions

1. Which of these observations should the nurse regard as normal? Which factors are abnormal?
2. Should the nurse modify routine labor care based on the postamniotomy assessments?

Adequate amniotic fluid is necessary for lung development throughout pregnancy. The fetus with prolonged oligohydramnios may have respiratory problems after birth because the lungs cannot expand normally.

The woman's temperature should be assessed at least every 2 to 4 hours after the membranes rupture. Elevations above 38°C (100.4°F) should be reported. A rising FHR and fetal tachycardia (above 160 bpm) may precede maternal fever.

Promoting Comfort. Amniotic fluid continues to leak from the woman's vagina. Regularly changed underpads keep her drier and reduce the moist environment that favors bacterial growth.

INDUCTION AND AUGMENTATION OF LABOR

Induction and augmentation of labor use artificial methods to stimulate uterine contractions. Techniques and nursing care are similar for both induction and augmentation.

Induction of labor is an increasingly common procedure in intrapartum units and has more than doubled in just over a decade. Inductions for 2009 were 23.2% of births and may have contributed to the higher cesarean birth rate of 32.9% for women of all racial origins. Induction rates were highest for non-Hispanic white mothers (27%) in contrast to non-Hispanic black mothers (21%) and Hispanic mothers (17.5%). It has been suggested that the shifting of deliveries toward earlier gestational ages may be due to increased use of induction, and other obstetric interventions such as cesarean delivery (Martin, Hamilton, Ventura et al., 2011).

Indications

Induction of labor is performed when a continued pregnancy may jeopardize the health of the woman or fetus and labor and vaginal birth are considered safe. Labor induction is not done if the fetus must be delivered more quickly than the process permits, in which case a cesarean birth is performed. Induction is indicated in the following conditions (American College of Obstetricians and Gynecologists [ACOG], 2009):

- Conditions in which the intrauterine environment is hostile to fetal well-being (e.g., intrauterine fetal growth restriction, maternal-fetal blood incompatibility)
- *Spontaneous rupture of the membranes* (SROM) at or near term without onset of labor, also called **premature rupture of the membranes** (PROM) if pregnancy is preterm, or less than 37 weeks (see Chapter 27).
- Postterm pregnancy
- Chorioamnionitis (inflammation of the amniotic sac)
- Hypertension associated with pregnancy or chronic hypertension, both of which are associated with reduced placental blood flow
- Abruptio placentae (large abruptions require immediate delivery; see Chapter 25)
- Maternal medical conditions that worsen with continuation of the pregnancy (such as diabetes, hypertension, renal disease, pulmonary disease, heart disease) (see Chapters 25 and 26)
- Fetal death

Induction solely for convenience is not recommended although it has become common. However, factors such as having a history of

rapid labors and living a long distance from the hospital may be valid reasons to induce labor because of the real possibility that the baby would be born in uncontrolled circumstances. Considerations such as maternity leave also may be valid. Reassurance of fetal lung maturity is essential before elective procedures such as induction or cesarean.

Prenatal testing sometimes identifies a fetal anomaly that will require specialized neonatal care at a distant facility. The mother may be transported to that facility for labor induction or cesarean with needed equipment and specialists to care for the newborn.

Augmentation of labor with oxytocin is considered when labor has begun spontaneously but progress has slowed or stopped, even if contractions seem to be adequate. Nonpharmacologic augmentation may be possible with nipple stimulation in the shower or a whirlpool.

Contraindications

Any contraindication to labor and vaginal birth is a contraindication to induction or augmentation of labor. Possible contraindications and cautions associated with induction may include the following:

- **Placenta previa** (placental implantation in the lower uterus), which would result in hemorrhage during labor
- **Vasa previa**, in which fetal umbilical cord vessels branch over the amniotic sac rather than inserting into the placenta; fetal hemorrhage is a possibility if the membranes rupture
- Umbilical cord prolapse, because immediate cesarean is indicated to stop cord compression
- Abnormal fetal presentation for which vaginal birth is often more hazardous
- Fetal presenting part above the pelvic inlet, which may be associated with **cephalopelvic disproportion** (fetal head that is too large to fit through the mother's pelvis) or a preterm fetus
- Previous surgery in the upper uterus, such as a previous classical cesarean incision (see p. 318) or extensive surgery for uterine fibroids

Other maternal or fetal conditions are not contraindications to induction but require individual evaluation, such as the following:

- One or more previous low transverse cesarean deliveries (see p. 319)
- Breech presentation (vaginal birth may be more hazardous; also, the fetus may turn to a normal position by the time spontaneous labor occurs)
- Conditions in which the uterus is overdistended, such as a multifetal pregnancy and hydramnios, because the risk of uterine rupture is higher
- Severe maternal conditions such as heart disease and severe hypertension
- Fetal presenting part above the pelvic inlet, which may be associated with cephalopelvic disproportion or a preterm fetus
- Nonreassuring FHR patterns, because the added stress of stimulated contractions will reduce placental perfusion

Risks

Induction and augmentation of labor, like spontaneous labor, are associated with the following risks:

- Hypertonic uterine activity (excessive frequency, duration, or intensity of contractions) can reduce placental perfusion and fetal oxygenation. Uterine hyperstimulation may or may not be accompanied by a nonreassuring FHR pattern.
- Uterine rupture may occur, which is more likely with overdistention of the uterus with excess amniotic fluid or a multifetal pregnancy.
- Maternal water intoxication occurs, which is more likely if a hypotonic intravenous (IV) solution is used to dilute the oxytocin and

with rates greater than 20 milliunits/min (Wing & Farinelli, 2012; Cunningham, Leveno, Bloom et al., 2010) (see *Drug Guide*, p. 309).

- Greater risk for chorioamnionitis and cesarean birth exists.

Elective labor induction at term is associated with increased risk for cesarean birth and newborn respiratory problems. Studies have demonstrated that nulliparous women who have their labor induced are two to three times more likely to have a surgical birth. Women having a Bishop score of less than 5 at the time of induction, indicating a cervix that is not favorable, had a greater risk for cesarean than women who had a score of 5 or more. Approximately 25% of inductions had no clearly documented medical or obstetric indication but were elective. The risk for cesarean after failed induction was similar whether women had medical or elective inductions. Risk for chorioamnionitis increases as the duration of ruptured membranes increases (Cunningham et al., 2010; Thorp, 2009; Wing & Farinelli, 2012).

Technique

Surgical and medical methods may be used for labor induction and augmentation. Amniotomy is the method of surgical induction and augmentation because rupturing membranes stimulates uterine contractions and occasionally may be adequate in itself if the cervix is very favorable. Medical methods for induction and augmentation use drugs such as prostaglandins, IV oxytocin (Pitocin), or both to stimulate contractions.

Determining Whether Induction Is Indicated

The birth attendant evaluates whether the benefits of ending the pregnancy outweigh those of continuing it for the woman and fetus. Labor is not induced if term gestation, fetal lung maturity, or both are not established unless a compelling reason exists. Also, induction is more likely to be successful at term because prelabor cervical changes favor dilation.

Cervical assessment estimates whether the cervix is favorable for induction. The Bishop scoring system (Table 16-1) is used to estimate cervical readiness for labor with five factors: cervical dilation, effacement, consistency, position, and fetal station. Vaginal birth is more likely to result if a Bishop score is higher than 8 (ACOG, 2009).

TABLE 16-1 BISHOP SCORING SYSTEM TO EVALUATE THE CERVIX*

FACTOR	SCORE			
	0	1	2	3
Dilation	0 cm	1-2 cm	3-4 cm	5-6 cm
Effacement	0-30%	40-50%	60-70%	≥80%
Fetal station	-3	-2	-1 or 0	+1 or +2
Cervical consistency	Firm	Medium	Soft	
Cervical position	Posterior	Middle	Anterior	

*This system is used to estimate how easily a woman's labor can be induced. Higher scores are associated with a greater likelihood of successful induction because her cervix has undergone prelabor changes, often called *ripening*. A woman who has given birth before usually has a successful induction when her Bishop score is 5 or higher. Delivery in a woman who is having her first baby is most successfully induced if her score is 7 or higher.

Modified from Bishop, E. H. (1964). Pelvic scoring for elective induction. *Obstetrics & Gynecology*, 24(2), 266-268.

Cervical Ripening

Procedures to ripen (soften) the cervix and make it more likely to dilate with the forces of labor are a common adjunct to induction. Most are done the day before the scheduled induction.

Medical Methods. Prostaglandin is a drug that may be used to cause cervical ripening. Prostaglandin E₂ (PGE₂) preparations may be given as an intravaginal gel, an intracervical gel, and a timed-release vaginal insert (Table 16-2). PGE₂ preparations are administered in a setting where fetal monitoring and emergency care, including immediate cesarean birth, are readily available.

Misoprostol (Cytotec) is a prostaglandin E₁ (PGE₁) analog usually given for gastric ulcers. Misoprostol can be used for both cervical ripening and induction of labor. Misoprostol for cervical ripening is currently an off-label use, and its manufacturer does not plan to seek U.S. Food and Drug Administration (FDA) approval for these purposes. In addition to its effectiveness, misoprostol is attractive for its lower cost and stability at room temperature (Cunningham et al., 2010; FDA, 2005; Wing & Farinelli, 2012). However, it should not be given to a woman who has had a previous cesarean birth because of its higher risk for uterine hyperstimulation.

Misoprostol is available in 100- and 200-mcg tablets. The usual dose is 25 mcg vaginally, one quarter of the already tiny, unscored 100-mcg tablet. A pharmacist should prepare the tablet to ensure dose accuracy when using an unscored tablet. The 25-mcg preparation of misoprostol is placed high in the vagina. An oral dose of misoprostol 100 mcg has also been reported to be effective (ACOG, 2009; Cunningham et al., 2010; Wing & Farinelli, 2012).

Because the major adverse effect of prostaglandins is hyperstimulation of uterine contractions, the drug is administered in a setting in which fetal monitoring and emergency care, including cesarean birth, are immediately available. To reduce leakage the woman should lie flat for 15 to 20 minutes after the gel form of prostaglandin is inserted. The FHR should be monitored for at least 30 minutes for changes, and the uterus should be assessed for excessive contractions.

Mechanical Methods. Mechanical methods are infrequently used for cervical ripening. However, the most common mechanical method involves placing hydrophilic (moisture-attracting) inserts into the cervical canal, where they absorb water and swell, gradually dilating the cervix. Examples of these dilators are as follows:

- Dilapan—a synthetic material
- Lamichel—a synthetic sponge containing 450 mg of magnesium sulfate
- *Laminaria* tents—sterile, cone-shaped preparations of dried seaweed

Oxytocin Administration

Oxytocin is the most common drug given for induction and augmentation of labor (see *Drug Guide*, p. 309). Oxytocin is a powerful drug, and predicting a woman's response to it is impossible. Several precautions reduce the chance of adverse reactions in the mother and fetus.

- Oxytocin is diluted in an isotonic solution and given as a secondary (piggyback) infusion so that it can be stopped quickly if complications develop (Figure 16-2).
- The oxytocin line is inserted into the primary (nonadditive or maintenance) IV line as close as possible to the venipuncture site (the proximal port) to limit the amount of drug infused after changing to the nonadditive fluid.
- Oxytocin is started slowly, increased gradually, and regulated with an infusion pump. The primary line is also regulated with an infusion pump.
- Uterine activity, FHR, and fetal heart patterns are monitored before induction for a baseline, when oxytocin is started, and throughout labor.

TABLE 16-2 PROSTAGLANDIN PREPARATIONS FOR CERVICAL RIPENING AT TERM

PROSTAGLANDIN GEL (DINOPROSTONE [PREPIDIL])	VAGINAL INSERT (DINOPROSTONE [CERVIDIL])	MISOPROSTOL (CYTOTEC)
Dosage* 0.5 mg applied to cervix; may be repeated 6-12 hours later. Maximum recommended dose is 1.5 mg applied to cervix in a 24-hr period. 2.5 mg vaginally.	10 mg in a time-release vaginal insert left in place for up to 12 hours. Remove with onset of active labor, membrane rupture, or uterine hyperstimulation.	One quarter of 100-mcg tablet vaginally (approximately 25 mcg; see precautions below). Also used for labor induction by repeating 25-mcg dose every 3-6 hours. A 50-mcg dose is associated with hypertonic contractions.
Actions for Hypertonic Contractions, with or without Nonreassuring Fetal Heart Rate Pattern Place woman in side-lying position. Provide oxygen by face mask at 8-10 L/min. Administer tocolytic drug such as terbutaline or magnesium sulfate. Typically begins 1 hour after gel application. Higher incidence with vaginal application.	Same as for dinoprostone gel. Remove insert. Hypertonic uterine activity may occur up to 9½ hours after insert placement. Greater incidence than with lower-dose intracervical dinoprostone gel.	Same as for dinoprostone gel. Higher dose or more frequent administration is more likely to cause excessive contractions, which may or may not be accompanied by a nonreassuring fetal heart rate pattern.
When Oxytocin Induction May Begin Safe interval has not been established. Delaying oxytocin administration for 6-12 hours after total intracervical dose of 1.5-mg or 2.5-mg vaginal dose recommended.	30-60 minutes after removal of insert.	At least 4 hours after last dose.
Precautions and Comments Limit dinoprostone gel to maximum of 1.5 mg in 24 hours. Woman should remain recumbent with lateral uterine displacement for 15-30 minutes after application. Has increased effect if combined with other oxytocics such as oxytocin (Pitocin). Increases hypertensive effect of herb ephedra. Use caution in women with asthma, hypertension, glaucoma, severe renal or hepatic dysfunction, or ischemic heart disease.	Remove after 12 hours or when active labor begins. Adverse effects can be reduced within 15 minutes of removal. Most expensive of prostaglandin options.	Misoprostol is currently FDA-approved only for treatment of peptic ulcers but is widely used for cervical ripening and induction of labor. Manufacturer does not intend to seek approval, but the ACOG supports its use for these purposes. 100-mcg tablet is not scored. Hospital pharmacy should prepare the 25-mcg dose for greater accuracy. Cost is about 1%-2% that of other prostaglandin preparations. Contraindicated in woman with a previous cesarean or other uterine surgery.

ACOG, American College of Obstetricians and Gynecologists; FDA, U.S. Food and Drug Administration.

*Doses may be higher in cases of fetal death.

From American Academy of Pediatrics (AAP) & American College of Obstetricians and Gynecologists (ACOG). (2012). *Guidelines for perinatal care* (7th ed.). Elk Grove Village, IL: Authors; American College of Obstetricians and Gynecologists (ACOG). (2009). *Induction of labor*. Practice Bulletin No. 107. Washington, DC: Author; Wing, D. A., & Farinelli, C. K. (2012). Abnormal labor and induction of labor. In S. G. Gabbe, J. R. Niebly, & J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed., pp. 287-310). Philadelphia: Saunders.

The woman's uterus becomes more sensitive to oxytocin as labor progresses. Therefore, the rate of oxytocin infusion may be gradually reduced when she is in the active phase of labor (about 5 to 6 cm of cervical dilation). It may be stopped or the rate reduced after her membranes rupture. When labor is augmented with oxytocin, a lower total dose usually is needed to achieve adequate contractions.

Serial Induction of Labor

Serial induction of labor is a variation that the nurse may occasionally encounter. Serial induction may be performed when the woman's cervix is not favorable and she has an indication for induction but same-day birth is not imperative. Risk of induction versus cesarean birth may also be considered. For example, serial induction may be

performed for postdate pregnancy (gestation past the expected delivery date).

Oxytocin solution is given over a 2- to 3-day period for about 8 to 10 hours each day. If the woman's labor has not made progress during the day, the oxytocin is stopped, she is given a light meal, and the infusion is resumed the next morning. At the end of the third day, the woman is reevaluated if she is not yet in labor.

Nursing Considerations

When providing care during cervical ripening and labor induction or augmentation, the nurse observes the woman and fetus for complications and takes corrective actions if abnormalities are noted. The nurse has a great responsibility when administering uterine stimulants to a

DRUG GUIDE

OXYTOCIN (PITOCIN)

Classification: Oxytocic.

Action: Synthetic compound identical to the natural hormone from the posterior pituitary. Stimulates uterine smooth muscle, resulting in increased strength, duration, and frequency of uterine contractions. Uterine sensitivity to oxytocin increases gradually during gestation. Oxytocin has vasoactive and antidiuretic properties.

Indications: Induction or augmentation of labor at or near term. Maintenance of firm uterine contractions after birth to control postpartum bleeding. Management of inevitable or incomplete abortion.

Dosage and Route**Induction or Augmentation of Labor**

1. Intravenous infusion via a secondary (piggyback) line. Oxytocin infusion is controlled with a pump. Various dilutions of oxytocin and balanced electrolyte solution may be used. Mixtures having 60 milliunits/mL are convenient because the milliliters per hour setting on the infusion pump is the same number as the milliunits per minute infused, reducing the chance for errors. Common mixtures that provide 60 milliunits/mL of oxytocin include (1) 15 units of oxytocin (1.5 mL) plus 250 mL of solution; (2) 30 units (3 mL) of oxytocin plus 500 mL of solution; and (3) 60 units (6 mL) of oxytocin plus 1000 mL of solution. Lower concentrations such as 10 to 20 units of oxytocin plus 1000 mL of solution may also be used. The drug may be given in 10-minute pulsed infusions rather than continuously. Oxytocin solutions may be standardized and premixed in the pharmacy to reduce risk for error.
2. Guidelines for oxytocin administration from the American College of Obstetricians and Gynecologists (ACOG, 2009) provide examples of low-dose and high-dose oxytocin labor induction protocols. Depending on the protocol followed, the following recommendations are provided: (1) starting doses of 0.5 to 6 milliunits/min, and (2) increasing the dose in 1 to 2 milliunits/min increments every 15 to 40 minutes. High-dose protocols may increase the dose in increments of up to 6 milliunits/min. The actual oxytocin dose is based on uterine response and absence of adverse effects. Higher starting doses, higher dose increases, and shorter intervals between dose increases are most likely to result in uterine hyperstimulation. A lower starting dose and lower rate increase increments are usually required to augment labor.
3. After an adequate contraction pattern is established and the cervix is dilated 5 to 6 cm, the oxytocin may be reduced by similar increments.

Control of Postpartum Bleeding

Intravenous infusion: Dilute 10 to 40 units in 1000 mL of intravenous solution. The rate of infusion must control uterine atony. Begin at a rate of 20 to 40 milliunits/min, increasing or decreasing the rate according to uterine response and the rate of postpartum bleeding. Any identifiable cause of the hemorrhage should also be corrected.

Intramuscular Injection

Inject 10 units after delivery of the placenta.

Inevitable or Incomplete Abortion

Dilute 10 units in 500 mL of intravenous solution and infuse at a rate of 10 to 20 milliunits/min. Other dilutions are acceptable.

Absorption: Intravenous, immediate; intramuscular, 3 to 5 minutes.

Excretion: Liver and urine.

Contraindications and Precautions: Include, but are not limited to, placenta previa, vasa previa, nonreassuring fetal heart rate patterns, abnormal fetal presentation, prolapsed umbilical cord, presenting part above the pelvic inlet, previous classic or other fundal uterine incision, active genital herpes infection, pelvic structural deformities, invasive cervical carcinoma.

Adverse Reactions: Most result from hypersensitivity to drug or excessive dosage. Adverse reactions include hypertonic uterine activity (tachysystole), impaired uterine blood flow, uterine rupture, and abruptio placentae. Uterine hypertonicity may result in fetal bradycardia, fetal tachycardia, reduced fetal heart rate variability, and late decelerations. Fetal asphyxia may occur with diminished uterine blood flow. Fetal or maternal trauma, or both, may occur from rapid birth. Prolonged administration may cause maternal fluid retention, leading to water intoxication. Hypotension (seen with rapid intravenous injection), tachycardia, cardiac dysrhythmias, and subarachnoid hemorrhage are rare adverse reactions.

Drug interactions include vasopressors and the herb ephedra, causing hypertension.

Nursing Considerations**Intrapartum**

Assess the fetal heart rate for at least 20 minutes before induction to identify reassuring or nonreassuring patterns. Perform Leopold's maneuvers, a vaginal examination, or both to verify a cephalic fetal presentation. If nonreassuring fetal heart rate patterns are identified or if fetal presentation is other than cephalic, notify the physician and do not begin induction until an ultrasound is done to ascertain fetal presentation.

Observe uterine activity for establishment of effective labor pattern: contraction frequency every 2 to 3 minutes, duration of 40 to 90 seconds, intensity of 50 to 80 mm Hg (if measured with an intrauterine pressure catheter). Observe for hypertonic uterine activity: contractions less than 2 minutes apart, rest interval shorter than 30 seconds, duration longer than 90 to 120 seconds, or an elevated resting tone greater than 20 mm Hg (if measured with an intrauterine pressure catheter).

Observe fetal heart rate for nonreassuring patterns such as tachycardia, bradycardia, decreased variability, and late decelerations.

If uterine hypertonicity or a nonreassuring fetal heart rate pattern occurs, intervene to reduce uterine activity and increase fetal oxygenation: stop the oxytocin infusion; increase the rate of nonadditive solution; position the woman in a side-lying position; and administer oxygen by snug face mask at 8 to 10 liters per minute (L/min). Notify the physician of adverse reactions, nursing interventions, and response to interventions and physician response. Record the maternal blood pressure, pulse rate, and respirations every 30 to 60 minutes or with each dose increase. Record intake and output.

Postpartum

Observe uterus for firmness, height, and deviation. Massage until firm if uterus is soft ("boggy"). Observe lochia for color, quantity, and presence of clots. Notify the birth attendant if the uterus fails to remain contracted or if lochia is bright red or contains large clots. Assess for cramping. Assess vital signs every 15 minutes or according to protocol for the recovery period. Monitor intake and output and breath sounds to identify fluid retention or bladder distention.

Inevitable or Incomplete Abortion

Observe for cramping, vaginal bleeding, clots, and passage of products of conception. Observe maternal vital signs, intake, and output as noted under postpartum nursing implications.

FIG 16-2 Intravenous (IV) Pump Setup for Infusion from Two IV Lines. Fluid in the primary line (nonadditive, or maintenance line) contains no medication but is regulated by the infusion pump to maintain the correct rate. Oxytocin solution is regulated by a secondary line in the same pump, giving the nurse options to change or discontinue the oxytocin infusion rate while maintaining the primary line infusion at the same rate. A single IV line at the lower part of the pump connects to the woman's infusion site. (Courtesy of Hospira, Inc., Lake Forest, IL.)

CRITICAL THINKING EXERCISE 16-2

A woman is having term labor induced with oxytocin. Her cervix is 4 cm dilated and fully effaced, and the fetal head is at station 0. The nurse notes that the fetal heart rate (external monitor) is near its baseline of 120 to 130 beats per minute (bpm), with a variability of 10 bpm. Contractions are firm and occur every 2 minutes (every 120 seconds), and the duration is usually 100 seconds. The nurse must palpate contractions because the woman has thick abdominal fat. With palpation the nurse notes that the woman's uterus does not fully relax before another contraction begins.

Questions

1. What is the correct interpretation of these assessments?
2. What are appropriate nursing actions in this situation, and why are they done?

pregnant woman. The nurse must decide when to start, change, and stop an oxytocin infusion using the facility's protocols and medical orders. Facility policies related to oxytocin must clearly support correct nursing and medical actions (Pearson, 2011).

Observe the Fetal Response

Oxytocin stimulates uterine contractions, and they may become too strong (tachysystole). Tachysystole may reduce placental blood flow (uteroplacental insufficiency), which decreases exchange of fetal oxygen and waste products. Before induction and augmentation of labor, the nurse determines whether the FHR and fetal heart patterns are reassuring. The FHR is charted in the labor record at least every 15 minutes during first-stage labor and every 5 minutes during second-stage labor (Macones, Hankins, Spong et al., 2008; Simpson, 2008a, b).

CRITICAL TO REMEMBER

Signs of Tachysystole (Hypertonic Uterine Activity)

- Contraction duration longer than 90 to 120 seconds
- Contractions occurring less than 2 minutes apart or relaxation of less than 30 seconds between contractions
- Uterine resting tone higher than 20 mm Hg (with intrauterine pressure catheter)
- Peak pressure higher than 90 mm Hg during first-stage labor (with intrauterine pressure catheter)
- Montevideo units (unit of measure for uterine contraction intensity) exceeding 400
- A fetal heart rate pattern of late decelerations accompanying hypertonic uterine activity

Nursing Actions for Tachysystole (Hypertonic Uterine Activity)

- Reduce rate or stop the oxytocin infusion.
- Increase the rate of the primary nonadditive infusion.
- Keep the laboring woman in a lateral position.
- Give oxygen by face mask, 8 to 10 liters per minute (L/min).
- Notify the physician or nurse-midwife

The nurse remains alert for fetal heart rate patterns that suggest reduced placental exchange secondary to tachysystole and contractions that are too frequent or too intense. Examples are fetal bradycardia (rate <110 bpm at term), tachycardia (persistent rate >160 bpm at term), late decelerations (slowing after the peak of the contraction), and decreased FHR variability (reduced rate fluctuations). Reduced placental exchange also may have causes other than excess uterine activity, such as maternal hypotension or maternal diabetes. The nurse must assess the woman and fetus carefully to identify the most likely cause of the problem and institute corrective actions. See [Chapter 14](#) for more detailed information on fetal monitoring.

If nonreassuring patterns occur or tachysystole is present, the nurse takes the following steps to reduce uterine activity and increase fetal oxygenation:

1. Reduce or stop the oxytocin infusion and increase the rate of the primary nonadditive infusion.
2. Keep the woman in a nonsupine position (usually side-lying) to prevent aortocaval compression and increase placental blood flow.
3. Give 100% oxygen by face mask at 8 to 10 liters per minute (L/min) to increase the woman's oxygen saturation, making more oxygen available for the fetus.

The physician may order a drug such as terbutaline (Brethine) or magnesium sulfate to reduce uterine activity. Terbutaline, 0.25 mg subcutaneously, can be given quickly to reduce uterine hyperstimulation.

Observe the Mother's Response

Uterine activity must be assessed for hypertonia that may reduce fetal oxygenation and contribute to uterine rupture. Contractions are assessed for frequency, duration, and intensity, and uterine resting tone is assessed for relaxation of at least 30 seconds between contractions. Uterine activity observations are charted at the same intervals as the FHR. Corrective actions for excessive uterine activity are the same as those listed in the discussion of the fetal response.

If the oxytocin must be discontinued, the medical decision about resuming it is individualized. The oxytocin infusion may be restarted at the same or a lower dose if the contractions are no longer too

frequent or too intense and the FHR is reassuring. If the oxytocin has been discontinued for as long as 40 minutes, the drug that was in the woman's system has been metabolized. Therefore, it should be restarted at the beginning dose ordered and advanced more slowly to prevent a recurrence of uterine hyperstimulation and nonreassuring FHR patterns.

The woman's blood pressure and pulse rate are taken every 30 minutes or with each oxytocin dose change increase to identify changes from her baseline. Her temperature is checked every 2 to 4 hours to identify infection.

The woman may need to use pharmacologic and nonpharmacologic pain management techniques sooner. Although the goal of induced and augmented labor is to mimic natural labor, stimulated contractions often increase in intensity more quickly. Cervical ripening may add to the quicker intensification of contractions.

Recording intake and output identifies fluid retention, which may precede water intoxication. Signs and symptoms of water intoxication include headache, blurred vision, behavioral changes, increased blood pressure and respirations, decreased pulse rate, rales, wheezing, and coughing.

After birth the mother is observed for postpartum hemorrhage caused by uterine relaxation, as is the mother who had spontaneous labor. Postpartum uterine atony is more likely if she has received oxytocin for a long time because the uterine muscle becomes fatigued and does not contract effectively to compress vessels at the placental site. It is manifested by a soft uterine fundus and excess amounts of lochia, usually with large clots. Hypovolemic shock may occur with hemorrhage. (See [Chapter 28](#).)

9. How can induction of labor with oxytocin contribute to postpartum hemorrhage?

VERSION

Either of two methods may be used to change fetal presentation: external cephalic **version** (ECV) and internal version. Each has different indications and technique. ECV is the more common method.

Indications

External Cephalic Version

The goal of ECV is to change the fetal position from a breech, shoulder (transverse lie), or oblique presentation. Successful version may allow the woman to avoid a cesarean birth by increasing her chance for vaginal birth. Research has also shown that a fetus often converts spontaneously to a cephalic presentation near the onset of labor ([American Academy of Pediatrics \[AAP\] & ACOG, 2012](#); [ACOG, 2012a](#); [Cunningham et al., 2010](#); [Lanni & Seeds, 2012](#)).

Internal Version

Malpresentation in twin gestations is usually managed by cesarean birth, but internal version is sometimes used for the vaginal birth of the second twin.

Contraindications

ECV is not done if a woman is unlikely to deliver vaginally, which is the goal of the procedure. Contraindications are similar for internal and external procedures. Maternal conditions that may contraindicate ECV or reduce its success include the following:

- Uterine malformations that limit the room available to perform the version and may be the reason for the abnormal fetal presentation.
- Previous cesarean birth with a vertical uterine incision. Manipulation of the fetus within the uterus may strain and rupture the old incision. A vertical uterine incision is most likely to rupture.
- Fetal size ≥ 4000 g.
- Disproportion between fetal size and maternal pelvic size.

Fetal conditions that may contraindicate the use of version include the following:

- Placenta previa. Manipulation of the fetus within the uterus may cause hemorrhage, endangering both mother and fetus. Placenta previa other than marginal is an indication for cesarean birth, even if no excessive bleeding has occurred (see [Chapter 25](#)).
- Multifetal gestation, which reduces the room available in which to turn the fetus or fetuses. ECV may be attempted after the first twin is born vaginally in a cephalic presentation.
- Oligohydramnios, ruptured membranes, and a cord around the fetal body or neck (**nuchal cord**). These conditions limit the room to turn the fetus and may lead to cord compression and fetal hypoxia.
- Uteroplacental insufficiency. Uterine contractions occurring during the version and labor may worsen the insufficiency and cause fetal compromise.
- Engagement of the fetal head into the pelvis.

Risks

Few risks to the woman are present, and few serious fetal risks exist. Changes to FHR pattern are common, but the pattern usually returns to normal after the version. A serious risk is that the fetus may become entangled in the umbilical cord, compressing its vessels and resulting in hypoxia. Abruptio placentae may occur if fetal manipulation disrupts the placental site. Fetal and maternal blood could become mixed within placental vessels, possibly resulting in maternal sensitization to the fetal blood type. Cesarean birth may be needed for fetal compromise at the time of the external version or later if the fetus returns to an abnormal presentation.

Technique

External Cephalic Version

ECV is performed at a location and time to allow emergency cesarean delivery if necessary. A nonstress test or biophysical profile (see [Chapter 10](#)) is done before the procedure to evaluate fetal health and placental function. If nonreassuring fetal signs are present, the version is not performed. ECV would add stress to the fetus, who already is functioning with reduced physiologic reserve. An ultrasound examination confirms fetal gestational age and presentation and identifies adequacy of amniotic fluid.

ECV usually is attempted after 37 to 39 weeks of gestation but before the woman is in labor, for the following reasons:

- As term nears, the fetus may spontaneously turn to a cephalic presentation.
- The fetus is more likely to return to an abnormal presentation if version is attempted before 37 weeks of gestation.
- If fetal compromise and onset of labor occur, a fetus born after 37 weeks of gestation is not likely to have major problems associated with preterm birth, such as respiratory distress syndrome.

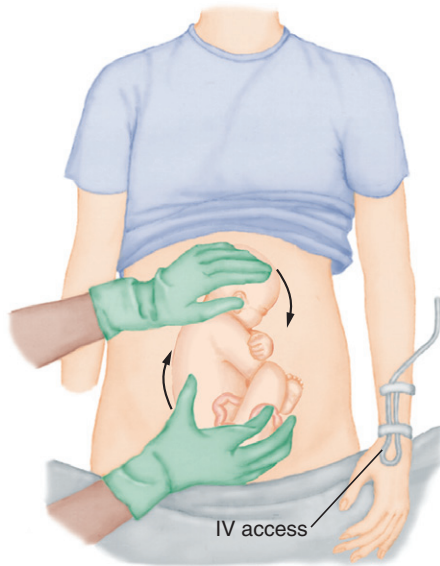

FIG 16-3 External Cephalic Version. Intravenous (IV) access is established, if needed. If terbutaline is used as a tocolytic or uterine relaxant medication, it is given by subcutaneous injection.

The woman often is given a tocolytic such as terbutaline 0.25 mg subcutaneously to relax the uterus while the version is performed. Epidural or spinal block may be given to reduce the mother's discomfort as the physician manipulates the fetus. Ultrasonography guides fetal manipulations during ECV and monitors the FHR about every 2 minutes. The physician gently pushes the breech out of the pelvis in a forward or backward roll (Figure 16-3).

If indicated, Rh immunoglobulin (RhoGAM) is given to the Rh-negative woman after external version to prevent Rh sensitization.

Labor induction may be done immediately after successful ECV, or the woman may await spontaneous labor or a later induction. Electronic fetal monitoring allows evaluation of fetal condition following the version.

Internal Version

Internal version is an uncommon procedure, most often for the second twin after the first delivers in the cephalic presentation. The physician reaches into the uterus with one hand and, with the other hand on the maternal abdomen, moves the fetus into a longitudinal lie (cephalic or breech) to allow vaginal birth.

Nursing Considerations

When caring for the woman having external version, the nurse provides information, assesses the woman and fetus, and helps reduce her anxiety.

Provide Information

The birth attendant explains the indications and risks for ECV to the woman before she signs an informed consent. Purposes and side effects of any planned tocolytic drug are reviewed. Tachycardia and tremors are common but brief side effects of tocolytics such as terbutaline stop shortly after the end of the procedure. If epidural or other analgesia is planned, its purposes and side effects are explained by the person who will administer the treatment, and the woman signs additional consents. The nurse verifies the woman's understanding of the purposes, risks, and limitations of the procedure and related treatments. Because cesarean birth may be required suddenly, permits to allow the surgery and initial care of her newborn are signed.

Promote Maternal and Fetal Health

Admission information is collected as if the woman were in labor or having a cesarean birth because the need for operative intervention may arise suddenly. The woman should have nothing by mouth 4 hours before and during this short procedure in case a cesarean is needed quickly. An IV line is placed for possible drug administration or fluid resuscitation if the FHR is not reassuring (category III).

Maternal vital signs are assessed, and fetal monitoring is begun to obtain baseline values and evaluate the initial nonstress test or biophysical profile. Nonreassuring FHR patterns should be reported promptly. Fetal bradycardia may occur during the procedure, but the FHR usually returns to normal when manipulation ends. The nurse administers the tocolytic drug. Terbutaline's onset of action is 6 to 15 minutes after subcutaneous injection. The blood pressure and pulse rate are checked every 5 minutes.

Real-time ultrasonography is used to guide the version and check the fetal heart rate periodically during the procedure.

The mother and fetus are observed for at least 1 hour after the procedure for a return of their vital signs to baseline values. Reassuring fetal signs are a heart rate within about the same range as on admission, resolution of any bradycardia, and the presence of FHR accelerations.

Maternal vital signs are taken every 15 to 30 minutes until they return to her baseline level. The woman's pulse rate should be no higher than 120 bpm. Discomfort should diminish quickly after the version, whether or not fetal position changes are successful. Persistent and continuous pain suggests a complication such as abruptio placentae. Maternal tachycardia, flushing, or headache may be present for up to 4 hours if terbutaline was given to relax the uterus.

If epidural or spinal analgesia was used and is now discontinued, observe for return of sensation before ambulation. Accompany the woman with her first ambulation and later ones as well until she can walk with no fear of falling.

Regular contractions suggest onset of labor. Spontaneous rupture of membranes sometimes occurs, with leakage of fluid from the mother's vagina. Rh immunoglobulin is given if indicated. The IV line is discontinued after the maternal and fetal conditions return to normal unless labor will be induced the same day.

Because the woman having ECV is near term, the nurse should review the signs of true labor and membrane rupture with her and explain guidelines for returning to the hospital if she will be discharged (see Chapter 13).

Reduce Anxiety

The woman may be anxious before version because its success is not certain and complications may require emergency cesarean delivery. Afterwards, she still may be anxious because the fetus can return to its previous position and vaginal birth is not certain, as it is not certain with the woman who did not have ECV. The nurse should keep the woman informed about what is occurring during the version to reduce her fear of the unknown.

The nurse can point out reassuring fetal monitor patterns such as a normal rate and rate accelerations to help reduce anxiety about the baby. If a problem such as bradycardia develops, the nurse should explain what has happened, what steps are being done to relieve it, and the result of these interventions.

A Solid blade Tucker-McLean forceps

Application of forceps with an open (fenestrated) blade

B

FIG 16-4 Obstetric Forceps and Their Application. **A**, Solid blade Tucker-McLean forceps. **B**, Direction of traction in a forceps-assisted birth.

OPERATIVE VAGINAL BIRTH

Operative vaginal birth, also called *forceps* or *vacuum extraction*, may be used by the physician to apply traction to the fetal head during birth, aiding the woman's expulsive efforts. Both techniques assist descent only, or the techniques assist both descent and rotation of the fetal head from an occiput posterior or occiput transverse position to the occiput anterior position. The use of forceps has fallen out of favor, whereas use of vacuum extractors has risen. However, as the rate of cesarean birth has increased, vaginal births assisted by either forceps or vacuum extractor have declined. Among vaginal births in 2009, 1% of the women were delivered with forceps and 4.5% with vacuum extraction. Use of either method is 61% lower than during the mid-1990s (Martin et al., 2011).

A vacuum extractor uses suction to grasp the fetal head while traction is applied (Figure 16-4). It is not used to deliver the fetus in a nonvertex presentation such as breech or face; otherwise, its use is similar to that of forceps. It also is not used for the fetus of 34 weeks or less gestation because the suction is more likely to injure the head, scalp, and intracranial vessels. No more than three "pop-offs" of the vacuum extractor should be allowed, and they should not be followed by attempts to deliver with forceps. The procedure should be terminated at this point. (ACOG, 2012; Boffill & Martin, 2008; Neilsen & Galan, 2012; Thorp, 2009).

Forceps are curved, metal instruments with two curved blades that can be locked in the center. Many styles are available for different needs. The blades may be closed or open and are shaped to grasp the fetal head (see Figure 16-4). Foam pads are available to cushion the fetal head from the blades. Piper forceps are a special type used to assist birth of the head, as it is born last in a vaginal breech birth. Forceps and a vacuum extractor also may be used during cesarean birth.

Indications

Forceps or vacuum extraction is considered if the second stage should be shortened for the well-being of the woman, fetus, or both and if vaginal birth can be accomplished quickly without undue trauma. Maternal indications may include exhaustion, inability to push effectively, and cardiac and pulmonary disease. Fetal indications may include nonreassuring FHR patterns, failure of the fetal presenting part to fully rotate and descend in the pelvis, partial separation of the placenta, or nonreassuring FHR patterns near the time of birth.

Contraindications

Cesarean birth is preferable if the maternal and fetal conditions mandate a more rapid birth than can be accomplished with forceps or vacuum extraction and if the procedure would be too traumatic. Examples of these conditions are severe fetal compromise, acute maternal conditions such as congestive heart failure and pulmonary edema, a high fetal station, and disproportion between the size of the fetus and maternal pelvis.

Risks

The main risk of forceps and vacuum extraction is trauma to maternal and fetal tissues. Because of the relative safety of cesarean birth, the attempt at an instrumental birth usually is abandoned if the fetal head does not descend easily.

Maternal risks include laceration and hematoma of the vagina. The infant may have ecchymoses, facial and scalp lacerations and abrasions, facial nerve injury, cephalhematoma, subgaleal hemorrhage, and intracranial hemorrhage. A vacuum extractor may create scalp edema called a *chignon* at the application area (Figure 16-5).

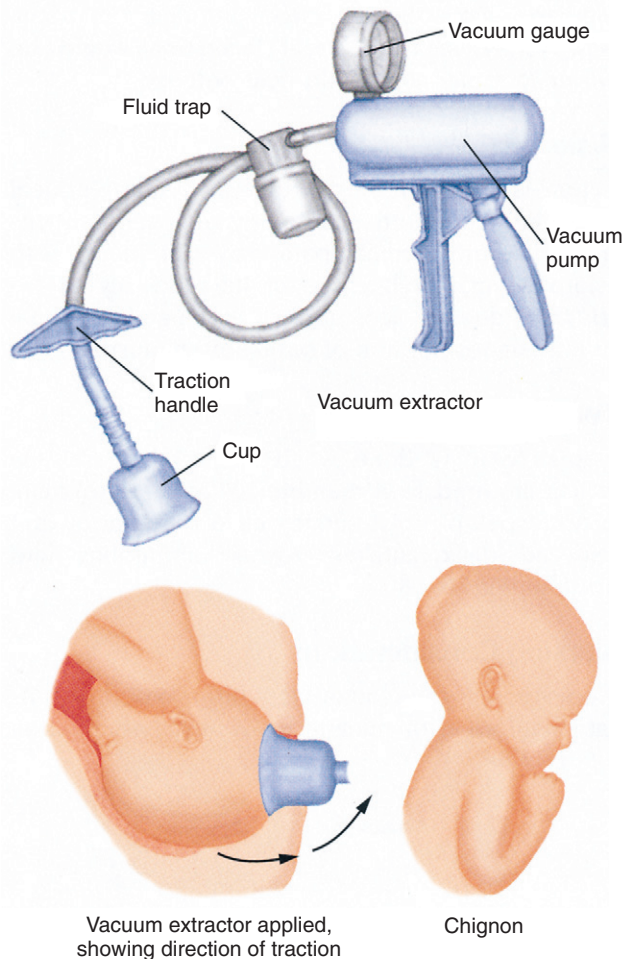

FIG 16-5 Birth Assisted with a Vacuum Extractor. The chignon is scalp edema that often forms under the suction cup when the vacuum extractor is used.

Technique

Preparation for vacuum extraction or forceps is similar to that for any vaginal birth. The presentation, position, and station of the fetal presenting part are verified. Membranes must be ruptured and the cervix completely dilated for forceps or vacuum extraction birth. The woman needs adequate anesthesia, usually a regional block such as an epidural.

Forceps and vacuum extractor–assisted births are classified according to the extent of descent of the fetal head into the pelvis during the procedure and necessary degree of rotation for the fetal head to be born. Describing descent in centimeters below the ischial spines is preferred (AAP & ACOG, 2012; ACOG, 2012b).

- Outlet operative vaginal delivery—The fetal head is at or on the perineum, with the scalp visible at the vaginal opening without separating the labia. The position is either right or left occiput anterior (ROA, LOA) or right or left occiput posterior (ROP, LOP).
- Low operative vaginal delivery—The leading edge of the fetal skull is at station +2 cm or lower. Low operative vaginal birth is subdivided according to the amount of rotation of the fetal head needed. Births requiring 45 degrees or less of fetal head rotation are simpler.
- Midpelvis operative vaginal delivery—The leading edge of the fetal skull is between a 0 (at the level of the ischial spines or engaged) and a +2 cm station.

The physician determines the presentation, position, and station of the fetal head and amount of cervical dilation. When the blades are correctly applied, the long axis of the blades lies over the fetal cheeks and parietal bones. After checking for proper application, the physician locks the two blades in the center and pulls gently as the woman pushes, following the curve of the pelvis. An **episiotomy** (surgical incision of the perineum) may be performed as the fetal head distends the perineum. The physician may keep the forceps on until the head is born or may remove the blades just before expulsion. The rest of the fetus is born in the usual way.

For vacuum extraction a hand pump is used to create suction to hold the vacuum cup on the fetal head in the midline of the occiput. The physician applies traction intermittently, as in a forceps–assisted birth. A vacuum release allows easy removal of the cup. Hospital policies usually limit to three the number of times the vacuum cup can be applied.

Nursing Considerations

When a forceps or vacuum extraction birth is anticipated, a catheter is often added to the instrument table for the birth unless the woman has an indwelling catheter. The physician specifies the type of vacuum cup or forceps. If the nurse must apply the suction to the cup, suction should not go outside the green zone on the suction indicator. FHR should be assessed and any rate lower than 100 bpm reported.

After birth the mother and infant are observed for trauma. The mother may have vaginal wall lacerations or hematoma. Vaginal wall lacerations bleed brighter red than normal lochia and somewhat continuously. The fundus usually is firm unless uterine atony also is present. Women with vaginal wall hematomas complain of severe and unrelenting pain and may have edema and discoloration of the labia and perineum. (See [Chapter 28](#).) Cold applications for the first 12 hours reduce pain by numbing the area and limit bruising and edema of the tissues. Heat applications after 12 hours aid resolution of the edema and bruising.

The infant often has reddening and mild bruising of the skin where the forceps were applied. These areas do not need treatment. Cold treatment is not done for an infant because of hypothermia. Skin breaks that allow entry of microorganisms should be noted and kept clean. Facial asymmetry, which is most obvious when the infant cries, suggests facial nerve injury. Temporary caput or scalp edema (**chignon**) is common at the location of the vacuum extractor cup.

After a forceps birth a parent may ask why the baby's cheeks are reddened or bruised. A good response is to explain that the pressure of the forceps on the baby's delicate skin may cause minor bruising that usually resolves without treatment. Point out improvement in the area during the postpartum stay. Parents may need an explanation for the scalp edema, or chignon, after a vaginal birth assisted with a vacuum extractor.

EPISIOTOMY

Episiotomy, or incision of the perineum just before birth, was once routine for vaginal births. The presumed maternal benefits of reducing pain, perineal tearing, and later pelvic relaxation with incontinence have not proven true (Cunningham et al., 2010; Kilpatrick & Garrison, 2012). However, the birth attendant must decide if one is needed, and indications are not always clear.

Indications

Following are examples of situations when the birth attendant may perform an episiotomy:

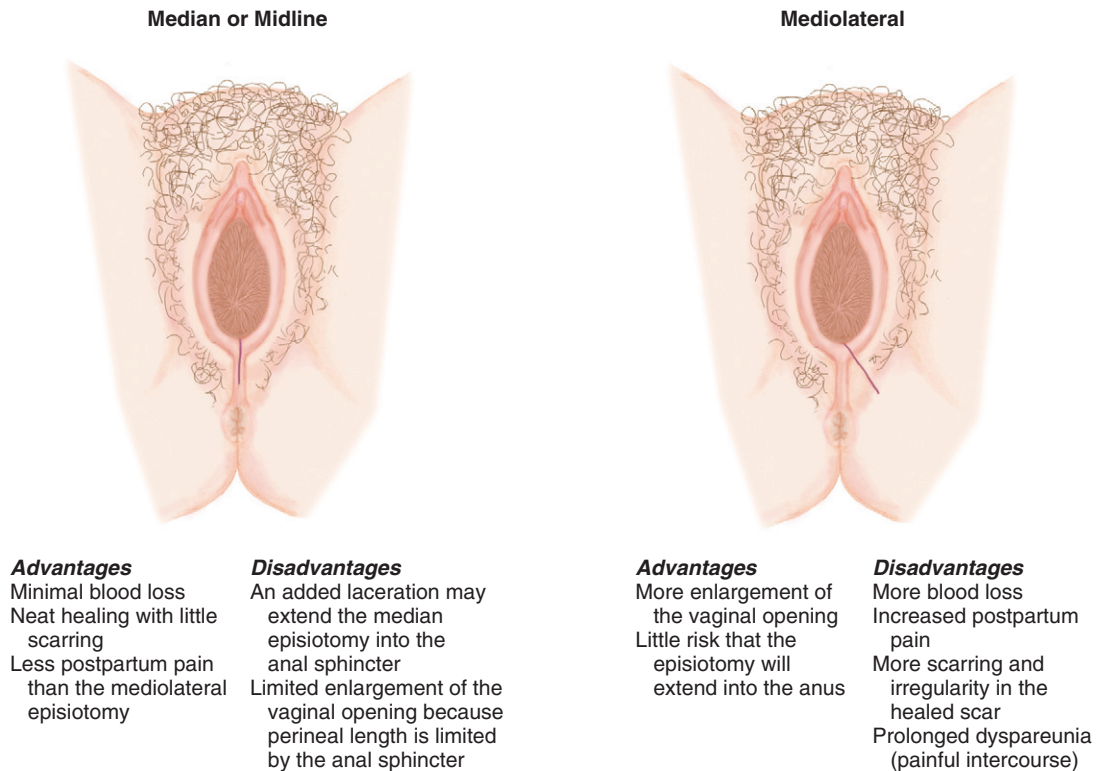

FIG 16-6 Types of Episiotomies.

- Rapid resolution of fetal shoulder dystocia, in which the shoulder of a fetus becomes lodged under the mother's symphysis during birth
- Vacuum extractor–assisted or forceps–assisted births
- Birth with the fetus in an occiput posterior (face-up) position
- Birth of a small preterm fetus to reduce pressure on the head

Risks

Infection is the main risk of episiotomy. Perineal pain occurs with both episiotomy and spontaneous tears. However, perineal pain may last longer with episiotomy, mainly because of its tendency to extend into deeper lacerations. Prolonged perineal pain impairs resumption of sexual intercourse and makes it uncomfortable for the woman.

Data since the 1980s have confirmed that midline episiotomies, more frequently done than mediolateral episiotomies, increase a woman's risk of the more extensive third-degree (into the anal sphincter) or fourth-degree (through the rectal sphincter) tear. Spontaneous lacerations are more likely to occur if a woman had an episiotomy with a previous pregnancy. However, despite data confirming maternal benefits of avoiding episiotomies, about 10% to 17% of elective, or routine, episiotomies continue to be performed (Alperin, Khron, & Parviainen, 2008; Cunningham et al., 2010; Kilpatrick & Garrison, 2012).

Technique

An episiotomy is done when the fetal presenting part has crowned to a diameter of about 3 to 4 cm. The two types of episiotomies have different advantages and disadvantages: median (midline) and mediolateral (Figure 16-6).

Nursing Considerations

An episiotomy sometimes can be avoided or limited in length with nursing measures. An upright position while pushing promotes

gradual stretching of the woman's perineum. Delaying pushing until the urge is felt also gradually distends the soft tissue of the pelvic floor. Pushing with an open-glottis technique rather than prolonged breath-holding when pushing also promotes gradual perineal stretching.

Daily perineal massage and stretching by the woman from 36 weeks until birth has been shown to reduce the risk for perineal trauma during birth. Women older than 30 years, having their first baby, and adhering to the daily 10-minute perineal massage showed greatest benefit (Albers & Borders, 2007).

Nursing interventions during the recovery and postpartum periods are similar for episiotomy and perineal laceration. The perineum should be observed for hematoma and edema. As with use of forceps, perineal cold applications are done for at least the first 12 hours followed by perineal heat applications after 12 hours.

CESAREAN BIRTH

In 1965, the cesarean birth rate in the United States was about 5% of all births, rising to almost 21% in 1996 when the percentage dropped slightly. Since 1996 the number of cesareans has steadily increased 50%

EVIDENCE-BASED PRACTICE

Implementation of a System-Wide Policy for Labor Induction

Induction of labor is common in labor and delivery units nationwide. Induction of labor may be medically indicated, such as in a woman with hypertension, or it may be done for nonessential reasons. Use of oxytocin is often part of malpractice litigation but is needed for labor induction. This article describes how Trinity Health, a Catholic health care system, gathered evidence related to developing a standardized process for induction that would be *no earlier than 39 completed weeks of gestation* for elective induction. Trinity Health had implemented an earlier standardized process for system-wide vaginal birth after cesarean (VBAC) care. Trinity has 26 hospitals with perinatal services in 10 states to implement standardized protocols and policies. Annual birth rates range from 50 to 8750.

Achievement of the goal for standardization of medically indicated and elective inductions included many professionals, some who were always in phone and direct meetings with the collaborative team and others who were available when needed. The team's goal was to cover all areas of induction. Standards and guidelines used in the process were from American College of Obstetricians and Gynecologists (ACOG), Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN), The Joint Commission (TJC), and Institute for Safe Medication Practices (ISMP). Pertinent research articles were reviewed by the committee for the development of evidence and standards base policy for induction of labor to be used by Trinity Health.

Potential controversies encountered in the process of standardization included oxytocin concentration and the intravenous solution, dosing regimen, and assured avoidance of elective inductions earlier than 39 weeks gestation. Resistance to change occurred in most aspects of standardizing the labor induction policy. Examples given were different concentrations of oxytocin, different IV diluents, varying intervals for oxytocin dose increase, frequency of maternal-fetal assessments, and definition of tachysystole. Not all Trinity Health facilities had focused on avoidance of late preterm births, and elective births before 37 and 38 weeks sometimes occurred. Local practices and a preference for "the way we've always done it" added to the slow process of reaching agreement on a policy. Creation of forms such as standard orders, informed consent, and oxytocin checklists were developed to assist clinicians in assessment and documentation of maternal and fetal status throughout the induction.

A table within this article describes aspects of labor induction for both elective and medically-indicated procedures that were standardized by Trinity Health. Items included are documentation of the reason for induction, patient consent with discussion of risks and benefits, avoidance of elective induction before 39 completed weeks of gestation, staff roles and responsibilities, standardized oxytocin concentration and dosing regimen, definition and treatment regimen for tachysystole, and a process for clinical disagreements.

Implementation for standardized inductions were put into place in 2010, so the outcome is not yet known; however, Trinity Health is confident that standardized care and avoidance of elective inductions before 39 completed weeks of gestation will promote safer care for mothers and their babies.

among all maternal age groups. Data for 2009 show that cesarean deliveries were 32.9% of all births, another all-time high (Martin, Kirmeyer, Osterman et al., 2009; Menacker & Hamilton, 2010).

Many factors contribute to the rise in the national cesarean birth rate, including the following (Martin et al., 2009):

- Women having their first baby are more likely to deliver by cesarean than women who have had one or more previous births vaginally.
- Women having their first baby induced have a greater risk for a cesarean.
- The high primary cesarean rate adds to the overall rate because more women will have repeat cesareans rather than attempting vaginal birth for their next children.
- Women are having children later, and cesareans are more common in the older pregnant woman.
- Electronic fetal monitoring often prompts concerns about fetal oxygen and acid-base status or progress of labor.
- Cesarean birth may be chosen if the baby remains in a breech presentation.
- A high threat of litigation if birth outcomes are not good causes physicians to opt for surgery quickly if the maternal or fetal condition or both seem to be at risk.
- Cesarean on maternal request rather than medical need is a recent issue, although those numbers have been low.

Evidence linking labor induction to increased risk for cesarean birth continues to accumulate. Studies have demonstrated that women who have their labor induced are two to three times more likely to have a surgical birth. Women having a Bishop score of less than 5 at the time of induction, indicating a cervix that is not favorable, had a greater risk for cesarean than women who had a score of 5 or more. The likelihood of a cesarean increases as the duration of induced labor increases. Approximately 25% of inductions had no clearly documented medical or obstetric indication but were elective. The risk for cesarean after failed induction was similar whether women had medical or elective inductions (Martin et al., 2009; Michelson et al., 2008; Thorp, 2009).

A national goal for the *Healthy People 2020* initiative is to reduce the rate of first-time cesarean births in low-risk women to no more than 23.9% using a baseline of 26.5% of births in 2007. Reducing repeat cesareans to 81.7% from the 2007 baseline of 90.8% of births to low-risk women is the second goal for cesarean births (U.S. Department of Health and Human Services, 2012). Promotion of vaginal birth after cesarean (VBAC) in women for whom it is appropriate is a major way to accomplish these goals. Other possibilities include more careful evaluation of **dystocia** of labor (difficult or prolonged labor) as a reason for cesarean and careful selection of women who are appropriate candidates for vaginal breech birth. ECV (see p. 311) may be an option to attempt to change the presentation of a near-term fetus in the breech presentation to a cephalic presentation.

Vaginal Birth after Cesarean

With the high and rising cesarean rate and the desire to lower the incidence, the decision about whether to have a VBAC has never been more difficult than now. At one time, the dictum "once a cesarean, always a cesarean" was accepted without question. For many years after this dictum, having no research backup, the only women who had VBACs were those who entered the hospital in such advanced labor that there was no time for a repeat cesarean.

As low transverse uterine incisions became the norm for almost all women having cesarean births, the safety of a trial of labor became established. VBAC gradually became an accepted way to lower the rise in cesarean births. Research continued on the safety of VBAC.

The AAP and the ACOG (2012) have affirmed their support for VBAC (see Box 16-1) but have urged caution when considering a trial of labor (TOL) or trial of labor after cesarean (TOLAC) because VBAC is associated with a small but significant risk of uterine rupture. For this and other reasons, many physicians are now conservative when discussing the option of VBAC with a woman. The risks and benefits of VBAC for each woman must be considered by her and her physician.

For example, the risk of uterine rupture increases as the number of prior uterine incisions increases, and a woman who has had two cesarean deliveries might be reluctant to attempt VBAC for her third birth because of this added risk. In addition, the woman who tries VBAC and still needs a repeat cesarean birth incurs more costs because she has both labor and surgical expenses. She and her infant are more likely to have infections that further complicate their recovery and add to costs. The hospital also incurs greater costs for personnel and supplies.

When making the decision about whether to attempt VBAC women need to know that surgical birth has risks just as all surgeries have risks. Besides risks common to any surgery, multiple cesarean births have risks such as greater risk for placental abnormalities such as placenta previa (low-lying placenta) or placenta accreta (abnormal adherence of the placenta to the uterine wall, often along the previous incision area) (ACOG, 2010; Berghella & Foley, 2012; Cunningham et al., 2010). Therefore, the woman and her physician must consider the risks and benefits of both.

Women may be anxious about attempting vaginal birth in a later pregnancy. A woman may know that she is a good candidate for VBAC but find it impossible to disregard even small risks. Scheduling a repeat cesarean may seem safer, simpler, and something that she can count on. The prospect of laboring and perhaps still needing a cesarean birth is worrisome as well.

The physician discusses VBAC during prenatal care if it is a reasonable option. The nurse reinforces these explanations and identifies misunderstandings. If the woman chooses VBAC, the nurse should reinforce the appropriateness of attempting VBAC and advantages of a vaginal birth, such as fewer overall complications individually. VBAC should be presented in a positive way if it is a real option, yet the possibility of cesarean delivery should be acknowledged because the surgery can be needed unexpectedly in any birth (Box 16-1).

Indications

Cesarean birth is performed when awaiting vaginal birth would compromise the mother, the fetus, or both. Possible indications for cesarean birth include, but are not limited to, the following:

- Dystocia
- Cephalopelvic (fetopelvic) disproportion
- Hypertension, if prompt delivery is necessary
- Maternal diseases such as diabetes, heart disease, or cervical cancer, if labor is not advisable
- Active genital herpes
- Some previous uterine surgical procedures such as a classic cesarean incision or removal of fibroid tumors
- Persistent nonreassuring FHR patterns
- Prolapsed umbilical cord
- Fetal malpresentations such as breech or transverse lie
- Hemorrhagic conditions such as abruptio placentae or placenta previa

A prior cesarean birth alone is not an indication for another cesarean birth for most women. Many women will choose repeat cesarean rather than a trial of labor, even if they are appropriate candidates for VBAC because of the small, but real, added risk for uterine rupture. In other cases, they choose elective (scheduled) repeat cesarean to avoid another unsuccessful experience or the pain of labor. For other women, trying to deliver their next baby vaginally—whether successful or not—is important to them.

Contraindications

Few absolute contraindications exist, but cesarean birth in some conditions is not desirable because the risks to the woman are too great

BOX 16-1 VAGINAL BIRTH AFTER CESAREAN BIRTH

Approximately 60% to 80% of women with one low transverse uterine incision from a previous cesarean birth have successful vaginal births.

Women who had their previous cesarean for a nonrecurring reason, such as breech presentation, are more likely to have a successful vaginal birth after cesarean birth (VBAC) than women who had their previous cesarean because of dystocia.

Women who have had a vaginal birth, before or since the prior cesarean birth, are more likely to have successful VBAC.

Higher probability of success in the woman who has spontaneous labor.

Possible Candidates and Requirements for VBAC

A woman who has one previous low transverse uterine incision

A woman with two prior cesarean deliveries may have a low risk of uterine rupture with VBAC

Absence of other uterine scars (e.g., removal of fibroid tumors) or a previous uterine rupture

A pelvis that is clinically adequate for the estimated fetal size

Immediate availability of a physician during active labor if an emergency cesarean is needed

Availability of anesthesia and personnel to perform an emergency cesarean

Management of Women Who Plan VBAC

External cephalic version is not contraindicated for the woman with a previous cesarean.

Epidural analgesia and anesthesia may be used.

Induction and augmentation of labor with oxytocin may be done. Use of prostaglandin gel appears to be safe. Misoprostol (Cytotec) should not be used.

Most authorities recommend electronic fetal monitoring.

Data from American College of Obstetricians and Gynecologists. (2010). *Vaginal delivery after previous cesarean birth. Practice Bulletin No. 115*. Washington, DC: Author; and American Academy of Pediatrics & American College of Obstetricians and Gynecologists. (2012). *Guidelines for perinatal care* (7th ed.). Elk Grove Village, IL: Authors.

compared with the potential benefits to the woman and fetus. These conditions include fetal death, a fetus that is too immature to survive, and maternal coagulation defects.

Risks

Cesarean birth is one of the safest major surgical procedures. However, it poses greater risk for the mother compared with vaginal birth. Maternal risks include the following:

- Infection
- Hemorrhage
- Urinary tract trauma or infection
- Thrombophlebitis, thromboembolism
- Paralytic ileus
- Atelectasis
- Anesthesia complications

Cesarean delivery poses added risks to the infant, which may include the following:

- Inadvertent preterm birth
- Transient tachypnea of the newborn caused by delayed absorption of lung fluid (see Chapter 30)
- Persistent pulmonary hypertension of the newborn (see Chapter 30)
- Injury such as laceration, bruising, fractures, or other trauma

Lung immaturity is the greatest risk if the fetus is delivered preterm. Therefore, tests for fetal lung maturity (see [Chapter 10](#)) are done if elective cesarean birth is planned. Other criteria for assuring fetal lung maturity at the time of cesarean birth include the following ([AAP & ACOG, 2012](#)):

- Documentation of fetal heart tones for 20 weeks by nonelectronic fetoscope or for 30 weeks by Doppler
- Passage of 36 weeks since positive results from a pregnancy test performed by a laboratory
- Ultrasound measurement of the crown-rump length at 6 to 11 weeks that supports a gestation of 39 weeks or more
- Clinical examinations between 12 and 20 weeks that support a gestation of 39 weeks or more

Technique Preparation

Routine laboratory studies vary with the mother's condition and type of anesthesia but may include a complete blood count, clotting studies such as prothrombin and partial thromboplastin times, and blood typing and screening. The physician may order one or more units of blood to be typed and screened or crossmatched to have available for transfusion if the woman's hemoglobin and hematocrit values are low or she has a high risk for hemorrhage, such as grand multiparity (five or more births).

Epidural or combined spinal-epidural (CSE) block is common for cesarean birth. General anesthesia may be required for either known or unexpected reasons. For emergency cesarean with no epidural in place, a general anesthetic may be chosen because it can be established the most quickly. A drug such as famotidine (Pepcid) or sodium citrate with citric acid (Bicitra) is given to reduce gastric acidity before surgery. The woman does not have routine premedication other than drugs to control gastric and respiratory secretions.

Additional preoperative care includes a "time out," in which all members of the team validate the woman's identity, surgical site, and consents. Staff members new to the woman identify themselves.

Fetal surveillance continues until just before the sterile abdominal skin prep (intermittent auscultation or external monitor) or just after the prep (internal monitor) ([AAP & ACOG, 2012](#)). A wedge placed under one hip prevents aortocaval compression and promotes placental blood flow.

A single intravenous dose of a prophylactic antibiotic such as ampicillin or a cephalosporin is often given to the mother after the cord is clamped. Additional antibiotic doses for 24 hours are common to prevent postoperative infections that are more likely to develop in the woman with prolonged rupture of membranes or a lengthy labor.

If a Pfannenstiel (transverse or "bikini") skin incision is planned, the woman's lower abdominal hair is clipped from about 3 inches above the pubic hairline to the mons pubis, about where her legs come together. The fronts of the upper thighs are also clipped. For a vertical skin incision, the upper border of the abdominal hair clipping is near the umbilicus. Cordless electric clippers with disposable heads reduce skin nicks that provide an entry point for microorganisms.

An indwelling catheter inserted after the regional block is established but before the surgery allows comfortable insertion and keeps the bladder away from the operative area to reduce the risk for injury. The catheter may also be placed before the block. The catheter allows accurate observation of urine output during and after surgery, which helps evaluate circulatory status. The catheter also allows delay of ambulation to the restroom for urination until the woman can safely ambulate.

A grounding pad for the electrocautery is applied to an area with no bony prominences, usually the thigh. After application of the pad,

the woman's legs are secured to the operating table with a wide, padded strap.

A sterile abdominal skin preparation is done just before sterile draping and allowed to dry before sterile drapes are applied. As in other surgical skin preparations, the direction of the scrub is generally circular, from the center of the operative area outward and from the pubic area downward on each upper thigh. It may be necessary to use wide tape to hold excess abdominal fat (the pannus, or "apron") upward, pulling it away from the skin incision area.

If a general anesthetic is required, preoperative preparations are completed before anesthesia is begun to reduce newborn exposure to anesthesia. The team scrubs, dons gowns and gloves, and drapes the woman before general anesthesia is induced.

Incisions

Two incisions are made, one in the abdominal wall (skin incision) and the other in the uterine wall. Either of two skin incisions are used: a midline vertical incision between the umbilicus and the symphysis or a low transverse (Pfannenstiel) incision just above the symphysis ([Figure 16-7](#)).

Three types of uterine incisions are possible, each with different indications and limitations: (1) low transverse, (2) low vertical, and (3) classic, a vertical incision into the upper uterus ([Figure 16-8](#)). The low transverse uterine incision is preferred because of its low risk for rupture in subsequent pregnancies. The uterine incision does not always match the skin incision. For example, a woman may have a vertical skin incision and a low transverse uterine incision, particularly if she is obese or has a preexisting vertical scar.

The low transverse uterine incision may not be suitable if the fetus is very large. The length of this incision is limited because the uterine artery and vein enter the uterus at its lower right and left sides. The low transverse incision may not be large enough to deliver a large fetus without tearing these large vessels. Sometimes, a vertical uterine incision must be added to a transverse one (making an inverted "T") to deliver a very large baby.

A classic uterine incision occasionally must be used when the other two incisions are not possible, such as when a placenta previa is located in the lower anterior uterus. The vertical uterine incision, especially the classic one, is more likely to rupture during later pregnancies.

Sequence of Events in a Cesarean Birth

The sequence of events in a cesarean birth is similar to that in a vaginal birth. When the woman is anesthetized and draped, the physician makes the skin incision. If general anesthesia is required, the level is very light until the fetus is delivered and is deepened after the umbilical cord is clamped.

The bladder is separated from the uterine wall and held downward with a wide bladder retractor. The uterus is incised, usually in a low transverse incision. If the membranes are intact, they are ruptured with a sharp instrument and amniotic fluid is suctioned from the operative field. As in vaginal births, the color, odor, and quantity of the amniotic fluid are noted and the time of rupture is recorded.

The physician lifts the fetal presenting part through the uterine incision. An assistant may push on the uterine fundus to help deliver the fetus through the abdominal incision. A vacuum extractor or forceps may be needed to facilitate birth of the fetal head.

The infant's face is wiped, and the mouth and nose are suctioned to remove secretions that would impair breathing. The cord is quickly clamped and cut. The physician collects cord blood for analysis.

After the infant's birth, the physician removes the placenta. Oxytocin is given IV to contract the uterus firmly. The physician then closes the uterine and abdominal incisions, approximating each layer

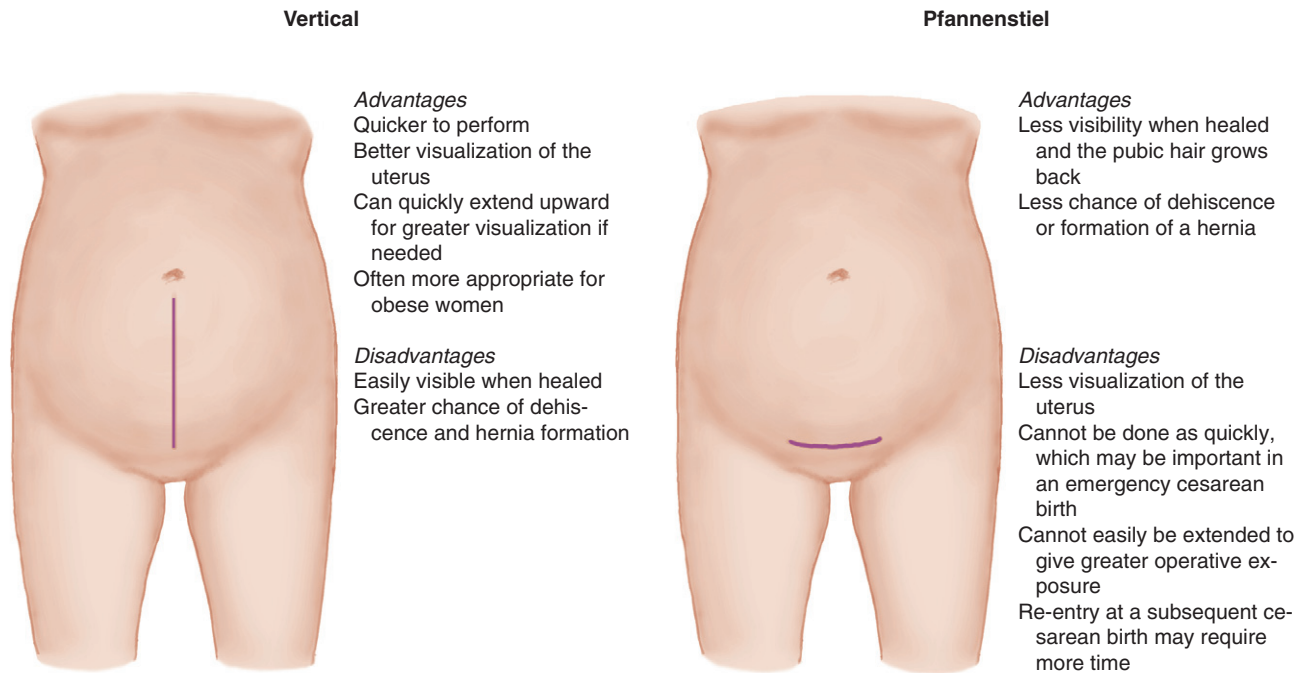

FIG 16-7 Skin (Abdominal Wall) Incisions for Cesarean Birth.

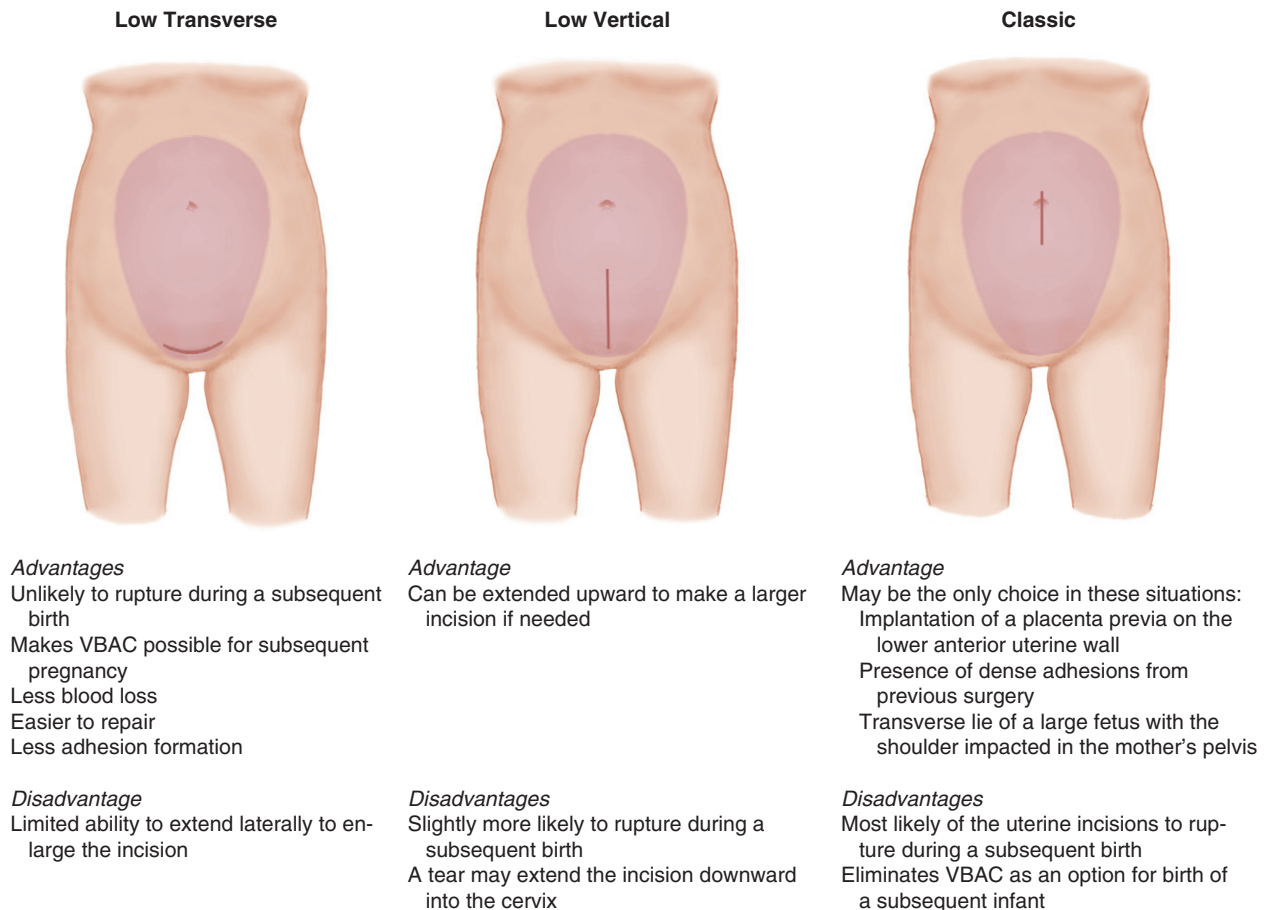

FIG 16-8 Uterine Incisions for Cesarean Birth. The abdominal and uterine incisions do not always match. VBAC, Vaginal birth after cesarean.

separately. Physicians may flush the operative area with saline or antibiotic solution before abdominal closure.

Nursing care for the infant is similar to that after vaginal birth. Resuscitation equipment should be readied for use before delivery. Professional personnel who care for the infant born by cesarean vary with the baby's anticipated condition and facility policy. A pediatrician, neonatal nurse practitioner, or neonatal team usually attends the infant at the time of cesarean birth. Newborn care personnel must be prepared for unexpected resuscitation measures as in any birth.

Nursing Considerations

Nursing care for a woman who has a cesarean birth varies according to the situation. She may be planning a cesarean birth, or a surgical birth may be unexpected. Even in these two situations, women differ. For example, is the planned cesarean her first, or has she had a cesarean birth before? Was her previous cesarean planned? An unplanned cesarean birth may occur after hours of unsuccessful labor or may be needed quickly in an emergency. The "time out" that precedes many medical procedures must be abbreviated in a true emergency cesarean.

Nursing care for women having cesarean childbirth is similar to that for vaginal birth, but the approach in each situation is different (Box 16-2). For example, although preoperative teaching is important, it must be abbreviated or even omitted in a true emergency.

Emotional Support

Emotional support may begin before and extend after the birth. A mother who has had a previous cesarean birth may harbor unresolved feelings of grief, guilt, or inadequacy because she perceives that she somehow failed in her expected birth experience. She may feel anxious about choosing repeat cesarean when given the choice of a VBAC. Therapeutic communication techniques help identify stressors and misunderstandings to promote a positive childbirth experience (Box 16-3).

The nurse in the prenatal setting can open the subject of a woman's previous cesarean birth with a broad lead such as "Tell me about your experience with the birth of your other baby."

Anxiety is an expected and normal reaction to surgery and is useful within limits. For example, mild to moderate anxiety may prompt the woman who expects a cesarean birth to learn more about her upcoming experience. However, high anxiety inhibits concentration. The woman who has an emergency cesarean birth is more likely to have high levels of anxiety, but the woman who expects the surgery also is vulnerable.

The staff's behavior can either reduce or increase the woman's anxiety. A calm and confident manner helps her feel that she is being cared for by competent professionals. A quiet, low voice is calming.

The nurse and the woman's significant others are important sources of emotional support. The nurse should remain with the woman and let her express her fears. Therapeutic communication helps clarify her concerns, so explanations to reduce her fear of the unknown can be most effective.

The father or other support person should be encouraged to remain with her during surgery if she has regional anesthesia. In many hospitals, the support person may come into the operating room after the woman is intubated for general anesthesia to foster attachment with the infant and help the mother integrate her birth experience afterward.

Nurses also support a woman's partner and significant others during the cesarean birth. The partner may be as anxious as the woman but afraid to express it because the woman needs so much support. The partner may be physically exhausted after hours of labor coaching.

BOX 16-2 NURSING CARE FOR A WOMAN HAVING CESAREAN BIRTH

Before the Cesarean Birth

1. Assess the time of last oral intake and what was eaten.
2. Assess for allergies. Include drug, food, and substance (e.g., latex) allergies.
3. Determine medications taken and last dose. Include herbal preparations.
4. Have the woman sign informed consents for surgery, anesthesia, and usually blood transfusion.
5. Obtain the ordered laboratory work.
6. Do preoperative teaching: what the woman can expect in the operating and recovery rooms, infant care, and who will be present.
7. Start the ordered intravenous infusion, and begin a fluid bolus for the regional anesthetic at the appropriate time (see the discussion on epidural block in Chapter 15).
8. Clip body hair from the skin area needed for planned incision.
9. Administer the ordered medication to control gastric secretions if not done by the anesthesiologist.
10. Insert an indwelling urinary catheter (or insert in operating room [OR] after regional block).
11. Assist the woman to the operating table, positioning her with a wedge under her hip to displace the uterus if the table is flat. Women having scheduled cesareans may walk to the OR.
12. Apply the grounding pad for electrocautery.
13. Perform sterile preparation of abdomen.
14. Call the infant care team if it is routine in the facility or if newborn complications are anticipated.

During the Recovery Period

1. Begin anesthesia-related interventions: pulse oximeter, oxygen administration, cardiac monitor.
 - a. Assess for return of sensation and movement if regional anesthesia was used.
 - b. Assess level of consciousness if general anesthesia was used.
2. Do routine assessments every 15 minutes for the first hour, every 30 minutes during the second hour, and hourly thereafter until the woman is transferred to the postpartum unit. Assess:
 - a. Vital signs; oxygen saturation
 - b. Electrocardiogram (ECG) pattern
 - c. Uterine fundus for firmness, height, and deviation (massage if poorly contracted)
 - d. Lochia for color, quantity, and presence of large clots
 - e. Urine output for color, quantity, and patency of the catheter and tubing
 - f. Abdominal dressing for drainage
 - g. Return of lower body movement if regional block
3. Assess need for analgesia, and administer as ordered.
4. Change position hourly if no contraindication exists. Have the woman breathe deeply and cough at each routine assessment time. Provide a small pillow to support her incision when coughing or turning if sensation is present.
5. Continue sequential compression device (SCD) function, if used during surgery

The staff should not expect more support from partners than can be reasonably provided.

Although cesarean births are routine in the intrapartum unit they are not routine to women who undergo them and to their families. Avoid belittling their fears by telling women and their families not to worry and that everything will be all right, especially if an emergency occurs.

BOX 16-3 NURSING DIAGNOSES FOR THE WOMAN UNDERGOING AN OPERATIVE OBSTETRIC PROCEDURE

Anxiety*
 Fear
 Pain, acute
 Risk for Impaired Spontaneous Ventilation (mother or newborn)
 Risk for Aspiration (general anesthesia)
 Risk for Injury*
 Hypothermia (mother or newborn)
 Readiness for Enhanced Family Coping

*Nursing diagnoses discussed in this chapter.

CASE STUDY 16-1 NURSING CARE PLAN*

ASSESSMENT: Christina is 22 years old and expecting her first baby. Her due date is 2 weeks from today, and a cesarean was scheduled for 1 week from today because her baby remains in a complete (full) breech presentation. Because her membranes ruptured this afternoon and she is in early labor, she will have her cesarean today. Epidural anesthesia is planned for her surgery. Although her physician has discussed cesarean birth with her, Christina is anxious and has many questions about what will happen to her and her baby. She says she is very nervous about the upcoming surgery. She has never been a patient in a hospital. Christina's mother and husband Bruce are with her.

NURSING DIAGNOSIS: Anxiety related to unfamiliarity with the setting and procedures for cesarean birth

EXPECTED OUTCOMES

Christina will:

1. State that she feels less apprehensive.
2. Verbalize understanding of preoperative and postoperative care.
3. Demonstrate postoperative techniques for coughing and deep breathing.

INTERVENTIONS AND RATIONALES

1. Assess Christina's level of anxiety. Mild to moderate levels of anxiety are expected *and may facilitate learning. High anxiety impairs learning.*
2. Remain with Christina as much as possible. Allow her to express her fears. Encourage her mother and Bruce to remain with her. *When Christina expresses her fears, it enables the nurse to answer these concerns specifically. Support comes from significant others and a caring nurse.*
3. Elicit Christina's feelings about surgery by using broad leads such as "What were your thoughts when you found out you might have your baby by cesarean?" *This identifies expectations of the birth experience so that actions can be taken to make it a positive one. If Christina's expected and actual experience closely match, she is likely to be more satisfied with it. Identifies misunderstandings and possible feelings of inadequacy and anger.*
4. Explain preoperative preparations using simple language, verifying Christina's understanding, and giving her the opportunity to ask questions.
 - a. The anesthesiology professional visits her to explain anesthesia. The epidural anesthetic will be started in the operating room. Postoperative pain control is planned to be epidural morphine (Duramorph).
 - b. Skin preparation using a clipper (a low transverse incision is planned): from about 3 inches above the pubic hair to the level where the thighs meet. Reassure Christina that the clipper head is disposed between patients.
 - c. Indwelling urinary catheter, which is usually inserted after epidural anesthesia is begun.

After birth, possibly as soon as postanesthesia care unit (PACU), visiting the mother and her family allows the nurse to answer questions about the surgery and fill in any gaps in their understanding. This helps them understand the experience and promotes a positive perception of the birth (*Case Study 16-1*).

Teaching

Knowledge may reduce fear of the unknown and increase a woman's sense of control over her infant's birth. The nurse cannot assume that a woman who had a previous cesarean birth already knows what will happen and why. If her previous surgery was done after a long labor or in an emergency, a woman may recall only parts and not understand those parts she does remember. Teaching should be given in simple language and include her support person.

- d. Operating room: appearance, narrow table, wedge under one hip (or tilted table), cool temperature, equipment.
 - e. People who will be in the operating room: circulating nurse, scrub nurse, surgeon's assistant, neonatal nurse, pediatrician, any others. *Knowledge decreases anxiety and fear of the unknown. Simple language improves understanding when a woman's attention is narrowed from anxiety. These interventions show respect and give Christina a greater sense of control.*
5. Explain what to expect postoperatively, demonstrating as needed.
 - a. Oxygen mask will be used briefly.
 - b. Pulse oximeter on finger or toe; automatic blood pressure cuff.
 - c. Frequent checks of her vital signs, fundus, lochia, and anesthesia-related assessments. Emphasize that nurses will be as gentle as possible when palpating her fundus.
 - d. Catheter usually remains in place up to 24 hours.
 - e. She will be kept as comfortable as possible with analgesics. For greatest effectiveness, she should tell the nurse if she needs pain medication before pain is too bad. Explain the longer duration of hourly respiratory assessment if epidural postoperative pain relief is expected.
 - f. She will be asked to move and change position several times.
 - g. Demonstrate effective coughing (splinting the abdomen with a pillow) and deep breathing techniques. Ask Christina to demonstrate each. *Explanations reduce anxiety and fear of the unknown and promote understanding and acceptance that care will be painful while providing reassurance of pain control. Return demonstration verifies learning and identifies the need for additional teaching. Analgesics are most effective if given before pain is severe.*
 6. Reduce unnecessary stimulation:
 - a. Keep lights low and noise to a minimum.
 - b. Limit unnecessary visitors and staff.
 - c. Plan operative preparations so that they are done efficiently.
 - d. Maintain calm and friendly behavior. *These measures avoid adding to Christina's anxiety and emphasize that a cesarean delivery is a birth, not just a surgical procedure.*

EVALUATION: Christina says she believes that a cesarean birth is best for her baby, although she would have preferred to have her baby "naturally." She has several friends and relatives who had cesareans, so it did not surprise her that she would also have a cesarean. She asks a few other questions and then states that she understands preoperative and postoperative care. She demonstrates effective coughing and deep breathing techniques.

*Continues on p. 322.

The nurse explains preoperative procedures such as hair clipping in the incisional area, indwelling catheter, IV lines, and dressings and their purposes. The catheter and IV lines usually remain in place no longer than 24 hours after birth. Devices such as TED hose or sequential compression devices (SCDs) may be used throughout surgery and until ambulating well to reduce the risk for deep vein thrombosis (DVT).

Women who have regional anesthesia such as an epidural or a subarachnoid block often fear that they will feel pain during surgery. They do feel pressure and pulling, but these sensations do not mean that the anesthesia is wearing off. The nurse reassures the woman that her pain management is regularly assessed by the anesthesiologist.

If a woman is having general anesthesia, the nurse explains why operative preparations are completed before she is anesthetized. The patient should be reassured that her surgery will not begin until she is asleep and she will not wake up during the procedure.

The nurse describes the operating room (OR) and who will be present to make it less intimidating to her. Staff she encounters in the OR should introduce themselves, if possible. The patient's labor nurse often is the circulating nurse during surgery and reassures her with a familiar face and voice. The OR is very cool in most cases, and the surgery table is narrow. However, the OR may be warm if a low-birth-weight (LBW) or preterm infant is expected.

The support person should be told when to expect to come into the OR. If it is not already in place, an epidural block often is established after the woman goes to the OR. The partner may not be brought in until the regional block and other preparations such as the indwelling catheter are complete. These preparations may take 30 to 45 minutes if no rush exists. Support persons should be told that they will not be forgotten and that apparent delays do not indicate problems. Surgery preparation time that moves quickly and efficiently for staff often moves very slowly for family and the main support person.

The PACU and any equipment that will be used, for example, a pulse oximeter, electrocardiogram (ECG) monitor, and automatic blood pressure cuff, are explained to the couple. The nurse reviews routine assessments and interventions such as fundus and lochia checks, coughing, and deep breathing. The woman is taught simple exercises to promote normal circulation. The nurse reassures her that every effort will be made to promote her comfort with medication, positioning, and other interventions.

Promoting Safety

The woman's food intake is assessed for type and time on admission because general anesthesia occasionally is necessary. Oral intake and emesis during labor are recorded and reported to the anesthesia clinician. Oral intake other than ordered medications and possibly ice chips is discontinued if a cesarean birth becomes likely. Drugs to control gastric and respiratory secretions are administered, as ordered.

The woman is transferred and positioned carefully to prevent injury, especially if she has received regional anesthesia that reduces motor control and sensation. An extra-large operating table is used if indicated by her size and weight. Bony prominences are cushioned. A safety strap placed across her thighs secures her on the narrow operating table. A wedge under one hip or a tilted operating table avoids aortocaval compression and reduced placental blood flow. During positioning the drain tube of the indwelling catheter should be routed under her leg to promote drainage and keep the tubing away from the operative area. The catheter bag is placed near the head of the table so that the anesthesia clinician can monitor urine output, an important measure of fluid balance.

The nurse verifies proper function of equipment such as suction devices, monitors, and electrocautery. Leads for the cardiac monitor,

CASE STUDY 16-1 NURSING CARE PLAN*

ASSESSMENT: Christina had soup and a sandwich about 2 hours before admission. She will have epidural anesthesia for the birth. Her vital signs are as follows: temperature, 37.2°C (99°F); pulse rate, 88 beats per minute (bpm); respirations, 20 breaths per minute; blood pressure, 122/70 mm Hg. The fetal heart rate (FHR) is 130 to 140 bpm and accelerates frequently.

Critical Thinking: *Does this assessment suggest another nursing diagnosis? What interventions should the nurse institute for the nursing diagnosis?*

Answer: *Risk for Aspiration would apply during the intraoperative period because general anesthesia might be needed unexpectedly and Christina probably has food in her stomach that might be vomited and aspirated. A woman is given nothing by mouth if general anesthesia is a possibility. The nurse should expect orders for a drug to reduce gastric acidity in the event that general anesthesia is needed.*

*Continued from p. 321; continues below.

CASE STUDY 16-1 NURSING CARE PLAN*

ASSESSMENT: Christina is transferred to the operating room, and epidural anesthesia is begun. She gives birth to a 3856-g (8-lb, 8-oz) baby girl. Christina is transferred with her baby, Victoria, to the postanesthesia care unit (PACU) for postoperative care. Initial nursing assessments of mother and child are normal. Christina's husband accompanies them.

NURSING DIAGNOSIS: Risk for Injury related to altered sensation from epidural anesthesia and use of electrical equipment during surgery

EXPECTED OUTCOMES: Christina will not have injury such as pressure areas, muscle strains, and electrical injury during the perioperative period.

INTERVENTIONS AND RATIONALES

1. Pad the operating table carefully, particularly under bony prominences. Avoid obstructing her popliteal area. Apply TED hose, sequential compression devices (SCDs), or other ordered interventions to prevent deep vein thrombosis (DVT). *Padding reduces potential for tissue damage caused by pressure and venous stasis with possible thrombus formation. Antithrombotic interventions help maintain circulation in lower extremities until Christina is ambulating regularly.*
2. Transfer Christina to and from the operating table carefully, using enough staff members to keep her body in alignment. Brace the bed and operating table to keep them from separating. *These measures reduce the risk of falls and muscle strains for both Christina and the staff.*
3. After the epidural is begun, position Christina on the operating table and secure her legs with a safety strap. She should have a wedge under one hip, or the table should be tilted. *After the epidural is begun, position Christina on the operating table and secure her legs with a safety strap. She should have a wedge under one hip, or the table should be tilted.*
4. Apply grounding pad to prevent electrical shock or burn if electrocautery is to be used.

EVALUATION: During surgery, Christina's body was secured in proper alignment with proper padding of all her bony prominences. The grounding pad ensured electrical safety for electrocautery. Christina was transferred to the PACU without incident. During the recovery period, she showed no signs of pressure, electrical, or musculoskeletal injury.

*Continued from above.

temperature, and pulse oximeter are placed to observe vital functions. A grounding pad permits safe use of electrocautery.

After the surgery, the incision area is cleansed with sterile water and a sterile dressing is applied. Blood and amniotic fluid are cleaned from the woman's abdomen, buttocks, and back before she is transferred to a bed. Smooth transfers reduce pain and hypotension.

Postoperative Care

Postoperative care for the mother who has had a cesarean birth is similar to that for one who has had a vaginal birth, with added interventions related to the incision. Her temperature is assessed on admission to the PACU and according to protocol thereafter. If her condition is stable, other assessments are done every 15 minutes during the first 1 to 2 hours and progress to every 30 minutes to 1 hour until she is transferred to her postpartum room. In addition to temperature, routine postoperative assessments include the following:

- Vital signs, respiratory character, and oxygen saturation
- Return of motion and sensation if a regional block was given
- Level of consciousness, particularly if general anesthesia and sedating drugs were given
- Abdominal dressing
- Uterine firmness and position (midline or deviated to one side)
- Lochia (color, quantity, presence and size of any clots)
- Urine output (quantity, color, other characteristics)
- IV infusion (fluid, rate, condition of IV site)
- Pain relief needs
- Function of the SCD

The nurse observes for return of motion and sensation if the woman had epidural or subarachnoid block anesthesia. The level of consciousness and respiratory status (skin and mucous membrane color, rate and quality of respirations, pulse oximeter readings) are important observations if she had general anesthesia. Respiratory observations also are important if the woman received epidural opioid narcotics, which can cause delayed respiratory depression. Naloxone (Narcan) should be available to reverse opioid-induced respiratory depression (see Chapter 15).

The pulse rate, respirations, blood pressure, and oxygen saturation level provide important clues to the woman's circulatory and respiratory status. If oxygen saturation falls below 95%, it usually can be raised with several deep breaths. A persistent respiratory rate of less than 12 breaths per minute suggests respiratory depression. Deep breathing and coughing move secretions out of the lungs. A small

pillow to support her incision reduces pain when she coughs. Position changes every 2 hours improve ventilation, reduce pooling of lung secretions, and decrease discomfort from constant pressure.

As with vaginal birth, the fundus is assessed for height, firmness, and position. This examination is painful after regional anesthesia wears off, but the postcesarean mother also can have uterine atony. To relax her abdominal muscles and thus reduce pain from fundus checks, she should flex her knees and take slow, deep breaths. The nurse can gently "walk" the fingers toward the fundus to determine uterine firmness. The woman who has a Pfannenstiel skin incision usually has less pain with fundus checks than the woman with a vertical skin incision. A firm fundus does not need massage. The dressing is checked for drainage with each fundus check.

The nurse assesses the lochia and urine output with other assessments. Lochia may pool under the mother's buttocks and lower back. Urine may be bloody temporarily if the cesarean delivery was done after a long labor or an attempted forceps delivery. The urine drain tubing should be observed for gradual clearing of the blood. Urine should drain freely to prevent bladder distention, which worsens pain and increases the risk for postpartum hemorrhage. The nurse must remember that falling urine output is an early sign of hypovolemia.

The woman's needs for pain relief should be regularly assessed. The woman who received an epidural opioid may not need other analgesia during the early postpartum period. If she needs added pain relief while the epidural opioid is still in effect, the dose ordered often is lower than if she had not had that form of analgesia. Oral analgesics usually replace parenteral ones the day after surgery. A nonsteroidal antiinflammatory drug (NSAID) such as ibuprofen provides long-acting analgesia to supplement the epidural opioid. If she did not receive an epidural opioid, analgesia usually is given by patient-controlled analgesia (PCA) pump.

CHECK YOUR READING

16. Why is the low transverse uterine incision preferred for cesarean birth?
17. What should a woman who expects a cesarean birth be taught about the operating room? The recovery room or the PACU?
18. How should the nurse modify recovery room care of the mother who had a cesarean birth from that of the mother who had a vaginal delivery?

SUMMARY CONCEPTS

- Prolapse and compression of the umbilical cord are the primary risks of amniotomy. As the fluid gushes out, the cord can become compressed between the fetal presenting part and the woman's pelvis.
- Infection is more likely to occur when membranes have been ruptured for a long time (such as 24 hours or longer).
- Induction of labor may be done if continuing the pregnancy is more hazardous to the maternal and fetal health than the induction. It is not done if a maternal or fetal contraindication to labor and vaginal birth exists.
- Oxytocin-stimulated uterine contractions may be hypertonic, decreasing placental perfusion.
- External cephalic version is done to promote vaginal birth by changing the fetal presentation from a breech or transverse lie to a cephalic presentation. Internal version sometimes is used to change presentation of a second twin after the birth of the first twin.
- Trauma to maternal and fetal tissue is the primary risk associated with use of forceps and vacuum extraction. Possible trauma to the mother includes vaginal wall laceration and hematoma. Trauma to the infant may include ecchymoses, lacerations, abrasions, facial nerve injury, and intracranial hemorrhage.
- The median episiotomy is less painful but more likely to extend into the rectum than the mediolateral episiotomy.
- The preferred uterine incision for cesarean birth is the low transverse incision because it is least likely to rupture in a subsequent pregnancy. The skin incision does not always match the uterine incision and is unrelated to the risk of later uterine rupture.
- Some women have feelings of guilt and inadequacy if they have a cesarean birth or if they choose not to try VBAC when given that choice. Therapeutic communication and sensitive, family-centered care are essential to help them achieve a positive perception of their birth experience.

THE CESAREAN BIRTH STORY

1. Vicky is in active labor. An epidural catheter allows injection of medications to provide analgesia during labor. Additional epidural medications can be used to provide anesthesia if surgery becomes necessary. An intravenous infusion precedes placement of the epidural block to offset the tendency of the block to cause hypotension.

2. Support under her left hip displaces Vicky's uterus, thus avoiding pressure on her inferior vena cava and aorta and enhancing placental circulation. An automatic blood pressure cuff records frequent blood pressure assessments that are necessary when an epidural block is first begun.

3. After rupturing the membranes, the nurse-midwife applies a spiral electrode to the fetal scalp to improve the accuracy of the fetal heart tracing on the monitor.

4. Because the fetal monitor shows patterns suggesting fetal compromise, Vicky will need a cesarean birth. Monitors for her blood pressure, pulse rate, and cardiac rhythm help identify maternal factors contributing to the fetal heart rate patterns. She receives oxygen by face mask to provide the maximal amount to her fetus.

5. While Vicky is prepared for surgery, fetal monitoring and maternal oxygen administration continue. If possible, the same nurses accompany the woman to the operating room so that she has a continuing relationship during the cesarean birth, as she would have for vaginal birth in most circumstances.

6. Vicky's abdomen skin hair is clipped and then is cleansed with an antimicrobial prep solution for surgery. Clipping skin hair extends from just above the umbilicus to the point where the legs come together if a vertical incision is expected. If a transverse (Pfannenstiel) incision is expected, the top border can be about 3 inches above the upper pubic hairline.

THE CESAREAN BIRTH STORY

7. An iodine-based preparation solution is used to cleanse the abdomen using a circular motion beginning at the incisional area and extending outward. The cleansing sponge should not be returned toward the center. During preparations for surgery, Vicky's trunk is tilted slightly toward her left side by a wedge under her right hip to promote circulation to the placenta. The internal fetal scalp electrode is removed before the incision is made so that it is not brought from the unsterile vagina through the incision as the baby is born.

8. After making a Pfannenstiel skin incision, the physician separates the layers until the uterus is reached. The uterus is then opened in a low transverse incision. Wide retractors hold the mother's tissues back to expose an area large enough to allow the fetus to emerge. A suction device is available to suction blood and amniotic fluid from the uterus when it is incised.

9. The fetal head is first brought through the incision. The bluish skin color is normal at this point.

10. After birth of the head has occurred, the mouth and nose are suctioned to remove blood and other secretions before the infant takes his first breath. This baby is grimacing with the suction, which usually is associated with adequate oxygenation.

11. Further infant suctioning is done after the baby emerges.

12. The infant is briefly given supplemental oxygen by face mask. His color is becoming pinker than it was immediately after birth because he has a larger proportion of oxygenated hemoglobin. At the same time, another nurse dries the baby to prevent cold stress, which could increase his oxygen needs. Note that the nurses handling the baby wear gloves to protect themselves from blood and other secretions.

THE CESAREAN BIRTH STORY

13. Heavy sutures are used to close the muscular layers of the transverse uterine incision.

14. Vicky is having a bilateral tubal ligation for sterilization. One fallopian tube is identified by its connection to the uterus to distinguish it from her ureter and then is doubly tied. A segment of each tube is cut away and sent to the pathology laboratory for analysis in two containers specifically labeled for the right and left fallopian tube.

15. As her surgery continues and the infant's condition is stable, Vicky sees her baby up close for the first time.

16. Vicky's husband, Greg, holds his newborn son shortly after birth.

CHAPTER 17

Postpartum Physiologic Adaptations

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain the physiologic changes that occur during the postpartum period.
2. Describe nursing assessments and nursing care during the postpartum period.
3. Discuss expected outcomes and interventions for common nursing diagnoses.
4. Explain the role of the nurse in health education and identify important areas of teaching.
5. Compare nursing assessments and care for women who have undergone cesarean birth and vaginal birth.
6. Describe criteria for discharge and available health care services.
7. Use critical thinking exercises to improve selected nursing care plans.

The first 6 weeks after the birth of an infant are known as the *postpartum period*, or **puerperium**. During this time, mothers experience numerous changes. Physiologic and psychosocial changes and their implications are presented in separate chapters, although in actual practice they occur at the same time. (See **Appendix B**, “Keys to Clinical Practice,” for a summary of postpartum assessment and care.)

CASE STUDY 17-1 INTRODUCTION*

Jenny, 27 years old, delivered her fourth baby vaginally after a normal pregnancy, labor, and delivery. Baby Paul weighs 3228 g (8 lb) and is 55.9 cm (22 in) long. “This is my biggest baby yet,” Jenny says proudly, as she breast-fed him shortly after birth. She and husband Mason have three sons at home aged 18 months, 4 years, and 6 years.

*Continues on p. 338.

Many of the physiologic changes are retrogressive in nature: changes that occurred in body systems during pregnancy are reversed as the body returns to the nonpregnant state. Progressive changes such as the initiation of lactation also occur.

REPRODUCTIVE SYSTEM

Involution of the Uterus

Involution refers to the changes the reproductive organs, particularly the uterus, undergo after childbirth to return to their nonpregnant size and condition. Uterine involution involves three processes: (1) contraction of muscle fibers, (2) **catabolism** (the process of converting cells into simpler compounds), and (3) regeneration of the uterine epithelium. Involution begins immediately after delivery of the placenta, when uterine muscle fibers contract firmly around maternal blood vessels at the area where the placenta was attached. This contraction controls bleeding from the area left denuded when the placenta separated. The uterus decreases in size as muscle fibers, which have been stretched for many months, contract and gradually regain their former contour and size.

Although the total number of cells remains unchanged, the enlarged uterine muscle cells undergo catabolic changes in protein cytoplasm that cause a reduction in individual cell size. The products of this catabolic process are absorbed by the bloodstream and excreted in the urine as nitrogenous waste.

Regeneration of the uterine epithelial lining begins soon after childbirth. The outer portion of the endometrial layer is expelled with the

placenta. Within 2 to 3 days, the remaining **decidua** (the endometrium during pregnancy) separates into two layers. The first layer is superficial and is shed in the lochia. The basal layer containing the residual endometrial glands remains to provide the source of new endometrium. Regeneration of the endometrium, except at the site of placental attachment, occurs by 2 to 3 weeks after birth (Blackburn, 2013).

Healing at the placental site occurs more slowly and requires approximately 6 weeks (Blackburn, 2013). The site, which is about 9 cm (3.5 in) in diameter immediately postpartum, heals by a process of *exfoliation* (scaling off of dead tissue) (Katz, 2012). New endometrium is generated at the site from the sides and from glands and tissue that remain in the lower layer of the decidua after separation of the placenta (Cunningham, Leveno, Bloom, et al., 2010). This process leaves the endometrial layer smooth and spongy, as it was before pregnancy, and the uterine lining is free of scar tissue unless the birth was cesarean. Scarring of the uterine lining may interfere with implantation of future pregnancies.

Descent of the Uterine Fundus

The location of the uterine fundus helps determine whether involution is progressing normally. Immediately after delivery, the uterus is about the size of a large grapefruit or softball and weighs approximately 1000 g (2.2 lb). The fundus can be palpated midway between the symphysis pubis and umbilicus and in the midline of the abdomen. Within 12 hours the fundus rises to approximately the level of the umbilicus (Blackburn, 2013).

The fundus descends by approximately 1 cm, or one fingerbreadth, per day. By the 14th day, it has descended into the pelvic cavity and cannot be palpated abdominally (Figure 17-1) (Blackburn, 2013). This process is normally slower when the uterus was distended during pregnancy with more than one fetus, a large fetus, or hydramnios (excessive amniotic fluid). When the process of involution does not occur properly, **subinvolution** occurs. Subinvolution can cause postpartum hemorrhage (see Chapter 28).

Descent is documented in relation to the umbilicus. For example, *U-1* or $\downarrow 1$ indicates that the fundus is palpable about 1 cm (a fingerbreadth) below the umbilicus. Within 1 week, the weight of the uterus decreases to about 500 g (1 lb); at 4 weeks, the uterus weighs 100 g (2 to 3 oz) or less (Cunningham et al., 2010).

Afterpains

Etiology. Intermittent uterine contractions, known as **afterpains**, are a source of discomfort for many women. The discomfort is more acute for multiparas because repeated stretching of muscle fibers leads to loss of muscle tone that causes repeated contraction and relaxation of the uterus.

The uterus of a primipara tends to remain contracted, but she may also experience severe afterpains if her uterus has been overdistended or if retained blood clots are present. Afterpains are particularly severe during breastfeeding. Oxytocin, released from the posterior pituitary

to stimulate the **milk-ejection reflex** (release of milk from the ducts of the breasts), causes strong contractions of uterine muscles.

Nursing Considerations. Analgesics are frequently used to lessen the discomfort of afterpains. Many breastfeeding mothers are reluctant to take medication for fear it will pass into the breast milk and harm the infant. However, health care experts generally agree that most common analgesics may be used for short-term pain relief without harm to the infant. The benefits of pain relief such as comfort and relaxation facilitate the milk-ejection reflex and usually outweigh the small effect of the medication on the infant. The woman should check with her health care provider before taking any medication.

Some mothers find that lying in a prone position with a small pillow or folded blanket under the abdomen helps keep the uterus contracted and provides relief. The nurse can reassure the mother that afterpains are self-limiting and decrease in frequency and intensity by the third day (Cunningham et al., 2010).

Lochia

Changes in the color and amount of lochia also provide information about whether involution is progressing normally. Table 17-1 summarizes the characteristics of normal and abnormal lochia.

Changes in Color. On days 1 to 3 after childbirth, lochia consists almost entirely of blood, with small particles of decidua and mucus. It

FIG 17-1 Involution of the Uterus. Height of the uterine fundus decreases by approximately 1 cm per day. The fundus is no longer palpable by 14 days.

TABLE 17-1 CHARACTERISTICS OF LOCHIA

TIME AND TYPE	NORMAL DISCHARGE	ABNORMAL DISCHARGE
Days 1-3: lochia rubra	Bloody; small clots; fleshy, earthy odor; dark red or red-brown	Large clots; saturated perineal pads; foul odor
Days 3-10: lochia serosa	Decreased amount; serosanguinous; pink or brown-tinged	Excessive amount; foul smell; continued or recurrent reddish color
Days 10-14 (or up to 3rd to 6th week): lochia alba	White, cream, or light yellow color; decreasing amounts	Persistent lochia serosa; return to lochia rubra; foul odor; discharge continuing

FIG 17-2 Guidelines for Assessing the Amount of Lochia on the Perineal Pad.

is called **lochia rubra** because of its dark red or red-brown color. The amount of blood decreases when leukocytes begin to invade the area, as they do any healing surface. The color of lochia then changes from red to pink or brown-tinged (**lochia serosa**). It lasts from days 3 to 10. Lochia serosa is composed of serous exudate, erythrocytes, leukocytes, and cervical mucus. By about the 10th day, the erythrocyte component decreases. The discharge becomes white, cream, or light yellow in color (**lochia alba**). Lochia alba contains leukocytes, decidua cells, epithelial cells, fat, cervical mucus, and bacteria. It may end by day 14 or persist until the end of the 3rd to the 6th week (Blackburn, 2013; Whitmer, 2011).

Amount. Because estimating the amount of lochia on a peripad (perineal pad) is difficult, nurses frequently document lochia in terms that are difficult to quantify, such as *scant*, *moderate*, and *heavy*. Agreement on the meanings of terms in an agency is important to make charting accurate. One method for recording the amount of lochia in 1 hour uses the following labels:

- Scant—less than a 2.5-cm (1-inch) stain on the peripad
- Light—less than 10-cm (4-inch) stain
- Moderate—less than 15-cm (6-inch) stain
- Heavy—saturated peripad in 1 hour
- Excessive—saturated peripad in 15 minutes (Whitmer, 2011).

Determining the time a peripad has been in place is important when assessing lochia. What appears to be a light amount of lochia may be a moderate flow if the peripad has been in use for less than an hour (Figure 17-2). The amount of lochia absorbed by a peripad varies according to the brand used.

The time between delivery and assessment of lochia also is important. Lochia flow will be greater immediately after delivery but will gradually decrease. It is less after cesarean birth because some of the endometrial lining is removed during surgery. The lochia of the woman who had a cesarean birth will go through the same phases as that of the woman who had a vaginal birth, but the amount will be reduced.

Lochia flow is often heavier when the new mother first gets out of bed after birth or after sleeping because gravity allows blood that pooled in the vagina during the hours of rest to flow freely when she stands.

Some women have a sudden, short episode of bleeding 7 to 14 days after birth. This bleeding occurs when the eschar over the placental site

sloughs. Increased bleeding lasting longer than 1 to 2 hours should be evaluated by the health care provider (Katz, 2012).

Cervix

Immediately after childbirth the cervix is dilated, edematous, and bruised. Small tears or lacerations may be present. Rapid healing takes place, and by the end of the first week the external cervical os is 1 cm in diameter (Whitmer, 2011). There may be some edema for as long as 3 to 4 months, however (Blackburn, 2013). The internal os closes as before pregnancy, but the shape of the external os is permanently changed. It remains slightly open and appears slitlike rather than round, as in the nulliparous woman.

Vagina

The vagina and vaginal introitus are greatly stretched during birth to allow passage of the fetus. Soon after childbirth, the vaginal walls appear edematous, and multiple small lacerations may be present. Very few vaginal rugae (folds) are present.

Although rugae begin to reappear by 3 to 4 weeks, 6 to 10 weeks are needed for the vaginal epithelium to be restored. The vagina regains tone and decreases in size although it does not completely return to the prepregnancy state (Blackburn, 2013).

During the postpartum period, vaginal mucosa becomes atrophic and vaginal walls do not regain their thickness until estrogen production by the ovaries is reestablished. Because ovarian function, and therefore estrogen production, is not well established during lactation, breastfeeding mothers are likely to experience vaginal dryness and may experience **dyspareunia** (discomfort during intercourse).

Perineum

The muscles of the pelvic floor stretch and thin greatly during the second stage of labor, a result of pressure from the fetal head. After childbirth, the perineum may be edematous and bruised. If the woman had an **episiotomy**, a surgical incision of the perineal area, it will begin to heal in 2 to 3 weeks. Complete healing of the episiotomy site may take 4 to 6 months (Blackburn, 2013).

The episiotomy may be a median or midline incision, extending straight back from the lower edge of the introitus toward the anus. A mediolateral incision, begun at the introitus and directed laterally and downward away from the rectum to either the right or the left side, may be performed to provide additional room for birth of the infant. This type of episiotomy results in more blood loss and pain but less likelihood of extension of the incision (Cunningham et al., 2010; Kilpatrick & Garrison, 2012).

Lacerations of the perineum may also occur during delivery. Lacerations and episiotomies are classified according to tissue involved (Box 17-1). See Chapter 16 for further discussion of episiotomies and lacerations.

Discomfort

Although the episiotomy is relatively small, the muscles of the perineum are involved in many activities (walking, sitting, stooping, squatting, bending, urinating, and defecating). An incision or laceration in this area can cause a great deal of discomfort. In addition, many pregnant women are affected by hemorrhoids (distended rectal veins), which are pushed out of the rectum during the second stage of labor.

Nursing Considerations

Hemorrhoids, as well as perineal trauma, episiotomy, or lacerations, can make physical activity or bowel elimination difficult during the postpartum period. Relief of perineal discomfort is a nursing priority. It includes teaching self-care measures such as applying ice, taking sitz

BOX 17-1 LACERATIONS OF THE BIRTH CANAL**Perineum**

Perineal lacerations are classified in degrees to describe the amount of tissue involved. Some physicians or nurse-midwives also use degrees to describe the extent of midline episiotomies.

- *First-degree:* Involves the superficial vaginal mucosa or perineal skin.
- *Second-degree:* Involves the vaginal mucosa, perineal skin, fascia, and muscles of the perineum.
- *Third-degree:* Same as second-degree lacerations but extends into or through the external anal sphincter.
- *Fourth-degree:* Extends through the anal sphincter and into the rectal mucosa.

Periurethral Area

A laceration in the area of the urethra may cause a woman to have difficulty urinating after birth. An indwelling catheter may be necessary for a day or two.

Vaginal Wall

A laceration involves the mucosa of the vaginal wall.

Cervix

Tears in the cervix may be a source of significant bleeding after birth.

baths, performing perineal care, using topical anesthetics and cooling astringent pads, and taking ordered analgesics.

CHECK YOUR READING

1. Which three processes are involved in involution of the uterus?
2. How is the fundus expected to descend after childbirth?
3. Which mothers are most likely to experience afterpains? How are they treated?
4. What are the differences among lochia rubra, lochia serosa, and lochia alba in appearance and expected duration?

CARDIOVASCULAR SYSTEM

Hypervolemia, which produces an average 30% to 45% increase in blood volume at term, allows the woman to tolerate a substantial blood loss during childbirth without ill effect. Up to 500 mL of blood is lost in vaginal deliveries and up to 1000 mL is lost in cesarean births (Blackburn, 2013).

Cardiac Output

Despite the blood loss, a transient increase in maternal cardiac output occurs after childbirth. This increase is caused by (1) an increased flow of blood back to the heart when blood from the uteroplacental unit returns to the central circulation, (2) decreased pressure from the pregnant uterus on the vessels, and (3) the mobilization of excess extracellular fluid into the vascular compartment.

The rise in cardiac output returns to prelabor values within an hour after delivery. Gradually, cardiac output returns to prepregnancy levels in most women by 6 to 12 weeks after childbirth (Blackburn, 2013).

Plasma Volume

The body rids itself of the excess plasma volume needed during pregnancy by diuresis and diaphoresis.

- Diuresis (increased excretion of urine) is facilitated by a decline in the adrenal hormone aldosterone, which is increased during pregnancy to counteract the salt-wasting effect of progesterone. As aldosterone production decreases, sodium retention declines and fluid excretion accelerates. A decrease in oxytocin, which promotes reabsorption of fluid, also contributes to diuresis. A urinary output of up to 3000 mL per day may occur, especially on days 2 through 5 postpartum (Blackburn, 2013).
- Diaphoresis (profuse perspiration) also rids the body of excess fluid. It can be uncomfortable and unsettling for the mother who is not prepared for it. Explanations of the cause and provision of comfort measures such as showers and dry clothing are generally sufficient.

Blood Values

Several components of the blood change during the postpartum period. The average increase in WBC is to 14,000 to 16,000/mm³ (Cunningham et al., 2010). Marked leukocytosis may occur, with the white blood cell (WBC) count increasing to as high as 30,000/mm³ during labor and the immediate postpartum period. Although the increased WBC count is not usually caused by infection, an increase of over 30% within 6 hours may indicate infection (Whitmer, 2011). The WBC falls to normal values by 6 days after birth (Blackburn, 2013).

Maternal hemoglobin and hematocrit values are difficult to interpret during the first few days after birth because of the remobilization and rapid excretion of excess body fluid. The hematocrit is low when plasma increases and dilutes the concentration of blood cells and other substances carried by the plasma. As excess fluid is excreted, the dilution is gradually reduced. Hematocrit should return to normal limits within 4 to 6 weeks unless excessive blood loss has occurred (Blackburn, 2013).

Coagulation

During pregnancy, plasma fibrinogen and other factors necessary for coagulation increase. As a result the mother's body has a greater ability to form clots and thus prevent excessive bleeding. Fibrinolytic activity (ability to break down clots) is decreased during pregnancy. Although fibrinolysis increases shortly after delivery, elevations in clotting factors continue for several days or longer, causing a continued risk of thrombus formation. It takes 4 to 6 weeks before the hemostasis returns to normal nonpregnant levels (Blackburn, 2013).

Although the incidence of thrombophlebitis has declined greatly as a result of early postpartum ambulation, new mothers are still at increased risk for thrombus formation (see Chapter 28). Women who have varicose veins, a history of thrombophlebitis, or a cesarean birth are at further risk, and the lower extremities should be monitored closely. Pneumatic compression devices or prophylaxis with heparin before a cesarean birth helps prevent thrombi (American College of Obstetricians and Gynecologists [ACOG], 2011; National Quality Forum, 2009).

GASTROINTESTINAL SYSTEM

Soon after childbirth, digestion begins to be active. The new mother is usually hungry because of the energy expended in labor. She is thirsty because of decreased oral intake during labor and fluid loss from exertion, mouth breathing, and early diaphoresis. Nurses anticipate the mother's needs and provide food and fluids soon after childbirth.

Constipation is a common problem during the postpartum period for a variety of reasons. Bowel tone and motility, which were diminished during pregnancy as a result of progesterone, remain sluggish for several days. In addition, relaxation of the abdominal muscles increases

constipation and distention with gas. Decreased food and fluid intake during labor often results in small, hard stools. Perineal trauma, episiotomy, and hemorrhoids cause discomfort and interfere with effective bowel elimination. In addition, many women anticipate pain when they attempt to defecate and are unwilling to exert pressure on the perineum. Women who are taking iron have an added cause of constipation.

Temporary constipation is not harmful, although it can cause a feeling of abdominal fullness and flatulence. Many women become extremely concerned about constipation, and stool softeners and laxatives frequently are prescribed to prevent or treat constipation. The first stool usually occurs within 2 to 3 days postpartum. Normal patterns of bowel elimination generally resume by 8 to 14 days after birth (Blackburn, 2013).

URINARY SYSTEM

Physical Changes

The kidneys return to normal function by 4 weeks after delivery (Whitmer, 2011). The dilation of the renal pelvis and the ureters that occurs during pregnancy ends within 2 to 8 weeks (Cunningham et al., 2010). Both protein and acetone may be present in the urine for the first few postpartum days. Acetone suggests dehydration that often occurs during the exertion of labor. Mild proteinuria usually is the result of the catabolic processes involved in uterine involution.

Changes during pregnancy cause the bladder of postpartum women to have increased capacity and decreased muscle tone. During childbirth, the urethra, bladder, and tissue around the urinary meatus may become edematous and traumatized as the fetal head passes beneath the bladder. The result is often diminished sensitivity to fluid pressure, and many new mothers have little or no sensation of needing to void even when the bladder is distended.

The bladder fills rapidly because of the diuresis that follows childbirth. It is not unusual for a postpartum woman to void 500 to 1000 mL at a time (Blackburn, 2013). However, the woman is at risk for overdistention of the bladder, incomplete emptying of the bladder, and retention of residual urine. Urinary retention is more common after the first vaginal delivery, regional anesthesia, and catheterization before delivery. Retention occurs in 1.7% to 17.9% of postpartum women (Blackburn, 2013).

Urinary retention and overdistention of the bladder may cause urinary tract infection and increased postpartum bleeding. Urinary tract infection occurs when urinary stasis allows time for bacteria to multiply. Risk of bleeding increases because uterine ligaments, which were stretched during pregnancy, allow the uterus to be displaced upward and laterally by the full bladder (Figure 17-3). The displacement results in decreased contraction of the uterine muscles (uterine atony), a primary cause of excessive bleeding.

Stress incontinence may occur during pregnancy or after giving birth. Approximately one third of women have urinary incontinence at 8 weeks postpartum, but only approximately 15% of postpartum women still have a problem at 12 weeks (Katz, 2012). For some women, the problem resolves with pelvic floor exercises and time for healing. Others may have continued problems (see Chapter 34).

MUSCULOSKELETAL SYSTEM

Muscles and Joints

In the first 1 to 2 days after childbirth, many women experience muscle fatigue and aches, particularly of the shoulders, neck, and arms, because of exertion during labor. Warmth and gentle massage increase circulation to the area and provide comfort and relaxation.

FIG 17-3 A full bladder displaces and prevents contraction of the uterus.

During the first few days, levels of the hormone relaxin gradually subside, and ligaments and cartilage of the pelvis begin to return to their prepregnancy positions. These changes can cause hip and joint pain that interferes with ambulation and exercise. The mother should be told that the discomfort is temporary and does not indicate a medical problem. Good body mechanics and correct posture are important during this time to help prevent low back pain and injury to the joints.

Abdominal Wall

During pregnancy, the abdominal walls stretch to accommodate the growing fetus, and muscle tone is diminished. Many women, expecting the abdomen to return to the prepregnancy condition immediately after childbirth, are dismayed to find the abdominal muscles weak, soft, and flabby.

In addition, the longitudinal muscles of the abdomen may separate (**diastasis recti**) during pregnancy (Figure 17-4). The separation may be minimal or extensive, but is usually 2 to 4 cm (1 to 2.5 cm) (Whitmer, 2011). The mother can determine the amount of separation by placing her fingertips at her umbilicus and raising the head and shoulders while in a supine position. She may benefit from gentle exercises to strengthen the abdominal wall, which usually returns to normal position by 6 weeks after birth (Whitmer, 2011; Figure 17-5).

INTEGUMENTARY SYSTEM

Many skin changes that occur during pregnancy are caused by an increase in hormones. When estrogen, progesterone, and melanocyte-stimulating hormones decline after childbirth, the skin gradually reverts to the nonpregnant state. This change is particularly noticeable when melasma, the “mask of pregnancy,” and linea nigra fade and disappear for many women. In addition, spider nevi and palmar erythema, which may develop during pregnancy as a result of increased estrogen level, gradually disappear.

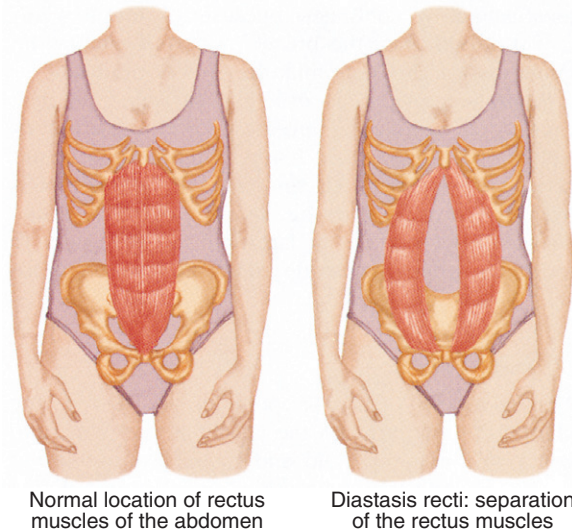

FIG 17-4 Diastasis recti occurs when the longitudinal muscles of the abdomen separate during pregnancy.

FIG 17-5 Abdominal Exercises for Diastasis Recti. **A**, The woman inhales and supports the abdominal wall firmly with her hands. **B**, Exhaling, the woman raises her head as she pulls the abdominal muscles together.

Striae gravidarum (stretch marks), which develop during pregnancy when connective tissues in the abdomen and breasts are stretched, gradually fade to silvery lines but do not disappear. Loss of hair may especially concern the woman. This is a normal response to the hormonal changes that caused decreased hair loss during pregnancy. Hair loss begins at 4 to 20 weeks after delivery and is regrown in 4 to 6 months for two thirds of women and by 15 months for the remainder of women (Blackburn, 2013).

CHECK YOUR READING

- Should the nurse be concerned if a woman who delivered a baby yesterday has a WBC count of $16,000/\text{mm}^3$? Why, or why not?
- Why is the mother at risk for urinary retention? Which two complications may result?
- Why does hyperpigmentation decrease after childbirth?

NEUROLOGIC SYSTEM

Discomfort and fatigue after childbirth are common. Afterpains, an episiotomy, laceration, or incision, muscle aches, and breast engorgement may increase a woman's discomfort and inability to sleep.

Analgesia or anesthesia may cause temporary neurologic changes such as lack of feeling in the legs and dizziness. During this time, prevention of injury from falling is a priority.

Complaints of headache require careful assessment. Frontal and bilateral headaches are common in the first week postpartum and may be a result of changes in fluid and electrolyte balance (Blackburn, 2013). Severe headaches are not common but may be postdural puncture headaches resulting from regional anesthesia (see Chapter 15). They may be most severe when the woman is in an upright position and are relieved by assuming a supine position. They should be reported to the appropriate health care provider, usually an anesthesiologist. Headache, along with blurred vision, photophobia, proteinuria, and abdominal pain, may indicate development or worsening of preeclampsia (see Chapter 25).

Pain continues after discharge from the hospital. Mothers report being surprised at the amount of pain they experience when they go home. Some mothers feel the pain interferes with their ability to care for themselves and their infants (Declercq, Cunningham, Johnson et al., 2008).

ENDOCRINE SYSTEM

After expulsion of the placenta, placental hormones such as estrogen, progesterone, and human placental lactogen decline fairly rapidly. If the mother is not breastfeeding, the pituitary hormone prolactin, which stimulates milk secretion, returns to nonpregnant levels in 14 days (Lawrence & Lawrence, 2011).

Resumption of Ovulation and Menstruation

Although the first few menstrual cycles for both lactating and nonlactating women are often anovulatory, ovulation may occur before the first menses (Whitmer, 2011). For some women, ovulation resumes as early as 3 weeks postpartum (Cunningham et al., 2010). Therefore, contraceptive measures are important considerations when sexual relations are resumed for both lactating and nonlactating women. Approximately 40% to 45% of non-nursing mothers resume menstruation at 6 to 8 weeks after childbirth, 75% by 12 weeks, and all within 6 months (Whitmer, 2011).

Breastfeeding delays the return of both ovulation and menstruation. Menses may resume as early as 12 weeks or as late as 18 months during lactation (Whitmer, 2011). Generally, women who breastfeed more often and use fewer supplements are likely to ovulate and menstruate later than women who breastfeed less often, use more supplements, and wean earlier (Kennedy, 2010). For the woman who is breastfeeding frequently and without supplements, contraception should be used by the time the infant is 6 months old or earlier because ovulation and menses are increasingly likely by that time (Kennedy & Trussell, 2011).

Lactation

During pregnancy, estrogen and progesterone prepare the breasts for lactation. Although prolactin also rises during pregnancy, lactation is inhibited at this time by the high level of estrogen and progesterone. After expulsion of the placenta, estrogen and progesterone levels decline rapidly, and prolactin initiates milk production within 2 to 3 days after childbirth. Once milk production is established, it continues because of frequent suckling by the infant and removal of milk from

the breast. That is, the more the infant nurses, the more milk the mother produces.

Oxytocin is necessary for milk ejection or “let-down.” This hormone, causes milk to be expressed from the alveoli into the lactiferous ducts during suckling (see [Chapter 22](#)).

Weight Loss

Approximately 4.5 to 5.8 kg (10 to 13 lb) are lost during childbirth. This includes the weight of the fetus, placenta, and amniotic fluid and blood lost during the birth. An additional 2.3 to 3.6 kg (5 to 8 lb) are lost as a result of diuresis and 0.9 kg to 1.4 kg (2 to 3 lb) from involution and lochia by the end of the first week ([Blackburn, 2013](#)).

Weight loss continues with the greatest loss during the first 3 months. If her weight gain during pregnancy has not been excessive, she will probably lose all but about 1 kg (2.2 lb) within a year if she follows a well-balanced diet. Younger women with lower prepregnant weight lose more weight and lose it sooner than other women ([Blackburn, 2013](#)).

Many mothers are frustrated because they want an immediate return to prepregnancy weight. Nurses can provide information about diet and exercise that will produce an acceptable weight loss without depleting the mother’s energy or impairing her health (see [Chapter 9](#)).

CHECK YOUR READING

8. When should a woman who is formula feeding her infant expect her menses to resume? When should a woman who is breastfeeding expect her menses to resume?
9. How does breastfeeding affect the resumption of ovulation and menstruation?
10. How much weight will the woman lose during childbirth? How much can she expect to lose by the end of the first week after childbirth?

POSTPARTUM ASSESSMENTS

Providing essential, cost-effective postpartum care to new families is a challenge for maternity nurses. Most women stay in the birth facility for 48 hours after an uncomplicated vaginal birth and 96 hours after a cesarean birth. Some women choose to go home at an earlier time.

Although the length of stay is short, the family’s need for care and information is extensive. This need causes nurses a great deal of concern for families who are discharged without adequate preparation or support. Nurses are actively involved in developing ways to provide continuing care in the home. They use measures such as clinical pathways to structure assessments, care, and teaching during the birth facility stay (see [Chapter 1](#)).

Initial Assessments

Caring for postpartum women exposes the nurse to the risk of contact with body fluids such as colostrum, breast milk, and lochia from the mother as well as urine, stool, and blood from the infant. Therefore, the recommendations of the Centers for Disease Control and Prevention (CDC) for standard blood and body fluid precautions must be followed diligently.

Postpartum assessments begin during the fourth stage of labor (the first 1 to 2 hours after childbirth). The mother is examined to determine whether she is physically stable. Initial assessments include:

- Vital signs
- Skin color
- Location and firmness of the fundus
- Amount and color of lochia
- Perineum (edema, episiotomy, lacerations, hematoma)

- Presence, degree, and location of pain
- Intravenous (IV) infusions: type of fluid, rate of administration, type and amount of added medications, patency of the IV line, and redness, pain, or edema of the site
- Urinary output: time and amount of last void or catheterization, presence of a catheter, color and character of urine
- Status of abdominal incision and dressing, if present
- Level of feeling and ability to move if regional anesthesia was administered

Chart Review

When the initial assessments confirm the mother’s physical condition is stable, nurses should review the chart to obtain pertinent information and determine if there are factors that increase the risk of complications during the postpartum period. Relevant information includes the following:

- Gravida, para
- Time and type of delivery (use of vacuum extractor, forceps, cesarean)
- Presence and degree of episiotomy or lacerations
- Anesthesia or medications administered
- Significant medical and surgical history, such as diabetes, hypertension, heart disease
- Medications given during labor or delivery or routinely taken and the reasons for their use
- Food and drug allergies
- Chosen method of infant feeding
- Condition of the baby

Laboratory data also are examined. Of particular interest are the prenatal hemoglobin and hematocrit values, blood type and Rh factor, hepatitis B surface antigen, rubella immune status, syphilis screen, and group B *Streptococcus* status (see [Chapter 26](#)).

Need for Rho(D) Immune Globulin

Prenatal and neonatal records are checked to determine whether Rho(D) immune globulin should be administered. It may be necessary if the mother is Rh-negative, the newborn is Rh-positive, and the mother is not already sensitized. Rho(D) immune globulin should be administered within 72 hours after childbirth to prevent the development of maternal antibodies that would affect subsequent pregnancies (see [Chapter 25](#) for Rh incompatibility and Rho[D] immune globulin drug guide).

Immunizations

Rubella Vaccine. A prenatal rubella antibody screen is performed on each pregnant woman to determine if she is immune to rubella. If she is not immune, rubella vaccine is recommended after childbirth to prevent her from acquiring rubella during subsequent pregnancies, when it can cause serious fetal anomalies.

Although there has been no evidence of fetal injury when the vaccine was inadvertently given to women during pregnancy, there is a theoretic risk of fetal defects because the vaccine is a live virus. Therefore, women are advised not to become pregnant for at least 28 days after receiving the vaccine ([Atkinson, Wolfe, & Hamborsky, 2012; CDC, 2011](#)).

Before administration, some agencies require a woman to sign a statement giving permission to receive the vaccine and indicating she understands the risks of becoming pregnant again too soon after the injection. If written permission from the mother is not required, the nurse should document in the chart that the risk has been explained and that the parents have verbalized their understanding (see [Drug Guide, p. 335](#)).

DRUG GUIDE

RUBELLA VACCINE

Classification: Attenuated live virus vaccine.

Action: Produces a modified rubella (German measles) infection that is not communicable, causing the formation of antibodies against rubella virus.

Indications for Childbearing Women: Administered at least 28 days before pregnancy or after childbirth or abortion to women whose antibody screen shows they are not immune to rubella. This vaccine prevents rubella infection and possible severe congenital defects in the fetus during a subsequent pregnancy.

Dosage and Route: 0.5 mL subcutaneously.

Absorption: Well absorbed.

Contraindications and Precautions: The vaccine is contraindicated in women who are immunosuppressed, pregnant, or sensitive to vaccine components, or have a moderate or severe illness. The attenuated virus may appear in breast milk and some infants may develop a rash, but this is not a contraindication to vaccination of lactating women. Although it can be given near the time of Rho(D) immune globulin administration, women receiving the vaccine should be tested for immune status at 6 to 8 weeks to be sure that they are immune.

Adverse Reactions: Transient stinging at site, fever, lymphadenopathy, arthralgia, and transient arthritis are most common.

Nursing Implications: Vials should be refrigerated. Reconstitute only with diluent supplied with the vial. Use immediately after reconstitution and discard if not used within 8 hours. Protect from light. Check with health care provider before giving near time of administration of Rho(D) immune globulin. Birth of infants with congenital rubella syndrome has not been documented when the vaccine has been given inadvertently during pregnancy, but women are advised to avoid pregnancy for at least 4 weeks after vaccination.

Reference: Atkinson, W., Wolfe, S., & Hamborsky, J. (Eds.). (2012). *Epidemiology and prevention of vaccine-preventable diseases* (12th ed.) Washington, DC: Public Health Foundation.

Pertussis Vaccine. Recent outbreaks of pertussis have had serious effects in infants and young children. Although most adults have been vaccinated as children, the effectiveness fades with time. Full protection of vaccinated infants does not occur until the entire series is completed. The [CDC \(2012\)](#) recommends that all adults in contact with infants and young children get a booster dose of pertussis vaccine. The vaccine may be offered to women during pregnancy or before hospital discharge after childbirth. It is usually administered along with diphtheria and tetanus vaccines (Tdap). See the CDC website at www.cdc.gov/vaccines for current information.

Varicella Vaccine. Varicella (chickenpox) in pregnant women can cause infection and serious complications in the fetus and newborn (see [Chapters 26 and 30](#)). Therefore, the [AAP and ACOG \(2012\)](#) recommend that women who are not immune to varicella should receive the first dose of varicella vaccine after delivery and before discharge from the birth facility. They should be advised not to become pregnant for 1 month after receiving the vaccine.

Risk Factors for Hemorrhage and Infection

Nurses must be aware of conditions that increase the risk of hemorrhage and infection, the two most common complications of puerperium.

CRITICAL TO REMEMBER

Postpartum Risk Factors

Hemorrhage

- Grand multiparity (five or more)
- Overdistention of the uterus (large baby, twins, hydramnios)
- Precipitous labor (less than 3 hours)
- Prolonged labor
- Retained placenta
- Placenta previa or accreta or abruptio placentae
- Drugs (tocolytics, magnesium sulfate, general anesthesia, prolonged use of oxytocin)
- Operative procedures (cesarean birth, vacuum extraction, forceps)

Infection

- Operative procedures (cesarean birth, vacuum extraction, forceps)
- Multiple cervical examinations
- Prolonged labor
- Prolonged rupture of membranes
- Manual extraction of placenta or retained fragments
- Diabetes
- Catheterization
- Bacterial colonization of lower genital tract

Focused Assessments after Vaginal Birth

Nurses perform postpartum assessments according to facility protocol. For example, a protocol might require assessment as follows:

- Every 15 minutes for the first hour
- Every 30 minutes for the second hour
- Every 4 hours for the first 24 hours
- Every 8 to 12 hours thereafter

Assessments are made more frequently if findings are abnormal. Although assessments vary depending on the particular problems presented, a focused assessment for a vaginal delivery generally includes the vital signs, fundus, lochia, perineum, bladder elimination, breasts, and lower extremities. The assessment for women who had a cesarean birth is more extensive (see p. 340).

Vital Signs

Blood Pressure. Blood pressure (BP) varies with position and the arm used. To obtain accurate results BP should be measured on the same arm with the mother in the same position each time. Postpartum BP should be compared with that of the predelivery period so that deviations from what is normal for the mother can be quickly identified. An increase from the baseline may be caused by pain or anxiety. If the BP is 140/90 mm Hg or higher, preeclampsia may be present. A decrease may indicate dehydration or hypovolemia resulting from excessive bleeding.

Orthostatic Hypotension. After birth a rapid decrease in intraabdominal pressure results in dilation of blood vessels supplying the viscera. The resulting engorgement of abdominal blood vessels contributes to a rapid fall in BP of 15 to 20 mm Hg systolic when the woman moves from the recumbent position to the sitting position. This change causes mothers to feel dizzy or lightheaded or to faint when they stand.

Hypotension may also indicate hypovolemia. Careful assessments for hemorrhage (location and firmness of the fundus, amount of lochia, pulse rate for tachycardia) should be made if the postpartum BP is significantly less than the prenatal baseline.

Pulse. Bradycardia, defined as a pulse rate of 40 to 50 beats per minute (bpm), may occur (James, 2008). The lower pulse rate may reflect the large amount of blood that returns to the central circulation after delivery of the placenta. The increase in central circulation results in increased stroke volume and allows a slower heart rate to provide adequate maternal circulation.

Tachycardia may indicate pain, excitement, anxiety, fatigue, dehydration, hypovolemia, anemia, or infection. If tachycardia is noted, additional assessments should include degree of pain, BP, location and firmness of the uterus, amount of lochia, estimated blood loss at delivery, and hemoglobin and hematocrit values. The objective of the additional assessments is to rule out excessive bleeding and to intervene at once if hemorrhage is suspected.

Respirations. A normal respiratory rate of 12 to 20 breaths per minute should be maintained. Assessing breath sounds is especially important for mothers who have a cesarean birth, are smokers, or have frequent or recent upper respiratory tract infections, asthma, or are receiving magnesium sulfate (see Chapter 25).

Temperature. A temperature of up to 38°C (100.4°F) is common during the first 24 hours after childbirth and may be caused by dehydration or normal postpartum leukocytosis. If the elevated

temperature persists for longer than 24 hours, or it exceeds 38°C (100.4°F), or the woman shows other signs of infection, the nurse should report it to the physician or nurse-midwife (see Chapter 28).

Pain. Pain should be assessed along with other vital signs to determine the type, location, and severity on a pain scale. Some new mothers are too excited by the birth of their child to complain of discomfort. Others do not want to “bother the nurse” or may be from cultures in which complaining is not acceptable. Nurses must remain alert to signs of afterpains, perineal discomfort, and breast tenderness. Nonspecific signs of discomfort include an inability to relax or sleep, a change in vital signs, restlessness, irritability, and facial grimaces. The nurse should encourage women to take prescribed medications as needed and should also assess the effectiveness of pain-relief measures.

Fundus

The fundus should be assessed for consistency and location (Procedure 17-1). It should be firmly contracted and at or near the level of the umbilicus. If the uterus is above the expected level or shifted from the middle of the abdomen or midline position (usually to the right), the bladder may be distended. The location of the fundus should be rechecked after the woman has emptied her bladder.

PROCEDURE 17-1 ASSESSING THE UTERINE FUNDUS

Purpose: To determine the location and firmness of the uterus

1. Explain the procedure and rationale before beginning the procedure. *Explanations reduce anxiety and elicit cooperation.*
2. Ask the mother to empty her bladder if she has not voided recently. *A distended bladder lifts and displaces the uterus.*
3. Place the mother in the supine position with her knees flexed. *This relaxes the abdominal muscles and permits accurate location of the fundus.*
4. Put on clean gloves and lower the perineal pads to observe lochia as the fundus is palpated. *Gloves are recommended whenever contact with body fluids may occur.*
5. Place your nondominant hand above the woman's symphysis pubis. *This supports and anchors the lower uterine segment.*

6. Use the flat part of your fingers (not the fingertips) for palpation. Palpation may be painful, particularly for the mother who had a cesarean birth. *The larger surface of the fingers provides more comfort.*
7. Begin palpation at the umbilicus, and palpate gently until the fundus is located. It should be firm, in the midline, and approximately at the level of the umbilicus. Locating the fundus is more difficult if the woman is obese or if the abdomen is distended. *Palpation helps determine the firmness and location of the fundus.*
8. If the fundus is difficult to locate or is “boggy,” (soft) keep the nondominant hand above the woman's symphysis pubis and massage the fundus with the dominant hand until the fundus is firm. *The nondominant hand anchors the lower segment of the uterus and prevents inversion while the uterus is massaged. The uterus contracts in response to tactile stimulation, and this helps control excessive bleeding.*
9. After massaging a boggy fundus until it is firm, press firmly to expel clots. Do not attempt to expel clots before the fundus is firm. Keep one hand pressed just above the symphysis (over the lower uterine segment) throughout. *Removing clots allows the uterus to contract properly. Attempting to expel clots on a boggy uterus might result in uterine inversion. A firm fundus and pressure over the lower uterine segment help prevent uterine inversion.*
10. If the fundus is above or below the umbilicus, use your fingers to determine the number of fingerbreadths between the fundus and the umbilicus. *Using the fingers to measure allows an approximation of the number of centimeters.*
11. Document the consistency and location of the fundus. Record consistency as “fundus firm,” “firm with massage,” or “boggy.” Record fundal height in fingerbreadths or centimeters above or below the umbilicus. For example, “fundus firm, midline, ↓1” (one fingerbreadth or 1 cm below the umbilicus); “fundus firm with light massage, U + 2 (two fingerbreadths or 2 cm above the umbilicus), displaced to right.” *This promotes accurate communication and identifies deviations from expected so that potential problems can be identified early.*

TABLE 17-2 ASSESSMENTS OF THE UTERINE FUNDUS AND NURSING ACTIONS

NORMAL FINDINGS	ABNORMAL FINDINGS	NURSING ACTIONS
Fundus firmly contracted	Fundus is soft, “boggy,” uncontracted, or difficult to locate.	Support lower uterine segment. Massage until firm.
Fundus remains contracted when massage is discontinued	Fundus becomes soft and uncontracted when massage is stopped.	Continue to support lower uterine segment. Massage fundus until firm; then apply pressure to express clots. Notify health care provider, and begin oxytocin or other drug administration, as prescribed, to maintain a firm fundus.
Fundus located at level of umbilicus and midline	Fundus is above umbilicus and/or displaced from midline.	Assess bladder elimination. Assist mother in urinating, or catheterize, if necessary, to empty bladder. Recheck the position and consistency of fundus after bladder is empty.

If the fundus is difficult to locate or is soft or “boggy,” the nurse stimulates the uterine muscle to contract by gently massaging the uterus. The nondominant hand must support and anchor the lower uterine segment during palpation and massage. Uterine massage is not necessary if the uterus is firmly contracted.

The uterus can continue to contract only if it is free of intrauterine clots. To expel clots, the nurse should support the lower uterine segment and massage the fundus until firm as illustrated in [Procedure 17-1](#). This support helps prevent inversion of the uterus (turning inside out) when the nurse applies firm pressure downward toward the vagina to express clots that have collected in the uterus. Nurses should observe the perineum for the number and size of clots expelled. If lochia is excessive or large clots are expelled, they should be weighed to estimate amount of blood loss (see [Chapter 28](#)). [Table 17-2](#) describes normal and abnormal findings of the uterine fundus and includes follow-up nursing actions for abnormal findings.

Drugs are sometimes needed to maintain contraction of the uterus and thus prevent postpartum hemorrhage. The most commonly used drug is oxytocin (Pitocin) (see [Drug Guide, p. 309](#)) Other drugs for excessive postpartum bleeding are discussed in [Chapter 28](#).

Lochia

Important assessments include the amount, color, and odor of lochia. Nurses observe the lochia on peripads and while checking the perineum. They also assess vaginal discharge while palpating or massaging the fundus to determine the amount of lochia and the number and size of any clots expressed during these procedures. Important guidelines include the following:

- A constant trickle, dribble, or oozing of lochia indicates excessive bleeding and requires immediate attention.
- Excessive lochia in the presence of a contracted uterus suggests lacerations of the birth canal. The health care provider must be notified so that lacerations can be located and repaired.

The odor of lochia is usually described as fleshy, earthy, or musty. A foul odor suggests endometrial infection, and assessments should be made for additional signs of infection. These signs include maternal fever, tachycardia, uterine tenderness, and pain.

Absence of lochia, like the presence of a foul odor, may also indicate infection. If the birth was cesarean, lochia may be scant because the uterine cavity was wiped by sponges, removing some of the endometrial lining. Lochia should not be entirely absent, however.

Perineum

The acronym **REEDA** is used as a reminder that the site of an episiotomy or a perineal laceration should be assessed for five signs: redness (R), edema (E), ecchymosis (bruising) (E), discharge (D), and approximation (the edges of the wound should be close, as though stuck or glued together) (A).

PROCEDURE 17-2 ASSESSING THE PERINEUM

Purpose: To assess perineal trauma and the state of healing.

1. Provide privacy, and explain the purpose of the procedure. *This elicits cooperation and reduces anxiety.*
2. Put on clean gloves. *Implements standard precautions to provide protection from possible contact with body fluids.*
3. Ask the mother to assume the Sims (side-lying) position and flex her upper leg. Lower the perineal pads, and lift her superior buttock. If necessary, use a flashlight to inspect the perineal area. *Position provides an unobstructed view of the perineum and allows assessment of lochia that may be under the mother; light allows better visualization.*
4. Note the extent and location of edema or bruising. *Extensive bruising or asymmetric edema may indicate formation of a hematoma (see [Chapter 28](#)).*
5. Examine the episiotomy or laceration for redness, ecchymosis, edema, discharge, and approximation (“REEDA”). *Redness, edema, or discharge may indicate infection of the wound; extensive bruising may delay healing; wound edges must be in direct contact for uncomplicated healing to occur.*
6. Note the number and size of hemorrhoids. *Swollen, painful hemorrhoids interfere with activity and bowel elimination.*

Redness of the wound may indicate the usual inflammatory response to injury. If accompanied by excessive pain or tenderness, however, it may indicate the beginning of localized infection. Ecchymosis or edema indicates soft tissue damage that can delay healing. No discharge should come from the wound. Rapid healing requires that the edges of the wound be closely approximated ([Procedure 17-2](#) describes the perineal examination.)

Bladder Elimination

Because the mother may not experience the urge to void even if the bladder is full, nurses must rely on physical assessment to determine whether the bladder is distended. Bladder distention often produces an obvious or palpable bulge that feels like a soft, movable mass above the symphysis pubis. Other signs include an upward and lateral displacement of the uterine fundus and increased lochia. Frequent voidings of less than 150 mL suggest urinary retention with overflow. Signs of an empty bladder include a firm fundus in the midline and a nonpalpable bladder.

Two to three voidings should be measured after birth or the removal of a catheter to determine if normal bladder function has returned. When the mother can void at least 300 to 400 mL, the bladder is usually empty. Regardless of the amount voided, if the fundus was displaced when assessed, it must be assessed again after the woman voids to confirm that the bladder is empty. Subjective symptoms of urgency, frequency, or dysuria suggest urinary tract infection and should be reported to the health care provider.

Breasts

For the first day or two after delivery, the breasts should be soft and nontender. After that, breast changes depend largely on whether the

mother is breastfeeding. The breasts should be examined even if she chooses formula feeding because engorgement may occur despite preventive measures. The size, symmetry, and shape of the breasts should be observed. Some mothers need reassurance that breast size has no relationship to successful breastfeeding. The skin should be inspected for dimpling or thickening, which, although rare, can indicate a breast tumor.

The areola and nipple should be carefully examined for potential problems such as flat or retracted nipples, which may make breastfeeding more difficult. Signs of nipple trauma (redness, blisters, or fissures) may be noted during the first days of breastfeeding, especially if the mother needs assistance in positioning the infant correctly (see Chapter 22).

The breasts should be palpated for firmness and tenderness, which indicate increased vascular and lymphatic circulation that may precede milk production. The breasts may feel “lumpy” as various lobes begin to produce milk.

The breast assessment is an excellent opportunity to provide information or reassurance about breast care and breastfeeding techniques. It is also an opportunity to teach the mother how to assess her own breasts so she can continue after discharge.

CASE STUDY 17-1 CRITICAL THINKING EXERCISE*

Jenny's nurse, Savannah, admitted Jenny to the Mother/Baby Unit 2 hours after the delivery from the labor, delivery, and recovery unit. An hour after transfer, Jenny's fundus is boggy, located three fingerbreadths above the umbilicus, and displaced to the right. Her perineal pads, which were changed just before transfer, are saturated. All previous assessments were normal.

Questions

1. What do these data suggest?
2. What nursing actions should be taken first? What follow-up assessments are necessary?
3. Why is it necessary to remind and assist Jenny to void?

Jenny was unable to void and Savannah catheterized her. Eight hundred mL of clear yellow urine were obtained. Her fundus returned to midline at the umbilicus and firm. Lochia was moderate. Savannah checked Jenny every 15 minutes for the next hour. All further assessments were normal.

*Continued from p. 328; continues on p. 341.

Lower Extremities

The legs are examined for varicosities and signs or symptoms of thrombophlebitis. Indications of thrombophlebitis include localized areas of redness, heat, edema, and tenderness. Pedal pulses may be obstructed by a thrombus and should be palpated with each assessment (see Chapter 28).

Homans' Sign. Discomfort in the calf with passive dorsiflexion of the foot is a positive Homans' sign (Figure 17-6) and may indicate deep vein thrombosis. Absence of discomfort indicates a negative Homans' sign. A positive Homans' sign (presence of discomfort) or redness, tenderness, or warmth of the leg should be reported to the health care provider. Confusion arises because a deep venous thrombosis may not produce calf pain with dorsiflexion. In addition, women may report pain that is caused by strained muscles from positioning and pushing during delivery.

Edema and Deep Tendon Reflexes. Pedal or pretibial edema may be present for the first few days, until excess interstitial fluid is remobilized and excreted. (Figure 17-7 shows how to assess for pitting edema.) Diuresis is highest between the 2nd and 5th days after birth.

FIG 17-6 Homans' sign is positive when the mother experiences discomfort in the calf on sharp dorsiflexion of the foot.

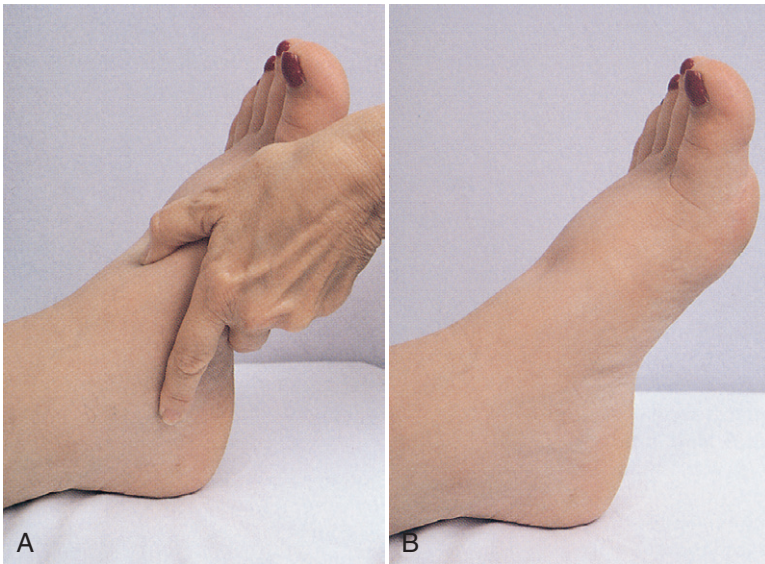

FIG 17-7 Pedal Edema. **A**, Apply pressure to foot. **B**, “Pit” appears when fluid moves into adjacent tissue and away from point of pressure.

Fluid and electrolyte balance should return to nonpregnant status by 21 days (Blackburn, 2013).

Deep tendon reflexes should be 1+ to 2+. Report brisker-than-average and hyperactive reflexes (3+ to 4+), which suggest preeclampsia (see p. 557 for a description of assessing deep tendon reflexes).

CARE IN THE IMMEDIATE POSTPARTUM PERIOD

Care of the mother during the immediate postpartum period focuses on physiologic safety of the mother (discussed previously), comfort measures, bladder elimination, and health education.

Providing Comfort Measures

Both cold and warmth are used to alleviate perineal pain after childbirth.

Ice Packs

Ice causes vasoconstriction and is most effective if applied soon after the birth to prevent edema and to numb the area. Chemical ice packs and plastic bags or non-latex gloves filled with ice may be used after a vaginal birth. The ice pack is wrapped in a washcloth or paper before it is applied to the perineum. It should be left in place until the ice melts. It is removed for 10 minutes before a fresh pack is applied. Some peripads have cold packs incorporated in them. Condensation from ice may dilute lochia and make it appear heavier than it actually is.

Care should be taken for women who are still numb from an epidural. Because they cannot feel the pack, they are at risk for cold burns. Ice should be used for short periods of time until sensation has returned (Petersen, 2011).

Some women have varicosities of the vulva and wish to use ice packs at home. An inexpensive way for women to apply cold to the perineum is to freeze a wet washcloth placed in a plastic bag and wrap it in a paper towel before applying it to the perineum.

Sitz Baths

In some facilities, sitz baths may be offered two to four times a day to women with episiotomies, painful hemorrhoids, or perineal edema. Sitz baths provide continuous circulation of water, cleansing and comforting the traumatized perineum. Cool water reduces pain caused by edema and may be most effective within the first 24 hours. Ice can be added to cool the water to a comfortable level as the woman sits in it. Warm water increases circulation, promotes healing, and may be most effective after 24 hours. Nurses must be sure that the emergency bell is within easy reach in case the mother feels faint during the sitz bath. Women often take the disposable sitz bath container home. They should be instructed to clean it well between uses.

Perineal Care

Perineal care consists of squirting warm water over the perineum after each voiding or bowel movement. This is important for all postpartum women whether the birth was vaginal or by cesarean. The bottle should not touch the perineum. Perineal care cleanses, provides comfort, and prevents infection of an area that often has an episiotomy or lacerations. The perineum is gently patted dry rather than wiped dry.

Topical Medications

Anesthetic sprays decrease surface discomfort and allow more comfortable ambulation. The mother is instructed to hold the nozzle of the spray 6 to 12 inches from her body and direct it toward the perineum. The spray should be used after perineal care and before clean pads are applied. Astringent compresses should be placed directly over the hemorrhoids to relieve pain. Hydrocortisone ointments may also be applied over hemorrhoids to increase comfort.

Sitting Measures

The mother should be advised to squeeze her buttocks together before sitting and to lower her weight slowly onto her buttocks. This measure prevents stretching of the perineal tissue and avoids sharp impact to the traumatized area. Sitting slightly to the side is also helpful to prevent the full weight from resting on the episiotomy site.

Analgesics

Mothers should be encouraged to take prescribed medications for afterpains and perineal discomfort. Many analgesics are combinations that include acetaminophen. The nurse should be careful that the woman receives no more than 4 g of acetaminophen in a 24-hour period. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen are often prescribed because of their antiinflammatory effects.

Promoting Bladder Elimination

Many new mothers have difficulty voiding because of edema and trauma of the perineum and diminished sensitivity to fluid pressure in the bladder. As soon as they are able to ambulate safely, mothers should be assisted to the bathroom. Providing privacy and allowing adequate time for the first voiding are important. Common measures to promote relaxation of the perineal muscles and stimulate the sensation of needing to void include:

- Medicating the woman for pain to help her relax
- Running water in the sink or shower, placing the mother's hands in warm water, and pouring water over the vulva
- Providing hot tea or fluids of choice
- Asking the mother to blow bubbles through a straw
- Helping the woman into the shower or sitz bath and encouraging her to void there

A nonpalpable bladder and firm fundus at or below the umbilicus and in the midline confirm that the bladder is empty and rule out urinary retention with overflow.

A distended bladder lifts and displaces the uterus, making it difficult for it to remain contracted. The resulting uterine atony (loss of tone), permits excessive bleeding. In addition, stasis of urine in the bladder predisposes the woman to urinary tract infection. Therefore, the mother must be catheterized if:

- She is unable to void.
- The amount voided is less than 150 mL, and the bladder can be palpated.
- The fundus is elevated or displaced from the midline.

Repeated catheterizations increase the chance of urinary tract infection because bacteria may be pushed into the bladder despite scrupulous aseptic technique. An indwelling catheter may be inserted for 24 hours if edema is excessive or catheterization is necessary more than once or twice.

CRITICAL TO REMEMBER

Signs of a Distended Bladder

Location of fundus above the baseline level (determined when the bladder is empty)
Fundus displaced to the side from midline
Excessive lochia
Bladder discomfort
Bulge of bladder above symphysis
Frequent voidings of less than 150 mL of urine, which may indicate urinary retention with overflow

CRITICAL THINKING EXERCISE 17-1

Lani has made good progress since she delivered her first baby yesterday morning by cesarean. Her patient-controlled analgesia was discontinued 4 hours ago. Her Foley catheter was removed 3 hours ago, and she was medicated with two Vicodin (hydrocodone 5 mg/acetaminophen 500 mg) tablets for pain 1 hour ago. Now she is wincing and moaning with pain and asking for more pain medication. She says she ambulated to the bathroom with her husband's help a short time after her catheter was removed and urinated but did not measure it. Her fundus is slightly above the umbilicus and slightly to the right. A thick pressure dressing covers the lower abdomen making it difficult to palpate the bladder. Lani says she does not have to urinate.

Questions

1. What other assessments should the nurse make?
2. What should the nurse do?
3. What are possible causes of Lani's pain?

Providing Fluids and Food

Adequate fluids help restore the balance altered by fluid loss during labor and the birth process. Women should be encouraged to drink approximately 2500 mL of fluids each day. Offering ice water or cold drinks may be culturally inappropriate for some women. They may prefer hot or room-temperature water instead.

If a woman is unable to tolerate oral fluids, IV administration may be necessary. Women usually are able to have ice chips soon after cesarean birth, and, although protocols vary, most are able to progress to a regular diet in a short time.

New mothers generally have a hearty appetite, and nurses should encourage healthy food choices with respect for ethnic background. Meals and snacks should be available at all times.

Preventing Thrombophlebitis

The woman should be assisted to ambulate early after childbirth to prevent the development of thrombi. Frequent trips to the bathroom will help accomplish this.

NURSING CARE AFTER CESAREAN BIRTH

In 2011, 32.8% of births in the United States were by cesarean delivery (Hamilton, Hoyert, Martin, et al., 2013). These mothers must recover from childbirth as well as from major surgery and need special care. The usual length of stay after a cesarean birth is 72 to 96 hours after surgery.

Assessment

In addition to the usual postpartum evaluation, following cesarean birth, the mother must be assessed like any other postoperative patient.

Pain Relief

Assessment of pain and the effectiveness of pain relief is important to the nursing care of women after cesarean birth, as they differ from typical postoperative patients in four important ways. First, they often are eager to be alert so that they can interact with their newborn infants. Second, they are concerned that the analgesics they receive may pass into their breast milk and harm their infants. Third, compared with other postoperative patients, after cesarean births, the women want to have more input and control of their care. Fourth, they are often healthier than patients who had surgery to correct a problem.

CASE STUDY 17-1 NURSING CARE PLAN*

ASSESSMENT: Jenny needed catheterization. Three hours later she called Savannah to ask for help to go to the bathroom. As she stood up, Jenny became weak and dizzy and said, "Everything is going black." Her gait was unsteady, and Savannah had to lower her back to bed to prevent her from fainting. Jenny's color was pale, and her pulse rate was rapid.

NURSING DIAGNOSIS: Risk for Injury related to physiologic effects of orthostatic hypotension

Critical Thinking: Does Savannah have enough data to make this diagnosis? If not, what other data are necessary? Why?

Answer: Although dizziness and feeling faint may indicate orthostatic hypotension, they may also indicate hypovolemia. Savannah must also assess Jenny for signs of excessive blood loss, as evidenced by the location and firmness of the uterine fundus, the amount of lochia, the pulse rate at rest, blood pressure (BP), and hemoglobin and hematocrit levels. Current hemoglobin and hematocrit levels should be compared with those before delivery and the estimated blood loss during delivery should be noted. If these data are within expected levels, a diagnosis of "Risk for Injury related to the effects of orthostatic hypotension" is appropriate.

Jenny's fundus was firm, midline, and at the umbilicus, and her lochia was moderate rubra. Her BP was 126/80 mm Hg (baseline 124/76 mm Hg), pulse 76 beats per minute (bpm) and respirations 18 breaths per minute which were similar to predelivery assessments. Her hemoglobin was 11, and hematocrit was 33 at admission to the labor and delivery unit. Estimated blood loss during delivery was 300 mL. Therefore, the nursing diagnosis is appropriate.

EXPECTED OUTCOME: Jenny will remain free of injury caused by fainting or falling during the postpartum period.

INTERVENTIONS AND RATIONALES

1. Allow Jenny to rest for a while before she attempts ambulation again. *Rest will allow circulation to stabilize and feelings of dizziness and weakness to pass.*

2. Obtain the assistance of another staff person each time ambulation is attempted until Jenny is able to ambulate without dizziness or feeling faint. *A second person helps prevent injury to the patient and the staff if Jenny should start to fall.*
3. Check Jenny's blood pressure while she is in the supine position and in the sitting position before getting her out of bed again. Use the same arm each time the BP is taken. *A decrease of 15 to 20 mm Hg in systolic pressure in the upright position indicates orthostatic hypotension. Measuring from the same arm provides more accurate information because the reading may differ slightly in each arm.*
4. Elevate the head of the bed for a few minutes, then help Jenny sit on the edge of the bed for several minutes before standing, and then help her to stand slowly. *Sitting and standing slowly allow time for the blood pressure to stabilize before she is fully upright, thus maintaining circulation to the brain.*
5. Instruct Jenny to bend her knees and move her feet constantly when she first stands. *Moving the feet increases venous return from the lower extremities to maintain cardiac output and increase cerebral circulation.*
6. Suggest that she take brief, tepid (not hot) showers and that she bend her knees and "march" during the shower. Provide a chair for her to use if she feels weak or faint while in the shower. *Hot water dilates peripheral blood vessels, allowing additional blood to remain in the vessels of the legs. Moving the feet and legs increases blood return from the legs and increases blood to the brain. Sitting takes less energy if she is feeling weak.*
7. Initiate measures to prevent injuries that could be sustained if she were to faint:
 - a. Stay with Jenny when she ambulates, and be prepared to assist her in sitting down and lowering her head or lower her gently to the floor if she becomes faint.
 - b. Call for additional assistance, if needed, before attempting to return her to bed. *Gravity increases blood flow to the brain when the head is lowered and helps prevent fainting. Adequate assistance prevents falling and possible injury.*
 - c. Remind her to call for assistance before trying to ambulate. Check to see that the call light is conveniently located. *This increases safety.*

EVALUATION: Jenny participated in self-care and sustained no injury during her hospital stay.

*Continued from p. 338; continues on p. 348.

Pain relief is provided in various ways. Patient-controlled analgesia (PCA) is administered by continuous IV infusion of a low-concentration narcotic solution using a pump specifically designed for that purpose. If analgesia is insufficient, the woman can self-administer intermittent small doses of narcotic from the infusion pump. The machine limits the amount of narcotic available within a specified time interval to prevent an overdose. This allows the woman to have pain relief immediately when she needs it without waiting for a nurse to administer it. Side effects include respiratory depression, itching (pruritus), nausea and vomiting, and urinary retention. Patient-controlled epidural analgesia (PCEA) is also used in the same way.

A single dose of opioid (such as preservative-free morphine or fentanyl) injected into the epidural or subarachnoid space immediately after surgery provides 18 to 24 hours of postcesarean analgesia (see Chapter 15). Itching and nausea are the major side effects. Other side effects are the same as for PCA use. Oral analgesics usually are effective if women need additional pain-relief measures. Occasionally, intramuscular analgesics are needed for one or two doses.

Respirations

When mothers receive epidural narcotics for postoperative pain relief, respirations must be assessed frequently because narcotics depress the respiratory center. A pulse oximeter or apnea monitor is used for 18 to 24 hours to detect decreased oxygen saturation from a decreased respiratory rate or depth. Capnography (end-tidal carbon dioxide monitoring) may also be used to detect opioid-related respiratory changes (Simpson, 2009). The devices emit an alarm if respirations decrease. The alarms should be loud enough to be heard easily outside the room. Oxygen saturation or respiratory rate is documented hourly or according to facility policy.

If a woman receiving epidural narcotics has a respiratory rate of 12 to 14 breaths per minute or less or the pulse oximeter shows a persistent oxygen saturation less than 95%, the nurse should do the following:

- Notify the anesthesiologist immediately.
- Elevate the head of the bed to facilitate lung expansion, and instruct the woman to breathe deeply.

FIG 17-8 This cesarean incision is closed with staples. Note the absence of all signs of infection, such as redness, edema, bruising (ecchymosis), discharge, and loss of approximation.

- Administer oxygen, and apply a pulse oximeter (if not already in place).
- Follow facility protocol to administer narcotic antagonists, such as naloxone hydrochloride (Narcan).
- Observe for recurrence of respiratory depression because the duration of naloxone is only approximately 30 minutes.
- Recognize that naloxone may reduce the level of pain relief.

In addition to observing the respiratory rate and depth, the nurse should auscultate the women's breath sounds because depressed respirations and a longer period of immobility allow secretions to pool in the bronchioles.

Abdomen

Nurses assess gastrointestinal function by auscultating for bowel sounds until normal peristalsis is noted in all abdominal quadrants. Although paralytic ileus (lack of movement in the intestines) is rare after cesarean birth, nurses must be aware of the signs. They include abdominal distention, absent or decreased bowel sounds, and failure to pass flatus or stool.

If a surgical dressing is present, it should be assessed for intactness and drainage. When the dressing is removed, nurses observe the incision, which should be approximated, and use the acronym REEDA to assess for signs of infection such as redness and edema (Figure 17-8). A topical skin adhesive may be used instead of staples. Assessment of the wound is the same.

It is just as important to assess the fundus after cesarean birth as it is with vaginal birth. However, palpation must be gentle because of increased discomfort caused by the abdominal incision.

Intake and Output

The IV should be monitored for patency, the rate of flow, and the condition of the site. Any signs of infiltration (edema, coolness at the site, pain) or signs of infection (edema, redness, warmth, pain) should be reported. Ice chips and clear fluids are allowed soon after birth. The amount, color, and clarity of urine should be monitored.

Interventions

The First 24 Hours

Nursing care for the mother who gave birth by cesarean is similar to that for other postoperative patients.

Providing Pain Relief. The nurse should determine the need for pain relief on a regular basis. If a woman has a PCA, the nurse should check how often she is using it. The effectiveness of analgesics should be evaluated. Pain relief enhances the woman's ability to increase her

activity, helps prevent thrombophlebitis, and promotes healing. For women with epidural or spinal opioids, the nurse should continue to assess the respiratory status.

Overcoming Effects of Immobility. The new mother is on bed rest for the first 8 to 12 hours. To prevent pooling of secretions in the airways, she must be assisted to turn, cough, and expand the lungs by breathing deeply at least every 2 hours while she is awake. Splinting the abdomen with a small pillow reduces incisional discomfort when she coughs. Incentive spirometers help expand the lungs to prevent hypostatic pneumonia that can result from immobility and shallow, slow respirations.

The woman should be encouraged to flex her knees and to move her legs and feet frequently while she is in bed to improve peripheral circulation and to prevent thrombi. Pneumatic compression devices may be used to prevent the pooling of blood in the lower extremities, especially for women who are obese or at high risk for thrombi.

Activity will be gradually increased. The woman needs assistance to sit and dangle her feet for the first few times before she gets out of bed. She should be helped to get out of bed and walk a short distance within 24 hours to decrease risk for thrombi. She will need support ambulating when the IV and the catheter are still in place.

Providing Comfort. Placing a pillow behind her back and one between her knees prevents strain and discomfort when the woman is lying on her side. Excellent physical care (oral hygiene, perineal care, a sponge bath, clean linen) comforts and refreshes her.

After 24 Hours

Resuming Normal Activities. After 24 hours following a cesarean birth, several normal functions return, and women are able to participate more actively in their own care:

- Both the indwelling catheter and the IV are usually discontinued.
- The dressing, if present, is removed in 24 hours. Staples (if present) are removed before discharge. Steri-Strips (small strips of adhesive) may be placed over the incision when staples are removed. A small nonstick dressing or a peripad may be placed over the incision to protect it from friction from clothing or adipose tissue, or the incision may be left open to air.
- The woman is helped to ambulate by the first postpartum day and is comfortable sitting in a chair for brief periods.
- Clear liquids are changed to a soft or regular diet when bowel sounds are audible or the woman is passing flatus. In some agencies, solids are provided earlier.

Nurses must encourage the woman to increase her activity and ambulation each postpartum day. By the second day, she usually is allowed to shower, if she wishes. Some health care providers request that the incision be covered with plastic; others permit showering without covering the incision.

Assisting the Mother with Infant Feeding. Pain after cesarean may interfere with the mother's ability to breastfeed and care for her infant. Ensuring adequate pain relief is important so the mother can focus on her infant.

It is important to help the mother find a comfortable position for holding and feeding her infant. Some mothers prefer sitting with a pillow on the lap to protect the incisional area. A side-lying position or football hold may be more comfortable because the infant is not putting pressure against the incision. In addition, the side-lying position allows the mother to rest while feeding (see Chapter 22). A support person or the nurse should be available to help the mother with infant care until she is able to take over herself.

Preventing Abdominal Distention. Abdominal distention is a major source of discomfort. Measures to prevent or minimize it include the following:

- Early, frequent ambulation
- Tightening and relaxing the abdominal muscles
- Avoidance of carbonated beverages and the use of straws, which increase the accumulation of intestinal gas
- Pelvic lifts—lying supine with her knees bent, the woman lifts her pelvis from the bed and repeats the exercise up to 10 times, several times each day
- Simethicone, as ordered, to help disperse upper gastrointestinal flatulence
- Rectal suppositories, as ordered, to help stimulate peristalsis and passage of flatus

Teaching for Discharge. Following cesarean births, mothers receive the same overall teaching as those who had vaginal births. Information about care of the incision and signs to report to the health care provider are added. In addition, women should have support at home, since they are recovering from major surgery as well as childbirth. In one study, women who had cesareans were more likely to report extreme tiredness at 6 and 12 months after the birth than women who had vaginal births (Woolhouse, Perlen, Gartland et al., 2012).

17. Which nursing measures are used to prevent or minimize abdominal distention?

APPLICATION OF THE NURSING PROCESS

■ Knowledge of Self-Care Assessment

Nurses are responsible for providing health education about a long list of subjects before the family is discharged from the birth facility. This is difficult because so much must be taught during this short time, which is not ideal for teaching mothers who are not fully recovered from the birth process. Some women feel they have difficulty concentrating during the first week postpartum.

Before beginning teaching, determine the learning needs and major concerns of the family. Multiparas remember some aspects of self-care but often benefit from a review. Primiparas may be anxious about self-care measures and all aspects of infant care. They may need more thorough teaching and more time for practice. Identify the effects of the most common barriers to learning: age and developmental level, cultural factors, and difficulty understanding the language.

Nursing Diagnosis

In general, women adapt well to the physiologic changes after childbirth, and most nursing care is wellness oriented. Some new mothers, however, lack knowledge of self-care and need education to prevent later problems. A nursing diagnosis that applies to many women is “Risk for Ineffective Health Maintenance related to insufficient knowledge of self-care, signs of complications, and preventive measures.” Common nursing diagnoses are listed in [Box 17-2](#).

Planning

Expected outcomes for this nursing diagnosis are that the woman will:

- Verbalize or demonstrate understanding of self-care instructions by (date).

BOX 17-2 COMMON NURSING DIAGNOSES FOR POSTPARTUM WOMEN

Anxiety
 Risk for Ineffective Health Maintenance*
 Risk for Ineffective Sexuality Pattern*
 Risk for Injury*
 Impaired Urinary Elimination
 Urinary Retention
 Constipation
 Readiness for Enhanced Childbearing Process
 Ineffective Breastfeeding
 Interrupted Family Processes
 Parental Role Conflict
 Sleep Deprivation

*Nursing diagnoses discussed in this chapter.

- Verbalize understanding of practices that promote maternal health by discharge.
- Describe plans for follow-up care and signs and symptoms that should be reported to the health care provider by discharge.

Interventions

Preparing for Teaching

Before beginning teaching sessions, be sure the woman is comfortable. Give pain medication, if needed, so that she is not distracted by discomfort. Schedule the teaching in such a way that it does not interfere with meals, infant care needs, or visiting.

Determining Teaching Topics

Make a teaching plan with the woman to include topics most important to her. Her perception of what is most important may differ from that of the nurse. Identifying the woman’s educational needs ensures her interest in the topics selected and makes best use of the short time available. Topics of less interest may require just a brief review. The review may elicit questions from the mother and interest in more in-depth information.

Teaching about the Process of Involution

Provide the woman with basic information about involution, including how to assess lochia and how to locate and palpate the fundus. This information allows her to recognize abnormal signs such as prolonged lochia, reappearance of bright-red lochia after lochia rubra has ended, and uterine tenderness, which should be reported to the health care provider. If the mother is a young adolescent, another family member may also need the information.

Teaching Self-Care

Handwashing. Emphasize the importance of thoroughly washing her hands before the woman touches her breasts, after diaper changes, after bladder and bowel elimination, before and after handling peripads, and always before handling the infant. Observing nurses model this behavior reinforces this teaching for parents.

Breast Care for Lactating Mothers. Instruct the breastfeeding mother to avoid using soap on her nipples because it will remove the natural lubrication secreted by Montgomery’s glands. Keeping the nipples dry between feedings helps prevent tissue damage, and wearing a good bra provides necessary support as breast size increases (see [Chapter 22](#)).

Measures to Suppress Lactation. If the mother chooses not to breastfeed, initiate measures to suppress lactation. Instruct the woman to wear a sports bra or other well-fitting bra 24 hours a day until the breasts become soft. Manage breast discomfort by application of ice, which reduces vasocongestion, and administration of analgesics. Advise the woman to refrain from allowing warm water to fall directly on the breasts during showers and pumping or massaging the breasts, as these actions will stimulate milk production. Tenderness and engorgement should return to normal in 48 to 72 hours (Janke, 2008).

Care of the Cesarean Incision. If the birth was by cesarean, the woman may have concerns about care of the incision. Staples, if used, are usually removed before the woman is discharged. The obese woman may go home with staples and have them removed by the health care provider after discharge. If adhesive strips have been applied over the incision, teach the woman that she can shower with them in place and that they will gradually detach.

If a topical skin adhesive was applied in surgery instead of staples or adhesive strips, there is no dressing, and the woman is generally allowed to shower. For each method, explain that the incision is closed and is unlikely to come apart. There should be little or no drainage from the incision. Instruct her to call her provider if the incision separates or drainage increases or has a foul odor.

Perineal Care. Teach the woman how to clean her perineum. The most common method is to fill a squeeze bottle with warm water and spray the perineal area from the front toward the back. Remind the new mother not to separate the labia during this procedure to avoid allowing water to enter the vagina. The tip of the bottle should not touch the perineum.

Toilet paper or moist antiseptic towelettes are used in a patting motion to dry the perineum. Teach the mother to dry from front to back to prevent fecal contamination of the vaginal introitus from the anal area. She should perform perineal cleansing and change peripads after each voiding or defecation.

Some women do not use peripads for menstrual protection and must be taught how to use them correctly. Mesh panties and adhering pads are used in most facilities. Careful handling to avoid contamination of the pads is important to prevent perineal infection.

- Thorough hand washing is a must before and after changing pads.
- Unused pads should be stored inside their packages.
- Pads should be applied without touching the side that comes into contact with the perineum.
- The pads should be applied and removed in a front-to-back direction to prevent contamination of the vagina and the perineum.
- Used pads must be wrapped and disposed of in a covered container.

Kegel Exercises. All women should become familiar with Kegel exercises (see Chapter 34). These movements strengthen the muscles that surround the vagina and urinary meatus. The exercise helps prevent the loss of muscle tone that can occur after childbirth and may decrease urinary incontinence.

The Kegel exercise involves contracting muscles around the vagina (as though stopping the flow of urine), holding tightly for 10 seconds, and then relaxing for 10 seconds. Each contraction should be of moderate to near maximum intensity, and a full 10 seconds should be allowed for relaxation between each contraction. The woman should work up to 30 contraction-relaxation cycles or more each day.

Promoting Rest and Sleep

Many women experience fatigue after childbirth that continues for weeks or months. This extreme fatigue has a variety of causes. Women are often tired when they begin the postpartum period because they slept poorly during the third trimester and are further exhausted by

the exertion of labor. Feelings of excitement and euphoria after childbirth interfere with rest. Numerous visitors and phone calls, hospital routines, noise, frequent interruptions, and an unfamiliar environment also interfere with rest. Afterpains, discomfort from an episiotomy or incision, muscle aches, and breast engorgement (swelling from increased blood flow, edema, and presence of milk) further contribute to a woman's discomfort and inability to sleep.

Most mothers are discharged from the facility within 24 to 48 hours after vaginal birth or 72 to 96 hours after cesarean birth, and they go home with a tremendous deficit in sleep and energy. Yet new parents may be unprepared for the conflict between their need for sleep and the infant's need for care and attention. The joys of parenting can easily be overshadowed by the exhaustion and frustration that result.

A telephone call to screen mothers for prolonged postpartum fatigue may be helpful in the days after discharge. Anemia, infection, and thyroid dysfunction may also cause postpartum fatigue. Women at risk for these conditions or suffering postpartum fatigue after the first 2 weeks should be evaluated and treated, if necessary.

Rest at the Birth Facility. Hospital routines continue around the clock, making undisturbed rest difficult to obtain during the birth facility stay. Make every effort to avoid interruptions and allow mothers adequate time for unbroken rest periods and relaxed time with their infants. Some agencies set aside a "quiet time" each afternoon where mothers are encouraged to rest without being disturbed.

Group assessments and care, and try to correlate them with times when the mother will be awake, such as just before or after meals, infant feeding times, and visiting hours. If the room is shared, providing care for both women at the same time also reduces activities that interrupt sleep.

Make plans with the mother for napping. Suggest she restrict phone calls and visitors during planned nap times. Encourage the mother to use a side-lying position for breastfeeding to allow her to rest during feedings. A quiet, softly lit environment also promotes sleep.

Rest at Home. Help the mother understand the impact her physical discomfort and the demands of the newborn and other family members will have on her energy during the first few weeks. If she understands that fatigue is normal and will continue for some time, she can plan ways to obtain extra help and conserve her energy. Suggest energy-saving measures such as the following:

- Maintain a relaxed, flexible routine that focuses on care of the mother and infant.
- Nap or rest when the infant sleeps, if possible.
- Plan simple meals and flexible meal times.
- Limit visitors.
- Accept assistance with food shopping, meal preparation, laundry, and housework.
- Ask family or friends to care for the infant to provide nap times for the mother.
- Put off housework that is not absolutely necessary.
- Postpone major household projects.
- Involve friends and family to provide care for other children.
- Avoid heavy meals or vigorous exercise near bedtime.

Explain to the mother that she should delay her return to employment, if possible, until the infant sleeps through the night (usually by 3 to 4 months) or later. It takes time to recover from the birth, as well as to adjust to the changes that occur with a new baby. Advise the mother to restrict intake of caffeine or to use caffeine-free versions for the first few weeks. Suggest relaxation exercises (lying quietly, alternately tightening and relaxing the muscles of the neck, shoulders, arms, legs, and feet), when a nap is not possible.

Emphasize to the mother the importance of asking for help when she begins to feel exhausted or overwhelmed. Encourage her to share

these feelings with her partner, other family members, friends, and other new mothers.

Infant Sleep and Feeding Schedules. Many families require information about infant sleep cycles, frequency of feeding, and probable crying episodes during the first weeks. Although newborns sleep much of the time, they may awaken every 2 to 3 hours for feeding (see [Chapter 22](#) regarding infant feeding and [Chapter 23](#) regarding parenting during the early weeks). If possible, having the father or another helper assist with nighttime care of the infant allows the mother longer sleep periods.

EVIDENCE-BASED PRACTICE

Coping with Postpartum Fatigue

Postpartum fatigue is a common problem for women in the early weeks and months after childbirth. It may have implications for maternal health and quality of child care. Doering and Durfor conducted a small grounded theory study of fatigue and sleep in nondepressed low-income women during the first 6 months after childbirth. Sixteen, mostly African-American, women were recruited from a large Midwestern urban care facility and interviewed at 1, 3, and 6 months after giving birth.

“Persevering toward normalcy” was the process the women used to manage intense fatigue, maximize sleep, and access social support over the 6 postpartum months. In spite of their exhaustion, they felt they needed to “deal with it” and “keep going” to meet the needs of the family because they felt no one else would do what was necessary. Although they got little sleep, they expected to “get used to it” and knew that things would get better with time.

The women found establishing a flexible routine for the infant and the family was helpful in easing the difficulties because it helped them know what to expect. Social support was important in relieving fatigue when family members would take care of the infant to allow the mother to sleep.

The first few weeks were the most difficult. Many returned to work at a month and the infant went to daycare. The routine of daycare helped improve infant sleep/wake patterns allowing the mother more sleep at night. Yet mothers still reported rarely getting “enough” sleep at 3 months. By 6 months routine, stability, and enjoyment had increased to normalize life. As the women obtained more rest, they increased social interactions that also made life feel more normal.

Ask mothers you know or in your health care facility how they coped with sleep deprivation during the early weeks and months after childbirth. Make a plan to teach new mothers to expect inadequate sleep and help them think of ways to increase rest during this time.

Reference: Doering, J., & Durfor, S. L. (2011). The process of “Preserving toward normalcy” after childbirth. *MCN: The American Journal of Maternal/Child Nursing*, 36(4), 258–265.

Providing Nutrition Counseling

Food Supply. Low-income families might benefit from referral to government-sponsored programs such as Temporary Assistance for Needy Families (TANF) or the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). Determining the facilities available for cooking and storing food also may be necessary. The new family may need referral to a social worker to identify the best solutions for their unique problems.

Diet. Although many women are unsatisfied with slow weight loss, they should avoid severe restriction of caloric intake. Advise the mother to select foods that provide adequate calories to meet her energy needs, taking into account the time and energy required to care for a newborn. Strict dieting should be avoided.

Women often lose weight by decreasing consumption of carbohydrates. However, their fat intake may increase if they skip meals and eat high-fat snacks or fast foods because of time constraints. A balanced, low-fat diet with adequate protein, complex carbohydrates, fruits, and vegetables provides the energy and nutrients needed (see [Chapter 9](#)).

Promoting Regular Bowel Elimination

Explain the role of progressive exercise, adequate fluid, and dietary fiber in preventing constipation. Walking is an excellent exercise, and the distance can be increased as strength and endurance increase. Drinking at least eight glasses of water daily helps maintain normal bowel elimination. Unpeeled fruits and vegetables are high in fiber and prunes are natural laxatives. Additional fiber is found in whole grain cereals, bread, and pasta.

A regular schedule of bowel elimination is important in overcoming constipation. For example, bowel elimination after breakfast allows the mother to take advantage of the gastrocolic reflex (stimulation of peristalsis induced in the colon when food is consumed on an empty stomach). Measures that reduce perineal and hemorrhoidal pain include witch hazel astringent compresses and hydrocortisone ointments, which also facilitate bowel elimination.

Promoting Good Body Mechanics

Exercise. Exercise has beneficial physical and psychological effects during the postpartum period. Teach exercises in the early postpartum period to strengthen the abdominal muscles and firm the waist ([Figure 17-9](#)). These mild exercises can be started soon after childbirth with five repetitions, twice a day. The number of exercises is increased gradually as the mother gains strength.

Reassure the woman that moderate exercise will not interfere with lactation and will lead to more rapid weight reduction. Exercise classes that sometimes include the infants are often available for postpartum women. Common barriers to postpartum exercise are child care needs and lack of time. Walking is a common exercise, and women can take the infant with them on walks. Women who exercise with a friend are more likely to fit it into their schedules.

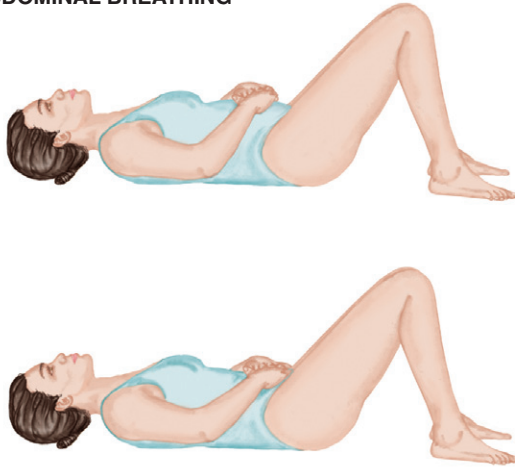

After cesarean births, mothers should follow the instructions of their health care provider. Generally, abdominal exercises should not start until 4 weeks after a cesarean birth ([James, 2008](#)). However, less strenuous activities such as walking are beneficial. The woman should not exercise if it causes her pain.

Prevention of Back Strain. Back strain often can be prevented if the mother and father find a location for infant care that does not require bending or leaning forward (e.g., a kitchen table or bathroom counter). For lifting objects, teach parents to hold the back straight as they squat and use their legs rather than bending at the waist (see [Figure 7-13](#)).

Counseling about Sexual Activity

The couple may have concerns about resuming sexual intercourse and contraceptive choices. Fatigue, pain, fear of pregnancy, concerns about the baby, and a feeling of unattractiveness may interfere with a woman’s sexual desire. Couples can begin intercourse as early as 2 weeks after giving birth, if desire and comfort allow ([Cunningham et al., 2010](#)). Low estrogen levels during the early postpartum period and during lactation cause vaginal dryness. Application of a water-soluble vaginal lubricant may increase comfort during intercourse.

Women with third- or fourth-degree lacerations or episiotomies may need more time for healing to be complete. One study found that women frequently waited 3 to 6 months or longer after giving birth to resume intercourse if they had lacerations of the vagina,

ABDOMINAL BREATHING

This is one of the simplest exercises and can be started on the first postpartum day. The woman assumes a supine position with knees bent. She inhales through the nose, keeps the rib cage as stationary as possible, and allows the abdomen to expand. She then contracts the abdominal muscles as she exhales slowly through the mouth.

MODIFIED SIT-UPS

Head lifts may progress to modified sit-ups with the approval of the health care provider; the mother should follow the advice of the health care provider about the number of repetitions.

The exercise begins with the mother supine with arms outstretched and the knees bent. She raises her head and shoulders as her hands reach for her knees. She raises the shoulders only as far as the back will bend; her waist remains on the floor.

HEAD LIFT

This exercise can be started within a few days after childbirth. The mother is supine with knees bent and arms outstretched at her side. She inhales deeply to begin, then exhales while lifting the head slowly; she holds the position for a few seconds and relaxes.

FIG 17-9 Postpartum Exercises. Exercises should be approved by the woman's physician, nurse-midwife, or nurse practitioner before she begins them.

KNEE AND LEG ROLLS

This is an excellent exercise to begin firming the waist. The mother lies flat on her back with knees bent and feet flat on the floor or bed; she keeps the shoulders and feet stationary and rolls the knees to touch first one side of the bed, then the other. She maintains a smooth motion as the exercise is repeated five times. Later, as flexibility increases, the exercise can be varied by the rolling of one knee only. The mother rolls her left knee to touch the right side of the bed, returns to center, and rolls the right knee to touch the left side of the bed.

CHEST EXERCISES

This is an excellent exercise to strengthen the chest muscles. The mother lies flat with arms extended straight out to the side; she brings the hands together above the chest while keeping the arms straight; she holds for a few seconds and returns to the starting position. She repeats the exercise five times initially and follows the advice of the health care provider for increasing the number of repetitions.

Isometric exercises also increase strength and tone; the mother bends her elbows, clasps her hands together above her chest, and presses her hands together for a few seconds. This is repeated at least five times.

FIG 17-9, cont'd

perineum, or involving the anal sphincter (Radestad, Olsson, Nissen, et al., 2008).

Some women have increased nipple sensitivity during lactation and do not want their breasts touched during love-making (Convery & Spatz, 2009). It is important that nurses provide such information to new mothers and their partners.

Many new parents are reluctant to ask about when to resume sexual activity and potential changes in sexuality resulting from pregnancy and childbirth. Nurses must be sensitive to unasked questions and should try to provide anticipatory guidance.

If couples do not indicate such concerns, introduce the topic in a general, nonspecific manner such as “You have an episiotomy that may cause some discomfort with intercourse until it is completely healed” or “Sometimes couples are not aware that some vaginal dryness occurs as a result of breastfeeding.” Such broad opening statements permit the couple to pursue the topic as they desire.

Cultural or religious convictions may restrict the choice of contraceptive method for some couples. The availability of health care or limited finances may dictate the choice for others. Discuss previous experience with contraceptives and the satisfaction with those methods. Some women choose to have a tubal ligation before discharge (see Chapter 31).

Instructing about Follow-Up Appointments

Remind the new mother to make an appointment with her physician or nurse-midwife for a postpartum examination at the time suggested by her provider. This is often 4 to 6 weeks after vaginal birth and 2 weeks after cesarean birth.

Emphasize the importance of the postpartum examination. It allows early assessment of postpartum healing and identification and treatment of problems that may develop. It also provides an opportunity for contraceptive counseling and planning for future pregnancies. Women who have had complications during the pregnancy or

CASE STUDY 17-1 NURSING CARE PLAN*

The next day, Savannah again cares for Jenny and Paul. Jenny has had no further problems with dizziness. Assessments have been normal for both mother and infant. Paul has breastfed well. Jenny is discussing going home the next day and has some concerns.

ASSESSMENT: Jenny wonders about how she will be able to care for her baby boy and the other children. "It's hard for me to have time for the kids and my husband as it is. He's good with the kids but it seems like we have little time together." She asks Savannah what she can do to prevent the pain she experienced during intercourse for several months after her last child was born. Her third-degree episiotomy is healing appropriately for this time.

NURSING DIAGNOSIS: Anxiety related to anticipated fatigue and discomfort

Critical Thinking: What assumption is the nurse making? How might the nurse validate the assumption? Can you identify another diagnosis that is more specific?

Answer: The nurse assumes the patient is anxious. Neither signs nor symptoms of anxiety are part of the assessment data. The nurse can validate the assumption by asking Jenny if she is anxious. "Anxiety" is a very broad diagnostic category. Based on data available, a more specific and therefore more helpful nursing diagnosis might be "Risk for Ineffective Sexuality Patterns related to fatigue and pain."

EXPECTED OUTCOMES: Before discharge, the couple will do the following:

1. Verbalize measures to promote comfort during sexual activity.
2. Verbalize a plan to reduce fatigue, which interferes with interest in and energy for sexual activity.

INTERVENTIONS AND RATIONALES

1. Recommend that the parents postpone vaginal intercourse until the perineum is no longer painful. Suggest that the mother continue perineal care and the use of topical agents until the perineum is healed. *These measures promote healing and reduce pain or fear of pain when sexual activity is resumed.*
2. Discuss measures that may lessen fatigue:
 - a. Recommend a 30-minute nap for each partner during the day or evening.

- b. Suggest that sexual activity be resumed in the morning or afternoon rather than at the end of a tiring day.
- c. Counsel the parents to rest when the infant sleeps and to postpone major home projects that will increase fatigue until the infant is sleeping through the night.

Fatigue is a major cause of decreased interest in sexual activity after childbirth for both mothers and fathers.

3. Remind the mother to perform Kegel exercises until she can comfortably do 30 contraction-relaxation cycles each day. *Kegel exercises strengthen the muscles around the vagina and increase sexual satisfaction.*
4. Advise Jenny to breastfeed the infant shortly before the parents initiate sexual activity. *Breastfeeding reduces the chance of leaking milk, which interferes with sexual pleasure for some couples. Feeding the infant may also allow uninterrupted time while the infant sleeps.*
5. Explain that sexual arousal may be slower because of decreased hormone levels and fatigue. More stimulation may be required before the mother is sexually aroused. *Knowledge of the physiologic changes reduces the anxiety and tension that occur if the parents are unprepared.*
6. Recommend the use of a water-soluble vaginal lubricant (Lubrin, Replens). *Breastfeeding decreases estrogen level and may result in vaginal dryness. A water-soluble lubricant increases comfort.*
7. Before vaginal intercourse, as part of foreplay, suggest that one finger be inserted into the vaginal introitus to determine areas of tenderness or pain. *Locating areas of discomfort and stretching the perineal scar gently help increase comfort.*
8. Suggest that Jenny assume the superior position during intercourse. *In this position, the woman controls the depth and location of penetration and can reduce her discomfort.*
9. Discuss the need for frank communication between partners about measures that reduce discomfort as well as specific concerns and needs. *Communication facilitates understanding and fosters a feeling of closeness that can enhance sexual interest.*

EVALUATION: Before discharge, the couple expresses interest in trying various measures to reduce fatigue and discomfort. They discuss a plan to provide rest for Jenny. Jenny states she thinks it will be helpful and is happy her husband is interested in helping so much.

*Continued from p. 341.

postpartum period may need to see their health care provider sooner or have more extensive follow-up than those without complications.

Teaching about Signs and Symptoms That Should Be Reported

Teach new mothers and at least one family member which physical signs and symptoms should be reported to the health care provider immediately. These include the following:

- Fever
- Localized area of redness, swelling, or pain in either breast
- Persistent abdominal tenderness
- Feelings of pelvic fullness or pelvic pressure
- Persistent perineal pain
- Frequency, urgency, or burning on urination
- Abnormal change in character of lochia (increased amount, resumption of bright red color, passage of clots, foul odor)
- Localized tenderness, redness, edema, or warmth of the legs
- Redness, separation or edema of, or foul drainage from an abdominal incision

Ensuring That All Elements Have Been Taught

Organize information so that it can be presented and absorbed in the time available. Group instruction and hospital classes such as those that demonstrate infant care and provide breastfeeding instructions make efficient use of the nurse's time. They provide an opportunity for mothers to ask questions about care needed by themselves and their infants that DVDs and television shows do not. An example is one hospital's luncheon where parents gather on the day they go home to eat, receive discharge education, and have a time for group questions (Lucia & Mullaly, 2009).

Individual instruction is also necessary. In some agencies, women are given information pertaining to postpartum self-care during the prenatal period. During the hospital stay, the nurse reviews and rechecks the mothers' understanding of previous teaching.

Although there are many topics to discuss in parent teaching, avoid covering too much information at a time. Interspersing small segments of teaching into normal care throughout the day will keep the woman from being overwhelmed and help her remember information better.

BOX 17-3 POSTPARTUM DISCHARGE TEACHING TOPICS

Uterine massage
 Lochia norms
 Involution
 Episiotomy care
 Care of abdominal incisions
 Breast care for lactating and nonlactating women
 Bowel function
 Urinary function
 Nutrition
 Rest
 Exercise
 Sexual activity
 Contraception
 Postpartum danger signs
 Follow-up care
 Medications
 Emotional responses and postpartum depression
 Infant care and feeding
 Family adjustment
 Available resources

Documenting Teaching

Documentation is an important aspect of teaching, just as it is for other aspects of nursing care. Documentation that discharge teaching was performed and that the patient has indicated comprehension of teaching is required by accrediting agencies. To prevent omissions, many hospitals use teaching checklists to record topics that must be taught (Box 17-3) (see Chapter 21 for teaching about infant care).

Evaluation

The mother's demonstration of correct breast and perineal hygiene provides evidence of her ability to perform self-care measures. Her ability to discuss practices that promote health in the areas of diet, exercise, rest, and sleep confirms her understanding of these measures. Her plan for future appointments with the health care provider for examinations or follow-up of complications increases the likelihood that she will experience an uncomplicated recovery.

SUMMARY CONCEPTS

- After childbirth the uterus returns to its nonpregnant size and condition by involution, which involves contraction of stretched muscle fibers, catabolic processes that reduce enlarged muscle cells, and regeneration of uterine epithelium.
- The site of placental attachment heals by a process of exfoliation, which leaves the endometrium smooth and without scars.
- Involution can be evaluated by measuring the descent of the fundus (about 1 cm/day). By about the 14th day after childbirth the fundus should no longer be palpable abdominally.
- Afterpains, or intermittent uterine contractions, cause discomfort for many women, particularly multiparas who breastfeed.
- Vaginal discharge (lochia) progresses from lochia rubra (dark red or red-brown) to lochia serosa (pink or brown-tinged) to lochia alba (white, cream, or light yellow) in a predictable time frame. Lochia should be assessed for amount, type, and odor. Foul odor suggests endometrial infection.
- Although vaginal rugae reappear by 3 to 4 weeks, it takes 6 to 10 weeks for the vaginal epithelium to return to normal. The vagina decreases in size and regains tone.
- Orthostatic hypotension occurs when the mother moves from a supine to standing position quickly.
- Tachycardia may be caused by pain, excitement, anxiety, fatigue, dehydration, hypovolemia, anemia, or dehydration. Additional assessments (e.g., lochia, fundus) are required to determine whether excessive bleeding is the cause.
- The postpartum woman should be afebrile, but her temperature may be higher during the first 24 hours after delivery because of dehydration and leukocytosis.
- Breastfeeding mothers are more likely to experience dyspareunia as a result of vaginal dryness that results from inadequate estrogen.
- Hemorrhoids and perineal trauma can cause a great deal of discomfort and interfere with activity and bladder and bowel elimination.

*Continued***Postpartum Discharge and Community-Based Care Criteria for Discharge**

Most women leave the hospital when they are just beginning to recover from giving birth and starting to learn how to care for themselves and their infants. Criteria for discharge of mothers have been developed by *The American Academy of Pediatrics & American College of Obstetricians and Gynecologists* (2012) and include the following:

- The mother has no complications, and assessments (including vital signs, pain level, lochia, fundus, urinary output, incisions, ambulation, ability to eat and drink, and emotional status) are normal.
- Pertinent laboratory data including blood type and hemoglobin or hematocrit have been reviewed, and Rho(D) immune globulin has been administered, if necessary.
- The mother has received instructions on self-care, deviations from normal, and proper response to danger signs and symptoms.
- The mother demonstrates knowledge, ability, and confidence to care for herself and her baby.
- The mother has received instructions on postpartum activity, exercises, and relief measures for common postpartum discomforts.
- Arrangements have been made for postpartum follow-up care.
- Family members or other support persons are available to the mother for the first few days after discharge.

Community-Based Care

Many assessments and interventions of postpartum women occur in the clinic or outpatient setting. Mothers leave the birth facility when they are not fully recovered from the childbirth experience. New parents must be made aware of local community care services. Information lines, telephone calls from birth facility staff, nurse-managed postpartum outpatient clinics, and, in some areas, home visits provide information and guidance for postpartum families. Breastfeeding and parenting classes, “baby and me” walks or exercise sessions, and postpartum support groups may also be available. See Chapter 23 for information about community care.

CHECK YOUR READING

18. How is lactation suppressed when the mother elects not to breastfeed?
19. What is the major challenge nurses have in preparing new mothers for discharge?
20. What are the criteria for discharge of the mother?

SUMMARY CONCEPTS—cont'd

- Cardiac output increases when blood from the uterus and placenta returns to the central circulation, uterine pressure on the vessels decreases, and extracellular fluid moves into the vascular compartment. Excess fluid is excreted by diuresis and diaphoresis.
- Increased clotting factors predispose the postpartum woman to thrombus formation. Early, frequent ambulation helps prevent thrombophlebitis.
- Constipation may occur from decreased food and fluid intake during labor, reduced activity, decreased muscle and bowel tone, and fear of pain during defecation.
- Increased bladder capacity and decreased sensitivity to fluid pressure may result in urinary retention. Stasis of urine allows time for bacteria to grow and can lead to urinary tract infection.
- A distended bladder displaces the uterus and can interfere with uterine contraction and cause excessive bleeding.
- Exercises to strengthen the abdominal muscles, good posture, and body mechanics may reduce musculoskeletal discomfort.
- As hormone levels decline, the skin gradually reverts to its nonpregnant state.
- Breastfeeding may delay the return of ovulation and menstruation, but ovulation may occur before the first menses. All mothers need information about family planning.
- Lactation may be suppressed by wearing a sports bra and avoiding stimulation of the breasts.
- Following cesarean birth, the woman requires postoperative and postpartum assessments and care. She may have problems with immobility and discomfort.
- Early discharge challenges nurses to streamline information and develop a plan for teaching self-care and infant care in a short time.

Postpartum Psychosocial Adaptations

evolve WEBSITE

<http://evolve.elsevier.com/Murray/foundations>

OBJECTIVES

After studying this chapter, you should be able to:

1. Explain the process of bonding and attachment, including maternal touch and verbal interactions.
2. Describe the progressive phases of maternal adaptation to childbirth and the stages of maternal role attainment.
3. Identify maternal concerns and the way they change over time.
4. Discuss the cause, manifestations, and interventions for postpartum blues.
5. Describe the processes of family adaptation to the birth of a baby.
6. Explain factors that affect family adaptation.
7. Discuss cultural influences on family adaptation.
8. Describe assessments and interventions related to postpartum psychosocial adaptations.
9. Discuss the need for additional care of the mother and infant after discharge from the birth facility.

Perhaps no other event requires such rapid change in family structure and function as the birth of a baby. The addition of a new baby requires that all family members adjust their roles. The mother progresses through restorative phases to replenish the energy lost during labor and childbirth and to gain confidence in her role as mother. Both the mother and the father continue the process of attachment with the newborn that began during pregnancy. Siblings must adapt to a new standing in the family structure. Numerous factors such as previous experience, available support system, and culture influence the family's adaptation.

The role of maternity nurses includes not only the care of the mother-infant dyad but also the well-being of the entire family. Nurses are concerned with the family's adjustment to childbearing during the hospital stay and during the early weeks at home. The first 12 weeks, as the family makes the transition to parenthood and adapts to changes in the family structure, are often called the **fourth trimester**.

THE PROCESS OF BECOMING ACQUAINTED

Nursing literature has described how parents and newborns become acquainted and progress to develop feelings of love, concern, and deep devotion that last throughout life. The terms bonding and attachment are commonly used to describe the initial steps. Although the terms are sometimes used interchangeably, their meanings differ.

Bonding

Bonding refers to the rapid initial attraction felt by parents for their infant. It is unidirectional, from parent to child, and is enhanced when parents and infants are permitted to touch and interact during the first 30 to 60 minutes after birth. During this time the infant is in a quiet, alert state and seems to gaze directly at the parents (**Figure 18-1**).

Infants are often placed skin-to-skin on the mother's chest or abdomen for bonding time immediately after delivery. Nurses frequently delay procedures, such as measurements and medication administration that would interfere with this time, so that parents can focus on their newborn baby.

Early and sustained contact between the parents and infant can enhance bonding and attachment. However, if early contact between parent and infant is limited because of an obstetric emergency or neonatal illness, bonding and attachment can still occur at a later time.

Attachment

Attachment is the process by which an enduring bond between a parent and child is developed through pleasurable, satisfying interaction. The process begins in pregnancy and extends for many months after childbirth. The infant receives warmth, food, and security from the parent. The parent, usually the mother, accepts responsibility for the infant's care and places the child's needs above her own for years to come. In return, she receives enjoyment and establishes her identity

FIG 18-1 The infant is quiet and alert during the initial sensitive period. The newborn gazes at the mother and responds to her voice and touch. The mother fingertips her infant by touching only with the fingertips.

as a mother. Both benefit from the formation of irreplaceable links that continue long after the child ceases to be dependent.

Attachment follows a progressive or developmental course that changes over time. It is rarely instantaneous. Attachment behaviors of inexperienced or first-time mothers do not differ significantly from those of experienced mothers (Mercer & Ferketich, 1994). Attachment occurs through mutually satisfying experiences. Therefore if the newly delivered mother is in pain or physically exhausted, she needs pain relief and assistance so she is able to enjoy the early experiences with the baby.

Unlike bonding, attachment is reciprocal—it occurs in both directions between parent and infant. It is facilitated by positive feedback, either real or perceived, from the infant. For example, an infant's grasp reflex around a parent's finger means "I love you" to the parent. Alert infants have a repertoire of responses called **reciprocal attachment behaviors**. These behaviors are the infant's part in the process of early attachment that progresses to lifelong, mutual devotion.

CRITICAL TO REMEMBER

Reciprocal Attachment Behaviors

Newborn infants have the ability to:

- Make eye contact and engage in prolonged, intense, mutual gazing.
- Move their eyes and attempt to "track" the parent's face.
- Grasp and hold the parent's finger.
- Move synchronously in response to rhythms and patterns of the parent's voice (called **entrainment**).
- Root, latch onto the breast, and suckle.
- Be comforted by the parent's voice or touch.

Maternal Touch

Maternal behavior, particularly maternal touch, changes rapidly as the mother progresses through a discovery phase with her infant. Initially the mother may not reach for the infant, but if the infant is placed in her arms, she holds the baby in an **en face** position with the infant's face in the same vertical plane as her own so they can have eye contact. When the infant is awake, the two engage in prolonged, mutual gazing (see [Figure 18-1](#)).

The mother needs time to get acquainted with the tiny stranger. She may gently explore the infant's face, fingers, and toes with her fingertips

FIG 18-2 The mother begins to stroke the infant as she progresses in becoming acquainted.

FIG 18-3 Mothers progress from exploratory touching to enfolding the infant. Their pleasure is enhanced by skin-to-skin contact.

only. This exploration, called **fingertipping**, is common during the early minutes.

After fingertipping the infant, the mother begins to stroke the baby's chest and legs with her palm ([Figure 18-2](#)). Next, she uses her entire hand and arms to enfold the infant and to bring her baby close to her body ([Figure 18-3](#)). She holds the newborn closer, strokes the baby's hair, presses her cheek against the infant's cheek, and finally feels comfortable enough to engage in a full range of consoling behaviors.

The mother next begins to identify specific features of the newborn: "Look how bright his eyes are." Then she begins to relate features to family members: "He has his father's chin and nose" ([Figure 18-4](#)). This identification process has been called claiming or binding-in (Rubin, 1977).

FIG 18-4 During the binding-in or claiming process the mother identifies her baby's specific features and relates them to other family members. This mother states, "His long toes are exactly like mine."

Verbal Behaviors

Verbal behaviors are also important indicators of maternal attachment. Most mothers speak to the infant in a high-pitched voice. Although many mothers have been calling the baby by name since seeing it on an ultrasound scan during pregnancy, others wait until after the birth to progress from calling the baby "it" to "he" or "she," and then to using the given name. "I can't believe it's here" rapidly becomes "Michele is such a good baby." Verbal behaviors may provide clues to a mother's early psychological relationship with her infant. Nurses observe the interactions of mothers and their infants and, if necessary, teach and model interactions that foster early attachment between them.

THE PROCESS OF MATERNAL ADAPTATION

Puerperal Phases

Rubin (1961) identified restorative phases that mothers go through to replenish the energy lost during labor and attain comfort in their new role. The puerperal phases are called *taking-in*, *taking-hold*, and *letting-go* and provide one method to observe progressive change in maternal behavior. Although they should not be used as strict guidelines for maternal assessment, the phases can help the nurse anticipate maternal needs and intervene to meet those needs.

Taking-In Phase

During the **taking-in** phase, the mother is focused primarily on her own need for fluid, food, and sleep. Inexperienced nurses may be puzzled by the mother's passive, dependent behavior as she

takes in or receives attention and physical care. She also takes in every detail of the neonate but seems content to allow others to make decisions.

A major task for the mother during this time is to integrate her birth experience into reality. To do this, she discusses her labor and delivery many times on the telephone or for visitors. She attempts to piece together all the details from those who were involved in the birth. This process helps the mother realize that the pregnancy is over and the newborn is now a separate individual.

Although Rubin believed that the taking-in phase lasted for approximately 2 days, it probably lasts a day or less today. The phase may be prolonged when a cesarean birth, especially in an emergency, has been necessary. These women may have difficulty assimilating the unfamiliar and intrusive procedures that occurred in rapid succession and may have negative perceptions of the birth experience. Women who have had cesarean births need continued attention and sensitive care that takes into account their physical and psychological needs.

Taking-Hold Phase

The mother becomes more independent during the **taking-hold** phase. She exhibits concern about managing her own body functions and assumes responsibility for her own care. When she feels more comfortable and in control of her body, she shifts her attention to the behaviors of the infant. She compares her infant with other infants to validate wellness and wholeness. She welcomes information about the wide variety of behaviors exhibited by newborns.

During the taking-hold phase, the mother may verbalize anxiety about her competence as a mother. She may compare her caretaking skills unfavorably with those of the nurse.

Nurses must be careful not to assume the mothering role in caring for the infant. Instead they should encourage the mother to perform as much of the caretaking as possible. Fathers should also be encouraged to participate in caretaking as they take on a new role. Nurses should praise each attempt, even if the parents' early care is awkward.

The taking-hold phase, which extends over several days, has been called the *teachable, reachable, referable moment*. Nurses who provide home or clinic care can take advantage of this ideal time to review previously taught material and provide additional instructions and demonstrations.

Letting-Go Phase

The **letting-go** phase is a time of relinquishment for the mother and often for the father. If this is their first child, the couple must give up their previous role as a childless couple and acknowledge the loss of their more carefree lifestyle. Many mothers must also give up idealized expectations of the birth experience. For example, they may have planned to have a vaginal birth with minimal or no anesthesia, but instead required a cesarean birth.

In addition, some mothers and fathers are disappointed in the size, gender, or characteristics of the infant who does not "match up" with the fantasy baby of pregnancy. They must relinquish the infant of their fantasies and accept the real infant.

These losses often provoke feelings of grief that are so subtle they may be unexamined or unacknowledged. Both parents may benefit, however, if given the opportunity to discuss unexpected feelings and realize that these feelings are common. If the mother is very young or the pregnancy was unplanned, the feelings of loss and grief may be acute.

During this phase, the mother refocuses on her relationship with her partner. She may also return to work at this time. This requires relinquishing part of the care of the infant to a caretaker.

CRITICAL THINKING EXERCISE 18-1

Callie, a 35-year-old primipara, had an infant daughter, Eloina, by cesarean birth after failure to progress in labor. She is very tired, although she is relatively comfortable. Her husband, Xavier, was present during the labor and birth and is excited about being a father. He expresses concern because he and Callie have no experience with children, and his job requires almost constant travel.

On the day of delivery, Callie readily accepts attention and assistance with hygiene. She passively follows the nurse's requests to turn, cough, and breathe deeply. She discusses the details of her labor with friends on the telephone. She examines Eloina closely and touches the face and hands gently with her fingertips. She remarks that she plans to breastfeed and is surprised that the infant sleeps so much.

Questions

1. What are Callie's priority needs at this time?
2. What phase of recovery is she manifesting? Why does she "fingertip" the infant?

The first postoperative day, Callie's catheter is removed and IV fluids are discontinued. Callie ambulates with minimal assistance and is pleased to be able to urinate without difficulty. She asks about bowel function and requests the prescribed stool softener. She spends a great deal of time getting the baby to breastfeed. She is very frustrated that Eloina does not breastfeed well and asks for assistance from the lactation consultant.

Questions

3. What are Callie's priority needs now?
4. How have her behaviors changed?

Before discharge, Callie is breastfeeding well. The infant latches on and nurses for 10 to 15 minutes on each breast, and Callie's nipples are free of tenderness or signs of trauma. She has no relatives in the area, and her husband is home for the weekend only. She states that she will just have to get along by herself.

Questions

5. What anticipatory guidance should Callie receive before she goes home?
6. What further nursing interventions would be most helpful to her?

Maternal Role Attainment

Role attainment is a process by which the mother achieves confidence in her ability to care for her infant and becomes comfortable with her identity as a mother. The process begins during pregnancy and continues for several months after childbirth.

The transition to the maternal or paternal role includes four stages (Mercer, 1995b):

1. The anticipatory stage begins during the pregnancy when the pregnant woman chooses a physician or nurse-midwife and a location for the infant's birth. She may attend childbirth classes to be prepared and feel she has some control over the birth experience. She seeks out role models to help her learn the mother role.
2. The formal stage begins with the birth of the infant and continues for approximately 4 to 6 weeks (Mercer, 1995a). During this stage, behaviors are largely guided by others such as health professionals, close friends, and parents. A major task during this stage is for parents to become acquainted with their infants so that the parents can mesh their caregiving with infant cues.
3. The informal stage, which may overlap the formal stage, begins when mothers have learned appropriate responses to their infants' cues and signals. The mothers begin to respond according to the unique needs of their infants and develop the maternal role that

fits them rather than following textbooks or health professionals' directives.

4. The personal stage is attained when the mother feels a sense of harmony in the role, enjoys the infant, sees the infant as a central person in her life, and has internalized the parental role. The mother accepts the role of parent and feels comfortable in this role. The range of time for achieving the maternal role is highly variable, with some mothers reaching that point in the first month and others taking much longer.

Maternal role attainment implies an end point when the woman adjusts to motherhood. However, the process could better be called *becoming a mother* because it continues throughout motherhood. The mothering role grows and evolves as the mother responds to the challenges of her child's growth and development (Mercer, 2004). Most mothers do not feel competent and self-confident in the mothering role until about 4 months after childbirth (Mercer & Walker, 2006).

Heading toward a New Normal

Martell (2001) provides another view of early postpartum changes with "Heading Toward the New Normal" as the theme. This view also has three phases as the woman reorganizes her life as a mother. Although the phases have distinctive characteristics, they are continuous rather than separate.

Appreciating the Body

This phase centers on the way the woman feels physically. She must cope with discomfort such as nipple and perineal pain. Her sleep is disrupted by excitement, hospital routines, and her physical discomfort, leaving her fatigued. Changes in her body function as she begins lactation and the differences in her appearance make her more aware of her physical self. The phase also involves dealing with emotional lability and changes in the way women think and retain information.

Settling-In

Settling-in involves becoming competent, developing confidence, and accommodating and integrating the infant into the parents' lives. A mother's desire to settle into her own environment may lead her to leave the hospital as soon as possible. During this phase a mother becomes more secure with her infant. As she gradually gains competence, her reliance on past methods of solving problems relaxes into comfort with the tasks of newborn care.

A mother may have little confidence in her own parenting abilities just after the birth and is glad to have help available. When immediate help is no longer available because her partner returns to work or her mother leaves, the new mother is concerned about being able to care for her baby alone. Confidence builds as the infant gains weight and the mother is able to soothe and care for the infant without help from others.

A mother must adapt her needs and activities to meet the needs of the infant. After a period of adjustment, some mothers find ways to integrate the infant into their usual activities with only minor changes.

Becoming a New Family

As women work toward becoming a new family, they modify relationships with their partners and other family members and develop new routines to include the infant. Although they are grateful for help from others, they are glad to be on their own and enjoy spending time alone with their newly developed family.

Redefined Roles

The mother is particularly concerned about redefining roles and focuses on maintaining a strong, adaptive relationship with her partner.

She observes him carefully for any change in behavior and is acutely sensitive to his interaction with the infant. From the father's perspective, anxieties about succeeding in his new role put added pressure on the family. Conflicting demands between work and home, feelings of exclusion, and concerns about his relationship with his partner present additional challenges.

The new parents may need to agree on a division of tasks and responsibilities that was not necessary before the birth of the infant. This process is accomplished quickly and with very little discord in some families. Role assignment in other families is much less flexible, and any change can be a source of tension and frustration.

Although nurses are not actively involved in redefining family roles, they can use their communication skills to assist the family in expressing their feelings and concerns so that the changes can be accomplished with minimal stress.

Role Conflict

Role conflict occurs when a person's perception of role responsibilities differs significantly from reality. For example, if the mother perceives her responsibility as providing most of the care and comfort for the infant, but reality dictates that she must place the infant with a caregiver and return to full-time employment, role conflict may occur. In the United States 64.8% of women with children under 6 years of age and 57% of mothers with infants younger than 1 year were employed in 2011 (U.S. Department of Labor, 2013). If possible, women should not return to work until they are comfortable in the parenting role and understand the infant's unique needs.

Primiparas often do not realize how strong their attachment to the infant will be or how difficult it will be for them to leave the infant to return to work. Many mothers feel guilty and experience intense "separation grief" when they first leave the infant with a caregiver. Some report feeling jealous of the caregiver, whom they fear will supplant them in the infant's affection.

The nurse can help by acknowledging these feelings and reassuring the mother that her emotions are normal. Anticipatory guidance from the nurse is important. The mother needs to plan for time to reestablish feelings of closeness when she comes home from work. She needs to develop a schedule that allows maximum time with the infant when she is at home. She may have to negotiate with another family member to take over some of the household tasks until she feels more comfortable with the situation (see [Nursing Care Plan](#)).

Major Maternal Concerns

As the mother gains confidence in her ability to care for the infant and her physical discomfort decreases, emotional concerns related to the self become more important. Body image and the experience of postpartum blues are particularly important.

Body Image

Women are very concerned about regaining their normal figures. Some mothers have unrealistic expectations about weight loss and the time it takes for the body to regain its nonpregnant shape. Nurses must emphasize that weight loss should be gradual. Rigid restriction of calories can lead to depleted energy and decreased immunity.

In addition, nurses should teach the importance of safe activities such as walking and graduated exercises to regain muscle tone (see [Chapter 17](#)). Some birth facilities offer classes for postpartum mothers that include exercise and nutrition, as well as the opportunity to share concerns with other postpartum women.

Smoking

Many women give up smoking during pregnancy to protect the health of the fetus. However, the majority of women resume smoking at some point during the first 6 months postpartum. Factors that increase the likelihood of relapse include weight concerns and failure to breastfeed (Forest, 2009; Levine, Marcus, Kalarchian et al., 2010). Other factors that may cause smoking are depression, living with a smoker, stress, and planning to quit only during the pregnancy. Women who breastfeed their infants are less likely to resume smoking by 26 weeks postpartum (Kendzor, Businelle, Costello et al., 2010).

Nurses should discuss smoking with postpartum women to offer resources for those who stopped smoking prenatally and are at risk for relapse in the postpartum period. Explanations of the hazards to the infant from smoking may also be helpful because some mothers may think the harmful effects occur only during pregnancy.

Postpartum Blues

Mild depression, also known as **postpartum blues**, *baby blues*, or *maternity blues*, is a frequent concern for new mothers. This mild, transient condition affects 60% to 80% of women who have given birth (Whitmer, 2011). The condition begins in the first week, peaks around day 5, and ends within 2 weeks. If it lasts beyond 2 weeks, it may be a more serious condition (Haskett, 2011).

Postpartum blues is characterized by insomnia, irritability, fatigue, tearfulness, mood instability, and anxiety. The symptoms are usually unrelated to events, and the condition does not seriously affect the mother's ability to care for the infant. Nurses should prepare women for the occurrence of mild depressed or negative thoughts, let them know it is normal, and offer emotional support and encouragement.

Although the direct cause is unknown, postpartum blues may be a result of the emotional letdown that occurs after birth, postpartum discomforts, fatigue, anxiety about her ability to care for the infant, and body image concern (Cunningham et al., 2010). Hormonal fluctuations have not been proven to be a cause.

Although postpartum blues is self-limiting, mothers benefit greatly when empathy and support are freely given by the family and the health care team. Because the condition is so common in postpartum women, caregivers or family members may not be as empathetic as they would be for a condition deemed more serious. Yet, the mother needs adequate attention to move through this period. She should be encouraged to rest, take time for herself, and discuss her feelings. In addition, reassurance should be given that such feelings are normal and generally last less than 2 weeks.

Postpartum blues must be distinguished from postpartum depression and postpartum psychosis, which are disabling conditions and require therapeutic management for full recovery. Screening for risk factors or early signs is important during the birth facility stay (see [Chapter 28](#)). Nurses should teach the woman and the family to call the health care provider if depression becomes severe, lasts longer than 2 weeks, or if she is unable to cope with daily life.

⊙ NURSING CARE PLAN

Adaptation of the Working Mother

ASSESSMENT: Claire, a 30-year-old single mother, gave birth to a baby boy, Drew, by cesarean delivery 6 days ago. She has made a good recovery and breastfeeding is going well. During her visit to a nurse-managed postpartum clinic, Claire discusses her need to return to work as a sales executive in 6 weeks. She states that she hates the thought of leaving baby Drew with someone else while she works. "I've always planned to stay home for at least 6 months when I had a baby, but it's impossible. How can I be a mother and work full time?"

NURSING DIAGNOSIS: Grieving related to inability to perform role of mother as she wishes because of the need to return to full-time employment

Critical Thinking: *Grieving is related to loss. What has Claire lost, or what must she give up?*

Answer: *Claire must give up her idealized picture of motherhood. She also must give up mothering tasks and time with the infant to a caregiver. She will have to modify her self-concept based on the perception of these losses.*

EXPECTED OUTCOMES: Claire will:

1. Describe her concerns and feelings about leaving Drew with a caregiver.
2. Verbalize plans to achieve maximal satisfaction in her role as mother by the time she returns to work.

INTERVENTIONS AND RATIONALES

1. Allow Claire to describe her perception of her role as a mother and express concerns about how employment will interfere with her ability to fulfill this role. *Venting can help Claire cope with the role conflict, stress, and grief that can result when a mother who envisions her role as the primary caregiver must leave her infant with another caregiver and return to her job.*
2. Suggest Claire openly express her feelings of anxiety, guilt, and jealousy to significant others and to her baby's care provider. *Candid expression of feelings helps to resolve them and allows for a discussion of measures that will help overcome the intense feelings that cause conflict.*
3. Acknowledge that Claire's feelings are difficult and reassure her that they are common. *Knowledge that the feelings are not trivial and are experienced by others reinforces their validity and importance.*
4. Suggest that Claire delay her return to employment, if possible, until Drew is at least 12 to 16 weeks old. Part-time work may also be a possibility for a time. *By 12 to 16 weeks most infants are able to sleep through the night, reducing the sleep deprivation that often adds to the stress of working and infant care.*

5. Recommend that Claire investigate several daycare providers before choosing one. She should check references, make unannounced visits, see required licenses and certification, discuss the number and ages of children cared for and the daily schedule, ask about the provider's philosophy of infant care and training in emergency measures, and know what emergency plans are in place. *A great deal of stress is eliminated if parents feel confident that a competent and nurturing daycare provider has been found. Mothers are more content with their return to work if they are satisfied with their child care arrangements.*
6. Suggest that she leave the infant with the chosen daycare provider for 2 to 3 days before resuming full-time employment. *Allowing both mother and infant to "practice separating" while their schedules are still somewhat flexible helps ease the transition and makes it less traumatic.*
7. Recommend that Claire pump her breasts and feed Drew by bottle at least once per day in the week or two before returning to work. *Becoming proficient at pumping the breasts and introducing the infant to bottle feeding prepares both the mother and the infant for all-day separation.*
8. Help Claire develop a schedule that allows her maximum time with Drew. *Feelings of frustration and stress can be alleviated if the mother has a plan that allows her long periods of uninterrupted time with the infant.*
 - a. Make a list of errands and supplies needed to avoid frequent stops that delay getting home from work.
 - b. Double the recipe when cooking, and freeze half for future use.
 - c. Pick up nutritious takeout meals to avoid cooking every evening.
 - d. Purchase nutritious prepackaged frozen meals to have available when needed.
 - e. Schedule appointments on the same day when possible.
 - f. Include Drew in daily walks, exercise, and social visits.
9. Recommend that Claire allow 30 to 45 minutes to hold Drew when she first gets home. Delay all other activities until this need is met for both mother and infant. *Time is needed to make the transition between work and home. It helps to reestablish feelings of closeness, comfort, and attachment.*
10. Advise Claire to try to get more rest in the early weeks after returning to work. *The return to work may increase fatigue. Extra rest will help Claire avoid undue fatigue or illness.*

EVALUATION: Claire freely expressed her feelings of guilt, anxiety, and concern about leaving Drew. She made a plan to investigate daycare in her area and discussed plans to reorganize her work and social schedule so that she can spend as much time as possible with her son.

CASE STUDY 18-1 INTRODUCTION*

Dawn, a 32-year-old primipara, gave birth to twin girls 22 hours ago. Her labor began at 39 weeks, and she delivered vaginally. Both she and her husband, David, are inexperienced in caring for infants. They attended breastfeeding and parenting classes during her pregnancy.

*Continues on p. 359.

THE PROCESS OF FAMILY ADAPTATION

The birth of an infant requires the reorganization of roles and relationships within the family. The previously childless couple now must integrate a new member into the family unit. Fathers learn new skills

and often adjust to new roles. Siblings must adapt to a new standing in the family structure. Expectations and involvement of grandparents vary widely. Each family member is affected.

Fathers

The father's developing bond with his newborn is facilitated by engrossment. **Engrossment** is an intense fascination and face-to-face observation between the father and newborn. It is characterized by the father's intense interest in how the infant looks and responds and a desire to touch and hold the baby. Many fathers comment on the baby's distinctive features and view the baby as perfect. They experience strong attraction to the infant and elation after the birth. The father's attachment behaviors increase when the infant is awake, makes eye contact, and responds to the father's voice (Figure 18-5).

FIG 18-5 Fathers' behaviors during initial contact with their infants often correspond to maternal behaviors. The intense fascination that fathers exhibit is called *engrossment*. Note eye-to-eye contact between the father and the infant.

THERAPEUTIC COMMUNICATIONS

Body Image

Mary Kay gave birth to her first baby 48 hours ago. Aubrey, her nurse, is reviewing self-care measures before Mary Kay's discharge from the birth facility.

Mary Kay: Look at me! I still look pregnant, and my husband calls me Tubby.

Aubrey: You were looking forward to your abdomen being flat after the baby was born. (*This clarifies the woman's concern by reflecting content.*)

Mary Kay: Well, I never had a big belly before. I thought it would all go away after I had the baby. I can't believe I look this fat.

Aubrey: Remember, it took 9 months for those muscles to stretch. You can't expect them to snap back in a few days. *This blocks communication by ignoring the feeling expressed. A more helpful response would be to acknowledge Mary Kay's distress and to delay giving information until feelings have been expressed. For example: "How disappointing for you! If you like, we can discuss some exercises that will help."*

Many fathers eagerly look forward to co-parenting with their mate. However, they may lack confidence in providing infant care and are sensitive to being left out of instructions and demonstrations of infant care. They may feel that others expect them only to provide support to the mother. The nurse can assist the new father by involving him in child care activities soon after birth to help him feel more confident and competent.

Although first-time fathers may attend prenatal classes about parenting, they often do not know what to expect from infants and need more information about normal growth and development during infancy. A review of information about child care presented in the

prenatal period is helpful after the baby is born, when the information seems more relevant and the father is ready to learn.

The additional work involved in care of a newborn may be a source of concern for both mothers and fathers. Parents should be encouraged to negotiate the division of household chores during pregnancy or shortly after delivery.

EVIDENCE-BASED PRACTICE

Learning about Fatherhood

Opportunities for fathers to learn about parenting from other men are not always available. St. George and Fletcher conducted a study on the concerns of new fathers as discussed in an Internet chat room in Australia. The study was conducted over 18 months. Participants included 23 first-time and experienced fathers who were the predominant users of the website. Twenty-two women also posted comments (which was not appreciated by some fathers, who felt the site should be just for men).

Researchers analyzed the chat room texts to describe the topics of discussion and then coded the underlying ideas and experiences. Topics concerned: 1) "isolation," the father's feelings of invisibility and complaints about lack of social services for men, 2) "fathers' practices," concerns about how to bond with the baby or how to help their partner after childbirth, 3) "social opinion," a discussion about breastfeeding, and 4) "announcements," about births and events of interest.

Overlapping Themes

Dads Left Out

The lack of opportunity to discuss fathering with other dads and the experience of often being the only father in social groups such as playgroups were common topics. Six fathers were stay-at-home dads who often perceived negative reactions from others about their choice to stay at home.

Breadwinners or Nurturers?

Fathers were conflicted about balancing work and family roles. Economic pressures and time pressures of family life were major concerns.

Making a Space for Fathers

1. Virtual space. There was much discussion about whether the website should be open to men only or include women. Some men wanted to learn about fathering from other men. Some felt embarrassed to discuss sensitive topics when women were part of the discussion. Others felt the site should include all.

2. Cultural space. The discussions were helping to change the quality of the fathers' cultures by creating a supportive environment for them.

What resources are available for fathers in your area? Are there classes or groups especially for new fathers? Ask new fathers if they would be interested in such sources.

Data from St. George, J. M., & Fletcher, R. J. (2011). Fathers online: Learning about fatherhood through the Internet. *Journal of Perinatal Education, 20*(3), 154–162.

Siblings

Siblings' response to the birth of a new brother or sister depends on their age and developmental level. Toddlers are usually not completely aware of the impending birth. When the baby arrives, they may view the infant as competition and fear they will be replaced in the parents' affection. They may have feelings of jealousy and resentment when they must share time and attention with a baby. Some toddlers exhibit hostile behaviors toward the mother, particularly when she holds or feeds the newborn. Sleep problems, an increase in attention-seeking efforts, and regression to more infantile behaviors such as renewed

bed-wetting and thumbsucking are common. These behaviors show the jealousy and frustration young children feel as they observe the mother's attention being given to another.

The parents can be taught to accept without judgment the strong feelings expressed by the toddler and to continue to reinforce the child's feelings of being loved. Plans for changes in routine, such as beginning toilet training, should be postponed until family adjustments have been made. Expecting 2-year-olds to welcome a "stranger" is not realistic until they feel secure in the affection of their parents.

Preschool siblings may engage in more looking than touching. Most spend at least some time in proximity to the infant and talk to the mother about the infant (Figure 18-6). Older children may adapt more easily. All siblings need extra attention from the parents and

FIG 18-6 **A**, Although they may hesitate to touch the infant, children often want to be close. **B**, This boy's relief and joy are obvious as he reclaims a favorite spot.

reassurance that they are loved and important. Sibling classes, available in many agencies, may help ease the transition (see Chapter 11). Siblings are often allowed to visit the mother on the postpartum unit where they can interact with the new baby.

At home a relaxed approach without time constraints may facilitate interactions between young children and infants. Special care must be taken by the parents, visitors, and nurses to pay as much attention to the sibling as to the new baby. Parents can emphasize the advantages of being an older sibling and can allow siblings to participate in age-appropriate aspects of infant care.

Grandparents

The involvement of grandparents with grandchildren depends on many factors. One of the most important is proximity. Grandparents who live near the child frequently develop a strong attachment. This evolves into unconditional love and a special relationship that brings joy to the grandparents and an added sense of security to the grandchildren (Figure 18-7).

When grandparents live many miles from grandchildren and have sporadic contact, forming a close attachment is more difficult. Grandparents must try to devise ways to foster a relationship with grandchildren they seldom see.

Expectations of the role of grandparents are also a factor in their adaptation to the birth of a grandchild. Many grandparents strive to be fully involved in the care and upbringing of the child, but others desire less involvement. The degree of grandparent involvement may cause some conflict with parents, or it may be a comfortable arrangement for both families.

Grandparents are often a major part of the support system that new parents need. Grandmothers, in particular, provide assistance with household tasks and infant care, which helps the mother recover from childbirth and make the transition to parenthood. Grandfathers who were very busy providing for their own children may enjoy the opportunity to nurture their grandchildren.

FACTORS THAT AFFECT FAMILY ADAPTATION

Numerous factors influence the family's adjustment. Some, such as discomfort and fatigue, can be anticipated because they are so common. Additional factors include knowledge of infant needs, expectations of the infant, previous experience, age of the parents, and temperaments of the mother and infant. Other events such as cesarean birth, birth of a preterm or ill infant, and birth of more than one infant also affect the ease and speed with which the family adjusts.

FIG 18-7 Grandparents may develop strong bonds with grandchildren.

CRITICAL TO REMEMBER**Factors That Affect Adaptation**

- Lingering discomfort or pain
- Chronic fatigue
- Knowledge of infant needs
- Available support system
- Expectations of the newborn
- Previous experience with infants
- Maternal temperament
- Infant characteristics
- Other factors: cesarean birth, preterm or ill infant, or birth of more than one infant (such as twins or triplets)

CASE STUDY 18-1 THERAPEUTIC COMMUNICATION*

Dawn's postpartum nurse, Jean, enters the room and finds Dawn in tears.

Dawn (crying): I can't do anything right. The pediatrician just asked me a bunch of questions, and I couldn't answer any of them.

Jean: Actually, you've been doing a lot right, but it's upsetting when you feel you don't have all the answers. (*Offering reassurance and acknowledging feelings.*)

Dawn: He just fired the questions at me and I couldn't think that fast!

Jean: You feel that you're not measuring up because you couldn't answer the questions. (*Paraphrasing and focusing on Dawn's feelings.*)

Dawn: Well, I want to be a good mother, but I'm so worried that I won't know what to do.

Jean: You have some concerns. (*Reflecting feelings without leading.*)

Dawn: There's just so much to taking care of babies. I don't know where to start.

Jean: It can be overwhelming at first. Which areas worry you most? (*Reflecting feelings and inviting the mother to describe specific concerns. By allowing Dawn to express her feelings, Jean has helped dissipate the feelings and set the stage for effective teaching.*)

*Continued from p. 356; continues on p. 361.

Discomfort and Fatigue

Normally, discomforts associated with childbirth resolve within the first days after birth but may make it difficult to focus on the newborn's needs. Fatigue often remains a problem during the first few weeks and months, when the infant's schedule is erratic and the chance for uninterrupted sleep is minimal. When the infant begins to sleep through the night (usually by 3 to 4 months), the parents can reestablish familiar patterns, and fatigue often becomes less of a factor.

Knowledge of Infant Needs

Parents experience powerful feelings of protectiveness when they discover that they can console their infant and the infant responds to their care. First-time parents, who are often unsure about how to care for a newborn, become very anxious if they are unable to console a crying infant. In addition, many are concerned about feeding and specific procedures such as care of the umbilical cord or circumcision. Breast-feeding benefits both the mother and the infant but may add to the stress initially experienced by parents who lack sufficient knowledge and support (see [Chapter 22](#) on breastfeeding and [Chapter 23](#) on early parenting).

Some parents have concerns about spoiling the infant. They may believe that responding each time the infant cries causes the baby to cry to get attention. It may be necessary to teach parents that infants

cry to indicate hunger, cold, wetness, and a need for cuddling or gentle stimulation and that responding to crying does not spoil the child. Suggesting a variety of methods to cope with crying may be helpful. Prompt, gentle response to crying helps the infant develop trust in the world as a safe, secure place. Trust is a basic developmental task of infancy and depends on the child learning that caregivers respond consistently and gently in meeting his or her needs.

Previous Experience

Previous experience with newborns may also affect family adjustment. Multiparas are more comfortable with infants and exhibit attachment behaviors earlier than primiparas, who may spend many more hours in the early discovery phase of attachment. Because they know what to expect, multiparas are more relaxed in caring for the new baby but have to establish new routines that fit the expanded family. The mother may find it more difficult to have time alone with her partner. She may need more help from family and friends than the primipara because of the lack of sleep and the time and energy involved in meeting the needs of all family members. Women with other children may need encouragement to take time for themselves and time alone with their partner. Support groups for multiparas may be helpful.

Mothers who have had a long interval between pregnancies may have forgotten much of the teaching received with the last birth and may need more instruction. Those who previously gave birth to infants with anomalies or infants who did not survive may need more time to feel comfortable with this infant.

Expectations about the Newborn

Unrealistic expectations of the infant also may influence adjustment. Parents who have little experience with newborns may be surprised and disappointed at the newborn's appearance. They may be unprepared for normal newborn characteristics such as cranial molding, blotchy skin, and newborn rash.

Nurses must teach them normal newborn characteristics and early growth and development. They should assist parents in working through misconceptions about newborn behavior. For example, the capacity of an infant's stomach is small, and the infant must be fed frequently. Also, infants are neurologically unable to sleep through the night during the early weeks. Increasing the time the mother spends with the infant during the postpartum stay provides extra opportunities for her to gain comfort with the physical characteristics as well as to learn infant care while a nurse is available to help her.

Some mothers may be very disappointed in the gender of their infants or sense that their partners are disappointed. These feelings must be acknowledged and resolved before attachment can take place. For example, a mother of four sons might be so disappointed that the fifth child is a boy that she cries and refuses to pick out a boy's name at first. Later, when she holds the baby and begins to observe differences between this infant and her other sons, she can begin her discovery period with this unique child.

Maternal Age

Adjustment to parenthood is a challenge for the teenager who has not achieved a strong sense of her own identity. In general, the adolescent may talk less, respond less, and appear more passive or less affectionate with her infant than older parents. She needs special assistance to develop necessary parenting skills that promote optimal development of the infant (see [Chapter 24](#)).

Maternal Temperament

Maternal personality traits greatly influence attachment. Mothers who are calm, secure in their ability to learn, and free from unnecessary

anxiety adjust more easily to the demands of motherhood. Conversely, mothers who are excitable, insecure, and anxious have more difficulty.

Temperament of the Infant

The infant's temperament also affects maternal adjustment. Infants who are calm, easily consoled, and enjoy cuddling increase parental confidence and feelings of competence. In contrast, irritable infants who are difficult to console and do not respond to cuddling increase parental frustration and interfere with attachment.

Availability of a Strong Support System

A strong, consistent support system is a major factor in the adjustment of the new mother. Friends and relatives who are parents can provide role modeling that is particularly important to first-time mothers. They can also provide encouragement, praise, and reassurance that she is a good mother. That others see the baby as special and demonstrate love and affection is very important to the new mother. Support may be needed for an extended period of time after childbirth. In addition, the mother needs practical assistance with household tasks such as meal preparation, laundry, and shopping.

Postpartum support groups are often available and can help the mother with early concerns of this period. They provide an opportunity for women to share their experiences with women who are having similar experiences. Some groups are focused on breastfeeding or exercise, but others simply provide an opportunity for interacting with other new mothers. Fathers may be included at all meetings or occasionally.

Other Factors

Cesarean Birth

A cesarean birth, especially one that was unexpected, can make parental adjustment more difficult. Cesarean childbirth includes a longer recovery time and additional discomfort for the mother, increased stress for the family, and possible financial strain. The mother's needs for recovery and attachment with her newborn must be considered in planning nursing care.

Preterm or Ill Infant

Birth of a preterm or ill infant results in additional concerns about the condition of the infant. Prolonged separation of parents and child may be necessary. Although attachment can occur in these situations, the separation may delay the process and create stress on the normally functioning family (see [Chapter 29](#)).

Birth of Multiple Infants

Multiple birth often follows a high-risk pregnancy in which the mother was confined to restricted activity or bed rest. There may have been one or more hospitalizations for preterm labor or other complications. The infants may be preterm and have health problems. Financial strain may occur because the mother had to stop work earlier than expected and expenses associated with the birth and future health care are higher. In addition, birth of more than one infant makes family relationships more complex, especially if there are other children.

Problems of attachment may occur when there is more than one newborn. Rooming-in helps the parents gain confidence in caretaking and facilitates the attachment process. If infants are in a neonatal intensive care unit, early, frequent contacts should be arranged.

Parents attach to the infants separately as they get to know each infant's unique characteristics. They need help to relate to each infant as an individual rather than part of a unit by pointing out the individual responses and characteristics of each infant. Arranging time for

the parents to interact with each child alone, especially in the early, getting-acquainted period, is important.

Mothers may be overwhelmed at the prospect of breastfeeding more than one infant. They need reassurance that they will produce an ample supply of milk for each infant because supply increases with demand (see [Chapter 22](#)).

CULTURAL INFLUENCES ON ADAPTATION

A major goal of nursing practice in the postpartum period is to provide culture-specific nursing care that fits the health beliefs, values, and practices of each woman. This can be difficult because of the wide ethnic diversity in countries such as the United States and Canada. A major challenge for nurses is to be aware of cultural beliefs and acknowledge their importance in family adaptation. The postpartum period often is thought to be a time of vulnerability for the woman and infant ([Mattson, 2011](#)). Many cultural factors relevant to this time can be grouped into communication, dietary practices, and health beliefs.

Communication

Verbal communication may be difficult because of the numerous dialects and languages spoken. An interpreter should be fluent in the language, of the same religion, and of the same country of origin, if possible. This compatibility is particularly important for Middle-Eastern families, whose religious orientation may vary widely and who come from countries with long histories of social and religious conflicts.

Respect for privacy and modesty of all people is important, but modesty is especially important in Hispanic, Middle-Eastern, and Asian cultures. Laws of modesty require that Muslim women cover their hair, body, arms, and legs except when at home with family or in all-female company ([Giger, 2013](#)).

Health care workers often place a premium on efficiency and come directly to the point, but direct communication can be distressing, particularly for some Hispanics and Native Americans. Clients from these cultures may approach a subject only after exchanging polite and gracious comments.

When the nurse and family speak different primary languages, verifying the family's understanding is important. Nodding or saying "Yes" may be a sign of courtesy rather than understanding or agreement. To be certain the message has been received, the nurse should ask family members to repeat in their own words what they have been told.

Many Asian and Hispanic women believe that not following traditional prescriptions may result in aches, pains, arthritis, and other problems in old age ([Galanti, 2008](#)). A woman may not indicate that she disagrees with what the nurse tells her to do because she does not want to show disrespect. She may simply not follow the nurse's instructions. She might also follow cultural requirements that differ from nursing expectations. Even if she does not really believe the requirements are necessary, she may follow them to avoid offending close relatives.

CASE STUDY 18-1 NURSING CARE PLAN*

ASSESSMENT: Both infants are in Dawn's room, and she moves anxiously from one to the other. She has examined the infants but has not had individual time with each one. She touches the infants cautiously and asks, "How in the world will I be able to take care of two babies?"

NURSING DIAGNOSIS: Risk for Impaired Attachment related to inadequate time with individual infants and lack of confidence in ability to provide care for two infants

Critical Thinking: *What data (behaviors) led to this diagnosis? What other data would confirm the diagnosis?*

Answer: *Time to learn an infant's characteristics is necessary for attachment. Dawn has not had time with each child individually. Observing the way she touches and interacts verbally with each child and noting that names have not been selected might confirm the diagnosis.*

GOALS/EXPECTED OUTCOMES: Dawn will:

1. Demonstrate progressive bonding behaviors with each infant before discharge.
2. Collaborate with nursing staff and her husband to devise a plan for caring for the infants during the early weeks at home.
3. Verbalize increased confidence in her ability to care for the infants before discharge.

INTERVENTIONS AND RATIONALES

1. Promote bonding and attachment with individual infants by arranging separate time with each infant and pointing out the unique characteristics of each child. *Parents attach more easily to one infant at a time. They must go through the getting-acquainted phases separately.*
2. Make sure that the parents have contact with the infant who is awake and responsive. *The infant must respond to the parent by some signal, such as eye contact or gazing, for attachment to occur.*

3. Foster a relaxed atmosphere that permits unlimited contact between the parents and twins. Model behaviors such as holding, consoling, and talking to the infants. *A relaxed atmosphere and prolonged contact with the twins enhance interaction that promotes bonding. Modeling is a very effective teaching strategy for demonstrating appropriate interactions.*
4. Encourage participation in infant care. Demonstrate infant care, and praise all maternal efforts to provide care. *Caring for the infants or successfully consoling a crying infant elicits feelings of nurturing and greatly increases feelings of confidence and competence.*
5. Assist Dawn in making a plan for caring for the twins. *During the time breastfeeding is being established, the mother needs information and encouragement. Collaborating on a plan for providing and recording care increases the parents' confidence in their ability to care for the infants. This is particularly true when the parents receive reassurance that care does not have to be on a strict schedule.*
 - a. Provide instruction on breastfeeding twins and refer parents to a lactation consultant for continuing support.
 - b. Suggest that the parents keep a record of care for each baby for the first few days at home so that they do not become confused.
 - c. Reassure parents that a daily bath for the infants is unnecessary. Suggest bathing every other day because the face, neck, and diaper area are cleaned as necessary.
6. Emphasize the importance of obtaining adequate rest. Suggest that the mother sleep when the infants sleep and the parents take turns caring for the infants. Recommend that they accept assistance with household tasks from family and friends so that they can concentrate on care of the twins. *Sleep deprivation and chronic fatigue can interfere with the joys of parenting unless the parents anticipate the problem and make plans to deal with it.*

EVALUATION: Dawn went from fingertipping to enfolding her babies and selected names for them. By discharge on the second postpartum day she stated she was feeling more confident with breastfeeding and caring for the infants but would need continued help. Both parents participated in infant care and identified family members who would assist them during the early weeks at home.

*Continued from p. 359; continues on p. 365.

Health Beliefs

Cultural beliefs and practices provide a sense of security for new mothers. Provision of care for the mother and baby by female relatives is a common thread among cultures. Women from parts of India return to the parents' home for 16 weeks postpartum while the new mother is cared for by her own mother. In rural areas of the Philippines, the maternal grandmother comes to the mother's home daily for 8 weeks to do the cooking and housework and bathe the new mother (Katz, 2012).

For many Southeast Asians the postpartum period is important to ensure health in later years. New mothers are expected to rest for 1 to 3 months while the grandmother or other female relatives assume the mother's usual responsibilities of cooking or housework and care for the mother, her baby, and other children. Care for the Korean mother and baby is traditionally performed by the mother-in-law (Callister, 2008).

Women's activities are often restricted for a period after birth to allow rest and recuperation. The time involved varies but is often 40 days as it is for Russian women (Callister et al., 2007). Laotian women stay home for 1 month near a fire or heater to help "dry up the womb" (Callister, 2008). Rest for 40 days is important for women from India (Grewal et al., 2008). Native American women and their infants stay

indoors and rest for 20 days or until the umbilical cord falls off (Callister, 2008).

"Doing the month" is very important for Chinese women. Mothers and their babies are cared for by a grandmother or they may hire a "month maid" to help them. They do not go outside and must keep warm to avoid "wind chill." They wear long sleeves and long pants and avoid washing their hair (Callister, Eads, & Diehl, 2011).

Many Southeast Asian and Hispanic women believe the mother should be kept warm to avoid upsetting the balance of hot and cold. Use of ice for perineal edema or breast engorgement may not be acceptable to these women. Mexican women stay warm, do not bathe or exercise, and eat special foods to promote warmth for 40 days after giving birth (D'Avanzo, 2008).

Many Mexican women follow the customs of *la cuarentena*. This 40-day period is a time when the woman is considered at risk because the entire body is open and subject to entrance of air, which would cause illness and various body aches. The woman may bind her abdomen and wear more clothes than usual to avoid becoming cold, even when the weather is hot. Sexual intercourse is avoided to prevent serious illness to the mother, father, and infant (Vaughn, 2011).

When women are unwilling to take baths or showers in the postpartum period, nurses may be concerned about hygiene. Perineal

cleansing is generally acceptable. If a sitz bath is indicated and this is explained to the mother, she may agree if she is kept warm throughout the process. Although an opportunity to wash or shower should be offered, it is up to the woman to decide her preference. Tact and sensitivity are necessary to determine what care is appropriate for each woman and to find a compromise, if necessary.

In some cultures, baths are an important part of postpartum recovery. Immediately after childbirth, Haitian women take a hot bath in water infused with herbs, then a cooler bath, and at the end of the month take a cold bath (Etienne & Pavlovich-Danis, 2010). Navajo women take a ritual bath on the fourth postpartum day (Mattson, 2011).

Specific religious practices should be accepted and supported. For instance, Muslim mothers are exempted from their obligation to pray while they are bleeding. However, the father and other family members kneel, place their heads on the floor, and pray five times per day. If possible, a clean, quiet room should be provided so that this obligation can be fulfilled without having to leave the birthing center.

Dietary Practices

Some cultural dietary practices to consider center on the hot-cold theory of health and diet. This theory refers to the intrinsic properties of certain foods instead of the temperature or spiciness of foods. For example, some Asians believe that after childbirth the woman should eat only “hot” foods such as chicken, meat, and fish. Others eat warm, salty foods and avoid fruits and green vegetables after childbirth (Mattson, 2011).

Although ice water is commonly given to hospital clients, it is not acceptable to many Asians. For example, Southeast Asian women may refuse cold or ice water and prefer hot water or other warm beverages to keep warm.

Food brought from home is a welcome sign of caring in many cultures. This is especially true if traditional foods are eaten after a woman gives birth. Nurses should encourage this practice and discuss any dietary restrictions with the family.

HOME AND COMMUNITY-BASED CARE

Because many mothers and infants are discharged from the birth facility soon after childbirth, some assessments and interventions described in this chapter occur in the home or clinic setting. Mothers may leave the birth facility when they still have discomfort and are just beginning to recover from the childbirth experience. Consequently, most psychosocial concerns such as family adaptation and postpartum blues surface later, when support from health care professionals is not as readily available.
