Management of the rectal stump is largely dependent on the severity of colitis at the time of operation, as well as the friability of the rectosigmoid. The options for handling the rectum include the Hartmann pouch, where a 30 Fr catheter is passed transanally and left in place for decompression, a mucus fistula, or closure of the rectal stump with exteriorization into the subcutaneous tissue. The mucus fistula presents the safest approach in handling the rectum in the instance that tissue is very friable. Closure of the rectum with exteriorization into the subcutaneous tissue has been reported, suggesting outcomes are associated with fewer pelvic septic complications and overall morbidity.<sup>31</sup> Regardless of management approach, it is important to recognize that the rectal stump can be a source of postoperative peritonitis if the patient suffers a stump blowout.

## MANAGEMENT OF CHRONIC COLITIS

Although patients with chronic colitis are in better overall condition than those with acute colitis, healing conditions remain far from ideal. Often, these patients have undergone long-term steroid therapy, which incurs a high risk of septic complications and conditions for poor anastomotic healing. For these reasons, a staged procedure is preferred to allow for reconstruction at a later time. With the benefit of added time, efforts should be made to optimize nutritional status and minimize steroid use.

In the following section, we discuss the options available for reconstruction. The best choice is not always obvious and is largely

dependent on patient circumstances of life, gender, occupation, age, and lifestyle. It is therefore critical that all options are discussed with the patient before a final decision is made, as it will drastically impact the patient's quality of life.

## Laparoscopic versus Open Approaches

Laparoscopic ileal pouch anal anastomosis (IPAA) was initially described in 1992. Although more recent evidence from several randomized controlled trials suggests elective laparoscopic colectomy fares better in short-term perioperative outcomes compared to the open approach, only a handful of centers have reported outcomes specifically in IBD.<sup>30,32</sup> Comparative studies have concluded that laparoscopic IPAA is deemed feasible and a safe approach with significant improvement in perioperative complications.<sup>29,30,32-34</sup> Few investigators have examined short-term outcomes and complications after laparoscopic IPAA, such as pouchitis and pouch dysfunctional incontinence, frequency, and sexual function, revealing little difference compared to the open approach.<sup>29,32,34</sup> In a study comparing open to laparoscopic IPAA, Fajardo and colleagues did not demonstrate differences in short-term outcomes between groups. However, patients who underwent laparoscopic reconstruction demonstrated a shorter elapsed time to ileostomy closure.<sup>35</sup> Currently, there is insufficient data to tout the claim that laparoscopic IPAA leads to faster recovery, as patients who undergo elective restorative proctocolectomy (RPC) are typically younger, healthier, and more motivated.

In this era of advancing surgical techniques, laparoscopic surgery has been shown to be a safe and feasible alternative to open surgery in IBD.<sup>29,33,36</sup> The outcomes generally studied include operative duration, intraoperative blood loss, time to return of bowel function, length of postoperative stay, and overall pain scores. Studies claim that the laparoscopic approach boasts decreased postoperative narcotic requirements, blood loss, and hospital length of stay, and decreased operative times, although results are inconsistent.<sup>29,33,34,37</sup> Other centers report additional reduction in the time to subsequent IPAA.<sup>33</sup> This aspect of a laparoscopic approach is particularly difficult to draw conclusions about, considering that the factors that influence delay to IPAA in UC is likely confounded by surgeon comfort and

preference, individual complication rates, and postoperative recovery times. Randomized controlled trials comparing laparoscopic and open approaches have shown lower rates of superficial surgical site infection (SSI) and earlier return of bowel function.<sup>38</sup> The majority of reported series describing laparoscopic RPC have utilized the stapled ileal J-pouch configuration. Less commonly, S-pouch techniques are employed. As Harms and colleagues have described, there is additional time required to creating an S- versus a J-pouch in surgery, contributing to the significant increase in intraoperative time to the procedure compared to the open approach. However, the added time provides little difference in the overall costs incurred in a laparoscopic approach, due to shorter hospital stays.<sup>37</sup> The greatest advantage to laparoscopic-assisted procedures is improved cosmesis due to reduced incision size. In a Cochrane review by Ahmed and colleagues, various series and clinical trials identified higher cosmesis scores and greater patient preference for laparoscopic approach compared to open.<sup>39</sup> As with any laparoscopic approach, conversion to open surgery remains an enduring possibility in each surgeon's mind. Studies estimate conversion rates ranging widely from 0% to 8%.<sup>29</sup>

To briefly summarize the laparoscopic technique, the procedure involves a completely laparoscopic, intracorporeal total colectomy followed by either open or laparoscopic proctectomy. In the instance of immediate reconstruction with an open proctectomy, an IPAA is performed with or without mucosectomy.<sup>37</sup> Two initial 12-mm ports are placed in the suprapubic and supraumbilical positions, followed by placement of two 5-mm ports in both left and right sides, to assume a diamond configuration. The colon is mobilized in a lateral-to-medial fashion and the omentum is preserved during mobilization of the transverse colon. Few series report routine removal of the omentum, with the notion that preserving it may increase the risk of obstruction from adhesion formation; however, there is no clear evidence to support this.<sup>40</sup> A bipolar cautery is used to divide the mesocolon, and simultaneous attention is paid to ligating the ileocolic vessels. Following this, colon extraction is accomplished via a 7- to 8-cm extension of the suprapubic incision. Proctectomy and pouch reconstruction are accomplished via placement of a wound retractor into the same extended incision. A handsewn or stapled IPAA is performed. A standard diverting ileostomy is placed in the left lower quadrant for fecal diversion.

Alternatively, the operation can be performed in a completely laparoscopic fashion. In this approach, the abdomen is accessed with three 5-mm trocars in the supraumbilical, suprapubic, and left lower quadrant. A 10/12-mm trocar is placed in the right lower quadrant, completing the diamond configuration. The abdominal colon is mobilized and the mesentery ligated beginning at the distal sigmoid colon, working around to the right side of the abdomen. The most common approach is a lateral-to-medial dissection. However, medial-to-lateral dissection of the entire colon can be performed and has been shown to be a very efficient approach.<sup>41</sup> In this approach, the mesentery is divided first, followed by complete medicalization of the colon. Once the entire abdominal colon is free from all attachments, attention is turned to the pelvis. The pelvic dissection is carried out under laparoscopic visualization. The proctectomy can be performed as a total mesorectal excision or, in the absence of a concern for malignancy or dysplasia, the dissection can be performed by skeletonizing the rectum and dividing the mesorectum with an energy device. Regardless of technique, the dissection is taken down to the top of the anorectal ring, at which point the rectum is divided with a laparoscopic stapling device. This portion of the procedure can prove to be quite difficult, and great care must be taken to divide the rectum low enough to ensure all disease is removed. Once this is completed, the colon and rectum must be extracted. This can be accomplished through the previously identified ileostomy site or through a suprapubic incision. The authors most commonly extract through the ileostomy site. Once the specimen is extracted, the ileal pouch is created in the standard fashion. The anvil of the circular stapler is inserted into the lumen of the pouch per anus and anvil is wed to the stapler. The ileostomy is then created through the extraction site.

## **Total Colectomy with Ileorectal Anastomosis**

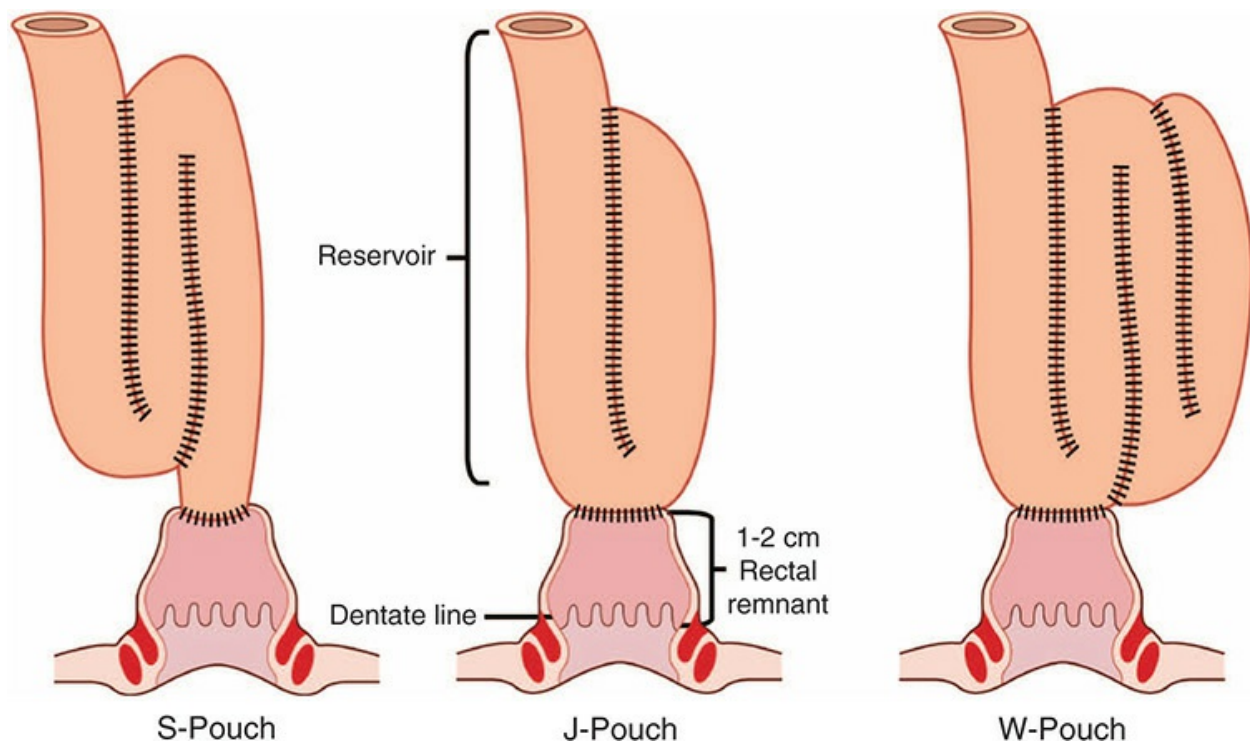

In select circumstances, ileorectal anastomosis (IRA) is an appropriate surgical option. Such an indication might be in a patient with chronic quiescent disease with a dysplastic lesion in the right colon. Following standard colectomy, the rectum is left intact, obviating deep pelvic dissection and potential injury to pelvic nerves. The benefits are perceived in the context of less impact on sexual function and fertility, owing to younger patients who have not completed their desires for childbearing. IRA was initially plagued by poor functional results and persistent rectal inflammation; this, however,

has improved over the years. As previously discussed, the rectal remnant requires continued medical therapy and surveillance, as the risks of colitis and later cancer have not been eliminated.

The anastomosis is commonly created at the level of the sacral promontory, where the superior hemorrhoidal vessels are left intact. A stapled or handsewn anastomosis can be performed in an end-to-end or end-to-side fashion.

## **Total Proctocolectomy with Ileal Pouch-Anal Anastomosis**

RPC with IPAA is the elective procedure of choice for UC. Total proctocolectomy (TPC) is carried out as described above. The terminal ileum is reconstructed to recreate a fecal reservoir in order to mimic anorectal continence after colectomy. This can be performed either as a single or staged procedure. Since its introduction in 1978,<sup>42</sup> numerous studies have demonstrated low morbidity, high quality of life, patient satisfaction, and good functional outcomes.<sup>43</sup> Many variations to the ileal pouch have been described, including the S, J, and W, with the most common being the J-pouch (Fig. 46-7).

**FIGURE 46-7** S, J, and W ileal pouch configurations.

In the J-pouch reconstruction, an adequate length of the ileocolic pedicle must be confirmed, and the distal ileum is used to construct the J-pouch. There is an inflow and outflow limb of the pouch creating the J-shape. These are typically anastomosed together using a linear stapler. The apex of the pouch is then anastomosed to the rectal cuff, which is performed with a circular stapler, but may also be handsewn to the anal verge.

## Ileal Pouch-Anal Anastomosis

There are two principle techniques that are currently used in pouch reconstruction, the handsewn and stapled techniques. There are three variations to how this procedure may be performed, separated in terms of the number of stages. A single-stage procedure encompasses removal of the colon and rectum with pouch reconstruction without a diverting ileostomy. The two-stage procedure involves total proctocolectomy with pouch reconstruction and diverting ileostomy, followed by closure of the ileostomy at a later time. The three-stage procedure involves an initial subtotal colectomy, followed by a completion proctectomy and pouch reconstruction with diverting ileostomy, completed by closure of the ileostomy.

A three-stage procedure is preferred when a patient presents with suboptimal conditions such as poor nutritional status, high steroid requirements, and severe colitis. This permits healing between operations so as to optimize the patient's subsequent preoperative state. The two-stage procedure is most commonly performed in elective scenarios.

## **HANDSEWN ANASTOMOSIS WITH MUCOSECTOMY OF THE ANAL TRANSITION ZONE**

Mucosectomy with handsewn anastomosis has long been the technique of choice for IPAA, particularly prior to the introduction of surgical staplers. This technique is more time-consuming and is associated with postoperative functional complications such as incontinence and seepage secondary to manipulation of the anal canal and sphincter stretching.<sup>44</sup> Mucosectomy removes the entire rectal mucosa as completely as possible. Although the stapled technique offers various advantages, several surgeons continue to opt for mucosectomy with handsewn anastomosis given the concern over the risk of ongoing inflammation or cancer developing in the rectal remnant. The difficulty with handsewn anastomoses is also perceived in obese patients, where the pouch may be under tension.

## **DOUBLE-STAPLED TECHNIQUE WITHOUT MUCOSECTOMY**

The stapled technique has gained much favor as the standard technique for IPAA given good outcomes and ease of approach. A stapled anastomosis is less likely to result in functional problems, however; utilization of the stapler head is introduced transanally, requiring a 1- to 2-cm remnant of rectal cuff, termed the anal transition zone (ATZ), which poses a risk for future development of cuffitis or dysplasia.

## **Brief Surgical Technique for IPAA**

It is essential to ensure adequate length of the mesentery to allow mobilization of the small bowel in construction of the pouch. This may be accomplished by ligating the ileocolic vessels as proximal to the level of the takeoff from the superior mesenteric artery (SMA). In the stapled

anastomosis, a transverse linear cutting stapler is used to staple off the rectum at the level of the levators, leaving 1 to 2 cm of rectal mucosa. Pouch reconstruction is initiated by ensuring complete mobilization of the small bowel. This involves taking down inter-loop adhesions and mobilization of the small bowel. A general rule of thumb to ensure adequate length for a stapled anastomosis involves ease with extending the mesentery to the level beyond the pubic symphysis.

Constructing a J-pouch involves creating two 15-cm limbs by folding the terminal ileum onto itself. A small enterotomy is created at the apex of the pouch on the antimesenteric side of the bowel. This serves to allow a linear stapler to pass through and create the J conformation of the pouch. Next, a purse-string suture is placed at the enterotomy, which will secure around the endoanal anvil stapler which is passed transanally. This creates the ileoanal anastomosis. The stapler is fired and removed, and inspected for both proximal and distal tissue donuts. A leak test is then performed, followed by creation of a diverting ileostomy. The ileostomy is often found in the right lower quadrant. [Figure 46-8](#) shows an endoscopic view of a normal J-pouch demonstrating the inlet and the blind end of the ileum comprising the tip of the “J”.

## **FIGURE 46-8** Normal J-pouch appearance.

In the handsewn anastomosis, a Lone Star retractor is placed in the patient's perineum. A solution of dilute epinephrine is injected into the submucosa to gently separate the mucosa away from the underlying tissue planes. The mucosectomy is then performed with electrocautery or via sharp dissection using Metzenbaum scissors, beginning at the level of the dentate line. The pouch is then gently advanced into the pelvis and the anastomosis between the ileal pouch and dentate line can be created using interrupted absorbable suture.

## **Total Colectomy or Proctocolectomy with End Ileostomy**

Permanent ileostomy may be a consideration for patients with contraindications to restorative surgery, tolerance, and preference, particular among the elderly. Management of the rectal remnant remains the most burdensome aspect when total abdominal colectomy and end ileostomy is definitive. The rectal stump requires surveillance, continuing to pose cancer risk and unpredictability in symptom control if the patient were to develop extensive proctitis. Patients may also struggle with societal pressures and insecurities with body image on a daily basis as a result of the ileostomy.

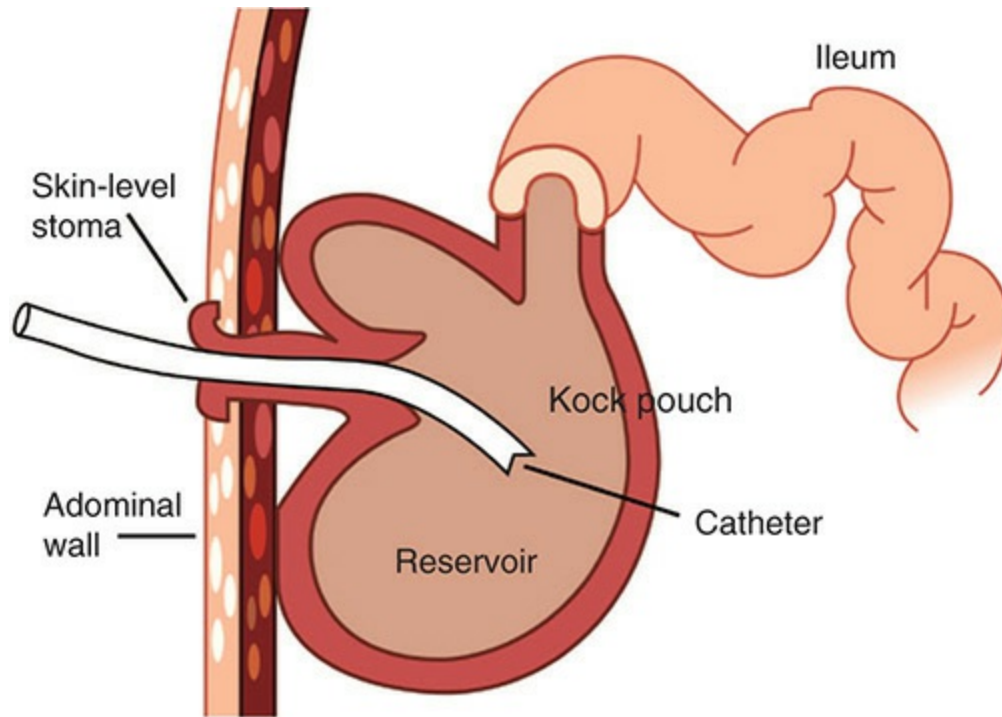

As a result of the rectal concerns, the vast majority of patients who opt for an end ileostomy as a definitive treatment of their UC should have a total proctocolectomy consisting of removing the abdominal colon in the standard fashion as well as removing the entire rectum via an abdominoperineal approach. This can be performed in the open or laparoscopic fashion. Regardless of approach, the colon is removed in the standard fashion followed by complete rectum and anus removal. Following ligation of the superior hemorrhoidal vessels and inferior mesenteric vessels, the plane between the presacral fascia posterior to the rectum and fascia propria of the rectum is entered. Dissection of the pelvic floor is initiated posteriorly, progressing laterally and lastly, anteriorly. Throughout the dissection, care is taken not to injure the left ureter and sympathetic nerves. The rectum is skeletonized from the mesorectum to reduce the risk of parasympathetic nerve injury. Anteriorly, the dissection is carried out as closely to the

specimen as possible, on the rectal side of Denonvilliers' fascia, also in avoidance of potential injuries to neighboring structures.

Upon completion of the abdominal and pelvic portion of the operations, the surgeon moves to the perineum. Assuming that there is no concern for cancer, an intersphincteric dissection of the anal canal can be performed to maintain pelvic muscular support of the perineal wound closure. In this technique, an incision is made around the anal canal and the intersphincteric space is entered circumferentially. The dissection is taken into the pelvis posteriorly and carried around both sides until the anus is completely free of all attachments in the perineum. The rectal specimen can then be extracted through the perineum. An intersphincteric resection enhances closure of the pelvic floor allowing closure of the healthy muscle. This theoretically decreases wound complications in the short and long term.

## **Kock Pouch**

A continent ileostomy was first described by Kock in 1969.<sup>45</sup> It was described as a high-volume, low-pressure reservoir maintained by an intussuscepted nipple valve (Fig. 46-9).<sup>45</sup> The design of the pouch was to permit fecal material to accumulate and be emptied at the patient's convenience several times a day. This was accomplished by inserting a tube at the level of the stoma into the reservoir to release its contents.<sup>25</sup> Although the concept proved promising, it was idealistic at best given Kock pouches failed to achieve high levels of acceptance due to frequent complications. Currently, the Kock pouch serves as a surgical rescue option following failed IPAA or for those who are not deemed appropriate IPAA candidates. Major complications include valve dysfunction, the most common of which is valve de-intussusception.<sup>25</sup>

**FIGURE 46-9** Kock pouch. A high volume, low-pressure reservoir maintained by an intussuscepted nipple valve. This design permits fecal material to accumulate and be emptied at the patient’s convenience several times a day. This is accomplished by inserting a tube at the level of the stoma into the reservoir to release its contents.

## POSTOPERATIVE COMPLICATIONS

Pouch-related complications are categorized broadly into those with septic and non-septic sequelae. Septic complications are those characterized by infections originating in the pouch which consequently spread to the pelvic space, and include anastomotic leak, abscess, and fistulas. Non-septic complications present a slightly larger repertoire of clinical events that arise over a longer postoperative time frame. These include obstructions, stricture, cuffitis, and pouchitis. Not uncommonly, septic-related complications present at earlier time courses; however, the majority of early complications are often attributed to predisposing patient factors such as local and general inflammatory changes, hypoalbuminemia, anemia, and prolonged steroid use.<sup>46</sup>

The J-pouch is created with two ridges corresponding to the anastomosis, creating a posterior appendage called the “J-pouch appendage.” The

appendage consists of the distalmost segment of the terminal ileum that is not incorporated into the reservoir. The length of the appendage is 1 to 2 cm and may potentially dilate over time, leading to downstream complications.

Lastly, the definition of pouch failure varies between series and authors. It is often referred to as either the need to remove the pouch and establish a permanent ileostomy or the need for an ileostomy without the anticipation of future closure.<sup>28</sup> Here, we discuss an overview of the most commonly encountered immediate and later-stage postoperative complications along with current management strategies.

## Immediate Complications

### ANASTOMOTIC LEAK

Anastomotic leak remains a worrisome early postoperative complication following pouch reconstruction. The majority of leaks occur at the pouch-anal anastomosis, but may occur at any suture or staple line. Patients often present with early symptoms of abdominal pain, fever, tachycardia, and potentially hypotension, rendering the diagnosis to be made clinically the majority of the time. However, this is often followed up with imaging, such as cross-sectional imaging or Gastrografin enema. The morbidity of anastomotic leaks may be monumental, resulting in sepsis, fistulas, strictures, and potentially pouch failure. Therefore, rapid and early diagnosis and treatment of ensuring pelvic sepsis is critical in order to prevent long-term pouch failure.

The overall anastomotic leak rate leading to pelvic sepsis following IPAA has been reported at between 2.9% and 19%.<sup>47-50</sup> In severe colitis, leak rates have been reported at 5%.<sup>51</sup>

Prevention plays a key role in maintaining the standard of improved quality of life. Techniques aimed at reducing leak rates include ensuring adequate blood supply in preventing ischemia and no tension to the anastomosis. Hence, pouch reconstruction is most often reserved as a subsequent surgery following colectomy in the setting of an acute UC flare or high-dose steroid requirements. Treatment for anastomotic leak varies from medical management to percutaneous drainage to operative intervention. The patient is usually started on antibiotic therapy, bowel rest, and intravenous fluid resuscitation. If nonsurgical methods fail, laparotomy for washout with

drain placement and potential primary repair is possible if tissue integrity and the defect are deemed reparable at the time of inspection. The most drastic repair warrants excision of the pouch if there is clear evidence of irreversible ischemia.

## **ABSCESS**

Contrary to common belief, pelvic abscess may form without anastomotic leak. The prevalence of abscess formation reported in various series ranges from 5% to 8%.<sup>48,49</sup> Diagnosis is achieved via CT imaging and clinical presentation of signs suggestive of sepsis and abdominal pain. In the presence of a sizable pelvic abscess, percutaneous drainage under CT guidance may prevent laparotomy. Antibiotic coverage should also be started, ensuring coverage includes both aerobic Gram-negative and anaerobic organisms. When drain outputs decrease to less than 100 mL over a 24-hour period, a tube or drain contrast study will provide additional information in deciding whether to remove or keep the drain.<sup>46</sup> Late complications from pelvic abscess formation include fistula formation, commonly with the urethra in males and the vagina in females. The etiology of abscess formation in the immediate postoperative period is likely attributed to pouch ischemia or leak, in contrast to late-forming abscesses, which may be suggestive of Crohn's disease.

## **Late Complications**

### **POUCH FISTULA**

Pouch fistula is considered a late presenting complication, often following abscess or anastomotic leak, and affects upward of 7% of patients.<sup>50</sup> The median time of presentation following IPAA has been reported as 10 months, but may occur as early as 3 months. The various types of fistula originate from the appendage, pouch-anal anastomosis, inflow limb, and the pouch reservoir proper. The distal connection can vary from the abdominal wall, bladder, small bowel loops, and vagina in women. The pouch-vaginal fistula is the most common form, affecting upward of 16% of women who develop this complication.<sup>52</sup> In order to develop a treatment plan, the origin of the fistula from the pouch must be determined, which can be accomplished by

direct visualization under general anesthesia, pouchoscopy, and via Gastrografin enema.

Treatment of pouch-related fistula is complicated by high recurrence rates and imperfect healing, often requiring multiple operations. Repair of pouch-vaginal fistulas is approached depending on the location of fistulization along the vaginal canal. A local approach is perineal or transvaginal. If the fistula arises above the ileoanal anastomosis, the abdominal approach includes primary repair of the vaginal defect, resection of the retained rectum, and mucosectomy with a new ileoanal anastomosis. This option offers the best recovery rates, ranging from 67% to 80%.<sup>52</sup> Perineal or transvaginal approaches involve full thickness flaps and are associated with lower healing success from 35% to 60%.<sup>52,53</sup> Appendage and bladder-associated fistulas are treated by resection of the appendage and restapling the blind end of the ileum. The bladder fistula is resected and primary closure of the pouch and bladder is performed.

## **SMALL BOWEL OBSTRUCTION**

Small bowel obstruction (SBO) is a well-known complication following abdominal surgery, and is no exception after IPAA. The two principle causes of SBO in this setting are due to adhesions and a redundant ileal pouch. With adhesive disease, treatment includes bowel rest, decompression, and resuscitation. Adhesiolysis is indicated when bowel rest fails and clinical symptoms worsen, although care must be taken not to damage the pouch intraoperatively. Non-adhesive obstruction is a later manifestation, presenting months following pouch reconstruction. It occurs as a mechanical obstruction secondary to the pouch having stretched out over time, subsequently flipping onto itself. This warrants surgical repair, at which time the redundant pouch may require resection, since a pexy procedure may only serve as temporary relief.

## **STRICTURE**

Ileal pouch stricture is another late complication occurring in 10% to 40% of cases due to ischemia, pelvic sepsis, or anastomotic leak.<sup>47</sup> The most common locations for stricture formation occur at the pouch-anal anastomosis or proximal to the inflow limb of the pouch. Several series have

evaluated the risk factors for fistula formation, which include pelvic sepsis, handsewn anastomosis, diverting loop ileostomy, mesenteric tension, high body mass index, and NSAID use.<sup>54</sup> Treatment modalities include serial dilations, which demonstrate a high success rate.<sup>52</sup> In the instance that dilations fail, advancement flap anoplasty serves as the surgical treatment of choice.

## MANAGEMENT OF POUCH-RELATED COMPLICATIONS

### Pouch Dysfunction

Pouch dysfunction is an umbrella term used to define any deviation from normal pouch function, or that which imparts negative impact on the patient's quality of life. Given the broad application of the term, the literature fails to identify a consistent definition of pouch dysfunction; however, the most common complaints include frequency of bowel movements, incontinence of liquid stool, clustering, urgency, and incomplete evacuation.

Failure of RPC with IPAA occurs from 3.5% to 15%.<sup>55</sup> Salvage surgery exists as a rescue procedure aimed at preserving the existing pouch and anal continence. The majority of patients who undergo salvage surgery often experience severe septic complications that are unamenable to medical therapies. Although surgical repair may successfully save the original pouch, subsequent failure remains an ongoing risk. One Italian series reported higher 5-year failure rates after salvage (28.8%) compared with primary IPAA (5.7%). An overall decrease in bowel frequency and urgency have been reported by patients at 3 years of follow-up.<sup>55</sup>

There is no doubt that a patient experiences a great deal of discomfort and stress related to pouch complications. Although clinicians encounter this scenario not uncommonly, they may not be fully aware of how pouch dysfunction affects the patient. A study by Brandsborg and colleagues revealed that physicians and patients' perspective on bowel dysfunction differ on parameters such as urgency, frequency, incontinence, and incomplete evacuation.<sup>43</sup> Even expert clinicians overestimated the importance of incontinence and frequency on quality of life and underestimated the impact

of clustering and urgency, compared to how these factors truly mattered to the patient.<sup>43</sup>

## Pouchitis

Pouchitis is perhaps the most common long-term complication following IPAA, and significantly impacts the patient's quality of life and long-term surgical outcome. It represents a spectrum of disease processes with variable risk factors, pathogenic pathways, clinical phenotypes, and prognoses. As a result, an enormous degree of effort and resources have been invested into this complication in hopes of better understanding the root causes of disease and to better prevent it.

There exists a wide range of clinical presentations, manifested by crampy abdominal pain, hematochezia, urgency, and frequency of bowel movements and fevers, all of which are not specific to pouchitis alone. Pouchitis has been reported to occur in up to 40% of patients within the first year following ileostomy closure.<sup>56</sup> The natural history of disease mimics that of UC, wherein dysregulated acute flares ultimately result in chronic inflammation. It is generally believed that pouchitis results from alterations in the intestinal microbiome, rendering the genetically predisposed host susceptible to developing abnormal immune responses.<sup>44</sup>

The risk factors associated with pouchitis have been studied extensively. Several authors have identified factors associated with acute or chronic pouchitis, as scientists are beginning to acquire a better understanding that these presentations are likely two different disease processes.<sup>57</sup> Smoking has been shown to be associated with acute pouchitis,<sup>58</sup> whereas long duration of IPAA, extraintestinal manifestation of UC, preoperative thrombocytosis, and postoperative IPAA complications are all associated with chronic pouchitis.<sup>59</sup>

Pouch endoscopy offers a highly valuable mode of diagnosing pouch disorders. It reveals the severity and extent of mucosal inflammation under direct visualization with the option of obtaining biopsies for histological assessment. Although histology serves a limited role in diagnosing severity of disease, it allows identification of specific features such as metaplasia, viral inclusion bodies (CMV infection), granulomas, and dysplasia.

Treatment is based on the type of pouchitis whether antibiotic-responsive or antibiotic-dependent (those with frequent relapses) to antibiotic refractory

pouchitis. Since the disease is triggered by microbial and immune aberrations, antibiotics serve as mainstream therapy. In antibiotic-responsive cases, first-line therapy includes metronidazole (15-20 mg/kg/d) or ciprofloxacin (1000 mg/d) for 2 weeks' duration. In the setting of antibiotic-resistant pouchitis, or chronic pouchitis, various immunologic agents, biologics (infliximab), steroids, and anti-inflammatory agents have been used. Management of chronic pouchitis remains a complex and challenging feat, as it is the most common cause of pouch failure. In the instance of resistance to medical therapy, a temporary diverting loop ileostomy may be warranted, versus pouch excision and end ileostomy.

## Cuffitis

Cuffitis is defined as chronic inflammation or recurrent disease within the remnant rectal mucosa left within the J-pouch. It has been referred to as a variant form of UC in the rectal cuff among patients with IPAA without mucosectomy (Fig. 46-10). As previously discussed, when IPAA is created, a 1- to 2-cm length segment of rectum resulting from the double-stapled technique in J-pouch reconstruction is retained. Few series have reported the incidence of cuffitis to occur in 4% to 17% of patients, and it is a clinically significant risk factor in the development of pouchitis.<sup>46,60</sup> Clinically, cuffitis is very similar to pouchitis, plagued by pain, low-grade fevers, and bloody stools. Diagnosis is made on endoscopy wherein the rectal cuff appears grossly inflamed in contrast to the remainder of the pouch demonstrating normal appearing mucosa. Mucosal biopsy is often performed providing definitive diagnosis, demonstrating inflammatory cell infiltration and ulceration within the rectal mucosa alone. Treatment is achieved by local therapy such as Canasa suppositories. Persistent or recurrent disease warrants further investigation, as Crohn's disease cannot be ruled out. Surgical intervention entails mucosectomy of the rectal remnant with pouch advancement.

**FIGURE 46-10** Pouch endoscopy revealing cuffitis. The mucosa demonstrates diffuse edema, granularity, and exudate.

## **Cancer and Dysplasia of the Pouch, Rectal Remnant, and Anal Cuff**

Although proctocolectomy eliminates the source of disease, the presumptive concerns over the inherent risk of cancer in the ATZ remain a source of controversy among surgeons. As discussed, the two techniques for RPC and IPAA are the stapled anastomosis versus a handsewn anastomosis. The debate as to whether the remnant rectal cuff poses a significant cancer risk to the patient post-IPAA has led some surgeons to recommend mucosectomy with handsewn IPAA. Numerous studies sought to identify the incidence of ATZ dysplasia or cancer between the stapled IPAA versus mucosectomy with handsewn IPAA, revealing an extremely low overall incidence of dysplasia and adenocarcinoma.<sup>61</sup>

Initial studies identified only 19 cases of dysplasia and cancer in the ATZ within the pouch, anal cuff, and ATZ, and interestingly in the majority of

these cases, patients underwent mucosectomy.<sup>61</sup> Recent studies have the benefit of longer follow-up duration, upward of 20 years following IPAA. Silva-Velazco and colleagues assessed a single institution experience on the long-term incidence of ATZ dysplasia among patients who had a stapled IPAA for greater than 20 years, revealing the incidence plateaued at 3.4% without any cases of adenocarcinoma.<sup>62</sup> In the instance of dysplasia and cancer, TPC should include total mesorectal excision. The circumference margin bears a significant prognostic impact on the rates of local recurrence, distant metastasis, and survival; hence, the circumferential margin serves as a surrogate marker of advanced disease as opposed to an indicator of incomplete excision.<sup>63</sup>

Neoplastic changes in the columnar cuff are rare, ranging from 0% to 0.03%.<sup>28</sup> Various studies have identified a close association of dysplasia or cancer after IPAA to be strongly associated with dysplasia or cancer in the resected proctocolectomy specimen.<sup>28</sup> The risk of adenocarcinoma following IPAA in patents with UC is increased with the length of time after surgery, as well the presence of cancer or dysplasia in the original proctocolectomy specimen.<sup>61</sup>

Increasing evidence suggests that long-term and consistent exposure to fecal material in concert with increased microbial burden in the pouch may result in inflammatory changes leading to colonic metaplasia, effectually mimicking UC. To that end, dysplasia and cancer may develop in the remaining rectal mucosa, anal transition zone, or the pouch itself. A systematic review of the literature revealed the cumulative risk of primary pouch-related cancers arising from the anorectal residual mucosa following IPAA is reported at a maximum of 0.4% at 20 years, with several series revealing 0% incidence.<sup>64</sup> It is plausible to venture that IPAA is safe and eliminates an overwhelming cancer risk of colorectal origin.

Surgery is warranted with high-grade dysplasia and cancer diagnoses. Mucosectomy with pouch advancement is generally performed. The approach to a stapled ileoanal anastomosis at the anorectal junction of a stapled IPAA leaves a 1- to 2-cm remnant of rectal mucosa. These patients require continued follow-up for potential neoplastic changes postoperatively.

Some authors note that chemotherapy did not negatively influence pouch function, in contrast to radiation therapy, which is associated with poor functional outcomes.<sup>28</sup> Multiple series discovered higher pouch failure rates

among cancer patients compared to non-cancer patients; however, results were not statistically different.<sup>28,65</sup>

## CONCLUSION

Patients with UC warranting surgical intervention require a well-established relationship with a gastroenterologist and surgeon. The complexities of this disease are best managed within a team of clinicians who are familiar with and experienced in all aspects of the patient's ongoing battle with UC. Patients are presented with a multitude of options when considering surgery for UC. It is clear that patients can undergo surgery with reconstruction and maintain an excellent quality of life. They should be fully informed and participatory in all decision-making with clinicians, particularly with respect to the risks, benefits, potential complications, and later implications of each procedure. In addition, the surgeon should be well-versed and experienced in the technical demands of the surgery and pre- and postoperative care in management of complications.

# PERSPECTIVE ON INFLAMMATORY BOWEL DISEASE

*Patricia L. Roberts*

Ulcerative colitis and Crohn's disease are gastrointestinal disorders of modern society, and their frequency has increased in developed countries since the mid-20th century. The highest incidence and prevalence of inflammatory bowel disease are seen in North America and Northern Europe, whereas the lowest rates are seen in continental Asia.<sup>1</sup> Despite the use of biologics and other advances in medical treatment, up to 15% to 30% of patients with ulcerative colitis and up to 70% of patients with Crohn's disease will require surgery during the course of their disease. Recent trends in inflammatory bowel disease have included the increased adoption of a laparoscopic or minimally invasive approach to surgery with the advantages of a faster recovery, fewer complications, less intra-abdominal adhesions, better cosmesis, and a shorter hospital stay. Biologics have changed the medical approach to inflammatory bowel disease, particularly in patients with Crohn's disease, with an increasing usage of a "top down" approach to treatment in an attempt to rapidly induce remission in patients. With increasing usage of biologics for treatment of inflammatory bowel disease,

there is increasing concern about the risk of infectious complications and other complications in patients on biologics who require surgery and the optimal perioperative management of these agents.

This perspective reviews trends in surgery for ulcerative colitis, the role and results of ileal pouch anal anastomosis surgery, the use of biologics around the time of surgery, and the management of dysplasia and cancer.

## ULCERATIVE COLITIS

Since its introduction by Parks and Nicholls in 1978, restorative proctocolectomy with ileal pouch anal anastomosis has become the standard operative approach for the majority of patients who require surgery for ulcerative colitis. Despite over 35 years of experience, the procedure remains technically demanding and is associated with a number of potential complications that are balanced by the patient's desire to avoid a permanent ileostomy. With appropriate expertise, outcomes are excellent and associated with improved quality of life and high patient satisfaction.

The ileoanal pouch procedure is performed in a staged approach, rarely in a single stage without an ileostomy and most commonly as a 2- or 3-stage procedure ([Table 47-1](#)). Indications for surgery for patients with ulcerative colitis include failure of medical therapy, intractable fulminant colitis, toxic colitis, perforation, uncontrolled bleeding, intolerable side effects of medications, strictures, growth retardation in children, high-grade or multifocal dysplasia and dysplasia-associated lesions or masses, and cancer. Patients with acute colitis or fulminant colitis and those who require emergency surgery are generally initially treated with total abdominal colectomy, ileostomy, and Hartmann closure of the rectum. In these nonelective situations, pouch construction is generally felt to be contraindicated.

**TABLE 47-1: RESTORATIVE PROCTOCOLECTOMY: 1-, 2-, AND 3-STAGE PROCEDURES**

#### 1-stage

- Proctocolectomy with ileal pouch creation and ileoanal anastomosis

#### 2-stage

- Proctocolectomy with ileal pouch creation and ileoanal anastomosis and diverting loop ileostomy
- Ileostomy takedown

#### 3-stage

- Total abdominal colectomy, ileostomy, and Hartmann closure of the rectum
  - Completion proctectomy, ileal pouch creation and ileoanal anastomosis, and diverting loop ileostomy
  - Ileostomy takedown
- 

Review of the Nationwide Inpatient Sample of over 1.5 million patients with ulcerative colitis admitted to a US hospital from 1991 to 2011 has shown an increase of ulcerative colitis–related admissions of 170% and an increase in the number of patients who required total abdominal colectomy of 44%.<sup>2</sup> In this time period, total abdominal colectomy increased by 15% (compared to proctocolectomy) and, since 2008, was more frequently performed as the initial operation for surgical intervention for ulcerative colitis.

Over the past several decades, there have been a number of refinements in the surgical technique or pouch construction. The ileoanal pouch procedure may be performed as a single stage in carefully selected patients. A number of centers have published series supporting the omission of a diverting ileostomy generally in young, healthy, low body mass index patients who are not anemic, are well nourished, and are not on immunosuppressive medications or biologics.<sup>3</sup> The number of patients who undergo the procedure as a single stage omitting a diverting ileostomy remains quite small. Technical aspects of the surgery in patients who are optimal for omitting a diverting ileostomy include no significant blood loss, no tension on the anastomosis, and a technically excellent procedure. These studies have shown similar results in the diverted and nondiverted groups with respect to leak rates and rates of pelvic sepsis but generally have been biased because the decision for an ileostomy was left to the discretion of the surgeon.

Although the use of an ileostomy does not prevent anastomotic leak, the clinically less severe consequences of the leak and pelvic sepsis in diverted patients is generally felt to have a favorable impact on subsequent pouch success and bowel function.

Pouch configuration, originally described as an S-pouch, now includes the J-pouch, the H-pouch, the S-pouch, and the W-pouch. Due to the ease and speed of construction, the J-pouch is the most common reservoir performed. A meta-analysis compared W-, J-, and S-pouches, and the functional results are essentially equivalent.<sup>4</sup> S-pouches are more likely to require intubation for evacuation, and there was slightly less bowel frequency and need for antidiarrheal medications with W-compared to J-pouches. S-pouches can provide an additional length of several centimeters and may facilitate getting the pouch to reach the anus in cases where a J-pouch will not reach. The efferent limb of the S-pouch, which should be initially constructed to be no longer than 2 cm, may elongate with time and cause obstructed defecation, which may require revision of the limb.

Although mucosectomy and double-stapled procedures are both options for the ileoanal anastomosis, the majority of patients undergo the double-stapled technique, which is technically easier to perform. The potential advantages of the technique include less tension on the anastomosis, ease of technical performance, and potentially improved functional results because of less dilatation of the anal canal and the preservation of the transition zone. In small trials, including 3 prospective randomized trials and 1 comparative study, the functional results of a double-stapled technique and mucosectomy have been similar.<sup>5-8</sup>

Recent studies have looked at the method of closure of the skin of the ileostomy takedown site and have demonstrated a marked reduction in surgical site infection with a purse string closure compared to primary closure in addition to higher satisfaction with the cosmetic outcome.<sup>9</sup>

A laparoscopic approach is increasingly used for the ileoanal pouch procedure with potential advantages of more rapid recovery and better cosmesis. Most series of laparoscopic pouches are small and avoid patients with a body mass index of greater than 30 kg/m<sup>2</sup>. A Cochrane review of 11 trials and over 600 patients found similar length of stay, morbidity, reoperation, and readmission with a laparoscopic versus open pouch procedures.<sup>10</sup> A laparoscopic approach was associated with longer operating

time, a small incision, and improved cosmesis. An additional advantage of the laparoscopic approach is less intra-abdominal adhesions and less adnexal adhesions, which could result in a decreased risk of infertility and decreased incidence of postoperative bowel obstruction.<sup>11</sup> Laparoscopic approaches include laparoscopically assisted, hand-assisted, and single-incision laparoscopic techniques.

Pouch failure, defined as the need to return to a permanent ileostomy with or without excision of the pouch, occurs in 5% to 10% of patients and may be due to pouch-related complications including pelvic sepsis, anastomotic leak and the development of fistula, the development of previously unsuspected Crohn's disease, and poor function. Pouchitis, one of the most common complications, occurs in up to 40% of patients within the first 10 years of pouch construction and up to 70% of patients within 20 years of surgery and is a rare cause of pouch failure.<sup>12</sup> The cause of pouchitis remains unknown. The majority of patients respond to antibiotics, whereas a small number of patients have chronic ongoing pouchitis. With increasing years of follow-up, a small cohort of patients may have late pouch failure because of poor bowel function and incontinence as a result of the known decrease in anal sphincter pressures associated with aging and the more liquid frequent bowel movements associated with the pouch.

Since its approval by the US Food and Drug Administration (FDA) for use in the United States for patients with ulcerative colitis in September 2005, increasing numbers of patients with ulcerative colitis have been treated with infliximab, an anti-tumor necrosis factor chimeric antibody. Results on the 3-year efficacy of infliximab as a rescue therapy in a previous placebo-controlled trial of infliximab used in acute steroid-refractory ulcerative colitis showed that after 3 years, 12 (50%) of 24 patients treated with infliximab and 16 (76%) of 21 of patients treated with placebo had required colectomy. The quality of life of the 2 groups was not different, as measured by the Short Form (SF)-36 and the Short Health Score questionnaire at the time of follow-up.<sup>13</sup>

The efficacy of biologic agents needs to be balanced with the morbidity associated with their use, particularly infectious complications. There has been continual debate with respect to the risk of postoperative complications in patients who receive biologics preoperatively. A study from the Mayo Clinic<sup>14</sup> advocated a 3-stage versus a 2-stage proctocolectomy in patients

with ulcerative colitis who were managed preoperatively with infliximab. Thus, initial total abdominal colectomy, ileostomy, and Hartmann closure of the rectum would be performed, which would then allow the patient to come off biologics prior to ileoanal pouch construction. A recent systematic review and meta-analysis looked at 7 papers including 162 patients and 468 controls who underwent primary pouch creation.<sup>15</sup> Studies included in this review have relatively small sample sizes and include heterogeneous study populations. Confounders such as severity of disease and disease duration are not accounted for. In this review, patients who received infliximab were more likely to have early and postileostomy closure ileoanal anastomosis–related complications. Interestingly, use of biologics was associated with a lower surgical site infection rate. Looking at any type of surgery, biologics were associated with a trend toward higher total and higher infectious complications, but the difference was not statistically significant.

With respect to pharmacokinetics, the half-life for elimination of infliximab is between 7 and 18.5 days, and by 12 weeks, the majority of inflammatory bowel disease patients have undetectable levels of infliximab. Should surgery be delayed in such patients for 12 weeks? It is unlikely that this is possible in patients with active ulcerative colitis without resulting in a potential flare of disease.

Patients with ulcerative colitis who are on infliximab presumably have more severe disease and should be considered for a 3-stage procedure with initial total abdominal colectomy and ileostomy followed by pouch creation and then ileostomy takedown. Along with patients who are on high-dose steroids, patients with ulcerative colitis on infliximab should be considered for initial colectomy and not ileoanal pouch creation because of the high risk of complications.

## **CROHN'S DISEASE**

Infliximab was first approved by the FDA for use in selected patients with Crohn's disease in 1998. Despite optimal medical therapy, however, approximately 70% of patients with Crohn's disease will require surgery within 10 years of diagnosis, and a substantial number of patients will require further surgery for recurrent disease. The use of infliximab and other biologic agents and the development of minimally invasive surgical techniques have

substantially changed the medical and surgical approach to such patients. Although biologics were initially felt to decrease the need for surgery, population-based studies have subsequently failed to demonstrate a reduced need for surgery.

Tumor necrosis factor (TNF)- $\alpha$  plays a role in the immune response, angiogenesis, and collagen synthesis, so a key concern is the risk of the development of infectious complications in patients with Crohn's disease who are maintained on biologics who require surgery. The results of a number of retrospective studies have been conflicting. A recent systematic review of 2 prior systematic reviews and 6 meta-analyses was performed.<sup>16</sup> This review examined all previous reviews, studies, and meta-analyses and included meta-analyses that included only a large number of patients and applied quality assessment. Patients with Crohn's disease who were treated with anti-TNF agents had an increased risk of postoperative complications including infectious or anastomotic-related complications after abdominal surgery. Although a preoperative drug-free interval may be considered, there may be an appreciable risk of a flare of disease. My approach to intraoperative management is as follows: for patients who are undergoing total abdominal colectomy for colonic Crohn's and rectal sparing and who are on biologics with or without steroids, I strongly consider fecal diversion with an ileostomy and perform either a Hartmann closure of the rectum or, depending on specific intraoperative factors, a primary anastomosis with a proximal loop ileostomy. For patients who are not candidates for fecal diversion, such as patients with diffuse jejunoileitis who undergo strictureplasty or patients who undergo ileocolic resection (in whom an ileostomy would be in the proximal ileum), increased vigilance in the perioperative period for prompt recognition and treatment of potential septic complications is warranted. In selected patients, a biologic-free period may be considered but is associated with a risk of flare of disease.

## **RISK OF CANCER**

Ulcerative colitis and Crohn's disease are both associated with an increased risk of colorectal cancer compared to the general population. A population-based series has reported an annual incidence rate of 0.06% to 0.2%, and a meta-analysis showed rates of 2.1%, 8.5%, and 17.8% at 10, 20, and 30

years, respectively.<sup>17-19</sup> Risk factors for the development of colorectal cancer in patients with ulcerative colitis include pancolitis, prolonged disease duration (>8 years), diagnosis at a young age, family history of inflammatory bowel disease, and associated primary sclerosing cholangitis. In patients with Crohn's disease, the risk factors are similar, although the association of cancer in patients with primary sclerosing cholangitis and Crohn's does not appear to be as strong. In addition, inflammatory pseudopolyps are also thought to increase the risk of cancer probably from longstanding inflammation, which is believed to be a risk factor for progression to colorectal cancer. Although surveillance colonoscopy is recommended, there is no clear evidence (based on a Cochrane review) that survival is improved in patients with extensive colitis.<sup>20</sup> However, cancers that were detected appeared to be detected at an earlier stage. Colonoscopic surveillance includes 2 sets of 4-quadrant biopsies in each segment of the colon (right, transverse, left, and rectum), which yield approximately 32 biopsies. Other groups have shown that 33 biopsies per examination were necessary to exclude a diagnosis of dysplasia with 90% confidence. A major limitation of optical colonoscopy is the difficulty in detecting dysplasia by visualization of the mucosa by the endoscopist. To potentially enhance the detection of dysplasia, targeted biopsies with use of magnification chromoendoscopy can be used. With this technique, indigo carmine or methylene blue is used and sprayed over the mucosa of the colon and rectum to improve the visualization of the mucosa. The uptake of the methylene blue dye is different for dysplastic compared to colitic mucosa; the use of indigo carmine details the space between the colonic crypts (facilitating detection of dysplastic tissue from colitis tissue). This technique may be combined with either narrow-band imaging or confocal laser endomicroscopy to further enhance the detection of dysplasia. An advantage of these techniques includes increased detection of dysplastic lesions. Despite this, at present, there are no longitudinal studies showing that the increased detection of lesions resulting from chromoendoscopy decreases cancer-related morbidity or mortality. Switching to chromoendoscopy may increase yield on dysplasia and increase number of colectomies without impacting on mortality and morbidity. The role of chromoendoscopy has promise and continues to evolve.

Patients with pancolitis who have had symptoms for 8 or more years should undergo surveillance colonoscopy every 1 to 2 years. Total proctocolectomy with or without ileal pouch–anal anastomosis is the

recommendation for patients with cancer, non-adenoma-like dysplasia-associated lesion or mass, or high-grade dysplasia.<sup>21</sup> The management of low-grade dysplasia in the setting of ulcerative colitis remains somewhat controversial. Progression to high-grade dysplasia rates vary widely from 0% to over 50%. There may be a role for chemoprevention with 5-aminosalicylic acid (5-ASA), but there are little prospective data. One meta-analysis of 9 observational studies showed a reduced risk of developing colorectal cancer or dysplasia with 5-ASA use.<sup>22</sup>

Following restorative proctocolectomy, routine surveillance of the ileal pouch mucosa for detection of dysplasia is generally not recommended.<sup>21</sup> A small number of pouch-related cancers have been reported, mainly in patients who had colorectal cancer and/or dysplasia at the time of initial pouch construction. Similarly, there is also little evidence to support routine surveillance of the 1- to 2-cm rectal cuff; however, there may be residual inflammation in this area, and a small number of cancers have been reported. Selected surveillance may be performed and patients counseled as to the potential risk of cancer. Patients with small bowel Crohn's disease are also at increased risk for small bowel cancer. When performing a strictureplasty, biopsy of the mucosa has been suggested.

# HEREDITARY COLORECTAL CANCER AND POLYPOSIS SYNDROMES

*Jennifer L. Irani • Elizabeth Breen • Joel Goldberg*

## OVERVIEW

Hereditary colon cancer is a heterogeneous conglomeration of genetic defects that are mostly autosomal dominant in nature and lead to variable risk of colon cancer and other associated cancers. Some of these syndromes are characterized by the formation of traditional adenomas and are caused by defects in tumor suppressor genes and others are in mismatch repair genes. The most common of these include mutations in the tumor suppressor adenomatous polyposis coli (APC) gene that is associated with familial polyposis. Genetic defects in tumor mismatch repair genes (MLH1, MSH2, MSH6, PMS2, and EPCAM) are also associated with the development of adenomas, and these occur in multiple genes that are associated with tumors that have high levels of microsatellite instability (MSI). Finally, there is a

group of less common genetic defects that result in hamartomatous polyposis syndromes such as juvenile polyposis and Peutz-Jeghers syndrome, to name the two most common. We will outline the genetic defects, epidemiology, diagnosis, clinical manifestations, and clinical management for these syndromes.

## FAMILIAL ADENOMATOUS POLYPOSIS

### Introduction

Familial adenomatous polyposis (FAP) is an inherited condition characterized by thousands of polyps in the colon. FAP occurs with a frequency of about 1:10,000 to 1:18,000 live births in Northern Europe and other similar Caucasian populations.<sup>1-3</sup> It accounts for less than 1% of all colorectal cancers. Males and females are affected equally.

### Genetics

FAP is an autosomal dominant colorectal cancer syndrome caused by a germline mutation in the APC gene, located on chromosome 5q21-22. The APC gene is a tumor suppressor gene that functions by suppressing the formation of adenomas in the colon and tumors elsewhere in the body. Approximately 10% to 25% of germline APC mutations are new in individuals without a family history of FAP.<sup>3-5</sup> There is nearly 100% penetrance of the colonic manifestations of FAP but variable penetrance of the extracolonic manifestations of the disease.<sup>6</sup>

Patients with FAP who inherit a single APC mutation acquire a somatic mutation (or “second hit”) in the second allele of the APC gene. A cell with this functional loss of the APC gene has no functional APC protein. This leads to defects in the Wnt signaling pathway, abnormal intracellular accumulation of beta-catenin, unregulated cell growth and division, and formation of adenomas.<sup>7,8</sup> Over 1000 different mutations in the APC gene associated with FAP have been described, and the location of the mutation may influence the phenotypic expression. In other words, there is variable phenotypic expression depending on the location of the mutation in the gene.<sup>9</sup>

For example, patients with mutations near codon 1300 generally develop particularly severe disease with over 1000 polyps and earlier cancer onset.<sup>9,10</sup> Attenuated FAP (<100 colorectal adenomas) is associated with mutations before codon 157 and after codon 1595.<sup>10</sup> Congenital hypertrophy of the retinal pigment epithelium (CHRPE) is associated with mutations between codons 311 and 1444. Mutations after codon 1444 have been linked to the development of desmoid tumors.<sup>10,11</sup>

## Clinical Manifestations

In addition to the numerous colorectal adenomas that characterize FAP, there are a variety of extracolonic manifestations with variable phenotypic expression. Initially, most patients with FAP are asymptomatic. Patients who develop cancer may present with rectal bleeding, abdominal pain, and loose stools. Patients with desmoids can have abdominal pain or bowel obstruction. Finally, patients can develop symptoms from duodenal adenomas and various skin lesions as well.

### COLONIC

Classic FAP is characterized by >100 colorectal adenomatous polyps prior to age 40. Nearly 100% of people with FAP will develop colorectal cancer because of the sheer number of adenomas that develop at an early age. One or more of these polyps usually progresses to form a cancer. Polyps usually start appearing in the late teens to early twenties, and progress to cancer by age 40.

Attenuated FAP is characterized by at least 10 to 20 adenomas, but fewer than 100. Patients usually present later in life than those with classic FAP, and have later onset of colorectal cancer (mean age 55).<sup>12</sup> In attenuated FAP the polyps are found more frequently proximal to the splenic flexure.

### EXTRACOLONIC

Extracolonic manifestations of FAP include upper gastrointestinal polyps that occur in nearly all patients with FAP. Fundic gland polyps occur in most patients with FAP; they are small and rarely progress to cancer.<sup>13,14</sup> In contrast, gastric adenomas are much less common in patients with FAP, are typically located in the antrum, and have a relatively low risk of cancer

progression.<sup>15</sup>

Around 90% of patients with FAP will develop duodenal adenomas; however, only about 5% progress to duodenal cancer.<sup>16</sup> Approximately half of duodenal cancers are ampullary or periampullary.<sup>17</sup>

## **DESMOID TUMORS**

After colorectal cancer and duodenal cancer, desmoid disease is the third leading cause of death in FAP patients.<sup>18</sup> Desmoid tumors are usually found in an intra-abdominal location, especially in the small bowel mesentery and in the abdominal wall. Risk factors for development include trauma, prior surgery, and female sex.<sup>19</sup> In fact, delay of prophylactic colectomy is advocated in patients at high risk for intra-abdominal desmoid disease, if safe. Surgery is to be avoided if possible for intra-abdominal desmoids as the majority are in the small bowel mesentery and can lead to extensive loss of bowel and bleeding. The primary treatment is medical, and includes NSAIDs and antiestrogen therapy.<sup>19</sup> More aggressive regimens include vinblastine/methotrexate and doxorubicin/dacarbazine, and imatinib.<sup>19-21</sup>

## **OTHER EXTRA-INTESTINAL MALIGNANCIES**

These include thyroid cancer, which is usually papillary, and presents in the second or third decade of life. Lifetime risk is about 2%. Annual physical exam with or without neck ultrasound is generally recommended.<sup>19</sup> Other associated tumors such as pancreatic adenocarcinoma, hepatoblastoma, medulloblastoma, and adrenal and biliary cancers have risks <2% in FAP patients, and therefore surveillance tests are not generally recommended unless there is a strong family history.<sup>19,22,23</sup>

CHRPEs are characterized by hyper- or hypopigmentation of the retinal epithelium that have no effect on vision. They are present in over 75% of FAP patients and can act as a screening tool or marker for FAP.<sup>24</sup>

Gardner syndrome was a term used to describe the constellation of colonic polyposis with a number of extracolonic manifestations including sebaceous or epidermoid cysts, lipomas, osteomas, fibromas, supernumerary teeth, gastric fundic gland polyps, desmoid tumors, juvenile nasopharyngeal angiofibromas, and CHRPE.<sup>6,25</sup> Now that it is clear that mutations in the

APC gene are the underlying cause of both Gardner syndrome and FAP, the term “Gardner syndrome” is obsolete as it is not a distinct entity.<sup>6</sup>

## Diagnosis

FAP should be suspected in any patient who is found on colonoscopy to have ten or greater colorectal adenomas. The diagnosis of attenuated FAP (AFAP) should be suspected in any patient who has ten or greater colorectal adenomas over a lifetime. In addition, FAP should be suspected if a patient has a history of colorectal adenomas plus extra-intestinal features of FAP such as duodenal/ampullary adenomas, papillary thyroid cancer, CHRPE, desmoid tumors, epidermal cysts, or osteomas.

The National Comprehensive Cancer Network (NCCN) recommends APC gene testing for persons with a personal history of 20 or greater adenomas, or a known deleterious APC mutation in the family. Per the NCCN guidelines (version 2; 2016) APC and MUTYH gene testing should be considered for patients with a personal history of desmoid tumor, hepatoblastoma, cribriform morular variant of papillary thyroid cancer, or multifocal/bilateral CHRPE. Patients who also have between 10 to 20 adenomas should also be tested for APC and MUTYH mutations.

If a mutation is found, mutation-specific genetic testing should be offered to at-risk family members. This includes all first-degree relatives of the index case and all first-degree relatives of those found to have the APC mutation. The age of testing generally begins around age 10 to 12 years, but may be earlier if the age of onset of polyps in the family is younger. If the familial mutation is found and an individual does not have it, that person can be discharged from surveillance, as they do not have FAP.<sup>22</sup> If a mutation is not found in an affected patient, then the patient and at-risk family members must be under regular surveillance. Genetic counseling should be offered prior to any genetic testing.

## Screening

NCCN Guidelines (version 2; 2016) recommends that patients with a positive APC mutation should have a colonoscopy every 12 months beginning at age 10 to 15 years. Patients should continue to undergo colonoscopic surveillance

while awaiting colectomy. Esophagogastroduodenoscopy (EGD) screening and thyroid ultrasound screening begin around age 20.

In patients with a known familial positive APC gene for attenuated FAP, colonoscopy begins in the late teens and continues every 2 to 3 years, unless polyps are identified. Upper endoscopy should start at age 20 to 25 years as well as an annual thyroid exam. If genetic testing is uninformative or a patient has not been gene tested, screening should still be performed.

## **Management and Surveillance**

In a patient with FAP, colorectal cancer is usually inevitable, so the goal is prevention with either colectomy or proctocolectomy. The timing of surgery and type of operation is individualized based on the patient's polyp burden, family history of age of cancer/polyp formation, and risk of desmoid formation. Most patients with classical FAP undergo surgery between the ages of 16 and 20 years.

Total abdominal colectomy (TAC) with ileorectal anastomosis can be considered if the rectal polyps are amenable to endoscopic surveillance and resection. It is technically simpler than a proctectomy, has a good functional outcome, avoids a permanent stoma, and avoids the risk of sexual or bladder dysfunction and decreased fecundity that can occur following proctectomy. The disadvantage, however, is risk of cancer in the remaining rectum.<sup>26,27</sup> The rectum must be closely surveyed at least annually.

Total proctocolectomy (TPC) with or without ileoanal pouch (ileal pouch-anal anastomosis [IPAA]) is recommended for patients with profuse polyposis or rectal cancer. While TPC with end ileostomy eliminates the risk of colorectal cancer, TPC with IPAA leaves a risk of cancer in the pouch and anal transition zone, and thus requires surveillance. The disadvantages of a rectal dissection include risk of sexual or bladder dysfunction, need for temporary or permanent ileostomy, and variable function (with IPAA).

If the polyps are controlled endoscopically in patients with attenuated FAP, then they may not need a colectomy. If cancer occurs or the polyp burden becomes too great, TAC with ileorectal anastomosis is usually sufficient, as the polyps are most often right-sided. Of course, if polyps are found more distally, then TPC must be entertained.

Surveillance following colectomy or TPC includes endoscopic evaluation

of the rectum or ileal pouch every year and of the ileostomy, if present, every 2 years.<sup>17</sup> Chemoprevention has been entertained to manage the rectum postop. There are currently no FDA-approved medications for this indication. While there are data to suggest that Sulindac is the most potent polyp regression medication, it is not known if the decrease in polyp burden decreases cancer risk.

## **UPPER GI POLYPOSIS**

In patients with classic or attenuated FAP, the American College of Gastroenterology recommends screening for gastric and proximal small bowel tumors using an upper endoscopy including duodenoscopy starting at age 25 to 30 years.<sup>17</sup> The Spigelman staging system of duodenal polyps (based on polyp number, size, histology, and degree of dysplasia) allows for an objective assessment of duodenal polyposis and thus recommended surveillance intervals.<sup>28</sup> Surveillance should be repeated every 0.5 to 4 years depending on the Spigelman stage of duodenal polyposis: 0 = 4 years, I = 2 to 3 years, II = 1 to 3 years, III = 6 to 12 months, IV = surgical evaluation. Examination of the stomach should include random sampling of fundic gland polyps. Low-grade dysplasia is common in fundic gland polyps, and surgery should be reserved for high-grade dysplasia or cancer.<sup>17</sup>

Treatment for duodenal polyposis includes endoscopic and surgical options; pharmacologic agents, namely, NSAIDs, have been used for early disease, although benefits have not been proven.<sup>19</sup> Endoscopic resection with polypectomy or endoscopic mucosal resection for more advanced polyps, and endoscopic thermal ablation of duodenal polyps are all options, although these may have high rates of recurrence.<sup>19</sup> According to the NCCN guidelines (version 2; 2016), surgery is recommended for invasive carcinoma as well as for dense polyposis or high-grade dysplasia that cannot be managed endoscopically. Premalignant lesions may be locally excised via duodenotomy if possible, otherwise pancreas-sparing duodenectomy or pancreaticoduodenectomy is needed, as they are for invasive cancer.<sup>19,29</sup>

## **THYROID CANCER**

Annual thyroid screening by ultrasound is recommended for patients with FAP and attenuated FAP starting in the late teens.<sup>17</sup>

## Summary FAP

Familial polyposis is due to genetic defects in the adenomatous polyposis coli tumor suppressor gene. Depending on the location of the mutation in the gene, there is variable phenotypic expression of the disease. Patients with fullblown FAP generally present in their teens and twenties with hundreds to thousands of polyps, and virtually 100% of these patients end up with colorectal cancer if left untreated by the age of 40. These patients are best managed with TPC with either an ileoanal J pouch or an ileostomy. Patients with attenuated FAP present in their 40s to 60s with tens to a hundred polyps. These patients often have rectal sparing from the polyps and an intermediate operation of TAC with ileorectal anastomosis and surveillance of the retained rectum. Thyroid cancer, desmoids and duodenal and gastric lesions also require close attention.

## MUTYH POLYPOSIS

### Introduction

MUTYH-associated polyposis (MAP) is an autosomal recessive condition associated with an increased risk of colorectal cancer and the early development of multiple adenomatous polyps. This is often referred to as the recessive form of familial polyposis, as many of the clinical manifestations are very similar.<sup>30</sup> Patients with biallelic MYH mutations account for less than 1% of all colorectal cancer cases.<sup>31</sup> Some patients will develop fewer than 100 polyps, while others may have hundreds.<sup>30</sup>

### Genetics

MAP is an autosomal recessive polyposis caused by biallelic (homozygous or compound heterozygous) mutations in the MUTYH gene. MUTYH is a base excision repair gene, and thus is involved with correcting the effects of oxidative damage to the DNA.<sup>17,32</sup> This leads to a G:C → A:T transversion in the APC and KRAS genes and hence adenomatous polyposis and serrated polyps. The two most prevalent MUTYH mutations in individuals of

European descent with MAP are two missense mutations, Y179C and G396D. Although many other distinct MUTYH mutations have been found, approximately 90% of Western MAP patients have at least one of these two mutations.<sup>17,33</sup>

## Clinical Manifestations

Colonic and extracolonic manifestations can be present in patients with MUTYH-associated polyposis. The colonic phenotype in patients with MAP can be variable, but patients with MAP usually develop 10 to 100 colorectal polyps.<sup>17,32</sup> Colorectal cancer develops at an average age of 48 years. Although patients with MAP predominantly have adenomas, multiple hyperplastic and/or sessile serrated polyps may occur. Patients with MAP have an approximate lifetime risk of colorectal cancer (CRC) of 70% to 75% while those with a monoallelic MUTYH mutations may only have a marginally increased risk.<sup>17,34,35</sup>

Data on extracolonic manifestations of MAP are limited. However, there does appear to be an increased risk of duodenal cancer.<sup>36</sup> Other extracolonic findings include gastric polyps, endometrial cancer, breast cancer, ovarian cancer, bladder cancer, various skin cancers, thyroid cancer, sebaceous gland adenomas, lipomas, CHRPE, osteomas, desmoid tumors, and epidermoid cysts.<sup>17,36</sup>

## Diagnosis

Patients with at least 10 adenomas in their lifetime, a known family germline mutation, or a history of adenomas in combination with extracolonic features associated with MUTYH-associated polyposis (duodenal adenomas, desmoid tumors, thyroid cancer, CHRPE, epidermal cysts, or osteomas) should be considered for genetic testing for MUTYH-associated polyposis.<sup>17,37</sup> The family history follows an autosomal recessive pattern of inheritance. The diagnosis is established by biallelic germline mutations in the MUTYH gene. If the mutation is found, mutation-specific genetic testing should be offered to at-risk relatives of the index case.

## Management and Surveillance

Patients at risk for or affected with MAP should undergo yearly colonoscopy starting at puberty.<sup>17</sup> If the polyp burden becomes unmanageable, or if cancer is present, then colectomy is indicated. The type of operation depends on rectal polyp burden. As for AFAP, if the rectum is manageable endoscopically, then total colectomy with ileorectal anastomosis can be entertained. TPC (with or without restoration) may be needed if the rectal polyp burden is unmanageable. Surveillance following colectomy or TPC includes endoscopic evaluation of the rectum or ileal pouch every year, and of the ileostomy, if present, every 2 years.<sup>17</sup>

Just as in patients with classic or attenuated FAP, the American College of Gastroenterology recommends MAP patients undergo screening for gastric and proximal small bowel tumors using an upper endoscopy including duodenoscopy starting at age 25 to 30 years.

There is no consensus as to whether monoallelic MUTYH mutations warrant increased CRC screening.<sup>17</sup>

## Summary MUTYH Polyposis

MUTYH polyposis is a defect in an autosomal recessive base excision repair gene. It is often called the recessive familial polyposis. Surgical therapy for the colon is predicated upon the number and distribution of polyps in the colon. It is generally best treated with TPC with ileoanal J pouch for patients with rectal involvement and TAC with ileorectal anastomosis for patients with a spared rectum. Although it is a different genetic defect, the management principles are like those for FAP. The surgeon should also be mindful that carriers of the recessive gene are at increased risk of colorectal cancer as well.

## HEREDITARY NONPOLYPOSIS COLORECTAL CANCER

### Introduction

Hereditary nonpolyposis colorectal cancer (HNPCC), also known as Lynch syndrome, is the most common form of inherited colon and rectal cancer. It is responsible for approximately 3% of all cases of both endometrial and colon cancer. It is inherited in an autosomal dominant fashion. Affected kindreds are characterized by multigenerational involvement, with the offspring of affected individuals having a 50% chance of inheriting the disorder such that in large kindreds several offspring can be affected. Individuals often have more than one index cancer and generally the cancers present before the age of 50 years. The most common cancers with associated lifetime risks without surveillance are colorectal cancer (80%), uterine cancer (50%), ovarian cancer (20%), transitional cell carcinoma (5%), gastric cancer (5%), and cancers of the pancreas (1%), small intestine (1%), and the biliary system (1%). Some families are also affected with prostate and breast cancer. The genetic defects responsible for HNPCC are germ line mutations in a DNA mismatch repair (MMR) gene. For the most part, tumors in affected patients have loss of MMR as well as being high in MSI. The diagnosis of HNPCC requires a high index of suspicion combined with sound interpretation of MSI status and immune-histochemical (IHC) staining in patients at risk. In patients with a suggestive clinical and family history if MSI status and IHC staining indicate HNPCC, germline testing should be undertaken.

## Genetics

The most common MMR mutations identified are MLH1 (chromosome 3p21) in 37% of affected individuals, MSH2 (chromosome 2p16) in 41% of affected individuals, MSH6 (chromosome 2p16) in 13% of affected individuals, and PMS2 (chromosome 7p22) in 9% of affected individuals.<sup>38</sup> In an even smaller group of patients a genetic defect in the 3' end of the epithelial cell adhesion molecule (EPCAM) carries over to the neighboring MSH2 gene, silencing the MSH2 gene, resulting in HNPCC. These patients are at increased risk of colon cancer but generally not the extracolonic cancers such as uterine cancer. Defects in the EPCAM gene on chromosome 2 account for less than 3% of cases of HNPCC.<sup>39</sup> Dr. Henry T. Lynch of Creighton University first identified two kindreds in 1966 with the clinical features of HNPCC.<sup>40</sup> The actual responsible genes were finally identified in the 1990s independently and simultaneously by the laboratories of Dr. Richard Kolodner at Dana Farber Cancer Institute and Dr. Bert Vogelstein at

Johns Hopkins.

Defects in MMR proteins result in an increased risk for the development of a multitude of cancers. These genes are responsible for repairing erroneously substituted base pairs, and insertions and/or deletions of segments of DNA that occur during cellular replication and division. Affected individuals have a mutation at one allele, and the second allele is usually inactivated by a variety of mechanisms that then results in failure to repair the aforementioned DNA mismatches. The regions most often affected are areas of repetitive nucleotide sequences called microsatellites. Hence a common feature of HNPCC is high levels of MSI. In turn, MSI affects genes that regulate cell death and growth, resulting in unregulated cell growth and/or cell death and thereby cancer.<sup>41</sup> In the last 25 years since the discovery of the MMR genes responsible for HNPCC identification, management and surveillance of affected individuals and their families has dramatically improved. The risk of developing cancer in known MMR carriers by each gene is lower than in the past. [Table 48-1](#) identifies the risk of each cancer depending on which gene is affected. Genetic defects in the PMS gene are rare and hence fewer patients with these mutations were identified and followed prospectively. Generally, it is felt that the risk for each of these cancers is even less in patients with a PMS 2 mutation.<sup>42</sup>

**TABLE 48-1: CANCER RISK BY MMR GENETIC DEFECT**

	MLH1	MSH2	MSH6
Colorectal cancer	46%	43%	15%
Endometrial cancer	43%	57%	46%
Ovarian cancer	10%	17%	13%
Upper GI cancers (bile duct, pancreas, duodenum, and gastric)	21%	10%	7%
Urinary tract cancers	8%	25%	11%
Prostate cancer	17%	32%	18%
Brain cancer (glioblastoma)	1%	5%	1%

## Clinical Manifestations

As previously mentioned, HNPCC is characterized by a multigenerational pattern with multiple affected family members with multiple cancers at a younger age than when diagnosed in a sporadic fashion. The average age at diagnosis for a patient with sporadic colon cancer is 70, whereas in HNPCC it is between 45 and 60 years of age.<sup>43-45</sup> Moreover, up to 7% of patients with HNPCC have a synchronous cancer or multiple cancers at the time of diagnosis.<sup>46</sup> In patients with documented HNPCC, the recommended operation is a TAC with ileorectal anastomosis or a subtotal colectomy with an ileosigmoid anastomosis. In patients who have only a segmental colectomy or an isolated rectal resection, the risk of metachronous cancers is shown in Table 48-2.<sup>47,48</sup>

**TABLE 48-2: APPROXIMATE RISK OF METACHRONOUS CANCER IN HNPCC WHEN FIRST CANCER IS TREATED WITH A SEGMENTAL RESECTION**

	Colon Cancer	Rectal Cancer
10 years	15%	20%
20 years	40%	45%
30 years	60%	70%

The increased risk for metachronous cancers outlined above underscores the importance of a high index of suspicion for HNPCC in patients diagnosed with either colon cancer at a young age and/or multiple cancers and/or those with multiple affected relatives with cancers of the gastrointestinal, genitourinary, and gynecologic organ systems. The name for Lynch syndrome (HNPCC) can be misleading and cause some people to assume that these cancers develop in the absence of polyps. HNPCC is so named to distinguish Lynch syndrome from traditional FAP, which has hundreds to thousands of polyps. HNPCC develops usually from a single polyp that tends more often to be flatter, villous, and located in the right colon than that seen in individuals with sporadic colon cancers. Moreover, the characteristic histopathologic features associated with HNPCC are such that these tumors have a higher incidence of mucinous and signet cell histology, tend to be

poorly differentiated, and tend to have a lymphocytic Crohn's-like infiltrate.<sup>49,50</sup> The progression from an adenoma to an invasive cancer is also more rapid in patients with HNPCC, being on the order of 1 to 2 years versus 10 years.<sup>51-53</sup>

The most common extracolonic manifestations of HNPCC are cancers of the gynecologic (uterine and ovarian cancer) and genitourinary system (see [Table 48-1](#)). Although colon cancer and endometrial cancer are the most commonly recognized cancer in HNPCC, careful attention must be paid to all associated cancers. The penetrance in patients who have a MMR defect is not 100%, and careful screening and surveillance reduces the risk of both subsequent cancers and death.

## Diagnosis and Management

Considerable effort has been placed on early diagnosis based on clinical criteria. This helps identify at-risk individuals for treatment, screening, and surveillance. The most accepted clinical criteria are the Amsterdam I ([Table 48-3](#)), defined in 1990 and Amsterdam II ([Table 48-4](#)), defined in 1999.<sup>54,55</sup> Additional clinical criteria include the Bethesda ([Table 48-5](#)), defined in 1997<sup>56</sup> and the revised Bethesda ([Table 48-6](#)), defined in 2004.<sup>57</sup> The Amsterdam criteria are the most commonly utilized. The 3-2-1 rule of thumb makes it easy to remember these criteria. Amsterdam I criteria applied only to patients with colorectal cancer. There had to be three affected family members where one was a first-degree relative of the other two affected individuals. Two generations had to be involved and one person had to be diagnosed prior to the age of 50 years. Amsterdam II criteria were expanded to include patients with extracolonic index cancers. In both sets of the Amsterdam criteria, familial polyposis had to be excluded as a cause for the cancer. The Bethesda criteria were created to determine which colorectal tumors and extracolonic tumors should have MSI testing. In addition, several prediction models have been developed to aid in assessing which patients with appropriate clinical criteria will have a positive MMR genetic test. In fact, these prediction models are often used to determine that patients with a less than 5% chance of having a positive test should not have germline testing, as it is not cost effective. The most prominent models are the MMRpredict model,<sup>58,59</sup> the MMRpro model,<sup>60</sup> and the PREMM model.<sup>61</sup>

**TABLE 48-3: AMSTERDAM I CRITERIA (1990)**

1. Three relatives with colorectal cancer with one whom is a first-degree relative of the other two.
2. These three relatives must involve two successive generations.
3. One person must be diagnosed before the age of 50 years.
4. Familial polyposis coli must be excluded.

**TABLE 48-4: AMSTERDAM II CRITERIA (1999)**

1. Three or more relatives with a HNPCC-associated cancer (colon, uterus, urinary tract, ovary, small intestine, stomach, hepatopancreatobiliary).
2. Two or more successive generations.
3. One person must be diagnosed before the age of 50 years.
4. One person must be a first-degree relative of the two affected individuals.
5. Familial polyposis coli must be excluded.
6. Histologic confirmation of the index cancer.

**TABLE 48-5: BETHESDA CRITERIA (1997)**

1. Individuals with cancer in families that meet the Amsterdam criteria
2. Individuals with two HNPCC-related cancers, including synchronous and metachronous colorectal cancers or associated extracolonic cancers (endometrial, ovarian, gastric, hepatobiliary, or small-bowel cancer or transitional cell carcinoma of the renal pelvis or ureter)
3. Individuals with colorectal cancer and a first-degree relative with colorectal cancer and/or HNPCC-related extracolonic cancer and/or a colorectal adenoma; one of the cancers diagnosed at age <50 yrs, and the adenoma diagnosed at age <40 yrs
4. Individuals with colorectal cancer or endometrial cancer diagnosed at age <50 yrs
5. Individuals with right-sided colorectal cancer with an undifferentiated

- pattern (solid/cribriform) on histopathology diagnosed at age <50 yrs
6. Individuals with signet-ring-cell-type colorectal cancer diagnosed at age <50 yrs
  7. Individuals with adenomas diagnosed at age <40 yrs
- 

**TABLE 48-6: REVISED BETHESDA CRITERIA (2004)**

1. Colorectal cancer diagnosed in a patient who is less than 50 yrs of age
  2. Presence of synchronous, metachronous colorectal, or other HNPCC-associated tumors (colorectal, endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, small bowel, brain, and sebaceous gland adenomas and keratoacanthomas), regardless of age
  3. Colorectal cancer with the MSI-high histology (presence of tumor infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern) diagnosed in a patient who is less than 60 yrs of age
  4. Colorectal cancer diagnosed in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed under age 50 yrs
  5. Colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age
- 

In addition to the outlined clinical criteria and above prediction models, some advocate for direct tumor testing for MMR defects, MSI testing, and/or IHC for MMR on tumor tissue. Many strategies exist using combinations of these tests. No method is 100% sensitive or specific for making the diagnosis of HNPCC. Ultimately the diagnosis is made by a combination of clinical suspicion, MSI and IHC testing on the tumor, and then confirmatory germline testing on known true positives in a kindred suggestive of HNPCC.

In several instances, conflicting data exists such that it appears a patient has HNPCC when in reality the cancer is sporadic. Some examples of this include hypermethylation of MLH1 promoter, loss of heterozygosity of the normal allele, and double somatic mutations in an MMR gene. In some instances of IHC staining, tumors will have a loss of IHC staining in MLH1 and PMS2. This is due to the hypermethylation of the MLH1 promoter (a

somatic defect) and this leads to loss of the function of MLH1 and a MSI-H tumor. At this point, testing for BRAF mutations is essential to rule out Lynch syndrome. A wild-type BRAF gene is unusual in a Lynch cancer. So an MSI-H tumor with a BRAF mutation is almost always due to a somatic mutation that leads to promoter hypermethylation and loss of MLH1 function and not a true Lynch syndrome cancer.<sup>62-64</sup> The management of patients with HNPCC requires a multidisciplinary approach. The first step is the identification and testing of at-risk patients and their families, followed by treatment of known cancers and then screening and surveillance of patients with a known MMR genetic defect.

## Screening

### COLORECTAL CANCER

Patients with known Lynch syndrome should have a yearly colonoscopy.<sup>52,65</sup> Those with a known MMR defect should start screening at the age of 25 or 5 years prior to the age of earliest diagnosis of a cancer in their family, whichever age is earlier.<sup>17,66</sup> Early and diligent colonoscopy has been shown to reduce the risk of colorectal cancer as well as the mortality in affected individuals.<sup>67</sup>

### GYNECOLOGIC MALIGNANCY

Women with known Lynch syndrome should have a yearly exam with their gynecologist to include an endometrial biopsy and a transvaginal pelvic ultrasound to evaluate the ovaries. Checking the CA-125 tumor marker is advocated by some clinicians every 6 to 12 months. Screening for gynecologic malignancy should start in the beginning of the fourth decade (30 years of age). Moreover, prophylactic total abdominal hysterectomy with bilateral salpingo-oophorectomy is recommended once childbearing is completed or at any time a colectomy is needed if it has not already been done.<sup>68</sup>

### GASTRIC CANCER

There is little evidence that prophylactic screening for gastric cancer in

Lynch syndrome patients reduces the risk of gastric cancer. Despite the lack of efficacy, most groups recommend every-3-year EGD with *Helicobacter pylori* testing at the same time as the colonoscopy. For patients with a history of gastric cancer in the kindred, yearly EGD is recommended. Due to the lethality of gastric cancer, most clinicians tend err on the side of caution and recommend screening, especially since this procedure can be done concomitantly with the yearly colonoscopy.

## **SMALL INTESTINE CANCER**

There is no role for routine screening of the small intestine in patients with Lynch syndrome. For patients with a family history of small intestine cancer and/or iron deficiency anemia or unexplained gastrointestinal (GI) symptoms, a wireless capsule endoscopy or magnetic resonance (MR) enterography can be performed every few years.<sup>69</sup>

## **PANCREATIC CANCER**

Once again, the lifetime risk of pancreatic in known carriers of an MMR defect is approximately 1%, so screening is not recommended for everyone. Lynch syndrome patients with a single first-degree relative with a history of pancreatic cancer should be considered for screening with yearly magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasound (EUS) of the pancreas. If a kindred has multiple instances of pancreatic cancer in non-first-degree relatives, careful consideration for screening should be undertaken.<sup>17,70</sup>

## **URINARY TRACT CANCER**

Urine cytology and urinalysis can be performed starting at the age of 30. However, in families without a known history of genitourinary tract tumors, sensitivity and specificity are low for the detection of urinary tract cancers. Certainly MMR defect carriers with gross or microscopic hematuria require further investigation of the genitourinary tract with ultrasound and/or CT imaging as well as cystoscopy. It is reasonable to screen Lynch families with a known history of urothelial cell carcinoma with yearly urine cytology and urinalysis.<sup>17</sup>

## SKIN CANCER

Yearly dermatologic exam to identify sebaceous adenomas and sebaceous adenocarcinoma should be undertaken. In a patient who has a sebaceous neoplasm, a directed family history focusing on Lynch syndrome–associated cancers should be performed.

## PROSTATE, BREAST, AND CENTRAL NERVOUS SYSTEM

Yearly screening for prostate and breast cancer as directed for the general population should suffice for patients with Lynch syndrome. Any central nervous system (CNS) symptoms should be promptly investigated.

## Surgical Management of Colorectal Cancer

The preferred treatment of colon cancer and endoscopically unresectable adenomas in patients with HNPCC is TAC with ileorectal anastomosis or subtotal colectomy (STC) with ileosigmoid anastomosis. A segmental colectomy leaves behind at-risk colon and makes screening more difficult because a full colonoscopy with a complete bowel preparation is required. The TAC or STC operations provide risk reduction by removing additional at-risk colon and make future screening much easier, as only a flexible sigmoidoscopy is needed. Moreover, most patients have excellent function, with an average of 3 to 4 bowel movements (BMs) daily with either a TAC or STC. Patients who have a segmental colectomy are at increased risk for metachronous colorectal cancer (see [Table 48-2](#)) as well as adenomas.<sup>71</sup> Patients with Lynch syndrome and rectal cancer pose a unique problem. Sphincter preservation is usually desired but risks a second surgery as these patients are at increased risk for metachronous colon cancers (see [Table 48-2](#)). Moreover, a more complex reoperation in the pelvis is a real risk. Hence there are four main operations outlined below for this cohort of patients. Each operation has its risks and benefits ([Table 48-7](#)):

**TABLE 48-7: RISKS AND BENEFITS OF OPERATIONS FOR RECTAL CANCER IN LYNCH SYNDROME**

	Risks/Negative Aspects	Benefits/Positive Aspects
LAR	At-risk colon Reoperative pelvis	Intact GI continuity No ostomy
APR	At-risk colon Permanent ostomy	No reoperative pelvis
TPC w/Ileostomy	Ileostomy (watery)	No at-risk colon
IPAA	Infertility (young women) Liquid BMs	Intact GI continuity No at-risk colon

1. Low anterior resection (LAR) with restoration of GI continuity.
2. Abdominal perineal resection (APR) with colostomy.
2. TPC with ileostomy.
4. TPC with ileoanal J pouch (IPAA) reconstruction.

In general, most patients want restoration of GI continuity, so that makes either an LAR or IPAA preferable to most affected individuals. The APR is reserved for patients with a rectal cancer invading the sphincter complex or a patient with poor sphincter function (preexisting difficulty controlling BMs). Men older than 70 and women older than 65 generally do not have good pouch function, so an IPAA is generally not offered in these age groups. The TPC with ileostomy is reserved for the patients with a rectal cancer invading the sphincter and a synchronous colon cancer, patients with poor sphincter function and synchronous cancers, or patients who do not mind an ostomy and desire maximum risk reduction.

## Summary HNPCC

Making the diagnosis of Lynch syndrome requires a high index of suspicion and careful decision making regarding which testing to order. Germline testing can be expensive and is often unrevealing. Using the Amsterdam criteria to identify at-risk patients and then doing microsatellite instability (MSI) testing and IHC staining on the tumor cells and normal tissue can further narrow the population that needs germline testing. For patients with HNPCC and a new colon cancer and good anal sphincter function, a TAC

with an ileorectal anastomosis is the preferred operation as it maximizes risk reduction and minimizes at-risk colon to screen. For HNPCC patients with rectal cancer there are several options, depending on sphincter function, location of tumor, patient's age, and the desire for restoration of GI continuity versus risk reduction. These are personal decisions, and the counsel of a surgeon experienced with caring for patients with the combination of HNPCC and rectal cancer can be very helpful in making the right surgical decision. For Lynch syndrome patients who have not had a colectomy, a yearly colonoscopy is recommended, and every 3 years an EGD. For women of childbearing age, yearly gynecologic exams with transvaginal ultrasound and endometrial biopsy  $\pm$  CA-125 is also recommended. Total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH-BSO) is recommended for all women who have completed childbearing.

## OTHER POLYPOSIS SYNDROMES

### Colon Cancer Syndrome X

Patients with genetic syndromes that increase their predisposition for developing colorectal cancers will benefit from having their syndromes better understood. The more that is known, the more likely that appropriate strategies for screening, counseling, and treatment for those patients and their relatives can be delivered. One genetic syndrome that is becoming better understood is HNPCC. Although these patients, similar to the majority of patients who develop colorectal cancers, develop adenomas as precursors to adenocarcinomas, they were named as nonpolyposis to contrast to them to familial syndromes where patients develop multitudes, often a hundred or more, polyps, such as FAP.<sup>72</sup> Patients with HNPCC are defined by what is known as the Amsterdam criteria.<sup>73</sup> The Amsterdam criteria is based on family history and requires that at least three family members are affected by colorectal cancer over two or more generations, with one being a first generation relative of the other two and at least one individual diagnosed before the age of 50.<sup>19,72,73</sup> There are subtypes of the Amsterdam criteria that depend on whether there are extracolonic manifestations or not. Amsterdam criteria one (AC1) involves all family members having colorectal cancer,

while Amsterdam criteria two (AC2) includes families with extracolonic cancers, such as endometrial and uroepithelial cancers.<sup>73,74</sup> It has been shown that a subgroup of families with HNPCC had genetic mutations in defined set of mismatch repair genes, and this cohort is referred to as Lynch syndrome. Another subset of families, who met the Amsterdam criteria but did not have any of these mutations in the mismatch repair genes, have been named as having colon cancer syndrome X.<sup>72,75</sup>

Less is known about colon cancer syndrome X than Lynch syndrome, but there appear to be differences between the two syndromes that may influence screening and management strategies for affected families and perhaps improve our understanding of colorectal cancer pathogenesis overall. The incidence of patients with colon cancer syndrome X, while not clearly defined, is estimated to be 2% to 4% of all colorectal cancers.<sup>76,77</sup> The patients with colon cancer syndrome X do not have mutations in the mismatch repair genes shown to harbor mutations in patients with Lynch syndrome. Early studies show that mutations that might be involved in colon cancer syndrome X include genes such as ZRANB1, CDC27, CENPE, CTBP2, IRF5, and BTNL2 that truncate proteins involved in cell shape, motility, mitosis, transcription, and immune response. These mutations may or may not be the cause. The complexity is heightened by the potential lack of penetrance in colon cancer syndrome X to begin with.<sup>78,79</sup> As of yet, there is no genetic testing to identify patients with colon cancer syndrome X.

Histopathologically, tumors from patients with colon cancer syndrome X differ from patients with Lynch syndrome. The tumors are more likely to be moderately differentiated rather than poorly differentiated. They are more likely to harbor a tubular architecture and have serrated projections. They also have less mucin production and presence of tumor-infiltrating lymphocytes.<sup>80</sup> A lack of clear similarity in the histopathology, however, has been noted. This lack of a distinctive morphology has led to the recommendation that a diagnosis of colon cancer syndrome X should involve morphology with a family history.<sup>81</sup>

Clinically, patients with colon cancer syndrome X are different than patients with Lynch syndrome. They tend to be a bit older at diagnosis, with an average age of 57 at presentation, harbor more left-sided tumors, have a slower progression from adenoma to adenocarcinoma, and have less risk of non-colorectal cancers.<sup>75,81</sup> Recommendations for surveillance colonoscopies

still begin at 5 to 10 years younger than the age at which any affected family member was diagnosed but allow for an interval of a follow-up colonoscopy of every 3 to 5 years.<sup>82</sup>

In summary, colon cancer syndrome X is found in patients who meet the Amsterdam II criteria but have no identifiable genetic mutation in an MMR gene. These patients have a predilection for colon and rectal cancer but not the other cancers associated with HNPCC. Surgical management of their colonic disease mirrors management for patients with Lynch syndrome.

## Juvenile Polyposis

Juvenile polyposis syndrome is a rare (1:100,000 births) autosomal dominant syndrome that leads to the development of polyps in the colon and rectum.<sup>83</sup> Although it is a genetic syndrome, a family history is only found in 20% to 50% of cases, implying that many patients are the first in their families to acquire the mutation responsible for the syndrome.<sup>84</sup> Mutations that have been identified include a mutation in the SMAD-4 tumor suppressor gene on chromosome 18q21 or in the BMPR1-A gene on chromosome 10q23.<sup>85</sup> The syndrome is characterized by the development of multiple hamartomatous polyps in the gastrointestinal tract. Although patients typically develop between 50 and 200 polyps, you only need one polyp plus a family history to be diagnosed with the syndrome. Patients can present with anemia or rectal bleeding from the polyps or pain from prolapsed polyps. Histologically, the polyps contain no smooth muscle and can detach from the bowel wall and pass per anus. If they are noted on colonoscopy, however, they should be removed, as they can contain adenomatous dysplasia and progress to adenocarcinoma. Patients have a 30% to 50% cumulative lifetime risk of developing colorectal carcinoma, a 13.7% risk of developing gastric cancer, a 10% to 20% risk of developing cancer in the upper GI tract, a 3.4% risk of developing duodenal, and a 3.4% risk of developing pancreatic cancer.<sup>83,84</sup> Surveillance is recommended to define the extent of the polyposis and remove the polyps. Patients begin receiving screening colonoscopies and esophagogastroduodenoscopies by age 15 or at the time of diagnosis. The screening continues every year until the polyps are cleared and is then repeated every 2 to 3 years thereafter.<sup>84</sup> If the polyps are too numerous to clear or too large to be removed endoscopically, patients may require a TAC

with an ileorectal anastomosis or a TPC with a restorative IPAA.

## Peutz-Jeghers Polyposis

Peutz-Jeghers syndrome is a rare (1:120,000-200,000 births) autosomal dominant syndrome with variable to high penetrance that leads to the development of polyps within the colon and rectum. Seventy percent of patients with Peutz-Jeghers syndrome have a mutation of the serine threonine kinase gene, STK11/LKB1. The syndrome is characterized by the development of multiple hamartomatous polyps in the gastrointestinal tract, most commonly in the small bowel and colon and rectum. Less commonly, patients can develop polyps in the stomach or urinary tract. The polyps can range in size from 0.5 cm to 5 cm and can develop adenomatous changes progressing to adenocarcinoma.<sup>19</sup>

Most visibly, patients with Peutz-Jeghers syndrome will develop mucocutaneous pigmentation in locations including the lips, buccal mucosa, eyes, nostrils, hands, and feet. This pigmentation occurs in infancy but fades by late adolescence or adulthood. The presence of the pigmentation allows patients to be identified for screening. These patients may be asymptomatic. The polyps, however, can lead to clinical presentation of symptoms of blood loss, anemia, and/or obstruction from bleeding or intussusception.<sup>86</sup> Patients have risks of developing malignancy in the polyps or other associated malignancies as well as the risks incurred from benign polyps that result in clinical scenarios resulting in multiple operations. The cancers occur in the breast (lifetime risk of 54%), colon and rectum (20%-39%), pancreas (30%-36%), small bowel, stomach (5%), esophagus, uterus, ovary, testicle, and lung.<sup>87</sup> Repeated laparotomies and bowel resections for bleeding and/or intussuscepting polyps can lead to short bowel or problematic adhesions. Surveillance strategies are designed to find lesions that are likely to become emergently symptomatic or are precursors to malignancy. To address the lesions within the small bowel, at age 8 to 10 patients undergo baseline EGD, barium studies, and capsule endoscopies, and repeat these studies every 2 to 3 years if they are revealing. If no small bowel polyps are seen, further studies are deferred until age 18, when they are resumed along with colonoscopies to address polyps within the colon and rectum. These studies are repeated every 2 to 3 years.<sup>88,89</sup> If at any point symptomatic polyps or asymptomatic polyps

greater than 1.5 cm in size are noted, they are removed. This can be done endoscopically or via combined laparotomy/laparoscopy with on-table enteroscopy or enterotomy. As these patients are at risk for extracolonic malignancies they are also screened for breast, testicular, pancreatic, uterine, and ovarian cancer with appropriate physical examinations, imaging, tumor marker, and genetic testing.<sup>88</sup>

## **Cowden Syndrome**

Cowden syndrome is a rare (1:200,000-250,000 births) autosomal dominant polyposis syndrome. The mutation that leads to this syndrome is in the PTEN gene, which interestingly is the same gene that is mutated in the phenotypically different Bannayan-Riley-Ruvalcaba syndrome.<sup>90</sup> Patients with Cowden syndrome develop polyps in the colon and rectum 30% to 90% of the time, for which there is a risk of development into adenocarcinoma.<sup>91</sup> The rarity of this disease has made it difficult to truly understand the risk of developing colorectal cancer and hence produce colonoscopic screening guidelines. Most authors, however, recommend that colonoscopic screening begin between the ages of 35 to 45 and proceed at a frequency determined by the degree of polyposis found at the scope.<sup>91-93</sup> Patients with Cowden syndrome also develop hamartomas in their mouth, leading to a nodular-appearing buccal mucosa, and elsewhere in their GI tracts. These patients are also at risk for macrocephaly, trichilemmomas, and benign and malignant neoplasms of thyroid, breast, uterus, and skin.<sup>94</sup>

## **Bannayan-Riley-Ruvalcaba Syndrome**

Bannayan-Riley-Ruvalcaba syndrome is a rare autosomal dominant polyposis syndrome. The mutation that leads to this syndrome is in the PTEN gene, which interestingly is the same gene that is mutated in the phenotypically different Cowden syndrome.<sup>95</sup> Patients with Bannayan-Riley-Ruvalcaba syndrome develop juvenile polyps 50% of the time. They are also at risk for developing pigmented macules on the penis, macrocephaly, intellectual disabilities, lipomatosis, and hemangiomas. The risk of developing colorectal cancer is unclear, thus screening recommendations are not standardized.<sup>96</sup>

## Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome is a very rare polyposis syndrome with no evidence of inheritance. In adulthood, these patients develop gastrointestinal hamartomas. The polyps are located predominantly in the duodenum, additional segments of the small bowel and the stomach. The polyps can develop adenomatous changes and there is a 10% risk of developing adenocarcinoma. The mucosa of the stomach can be abnormal, leading to malabsorption, protein loss, and hypokalemia. In addition, these patients are at risk to develop alopecia, onychodystrophy, and hyperpigmentation of the skin of the face and eyelids.<sup>85,97</sup>

## CONCLUSION

Polyposis syndromes are a variable group of genetic diseases that account for a small but measurable number of patients with colorectal cancer as well as other associated extracolonic neoplasms. Most are autosomal dominant but a few recessive variants exist. Known kindreds should be enrolled in a genetic registry, and a formal screening plan should be in place for all affected family members. Unaffected family members can be screened for colorectal cancer as a normal person in the population at large. Furthermore, a high index of suspicion in patients with a strong family history of cancer may identify new undiagnosed kindreds that can then lead to a screening program for that extended family. This has the potential to prevent many cancers or manage those diagnosed at an early and curable stage.

# TUMORS OF THE COLON

*Trevor M. Yeung • Neil J. Mortensen*

## INTRODUCTION

*Tumor* is a descriptive term for a growth or mass of cells that are independent of the physiologic function or demand of their surrounding structures. The 2 characteristic biologic growth patterns of tumors include the ability to (1) disrespect tissue boundaries and invade other structures (*invasiveness*) and (2) gain access to blood and lymph vessels or other structures to spread tumor cells to distant locations and allow these specially equipped cells to survive and grow new remote tumors (*metastases*). If a tumor does not have either property, it is *benign*; if a tumor can invade locally but even at a large size does not have a tendency to metastasize, it is called *semimalignant*; and if a tumor has the ability to metastasize once a sufficient size is reached, it is a *malignant* tumor.

Colorectal lesions may be classified as benign, potentially malignant, or malignant based on their pathologic features ([Table 49-1](#)); the semimalignant variant with invasion only but no affinity to later form of metastases is not common in the colon. The overwhelming majority of colorectal tumors are of epithelial origin and arise from the mucosal surface, where they become visible descriptively as a polyp. Benign polyps include nonneoplastic polyps

(eg, hyperplastic, hamartomatous, or inflammatory polyps); the potentially malignant group consists of adenomatous polyps. Once dysplastic cells in a polyp cross the boundaries of the mucosa (basement membrane and muscularis mucosae) and start to invade the submucosa and the muscularis mucosae, a true cancer (carcinoma) with the potential to metastasize is established. Tumors of nonepithelial or mesenchymal origin are comparably rare and include, among others, lipoma, lymphoma, carcinoid, and sarcoma.<sup>1-3</sup>

**TABLE 49-1: INTRODUCTION: CLASSIFICATION OF COLON TUMORS**

**A. Epithelial Tumors of the Colon**

Type	Class	Subclassification
Benign lesions	Hyperplastic polyps Noninherited gastrointestinal polyposis syndromes Hamartomas Inflammatory polyps	— Hyperplastic polyposis Juvenile polyps Cowden syndrome Bannayan-Riley-Ruvalcaba syndrome Cronkite-Canada syndrome —
Potentially malignant lesions/syndromes	Adenomatous polyps Hereditary adenomatous polyposis syndromes Noninherited gastrointestinal polyposis syndromes Inherited hamartomatous polyposis syndromes	Sporadic colon cancers Hereditary colon cancers Familial adenomatous polyposis (FAP) Attenuated familial adenomatous polyposis (AFAP) Cronkite-Canada syndrome Juvenile polyposis syndromes Peutz-Jeghers syndrome
Malignant lesions	Epithelial tumors of the colon	Sporadic colon cancers Familial colorectal cancer Hereditary nonpolyposis colon cancers (HNPCC) Familial/hereditary polyposis coli cancers

**B. Nonepithelial Tumors of the Colon**

Type	Class
Benign lesions	Lipomas and lipomatous polyposis
Potentially malignant lesions/syndromes	Carcinoid/neuroendocrine tumors Gastrointestinal stromal tumors (GISTs)
Malignant lesions	Nodular lymphoid hyperplasia of the colon Lymphoma

**C. Secondary Tumors to the Colon**

Type	Class
Benign lesions	Endometriosis
Potentially malignant lesions/syndromes	Leukemia Endometriosis transforming to cancer
Malignant lesions	Lymphoma Malignant melanoma Carcinomas from other primary sites

Colonic tumors are important for 2 reasons. First, they are frequent and account for both a significant mortality rate as well as high cumulative health care costs. Second, the sequence of events leading from a normal mucosa to a manifest cancer occurs through largely preventable precursor stages over the course of several years. Thus, this chapter predominantly focuses on the detection, management, and prevention of these conditions.

## **EPIDEMIOLOGY**

Colorectal cancer is the most common malignancy in the gastrointestinal tract. In the United States, colorectal cancer is the third leading cause of cancer death in both men and women and the second leading cause of cancer death when men and women are combined.<sup>4</sup> With an estimated 134,490 newly diagnosed cases, this disease will be responsible for an estimated 49,290 deaths in the year 2016. The lifetime risk of approximately 6% in our Western civilization means that 1 in 18 individuals of the general population will be affected by colorectal cancer and many more by polyps, making it an important public health issue.<sup>5</sup> Worldwide, colorectal cancer shows large geographical differences, with a crude incidence of 6.5 and 7.7 cases per 100,000 females and males, respectively, in less developed areas as opposed to 50.9 and 60.8 cases, respectively, in more developed regions.<sup>6</sup> Regardless of ethnicity, there is an age-dependent increase in incidence with each decade starting at age of 40 years, and the mean age at presentation is around 70 to 75 years.

In the period between 1975 and 2006, the Surveillance, Epidemiology, and End Results (SEER) Registry of the National Cancer Institute (NCI) showed a gradual decline in all cases of colorectal cancer in the United States from 69.7 to 50.6 cases per 100,000.<sup>7</sup> However, although these numbers reflect the trend in whites, the incidence of colorectal cancer in the United States for African Americans has remained at the same level of 59.3 to 61.5 cases per 100,000 individuals. African American males therefore now represent the ethnic subgroup with the highest risk.<sup>8,9</sup>

## **RISK FACTORS, PREVENTION, AND SCREENING**

The specific cause of colorectal cancer is not known. However, a number of genetic and environmental risk factors have been associated with the disease.<sup>10</sup> From a practical and screening standpoint, it has been helpful to group individuals into 3 risk categories (ie, average risk, increased risk, and high risk) based on their presumptive genetic profile as reflected in their individual and family history.<sup>11,12</sup> The high-risk and increased-risk groups consist of patients with known hereditary syndromes or bowel diseases or patients with a personal or family history of polyps or cancer, all of which are discussed in a later section of the chapter (Table 49-2).

**TABLE 49-2: COMPARISON OF MAJOR RISK CATEGORIES**

	SCC	FAP	HNPCC	IBD
Variants		AFAP, Gardner, Turcot	Lynch I/II	Ulcerative colitis, Crohn's disease
Genetics		+ Autosomal dominant	+ Autosomal dominant	?
Genes	Chromosomal deletions, <i>K-ras</i> , <i>DCC</i> , <i>p53</i> , <i>APC</i>	<i>APC</i>	<i>MSH2</i> , <i>MLH1</i> , <i>PMS1/2</i> , <i>MSH6</i>	?
Age of onset	>40 y Average 70-75	Polyps start after age 10-20, cancer in 100% at age 40	<50 y	Any, often young patients
Number of polyps	Variable, <10	>100	<10	Inflammatory pseudopolyps
Risk	5%-6% of population	100%	>80%	Depending on age at onset, duration of disease, extent of active disease
Location	Left > right colon	Any location	Right > left colon	Active disease
Chemoprevention	NSAID? vitamins? calcium?	NSAID	?	IBD suppression?
Screening	>50 y (45 y in African Americans)	>10-15 y Genetic counseling	>25 or 10-15 y before cancer onset in youngest family member Genetic counseling	7 y after onset, annually
Associated risks	?	Desmoids	Endometrium and other cancers	Extracolonic disease

Abbreviations: AFAP, attenuated FAP; FAP, familial polyposis syndromes; HNPCC, hereditary nonpolyposis colon cancer; IBD, inflammatory bowel disease; NSAID, nonsteroidal anti-inflammatory drug; SCC, sporadic colon cancer.

The majority of cases, however, are sporadic colon cancers that typically arise within a polyp. Geographic and migrational studies have suggested that the Western lifestyle increases the risk for colon cancer, hence suggesting that nutritional and environmental factors may play a key role.<sup>13</sup> A large number of epidemiologic studies have been undertaken to identify these individual, nutritional, lifestyle, genetic, and environmental factors that would either predispose to or prevent the development of colorectal polyps

and cancer (Table 49-3).<sup>14-19</sup>

**TABLE 49-3: RISK FACTORS ASSOCIATED WITH COLON CANCER**

<b>Risk Factor</b>	<b>Comment</b>
Geographic variation	Highest risk in Western countries and lowest in developing countries
Age	Risk increases sharply after the fifth decade
Diet	Increased with high total- and animal-fat diets
Physical inactivity	Increased with obesity and sedentary lifestyle
Adenoma	Risk dependent on type and size
FAP penetrance in gene carriers	100%
HNPCC penetrance in gene carriers	80%
Hamartomatous syndromes	Risk increased with Peutz-Jeghers syndrome and juvenile polyposis but not isolated juvenile polyps
Previous history of colon cancer	Increased risk for recurrent cancer
Ulcerative colitis	10%-20% after 20 y
Radiation	Associated with a mucinous histology and poor prognosis
Ureterosigmoidostomy	100-500 times increased risk at or adjacent to the ureterocolonic anastomosis

Abbreviations: FAP, familial polyposis syndromes; HNPCC, hereditary non-polyposis colon cancer.

Data from Wu JS, Fazio VW: Colon cancer, *Dis Colon Rectum*. 2000; Nov; 43(11): 1473-1486.

## Extrinsic Risk Factors

### DIETARY FIBER, MEAT, AND FAT

One of the characteristics of a Western diet generally has been the lack of fiber as opposed to the increased amount of meat, total fat, and animal fats.<sup>20,21</sup> In view of the known geographic differences, with the highest colorectal cancer incidence in industrialized nations,<sup>6</sup> a high-fat and low-fiber diet generally has been considered a risk factor for the development of colorectal cancer.<sup>22</sup> This concept gained support from epidemiologic studies<sup>23</sup> and resulted in common recommendations of high-fiber supplements to increase the stool bulk, dilute toxins, and reduce the colonic transit time and thus the exposure time to fecal carcinogens.<sup>24-27</sup> More recent prospective trials, however, have questioned the benefit of dietary fiber supplementation in that they were at best inconclusive and did not reduce the incidence of colorectal cancer.<sup>28,29</sup> However, selected fats such as *n*-3 fatty acids found in fish oils may have a protective effect,<sup>30</sup> even though a direct effect to the mucosa could not be observed.<sup>31</sup> Therefore, it could be concluded that the total amount of fats or fibers is of lesser importance than their quality and origin.<sup>19,20,32</sup> The protective effect of vegetables and fruits<sup>33,34</sup> may come not only from their fiber content but also from the content of antioxidative and antiproliferative agents, such as isothiocyanates in cruciferous vegetables (eg, broccoli), which may enhance the expression of carcinogen-metabolizing enzymes and induce apoptosis in neoplastic cells.<sup>16,35</sup>

### CALCIUM, VITAMINS, AND MICRONUTRIENTS

Several prospective studies suggested that increased oral calcium and selenium intake may protect from colorectal polyps and cancers,<sup>36-41</sup> whereas other studies could not verify a significant benefit.<sup>42</sup> The mechanism by which calcium supplements are thought to reduce the risk of colon cancer is 2-fold. First, calcium can bind bile and fatty acids in the stool to insoluble complexes that are less likely to attack the colonic mucosa, and second, it can interfere directly with the mucosal cells and decrease their proliferative potential on a cellular level.<sup>23</sup>

Several vitamins were found to have a cancer-protective effect. Vitamins A, C, and E have been shown to have antioxidant activity. Results from interventional studies, however, have remained somewhat disappointing or controversial.<sup>43,44</sup>

In a study on postmenopausal women, another correlation was found between dietary heme iron and an increased risk of proximal colon cancer, especially in conjunction with alcohol consumption, whereas intake of dietary zinc reduced the risk of both proximal and distal colon cancer.<sup>45</sup>

## **ASPIRIN AND COX-2 INHIBITORS**

Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) may interfere with the development of colorectal neoplasms by blocking the cyclooxygenase (COX)-dependent prostaglandin pathway.<sup>46</sup> The targets are the constitutive COX-1, as well as the cytokine-inducible COX-2, which has been found at increased expression levels in both polyps and cancers.<sup>47</sup> Therefore, several trials have studied these agents (eg, aspirin and sulindac) for the chemoprevention of colorectal cancer both in sporadic polyps and cancers<sup>48</sup> and in familial adenomatous polyposis (FAP).<sup>49-51</sup> In both settings, controlled studies have provided contradictory results.<sup>52</sup> Regular prophylactic medication with low-dose aspirin may reduce the risk of sporadic colorectal cancer.<sup>48,53</sup> Data from chemoprevention trials in FAP suggest that COX inhibition may delay the onset and number of adenomatous polyps, but it is not yet clear whether it is able to prevent the cancers overall or reduce their respective risk.<sup>49-51</sup> COX-2-independent mechanisms may play a role in the beneficial effect of some COX-2 inhibitors.<sup>46</sup> A major concern, however, has been the documented increased risk of serious cardiovascular events with the use of COX-2 inhibitors.<sup>54,55</sup>

Because data on the benefits remain conflicting, physicians must decide how to use these pharmacologic tools in the management of their patients. Based on the presumed small risks in general and the supporting data on a possible benefit, most physicians would be inclined to err on the side of a potential benefit in preventing colon polyp formation. Low doses of aspirin and calcium may be helpful in preventing polyps and cancers. However, concern about cardiovascular side effects and increased mortality has resulted in a withdrawal of more potent COX-2 inhibitors until further redefinition of

the indications and risk groups has been accomplished.<sup>54,55</sup>

## **CHOLECYSTECTOMY AND BILE ACIDS**

Evidence that bile acids may act as cocarcinogens or tumor promoters comes from both experimental and epidemiologic studies.<sup>56,57</sup> Bile acids can induce hyperproliferation of the intestinal mucosa via a number of intracellular mechanisms. Cholecystectomy, which alters the enterohepatic cycle of bile acids, has been associated with a moderately increased risk of proximal colon cancers.<sup>58,59</sup> It cannot be ruled out, however, that it is less the effect of the cholecystectomy than the impact of other, not yet identified factors in the lithogenic bile of such patients. A number of cofactors have been identified that may enhance or neutralize the carcinogenic effects of bile acids, for example, the amount of dietary fat, fiber,<sup>23</sup> or calcium.<sup>60</sup> Calcium, in fact, binds bile acids and thus may reduce their negative impact. However, other more intrinsic mucosa-protective mechanisms of calcium supplements probably are more relevant for the demonstrated reduction of recurrent adenomatous colon polyps.

## **SMOKING AND ALCOHOL CONSUMPTION**

The risk of colorectal cancer is increased, though modestly, among long-term smokers compared with nonsmokers.<sup>26,45,61,62</sup> The data suggested a dose-response relationship between pack-years of tobacco use and the development of adenomatous polyps.<sup>63-66</sup> Equally, excessive alcohol consumption has been associated with an increased risk for colon cancer.<sup>26,45,61,62</sup>

## **OTHER FACTORS**

An ever-increasing number of other factors are accumulating that have been attributed to an increased risk of colon cancer, such as lack of physical activity, diabetes, serum insulin levels, elevated concentrations of insulin-like growth factor 1, and low concentrations of insulin-like growth factor-binding protein 3 (IGFBP-3).<sup>67</sup> The complexity of interactions between these factors and the previously mentioned parameters, however, makes it difficult at the present time to draw conclusions that have an impact on clinical practice.

## Intrinsic Risk Factors

### PERSONAL AND FAMILY HISTORY

There is generally little debate on whether the presence of an adenomatous pathology or chronic inflammatory bowel disease (IBD) in itself represents a risk factor for a subsequent colon cancer. In patients with a colon cancer, synchronous colorectal cancers are found in 5% to 10%, whereas about 10% to 20% of patients with a history of colorectal cancer will develop metachronous primary cancers in the large intestine. A personal history of adenomatous colonic polyps is an indicator for an increased colonic predisposition to develop subsequent adenomatous or cancerous changes.<sup>12,68-72</sup>

Compared with the general population, relatives of patients with colon cancer have a 2 to 4 times increased risk of developing the disease themselves (Table 49-4).<sup>26,73,74</sup> A similar, even though proportionally lesser, risk is observed for family members of individuals with colonic adenomatous polyps.

**TABLE 49-4: LIFETIME RISKS OF COLORECTAL CANCER IN FIRST-DEGREE RELATIVES OF PATIENTS WITH COLON CANCER**

Population risk without risk factors	1 in 50
One relative affected	1 in 17
One first-degree relative and one second-degree relative affected	1 in 12
One relative aged <45 y affected	1 in 10
Two first-degree relatives affected	1 in 6
Dominant pedigree	1 in 2

Reproduced with permission from Houlston RS, Murday V, Harocopos C, et al: Screening and genetic counseling for relatives of patients with colorectal cancer in a family cancer clinic. *BMJ* 1990;Aug 18-25:301(6748):366-368.

### INFLAMMATORY BOWEL DISEASE

IBD is a strong risk factor for colorectal cancer. The risk correlates with the age of onset and extent and duration of active disease.<sup>75,76</sup> In contrast,

however, the disease activity historically was not thought to be correlated with the risk, but recent studies have challenged this view.<sup>77</sup> In patients with ulcerative colitis, the risk of colorectal cancer increases from approximately 3% in the first decade to 10% to 20% in the second decade.<sup>75,76</sup> In patients with Crohn's disease with colonic involvement, the disease-associated risk for colorectal cancer is also elevated but generally to a lesser extent.<sup>78-80</sup>

## **OTHER FACTORS**

Less frequent risk factors for colorectal cancers may include a history of a ureterocolostomy<sup>81</sup> or previous radiation treatment.<sup>82</sup> The former requires the combination of fecal bacteria and urine because the microbes degrade urinary metabolites into strong carcinogens.<sup>81,83,84</sup> When colonic mucosa is used for bladder augmentation, no increased cancer risk is observed owing to the absence of bacteria. The findings in radiation-induced colorectal cancer are a little less clear, but it has been suggested that it may be associated with a mucinous histology and poor prognosis.<sup>82</sup>

## **Prevention and Screening**

Because symptoms are not reliable for early detection of colorectal cancer, risk-adjusted screening programs for asymptomatic individuals are important. Effective screening has to be based on an understanding of the adenoma-carcinoma sequence, which may take up to 5 to 10 years from the first molecular change to a clinically manifest cancer, and should reflect an individual's genetic and disease- or age-dependent risk for the development of colorectal cancer.<sup>11,12, 85-87</sup> Any prevention program has to be sensitive but also practical and cost-effective in order to achieve a broad screening of the population at risk. The term "screening" is applicable only to asymptomatic people; if symptoms are present, it is not screening but diagnostic tests that are initiated. Common tools for screening include fecal occult blood tests (FOBTs), flexible sigmoidoscopies or colonoscopies, and contrast enemas or computed tomography (CT) colonography.<sup>88</sup>

The American Cancer Society, endorsed by the major professional societies, recommends starting colorectal cancer screening in asymptomatic average-risk adults at age 50.<sup>11,12,85-87</sup> A slightly earlier screening start at age

of 45 has been recommended recently for African American patients based on their statistically significant increased risk.<sup>9</sup> A first baseline colonoscopy is to be performed and, if no pathology is found, repeated every 10 years. In addition, an FOBT should be done on an annual basis, and any positive result should precipitate a full colonic evaluation. Every 5 years, a limited endoscopy (flexible sigmoidoscopy) or barium enema is indicated. If precursor lesions are found, they should be removed, and a colonoscopy should be performed after 1 to 3 years to detect missed (20%) or recurrent polyps.<sup>89-91</sup>

In individuals at increased risk (eg, personal/family history of polyps or cancer or African American ethnicity) or at high risk (eg, cancer syndromes or IBD), the screening has to start earlier (see [Table 49-2](#)) and has to be performed at a higher frequency.<sup>9</sup> Successful screening programs have been shown to reduce the colorectal cancer incidence by 76% to 90%.<sup>92</sup>

## **PATHOGENESIS OF COLONIC CANCER**

Carcinogenesis in the colon is a complex multistep process in which a multitude of alterations must coincide in order to transform a normal cell into a malignant cell. Several categories of genes are involved that normally are regulated in a sophisticated network to keep a tight balance between cell growth and turnover, cell death, DNA replication, and mismatch repair. Disruption of the fine balance between oncogenes, which promote cell proliferation, and tumor suppressor genes, which inhibit excessive growth, results in a growth advantage and allows malignant cells to expand.

### **Colon Cancer: A Genetic Disease**

All cells of even such a complex organism as a human being have DNA that is virtually identical to the DNA found in the zygotes. DNA mutations can occur either as a germline mutation or as a somatic mutation. The former may be transmitted from one to the next generation as an inherited defect. More commonly, a spontaneous mutation occurs in a non-germline cell during the growth, development, and maintenance of a tissue or organ (somatic mutation). Even in the cycle of a normally functioning cell, there is a high chance of spontaneous gene mutations, most of which will not result in a

growth advantage to the harboring cell. Genesis of a cancer therefore requires several independent accidents to occur in 1 cell. One can assume that a normal cell will be able to detect damage to its own DNA and maintain an effective repair mechanism. However, if the cell is too severely damaged, it might rather initiate the inherent suicide program called *apoptosis*. When a cell fails to recognize or correct DNA damage and continues to replicate, accumulation of faulty gene products within the cell may eventually lead to a proliferative response. If that replication exceeds the growth potential of the neighboring normal cells, the mutation provides a growth advantage that will increase the state of “genetic instability” and hence lead toward a malignant cell.<sup>93</sup> Despite this potential, most mutations are silent or lethal to the cell rather than beneficial in terms of providing the cell a biologic advantage. The triggers and the step-by-step cumulative failures that lead to carcinogenesis still are relatively poorly understood.

Two types of genetic instability may occur: at the chromosome level or at the DNA level. A loss of chromosomal material, that is, a *chromosomal instability* (CIN), results when the chromosomes are not divided symmetrically during mitosis such that 1 daughter cell receives both copies and the other cell receives none. On an electrophoretic gel, this can be visualized as a loss of 1 or more bands, which is described as *loss of heterozygosity* (LOH), and has been associated with a worse prognosis in colorectal cancer.<sup>2</sup> The second form of genetic instability, at the DNA level, occurs when replication errors in repetitive short polymorphisms lead to an additional band or bands.<sup>94</sup> This phenomenon is described as *microsatellite instability* (MSI), and it has been a characteristic feature of hereditary nonpolyposis colon cancers (HNPCCs).<sup>95</sup>

During the process of cell division, DNA is duplicated, with the original DNA serving as a template for the replicated copy. DNA polymerase serves as a “proofreader” that recognizes mismatched genes, halts the DNA synthesis, removes the defective sequence, and then resynthesizes the DNA. Failure of the DNA mismatch repair system predisposes to the development of mutations within daughter cells. Enzymes that monitor newly formed DNA and correct replication errors are called *DNA mismatch repair* (MMR) systems.

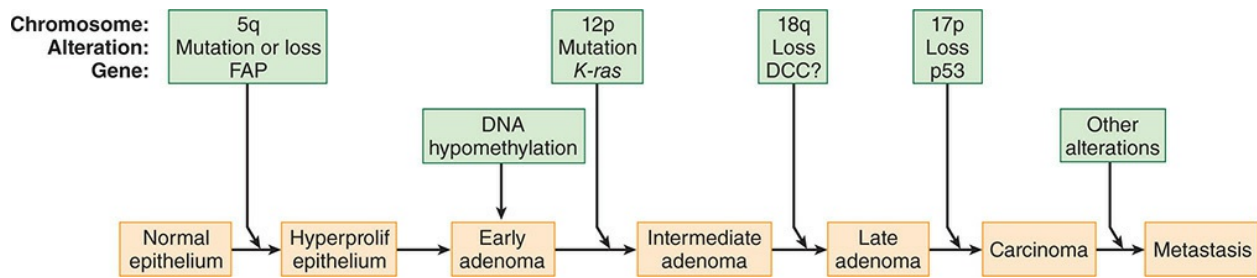

Specific gene functions are lost when both copies (alleles) of a gene are inactivated. Thus, when a germline mutation occurs in a suppressor gene,

only the mutation of the remaining normal allele is required for the gene's loss of function. When both copies of the gene are normal, 2 mutational events are required for the gene's loss of function. This 2-hit hypothesis may explain why inherited diseases usually manifest at an earlier age than sporadic disease.<sup>5</sup>

## The Adenoma-Carcinoma Model

After identifying several genetic alterations in colorectal specimens at various stages of their neoplastic transformation and progression, Vogelstein and colleagues in 1988 pioneered a genetic model for colorectal tumorigenesis that since has been known as the *adenoma-carcinoma sequence* (Fig. 49-1).<sup>3</sup> This multistep model described the carcinogenesis as an accumulation of genetic events, uninhibited cell growth, and proliferation and clonal development. Gene mutations and chromosomal/gene losses that were observed in sporadic colon cancer include the *APC* gene (adenoma–polyposis coli), *MMC* gene (mutated in colon cancer), *K-ras*, *DCC* (deleted in colon cancer), and *p53*.<sup>2,96,97</sup> Mutations of the *APC* gene, which is involved in the control of cell-to-cell adhesions and intercellular communication, are found in 60% of even small adenomatous polyps, as well as in carcinomas,<sup>98</sup> and therefore are believed to occur as a very early event in carcinogenesis. Mutations of *K-ras*, which under normal function plays a role in intracellular signal transduction and stimulated cell division, occur in larger adenomas and carcinomas and are thought to stimulate cell growth. Deletion of the tumor suppressor gene *DCC* may be important in the progression from a benign polyp to a malignant condition.<sup>99</sup> Mutations of the *p53* gene, which are among the most frequent gene mutations in human cancers, are also common in invasive colon cancers but rare in adenomas, suggesting that *p53* mutations occur as a late event in the development of the invasive phenotype.<sup>100</sup> The wide range of gene mutations, inactivations, and deletions in the progression to carcinoma seems to hold the secret code for the various tumor behaviors observed in the clinical setting. It is important to note, however, that an increasing number of other genetic events have been observed and reported and that no single event seems to be equally present in all colon cancers. One therefore should caution that the described sequence is only one possible model and that the scenario may not reflect all aspects of colonic

carcinogenesis.

**FIGURE 49-1** Genetic model for colorectal tumorigenesis (adenoma-carcinoma sequence). FAP, familial adenomatous polyposis. (Reproduced with permission from Fearon ER, Vogelstein B: A genetic model for colorectal tumorigenesis, *Cell* 1990;June 1;61(5):759–767.)

## The Cancer Stem Cell Model

Tumors arise from the expansion of a mutated cell and contain a heterogenous cellular population. There is increasing evidence that not all cells within a tumor have the same capacity for proliferation and tumorigenesis. Instead, tumor growth is driven by a subset of the population, termed cancer stem cells, that have the ability to self-renew and differentiate to form all the lineages found within the tumor. This has implications for future therapeutic treatment as current radiotherapy and chemotherapy target all rapidly dividing cells nonspecifically. If all cancer stem cells within the tumor are not destroyed, this could lead to disease relapse and metastasis.<sup>101,102</sup>

Cancer stem cells are thought to arise from normal stem cells that have lost their regulation of self-renewal or from progenitor cells with a defined lineage fate that have obtained the ability to self-renew. Normal stem cells are likely targets for transformation because the machinery for self-renewal is already active, and they can persist in normal tissue for a long time and accumulate transforming DNA damage. The intestinal stem cell niche provides a unique environment to regulate self-renewal and differentiation of these stem cells. Multiple signaling pathways are used to regulate stemness within the niche, including the Wnt, BMP, and Hedgehog pathways, and aberrations in these signals can disrupt the normal crypt-villus axis.<sup>103</sup> Myofibroblasts are thought to play an important role in regulating the microenvironment found within the stem cell niche, in normal tissue, primary tumors, and metastatic lymph node disease.<sup>104</sup> The centers of tumors often

have a lack of blood supply and oxygen, and there is evidence that hypoxia maintains the niche for colorectal cancer stem cells by maintaining stemness and inhibiting lineage differentiation via BMI1 and Notch1.<sup>105</sup> Various cell surface markers have been identified to enrich for colorectal cancer stem cells, including CD133,<sup>106,107</sup> CD44,<sup>102</sup> and CD24.<sup>102</sup> It is hoped that treatments that specifically target the cancer stem cell population within a tumor will allow more complete treatment of the disease and prevent relapse.

## HEREDITARY AND NONHEREDITARY COLON TUMORS

### Nonhereditary Colon Cancer

#### SPORADIC COLON CANCER

Sporadic colon cancer, that is, colon cancer arising in individuals without a family history or an inherited predisposition, accounts for approximately 60% of all colorectal cancers and affects patients commonly older than 50 years. The risk factors associated with sporadic development of colon cancer have been discussed previously in the epidemiology section of this chapter (see [Table 49-3](#)).

#### FAMILIAL COLON CANCER

Familial colon cancer is the second most common (25%-30%)<sup>5</sup> and, at the same time, least understood pattern of genetic colon cancer development. In affected families, colon cancer develops too frequently to be considered a sporadic colon cancer, but the pattern is not consistent with the known inherited syndromes.<sup>108</sup> An association of familial colon cancer has been found with polymorphisms, which reflect subtle genetic changes in the form of variations in the nucleotide base sequences but which do not affect protein structure.<sup>5</sup> Familial colon cancer in the Ashkenazi Jewish population probably is the result of an *APC* germline mutation on codon 1307 (I1307K). This mutation, which predisposes to sporadic mutations at distant sites of the gene and later results in structural protein abnormalities, is found in 6% of all Ashkenazi Jews and in 28% of those with both a personal and a family

history of colon cancer.<sup>109</sup>

## Hereditary Colon Cancer

### FAMILIAL ADENOMATOUS POLYPOSIS

*Familial adenomatous polyposis* (FAP) is an autosomal dominant inherited syndrome with near-complete penetrance. The offspring of affected individuals thus have a 50% risk of inheriting FAP. However, up to 20% of patients with FAP have new mutations without a family history. This condition is attributed to a truncating mutation in the germline adenomatous polyposis coli (*APC*) gene on chromosome 5q21.<sup>110</sup> Variants of the polyposis syndrome are classified as Gardner syndrome (ie, osteomas, desmoid tumors, thyroid neoplasms, and congenital hypertrophy of the retinal pigment epithelium) and Turcot syndrome (ie, brain tumors).

The inherited syndrome of FAP and its variants accounts for less than 1% of all colon cancers. It is characterized by greater than 100 and often several thousand adenomatous intestinal polyps that start to develop in the late teens and early twenties and turn into cancer by age 40 to 45. An attenuated variant of the disease is relatively rare and is characterized by a lower number and a later onset of both the polyps and the resulting cancer (see the following text). Nearly all FAP patients develop duodenal adenomas that are severe in 10% and account for the group's second highest cancer risk, with adenocarcinoma developing in the periampullary region in 3% to 10% of patients.<sup>111,112</sup> Carcinoma arising in the antrum and duodenum after colectomy is the main cause of cancer-related deaths in FAP patients.<sup>111,113,114</sup> Nonadenomatous fundic gastric polyps develop in approximately 10% to 30% of patients with FAP<sup>114</sup> but usually do not have a malignant potential. Ten percent of FAP patients develop desmoid tumors either intra-abdominally or on the abdominal wall, extremities, and trunk.<sup>115</sup> Histologically, desmoids are fibromatous lesions consisting of large proliferation of myofibroblasts. Even though they do not necessarily carry features of a malignant lesion, the recent literature suggests a low-grade sarcoma-like behavior. Desmoids are lethal in 10% and are the third most frequent cause for mortality of FAP patients, mainly due to the intra-abdominal variants, which cause small bowel and ureteral obstructions.<sup>115,116</sup>

Approximately 25% of FAP patients remain without an identified *APC* mutation (*APC* negative),<sup>116,117</sup> and using a detailed analysis, they seem to differ in terms of lower polyp number, later age at diagnosis, and lower occurrence of extracolonic manifestations as compared with classic FAP patients.<sup>114,118</sup> This variant of FAP is known as *attenuated familial adenomatous polyposis* (AFAP).

## HEREDITARY NONPOLYPOSIS COLON CANCERS

*Hereditary nonpolyposis colon cancer* (HNPCC), also known as *Lynch I* and *II syndromes*, is an inherited autosomal dominant disease that accounts for 3% to 5% of all colorectal cancers.<sup>119</sup> It is characterized by an early onset of colorectal cancers predominantly but not exclusively on the right side of the colon with synchronous and metachronous cancers. Despite its name, these cancers typically arise from colonic polyps, but a diffuse polyposis is not present. The penetrance of the HNPCC predisposition is high and results in an 80% to 85% lifetime risk of colorectal cancer and a 40% to 50% risk of endometrial cancer.<sup>15,120,121</sup> Furthermore, HNPCC patients are at increased risk of developing extracolonic malignancies, such as cancer of the small bowel, stomach, hepatobiliary tract, urinary tract, ovary, and brain. The Lynch variants describe patients with predominantly colorectal cancer at a young age (Lynch I) and those with both colorectal and extracolonic cancers (Lynch II).<sup>119</sup>

An initial observation of expansions and contractions of microsatellite DNA in the genome of colorectal tumor specimens from HNPCC patients established a link between HNPCC and the DNA MMR system.<sup>122-124</sup> In contrast to the gatekeeper concept applicable to the *APC* gene in FAP, the DNA MMR genes belong to the so-called caretakers, which, when inactivated, do not promote tumorigenesis directly but rather lead to a genetic instability that then promotes tumor growth indirectly.<sup>125</sup>

To facilitate the clinical diagnosis of HNPCC, the International Collaborative Group on HNPCC (ICG-HNPCC) proposed the Amsterdam Criteria in 1990.<sup>119</sup> Linkage studies in HNPCC families fulfilling Amsterdam Criteria I (Table 49-5) led to the discovery of the first 2 human MMR genes—*hMSH2* and *hMLH1*. These genes accounted for 45% to 86% of all classic HNPCC families.<sup>126</sup> There also was a higher risk for *hMSH2* mutation

carriers to develop extracolonic cancers, in particular endometrial cancer, as compared with *hMLH1* mutation carriers.<sup>121,127</sup> Several other MMR genes have been identified in conjunction with HNPCC and include *hPMS1*, *hPMS2*, and *hMSH6*. A recent study reported that endometrial cancer represents the most common clinical manifestation of HNPCC among female *hMSH6* mutation carriers and that colorectal cancer cannot be considered an obligate requisite to define HNPCC.<sup>128</sup> The ICG-HNPCC therefore revised the criteria (Amsterdam Criteria II), which now better weigh extracolonic manifestations (eg, endometrial, breast, small bowel, and upper renal tract cancers) as part of the family history (see [Table 49-5](#)). In addition, the less restrictive revised Bethesda Criteria ([Table 49-6](#)) were adopted to better serve patients who carry *hMSH2* or *hMLH1* gene mutations but otherwise do not fulfill the Amsterdam Criteria. Testing for MSI has become a valuable diagnostic tool to identify individuals with suspected HNPCC because 85% to 90% of HNPCC tumors have MSI as opposed to only 15% to 20% of sporadic colon cancers.<sup>95</sup>

**TABLE 49-5: AMSTERDAM CRITERIA I AND II**

**Amsterdam Criteria I  
(1990)**

**Amsterdam Criteria II  
(1999)**

At least 3 relatives with colorectal cancer, 1 of whom should be a first-degree relative of the other 2.

There should be at least 3 relatives with HNPCC-associated cancer (colorectal cancer, cancer of the endometrium, small bowel, and ureter), 1 of whom should be a first-degree relative of the other 2.

At least 2 successive generations should be affected.

At least 2 successive generations should be affected.

At least 1 colorectal cancer should be diagnosed before the age 50 y.

At least 1 colorectal cancer should be diagnosed before the age 50 y.

FAP should be excluded.

FAP should be excluded.

Tumors should be verified by a pathologist.

Tumors should be verified by a pathologist.

Benign tumors, by definition, do not invade adjacent tissue borders, nor do they metastasize to distal sites. By contrast, malignant tumors have the added property of invading contiguous tissues and metastasizing to distant site.

A polyp is defined as a mass that protrudes into the lumen of the colon. They are subdivided according to the attachment to the bowel wall (eg, sessile or pedunculated), their histologic appearance (eg, hyperplastic or adenomas), and their neoplastic potential (ie, benign or malignant).

**TABLE 49-6: REVISED BETHESDA GUIDELINES (2002) FOR TESTING COLORECTAL TUMORS FOR MSI**

<b>Criterion</b>	<b>Comment</b>
Colorectal cancer diagnosed in a patient age <50 y	
Presence of synchronous, metachronous colorectal cancer, or other HNPCC-associated tumor, regardless of age	Stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain, sebaceous gland adenomas and keratoacanthomas, and small bowel
Colorectal cancer with MSI-high histology diagnosed in a patient age <60 y	Tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern
Colorectal cancer diagnosed in at least 1 first-degree relative with an HNPCC-related tumor diagnosed under age 50	
Colorectal cancer diagnosed in 2 or more first- or second-degree relatives with HNPCC-related tumors, regardless of age	

Abbreviations: HNPCC, hereditary nonpolyposis colon cancer; MSI, microsatellite instability.

Data from Umar A, Boland CR, Terdiman JP, et al. Revised Bethesda Guidelines for hereditary nonpolyposis colorectal cancer (Lynch syndrome) and microsatellite instability, *J Natl Cancer Inst* 2004 Feb 18;96(4):261-268.

## **HAMARTOMATOUS POLYPOSIS SYNDROMES**

Approximately 4% of colonic cancers are seen in the context of rare syndromes. Among these are inherited hamartomatous polyposis syndromes that are characterized by the presence of gastrointestinal hamartomatous

polyps and an increased risk of gastrointestinal malignancy. Hamartomas result from a disordered differentiation during embryonic development and are characterized morphologically by disrupted representations of normal tissue components.

**Peutz-Jeghers Syndrome.** Peutz-Jeghers syndrome is the second most common hamartomatous syndrome, occurring as an autosomal dominant condition with variable penetrance. Genetic alterations in the *LKB1/STK* (19p13) gene are responsible for approximately 50% of the cases of Peutz-Jeghers syndrome.<sup>129</sup> The syndrome is associated with hamartomatous polyps of the gastrointestinal tract and cutaneous melanin deposition. The most common location of Peutz-Jeghers polyps is in the upper gastrointestinal tract, specifically the upper jejunum. One of the most characteristic features is the melanin depositions, which are seen most frequently in the perioral region or buccal mucosa but also can occur in the genital region and on the hands and the feet. While a majority of these patients remain relatively asymptomatic, some may present with abdominal pain secondary to obstruction or impending obstruction due to an intussuscepted polyp and others with gastrointestinal bleeding. Patients with Peutz-Jeghers syndrome have a moderately increased risk in the range of 2% to 3% to develop gastrointestinal malignancies and extraintestinal malignancies.

**Juvenile Polyposis Syndrome.** Juvenile polyposis syndrome is the most common hamartomatous syndrome and is inherited as an autosomal dominant trait. The average age of onset is approximately 18 years, and there is an association with congenital birth defects in 15% of patients.<sup>130</sup> Although the diagnostic criteria for juvenile polyposis syndrome are somewhat controversial, the most commonly used criteria include 3 or more juvenile polyps of the colon, polyposis involving the entire gastrointestinal tract, or any number of polyps in a member of a family with a known history of juvenile polyps.<sup>131</sup>

In infancy, patients may present with acute or chronic gastrointestinal bleeding, intussusception, rectal prolapse, or a protein-losing enteropathy. In adulthood, patients commonly present with either acute or chronic gastrointestinal blood loss. Most of these patients will be found to have polyps, which are located most frequently in the rectosigmoid region.

A germline mutation in the *SMAD-4* gene (18q21) accounts for

approximately 50% of the reported cases of the syndrome.<sup>132</sup> A significant risk of colorectal cancer is associated with juvenile polyposis syndrome, and this syndrome should not be confused with isolated juvenile polyps because the latter have virtually no malignant potential.

**Cowden Disease.** Cowden disease, first described in 1963, is known as multiple hamartoma-neoplasia syndrome. It is an autosomal dominant condition with nearly complete penetrance by age 20 that is caused by germline mutations in the *PTEN* tumor suppressor gene located at 10q22.<sup>133,134</sup> Cowden disease is unique among the hamartomatous syndromes because polyps arise more commonly from ectodermal rather than endodermal elements. Eighty percent of patients present with trichilemmoma, a benign tumor of the hair shaft. The central nervous system is the second most involved system, with approximately 40% of affected individuals suffering from macrocephaly. Only 35% of patients who meet the diagnostic criteria for Cowden disease have gastrointestinal polyposis, but no increased risk of invasive gastrointestinal malignancy has been reported to date. The majority of patients with Cowden disease suffer from benign thyroid or breast disease, in addition to a projected lifetime risk of 10% for thyroid cancer and of 30% to 50% for breast cancer.

**Bannayan-Riley-Ruvalcaba Syndrome.** Formerly known as its subentity, the Ruvalcaba-Myhre-Smith syndrome, this rare autosomal dominant condition includes 2 other syndromes, both of which, like Cowden disease, are associated with genetic alterations in the *PTEN* gene on chromosome 10q23 and may be considered a variant of juvenile polyposis coli.<sup>135-137</sup> It is characterized by hamartomatous polyps of the gastrointestinal tract, macrocephaly, mental retardation, delayed psychomotor development, lipid storage myopathy, Hashimoto thyroiditis, and hyperpigmentation of the skin of the penis. No increased risk of colorectal carcinoma, other gastrointestinal malignancies, or extraintestinal malignancy has been documented in these patients.

**Cronkite-Canada Syndrome.** Cronkite-Canada syndrome is characterized by diffuse polyposis and ectodermal abnormalities such as alopecia, onychodystrophy, and skin hyperpigmentation. The syndrome can be distinguished by the diffuse distribution of polyps throughout the entire

gastrointestinal tract with exception of the esophagus, which is spared.<sup>138</sup> Symptoms include diarrhea, weight loss, nausea, vomiting, and anorexia, as well as paresthesias, seizures, and tetany related to electrolyte abnormalities. Cancer occurs in the stomach, colon, and rectum, but it remains controversial whether polyps in Cronkite-Canada syndrome possess malignant potential. As many as 15% of patients with Cronkite-Canada syndrome have a malignant tumor at the time of diagnosis.

## PATHOLOGY AND STAGING

### Polyps

*Polyp* is a descriptive clinical term for any mucosal elevation. Polyps are further categorized along several dimensions, including

1. Size
2. Character of their attachment to the bowel wall (eg, sessile or pedunculated)
3. Cellular architecture (eg, adenomas, hyperplastic, hamartomas, inflammatory) and histologic appearance (eg, tubulovillous, villous)
4. Progression from benign to malignant behavior (eg, benign, dysplastic, cancer)

Most polyps are neoplastic but not necessarily malignancies. Neoplastic polyps consist of cells with the potential to acquire over time the ability to invade and to spread, that is, metastasize. *Dysplasia* is a term used to describe the intervening state between normal tissue and invasive malignancy.

### POLYP SIZE

The most immediate way in which a polyp can be described is by its size. Intuitively, polyps with a larger mass have a greater volume of neoplastic cells, and hence a higher likelihood of harboring cancer. The relationship between adenomatous polyp size and the presence of invasive malignancy was analyzed elegantly by Nusko et al<sup>139</sup> (Table 49-7).

**TABLE 49-7: RISK OF INVASIVE CARCINOMA IN ADENOMATOUS POLYPS**

Polyp Size (mm)	Number	% With Invasive Carcinoma
≤5	5137	0
6-15	3581	2.2
16-25	1069	18.6
16-36	516	42.8
37-42	219	63.9
>42	677	78.9

Data from Nusko G, Mansmann U, Kirchner T, et al: Risk related surveillance following colorectal polypectomy, *Gut* 2002 Sep;51(3):424-428.

## **POLYP ATTACHMENT TO BOWEL WALL**

Polyps of any size or architecture may be pedunculated, sessile, or some combination of both. The main clinical relevance of this distinction lies in the ease of endoscopic removal, with pedunculated polyps being clearly more amenable to removal without surgical intervention.<sup>140,141</sup>

It is important to note that the way in which a polyp is attached to the wall of the colorectum does not accurately predict the presence versus absence of an invasive malignancy. Malignant polyps of the colon can be either pedunculated or sessile. The type of treatment that should be offered to a patient depends much more on the other characteristics of the polyp.

## **POLYP ARCHITECTURE**

Based on their histologic structure, polyps can be categorized into adenomatous and nonadenomatous polyps, the latter of which consists of hyperplastic, hamartomatous, and inflammatory polyps.

**Adenomatous Polyps (Adenomas).** The most common type of polyp in the colon is the adenomatous polyp. Adenomatous polyps are categorized as tubular, tubulovillous, or villous based on the extent to which the dysplastic epithelium is organized with the normal-appearing tubular architecture.<sup>142</sup>

Tubular adenomas are defined by the presence of tubules within 80% or more of the lesion; adenomas with less than 20% showing a tubular configuration are villous lesions; and the remainder is considered tubulovillous. The majority of polyps are tubular (87%), with a minority being either tubulovillous (8%) or villous (5%).<sup>143</sup>

With few exceptions, the treatment for an adenomatous polyp is endoscopic polypectomy. Colorectal cancer screening programs that include colonoscopy with polypectomy have demonstrated a reduction in the incidence of colorectal cancer and colorectal cancer mortality.<sup>144</sup> It is difficult, however, to estimate the likelihood that a small adenoma will progress to a dysplastic adenoma and eventually into cancer. A number of biologic and molecular markers have been analyzed as predictors of a malignant potential, but these are not widely used.<sup>145</sup> Longitudinal and comparative data suggest that polyps not only progress but also may regress.<sup>146</sup> Despite these vagaries, any adenomatous polyp should be considered a premalignant lesion and be treated as such.

Invasive carcinoma is present in 5% of all adenomas, but the incidence correlates with the size and type of the adenoma (Table 49-8).<sup>139,147</sup>

 **TABLE 49-8: ADENOMATOUS POLYPS AND VILLOUS ADENOMA: SIZE, HISTOLOGIC TYPE, AND PERCENTAGE OF CARCINOMA**

Histologic Type	Size		
	<1 cm	1-2 cm	>2 cm
Tubular adenoma	1% (1382)	10.2% (392)	34.7% (101)
Intermediate type	3.9% (76)	7.4% (149)	45.8% (155)
Villous adenoma	9.5% (21)	10.3% (39)	52.9% (174)

Reproduced with permission from Muto T, Bussey HJ, Morson BC: The evolution of cancer of the colon and rectum, *Cancer* 1975;Dec;36(6):2251–2270.

The Haggitt classification, which defines 4 levels within the polyp, has evolved as a useful tool to describe the degree of cancer invasion into a pedunculated or sessile adenomatous polyp.<sup>148</sup> This classification forms the basis of the management of malignant polyps (Fig. 49-2). In Haggitt levels 1, 2, and 3, the risk of lymph node metastasis in a surgical specimen is less than

1%, whereas a level 4 invasion of the stalk behaves like a sessile T1 lesion and carries a higher risk of 12% to 25% of having lymph node metastases. A similar, but less well-known, classification was developed in 1993 by Kudo and associates, who for prognostic purposes suggested to divide the submucosal invasion of sessile malignant lesions into 3 levels (Sm1, Sm2, and Sm3) (Fig. 49-3).<sup>149</sup>

**FIGURE 49-2** Haggitt classification of tumor invasion in pedunculated or sessile polyp. Pedunculated polyps: level 0—not invasive carcinoma; level 1—invasion to the head of the pedunculated polyp; level 2—invasion to the neck of the pedunculated polyp; level 3—invasion to the stalk of the pedunculated polyp; level 4—invasion to the base of the pedunculated polyp. Sessile polyps: All lesions are level 4. (Reproduced with permission from Haggitt RC, Glotzbach RE, Soffer EE, et al: Prognostic factors in colorectal carcinomas arising in adenomas: Implications for lesions removed by endoscopic polypectomy, *Gastroenterology* 1985;Aug:89(2):328–336.)

**FIGURE 49-3** Depth of submucosal invasion in sessile malignant polyps. Sm1—invasion into upper third of submucosa; Sm2—invasion into middle third of submucosa; Sm3—invasion into lower third of submucosa. (Reproduced with permission from Nivatvongs S: Surgical management of early colorectal cancer, *World J Surg* 2000;Sep;24(9):1052–1055.)

Flat and/or depressed adenomas are a subtype of colonic adenoma with a propensity for high-grade dysplasia in 10% to 41% of affected patients regardless of the small size of these lesions.<sup>150</sup> The entity was first described in Japan, where they seem to occur at a regular frequency. These lesions, which are flat or slightly raised to less than 2 mm and commonly less than 1 cm in size, may be overlooked easily on colonoscopy and turn into a cancer before having reached a size comparable with classic cancers.<sup>150-153</sup> Recent screening studies, which took advantage of chromoendoscopy techniques, have confirmed that flat adenomas represent up to 25% to 36% of all polyps found in a random cohort and are present in 8% to 11% of the population.<sup>153,154</sup>

**Hamartomatous Polyps.** A hamartomatous polyp is composed of a spectrum of different cellular elements and is considered a nonneoplastic entity with no significant premalignant potential.<sup>155,156</sup> Several clinical syndromes manifest with a polyposis of hamartomatous polyps (eg, juvenile polyposis, Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, Cronkite-Canada syndrome), and these have been discussed earlier in this chapter. These syndromes carry varying risks of intestinal and extraintestinal disease, and several also impose an increased likelihood of developing intestinal cancer due to immature glandular elements in the hamartomatous polyp. Stable estimates of this risk are difficult to calculate because of the relative rarity of these diseases.

**Hyperplastic Polyps.** Hyperplastic polyps are small, sessile mucosal outgrowths that display an exaggerated crypt architecture. They are usually small, with only very few (1%-4%) larger than 1 cm; however, these larger polyps actually may be serrated adenomas rather than hyperplastic polyps (see the following text).<sup>157</sup> Within the colorectum, hyperplastic polyps commonly have a distal distribution pattern, predominantly in the rectum and sigmoid colon, and they have been reported in up to 75% of patients older than 60 years at autopsy.<sup>158</sup> It is not unusual to find several of these polyps in a single individual.

Histologically, hyperplastic polyps display well-formed glands and crypts that are lined by nonneoplastic epithelial cells. Because of their small size, hyperplastic polyps are generally clinically silent, but large or multiple hyperplastic polyps occasionally can be responsible for gastrointestinal symptoms.

Historically, hyperplastic polyps have been considered benign and not premalignant.<sup>157</sup> This paradigm has been increasingly questioned, beginning in 1990 with work by Longacre and Fenoglio-Preiser.<sup>159</sup> The ability of hyperplastic polyps to develop defective mismatch repair genes and foci of microsatellite unstable cancers has been documented, strengthening this concept.<sup>160</sup> Additional research has illuminated an epigenetic pathway, whereby a promoter region in the DNA of hyperplastic polyps is methylated, resulting in progression along a sequence of steps that leads to a serrated adenoma and eventually carcinoma.<sup>161</sup> The clinical significance of hyperplastic polyps and serrated adenomas is a topic of emerging importance in the field of colorectal cancer prevention.

As with adenomatous polyps, individuals who have a predisposition to developing hyperplastic polyps may be at increased risk for developing colorectal cancer. The endoscopic and radiologic appearance of the mucosal abnormalities in hyperplastic polyposis closely resembles FAP, but the syndrome is not believed to be heritable and does not have any extraintestinal manifestations. The World Health Organization (WHO) has defined criteria for this entity as follows: (1) at least 5 histologically diagnosed hyperplastic polyps of which 2 are greater than 20 mm or (2) any number of hyperplastic polyps occurring proximal to the sigmoid colon in someone who has a first-degree relative with hyperplastic polyposis, or (3) more than 30 hyperplastic polyps of any size that are distributed throughout the colon and rectum.<sup>162</sup>

The risk of colorectal cancer being present or developing subsequently in a patient meeting these criteria is high in case series, but population-based studies have not yet been performed.<sup>163</sup> While prophylactic colectomy has been proposed for patients with hyperplastic polyposis, there are no consensus opinions at this time regarding the appropriateness of this approach.<sup>164</sup> At a minimum, a program of intensive colonic surveillance is indicated.

**Inflammatory Polyps.** Inflammatory polyps are the result of reactive regenerative processes occurring in or next to a damaged epithelium. Because of the extent and chronicity of IBD, inflammatory polyps are most commonly seen in that context. The prominence of inflammatory pseudopolyps often is the result of the presence of adjacent ulcerations. Histologically, a combination of distorted crypt architecture in conjunction with granulation tissue and inflammatory infiltrates is characteristic. Even though the underlying chronic IBD represents a high risk for colorectal cancer, the inflammatory polyps as such do not carry a malignant potential. Biopsies in IBD should therefore also include the more flat-appearing areas rather than the polyps only.

## **POLYP TRANSFORMATION**

By definition, the neoplastic nature of an adenomatous polyp represents dysplasia. In an effort to quantify the clinical severity/importance of dysplasia, however, the degree of dysplasia is categorized and reported in 3 grades. This categorization is based on the histopathologic differentiation and architecture of the epithelial cells within the polyp.

Common terms for polyps include *low-grade dysplasia*, *intermediate-grade dysplasia*, and *high-grade dysplasia* (by some also referred to as *in situ [Tis] adenocarcinoma*). Once there are clear microscopic features of tumor invasion through the muscularis mucosa of the colorectum, an invasive cancer (T1 or greater) is present. This important demarcation is based on the finding that lymphatic vessels are almost never found superficial to the muscularis mucosa. The descriptive terms for invasive cancer include *well-differentiated* (grade I), *moderately differentiated* (grade II), or *poorly differentiated* (grade III) adenocarcinoma.

## MANAGEMENT OF COLORECTAL POLYPS

The overarching goal of physicians treating patients with colorectal polyps is to minimize the risks associated with invasive malignancy, while simultaneously avoiding complications of diagnosis and treatment. Colorectal cancer prevention programs are widely believed to reduce the risk of colorectal cancer mortality through endoscopic removal of premalignant lesions and the detection of invasive lesions at a point in their progression where they are asymptomatic. The efficacy of colorectal cancer prevention programs has been proven in multiple randomized and nonrandomized studies.<sup>144,165-169</sup>

The majority of colonic polyps can be removed via colonoscopy, but this may not be the case for 1 of 2 reasons. First, a polyp may not be resectable due to size, attachment to bowel wall, or other reasons related to the anatomy of the patient or polyp. In these situations, a careful assessment of the risks of surgical resection versus observational management is warranted, as 12% to 18% of these polyps harbor an invasive malignancy.<sup>170-172</sup> Second, polypectomy may not be reasonable in the presence of innumerable polyps.

When invasive cancer is found in a polyp, the management is based mainly on the level of invasion and the completeness of the polypectomy. Based on Haggitt's observations (see Fig. 49-2), it has been suggested that colonic cancers invasive to Haggitt levels 1, 2, and 3 can be adequately treated with polypectomy (2-mm margin), whereas polyps with invasion into Haggitt level 4 should be treated like a sessile lesion.<sup>148,173</sup>

Management of sessile lesions is more controversial. If a sessile lesion cannot be snared in 1 intact piece with a microscopically clear margin of at least 2 mm or if it demonstrates lymphovascular invasion or deep invasion into level Sm3 (lower third of submucosa) (see Fig. 49-3), the patient should undergo a formal oncologic resection of the colon. The approach for an adequately removed lesion with a lesser extent of invasion into the submucosa—Sm1 (invasion only into upper third of submucosa) or Sm2 (invasion only into upper two-thirds of submucosa)—should be individualized based on the risk of a surgery versus the risk of lymph node metastases.<sup>173,174</sup> It is advisable in any case to tattoo the area of a suspect polyp endoscopically with India ink for later identification of the site.

## Malignant Tumors of the Colon

The vast majority of malignant colon neoplasms are cancers (carcinoma), that is, malignant neoplasms of epithelial origin. Based on the endodermal glandular tissue origin, adenocarcinoma and its histologic variants are by far the predominant histopathology and account for 90% to 95% of all colorectal malignancies. The majority of this section is therefore devoted to these types of tumors, but it also briefly discusses nonepithelial tumors of the colon.

### ADENOCARCINOMA

Colorectal cancer (adenocarcinoma) is the most frequent malignancy of the gastrointestinal tract, the fourth most frequently diagnosed malignancy, and the fourth most common cause of cancer-related mortality in the world.<sup>175</sup> Squamous and adenosquamous carcinomas are exceptionally rare and are located characteristically in the rectoanal junction. The histopathologic classification of colorectal cancer as defined by the WHO is illustrated in [Table 49-9](#).

**TABLE 49-9: WHO HISTOPATHOLOGIC CLASSIFICATION OF COLORECTAL CANCERS AND THEIR SIGNIFICANCE**

Histopathologic Types	Pathology	Prognosis
Adenocarcinoma	90%-95% of the colorectal malignancies	
Mucinous adenocarcinoma	10% of all colorectal cancers; the extracellular type is more common than the intracellular type	Controversial whether mucinous histology itself is an independent negative prognostic factor
Signet ring cell carcinoma		
Small cell carcinoma (oat cell)	<1%; histologically identical to small cell carcinoma of the lung	Extremely poor prognosis and almost all cases have lymph node, liver, and brain metastasis
Small cell adenosquamous carcinoma		
Squamous cell carcinoma		
Undifferentiated carcinoma (medullary)		

Macroscopically, most colorectal cancers have either a polypoid or an ulcerative-infiltrating appearance, but combinations are frequent. Very rarely, colorectal cancer may have a dissolute growth pattern and resemble linitis plastica of the stomach, in which case a metastatic lesion from another primary site (eg, lobular breast cancer, stomach cancer) or a nonepithelial neoplasia (eg, lymphoma, carcinoid) would need to be ruled out.

Adenocarcinoma, the exceedingly predominant histopathology of colon

cancer, has a less frequent variant of mucinous adenocarcinoma that includes signet ring cell carcinoma and accounts for approximately 10% of all colorectal cancers. Compared to nonmucinous colon cancers, mucinous carcinomas usually present at a more advanced stage and thus have an overall poorer prognosis.<sup>176-178</sup>

A rare variant of colorectal cancer is small cell cancer, which accounts for less than 1% of all cases and, similar to small cell cancer of the lung, appears to be related to some degree to a neuroendocrine origin. These tumors have a high tendency to develop widespread metastasis early in the course and have an extremely poor prognosis.

The distribution of colorectal cancers among the various segments has seen a continued shift toward right-sided colon cancer.<sup>179-180</sup> An estimated 45% to 55% of colorectal cancers are located in the rectum (10%-15%) or sigmoid colon (40%), and 25% to 35% are located in the cecum or ascending colon, whereas the remaining are equally distributed through the rest of the colon. The local growth pattern for colorectal cancer involves circumferential and transmural invasion of the tumor through the intestinal wall into the peritoneal cavity or surrounding organ structures. Tumor dissemination primarily occurs through access to the lymphatic vessels into the locoregional lymph nodes or through access to the bloodstream as hematogenous metastasis to distant organs. The most common site of bloodborne spread is via the portal venous system to the liver; other secondary locations include the lung or, less frequently, kidneys, bone, and other sites. In addition, tumor dissemination can occur by transperitoneal seeding and result in peritoneal carcinomatosis.<sup>181</sup> Following gravity, peritoneal seeds may accumulate in the pelvic cul-de-sac or paracolic gutters where they can grow to a considerable size (Blumer's shelf). Growth by perineural infiltration may be seen on microscopic examination and has a negative prognostic impact. About 20% of the patients have evidence of distant metastases (stage IV disease) at the time of presentation.

## **STAGING OF COLON CANCER**

Modern staging of colorectal cancer defines 4 clinical stages (I-IV) based on the TNM (tumor-node-metastasis) system, which has just recently been updated by the American Joint Committee on Cancer (AJCC) (Tables 49-10 and 49-11).<sup>176,182,183</sup> Independent parameters are (1) the depth of tumor

invasion (T) into or through the layers of the intestinal wall with or without invasion of adjacent organs, (2) the number of regional lymph nodes involved (N), and (3) the presence or absence of distant metastases (M). Additional modifiers are used to reflect the method of stage determination (p for pathology, c for clinical, u for ultrasound); y indicates the status after neoadjuvant treatment.

**TABLE 49-10: TNM STAGING OF COLON CANCER**

Stage	Definition
<b>Primary Tumor (T)</b>	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i> , intramucosal carcinoma (involvement of lamina propria with no extension through muscularis mucosae)
T1	Tumor invades the submucosa (through the muscularis mucosa but not into the muscularis propria)
T2	Tumor invades the muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organ or structure
T4a	Tumor invades through the visceral peritoneum (including gross perforation of the bowel through tumor and continuous invasion of tumor through areas of inflammation to the surface of the visceral peritoneum)
T4b	Tumor directly invades or adheres to adjacent organs or structures
<b>Regional lymph nodes (N)</b>	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One to three regional lymph nodes are positive (tumor in lymph nodes measuring $\geq 0.2$ mm), or any number of tumor deposits are present and all identifiable lymph nodes are negative
N1a	One regional lymph node is positive
N1b	Two or three regional lymph nodes are positive
N1c	No regional lymph nodes are positive, but there are tumor deposits in the <ul style="list-style-type: none"> <li>• subserosa</li> <li>• mesentery</li> <li>• or nonperitonealized pericolic, or perirectal/mesorectal tissues.</li> </ul>
N2	Four or more regional nodes are positive
N2a	Four to six regional lymph nodes are positive
N2b	Seven or more regional lymph nodes are positive
<b>Distant metastasis (M)</b>	
M0	No distant metastasis by imaging, etc.; no evidence of tumor in distant sites or organs (This category is not assigned by pathologists.)
M1	Metastasis to one or more distant sites or organs or peritoneal metastasis is identified
M1a	Metastasis to one site or organ is identified without peritoneal metastasis
M1b	Metastasis to two or more sites or organs is identified without peritoneal metastasis
M1c	Metastasis to the peritoneal surface is identified alone or with other site or organ metastases

Historical classifications such as Dukes and Astler-Coller are still sporadically in use but largely have been and should be abandoned.

Because the extent of tumor resection (complete vs incomplete) strongly correlates with prognosis, the AJCC released additional guidelines to reflect the extent of residual tumor after a surgical resection with the letter *R* (see [Table 49-10](#)).<sup>183</sup>

## Nonepithelial Tumors of the Colon

### BENIGN NONEPITHELIAL TUMORS

**Lipomas and Lipomatous Polyposis.** Lipomas are submucosal lesions that develop in the fifth or sixth decade of life and are more common in the large than in the small intestine. Histologically, the polyps consist of a submucosal lump of adipose tissue that is covered with a normal colonic mucosa. Whereas solitary lipomas tend to occur more frequently on the right side of the colon in the vicinity of the ileocecal valve or the ascending colon, *lipomatous polyposis* may diffusely involve the entire small and large intestine.

Lipomas generally are asymptomatic but may be found incidentally on colonoscopy. The characteristic appearance is a smooth mass with normal overlying mucosa. The soft nature of the lipoma can be demonstrated by poking the tumor with an endoscopic instrument (“pillow test”). Asymptomatic, incidentally detected lesions should be left alone.

Occasionally, when lipomas become large enough to protrude into the lumen, they may cause symptoms such as gastrointestinal bleeding, diarrhea, intussusception, or bowel obstruction.<sup>184</sup> Endoscopic removal of such a lipoma with a snare often is possible but has a risk of hemorrhage because the fat may prevent the cautery from adequately transmitting the energy to the blood vessels in the stalk. Surgery may be required if such a complication occurs; therefore, it should be considered preemptively for very large symptomatic lipomas. Alternatively, the mucosa overlying the lipoma may be opened endoscopically to allow the lipoma to spontaneously enucleate into the lumen.

## **POTENTIALLY MALIGNANT NONEPITHELIAL TUMORS OF THE COLON**

**Carcinoid or Neuroendocrine Tumors.** Modern nomenclature classifies carcinoids as neuroendocrine tumors based on their neuroendocrine origin. They are characterized by subepithelial nests of epithelial-appearing cell elements. Carcinoid tumors may occur anywhere in the entire body. A recent study on 11,427 patients from the SEER database found that the gastrointestinal tract is affected in 55% of patients, with the most frequent locations being the small intestine (44.7%), the rectum (19.6%), the appendix (16.7%), and the colon (10.6%),<sup>185</sup> a finding that contrasts with traditional reports that the appendix is the most frequent site in the gastrointestinal tract. The annual incidences for the colon and rectum were reported to be 2.0 and

4.2 cases per 100,000 people per year, with the risk of metastasis proportional to the size of the carcinoid.<sup>185</sup> Unlike most neoplasms, invasiveness of carcinoid tumors is not entirely based on histologic criteria (eg, invasion of muscularis propria) but includes clinical aspects. In absence of other definite indicators for malignant behavior, carcinoids smaller than 1 cm are considered benign, lesions larger than 2 cm are likely malignant, and the gray zone in between remains undetermined or potentially malignant.<sup>186</sup> Malignant carcinoids may spread locoregionally into the lymph nodes or directly to the liver.

Patients with a gastrointestinal carcinoid tumor may be either completely asymptomatic or present with intestinal obstruction, bleeding, carcinoid syndrome, or carcinoid heart disease, that is, acquired and commonly right-sided valvular heart disease.<sup>187,188</sup> Vasoactive substances (eg, serotonin and 5-hydroxyindolacetic acid [5-HIAA]) are released from carcinoid tumors but for the most part are eliminated in a hepatic first-pass effect before reaching the systemic circulation. Carcinoid syndrome is therefore a bad prognostic sign because it does not typically develop until metastatic lesions in the liver directly release their products into the systemic circulation. Hindgut carcinoid tumors (those located in the distal transverse colon and beyond) classically do not cause carcinoid syndrome because they are less endocrinologically active.

Diagnosis of a carcinoid may be suspected clinically but can be difficult to confirm histologically short of a surgical resection because the lesions are submucosal and not commonly in reach of an endoscopic biopsy. A preoperative workup for a carcinoid tumor should include a 24-hour urine collection of 5-HIAA and a plasma chromogranin A. Both parameters can also be used for postoperative surveillance. Cross-sectional imaging and somatostatin receptor scintigraphy are tools to evaluate for systemic disease. Multicentricity and associated high rates of synchronous gastrointestinal and genitourinary malignancies warrant both an upper and lower gastrointestinal endoscopy.<sup>189</sup>

An oncologic resection should be performed in all carcinoids larger than 2 cm unless contraindicated by clinical circumstances. Tumors less than 1 cm in size may be managed locally, whereas the management of lesions measuring 1 to 2 cm remains controversial.<sup>186</sup>

**Gastrointestinal Stromal Tumors (GISTs).** GISTs are the most common mesenchymal tumors of the gastrointestinal tracts and originate from the

intestinal pacemaker cells, the interstitial cells of Cajal.<sup>190</sup> Sixty percent of GISTs are found in the stomach; 29% in the small intestine; 2% in the colon, rectum, and rectovaginal septum; and 9% in the esophagus.<sup>191</sup> Symptoms are nonspecific and include pain, obstruction, bleeding, and a mass. Distinction from other mesenchymal tumors (eg, leiomyosarcoma) is important from a prognostic point of view. Tumor size and light microscopic determination of the mitotic rate (mitotic figures per x number of high-power fields) are the most important conventional prognostic indicators.<sup>190</sup> The diagnosis of GISTs is based on morphologic features and immunohistochemical demonstration of *c-kit* (CD117) expression. This marker is seen in almost all GISTs and is regarded as one of the key diagnostic elements, but a few otherwise characteristic tumors are found to be *c-kit* negative.<sup>192</sup> While the majority of GISTs have activating mutations of the KIT receptor tyrosine kinase, another subset of tumors show mutations in the KIT-related kinase gene platelet-derived growth factor receptor alpha (PDGFRA).<sup>193</sup> KIT and PDGFRA mutations appear to be alternative and mutually exclusive oncogenic mechanisms in GISTs.<sup>194</sup> Determination of CD117 expression is of practical importance because positivity correlates with a tumor response to treatment with imatinib (Gleevec), which inhibits KIT kinase activity. Surgical resection is the primary treatment for localized GISTs that are resectable without mutilation. Recurrent and locally advanced or metastatic tumors are treated increasingly with imatinib in a palliative, adjuvant, or neoadjuvant setting.

**Nodular Lymphoid Hyperplasia.** This condition is characterized by numerous polyps in the small and large intestine, rarely in the stomach, which consist of enlarged submucosal lymphoid follicles. Associated diseases are immune deficiencies of various origins (eg, tumors, hematoproliferative disorders, immunoglobulin A deficiency, and human immunodeficiency virus [HIV] infection), in which case recurrent infections (eg, giardiasis) appear to promote the nodular lymphoid hyperplasia. Immunocompetent patients usually are asymptomatic, and the nodular lymphoid hyperplasia is an incidental finding. Nodular lymphoid hyperplasia has been associated with an increased subsequent incidence of lymphoma (small bowel).<sup>195</sup>

## **MALIGNANT NONEPITHELIAL TUMORS OF THE**

## COLON

**Lymphoma.** Primary malignant lymphoma of the colon is uncommon and accounts for only 0.2% to 0.4% of all colonic malignancies and 10% to 15% of all primary lymphomas of the gastrointestinal tract, which themselves account for about 30% of extranodal lymphomas.<sup>196</sup> The most frequent colonic location is the cecum (70%), followed by the rectum and ascending colon. The gross appearance may be a circumferential or polypoid mass, an ulceration, or a diffuse infiltration with stricturing and bowel wall thickening.<sup>197</sup> Eighty-six percent of the lesions are solitary, but they can be multiple and diffuse in nature. The intestinal lymphomas may be subclassified into B-cell lymphomas (85%) and T-cell lymphomas (15%). Among the B-cell lymphomas, mantle cell lymphoma has a worse prognosis, whereas mucosa-associated lymphoid tissue (MALT) lymphomas have a better prognosis than other B-cell tumor types.<sup>197</sup> While surgical treatment may be indicated for some localized tumors, many authors consider medical management to be the primary treatment. It may include new approaches such as anti-infectious treatment for MALT lymphoma or reconstitution of the patient's immune status, for example, by means of antiretroviral treatment in HIV-associated B-cell lymphoma.<sup>198</sup>

Multiple lymphomatous polyposis of the gastrointestinal tract is a distinct clinicopathologic entity. This rare form of primary gastrointestinal lymphoma occurs most often in elderly patients and accounts for 9% of all gastrointestinal lymphomas.<sup>199</sup> The polyps can be widespread throughout multiple segments of the gastrointestinal tract. Histopathologic and immunohistochemical techniques are required to differentiate lymphomatous polyposis from other forms of gastrointestinal polyposis.

**Kaposi Sarcoma.** This commonly multifocal angiosarcoma has been associated with herpesvirus-8 (HHV-8) infection in conjunction with immunosuppression (eg, HIV/AIDS, chronic steroid or immunosuppressant medication). The incidence in organ transplant recipients is about 0.5% to 0.6% but most frequently involves the skin. In rare cases, however, the anorectum or intestines are involved and show characteristic bluish-purple submucosal nodules. Treatment is primarily aimed at improving the immune status, but chemotherapy and, rarely, radiotherapy may be indicated in patients in whom the immune status cannot be restored.<sup>200</sup>

**Smooth Muscle Tumors.** Smooth muscle tumors of the colon are rare and occur most commonly in the form of a pedunculated leiomyoma of the muscularis mucosa. Leiomyosarcomas, which consist histologically of spindle cells that resemble smooth muscle cells, are even less frequent but are characterized by an extremely aggressive and rapidly fatal growth pattern. Whenever possible, oncologic resection and adjuvant chemotherapy are the treatment of choice.<sup>201</sup>

## SECONDARY TUMORS TO THE COLON

**Endometriosis.** Endometriosis may involve the colon or rectum in approximately 15% to 20% of cases and may mimic colonic carcinoma. The lesions are rarely larger than 5 cm, involve the subserosa and muscle coats, and may project into the lumen of the bowel. When endometrial tissue extends through to the colonic mucosa, biopsy may be mistaken for adenocarcinoma.

**Invasion From Extracolonic Cancers.** Locally advanced tumors from noncolonic primary cancers may directly invade the colon and cause symptoms suggestive of colon cancer (bleeding, obstruction, fistula). These tumors originate from organs in close adjacency to the colon (female organs, bladder, prostate, kidneys, pancreas, duodenum, liver).

**Metastatic Cancer.** Carcinomas from other primary sites may metastasize to the colon and occasionally mimic a primary colon cancer. Metastases originate most commonly from lobular breast cancer, stomach cancer, ovarian cancer, malignant melanoma, and leukemia, the latter of which can be diagnosed by the hematopoietic infiltrates.

## SURGICAL ANATOMY OF THE COLON

A fundamental knowledge of the anatomy is unquestionably a key to success-oriented surgical technique aimed at the best oncologic outcome and a minimized morbidity. The large intestine starts at the ileocecal junction and extends to the anus. It is about 5 to 6 ft (125-150 cm) long and can be divided into the cecum with the appendix, the ascending colon, the transverse colon, the descending colon, the sigmoid colon, and the rectum. Definitions of

where the sigmoid colon ends and the rectum begins have not always been uniform. The best definition of the rectosigmoid junction from a functional and surgical viewpoint is the confluence of the teniae coli.<sup>202</sup> However, the inability to visualize this anatomic reference point endoscopically recently led the NCI and other expert committees to define the rectum for the purpose of uniformity in clinical trials as the last 12 to 15 cm above the anal verge as measured by rigid sigmoidoscopy.<sup>203</sup> This endoscopic definition is necessary in order to determine the appropriateness of preoperative (neoadjuvant) chemoradiation for rectal but not sigmoid cancer.<sup>203</sup> Obsolete, variable, and thus inaccurate definitions relate the rectosigmoid junction to the level of (1) the peritoneal reflection or (2) the sacral promontory.

The arterial and venous blood supply and the lymphatics of the colon are summarized in [Figure 49-4](#). The arterial blood supply to the colon comes from the superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA), which communicate in a watershed area in the splenic flexure (artery of Drummond). The rectum has additional branches from the internal iliac vessels. With a significant degree of anatomic variation, the major vascular stalks to the colonic segments consist of the ileocecal and right colic artery (last branch of the SMA), the middle colic artery (second branch of the SMA), the left colic artery (first branch of the IMA), and the superior hemorrhoidal artery (distal branch of the IMA). The venous blood supply peripherally follows the arterial branches but more centrally divides into the superior mesenteric vein and the inferior mesenteric vein, which connect at separate levels to the portal system. The lymphatic drainage starts with lymphatic follicles in the colonic submucosa, drains through the colonic muscle wall into the epicolic nodes, and continues to the paracolic lymph nodes that follow the blood vessels to the bowel, along the major arteries to the principal lymph nodes at the level of the arterial runoff from the aorta. These lymph node groups consist of the celiac, the superior mesenteric, and the inferior mesenteric groups of lymph nodes.

**FIGURE 49-4** Anatomy of the colon. **A.** Arterial and venous supply of the colon. **B.** Lymphatic drainage of the colon.

For a safe surgical technique, the relationship of the colon with adjacent structures, mostly in the retroperitoneum, has to be fully understood. The colon is only a partially intraperitoneal organ. Only the transverse colon and the sigmoid colon are fully peritonealized and have a free mesocolon; the ascending colon and the descending colon, including both flexures, are partially located in the retroperitoneum and therefore reside in proximity to essential anatomic structures. The structures most at risk during a right hemicolectomy include the right ureter and the duodenum; during a transverse colon resection, the SMA/superior mesenteric vein (and its branches) and the gastroepiploic vessels at the gastric curvature; during a takedown of the splenic flexure, the spleen, pancreas, and left kidney; and during a left colon or sigmoid resection, the left ureter, the gonadal vessels, and the hypogastric nerves.

## CLINICAL PRESENTATION OF COLORECTAL CANCER

### Symptoms and Differential Diagnosis

Colorectal cancer does not have any early signs. In fact, symptoms are often absent until a tumor has grown to a significant size. Unless a patient presents with a tumor complication (eg, bowel obstruction, bleeding, perforation, or fistula formation), symptoms mostly are subtle or uncharacteristic and vague. They may consist of unexplained weight loss, anemia and weakness from chronic blood loss, flatulence, or episodes of colicky abdominal pain. If present, these symptoms therefore always should be suspicious for a locally relatively advanced tumor stage, which is also reflected by the fact that about 20% of colorectal cancer patients at the time of their first presentation already have stage IV disease with distant metastases (Table 49-12). Because the stool in the proximal colon is still liquid or at most semisolid, proximal colon tumors may grow to relatively large size before they cause an obstruction. The more distal a lesion is localized (eg, left colon or rectum), the more likely the changes in bowel habits occur. These include rectal bleeding or mucous discharge in or with the stool, sudden onset of constipation, alternating periods of diarrhea and constipation, or a decreasing diameter of the stool. Pelvic or anal pain is an ominous sign because it may occur with increasing size, perforation, or sphincter invasion of a rectal cancer.

**TABLE 49-12: DISTRIBUTION OF SINGLE COLON PRIMARY CANCER BY STAGE**

Stage	Number	%
0, I	1845	37.8
II	1085	22.2
III	825	16.9
IV	955	19.6
Unspecified	168	3.4

Data from Passman MA, Petrelli N, Carlin A, et al. Guidelines 2000 for colon and rectal cancer surgery, *J Natl Cancer Inst* 2001 Apr 18;93(8):583-596.

Any large bowel obstruction, bleeding per rectum, gas or stool passage other than through the anus, or peritoneal signs should raise the index of suspicion for a colorectal malignancy until proven otherwise. Several other conditions and diseases have to be considered in the differential diagnosis. Obstructive symptoms may result from chronic diverticulitis, benign polyps,

Crohn's disease, endometriosis, or a postischemic stricture. A fistula may suggest complicated diverticulitis, Crohn's disease, or tuberculosis. Bleeding per rectum may also be found in hemorrhoids and other benign anorectal conditions, diverticular disease, arteriovenous malformations, endometriosis, and proctitis or colitis. However, even if 1 of these benign diseases is found on clinical evaluation, the symptoms should not be attributed automatically to them before a malignant disease of the large intestine has been ruled out.

Because symptoms are not reliable for the prevention or early detection of colorectal cancer, risk-adjusted screening programs for otherwise asymptomatic individuals (as discussed in an earlier section of the chapter) are crucial in order to achieve a reduction in cancer mortality.

Management planning in a situation with acute cancer complications should include strategies to alleviate symptoms and minimize the morbidity from the complication and also provide an oncologically adequate treatment for the tumor.

## **History and Physical Examination**

A careful history and physical examination remain the cornerstone in all patients presenting with gastrointestinal symptoms. This review should include questions about changes in bowel habits, time of last stool and gas passage, weight loss, and a personal or family history of cancer, particularly of colorectal cancer or its precursor lesions. Awareness of possible underlying diseases and genetics that predispose to colorectal cancer is of utmost importance not only for the management of the individual patient, but also for adequate counseling of potentially affected family members.

A careful physical examination follows to identify any palpable tumor masses and/or signs of tumor complication or dissemination. Apart from vital signs and temperature, the patient's general appearance may reveal evidence of cachexia, dehydration, jaundice, or lymph node enlargements. For example, enlargement of the left supraclavicular nodes may be the first but late sign of a disseminated gastrointestinal malignancy (Troisier sign). The abdomen is examined for a palpable primary tumor, hepatomegaly (liver metastasis?), distension, and/or tympanitic bowel sounds (partial or complete bowel obstruction?). Presence of peritoneal signs such as guarding with local direct and rebound tenderness or percussion tenderness may indicate a tumor perforation. A digital rectal examination and proctoscopy are mandatory to

rule out involvement of the rectum or to determine the exact distance of a distal and possibly palpable tumor from the anal verge, its axial and circumferential extent, and the mobility of the tumor against surrounding structures (eg, sacrum, prostate/vagina, anal sphincter muscle). In addition, the checking finger should assess the rectal vault for the presence of stool, blood, or melena.

A thorough general physical examination is necessary to evaluate the patient's general health status regarding the ability to tolerate a major abdominal procedure under general anesthesia. Particular attention has to be paid to patients who present with acute symptoms in an emergency setting. Prolonged fasting, nausea or vomiting, and translocation of fluids into the third space during a period of bowel obstruction or after a perforation will rapidly result in a state of malnutrition and dehydration. Developing sepsis or acute and recurrent blood loss potentially aggravate these symptoms and may result in a severe volume loss. Alarming signs are a decrease in urine output, tachycardia, hypotension, elevated temperature, short-term weight loss, standing skin folds, dry oral mucosa, and acidosis. Immediate fluid and volume resuscitation has to parallel the further clinical workup and monitoring. Blood tests have to be interpreted with caution; for example, dehydration may result in an artificially high hematocrit and mask a significant loss of blood.

## **Investigations**

Patients with symptoms suggestive of colorectal cancer should undergo a series of timely investigations with 3 goals: (1) to assess the large bowel regarding the primary lesion, concomitant lesions, and a potential underlying colonic disease; (2) to determine whether the tumor has metastasized; and (3) to assess the patient's operability (overall condition and comorbidities).

## **COMPLETE EVALUATION OF THE LARGE INTESTINE**

Irrespective of the method used, the primary goal is to document the presence of a malignant pathology and to rule out concomitant lesions in other segments of the large intestine. Both endoscopic and radiologic techniques are available for evaluation of the colon and rectum, and each type of examination has inherent strengths and weaknesses.

**Rigid Proctoscopy and Flexible Sigmoidoscopy.** These first-line diagnostic tools are used mostly in the outpatient setting to accurately assess lesions in the distal colon and rectum. The 2 methods are rapid, widely available, and require only minimal bowel preparation (enema). However, they do not provide complete information about the rest of the colon, and therefore, a complementary study is indicated before surgery. Furthermore, the flexible sigmoidoscope is notorious for giving inaccurate measurements of the level of the tumor. Determination of the rectal versus colonic location of the tumor should be done with a rigid proctoscope.

**Colonoscopy.** Conventional white light colonoscopy is currently the gold standard for the detection and treatment of colorectal polyps. It provides accurate information about the entire colonic mucosa (ie, polyps, synchronous cancer, colitis, melanosis, and diverticula), and it may be used to remove synchronous neoplastic polyps. Apart from determining the circumferential and longitudinal extent of a colonic lesion, colonoscopy addresses functional aspects such as active bleeding or an imminent obstruction by cauterization, laser ablation, or placement of a self-expanding metallic wall stent, hence allowing for turning an emergency situation into an elective one.

While the overall risk of colonoscopy is very low with a much less than 1% incidence of bowel perforation, there are some limitations to the technique. There is an estimated 10% incidence that the cecum may not be reached as a result of technical reasons. In addition, the precise position of a lesion seen on colonoscopy may not be determined adequately unless 1 of the 2 absolute landmarks (dentate line or the carpet-like villi of the terminal ileum) is in direct proximity. Relative landmarks (eg, assessment of the endoscopic shape of the colon, liver and spleen shadow, ileocecal valve, appendiceal orifice) and the length of instrument insertion from the anal verge vary considerably and should not be used. In practical terms, however, this handicap may be overcome by India ink tattooing of the area of a lesion for better identification during surgery or repeat endoscopy.

Studies have shown that 22% of polyps may be missed on the initial colonoscopy.<sup>204</sup> Furthermore, flat and depressed lesions are difficult to visualize during conventional colonoscopy using white light.<sup>205</sup> New advances in endoscopy visualization help increase the detection rate of lesions that would otherwise be missed.

Chromoendoscopy involves the use of dyes or compounds (eg, methylene blue and indigo carmine) that highlight differences on mucosal surfaces, which increases the detection of neoplastic polyps compared with conventional colonoscopy.<sup>206</sup> Once a lesion has been identified, the dye also allows the demarcation of the affected area to ensure complete removal during polypectomy. To answer the question about whether the use of dye spray increases the detection of polyps and neoplasia during colonoscopy, there have been a number of randomized controlled trials comparing chromoendoscopy with conventional colonoscopy. A recent Cochrane review analyzed 5 such trials and found a significant difference in favor of chromoendoscopy for all detection outcomes.<sup>207</sup>

Because the application of dye spray on colonic mucosa during chromoendoscopic examination may be cumbersome and time consuming, there have been technologic developments that have been able to improve the contrast between normal and neoplastic mucosa without using dyes. Narrow-band imaging (NBI) is one such modality, where the use of bandwidth filters increases the blue spectrum intensity of the light used. This lower wavelength is more readily absorbed by hemoglobin and is less able to penetrate surfaces, thereby enhancing the visualization of superficial capillaries. Because tumors are angiogenic, the vascular network is more prominent and has a higher density in neoplastic tissue than normal mucosa.<sup>208</sup> The advantages of NBI include enhancing contrast at the push of a button on the colonoscope and the ease of differentiating between neoplastic and nonneoplastic lesions. However, NBI results in poorer illumination of the background. Studies that have compared NBI versus chromoendoscopy demonstrate equivalent adenoma detection rates and similar abilities in differentiating between neoplastic and nonneoplastic lesions.<sup>209,210</sup>

Other new developments include FICE (Fujinon intelligent color enhancement),<sup>211</sup> autofluorescence imaging,<sup>212,213</sup> and i-Scan,<sup>214</sup> which improve tissue contrast by optical means. Zoom endoscopy using magnification may be combined with different modalities to help further characterize colonic lesions.<sup>215,216</sup> Confocal laser endomicroscopy combines the benefits of confocal microscopy with endoscopy and provides live in vivo high-resolution optical sections of tissue. It may be particularly useful in the surveillance of patients with long-standing ulcerative colitis, reducing the number of random biopsies.<sup>217,218</sup>

**Contrast Enema.** Radiographic contrast enemas alternatively can be used for a colonic evaluation. Contrast enemas are an especially valuable adjunct to colonoscopy in patients with near-obstructing colonic lesions. Furthermore, they have the advantage of more accurately visualizing the anatomic position of a colonic lesion (road map). Ideally, a barium-air double-contrast technique will be used after bowel cleansing; however, in a more acute setting, particularly if there is suspicion of a colonic perforation, administration of barium is contraindicated (risk of barium peritonitis), and instead, a water-soluble contrast material (eg, Gastrografin [diatrizoate meglumine]) should be used in a single-column technique.

The typical aspect of a colon cancer is a fixed filling defect with destruction of the mucosal pattern in an annular configuration (“apple core”), as opposed to an intact mucosal pattern in a filling defect from an extramucosal compression or from chronic diverticulitis. Although preoperative histologic confirmation of a colon cancer is preferable, an unequivocal and characteristic morphology on a barium enema or endoscopy is sufficient evidence to proceed to surgery. The advantages of contrast studies include better passage through even severely obstructing lesions and the fact that they commonly reach the cecum. In addition, they are superior in visualizing diverticula or a suspected fistula between the colorectum and other pelvic organs. The major disadvantage of contrast studies is the inability to take biopsies and to detect small lesions.<sup>91</sup>

**Evolving Techniques.** CT colonography (“virtual colonoscopy”)<sup>219,220</sup> and the microcapsule study have evolved in the last decade as high-tech alternatives to the 2 previously described methods. It should be noted that CT colonography still requires patients to undergo a bowel preparation and that air insufflation is necessary. While there is certainly a lot of promise for both new approaches, which likely will continue to improve over time, the definite role of these techniques awaits further clarification.

Early studies suggested that CT colonography had a considerable rate of false-negative and false-positive results.<sup>220,221</sup> In a recent study of 937 patients with risk factors for colorectal cancer, CT colonography had a sensitivity of 85% for lesions 6 mm or larger.<sup>88</sup> So far, the technology has not been approved by Medicare for screening purposes, but this may change in the future with additional validation studies. Unfortunately, incidental extracolonic findings may precipitate a large number of unwarranted tests,

which add tremendous cost to the health care system. Currently, CT colonography may serve a useful purpose in patients for whom a colonoscopy is undesirable or unsuccessful.

## **EVALUATION OF THE LOCAL TUMOR EXTENT AND OF METASTATIC DISSEMINATION**

Traditionally, the preoperative staging for colon cancer did not mandate further imaging studies because, in the majority of cases, they do not change the local surgical approach. Increasingly, however, preoperative cross-sectional imaging (CT or magnetic resonance imaging) has become the standard of care.<sup>222,223</sup> The justification for this shift is two-fold. First, patients with a significant burden of liver disease (>50% liver replacement) may carry a prohibitive risk for general anesthesia and should be treated with chemotherapy either in advance of surgery or instead of it. CT scans are the most commonly used cross-sectional imaging technique in the United States and have a 90% and 95% sensitivity and specificity in detecting liver lesions larger than 1 cm.<sup>224</sup> Second, the surgeon can be alerted to evidence of advanced locoregional disease that may alter the operative plan and necessitate the involvement of other operative expertise (eg, hepatobiliary surgery, urology, gynecology).

To rule out extrahepatic metastases, in particular pulmonary metastases, a chest x-ray in 2 planes commonly is sufficient, although the yield of this test is relatively low. A CT scan of the chest may be necessary to substantiate a concern from conventional images and is only a minimal incremental burden for a patient who is already undergoing such a study of the abdomen and pelvis.

Positron emission tomography (PET) has an evolving role in the evaluation of metastatic disease. While the routine use of PET scanning in the primary management of colorectal cancer is not recommended at this time, this technology does appear to have greater sensitivity for metastatic disease.<sup>225</sup> The extent to which this greater sensitivity can be translated into an algorithmic approach to staging remains to be seen. Its greatest utility at the current time is (1) in patients in whom systemic disease is suspected (eg, high tumor markers) but not proven and (2) under special circumstances where the presence of previously unknown tumor manifestations (eg, recurrence vs scar tissue, solitary vs multiple liver metastases, and presence

of extrahepatic metastases) would have an impact on the treatment approach (eg, operative vs nonoperative).

## **LABORATORY AND PREOPERATIVE TESTS**

Preoperative laboratory tests are aimed at providing evidence for pathophysiologic effects of the tumor and ruling out general health problems that could have an effect on the patient's general operability. A comprehensive workup includes a complete blood count, electrolytes, creatinine/blood urea nitrogen (BUN), glucose, liver function tests (alkaline phosphatase, aspartate aminotransferase [AST], alanine aminotransferase [ALT], bilirubin, total protein, albumin), and coagulation parameters (prothrombin time [PT], partial thromboplastin time [PTT], international normalized ratio [INR]). Arterial blood gas analysis and additional tests will be ordered in an emergency setting or according to the individual patient's risk assessment (eg, cardiac enzymes).

Even though tumor markers such as carcinoembryonic antigen (CEA) are determined routinely, their role is limited because of the low sensitivity and specificity for colonic carcinoma and because the measured value virtually never changes the management. CEA can also be elevated in proximal gastrointestinal cancers, benign inflammatory conditions of the bowel, lung and breast cancer, and smoking. Nonetheless, CEA level determination may prove helpful in some settings, for example, when the return of an elevated preoperative CEA level to normal indicates a complete tumor resection or when a postoperatively elevated level may indicate residual or recurrent disease.<sup>226</sup>

Preoperative standard evaluation includes a chest x-ray in 2 planes for cardiopulmonary assessment and for detection of pulmonary metastases (see previous sections). Electrocardiogram (ECG) and pulmonary function tests (forced vital capacity [FVC], forced expiratory volume in 1 second [FEV<sub>1</sub>], residual volume [RV], and diffusion capacity) are indicated in patients either older than 40 years or with a respective personal history. Specialized tests such as cardiac stress tests, echocardiogram, perfusion scintigraphy, or interventional cardiologic studies depend on the individual patient's history and risk assessment.

# TREATMENT

## Principles of Surgical Management

As a basic principle, any colorectal cancer is an indication for surgery unless widespread tumor dissemination or general contraindications from the patient's overall health status are present. Furthermore, any precursor pathology with statistical risk for cancer (eg, large sessile polyp in an otherwise healthy individual or dysplasia in a patient with ulcerative colitis) that cannot be managed nonoperatively is an indication for surgery.

The general goal for surgical management is either to achieve cure from the tumor and extension of survival or at least disease-free survival or, in the case of a precursor pathology with or without an underlying disease (eg, ulcerative colitis or FAP), to prevent the cancer and ideally to remove the risk-bearing disease. In a palliative setting, the goal is to prolong the period of symptom-free survival.

Local tumor control generally is the primary treatment objective to prevent local tumor complications, that is, obstruction, perforation, fistula formation, bleeding, and pain. Even in the presence of distant metastases in the liver or lung, resection of the primary tumor remains a reasonable priority. Because solitary or a limited number of metastases in the liver or lung often may be treated surgically by partial organ resection or metastasectomy with a cure rate of up to 35%, their presence should not necessarily alter the surgical approach to do a curative resection at the primary site. However, if there are extensive metastases or peritoneal carcinomatosis and cancer cure is not a reasonable goal, alleviation of symptoms and prevention of impending local complications, for example by restoring the intestinal continuity, are the best palliation.

The specific surgical and oncologic strategy planning is based on a number of factors. It has to take into account the exact localization of the tumor, the tumor stage, the presence of synchronous colonic lesions or an underlying colonic disease, the risk for metachronous lesions, the patient's age and general condition, the extent of the local procedure, and the timing. Only after the extent of the operation has been defined can the method and approach to be used be discussed as to whether the procedure is only suitable for an open laparotomy approach or laparoscopy may be reasonable and

beneficial.

In contrast to rectal cancer, neoadjuvant treatment (ie, preoperative chemoradiation) is not indicated in the overwhelming majority of colonic cases. In patients with resectable metastases, preoperative chemotherapy followed by a combined colon and liver resection may be an attractive alternative to a staged resection and may help in assessing the tumor response to a particular chemotherapy regimen. Only rarely is a locally very advanced lesion treated with chemotherapy in anticipation of an otherwise unresectable mass. Adjuvant (ie, postoperative) treatment is discussed in a later section.

## **PREPARATION FOR SURGERY**

When a patient is considered an operative candidate, several preparatory steps need to be addressed.

**Transfusion.** Most colonic operations can be performed without a blood transfusion. Blood-sparing surgical techniques have reduced the need, while the threshold to transfuse has substantially increased. The indication will depend on the starting hemoglobin, the patient's age and physiologic status, a history of ischemic events (eg, coronary, stroke), and the extent of expected and real intraoperative blood loss. As a routine, it is recommended to have the patient's blood typed and screened but to reserve crossmatching units of blood for these higher risk situations.

While the risk of bloodborne infections is very low, there is some controversy as to the immunologic effect of blood transfusions on the overall prognosis of colorectal cancer. Despite an initial report that transfusion may be associated with an increased likelihood of recurrence,<sup>227</sup> many subsequent reports have reached conflicting conclusions. Meta-analysis studies have strongly questioned whether there is a true causal effect present.<sup>228</sup> Other factors such as extent of resection required, tumor location, and experience of the surgeon actually may be the more relevant cause for recurrence, but transfusion may be an indirect reflection of extensive disease and surgery. Furthermore, a randomized trial comparing the use of autologous versus allogenic blood in patients undergoing colorectal resections did not show any statistical difference in prognosis.<sup>229</sup>

**Bowel Cleansing.** Traditionally, bowel cleansing was considered an essential

preparation to any elective colon surgery. The rationale is based on the colon being a large reservoir for numerous anaerobic and aerobic bacteria. However, recent prospective, randomized, controlled studies and meta-analyses comparing mechanical preparation versus no preparation for elective colorectal surgery have failed to demonstrate any appreciable decrease in infection rates, anastomotic leaks, or mortality rates in patients undergoing mechanical bowel preparation.<sup>230-236</sup> Contrasting with the evidence, however, the majority of colorectal surgeons still perform bowel cleansing in their patients. The indisputable advantages of a bowel preparation remain (1) the intraoperative ability to perform a colonoscopy if that were needed and (2) the absence of a preanastomotic stool load if a primary anastomosis or the tissue quality were unexpectedly less than optimal and required a fecal diversion.

There are a wide variety of laxatives, washouts, and enemas available on the market for mechanical cleansing, but the products used generally are based on either polyethylene glycol (eg, GoLYTELY) or sodium phosphate (Fleet Phospho Soda), the latter of which is contraindicated in patients with renal failure and has come under more broad scrutiny in the United States. In the absence of a consensus regarding the best regimens (ie, orthograde cleansing alone or combined with retrograde enemas), the choice often is a matter of personal preference. Depending on an individual patient's constitution and the degree of obstruction, the bowel cleansing should be started 1 or even 2 days before surgery. The cathartic may result in significant fluid and electrolyte imbalances. Therefore, elderly patients, who are more prone to this adverse effect, should preemptively be given intravenous fluids and electrolytes.

**Antibiotic Prophylaxis.** Perioperative administration of prophylactic antibiotics aims at reducing colonic and dermal bacterial concentrations and is considered a crucial component of colorectal procedures. The benchmark is the rate of surgical site infections in relation to the level of wound contamination. Prophylaxis has to be distinguished from therapeutic antibiotic treatment in patients who already have an established infection. Prophylaxis (ie, in patients who do not primarily suffer from an infection) should be targeted, adequately dosed, and short (ie, start within 1 hour of the incision and be limited to less than 24 hours) in order to minimize antibiotic side effects and propagation of resistances. Coverage should include both

aerobic bacteria (eg, *Staphylococcus*, *Escherichia coli*, *Klebsiella*, *Proteus*) and anaerobic bacteria (eg, *Bacteroides fragilis*, *Clostridium*).

Intravenous administration of broad-spectrum antibiotics is the most common form of prophylaxis and includes several acceptable antibiotic selections: (1) single antibiotics (ertapenem, piperacillin-tazobactam); (2) combination of 2 antibiotics (second- or third-generation cephalosporin + metronidazole, fluoroquinolone + metronidazole, clindamycin + aminoglycoside, clindamycin + quinolone, clindamycin + aztreonam); or (3) triple combinations, such as amoxicillin-clavulanic acid + metronidazole + aminoglycoside. Oral antibiotics (eg, metronidazole combined with nonabsorbable neomycin) in conjunction with a mechanical bowel preparation may yield similar results but may increase the risk of nosocomial superinfections, in particular with *Clostridium difficile*.

Special considerations according to national guidelines have to be followed for prophylaxis in patients at risk for endocarditis (eg, patients with mechanical heart valve).

**Thromboembolic Prophylaxis.** Thromboembolic prophylaxis is recommended in all patients undergoing major surgical procedures to reduce the incidence of postoperative deep venous thrombosis and pulmonary embolism. Both pharmacologic prophylaxis and physical prophylaxis (eg, pneumatic calf compression) have been proven to be effective,<sup>237</sup> but the use of pharmacologic prophylaxis has been endorsed by a task force recommendation.<sup>238</sup> Both low-dose unfractionated heparin and low-molecular-weight heparins (LMWHs) have been shown to be equally effective in reducing the incidence of postoperative thromboembolic events without resulting in significant complications.<sup>239</sup> A more recent randomized study, however, showed that LMWHs have a slightly higher rate of minor bleeding events.<sup>240</sup> Based on economic analysis, the data favor the use of subcutaneous heparin as being more cost-effective than LMWHs.<sup>241</sup> It is recommended that these drugs be commenced at least 2 hours before surgery and continued postoperatively until the patient has obtained full ambulation. Intermittent pneumatic calf-compression boots are an alternative to heparin that has been demonstrated to be equally successful in preventing deep venous thrombosis and possessing the advantage of no risk of increased bleeding.<sup>242</sup> It remains to be determined whether a combination of chemical agents and pneumatic calf-compression boots for patients undergoing colonic

resection will be an advantage.

Anticoagulated patients who need to take warfarin (eg, due to a mechanical heart valve) should be switched perioperatively to intravenous heparin to allow for stopping the warfarin medication and antagonizing its effect with vitamin K. Four hours before incision, the heparin may be discontinued and resumed within 24 hours postoperatively with a stepwise increase in the dose.

**Urinary Catheters/Stents.** After induction of general anesthesia, bladder catheterization should be performed in all major cases to adequately monitor the urine output peri- and postoperatively. In selected patients with a previous history of colorectal or pelvic dissections, placement of ureteral stents allows better intraoperative identification and protection of these crucial structures. Laparoscopic colon procedures do not routinely need ureteral stents; however, selective use of lighted ureteral stents during challenging laparoscopic procedures may facilitate identification of these structures.

**Nasogastric Tube.** Placement of a nasogastric tube is not necessary on a routine basis for patients undergoing resection of the colon or rectum and should be avoided unless they present with a complete or partial bowel obstruction.<sup>243</sup>

**Preoperative Marking of Ostomy Site.** In patients who may need permanent or temporary placement of an ostomy during the surgical procedure, preoperative marking of the ideal stoma site by a stoma nurse helps to facilitate postoperative ostomy handling by the patient.

**Preemptive Pain Management.** Effective pain management is an important factor not just for patient comfort but to reduce the incidence of postoperative pulmonary complications. Preoperative placement of epidural analgesia is a very valuable strategy, which, in addition to its pain-relieving effect, promotes the earlier resumption of postoperative bowel function as a result of its suppression of sympathetic nerves. The relevant segments that need to be blocked for an abdominal incision are located at a thoracic level (T6-T12).

## **Surgery**

## GENERAL TECHNICAL PRINCIPLES

The objective of surgery for colonic cancer is to perform a curative resection by removing the cancerous segment of colon, the mesentery with the primary feeding vessel and the lymphatics, and any organ with direct tumor involvement. Because the lymphatics run with the arterial supply of the colon, the primary artery supplying the segment of the colon to be resected is divided at its origin. Ligation at the origin of the vessel ensures inclusion of apical nodes, which may convey prognostic significance for the patient.<sup>244</sup> While careful dissection in the right place is the mainstay of a successful surgery, the historical Turnbull no-touch technique with early vascular ligation and occlusion of the bowel with tapes to prevent embolization of tumor and improve survival has not shown any advantage.<sup>245</sup>

The length of bowel and mesentery resected is dictated by tumor location and distribution of the primary artery (Table 49-13), but a radical resection of a colonic tumor should achieve at least a 5-cm clearance at the proximal and distal margin. Extended resections for confined tumors outside of high-risk patients have not been shown to confer additional survival benefit<sup>246</sup>; however, tumors located in “border zones” should be resected with both neighboring lymphatics to encompass possible bidirectional spread. If a tumor is adherent to or invading an adjacent organ such as the kidney or small bowel, an en bloc resection should be performed where technically feasible. Because adhesions between the tumor and adjacent organ may not necessarily be inflammatory but a result of carcinoma, mere division or “pinching” of a tumor from an adjacent organ is not an acceptable surgical technique because it may reduce the chance of cure.

TABLE 49-13: STANDARD RESECTIONS OF THE COLON

Tumor Location	Resection	Description of Extent	Major Blood Vessel	Safety Margin (cm)
Cecum	Right hemicolectomy	Terminal ileum to midtransverse colon, right flexure included	Ileocolic artery, right colic artery, right branch of midcolic artery	5
Ascending colon	Right hemicolectomy	Terminal ileum to midtransverse colon, right flexure included	Ileocolic artery, right colic artery, right branch of midcolic artery	5
Hepatic flexure	Extended right hemicolectomy	Terminal ileum to descending colon (distal to left flexure)	Ileocolic artery, right colic artery, midcolic artery	5
Transverse colon	Extended right hemicolectomy	Terminal ileum to descending colon (distal to left flexure)	Ileocolic artery, right colic artery, midcolic artery	5
	(Transverse colon resection)	Transverse colon (including both flexures)	Midcolic artery	
Splenic flexure	Extended left hemicolectomy	Right flexure to rectosigmoid colon (sigmoid, beginning of rectum)	Midcolic artery, left colic artery, inferior mesenteric artery	5
Descending colon	Left hemicolectomy	Left flexure to sigmoid colon (beginning of rectum)	Inferior mesenteric artery, left branch of midcolic artery	5
Sigmoid colon	Rectosigmoid resection	Descending colon to rectum	Superior hemorrhoidal artery, inferior mesenteric artery	5

When synchronous cancers are present in the colon, an extended resection or even total colectomy, with ideally only 1 anastomosis, should be performed. Occasionally, 2 separate resections (eg, right hemicolectomy and low anterior resection) with 2 anastomoses are preferable to preserve colon length and to avoid postcolectomy diarrhea. Cancer on the basis of an underlying pancolonic disease (eg, ulcerative colitis or FAP) requires a total proctocolectomy with either an ileoanal pull-through procedure or an ileostomy<sup>76</sup>; young patients (<50 years, with or without proven HNPCC gene constellation) presenting with tumors proximal to the sigmoid colon should be offered a total abdominal colectomy to reduce the risk of metachronous cancers and to facilitate surveillance.<sup>247</sup>

A limited wedge resection may be considered for an unfit patient or for palliative resection in those with widespread tumor. This will relieve the patient's symptoms and prevent future obstruction and bleeding from the primary tumor.

## INTRAOPERATIVE SURGICAL TECHNIQUE

**Positioning.** For all left-sided colonic resections, it is advisable to place the patient in a modified lithotomy position, which gives access to the anus (eg, for a stapled anastomosis) and allows an assistant or the surgeon to stand between the legs for retraction or an excellent view to mobilize the splenic flexure, respectively. The same positioning obviously also can be used for all

other colon resections, but a supine position usually is sufficient and faster. Laparoscopic procedures typically require the operating table to be tilted and moved to steep Trendelenburg position; appropriate fixation and securing of the patient is therefore mandatory.

**Incision.** For an open procedure, the peritoneal cavity is most commonly entered through a midline laparotomy incision. For a proctocolectomy, we usually recommend the use of an infraumbilical incision in order to provide good exposure for the pelvic dissection. For a more proximal segmental colon resection, however, an equally short but higher midline incision may be more convenient. In addition, a transverse incision or even a subcostal incision may give excellent exposure for a right hemicolectomy.

For a laparoscopic procedure, a first camera trocar is placed in either Veress needle or in open Hasson technique. The site should be chosen such that additional working ports can be placed along a circle with the target in the center.

**Exploration.** After the peritoneal cavity is entered (open or laparoscopically), the abdomen is explored systematically to determine the resectability of the tumor. Special attention is addressed to the presence of distant metastases in the liver, peritoneal carcinomatosis, or additional synchronous lesions throughout the large intestine. Other accessible organ systems are assessed equally, for example, the gallbladder and the female reproductive organs.

**Colon Resection.** The surgical technique has been standardized for 3 segments: right colon, left colon, and rectosigmoid. Depending on the extent of the resection eventually needed in an individual patient, the technique for those segments may be combined (see [Table 49-13](#)). With a detailed description of the maximal resection, that is, an open total colectomy/proctocolectomy, all information about the individual steps necessary to perform any colorectal resection of lesser extent will therefore be provided.

The same steps should be achieved with laparoscopic resections; however, depending on the surgeon's preference and skills, a medial-to-lateral mobilization of the colon (ie, starting at the feeding vascular stalks before moving to the retroperitoneal attachments) supports the autoretraction of the

colon throughout the critical steps.

On careful exploration of the abdomen, mobilization of the colon starts on the right side. Use of a mobile (eg, Richardson retractor) instead of a fixed (eg, Balfour or Bookwalter retractor) abdominal wall retractor in this first phase will allow a more flexible and unidirectional exposure according to rapidly changing needs. The small bowel is eviscerated from the abdomen and moved to the left. The abdominal wall is retracted to the right side while exerting countertraction on the cecum and ascending colon. A small incision is made at the exposed white line of Toldt to enter the retroperitoneum. Elevating the ascending colon from the retroperitoneal structures, the peritoneum is divided along the lateral gutter from the terminal ileum to the hepatic flexure. On the right side, the ureter is at fairly low risk and routinely falls away; however, special care is needed to avoid damage to the third part of the duodenum. The mobilization is facilitated by firm traction placed on the colon and the surgeon's left hand inserted into the retroperitoneum as a guide to divide along the peritoneal reflection. Because of the limited view around the hepatic flexure and the presence of small vessels at this level, transection of the peritoneum with cautery is often advisable.

As the right edge of the gastrocolic ligament is reached, it may be easier to complete the dissection of the hepatic flexure in retrograde direction. The abdominal wall retractor is moved quickly into the upper end of the incision in order to pull in a cephalad direction. The lesser sac is entered far to the left in an avascular portion of the omentum, and the greater omentum is divided inferior to the gastroepiploic vessels between clamps and ligatures. While the omentum may be preserved in benign diseases, its resection with the respective colon segment is part of an oncologic resection. Dissection of the gastrocolic ligament is carried out from the left to the right. Connective tissue attachments between the antrum, duodenum, and transverse mesocolon and the hepatic flexure are divided stepwise by a combination of blunt digital tunneling and sharp dissection using both hands. Care should be taken at this point to avoid dissecting too deeply into the retroperitoneum, where large blood vessels can be encountered. Once the mobilization has been completed around the hepatic flexure, the right colon and transverse colon are attached only to their vascular supply and are ready for resection. This would be used for any standard right hemicolectomy or the first part of an extended transverse colectomy. For total colectomy, mobilization of the whole colon commonly is continued before dividing the major vessels.

At this point, the abdominal wall retractor is moved to the left side of the abdomen, and traction is placed to expose the left portion of the colon. The dissection is initiated at the level of the sigmoid, where the white line of Toldt again is incised and the retroperitoneum entered. Once the areolar tissues are identified, a small sponge is taken, and with firm pressure against the sigmoid mesentery, the retroperitoneal tissues are bluntly reflected, and the left ureter is exposed. Only after the ureter has been clearly identified and moved out of the way is incision of the peritoneum continued into the pelvis for a short distance and up to the splenic flexure along the left gutter. The colon is reflected bluntly from the retroperitoneal tissues, and with firm traction the peritoneal incision is continued. Gentle traction on the transverse and descending colon will help to lower the splenic flexure until it can be visualized fully. A hand placed in the retroperitoneum will help to mobilize the splenic flexure, and under direct vision, the peritoneum over the splenic flexure can be incised. Care must be taken at this point to protect the spleen from direct or traction injury. The final attachments of the splenocolic ligament that hold the splenic flexure are clamped and divided in appropriate tissue portions. Clamping and ligating this tissue are recommended because even small vessels retracting into the left upper quadrant can be a nuisance.

After completion of the first 2 parts, the colon is mobilized completely from its retroperitoneal attachments from the terminal ileum to the upper rectum. Elevation of the colon allows identification of all primary feeding vessels. In order to ligate the inferior mesenteric vessels, the surgeon is on the patient's left and the colon is reflected to the left. The attachments that run over the sacral promontory and up along the left gutter are incised, and a hand is used to dissect the tissues bluntly from behind the inferior mesenteric vessels. By identifying the inferior mesenteric vessels and making the window just under those, the hypogastric nerves going down into the pelvis are protected routinely. Sometimes, for example, if there is concern about cancer in the rectum or if the patient is very obese, these structures need to be freed up more to elevate the nerves initially and later to dissect them out under direct vision. The avascular window around the origin of feeding vessels then is opened. In the case of the inferior mesenteric vessels, the left hand is placed behind the inferior mesenteric stalk, and the thumb and opposing index finger can clear a window of avascular tissue above it. Dissection of redundant adipose tissue around the vessels is carried out under direct vision, before the vessels are clamped. Before transection and ligature

of the vessels, the remote location of the ureter is confirmed once more. If the ureter is not identified properly before dividing the vascular pedicle, accidental dissection of the ureter can occur and requires a repair. If unrecognized intraoperatively, the ureter injury may result in a urinoma. In difficult cases (eg, repeat operation or recurrence), it is therefore advisable to place preoperative ureteral stents to allow better identification. The whole vascular stalk may be ligated with a double ligature or a suture ligature. Individual ligature of the artery and vein is optional and has not been shown to provide an advantage. For the reason mentioned earlier, it is recommended to ligate the vessels as proximally as possible, but from an oncologic standpoint a high ligation of the IMA does not provide any advantage in comparison with a low ligature distal to the origin of the left colic artery.<sup>248,249</sup>

The vascular dissection is then continued around the colonic mesentery. The avascular tissue can be divided sharply while clamping is applied to vessels when they are encountered. The vascular anatomy of the colon is quite variable. However, if one is truly in the retroperitoneum and ligating named vessels at their origin, the colon can be taken out with as few as 3 to 4 clamps. In particular, the inferior mesenteric, middle colic, and ileocolic vessels need to be ligated. The presence of additional right and left colic vessels sometimes requires the use of 5 or 6 clamps. By taking the vessels closer to their origin, that is, before they branch off into multiple subsegments, fewer clamps are necessary and the dissection proceeds more rapidly.

Once the vessels have been ligated, the bowel may be divided by means of cutting linear stapling devices at the previously determined levels. In patients with an underlying disease (eg, ulcerative colitis or FAP), the dissection at this point would be continued as a total mesorectal excision down into the pelvis to the pelvic floor (see respective chapters). It is strongly recommended to have the specimen assessed macroscopically to verify the pathology. Tumor in the resection margin means an inadequate cancer operation requiring a re-resection. Intraoperative frozen sections of the resection margins should be requested whenever there is any doubt about the completeness of the resection.

Recently, there has been much debate on the topic of complete mesocolic excision (CME) with central vascular ligation (CVL), following the principles of total mesorectal excision (TME), allowing for a higher quality

of surgical specimen and a higher number of retrieved lymph nodes compared to conventional colectomy.<sup>250,251</sup> However, there is no strong evidence that a CME colectomy offers any improved long-term survival benefit compared to standard colectomy.<sup>251-253</sup>

**Reconstruction/Diversion.** After the resection has been completed, either the bowel ends can be reanastomosed or the proximal end may be brought out as an ostomy. Prerequisites for a successful anastomosis are meticulous technique, well-vascularized and healthy-appearing tissues, apposition of bowel ends without any tension, and good nutritional status of the patient with an albumin level greater than 3.0 mg/dL. Constructing an anastomosis under tension and/or with poor blood supply increases the risk of an anastomotic leak that may cause an infection and sepsis. A protective diverting ostomy does not prevent the leak as such but should diminish the life-threatening complications of an anastomotic leak. While a stapled functional end-to-end anastomosis between the ileum and the colon (ie, an enterocolonic anastomosis) is reasonable, this type of anastomosis may potentially be less desirable between 2 colon segments (ie, a colocolonic anastomosis) because it can result in an iatrogenic giant diverticulum that may interfere with the propulsion of formed stool or impede the performance of a surveillance colonoscopy. Performing an end-to-end anastomosis, either hand-sewn or by means of a circular stapler, will avoid these problems. An ileocolonic anastomosis in most instances can be performed in an unprepared bowel, whereas a colocolonic anastomosis on the left side traditionally requires pre- or intraoperative reduction in the stool load unless a colostomy was performed. As mentioned previously, this view has come under scrutiny.

**Drains.** Placement of drains is more often a matter of personal preference than of scientific objectiveness.<sup>254-256</sup> Most bowel anastomoses, even colocolonic anastomoses, do not need to be drained. The use of drains generally may be recommended when a pelvic dissection and anastomosis have been performed and accumulation of fluid and blood in the dependent areas around the anastomosis should be avoided. Whether prospective, but underpowered, studies are sufficient evidence to effectuate a change in this practice needs to be determined.<sup>257,258</sup>

## TECHNICAL CONSIDERATIONS

**Laparotomy Versus Laparoscopy.** Laparoscopic colon surgery has a clearly established place in the management of both benign and malignant colon diseases. In many specialized centers, it is even regarded the first-line approach unless patient-specific factors suggest otherwise. The path to a nearly unanimous endorsement of the technique at least for right-sided, left-sided, and sigmoid resections for colon cancer started in the early 1990s,<sup>259</sup> moved from palliative resections to institutional case series in curative intent, and culminated in several prospective randomized trials throughout the world,<sup>260-265</sup> the first large-scale trial being a multicenter study by the NCI.<sup>261</sup> This study, which enrolled 872 patients with stage I to III colon cancer, confirmed that there was a moderate quality-of-life benefit for the laparoscopic approach<sup>266</sup> but otherwise no difference in oncologic outcome and survival between the laparoscopic and open-resection groups.<sup>261</sup> Subsequently, 2 large-scale European prospective multicenter trials (ie, the COLOR [Colon Cancer Laparoscopic or Open Resection] trial with 1248 patients and the CLASICC [Conventional Versus Laparoscopic-Assisted Surgery in Colorectal Cancer] trial with 794 patients) have confirmed similar results.<sup>267,268</sup> This equality of the study results offered the unique opportunity for both opponents and proponents of the laparoscopic approach to justify their personal preference for either the open or laparoscopic technique depending on their background and skills. In contrast to one early report of a high incidence of port-site recurrences, it has become clear subsequently that with appropriate surgical technique, the incidence is in the range of 0.8% to 1.3% and, on a stage-by-stage comparison, not higher than wound implants after open surgery.

For the laparoscopic procedure, about 3 to 5 trocars are inserted. Lacking the tactile sensation of open procedures, tattooing of the target lesion should generally be performed prior to the surgery. The colon should be mobilized to the same extent as during open surgery, but it may be advantageous to start with the vascular pedicle rather than with the retroperitoneal attachments. The technical equipment to perform an intracorporeal resection and anastomosis is available, but it is questionable whether there is any advantage to this because at some point an incision must be made anyway to retrieve the specimen. In the laparoscopically assisted technique, the segment, once it has been mobilized to the required extent, therefore is exteriorized through a small sleeve-protected abdominal incision, and an extra-abdominal resection

and anastomoses are performed. The bowels are returned into the abdomen, the fascia is closed, and the pneumoperitoneum may be reinstalled to inspect the peritoneal cavity again. To facilitate complex resections, some surgeons use hand-assisted laparoscopic surgery (HALS) to combine tactile sensation with a minimally invasive approach.

**Fluorescent Image-Guided Surgery (FIGS).** The use of fluorescent agents to help guide surgeons intraoperatively is rapidly expanding. Together with the development of suitable endoscopic imaging equipment, this technology is able to help by identifying normal anatomy and minimizing complications.

Iatrogenic ureteric injury is a potentially serious complication of colorectal surgery, with an incidence ranging from 0.7% to 10%. Methylene blue is a fluorescent agent that has been used in patients for many years as a reflectance dye. Intravenously administered methylene blue is excreted renally and concentrated in the urine. It can be excited at 660 nm and emits light typically in the far red/near-infrared region (~700 nm), in which light penetration in tissue is considerably higher than using white light alone. A recent study demonstrated that low-dose intravenous methylene blue was able to identify 10 of 11 ureters intraoperatively when viewed using fluorescence-capable laparoscopes.<sup>269</sup> This technique could potentially be very useful, particularly in challenging procedures where the location of the ureters may not be readily identified under white light visualization alone, for example, in patients with previous radiotherapy or retroperitoneal fibrosis or patients undergoing reoperative surgery.

The use of near-infrared (NIR) laparoscopy together with indocyanine green (ICG) has been investigated to assess the perfusion of bowel anastomosis intraoperatively. In a recent study of 30 patients undergoing colorectal resections, a high-quality intraoperative ICG angiogram was achieved in 29 patients. Anastomotic perfusion was documented as being satisfactory in each successful case and encouraged avoidance of defunctioning stomas in 3 patients with low anastomoses. There were no postoperative anastomotic leaks in this series.<sup>270</sup> This technique is potentially useful as it can identify anastomoses with a poor blood supply that require further proximal re-resection and that would have been missed on white light visualization alone, thereby potentially preventing an anastomotic leak.<sup>271,272</sup>

## SPECIAL CIRCUMSTANCES IN EMERGENCY SURGERY

Approximately 20% of patients with colon cancer present as an emergency requiring an urgent operation for a tumor-related complication (eg, bowel obstruction, perforation, or massive bleeding).<sup>273</sup> Morbidity and mortality are significantly higher than under elective conditions. Contributing factors are the lack of a mechanical bowel preparation and the patient's impaired overall status, which typically is characterized by dehydration, third spacing of fluids, anemia, a deranged metabolism with electrolyte imbalances, and possible sepsis. The risks for wound and intra-abdominal infections and anastomotic leakages are 3 to 6 times higher.<sup>274</sup>

**Tumor Obstruction.** Sixteen percent of patients with colon cancer present with a bowel obstruction and complain of colicky abdominal pain, abdominal distension, vomiting, constipation, and, occasionally, paradoxical diarrhea. Imaging studies (abdominal x-ray or CT scan) characteristically demonstrate the features of a large or small bowel obstruction depending on how proximal in the colon the obstruction is located and whether the ileocecal valve is competent. Attention should be paid to the diameter of the cecum, which presents a risk of cecal perforation if the diameter reaches 12 cm or more. Urgent intervention is required in such circumstances to prevent cecal perforation. The most important differential diagnosis is pseudo-obstruction (Ogilvie syndrome), which is seen as a result of various medical conditions and may mimic the features of bowel obstruction. Every patient therefore should have a rigid proctoscopy, followed by a water-soluble contrast enema, which should visualize only the colon up to the site of obstruction but not beyond the stenosis because the hyperosmolar nature of the contrast material can result in an increase in the intraluminal volume and trigger a perforation.

If the level of obstruction in the colon is proximal enough, a resection with primary enterocolonic anastomosis, for example, right hemicolectomy, extended right hemicolectomy, or subtotal colectomy, may be carried out. If the tumor is located on the left side of the colon, adjustments to the surgical approach are necessary because the stool load proximal to the obstruction is of concern for a colocolonic anastomosis and because that segment of the colon could not be cleared before the operation. Synchronous lesions, which in the setting of an obstructing lesion may occur in up to 15% of patients, may be missed and necessitate further intervention in the future. Strategies

then include either (1) a subtotal colectomy; (2) an on-table lavage with segmental colon resection, intraoperative colonoscopy, and primary anastomosis; or (3) performance of a 2- or even 3-stage procedure instead of the elective 1-stage approach. Historically, obstructed left-sided tumors were treated with a 3-stage approach starting with a defunctioning loop colostomy, followed by resection and anastomosis, and finally by closure of the defunctioning stoma. The Hartmann procedure, the classic example among several 2-stage procedures, consists of a discontinuous rectosigmoid resection with creation of a terminal colostomy and a blind rectal stump in the first stage, followed by a colostomy takedown and reanastomosis in a second operation.

More recently, there has been a trend toward attempting to relieve the acute obstruction at the tumor-bearing segment by colonoscopic insertion of a self-expanding metallic stent. Successful decompression of the prestenotic colon converts the emergency situation into an elective setting, allowing for stabilization of the patient and performance of bowel preparation. The risk of a colonic perforation during stent placement is relatively low but acceptable because an emergency operation would be necessary anyway if the stent could not be placed successfully. Several nonrandomized, noncontrolled case series have demonstrated that colonic stenting for acute obstruction is safe and highly successful.<sup>275-278</sup> A proximal diversion hence may be avoided with this procedure.

**Tumor-Related Perforation.** Colonic perforation secondary to a tumor occurs in 2 different settings. Either a transmural tumor perforates itself, or the proximal colon becomes overdilated, particularly in the case of a competent ileocecal valve. Both conditions may result in diffuse fecal peritonitis with significant morbidity and mortality. In addition, the tumor perforation results in spillage of tumor cells and thus has to be considered a stage IV tumor. Surgical management is indicated in every case and requires not only addressing the site of colonic perforation but also removing the tumor in an oncologically correct fashion.<sup>273</sup> The same tactical principles described in the preceding section apply.

**Massive Colonic Bleeding.** Massive bleeding from a colonic tumor is a relatively rare complication. The general algorithms for the workup and management of lower gastrointestinal bleedings apply, but most commonly,

the bleeding site can be easily identified. If the bleeding is minor or self-limited, the standard workup can be performed. If the patient is or remains unstable and requires repeated transfusions, surgical management is indicated.

## **MANAGEMENT OF ADVANCED DISEASE**

**Locally Advanced Disease.** It has been estimated that approximately 15% of colonic tumors will be adherent to adjacent organs.<sup>279</sup> With locally advanced colon tumors, it is still possible to achieve cure if the surgeon is prepared to resect involved adjacent organs. Unfortunately, it is often impossible to distinguish between malignant and inflammatory adhesions, but at least 40% of these adhesions are expected to harbor malignant cells. The surgeon therefore has to consider them malignant until proven otherwise and perform an en bloc resection to achieve a tumor-free margin.<sup>280</sup>

**Operable Metastases.** At the time of presentation, 20% of patients with colorectal cancer have stage IV disease. Distant metastasis, particularly liver and lung, is a major cause of death in patients with colorectal carcinoma. However, patients with asymptomatic liver metastases may have a statistically natural life expectancy of several months up to almost 2 years without any treatment. Chemotherapy and surgical metastasectomy in selected patients may improve disease-free and overall survival substantially, resulting in a cure rate of 30%.<sup>281</sup> In the case of potentially resectable metastases, resection of the colonic primary tumor should be performed in an oncologic fashion.

**Inoperable Disseminated Disease.** In patients with unresectable metastatic disease, the surgical treatment goal is to provide palliation and to prevent predictable complications. In contrast to the oncologically defined standard resections, a limited segmental wedge resection of the colon is acceptable in this setting. In particular, tumors located in the sigmoid colon or in the cecum and ascending colon are suitable for a laparoscopic or laparoscopically assisted resection because these segments can be mobilized easily to a sufficient extent to ensure a safe anastomosis. If a tumor in a patient with metastatic disease is too advanced locally to be resected safely (eg, infiltration of other organs), palliation may be achieved by creating an

internal bypass or a proximal diversion.

## **POSTOPERATIVE MANAGEMENT**

Postoperative fast-track management after a colorectal resection has become very straightforward and routine. The immediate postoperative monitoring of vital signs, fluids, and electrolytes, as well as adequate pain control, is not different from any other major surgery. However, there has been an increased emphasis on epidural pain management, early mobilization and regular spirometry exercises, avoidance of tubes and drains (eg, nasogastric tubes), and early resumption of oral intake no later than on the first or second postoperative day with advancement to a regular diet as tolerated. Daily assessment of the abdomen and bowel activity is crucial, including careful auscultation and palpation of the abdomen to assess bowel sounds or peritoneal signs. Unless soaking, a wound dressing may be left in place until the second postoperative day or even for 5 to 10 days if an occlusive transparent dressing is used. The incision has to be checked daily for the presence of induration, hematoma, redness, dehiscence, or discharge of fluids (eg, pus, hematoma, or serosanguineous fluid). Large amounts of serous fluids draining from the wound should not be mistaken for a seroma but indicate a fascial dehiscence until proven otherwise. The average length of stay after colorectal resections depends on the patient's constitution but generally is in the range between 5 and 7 days for an open standard procedure, and 2 and 5 days for a laparoscopic approach. Before discharge, further tumor treatment should have been addressed with the patient. Adjuvant chemotherapy (and rarely radiation therapy) typically are not initiated before 3 to 4 weeks after surgery and may be delayed if infectious complications or anastomotic leaks occur.

## **Complications of Surgery**

The overall perioperative mortality within 30 days of colorectal resections is between 3.5% and 6%,<sup>282</sup> with less than 2% after elective operations but up to 20% after emergency operations. Complications of surgery may be of a general or surgery-specific nature and can be classified based on the time of their occurrence as either early (within the first 30 days) or late (after 30 days). Intraoperative complications like injury to relevant anatomic structures

such as ureters, spleen, bowel, and duodenum are related to the surgical technique, to blurred anatomic landmarks and layers owing to the disease (eg, peritonitis or massive adhesions), or to the patient's habitus (eg, obesity). Early surgery-specific complications include bleeding, most frequently within the first few days of the resection, nonspecific infections, or infections related to an anastomotic dehiscence. Other more general complications in the early postoperative period (postoperative days 1-3) commonly are related to the cardiopulmonary system and include pulmonary problems (eg, atelectasis, pneumonia, aspiration, and pulmonary embolism) and cardiac events (eg, arrhythmia, myocardial ischemia, and dysfunction). Insufficient pain control has been recognized as an important factor promoting these conditions because it results in a poor respiratory effort by the patient and the inability to cough up sputum, leading to superficial respiration and suboptimal saturation. Thus, high fever in the 3 days after surgery may be related to the development of an atelectasis rather than to an early infection.

Infectious complications usually occur after the third postoperative day and may be located intra-abdominally, in the wound, in the urinary tract, or in the lungs. The primary workup therefore includes bacteriologic cultures and stains, blood and urine analysis, and a chest x-ray.

Abdominal complications consist of delayed return of upper and lower gastrointestinal function (also referred to as *postoperative ileus*), fascial dehiscence, and anastomotic breakdown. Clinical leaks occur in 1% to 2% of all colonic resections, but subclinical leaks are more frequent and may be seen incidentally on contrast studies in otherwise asymptomatic patients. A leak may present with insidious symptoms such as fever, tachycardia, abdominal distension, ileus, feces draining through a drain or the wound, or local and generalized peritonitis. Occasionally, a leak may present with sudden deterioration, generalized peritonitis, and septic shock as the result of a significant and rapid contamination of the peritoneal cavity. Due to the heterogeneous symptoms, a leak should be suspected in any patient who is not progressing to the expected degree. Blood parameters such as white blood cell counts and C-reactive protein may be elevated but are nonspecific and difficult to distinguish from a normal postoperative reaction. After an abdominal operation, normal free air should be resorbed within 7 to 10 days.<sup>283</sup> The presence of substantial free subdiaphragmatic air later in the course should therefore raise the index of suspicion for an anastomotic leak.

Imaging studies to define the presence of an anastomotic leak include a

water-soluble contrast enema to visualize extravasation of the contrast material and/or a CT scan with oral, intravenous, and possibly rectal contrast material. Apart from antibiotic treatment, the management of an anastomotic leak depends on its presumed extent and the clinical presentation. A patient with generalized peritonitis requires a relaparotomy after appropriate resuscitation. Depending on its location, the anastomosis should be taken down and the ends should be exteriorized or, in more favorable conditions, resected, and a new anastomosis performed with healthy-looking bowel ends, either with or without proximal diversion. A local repair alone carries a high risk of failure but may succeed in combination with drain placement and a proximal diverting ostomy. By the time of the reexploration, the prolonged peritonitis in some cases already may have transformed the bowel loops into rigid pipes that would not allow any mobilization for an ostomy or for a new anastomosis. In such a case, creation of a confined leak by means of a catheter enterostomy may be a desperate attempt for local control. A fecal fistula can be managed in a conservative manner if there is no evidence of generalized peritonitis or uncontrolled sepsis. Under favorable conditions, including good nutritional support and absence of a distal obstruction or disease of the involved bowel segment, the fistula may close spontaneously. The surrounding skin will need special care, and a stoma therapist will be helpful in this regard.

## **Adjuvant Chemotherapy and Radiotherapy**

The rationale for adjuvant chemotherapy is based on the fact that we are clearly not as successful with surgical treatment as we would like to be. Fluorouracil (FU) was the first and most extensively evaluated drug for the treatment of colorectal cancer. Multiple studies had been completed without proof of value until Krook's study.<sup>284</sup> Subsequently, a review of 29 randomized trials concluded that adjuvant chemotherapy for colon cancer resulted in a 5% improvement in survival.<sup>285</sup> When studies using FU-based regimens are analyzed, there is a 2.3% to 5.7% absolute improvement in 5-year overall survival. However, when just those at high risk of recurrence are treated, the improvement in survival in this group is closer to 30%. Patients with stage III colon cancer are recognized to be at high risk for recurrence, and administration of FU/leucovorin (LV) for 6 months after surgery has proven to decrease recurrence and improve long-term survival.<sup>286</sup> The

combination treatment of FU/LV for 6 months was proven to be equivalent in efficacy to 12 months, and the addition of levamisole to FU/LV did not seem to add any benefit.<sup>287</sup> Low-dose LV also was demonstrated to be equally efficacious as high-dose LV when used in combination with FU. Thus, the first-line standard of treatment from 1998 to 2000 was a combination of FU and low-dose LV (folinic acid) given for 6 months on either a weekly schedule or 5 consecutive days every 4 weeks. At present, there is not enough evidence to recommend the routine use of adjuvant chemotherapy in stage II disease. Lenz and colleagues have demonstrated that molecular or genetic markers may better identify subgroups of patients who are likely to benefit from adjuvant chemotherapy.<sup>288-290</sup>

Several new agents, for example, irinotecan<sup>291,292</sup> and oxaliplatin,<sup>293-295</sup> have demonstrated significantly superior activity in combination with FU/LV in the metastatic setting. Irinotecan/FU/LV (IFL)<sup>291</sup> and oxaliplatin/FU/LV (FOLFOX) have been entered into randomized clinical trials against FU/LV in resected stage III colon cancer.<sup>296</sup> Both of these studies prove that the new agents in association with FU/LV were superior to FU/LV alone. Because of these successes, IFL was approved as first-line chemotherapy in 2000. In 2005, FU/LV with oxaliplatin (FOLFOX) was approved for adjuvant therapy and has evolved in most centers as the treatment of choice. The FOLFOX regimen has been compared in a large randomized controlled trial with IFL and irinotecan/oxaliplatin (IROX) in patients with previously untreated metastatic colorectal cancer.<sup>296</sup> This study showed significantly superior results with the FOLFOX regimen for all end points. The median time to progression observed for FOLFOX was 8.7 months, response rate was 45%, and the median survival time was 19.5 months. The FOLFOX regimen had significantly lower rates of severe nausea, vomiting, diarrhea, febrile neutropenia, and dehydration. Sensory neuropathy and neutropenia were common with the regimens containing oxaliplatin.

Capecitabine (Xeloda), an oral agent designed to generate FU preferentially in tumor tissue, is an exciting new development with improved convenience. A randomized phase III study comparing oral capecitabine versus intravenous FU/LV concluded that capecitabine demonstrated a statistically significantly greater response rate compared with FU/LV (26% vs 17%;  $P < .002$ ) and an equivalent time to progression and overall survival.<sup>297</sup> This study demonstrated that capecitabine is a suitable alternative

to intravenous FU and perhaps a replacement in the future. Currently, phase II trials are being conducted on capecitabine/oxaliplatin (CAPEOX) and capecitabine/irinotecan (CAPEIRI).<sup>298-302</sup>

Two of the most fascinating targets in the treatment of colorectal cancer are the epithelial growth factor receptor (EGFR) and vascular endothelial growth factor (VEGF) blockers.<sup>303,304</sup> Agents that inhibit the EGFR or bind to VEGF have demonstrated clinical activity as single agents and in combination with chemotherapy in phase II and III clinical trials. The most promising of these agents are the monoclonal antibodies cetuximab, which blocks the binding of epithelial growth factor, and bevacizumab, which binds free VEGF.<sup>303,304</sup> However, the benefit of cetuximab is limited to patients with a tumor bearing wild-type *K-ras*, while tumors bearing mutated *K-ras* do not show any response.<sup>305,306</sup> Both agents have proven benefit and seem to work best as first-line therapy for metastatic colorectal cancer. Introduction into the primary adjuvant treatment after curative resection of stage II and III tumors will remain a subject of future trials. We await future development of these and other newer drugs and their impact in the fight against colorectal cancer.

Generally, radiotherapy does not play a primary role in the adjuvant treatment of colon cancer. However, it may be considered as a locoregional field radiation in selected locally advanced T4N0-N1 tumors.<sup>307,309</sup>

## Outcome and Prognosis

Recent years have produced a trend toward better outcome and survival in patients diagnosed with colorectal cancer. This may be related to safer and more successful surgical treatment in combination with better nonoperative and adjuvant treatments. The perioperative mortality within 30 days of elective colorectal resections is less than 2%, even though it still may be relatively high after an emergency operation, thus resulting in an overall mortality of 3.5% to 5.5%.<sup>282</sup> SEER data demonstrate an overall decline in colorectal cancer mortality. While the overall 5-year survival of patients with colon cancer was at 41% between 1950 and 1952, it has since increased steadily to 63.8% between 1995 and 2000. Analyzed for each stage as defined by the AJCC sixth edition system (Table 49-14) separately, 5-year survival was 93.2% for stage I, 84.7% for stage IIa, 72.2% for stage IIb,

83.4% for stage IIIa, 64.1% for stage IIIb, 44.3% for stage IIIc, and 8.1% for stage IV cancer.<sup>176</sup> The prognosis of patients with synchronous primary colon tumors is not different from that of patients with solitary tumors if they are compared on the basis of the most advanced stage (see Table 49-14).<sup>310</sup>

**TABLE 49-14: FIVE-YEAR SURVIVAL FOR SINGLE AND SYNCHRONOUS COLON CANCER PRIMARY TUMORS**

Stage	Single (n = 4817; %)	Synchronous by Highest Stage (n = 160; %)	P <sup>a</sup>
0, I	83	87	NS
II	71	67	NS
III	53	50	NS
IV	9	14	NS

Abbreviation: NS, not significant.

<sup>a</sup> By long-rank test.

Data from Passman MA, Pommier RF, Vetto JT. Synchronous colon primaries have the same prognosis as solitary colon cancers, *Dis Colon Rectum* 1996 Mar;39(3): 329-334.

# LAPAROSCOPIC COLORECTAL PROCEDURES

*Dorin Colibaseanu • Heidi Nelson*

## INTRODUCTION

Laparoscopic surgery has steadily gained acceptance over the past two decades, and now it has replaced open surgery for many abdominal procedures (such as appendectomy and cholecystectomy); it is also becoming the preferred approach to many colorectal procedures (such as colectomy).<sup>1</sup> The reasons for the widespread adaptation of laparoscopic techniques are multiple, as listed in [Table 50-1](#). Laparoscopic techniques, when coupled with enhanced recovery pathways, also allow patients to enjoy a speedier recovery, and are associated with fewer complication rates.<sup>2</sup>

### TABLE 50-1: ADVANTAGES OF LAPAROSCOPY

1. Smaller incision

2. Less post-op pain
  3. Shorter hospitalization
  4. Improved quality of life
  5. Shorter posthospital recovery
  6. Better cosmetic result
  7. Reduction in post-op adhesions
- 

The introduction of hand-assisted laparoscopic surgery (HALS) and the early exposure of trainees to diverse laparoscopic techniques have increased the availability of laparoscopic surgery to more practitioners and patients.<sup>3</sup> Knowledge and experience gained from the evolving laparoscopic practice over the past nearly two decades has provided clarity on indications, contraindications, and technical advancements. This chapter provides a review of the principles behind the practice of laparoscopic colon and rectal surgery. It also provides a brief review of the special considerations for cancer of the colon and the rectum, focusing on providing a contemporary description of the laparoscopic and HALS approaches to segmental resections of the colon and the rectum, and the combined resections of the colon and rectum with creation of pelvic pouches. Finally, a perspective on natural orifice specimen extraction (NOSE), natural orifice transluminal endoscopic surgery (NOTES), and the growing practice of robotic surgery is offered at the conclusion of this chapter.

## **PATIENT SELECTION**

### **Indications, Contraindications, Evaluations**

Laparoscopic surgery can be considered an option for virtually any patient with a colon or rectal condition requiring surgery. With that said, not all patients will be ideal candidates and not all procedures can be performed by all surgeons. All surgeons must find their comfort zone with laparoscopic cases. The initiate to laparoscopy should consider limiting their early practice to right colectomies in patients who are thin and have limited risks of adhesions, as well as benign disease process such as polyps or ileocolonic Crohn's strictures. Surgeons with advanced skills may be comfortable doing

an entire total proctocolectomy and ileal pouch-anal anastomosis. All of these procedures are technically described in this chapter to provide a range of procedures that are feasible. In addition to the technical range of possibilities, there is a range with respect to which patients will do well with the laparoscopic approach. As with any laparoscopic approach, for example, there would be some cases where a pneumoperitoneum is contraindicated and others where the disease or technical considerations represent contraindications. Indications and contraindications along with pre- and intraoperative evaluations specific to the colon and rectal diseases and patient conditions are provided, followed by focused discussion on oncologic issues relevant to colon and rectal cancer.

## INDICATIONS

The indications for laparoscopic surgery for conditions of the colon and rectum are predominantly the same as those for open surgery ([Table 50-2](#)). For inflammatory bowel disease, the list of indications includes symptomatic failure of medical therapy, dysplasia, and presence of strictures, abscess, and fistula. In acute colitis, urgent subtotal colectomy with end ileostomy may be performed initially as a part of a two or three-stage procedure. Procedures may include strictureplasty, small bowel resection, segmental colonic resection, or proctocolectomy. For diverticulitis, the current American Society of Colon and Rectal Surgeons (ASCRS) guidelines recommend that the decision for elective resection of sigmoid after recovering from acute diverticulitis should be made on a case-by-case basis, and the laparoscopic approach is recommended in selected patients.<sup>4</sup> Large colonic polyps not amenable for resection through the endoscope may be resected through the laparoscopic approach. The laparoscopic approach has been proven to produce equivalent outcomes with open resection for localized colon cancer, when oncological principles are practiced. Faster recovery and fewer postoperative complications are seen with laparoscopic colon resections, thus surgeons who are appropriately trained should use this method.<sup>5,6</sup> Similar results are found with laparoscopic resections for rectal cancer, though the operations are significantly more difficult, and long-term data with regard to outcomes is still emerging.<sup>7,8</sup> Robotic surgery has been used for colon resections as well, though its advantages are most accentuated in the pelvis. Some of the technical advantages to robotic pelvic surgery include a stable

camera platform, better visualization, and increased articulation; in skilled hands it is a useful tool. However, it is associated with increased costs and increased operative times. The data supporting the use of robotic surgery are by no means definitive, though the ROLARR (RObotic vs LAparoscopic Resection for Rectal Cancer) trial should help answer whether the robotic approach is better, or at least equal to laparoscopic resection for rectal cancer. Solitary metastatic lesion in the liver with localized tumor in the colon can also be resected laparoscopically in competent hands.

**TABLE 50-2: INDICATIONS IN COLON AND RECTAL DISEASES**

1. Ulcerative colitis—refractory disease, dysplasia
2. Crohn’s disease—refractory disease, bleeding, strictures, confined abscess, fistula
3. Diverticular disease—recurrent, noncomplicated
4. Volvulus
5. Colon polyps—not amenable to endoscopic resection
6. Carcinoma colon—localized lesions amenable to 8-cm extraction site
7. Rectal prolapse
8. Rectal cancer (in controlled trials)

The laparoscopic approach is preferred in the repair of rectal prolapse. Resection rectopexy and mesh rectopexy both can be performed through the laparoscopic approach. Laparoscopic rectopexy has similar long-term functional outcomes and low recurrence rates.<sup>9</sup>

## **CONTRAINDICATIONS**

General health conditions that would contraindicate a minimally invasive approach requiring a pneumoperitoneum typically include any severe manifestation of organ failure (Table 50-3). Patients with severe chronic obstructive pulmonary disease (COPD), reactive airway disease, or other causes of respiratory compromise are usually not tolerant of pneumoperitoneum necessary for laparoscopic procedures. Patients with advanced cardiovascular disease are also typically intolerant of the

pneumoperitoneum, as it can restrict the fragile dynamics of cardiac output. Finally, patients with end-organ renal failure and severe electrolyte or fluid disturbances and those with liver failure, ascites, or other sources of bleeding disorders are best served with a more controlled, open approach. Sometimes these conditions are not appreciated as problematic until the procedure is under way and the anesthesiologist is experiencing difficulties managing the patient's hemodynamics. Accordingly, open lines of communication between the surgeon and the anesthesiologist as well as a willingness to convert to open surgery should be the rule and not the exception.

#### **TABLE 50-3: CONTRAINDICATIONS TO LAPAROSCOPY**

Absolute contraindications	<ul style="list-style-type: none"> <li>• Inability to tolerate pneumoperitoneum</li> <li>• Poor risk for general anesthesia</li> <li>• Poorly controlled coagulopathy</li> <li>• Severe systemic disease that is constant threat to life</li> <li>• Moribund patient, unlikely to survive for 24 h with/without surgery</li> </ul>
Relative contraindications	<ul style="list-style-type: none"> <li>• Multiple abdominal procedures</li> <li>• Cardiac abnormalities</li> <li>• Pulmonary gas exchange abnormalities</li> <li>• Chronic liver disease</li> <li>• Morbid obesity</li> </ul>
Contraindications in colon diseases	<ul style="list-style-type: none"> <li>• Large phlegmon or mass</li> <li>• Complex fistulizing disease</li> <li>• Tumor infiltrated into adjacent structures (T4 disease)</li> <li>• Bowel obstruction</li> <li>• Toxic dilation of the colon</li> <li>• Perforation</li> <li>• Significant adhesions</li> </ul>
Contraindications in rectal diseases	<ul style="list-style-type: none"> <li>• Large phlegmon or mass</li> <li>• Complex fistulizing disease</li> <li>• Locally infiltrative rectal cancer</li> <li>• Recurrent rectal cancer</li> <li>• Bowel obstruction</li> <li>• Toxic dilation of the colon</li> <li>• Perforation</li> <li>• Significant adhesions</li> </ul>

---

Less absolute contraindications of laparoscopy include the presence of adhesions, cardiac abnormalities, pulmonary gas exchange abnormalities, chronic liver disease, and obesity. None of these are clear-cut or absolute. For example, patients may have several abdominal scars and have undergone numerous prior procedures, even near the site of the anticipated colon

resection, but they may not have prohibitive adhesions. Unless we know the patient has prohibitive adhesions, we would approach the case laparoscopically with a cautionary note to the patient that the risk of conversion may be higher than 10% to 15%. The same can be said for obesity. Managing obese patients is sometimes facilitated by laparoscopy, such as when the fat is predominantly in the abdominal wall. However, some obesity cases cannot be conducted using laparoscopic techniques—for example, when there is insufficient intra-abdominal space to operate, or when appropriate traction cannot be achieved. In addition, laparoscopic colorectal surgery requires extreme positioning, and an obese patient might be difficult to ventilate in Trendelenburg position and/or might be difficult to position due to the patient's size/weight.

A final category of absolute and relative contraindications includes those specific to the disease under treatment. For inflammatory bowel disease, a large phlegmonous mass, complex or large abscess, or complex fistulizing disease may not be possible to fully mobilize or to extract the specimen with laparoscopic techniques. Similarly, a toxic abdomen from sepsis or fecal contamination may not be ideal for laparoscopic surgery. Massive dilation of the large or small bowel can prohibit both intra-abdominal visualization and the safe movement of instruments throughout the abdominal cavity. In cases of cancer, there is little evidence in support of tackling large fixed or recurrent tumors through small incisions. The risk-benefit ratio for large, fixed, and recurrent tumors would likely favor open surgery, although it has never been prospectively studied.

## **PREOPERATIVE EVALUATIONS UNIQUE TO LAPAROSCOPIC SURGERY**

A word must be said about the workup of patients who are scheduled for the minimally invasive surgical approach. Although the preoperative evaluations are usually the same as for any other laparotomy approach, it is generally advised that the diagnostic tests for the disease and the treatment be as definitive and clear as possible before laparoscopic surgery. The absence of tactile information demands better preoperative assessments than historically considered necessary for open surgery. This was first realized with tumor staging. The traditional approach with open surgery was to palpate the liver at the time of laparotomy to locate metastatic tumor deposits in the abdomen,

including such sites as the liver, ovaries, peritoneal cavity, omentum, or retroperitoneal lymph nodes. Current imaging with computerized tomography (CT) has improved to the point that such novel findings at surgery are rare. Surgeons may identify small superficial hepatic metastases or peritoneal tumors at the time of surgery, but this is less common than it was when laparoscopic surgery was initiated in the early 1990s.

In a similar fashion, primary tumors need to be well localized prior to surgery. For the most part this can be accomplished by combining endoscopy with tattooing for small, benign lesions, or with CT imaging for large or malignant neoplasms. Endoscopy, although usually accurate, can be misleading because there are no consistent endoluminal landmarks for identifying colonic location. Early experiences with missed lesions and wrong-site resections brought these lessons forward. For malignant lesions it is often possible to see the mass on staging CT scan; this can be very reassuring for accurate localization. In addition to the preoperative testing, we advise that one never leave the operating room without first confirming that the target lesion has been confidently removed and identified in a specimen. Because colonoscopy can misjudge the anatomic colonic location of a lesion by more than one colonic segment, this safety measure seems simple and warranted.

For benign conditions, it is equally important to localize the site of diseased bowel and understand the exact extent of disease. Does the patient have a complex versus simple fistula, or a contained mesenteric abscess versus poorly contained complex or perforated abscess? Of course, the size of the specimen will dictate the size of the extraction site. The larger the lesion to be extracted and the larger the incision, the less the benefit there is to the laparoscopic approach. For Crohn's disease, CT enterography may help to reveal secondary sites of disease. We would also advise a complete intraoperative assessment of the small bowel in cases of Crohn's disease, especially in cases of stricturing disease.

## **INTRAOPERATIVE EVALUATIONS AND REASONS FOR CONVERSION**

Conversion of laparoscopic procedure to open procedure may be required when difficulties are encountered. The reasons for conversion may include unexpected disease, significant adhesions, and the inability to identify vital

structures such as ureters. It is important to remember that conversion itself is not a complication, even though intraoperative complications necessitate conversion. It should not be viewed as failure but rather as an application of sound surgical judgment. It is probably safer for a surgeon to have a low threshold for conversion, because the timing of conversion is critical to reduce not only overall costs but also complications. A decision to convert is best made early in the procedure, thus avoiding an increased risk of complications and reducing operative time. An early decision to convert will ensure that the rates of morbidity and mortality are maintained at acceptable levels.

For patients who are known to have frail tissues from chronic immunosuppression or other systemic conditions with adverse effects on tissues, extra caution should be taken in handling the bowel in particular but other tissues as well during the surgery. It is more difficult to judge the impact of instruments when there is an inability to use tactile information. For this reason, these cases may benefit from the hand-assisted approach.

A final note should be made about the use of ureteral stents in minimally invasive cases. In general, we would not use ureteral stents for any case that would not be required in the open approach. However, we have a low threshold for placing ureteral stents either preoperatively or during surgery when an inflammatory or tumor process obscures the anatomic location of the either ureter. If they are available and make a difference, the lighted ureteral stents can also be used in the location of the ureter.

## **ONCOLOGIC ISSUES SPECIFIC TO LAPAROSCOPIC SURGERY IN COLON AND RECTAL CANCER**

Because of the unique controversies that emerged with the introduction of laparoscopic colectomy for cancer, we offer here a section that specifically covers this topic for both colon cancer and rectal cancer. Soon after the introduction of the laparoscopic colectomy in 1991,<sup>1</sup> a number of concerns regarding the application of this technique in colon cancer arose, including reports of tumor wound recurrences at trocar sites and tumor extraction sites.<sup>10-12</sup> Such reports were frequent enough that national statements were issued recommending a moratorium on laparoscopic colectomy for cancer outside of clinical trials.<sup>13</sup> In response, a number of randomized clinical trials were initiated simultaneously in North America, Canada, and Europe. At

least four large prospective, randomized trials have been completed and have reported both short- and long-term outcomes. To date, 3133 patients have been studied by random allocation to laparoscopic versus open surgery and followed for cancer outcomes. These patients are reported from four international trials, including the Barcelona trial<sup>14</sup> (219 patients), the COST (Clinical Outcomes of Surgical Therapy) trial<sup>15</sup> (872 patients), the COLOR (COlon cancer Laparoscopic or Open Resection) trial<sup>16,17</sup> (1248 patients), and the CLASICC (Conventional versus Laparoscopic-Assisted Surgery In Colorectal Cancer) trial<sup>18,19</sup> (794 patients). Short-term results from all four studies confirm equivalent mortality and rates of morbidity between the laparoscopic and the open arms. They also consistently demonstrate reductions in length of hospital stay, time to first feed, and time to first bowel movement. Quality of life, although modest, has also been confirmed.

At least three of these trials, the Barcelona, COST, and COLOR trials, have completed 5-year follow-up for the entire cohort of patients. It has been reassuring that these trials have not demonstrated inferiority for the laparoscopic arm with respect to overall survival or disease-free survival. A pooled analysis of all four trials examining 3-year median survival was also conducted, and it confirms the same, that no difference in overall survival or disease-free survival was identified between the open and laparoscopic arms.<sup>20</sup> Subsequently, a 10-year follow-up of the CLASSIC trial has shown that laparoscopic surgery remains oncologically equivalent to open surgery.<sup>5</sup> A 5-year follow-up study of the COLOR trial maintains that the oncological outcomes between laparoscopic and open colon surgery are similar.<sup>21</sup> These data have encouraged the adoption of laparoscopic colectomy for colon cancer in the absence of harm and in the presence of confirmed benefits.

The initial concern with using laparoscopic techniques in colon cancer focused on the potential for abnormal distribution of cancer cells due to the pneumoperitoneum. It was thought that the pneumoperitoneum created a “chimney effect”<sup>22</sup> that caused a focusing of tumor cells at incision sites, such as trocar or extraction sites, increasing the risk of tumor implants.<sup>23</sup> There was also at least a theoretical risk that it could cause dissemination of tumor cells through abnormal patterns. This has not been borne out in colon cancer and is not considered relevant, therefore, in rectal cancer. What is considered of relevance in rectal cancer is whether laparoscopic techniques can achieve tumor-free margins with the same rate as open surgery.<sup>24</sup> It could

be argued that the pelvic dissection is facilitated by laparoscopic equipment and access to the deep pelvis with lighting and visualization superior to open surgery in some cases. However, this has not been proven in diverse practice settings. An additional concern is the ability to achieve distal stapling due to the limits of current instrumentation. The results of the European COLOR II trial indicate that laparoscopic and open surgery are equivalent with respect to local recurrence, and disease-free and overall survival.<sup>25</sup> These issues are also being addressed by a prospective randomized trial conducted by the American College of Surgeons Oncology Group (ACOSOG).<sup>26</sup>

The ACOSOG Z6051 trial is a multicenter, phase III, randomized clinical trial with the primary objective of proving that laparoscopic-assisted resection for rectal cancer is not inferior to open rectal resection, based on composite primary end point of oncologic factors that are indicative of a safe and feasible operation. The end point of this noninferiority trial is based on detailed and standardized pathologic evaluation of the specimen, including circumferential and distal margins and the completeness of the total mesorectal excision. The primary end point is a novel, surrogate end point for long-term oncologic outcome that reduces both the necessary accrual target of the trial and its time to maturation. The secondary end points include patient-related benefits (blood loss, length of stay, pain medicine utilization), 2-year local recurrence, and quality of life. The eligible criteria for the disease include T3N0M0, T1-3N1M0 adenocarcinoma of the rectum with the lower edge 12 cm or less from the anal verge, and completion of 5-fluorouracil (5-FU) or capecitabine-based chemotherapy/radiotherapy in the last 4 weeks. The other patient criteria include age 18 years or greater, ECOG (Eastern Cooperative Oncology Group) performance status 2 or less, body mass index (BMI) 34 or less, no evidence of laparoscopic contraindications, no evidence of systemic disease precluding surgery, nonpregnant, nonlactating, no history of current or previous invasive pelvic malignancy, and no history of psychiatric illness. Surgeon credentialing in both laparoscopic colon and laparoscopic rectal surgery is required for participation in this study. This is based on having completed 20 laparoscopic-assisted resections each of the colon and rectum. The operative reports and the pathology reports of those cases and an unedited videotape of the laparoscopic rectal technique are reviewed by two designated investigators. This noninferiority trial funded by the National Cancer Institute (NCI) is projected to enroll 650 eligible patients in the United States and

Canada. Further details and contact information can be obtained from the following website: <http://www.cancer.gov/clinicaltrials/ACOSOG-Z6051>.

## Key Points

1. Accurate preoperative assessment of disease extent is a prerequisite to make the procedure successful.
2. Preoperative tattooing of the lesion with colonoscopy will aid in the localization of the tumor during the procedure.
3. Dense adhesions or extensive disease that prevents accurate identification of the vital structures and increases the risk of complications should cause the surgeon to convert early to an open procedure.
4. Care should be taken during handling of bowel in patients, particularly on high-dose steroids, due to increased fragility of the tissues. Atraumatic graspers or the HALS approach is preferred to avoid direct grasping of the colon.
5. Placement of a ureteral stent should be considered when there is difficulty in locating one or both ureters as a result of inflammation or tumor in the retroperitoneum.
6. In cases of malignancy or dysplasia, it is essential to perform a complete oncological resection. This includes adequate mobilization, high vascular ligation, satisfactory lymph node harvest, and negative resection margins. Intracorporeal ligation is required to achieve high vascular ligation.

## GENERAL TECHNICAL INFORMATION

### Equipment and Instruments

Basic laparoscopic equipment is common for most of the cases and is detailed in the previous chapters (Table 50-4 and Fig. 50-1). Surgeon acquaintance and comfort with the equipment is more important than the exact specifications. A 30-degree laparoscope is more useful than the 0-degree laparoscope, particularly for visualization during mobilization of the flexures and working in the pelvis. Trocars should have the ability to be sutured or have stability threads to prevent dislodgement or leakage during

the case. The cautery attachment should be on the upper side of the instruments so it does not interfere with hand movements during dissection or slip off as a result of gravity and repeated hand movements. Monitors, light source, camera unit, and CO<sub>2</sub> insufflator should all be placed on readily mobile units to allow easy positioning and provide the surgeon with better ergonomics. Dedicated laparoscopic operating rooms with multiple monitors, and dedicated laparoscopic towers are increasingly being used. Bowel handling graspers should be atraumatic in order to prevent serosal injury. The Babcock forceps are best applied alongside the bowel, on the mesentery, or on the opposing peritoneal surface. The atraumatic alligator bowel grasper can supplement the Babcock graspers while mobilizing the bowel because of its large surface area.

**TABLE 50-4: COMMONLY USED LAPAROSCOPIC INSTRUMENTS**

  2. Automatic clip applier (optional)
  3. LigaSure (optional)
  4. Harmonic scalpel (optional)
-

**FIGURE 50-1** Laparoscopic instruments.

Although some might prefer the Veress needle for insufflating, we prefer the Hassan-type cannula and open insertion technique as they minimize the risk of injury to intra-abdominal structures. Instruments should be of sufficient length to reach up to the flexures and down into the pelvis from centrally located ports; this minimizes the need for extra ports. Total proctocolectomy and abdominal perineal resection (APR) procedures in particular require long instruments that are at least 38 to 40 cm. Care should

be taken with the use of energy devices (electrocautery and ultrasonic cutting devices) to minimize the risk of complications from the exposed metal components of the tools. The curved scissors allow more maneuverability, and the ability to cauterize with the curved scissors can save time.

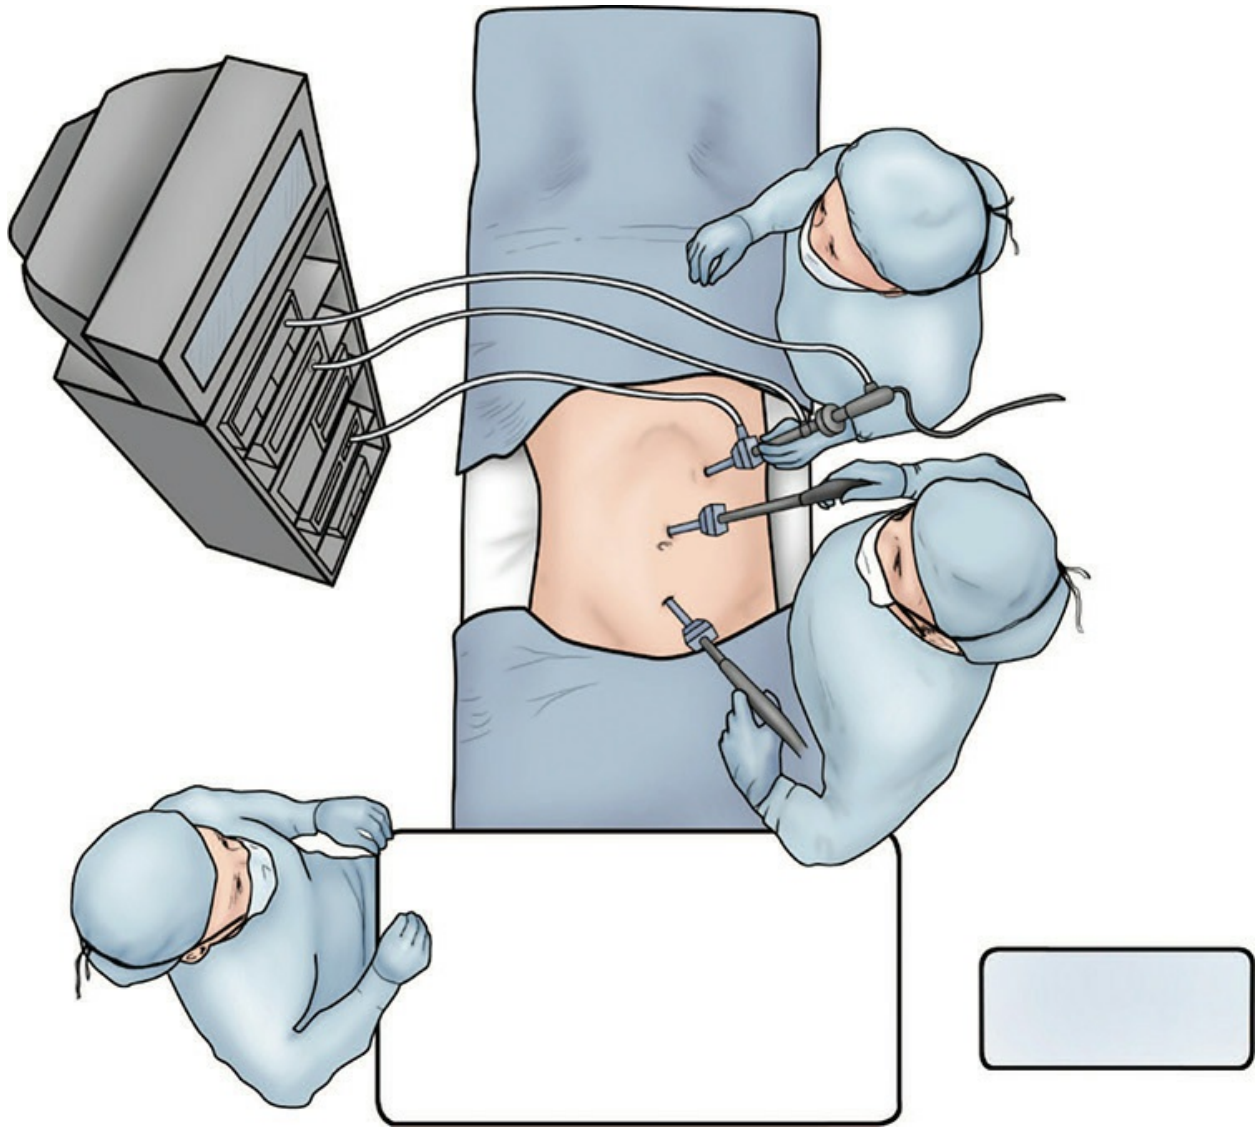

## **SPECIAL DEVICES IN COLON AND RECTAL LAPAROSCOPIC SURGERY**

Several options are now available for handling the colon mesentery. The automatic clip applier can be useful for dissecting the mesenteric vessels or controlling small to medium-size bleeding vessels. LigaSure (ValleyLab, Boulder, CO) is used to fuse tissue bundles and vessels up to 7 mm diameter using a combination of pressure and thermal energy. The Harmonic scalpel utilizes ultrasonic energy in cutting and coagulating the tissues simultaneously and offers better precision. The laparoscopic linear stapler can serve a dual purpose, as it allows transection of the colon without contamination and a vascular load can be used to transect a vascular pedicle. Special maneuvers with the linear stapler aid in the preparation of J-pouch and making of side-to-side anastomosis. Circular anastomotic stapler is used for making colocolic or ileocolic anastomosis.

## **PATIENT POSITION AND ROOM SETUP**

Careful positioning and securing of the patient on the operating table is essential for safety of the procedure because steep inclinations of the operating table are required to assist in achieving proper exposure of the operative field. For the supine position, ankle straps ensure that steep Trendelenburg position is tolerated, and shoulder straps or bean bags can ensure that the patient does not shift side to side when the table is tilted to the left or right. For synchronous cases, having the lower extremities secured in stirrups creates the same effect as ankle straps. For most cases, it is ideal to have the arms securely padded and strapped to the sides of the table. Generous padding at the elbow and neutral positioning of the wrist will minimize the risk of ulnar or median nerve injury, respectively, from pressure during long-duration surgery. A urinary catheter decompresses the bladder and an orogastric or a nasogastric tube decompresses the stomach to avoid inadvertent injury and to maximize space in the abdominal cavity. The

surgeon and the surgical assistant stand on the patient's side with the monitor on the opposite side to achieve consistent and in-line orientation of the field. The surgeon's eyes, hands, trocars, instrument tips, and monitor should all be directly parallel and closely aligned to minimize the difficulties associated with reverse image operating (Fig. 50-2).

**FIGURE 50-2** Position of equipment and the surgical team for laparoscopic right hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## **PORT PLACEMENT TECHNIQUE**

A cut-down technique is used to insert Hassan's trocar, with Hassan's

cannula as the first port. Pneumoperitoneum is achieved by insufflation of carbon dioxide to 12 to 14 mm Hg. A 30-degree laparoscope is the preferred camera as it offers the optimal operative view. The rest of the ports are inserted under direct visual guidance.

## **WOUND CLOSURE**

Trocars are removed after the pneumoperitoneum is fully released through the cannulas to avoid sucking of the bowel into the port sites and to avoid the concentration of tumor cells at the trocar sites in cancer cases. The 5-mm port sites do not require fascial closure unless there is significant enlargement of the fascia during the procedure. Port site closure should include peritoneum and fascia when they are 10 mm or greater. The lateral ports are closed under direct visualization prior to closure of midline wounds. The “Endo Close” spring-loaded suturing device can be used to close the incision. The fascia is closed with a figure-of-eight suture and an extracorporeal knot is tied. A purse-string suture is an option for closing the periumbilical site.

## **Right Hemicolectomy**

### **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is carefully positioned supine and secured on the operating table as described previously. The surgeon and the surgical assistant stand on the patient’s left side with the monitor on the right side to achieve consistent and in-line orientation of the field. The instrument table is easily accommodated at the foot of the bed and the scrub nurse on the patient’s right side.

### **STEP 2: PORT PLACEMENT AND EXPLORATION**

A 10 to 12 mm port is placed in the supraumbilical area using an open cut-down technique. A different site is preferred (typically left upper quadrant [LUQ]) when a midline scar is present and extensive adhesions are anticipated. A 30-degree camera is passed through this port, and under direct vision two 5-mm trocars are placed—one in the LUQ lateral to the epigastric vessels and 2 cm below the costal margin, and the other in the suprapubic midline (Fig. 50-3). As an alternative, one can place three 10- to 12-mm

trocars; this allows maximum flexibility for placement of instruments and the camera, but the more experienced surgeon may exchange one or more for 5-mm trocars.

**FIGURE 50-3** Position of laparoscopic instruments for right hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Simple adhesions encountered at this stage should be divided. Then, an inspection of the abdominal cavity should be performed to confirm the pathology for which surgery was indicated and to exclude other pathology. The presence of a locally adherent or bulky tumor should be approached with a conversion to open surgery. The liver is carefully inspected for metastatic disease. If resectable metastases are identified, we would convert to open surgery. Some surgeons are comfortable with laparoscopic removal of hepatic metastasis or choose to address this at subsequent surgery. Alligator or Babcock graspers are preferred to raise each liver lobe to view all surfaces. The peritoneal surfaces should then be inspected to exclude metastases. In cases of Crohn's disease, the entire small bowel should be inspected for secondary sites of disease not detected by preoperative imaging.

### **STEP 3: MOBILIZATION OF THE CECUM**

The patient is placed in a steep Trendelenburg position, with the right side of the table inclined upward. The 30-degree laparoscope is deployed through the LUQ port. The pelvis is viewed to ensure that the small bowel loops can be moved up into the upper abdomen; in the absence of adhesions it is often simplest to sweep the mesentery of the bowel along with the bowel into the left upper quadrant. Right lower quadrant (RLQ) adhesions are not uncommon due to the prevalence of hysterectomy, oophorectomy, and appendectomy procedures in the general population. Presence of significant adhesions in the pelvis (eg, inability to extract terminal ileum from the pelvis) is an indication for early conversion to open procedure at this point, as full exteriorization will not be possible later.

The next step is to identify the right ureter at the pelvic brim, where it runs over the bifurcation of the common iliac artery (Fig. 50-4). In an obese patient, the ureter is identified after opening the peritoneum. It is important to be patient and wait to observe peristalsis in the ureter to avoid mistaking the psoas tendon or the gonadal vessels for the ureter. The cecum is then pushed or gently grasped with a Babcock from the supra umbilical port and elevated medially and toward the head. The peritoneum around the base of the terminal ileum and the cecum is then opened with the scissors through supraumbilical port, and correct retroperitoneal plane is entered. Using a grasper on the cut peritoneal edge and not on the bowel, the right lateral peritoneal reflection is opened along the white line of Toldt toward the

hepatic flexure. Care should be taken to initially divide only the superficial layer of the peritoneum. As the dissection proceeds toward the hepatic flexure, the pneumoperitoneum helps separate the tissue planes. The plane between the colon mesentery and the Gerota fascia is then developed using a combination of blunt dissection and cautery, and care must be taken to avoid dissection behind the kidney.

**FIGURE 50-4** Mobilization of cecum. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

The peritoneum on the medial side of the terminal ileum should be incised to allow full mobilization of the cecum. Upward tension should be applied on the peritoneal fold medial to the terminal ileum, and incision is made in the superficial peritoneal layer alongside the pelvic brim superior and parallel to the right iliac artery. The dissection is continued up to the level of the duodenum. Then the lateral dissection is advanced medially with care until the inferior vena cava inferiorly and duodenum superiorly. These two structures indicate the achievement of sufficient dissection.

#### **STEP 4: MOBILIZATION OF THE HEPATIC FLEXURE**

The patient is now placed in reverse Trendelenburg position with the right side steeply inclined upward. The laparoscope is shifted into the suprapubic port, and the surgeon and the assistant trade positions. The hepatocolic ligaments are grasped just cephalad to the colon and traction placed obliquely to elevate the tissues toward the anterior abdominal wall and inferiorly. The hepatocolic ligament is divided with electrocautery scissors or an ultrasonic dissector, as preferred. Blunt dissection is then performed to separate the underlying tissue from the peritoneum. Occasionally larger vessels encountered require clips. The dissection is then continued along the gastrocolic ligament, identifying the plane between this and the transverse mesorectum, until the level of falciform ligament is reached. Care should be taken during this dissection not to damage the duodenum as the hepatic flexure is mobilized off the retroperitoneum in the right upper quadrant (RUQ) (Fig. 50-5). At this point, the whole right colon is mobilized to the midline and the right retroperitoneum is exposed, allowing visualization of the duodenum, Gerota fascia, and right ureter.

**FIGURE 50-5** Mobilization of hepatic flexure. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## **STEP 5: VASCULAR DIVISION**

Vascular ligation and division of the mesenteric vessels can be performed either by intra or extracorporeal method. The surgeon and the assistant are back to original positions with the laparoscope placed through the LUQ port. The intracorporeal method should be used for obese patients, as it is difficult to exteriorize the ileocolic pedicle. Intracorporeal ligation is preferred for the malignant diseases to ensure proximal ligation of the vessels (Fig. 50-6). Upward tension is applied on the right colon to display the ileocolic and right

colic vessels, and once mesenteric windows are created, the vessels are ligated with hemoclip, Endoloop devices (Ethicon, Cincinnati, OH), or a linear vascular stapler. It is important to visualize or palpate the junction of the ileocolic and superior mesenteric vessels to provide proximal resection of lymphatics in cancer cases without compromising blood flow to the rest of the small bowel.

**FIGURE 50-6** Intracorporeal division of vasculature of right colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## **STEP 6: EXTERIORIZATION**

Once intracorporeal ligation has been completed or if extracorporeal ligation has to be performed, the table is returned to a neutral position. A Babcock grasper is placed through the suprapubic port and applied to the appendix or ligament of Treves or the mesentery of the cecum. The pneumoperitoneum is vented out through the ports and the camera equipment removed. Then a

small (4-6 cm) vertical incision is made for purposes of colon exteriorization; typically it is more cephalad than caudal to the umbilicus. The wound edges are protected with a wound guard and then the bowel is exteriorized with the help of Babcock grasper left already at the level of the cecum. The right colon is exteriorized from the terminal ileum to the transverse colon (Fig. 50-7). It is generally not necessary to have divided the omentum intracorporeally as it can also be exteriorized through the incision unless it is bulky. Once the bowel is exteriorized, vascular ligation is performed in a standard manner.

**FIGURE 50-7** Exteriorization of right colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

### **STEP 7: ANASTOMOSIS**

The mesenteric and bowel division, vascular ligation if appropriate, and anastomosis can be completed after exteriorization in an identical way to

standard laparotomy. This degree of mobilization allows for a handsewn end-to-end anastomosis or a wide, stapled side-to-side anastomosis. Following anastomosis, the bowel is gently returned into the abdominal cavity. Irrigation of the abdominal cavity is performed at this time. The irrigation process is conducted through the open wound and can make use of standard suction devices without the need for the laparoscopic suction irrigator equipment. The aspirate from the irrigation process is inspected to determine whether it is clear or bloody. If the aspirate is blood-stained, the abdomen may need to be reevaluated by reestablishing the pneumoperitoneum. In our experience, it is rare to have to reinspect using the pneumoperitoneum. By using Harrington-type retractor, inspection through the periumbilical incision allows for visualization of the port sites as the trocars are removed. Copious irrigation of all the wounds is then performed. The incisions are closed in two layers: fascia and skin.

## **Alternative Technique for Right Hemicolectomy**

An alternative technique, in which the dissection starts from the medial aspect and extends laterally, is also practiced for right hemicolectomy. The dissection commences with the opening the peritoneum of right mesocolon. This allows for the mobilization of the colon with minimal manipulations. The right colic and ileocolic vessels are identified first and ligated using clips or vascular stapler. Then the peritoneal incision is extended superiorly toward the transverse colon, and then the dissection continues along the transverse colon inferiorly and along the hepatic flexure, ascending colon, and cecum medially. After the colon is freed from the peritoneal attachments on the medial side, the dissection continues along the white line of Toldt, starting from the cecum to the hepatic flexure and the transverse colon (Fig. 50-8). The right colon is detached from all the attachments and is then brought outside from the extended skin incision at the umbilicus. Then the right colon is resected extracorporeally and ileocolic anastomosis is performed as described in the previously mentioned method.

**FIGURE 50-8** Alternative technique for right hemicolectomy—medial to lateral dissection. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## Left Hemicolectomy

The left hemicolectomy procedure is similar to the right colectomy, only in mirror-image reverse. One major difference is the care that must be taken around the spleen. The hand-assisted approach can facilitate management of the splenic flexure and therefore it is described as an alternative approach.

### STEP 1: PATIENT POSITION AND ROOM SETUP

Positioning and securing of the patient on the operating table is done in a similar fashion as right hemicolectomy. The surgeon and the surgical

assistant stand on the right side with the monitor on the left side and parallel in-line orientation is maintained. The instrument table is accommodated at the foot of the bed and the scrub nurse is on the patient's left side.

## **STEP 2: PORT PLACEMENT AND EXPLORATION**

A four-port technique is used, with ports in the supraumbilical area, suprapubic area, right upper quadrant, and left lower quadrant (LLQ) (Fig. 50-9). Simple adhesions encountered at this stage should be divided. Then a careful inspection should be performed to confirm the pathology and any presence of additional disease. Conversion to open procedure should be made for the same conditions and indications as described for the right colectomy.

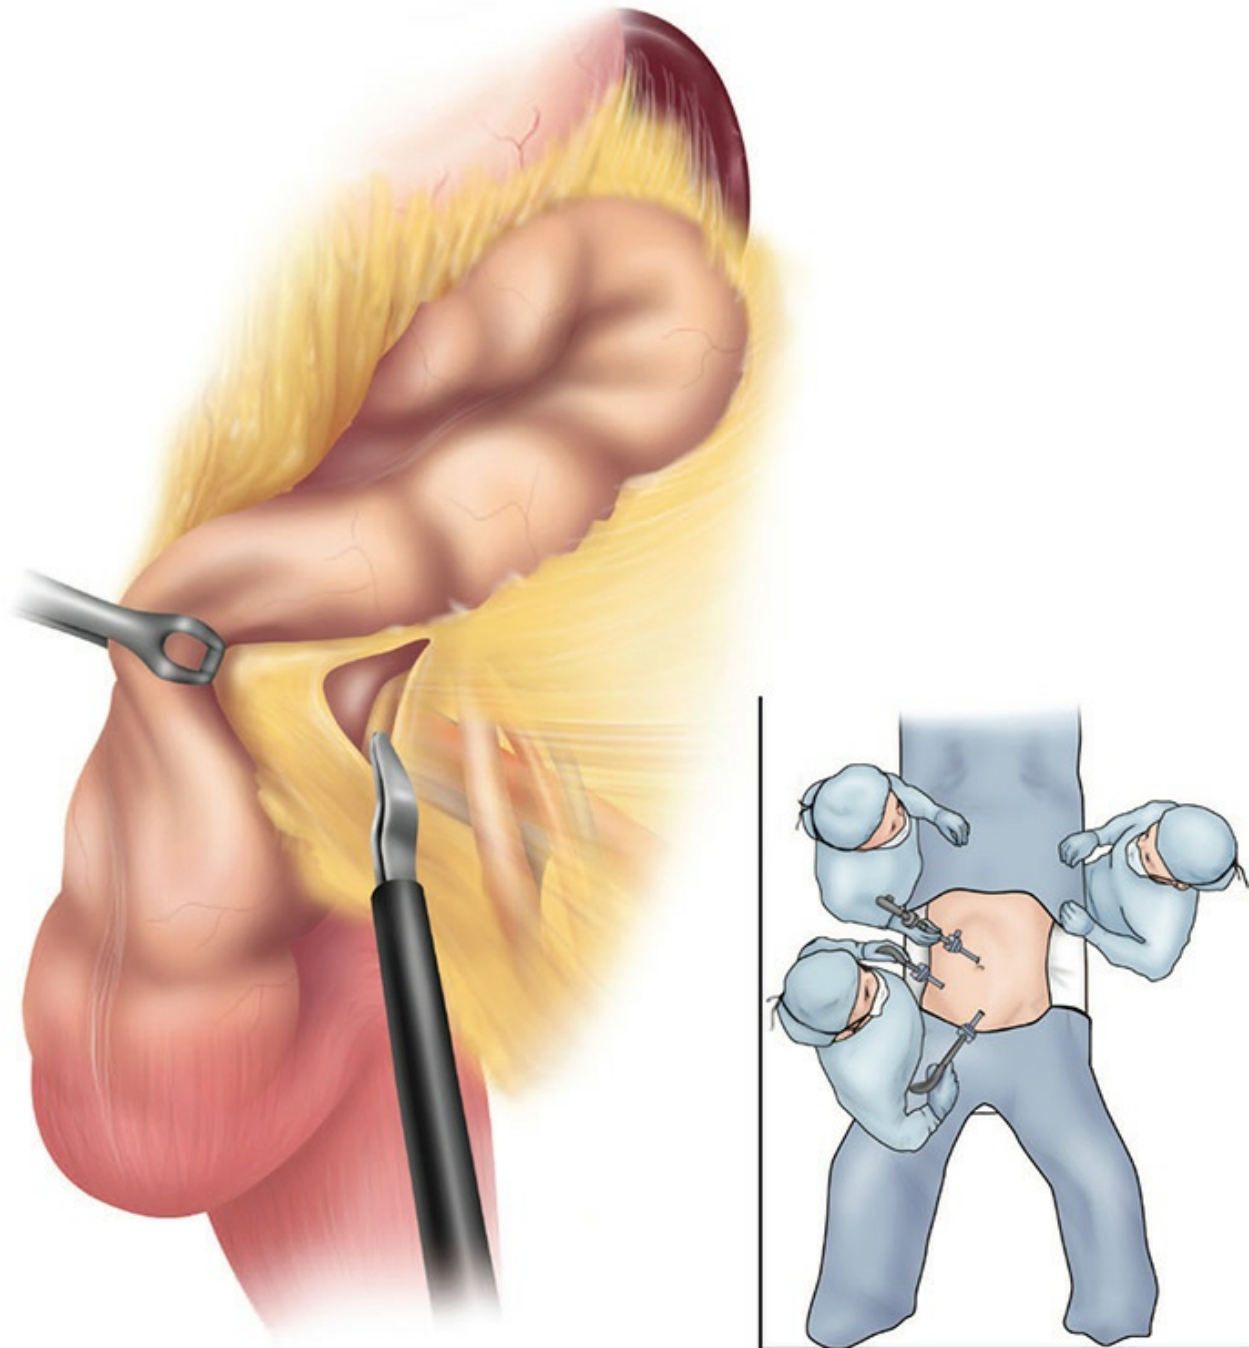

**FIGURE 50-9** Position of laparoscopic ports for left hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

### **STEP 3: MOBILIZATION OF THE LEFT COLON**

The patient is placed in a steep Trendelenburg position, with the left side of the table inclined upward, and the small bowel loops are swept to the right side of the abdominal cavity using the graspers. The left ureter is identified before proceeding with the dissection. The dissection commences lateral to

the proximal sigmoid colon. The peritoneum is incised and then dissected along the white line of Toldt toward the splenic flexure (Fig. 50-10). The plane is developed carefully, avoiding kidney injury, between the colon mesentery and the Gerota fascia. Then the lateral dissection is advanced medially until the aorta is reached.

**FIGURE 50-10** Mobilization of left colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## STEP 4: MOBILIZATION OF THE SPLENIC FLEXURE

The patient is now placed in reverse Trendelenburg position with the left side steeply inclined upward. The surgeon standing between the legs of the patient and the assistant on the right side with in-line arrangement of camera, monitor, and the instruments provide better surgical ergonomics. The instruments are repositioned with grasper through the suprapubic port and the cutting instrument through the left lateral port. The assistant grasps the greater omentum superior to the distal transverse colon through the right lateral port and retracts upward toward the abdominal wall cranially (Fig. 50-11). With the countertraction, the surgeon incises the peritoneum and enters the lesser sac. The dissection is then advanced parallel to the transverse colon to open up the lesser sac and mobilize the transverse colon. The dissection is then advanced toward the lateral dissection so that the splenic flexure is completely mobilized to the level of the umbilicus.

**FIGURE 50-11** Mobilization of splenic flexure. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## **STEPS 5–7: VASCULAR DIVISION, EXTERIORIZATION, AND ANASTOMOSIS**

Vascular ligation and division of the mesenteric vessels are performed either by incorporeal or extracorporeal method. The colon is exteriorized through the 4- to 6-cm midline vertical incision and anastomosis is performed in a similar fashion as in right hemicolectomy.

## **HAND-ASSISTED LAPAROSCOPIC SURGERY**

### **Hand-Assisted Laparoscopic Left Hemicolectomy**

#### **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is positioned and secured on the operating table in a similar fashion as for a laparoscopic-assisted procedure.

#### **STEP 2: PORT PLACEMENT AND EXPLORATION**

Lower midline incision is made below the umbilicus. The hand port should be placed in such a position where the nondominant hand acts like a laparoscopic retractor. The incision size should be one-half size smaller than the operator's hand size, and the incision length should remain the same through all layers of the abdomen to avoid leakage of air around the hand port (Fig. 50-12). Gelport is the new generation of multifunctional hand port that allows the usage of hand, laparoscope, and laparoscopic trocars, and maintains an airtight seal when the hand is removed. The surgeon's hand through the hand port guides the insertion of the 30-degree laparoscope in the periumbilical region. A 5/10-mm port for scissors with cautery is made in the LLQ under laparoscopic visualization (Fig. 50-13).

**FIGURE 50-12** Position of hand following insertion through hand port. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

**FIGURE 50-13** Position of incision for hand port and laparoscopic ports for left hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

### **STEP 3: MOBILIZATION OF THE LEFT COLON AND SPLENIC FLEXURE**

Traction is achieved when the hand and the colon is dissected in the similar

fashion described previously for the laparoscopic hemicolectomy (Figs 50-14 through 50-16). A grasper can be introduced through a 5-mm cannula in the RLQ to achieve additional traction for adequate mobilization of the spleen.

**FIGURE 50-14** Hand-assisted mobilization of left colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

**FIGURE 50-15** Hand-assisted mobilization of splenic flexure—omental attachments. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

**FIGURE 50-16** Hand-assisted mobilization of splenic flexure. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## **STEPS 4–6: VASCULAR DIVISION, EXTERIORIZATION, AND ANASTOMOSIS**

Vascular ligation and division of the vessels is typically performed using intracorporeal techniques. The colon is exteriorized through the hand port and divided, and anastomosis is performed with either handsewn technique or standard stapled method.

## **Sigmoid Colectomy**

### **STEP 1: PATIENT POSITION**

The patient is placed and secured on the operating table in modified lithotomy position the same as for left hemicolectomy. The surgeon and the

surgical assistant stand on the right side of the patient, and the camera, trocars, and monitor are aligned parallel to minimize reverse-image operating.

## **STEP 2: PORT PLACEMENT AND EXPLORATION**

The laparoscope is inserted through the supraumbilical port and the trocars are placed under visualization in suprapubic, right, and left lower lateral positions ([Fig. 50-17](#)). The abdominal cavity should be inspected with confirmation of the indicated pathology and other pathology excluded, as previously described.

**FIGURE 50-17** Position of laparoscopic ports for sigmoid colectomy and anterior resection. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

### **STEP 3: MOBILIZATION OF THE PROXIMAL SIGMOID AND DESCENDING COLON**

The patient is placed in steep Trendelenburg position with the left side of the table inclined upward. The 30-degree laparoscope is deployed through the supraumbilical port and the small bowel loops are swept to the right side. The left ureter is identified at the pelvic brim. Conversion to an open procedure is necessary if the ureter cannot be identified confidently. The ureter is swept down and away in order to avoid injury during ligation of the mesenteric vessels. The dissection commences lateral into the left ureter by incising peritoneum lateral to the sigmoid colon. The dissection continues along the white line of Toldt toward the splenic flexure in the same manner as done for left hemicolectomy. Mobilization of splenic flexure is performed as required.

#### **STEP 4: MOBILIZATION OF THE DISTAL SIGMOID COLON AND UPPER RECTUM**

After mobilizing the descending colon completely, the dissection is now directed caudally. With the retraction of the sigmoid colon cephalad and medially, the peritoneal incision is then extended distally to the midrectum entering the presacral space. The left ureter and the iliac vessels are identified and protected throughout this part of the procedure ([Fig. 50-18](#)). The presacral space is developed by the division of the fine adhesions and care should be taken to protect hypogastric nerves by sweeping them backward toward the sacrum.

**FIGURE 50-18** Mobilization of upper rectum. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## **STEPS 5 AND 6: VASCULAR LIGATION AND EXTERIORIZATION**

The sigmoid colon is elevated anteriorly and inferiorly to expose the mesenteric vessels. Then incision is made in the avascular plane on both sides of the vessels. The superior hemorrhoidal and sigmoid vessels are isolated and ligated at the level of aortic bifurcation using vascular staplers, clips, or Endoloop devices (Fig. 50-19). We ligate just distal to the takeoff of the left colic vessel. Some surgeons express a preference for ligation at the origin of the inferior mesenteric artery, proximal to the left colic branch. The sigmoid becomes more mobile after the ligation of the vascular pedicle. The upper rectum is then divided using a linear cutting stapler (Fig. 50-20).

**FIGURE 50-19** Intracorporeal vascular division of superior hemorrhoidal and sigmoidal vessels. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

**FIGURE 50-20** Division of upper rectum with linear stapler. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Then the pneumoperitoneum is vented out via the laparoscopic ports. The divided sigmoid colon is brought out through the extension of the LLQ incision. The proximal colon is divided at the sigmoid and descending colon junction.

## **STEP 7: ANASTOMOSIS**

A purse-string suture is inserted around the colon that is tied around the anvil of the stapler inserted into the lumen. Then the colon is returned to the abdominal cavity. The peritoneal cavity is irrigated and checked for blood, and the fascial defects are closed. After the reinsufflation of the abdominal cavity, the stapling device is introduced through the anus. The anvil attached

to the shaft of the stapling device is advanced across the staple line under direct visualization. The anvil is attached to the gun, approximating the bowel ends, and then the device is fired. The anastomotic integrity and hemostasis can then be assessed using a proctoscope. The pneumoperitoneum is released after withdrawing cannulas under direct visualization.

The alternative approach is to perform a handsewn anastomosis through a small lower midline incision of 5 to 6 cm. After bowel exteriorization, the bowel is excised and end-to-end anastomosis is performed, taking care to ensure proper alignment of the mesentery.

## **Hand-Assisted Laparoscopic Sigmoidectomy**

The patient is positioned in the same way as for the laparoscopic-assisted approach. The hand port is placed in the lower midline incision in the lower abdomen 1 cm above the pubic symphysis. The incision size should be one half-size smaller than the surgeon's hand to maintain effective pneumoperitoneum. Then the surgeon's left hand in the gel port guides the placement of other trocars. A 30-degree laparoscope is placed in the supraumbilical port and cautery attached to the scissors is placed in the RLQ port. The surgeon, standing on the left side of the patient, uses the left hand to provide retraction of the sigmoid colon while the cautery is operated with the right hand. The diseased specimen is extracted through the incision made for the hand port, and extracorporeal division of the vasculature can be performed. The anastomosis is made using the stapling device in the same manner as described previously. The pneumoperitoneum is reinstated, and the abdominal cavity is irrigated and inspected for hemostasis. Then the anastomotic site is inspected for leakage. Normal saline is placed in the abdomen and pelvis such that the anastomosis is submerged. A noncrushing clamp is placed proximal to the anastomosis and the rectum is then insufflated using a flexible sigmoidoscope. If bubbles are detected, either the anastomosis needs to be repaired at the site of the leak or the case needs proximal diversion with an ileostomy. Then the abdomen is closed after venting the pneumoperitoneum.

## **Transverse Colectomy**

## **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is placed and secured well on the operating table in supine or modified lithotomy position, depending on whether the pathology is closer to the right or left colon, respectively.

## **STEP 2: PORT PLACEMENT AND EXPLORATION**

The laparoscope is inserted through the supraumbilical port, and two cannulas are inserted in the right and left lower quadrants under direct visualization. The surgeon shifts sides depending on the mobilization of the hepatic flexure or the splenic flexure.

## **STEP 3: MOBILIZATION OF THE HEPATIC FLEXURE**

Dissection and mobilization of the hepatic flexure is performed as described under right hemicolectomy.

## **STEP 4: MOBILIZATION OF THE SPLENIC FLEXURE**

Dissection and mobilization of the splenic flexure is performed as described under left hemicolectomy.

## **STEP 5: MOBILIZATION OF THE TRANSVERSE COLON**

The stomach is lifted up, and with retraction of transverse colon downward the omentum is divided. Thus the transverse colon is freed from its attachments on either side.

## **STEPS 6–8: VASCULAR DIVISION, EXTERIORIZATION, AND ANASTOMOSIS**

The vascular pedicle is divided intracorporeally, and the mobilized transverse colon is exteriorized through the extended incision in the supraumbilical area. Care should be taken around the vascular pedicle of the transverse colon. The middle colic vessels are quite short, and the vein branches easily tear and cause difficult bleeding. Too much traction on these vessels can result in disruption of venous branches and significant bleeding. The bowel is then

divided and anastomosis of the free ends is done with handsewn technique or standard stapled technique.

## **TECHNICAL PROCEDURES FOR RECTAL DISEASES**

Anterior resection, or sometimes referred to as a high anterior resection, is a surgical procedure used for resection of tumors or pathology present in the proximal rectum or distal sigmoid (>12 cm from the anal verge). In contrast to the anterior resection, the low anterior resection is used to treat tumors or pathology in the mid- to distal rectum, and an ultralow anterior resection is a sphincter-preserving approach where the anal canal is spared and a coloanal anastomosis or ileal J-pouch anastomosis is performed. APR is a two-part procedure that involves an abdominal and pelvic procedure where the rectum and colon are mobilized along with a perineal procedure where the rectum and the anus are resected. With this procedure, the patient is left with a permanent colostomy. An APR is required for tumors within 1 cm of the top of the anal canal ([Fig. 50-21](#)).

**FIGURE 50-21** Levels of resection in rectal surgery—anterior resection, low anterior resection (LAR), coloanal, and abdominal perineal resection (APR). (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Rectopexy, or repair of rectum, is typically combined with sigmoid resection but can be performed by itself for treatment of rectal prolapse. We

typically perform a sigmoid resection and colorectal anastomosis; also, we secure the lateral parts of the rectum to the presacrum to generate additional fixation.

## **Anterior Resection**

### **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is placed in modified lithotomy position or synchronous position and securely strapped to the operating table. The setup is similar to that for sigmoid colectomy.

### **STEP 2: PORT PLACEMENT AND EXPLORATION**

A four-port technique is used in which trocars are positioned at supraumbilical, suprapubic, and right and left lower quadrants. The abdomen is inspected to confirm the pathology and rule out metastases. Estimation of lower margins of the rectum and the pathology is crucial to decide the procedure in advance of conducting the operation.

### **STEP 3: MOBILIZATION OF THE LEFT COLON AND SIGMOID COLON**

Dissection of the left colon and the sigmoid colon is carried out in a similar fashion as explained in the sigmoid resection.

### **STEP 4: VASCULAR LIGATION**

For cancers, the vascular pedicle needs to be taken proximal, incorporating at least the superior hemorrhoidal and sigmoidal vessels. A vascular stapler, LigaSure, or a Harmonic scalpel can be utilized for intracorporeal ligation. Both ureters should be visualized and moved out of harm's way prior to vascular pedicle ligation. The left ureter courses close to the sigmoidal and hemorrhoidal vessel in the retroperitoneum above the pelvic brim. For nononcologic pathologies, vessels can be ligated at more distal locations. Extracorporeal ligation of the vessels is an alternative if adequate exposure can be obtained through the extraction site.

## **STEP 5: MOBILIZATION OF THE RECTUM**

After vascular ligation, the presacral space is entered to start the dissection of the rectum. The ureters should be identified to avoid injury to them. Presacral nerves are carefully protected by gently sweeping them down and away from the dissection plane. The dissection continues laterally on either side until it meets posteriorly, developing a presacral plane (see [Fig. 50-18](#)). The rectum is mobilized by creating a plane anteriorly between the rectum and seminal vesicles and prostate in men, and between rectum and posterior vaginal wall in women. Complete mesorectal excision along with distal and circumferential clearance is the key factor for achieving complete oncologic resection. For cancers, the level of rectum for the site of transection is marked using ink tattoo preoperatively, and this is visualized at the time of the surgery with endoscopy. The level of transection is typically identified and tattooed before starting neoadjuvant chemoradiation for patients requiring it.

## **STEP 6: EXCISION OF THE RECTUM AND EXTERIORIZATION**

The rectum is excised at the marked position with the linear stapler gun (see [Fig. 50-20](#)) and then the specimen is extracted out through the extended incision in the supraumbilical region. The proximal end of the specimen is then dissected extracorporeally and the remaining colon reintroduced with the anvil of the stapler gun held by the purse-string sutures.

## **STEP 7: ANASTOMOSIS**

The anastomosis is performed in a fashion similar to what was described for sigmoid colectomy and low anterior resection using the circular stapler. The integrity of the anastomosis is always checked prior to closing the abdomen. Conversion is rarely needed when the anastomosis is at this high level, and is typically reserved for circumstances where the tissue is of poor quality.

## **Low Anterior Resection**

### **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is placed in the combined synchronous or modified lithotomy

position and secured well on the operating table. The thighs can be kept more at the level of abdominal wall to avoid interference with the laparoscopic instruments used in the lower ports. The surgeon stands on the right side of the patient and faces toward the LLQ of the patient. The surgeon may have to shift to between the patient's legs if mobilization of the splenic flexure is required. The surgeon's assistant stands on the right and the scrub nurse on the left. The camera positioned to the left of patient's hips in the beginning is moved cephalad as the mobilization of the sigmoid colon and descending colon continues.

## **STEP 2: PORT PLACEMENT AND EXPLORATION**

A 30-degree laparoscope is introduced through the supraumbilical position. Under direct visualization, three 5-mm trocars are in suprapubic position, right lower lateral quadrant, and left lower lateral quadrant positions (see [Fig. 50-17](#)). Lower quadrant trocars are inserted lateral to the epigastric vessels.

## **STEP 3: MOBILIZATION OF THE LEFT COLON**

The patient is placed in the steep Trendelenburg position with the left side of the abdomen inclined upward. The peritoneum lateral to the sigmoid colon is grasped and pulled medially to expose the left peritoneal reflection, which is then opened along the white line of Toldt using cautery or scissors. The left ureter is identified at the base of the sigmoidal fossa on the medial aspect. Remaining in the correct retroperitoneal plane exposes the Gerota fascia and left ureter. Care should be taken to avoid injury to the ureter and left kidney. Depending on the need for splenic flexure mobilization, the dissection can be extended further cephalad at this moment. Mobilization of the splenic flexure is performed as described earlier in the left hemicolectomy section.

## **STEP 4: VASCULAR PEDICLE LIGATION**

By scoring the right and perirectal peritoneum on a cephalad direction, the origin of superior hemorrhoidal and sigmoidal vessels can be exposed. The window in the mesentery on either side of the vessels is identified and developed. After ensuring that both ureters are not in the field, the vascular pedicle at the level of superior hemorrhoidal and sigmoidal vessels can be divided at the level of aortic bifurcation or just below the takeoff of the left

colic vessels. The vascular stapler, Harmonic scalpel, or LigaSure can be used according to the preference of the surgeon.

## **STEP 5: MOBILIZATION OF THE RECTUM**

During oncologic resection, care should be taken to avoid penetration of the mesorectal fascia. With the left side of the table inclined upward, the rectum is retracted anteriorly and right, and the left lateral dissection of the sigmoid is continued along the left lateral aspect of the rectum. The proximal aspect of the presacral space is exposed, which can be partially entered and developed. The operating table is now positioned with the right side inclined slightly upward. Retraction of the sigmoid colon and proximal rectum anteriorly, the right perirectal area is open and further retraction on the peritoneum allows for creating the presacral space. The presacral space is now developed with sharp dissection to the pelvic floor. Care should be taken to identify and protect the hypogastric nerves; they should be gently swept down toward the sacrum. The right presacral plane is opened to meet the left presacral plane. The rectum is then elevated anteriorly with sufficient traction that the presacral plane can be developed as far distally as needed to achieve at least 4 cm of distal mesorectal and 2 cm of distal bowel clearance below the tumor. It is generally necessary to work from the posterior section to the lateral section and anterior section and then again going deeper to all, repeating the steps until the dissection is carried well below the tumor. The anterior dissection should include the Denonvilliers' fascia in cases of cancer. We would go above the peritoneal reflection anteriorly and take the anterior peritoneal reflection with the specimen. The lateral stalks would typically need to be divided to facilitate deep exposure of the pelvis and mobilization of the rectum for any tumors that present below the upper rectum.

Once the dissection is carried to levators, endoscopy can confirm the optimal level of rectal and mesorectal transection.

## **STEP 6: EXCISION OF THE RECTUM**

The mesorectum can be divided with a LigaSure or Harmonic scalpel. A stapler is required to transect the rectum. The introduction of the stapler typically occurs through a small suprapubic incision or the hand port. The dissected rectum can be divided intracorporeally with a laparoscopic

articulating linear stapler at both of the ends. The resected specimen is then extracted out through the supraumbilical incision. Of note, it is also feasible to transect the distal rectum with a TA stapler, introduced through a small suprapubic incision that can be used later for specimen extraction (Fig. 50-22).

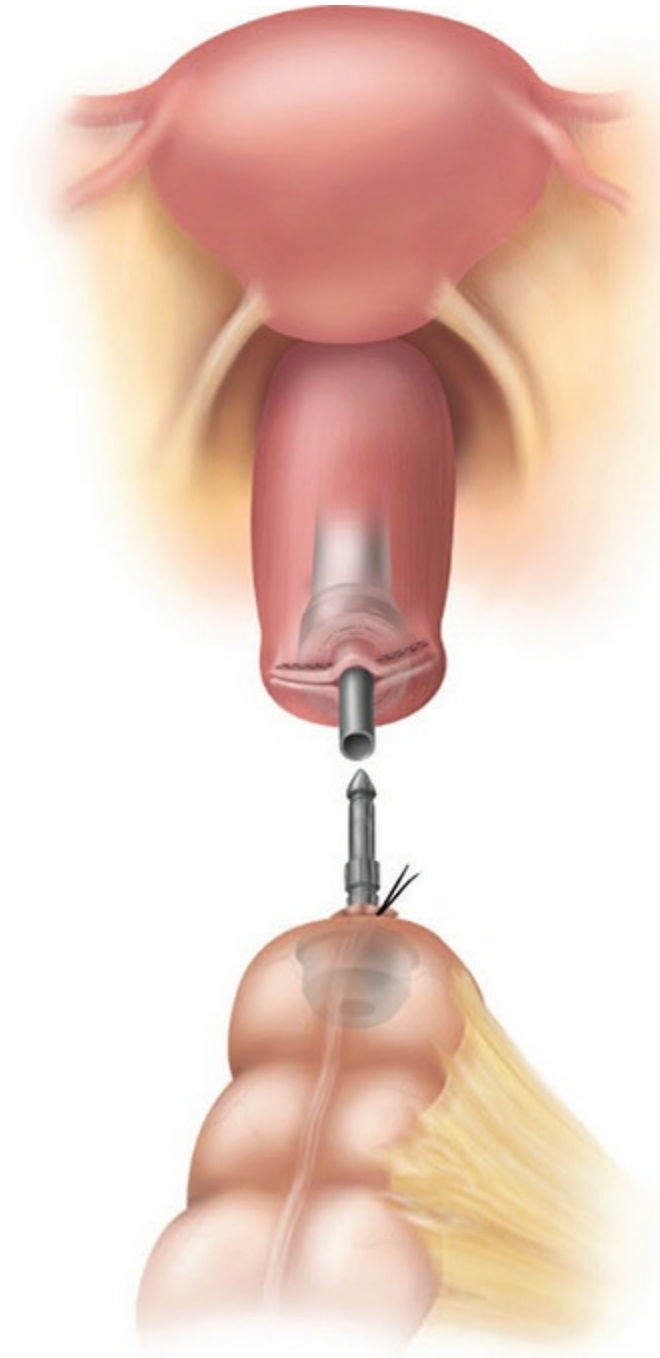

**FIGURE 50-22** Division of lower rectum with transverse stapler. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## STEP 7: ANASTOMOSIS

A purse-string suture is placed in the proximal resection margin and the anvil is tied around the margin of the colon. Then the proximal colon with the anvil is returned to the abdomen. The incision is then closed and the pneumoperitoneum is reestablished. The circular stapler is inserted through the anus, and the anvil attached to the shaft of the stapling device is advanced across the staple line under direct visualization (Fig. 50-23). The anvil of the proximal colon is attached to the stapler, approximating the bowel ends, and then the device is fired under direct visualization. The abdomen is then

irrigated with saline and hemostasis ensured. The anastomosis is checked for any leaks by filling the pelvis with saline, insufflating the rectum with air from the flexible scope, including the proximal colon with an alligator clamp, and observing for any air bubbles. If there is evidence of a leak, that area should be reinforced with sutures or diversion created. The pneumoperitoneum is vented and the port sites are closed as described previously.

**FIGURE 50-23** Colorectal anastomosis. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

## **Hand-Assisted Laparoscopic Low Anterior Resection**

The patient is positioned in the same way as for the laparoscopic procedure. A 6- to 8-cm lower midline longitudinal incision is made to accommodate the hand port. The incision size should be a half-size smaller than the surgeon's hand to maintain effective pneumoperitoneum. Then the surgeon's left hand in the gel port guides the placement of other trocars. A 30-degree laparoscope is placed in the supraumbilical port and cautery attached to the scissors is placed in the RLQ port. The surgeon's left hand provides retraction of the sigmoid colon and the rectum to aid in the dissection. The vessels are divided intracorporeally with the help of LigaSure or vascular stapler. After a clear plane is developed around the rectum, the rectum is divided with the linear TA stapler at the marked site. The rectosigmoid along with the mesorectum is extracted out through the incision made for the hand port. The coloanal anastomosis is performed using the circular stapling device in the same manner as detailed for the laparoscopic procedure above. Then the anastomotic site is checked for any leakage before closing of the abdomen.

## **Laparoscopic Abdominal Perineal Resection**

### **STEP 1: PATIENT POSITION AND ROOM SETUP**

Preoperative marking of the stoma site is essential to ensure proper stomal positioning and optimal postoperative care and function. The patient is placed in a modified lithotomy position and securely strapped. The surgeon stands on the right side of the patient initially during sigmoid and left colon dissection and later moves toward the patient's left side for the majority of the rectal dissection. The monitor should be positioned according to the position of the surgeon. Using two monitors can alleviate having to reposition the monitor during surgeon relocation.

### **STEP 2: PORT PLACEMENT AND EXPLORATION**

The use of five ports offers more flexibility in doing an APR. A 30-degree laparoscope is introduced through an infraumbilical trocar. One of the trocars is introduced at the stoma site marking, while the other three trocars are inserted in the right upper, right lower, and left lower quadrants ([Fig. 50-24](#)). Using 10-mm trocars allows the surgeon to transfer the laparoscope to other ports to get better access during the procedure. Inspection of the abdomen is carried out to confirm the pathology.

**FIGURE 50-24** Position of laparoscopic ports for abdominal perineal resection (APR). (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

### **STEP 3: VASCULAR LIGATION**

The origin of the superior hemorrhoidal and sigmoidal vessels can be

exposed by scoring the right and perirectal peritoneum in the cephalad direction. After the window in the mesentery on either side of the vessels is developed and it is ensured that both ureters are not in the field, the vascular pedicle at the level of superior hemorrhoidal and sigmoidal vessels can be divided at the level of aortic bifurcation or just below the takeoff of the left colic vessels, as described for the anterior resection.

#### **STEP 4: MOBILIZATION OF THE SIGMOID COLON AND THE RECTUM (ABDOMINAL PORTION)**

The mobilization of the sigmoid colon and the rectum is performed as described in low anterior resection. During oncologic resection, care should be taken to avoid penetration of the rectum or the mesorectal fascia. With the left side of the table inclined upward, the rectum is retracted anteriorly and right, and the left lateral dissection of the sigmoid along the white line of Toldt is continued along the left lateral aspect of the rectum. Then the left ureter should be identified at the base of the sigmoidal fossa. The proximal aspect of the presacral space is exposed, which can be partially entered and developed (see [Fig. 50-18](#)). The operating table is now positioned with the right side inclined slightly upward. Retraction of the sigmoid colon and proximal rectum anteriorly, the right perirectal area is open and further retraction on the peritoneum allows for creating the presacral space. The presacral space is now developed with sharp dissection to the pelvic floor. Care should be taken to identify and protect the hypogastric nerves; they should be gently swept down toward the sacrum and to identify the ureters. The rectum is then elevated anteriorly with sufficient traction that the presacral plane can be developed as far distally as needed to achieve at least 4 cm of distal mesorectal and 2 cm of distal bowel clearance below the tumor. It is generally necessary to work from the posterior section to the lateral section and anterior section and then again going deeper to all, repeating the steps until the dissection is carried well below the tumor. The anterior dissection should include the Denonvilliers' fascia in cases of cancer. We would go above the peritoneal reflection anteriorly and take the anterior peritoneal reflection with the specimen. The lateral stalks should be divided to facilitate deep exposure of the pelvis and mobilization of the rectum for any tumors that present below the upper rectum. Then the mesorectum is divided at the chosen level with the ultrasonic scissors. The rectal dissection

is now performed anteriorly without drifting away from the mesorectal plane into the seminal vesicles and prostate or the vagina anteriorly.

## **STEP 5: PERINEAL RESECTION**

The perineal dissection is performed as for conventional APR. A purse-string suture is used to close the diamond-shaped perianal incision that is created just outside the sphincter complex to include the sphincters in the specimens. The dissection of the ischial rectal fat is carried out posteriorly all the way to level of levators. Next, the anterior fat is divided in a similar fashion. Using the tip of the coccyx as a guide, a scissors is brought just anterior to the tip of the coccyx and placed into the pelvis and spread. Withdrawing the scissors in a spread position creates a common hole between the pelvis and the perineum. A finger then can be placed along the left levator and the levators divided on both the left and right sides. Hemostasis is achieved with the cautery and suture ligation as needed. The resulting defect in the pelvic floor is typically large enough that the rectum can be brought out from the abdomen and pelvis through the posterior perineal wound.

## **STEP 6: EXTERIORIZATION OF THE SPECIMEN AND WOUND CLOSURE**

Anterior levators are divided on both sides along the edge of the everted rectum. Care must be taken to avoid inadvertently creating a defect in the rectum in cases of cancer. Last, the direct anterior dissection is completed, and here we would avoid any excessive use of cautery in the male in particular. The urethra is quite close to the rectal dissection and it is highly sensitive to heat. A delayed urethral leak will occur if excessive heat is applied during the anterior dissection. Finally, the rectum is extracted out through the perineal wound. The perineal wound is closed in sequential layers with absorbable sutures leaving closed-suction drains either from the abdomen down to the pelvis or, if preferred, through the perineum. The drains are clamped and pneumoperitoneum can be recreated. The descending colon is inspected to ensure that it is not twisted or rotated on its mesentery, as it is going to be used for the colostomy.

## **STEP 7: COLOSTOMY**

The distal end of the colon is now brought to the colostomy orifice using a grasper. At least 3 cm of colon is extracted out through the skin and the colostomy is matured in a Brooke fashion by inverting the bowel wall so that the stoma is slightly raised above the skin.

## **Hand-Assisted Laparoscopic Abdominal Perineal Resection**

The abdominal portion of the procedure is assisted using the hand port. The sigmoid colon and the rectum are mobilized as detailed previously for the low anterior resection. The perineal resection is performed as for conventional APR.

## **LAPAROSCOPIC RECTOPEXY**

### **Resection Rectopexy**

This procedure is essentially the same as for anterior resection with the exception being the addition of presacral fixation.

### **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is placed in the modified lithotomy position and carefully positioned and strapped on the operating table. The surgeon and the assistant stand on the right side of the patient, while the monitor is placed on the patient's left side in the caudal end.

### **STEP 2: PORT POSITION AND EXPLORATION**

A 30-degree laparoscope is introduced through the 10/12-mm subumbilical port. A careful inspection of the liver, small bowel, and the peritoneal surfaces is performed. Under direct visualization, three ports are made in right lower, right upper, and left lower quadrants.

### **STEP 3: VASCULAR LIGATION**

The table is now positioned with left side and feet upward, and then the bowel loops are swept to the right side of the abdomen to make the operative field clear. The retroperitoneal structures are dissected to identify the sigmoidal and superior hemorrhoidal vessels and ureters. Because this procedure is indicated for benign cases, the vascular ligation can be performed more distally. The nerves should be spared and the ureters identified. The mesentery can be taken close to the bowel if the surgeon attempts to preserve the vascular pedicle.

#### **STEP 4: MOBILIZATION OF THE RECTOSIGMOID**

The sigmoid colon is mobilized by developing a plane between the mesentery and the sigmoid colon. The rectosigmoid junction is drawn toward the patient's right side and the lateral attachments are divided. The dissection of the descending colon should be kept as minimal as possible.

#### **STEP 5: MOBILIZATION OF THE RECTUM**

The rectum is mobilized in a similar fashion as detailed in low anterior resection, with some modifications. To minimize chances of rectal prolapse recurrence (particularly in patients presenting with early-onset prolapse), we would dissect the rectum all the way to the levators. Although we favor transection of the lateral stalks, this should be at the discretion of the surgeon and based on factors of risk of recurrence versus risk of pelvic floor dysfunction. To not divide the rectal stalk puts the patient at a higher risk of recurrent prolapse. However, to transect both rectal stalks makes the patient at least theoretically at risk for more pelvic floor dysfunction and also removes a source of blood supply (ie, the middle hemorrhoidal). We typically preserve the superior hemorrhoidal and then transect the lateral stalks, so the rectum is supplied by inferior and superior hemorrhoidal vessels.

#### **STEP 6: DIVISION OF THE RECTUM AND ANASTOMOSIS**

Before the proximal or distal rectum is divided, careful measurements should be made of where the two ends of the colon and rectum match up. There should be no tension on the anastomosis once it is complete, and yet there

should be little to no laxity in the residual bowel as it lies in the pelvis. This will help reduce the risk of recurrent prolapse. Of note, some do not prefer to conduct a colon resection, and we would agree that if there is no redundancy in the colon and the patient suffers from fecal incontinence rather than from constipation, we might also choose not to resect the bowel. Once the level of colon and rectal transection has been determined to create a tension-free but nonlaxed anastomosis, the rectum is divided with a linear stapler. The division point of the rectum should be just below the level of the sacral promontory. The specimen is extracted through a small lower midline incision. In those cases where a hand port is performed, the specimen is readily extracted through the port site. The proximal end of the colon is divided, and the angle of the circular stapler is inserted and closed with a purse-string suture. The circular stapler is inserted through the anus with the trocar brought out just in front of or behind the transverse staple line. The two parts of the stapler are coupled and the device then fired. We often place a row of seromuscular sutures around the anastomosis, especially if there is any evidence of leakage when it is tested in a saline-filled pelvis.

## **STEP 7: RECTOPEXY**

Once the anastomosis is complete, the mesorectum is then attached to the sacral promontory or as one of two with two or three nonabsorbable sutures. We would incorporate the lateral edge of the rectal tissue with care being taken to find the mesorectal tissue without major vessels or nerves. We would also take care to offset the left and right sutures to avoid “crimping” or occluding the rectal lumen from this fixation process. Care should also be taken to insert the needle into some of the presacral periosteum and away from the area of the sacral nerve and internal iliac vessels.

## **Laparoscopic Subtotal Colectomy with Ileorectal Anastomosis**

### **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is carefully placed in a modified lithotomy position and securely strapped and padded to the operating table, thus keeping the patient stable when the operating table is tilted side to side during surgery. The surgeon

stands on the right or left side of the patient, depending on the segment of the colon. The video monitors are adjusted according to the surgeon's position to maintain the alignment of the camera, instruments, and surgical fields. Two monitors are used for convenience because the surgeon will have to reposition at least twice. If an ileostomy is planned, the site should be identified by stomal therapists preoperatively and marked before surgery starts.

## **STEP 2: PORT PLACEMENT AND EXPLORATION**

A 10/12-mm port is made in the supraumbilical region and laparoscope is introduced. Under direct visual guidance, four ports are placed, one each in all four quadrants of the abdomen. A 10-mm port is placed in the RLQ to allow the endoscopic stapler; the remaining ports are 5 mm in size. If camera position needs to be changed, a 5-mm port can be changed to a 10-mm cannula.

## **STEP 3: MOBILIZATION OF THE COLON—LEFT COLON, SIGMOID COLON, AND RIGHT COLON**

The colon is mobilized sequentially starting from splenic flexure and left colon, followed by right colon and then the sigmoid colon as previously described under individual hemicolectomies. The vessels are ligated intracorporeally and simultaneously along with the dissection of its respective segment. In cases of benign pathology, the vessels can be ligated closer to the bowel and a LigaSure or other vascular transecting device can be used for most, if not all, of the vessels.

## **STEP 4: EXTERIORIZATION OF THE COLON AND DIVISION OF THE VASCULATURE**

The colon is confirmed free from all attachments with the help of a grasper before exteriorization of the specimen. The pneumoperitoneum is vented and supraumbilical incision is extended for 4 to 6 cm inferiorly. The colon is exteriorized through this incision. Any remaining vascular pedicles can be ligated using standard open technique extracorporeally. The orientation of the ileal mesentery should be preserved to prevent torsion and small bowel

internal herniation.

## **STEP 5: FORMATION OF ILEORECTAL ANASTOMOSIS**

An ileorectal anastomosis is performed with the help of the circular stapler in a fashion similar to that described previously for colorectal anastomosis. The tricky part of the ileorectal anastomosis is finding the optimal orientation for the small bowel and its mesentery as it comes to a lie within the pelvis. It is often difficult to get the best orientation because the ileum typically is in the RLQ, not in the LLQ. In some cases, it will easily work end-to-end for an anastomosis, but in most cases a side ileum to end of rectum may be best to achieve a mesenteric alignment to avoid seeping. If a side of ileum to end of rectum anastomosis looks best, the stapled distal end of the small bowel can be oversewn with seromuscular sutures and a separate antimesenteric site chosen to conduct the anastomosis. In this case, the anvil of the stapler can be placed in the bowel and closed with a purse-string suture and the shaft of the stapler brought across the anus into the rectum and coupled, closed, and fired in the typical fashion.

## **RESTORATIVE TOTAL PROCTOCOLECTOMY WITH ILEAL J-POUCH ANAL ANASTOMOSIS**

### **Laparoscopic Ileal Pouch-Anal Anastomosis**

This procedure is essentially the same as the subtotal colectomy plus ultralow anterior rectal resection. The main difference here is the creation of an ileal J-pouch rather than a colon J-pouch.

## **STEP 1: PATIENT POSITION AND ROOM SETUP**

The patient is placed in modified lithotomy position and securely and safely strapped to avoid movements and injury during the procedure. The position of the surgeon should be ergonomically altered depending on the dissection of individual segment of the colon. The key to the appropriate position of the surgeon is to maintain a parallel view with the laparoscope, working instruments, and the monitors.

## **STEP 2: PORT PLACEMENT AND EXPLORATION**

The 30-degree laparoscope is introduced through the 10-mm trocar in the infraumbilical site. The abdomen is inspected to confirm the pathology. Under direct visual guidance, four trocars are introduced in the four quadrants ([Fig. 50-25](#)). A 10-mm trocar is inserted in the right lower quadrant, while the rest of the trocars can be of 5 mm caliber. Using 10-mm trocars at all the ports will allow flexibility to the surgeon in using the laparoscope from any of the ports.

**FIGURE 50-25** Position of laparoscopic ports for total proctocolectomy.  
(Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

### **STEP 3: COLON MOBILIZATION**

The colon is mobilized sequentially starting from splenic flexure and left colon, followed by right colon, and then the transverse and sigmoid colon as

previously described under individual hemicolectomies. We prefer to mobilize the splenic flexure early while all natural attachments are intact. Intracorporeal vascular ligation and division is performed simultaneously with the dissection and mobilization of the colon using a vascular stapling device for larger vessels such as ileocolic and the LigaSure or similar device for smaller vessels.

#### **STEP 4: RECTAL MOBILIZATION**

The surgeon continues the dissection from the sigmoid colon toward the rectum. The rectum is fully mobilized to the pelvic floor as previously described in the section on ultralow anterior resection. The rectum is then divided at the pelvic floor using an Endo GIA (Covidien, Mansfield, MA) linear cutting stapler. If the stapler cannot reach the pelvic floor, the stapler can be introduced through a small suprapubic incision or the hand port incision, or alternatively using a transanal approach. For the transanal approach, the anal canal is exposed using a Lone Star retractor (Lone Star Medical Products, Stafford, TX) or Gelpi retractor. Diluted epinephrine solution is then injected to raise the mucosal layer to assist in mucosectomy and to minimize bleeding. Cautery dissection starts at the dentate line and is continued cephalad by lifting the mucosal layer up to the level of puborectalis, that is, the top of the anal canal. At this point, the dissection is carried full thickness to complete the distal transection of the rectum with complete mucosal removal but with preservation of the internal sphincter. This approach is used when the entire specimen can be removed through the anus.

#### **STEP 5: EXTERIORIZATION OF COLON AND RECTUM**

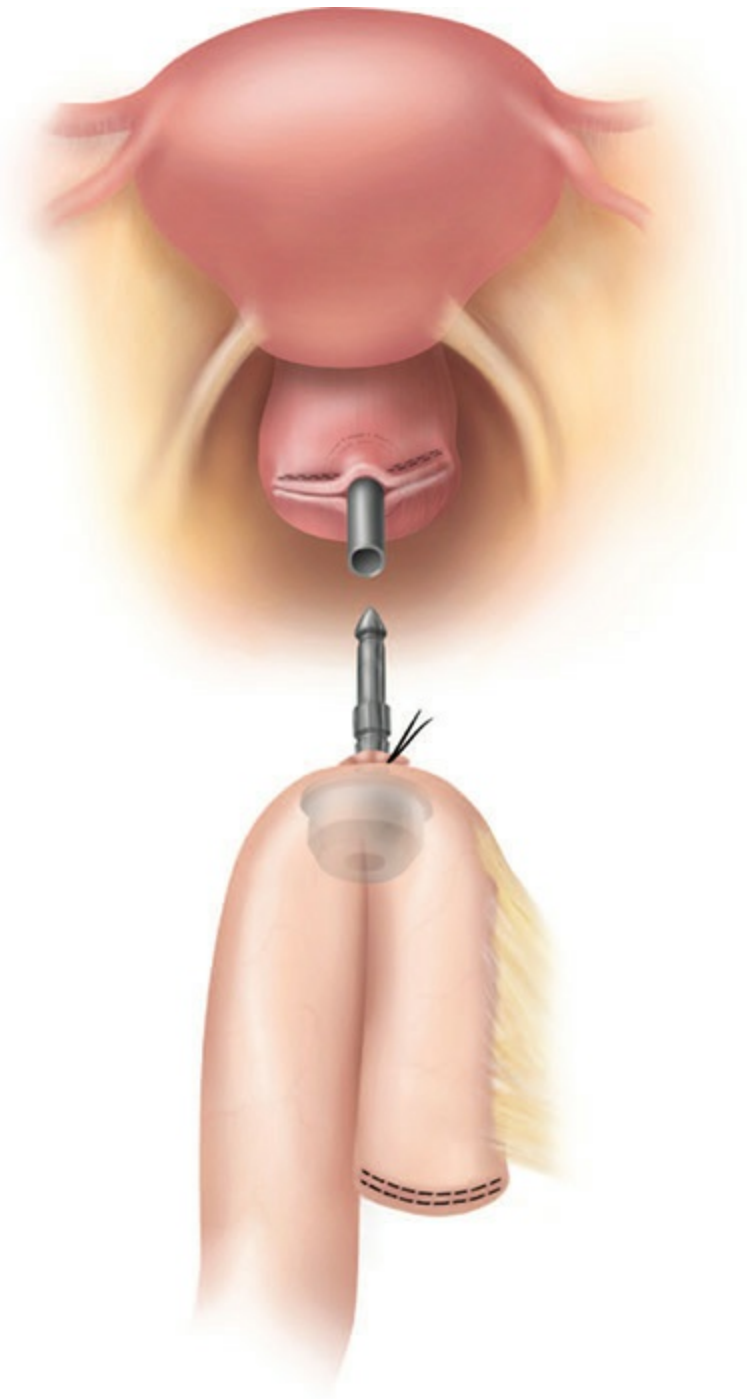

The infraumbilical incision is extended by 4 to 6 cm inferiorly after the pneumoperitoneum is vented through the cannulas. The colon is exteriorized through this incision if it has not been removed through the anus while in transanal resection. The vascular pedicles are ligated and divided using standard open technique extracorporeally unless the vessels are ligated and cut intracorporeally. The ileum at the junction with the right colon is stapled and transected.

## **STEP 6: FORMATION OF ILEAL J-POUCH–ANAL ANASTOMOSIS**

The distal staple line of the ileum is oversewn with a seromuscular layer. Next, one makes sure that the blood supply and the vascular pedicle of the ileum are properly oriented without twists. At this juncture one needs to make sure that the apex of the pouch can reach the level of the top of the anal canal. Lengthening of the ileum to achieve the pouch–anal anastomosis must be performed before the pouch is stapled and actually created. The mesentery of the small bowel needs to be fully mobilized all the way up to the base of the stomach near the pancreas. Vascular arcades can be ligated in order to get the pouch to reach in extreme cases, and after a period of temporary bulldog clamping has been performed to ensure good blood supply. Once the pouch is thought to reach, the “J” configuration is created using two 15-cm limbs of small bowel. Seromuscular suture helps secure the correct orientation and reinforce the staple line that is to be created. At this juncture, a small enterotomy is made in the apex of the pouch, and this allows multiple firings of the 80- to 100-mm linear stapler to create the pouch itself. Once the stapling is completed (two, at most three firings), look for and correct any defects at the intersections of the staple line and check for pouch hemostasis prior to placing the handle and the purse-string in the apex.

The purse-string is made in the pouch apex, and the circular stapler is placed and suture is tightened. The pouch is returned to the abdominal cavity with proper orientation and laid in the pelvis. The midline incision is closed so that the pneumoperitoneum can be restored and the anastomosis completed. The circular stapling device is inserted through the anus and the trocar advanced under direct vision across the transverse staple line or purse-string at the anal level. The anvil of the stapler is then attached using a specially designed laparoscopic instrument ensuring that the pouch and its mesentery are lying in the correct orientation and not rotated. The stapler is coupled, closed, fired, and withdrawn. Removing the purse-strings allows us to see if the donuts are intact. Anastomotic integrity of the pouch is checked before wound closure ([Fig. 50-26](#)).

**FIGURE 50-26** J-pouch–anal anastomosis. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

When a transanal approach is utilized to transect the distal end of the rectum, the pouch is delivered to the anal opening and two layers of absorbable sutures are placed. The first layer is seromuscular suturing of the pouch to the anal canal musculature, that is, an anchoring layer. The pouch is

then opened and four quadrant sutures are next placed between the full thickness of the pouch and the residual anal mucosal layer. Supplemental sutures complete this layer.

## **STEP 7: FORMATION OF LOOP ILEOSTOMY**

The ileum proximal to the pouch by roughly 30 to 50 cm is grasped and brought out to the RLQ port. A defunctioning loop ileostomy is made, ensuring that the orientation is properly defined. Pelvic drains are placed through the laparoscopic ports. The skin is then closed and the ileostomy matured.

## **Hand-Assisted Ileal J-Pouch–Anal Anastomosis**

The patient is placed in modified lithotomy position and securely strapped to the operating table. The hand port is placed in a lower midline incision. Three ports are made respectively at supraumbilicus, right lower, and left upper quadrants. The surgeon may stand on the right or left of the patient; alternatively, it is often convenient for the surgeon to stand between the legs, especially for takedown of flexures and the transverse colon. A 10-mm port is preferred to a 5-mm port as it allows the surgeon to use the laparoscope from any of the ports. The colonic mobilization commences at the splenic flexure. Additional assistance for the splenic mobilization can be provided with a grasper placed in the RLQ. After mobilizing the splenic flexure and left colon, the surgeon shifts position to mobilize the right colon and the transverse colon. Vascular ligation and division can be performed in intra- or extracorporeal manner depending on the mobilization of the colon. The rectum can be mobilized and resected at the pelvic floor with a linear stapler or with a transverse stapler as described above. The rectum and colon are then delivered through the wound and the terminal ileum divided with the linear stapler. A J-pouch is then fashioned in the same manner as described previously and anastomosed to the anus with circular stapler inserted through the anus. If a defunctioning loop ileostomy is planned, a loop of proximal ileum is passed through the RLQ port and the ileostomy matured. Care should be taken to avoid torsion of the vascular pedicle and small bowel intussusception. Drains are placed into the pelvis through the lower quadrant port. After checking for anastomotic integrity and hemostasis is done, the

hand port wound is closed in two layers as regular wound incision.

## COMPLICATIONS

Intraoperative complications including management and prevention can be seen in [Tables 50-5](#) through [50-7](#). [Table 50-8](#) shows the advantages and disadvantages with robotics.

**TABLE 50-5: INTRAOPERATIVE COMPLICATIONS**

### Complications

---

Patient position related	<ul style="list-style-type: none"><li>• Lower extremity neuropathies (peroneal nerve and compartment syndrome)</li><li>• Upper extremity neuropathies (brachial plexus, median, and ulnar nerves)</li></ul>
Veress needle or trocar insertion related	<ul style="list-style-type: none"><li>• Increased intra-abdominal pressure</li><li>• Vessel puncture and hemorrhage</li><li>• Bowel perforation</li></ul>
Pneumoperitoneum related	<ul style="list-style-type: none"><li>• Increased intra-abdominal pressure</li><li>• Hypothermia</li><li>• Hypercarbia and acidemia</li><li>• Insufflation with misplaced needle</li></ul>
Technique related	<ul style="list-style-type: none"><li>• Hemorrhage</li><li>• Anastomotic leakage</li><li>• Infection</li></ul>

---

**TABLE 50-6: MANAGEMENT OF INTRAOPERATIVE COMPLICATIONS**

Intraoperative Complications	Management
Perforation	Laparoscopic repair, if technically feasible, or conversion to open surgery
Splenic injury	Control of capsular bleeding, electrocautery, topical hemostatic agent, conversion, and/or splenectomy
Ureteral injury	Conversion to open surgery and repair over a stent
Bladder injury	Laparoscopic repair, if feasible, or conversion
Mesenteric bleeding	Laparoscopic clip, suture control, or conversion
Anastomotic leak	Repair and/or diversion

**TABLE 50-7: PREVENTION OF INTRAOPERATIVE COMPLICATIONS**

Technique-Related Complications	Prevention
Perforation	Use atraumatic instruments; exert traction on peritoneal attachments rather than on bowel; use gentle manipulation; avoid cautery injury to well-insulated laparoscopic tools and adequate visualization of tools during the application of cautery
Splenic injury	Ensure adequate visualization when at the splenic flexure, and place gentle traction on tissues attached to the spleen
Ureteral injury	Properly identify and avoid cautery in the ureter field; use ureteral stents as necessary
Bladder injury	Use catheter decompression
Mesenteric bleeding	Create mesenteric windows in avascular plane, use of double-clip technique or suture ligation for major vessels
Anastomotic leak	Ensure proper bowel alignment, avoid tension, and check for good vascularization of proximal and distal ends, use suturing or stapling techniques, and check bleeding
Wound/trocar site infection	Proper antibiotic prophylaxis and ensure hemostasis and irrigation of trocar site
Trocar site recurrence	Protect the port site, use bag for specimen extraction, and avoid chimney effect.

**TABLE 50-8: ADVANTAGES AND DISADVANTAGES WITH ROBOTICS**

## Advantages

1. 3D visualization
2. Better movement of instruments
3. Absence of fulcrum effect
4. Less fatigue
5. Elimination of tremor

## Disadvantages

1. High initial maintenance and cost
2. Absence of tactile sensation
3. Long setup time for instruments
4. Technical experience required

## LEARNING CURVE AND CREDENTIALING

Laparoscopic colectomy is different from other laparoscopic surgery as it requires working in multiple fields and different orientations. Proper training and experience along with appropriate help from the first assistant and the scrub nurse are vital in performing laparoscopic colectomy. There is a significant learning curve during which the length of each procedure may be longer and rate of conversion to open may be greater, although the incidence of complications is not altered.<sup>27</sup> It is recommended that surgeons develop their laparoscopic skills initially with simpler procedures such as appendectomy, cholecystectomy, and right colectomy before they graduate to benign complex operations and undertake cancer resections. Based on the prerequisite of 20 laparoscopic colectomies for COST trial, ASCRS recommended that surgeons perform 20 laparoscopic resections before undertaking procedures for cancer. HALS is easily adaptable for routine and complex cases.<sup>28</sup> The steep learning curve of laparoscopic-assisted colectomy can be overcome by starting with the HALS approach.

## FUTURE CONSIDERATIONS—ROBOTICS AND NOTES

Successful telerobotic-assisted laparoscopic sigmoid and right colectomies were first reported by Weber et al.<sup>29</sup> in 2002 when actual dissection and mobilization were performed with robotic assistance, and a lot of progress was achieved in technological inventions and its application in various operations. D'Annibale et al. reported the results of 53 robotic colorectal

surgeries in 2004 and concluded that the outcomes are similar to laparoscopic surgery.<sup>30</sup> Short-term outcomes of a randomized pilot study by Baik et al. comparing robotic-assisted low anterior resection and laparoscopic low anterior resection concluded the safety and feasibility of robotics (da Vinci robots [Intuitive Surgical, Inc., Sunnyvale, CA]) in colorectal surgery.<sup>31</sup>

Robotic-assisted surgery (da Vinci robots) offers many advantages over laparoscopic surgery such as 3D visualization, increased degrees of freedom of movement, absence of fulcrum effect, reduced fatigue, and elimination of tremor and better ergonomics for surgeon.<sup>29-31</sup> The biggest drawback for robotics is the high cost. Minor drawbacks include the absence of tactile sensation and the lengthy time required for setup, longer operative times, as well as increased expense.<sup>32</sup> Robotic surgery in the colorectal field has increased in popularity and is increasingly being used in pelvic surgery especially. The results of the ROLARR trial, a multinational, multicenter prospective trial comparing laparoscopic and robotic surgery for rectal cancer, will shed light on its usefulness in colorectal surgery. At this point, there is no shortage of enthusiasm in its application, especially with the new XI platform, which permits multiquadrant surgery. Most studies are retrospective, single-institution, and have mixed recommendations. Thus far it does not appear to be inferior to laparoscopic surgery, and though some studies found that conversion to open surgery is lower, a recent meta-analysis found that the conversion rate is higher.<sup>32,33</sup>

NOSE (natural orifice specimen extraction) technique was performed in colon and rectal surgery specimen extraction through the transanal and transvaginal routes in the recent past and was considered a prequel to NOTES (natural orifice transluminal endoscopic surgery).<sup>34</sup>

NOTES is an interesting concept that is gaining enthusiasm. It utilizes the concept of approaching the internal viscera through natural openings such as the mouth (stomach), the anus, and the vagina. NOTES was first performed in India by Reddy and Rao in a burn patient where abdominal incision was not feasible.<sup>35</sup> Initial studies were focused mainly on animal studies.<sup>36</sup> The Natural Orifice Surgery Consortium for Assessment for Research (NOSCAR) was formed in 2005, and it identified the potential barriers in clinical practice of NOTES and set guidelines for future research and development.<sup>37</sup> Patients prefer to undergo the NOTES approach over laparoscopic cholecystectomy for lack of pain (99%) and external scarring (89%).<sup>38</sup> The potential

advantages of NOTES include no scars, less pain, fewer wound complications, earlier mobility,<sup>36</sup> and potential to offer therapy outside of the operating room (intensive care unit [ICU]).<sup>39</sup>

# PERSPECTIVE ON COLORECTAL NEOPLASMS

*Martin R. Weiser*

## ROBOTIC SURGERY

Robotic surgery builds on the innovations of laparoscopy, which has been increasingly adopted for colon and rectal cancer surgery over the past 2 decades, with numerous well-designed trials demonstrating short-term advantages in terms of recovery and complication rates, along with long-term oncologic outcomes at least equivalent to those of open surgery. These advantages likely result from the fact that laparoscopic approaches provide improved visualization of the surgical field, which translates into greater operative exposure, exploiting one of surgery's most fundamental tenets.

As the technical challenges of laparoscopy have limited its adoption for colorectal cancer treatment, robotic systems, which resolve many of the mechanical and optical limitations of laparoscopy, are a promising technologic advance. In place of the rigid nonarticulating instruments and suboptimal visualization employed in manual minimally invasive procedures, robotic surgical equipment provides flexible instrumentation and wristed movement capabilities. Reliance on a secondary expert surgeon is reduced

due to a third robotic arm for self-assistance, and perspective is enhanced by high-definition 3-dimensional views from a mounted, stabilized, surgeon-controlled camera.<sup>1,2</sup> The superior ergonomics and surgical dexterity provided by the robot result from the instruments' 7 degrees of freedom and 90-degree articulation, permitting manipulation within small spaces, a capability particularly relevant in the narrow, bony pelvis.<sup>3,4</sup>

Compared to laparoscopy, robotic technology has been shown to enhance dexterity by 65%, reduce skill-based errors by 93%, and shorten the time needed to complete a task by 40%.<sup>5</sup> Robotic technology also provides motion scaling and tremor filtering, facilitating precise dissection and suturing, which is particularly valuable in dissecting along the origins of the mesenteric vessels during complete mesocolic excision or in performing total mesorectal excision (TME) within the pelvis.<sup>6</sup> In addition, the robotic platform enables an integrated and supervised teaching environment without compromising operative or long-term outcomes.<sup>4</sup>

There are no absolute contraindications to robotic colon and rectal cancer surgery, and its application is limited primarily by the surgeon's experience and expertise. Relative contraindications, depending on the surgeon's judgment, are locally invasive tumors and recurrent disease, which often obscure normal anatomic planes. In addition, consideration should be given to whether a patient can tolerate pneumoperitoneum and steep positioning.

Another advantage of robotic systems is that they simplify complex surgical maneuvers such as intracorporeal suturing and creation of intracorporeal anastomoses. Creation of the bowel anastomosis intracorporeally after colon resection may cause less visceral trauma and tissue stretching and might therefore contribute to faster recovery of bowel function and, consequently, reduced length of hospital stay.<sup>7-9</sup> In addition, after completion of an intracorporeal anastomosis, the specimen can be removed through a smaller or alternate site, which may reduce the risk of surgical site infections and incisional hernias.<sup>4,10</sup>

The Robotic Versus Laparoscopic Resection for Rectal Cancer (ROLARR) trial was the first multicenter, prospective, randomized controlled trial examining robotic surgery versus conventional laparoscopic surgery for the curative treatment of rectal cancer.<sup>11</sup> The trial was conducted from 2011 to 2014 and involved 40 surgeons from 29 sites in 10 countries, with 51.4% of the patients randomized by surgeons recruiting >20 patients. The median

numbers of procedures previously performed by each surgeon were 91 laparoscopic TMEs and 50 robotic TMEs. Of the total 471 patients, 237 were randomized to robotic resection and 234 were randomized to laparoscopic resection, with 466 patients ultimately undergoing surgery.

The conversion rate to open surgery (overall 10.1%) was 12.2% in the laparoscopic arm compared to 8.1% in the robotic arm (adjusted odds ratio [OR], 0.61;  $P = .16$ ). In multilevel logistic regression, significantly greater odds of conversion were noted in obese patients (adjusted OR, 4.69;  $P < .001$ ) and in men compared to women (adjusted OR, 2.44;  $P = .04$ ).<sup>11</sup> Operating surgeon experience had a mild-to-moderate effect on the odds of conversion based on the intraclass correlation coefficient estimate of 0.05, suggesting that most participating surgeons were experts in conventional laparoscopic surgery but still learning robotic surgery. The authors concluded that laparoscopic experience has a negligible influence on surgeons' gains in robotic skills over time. Surgeons who had completed approximately 28 robotic procedures had the same odds of conversion as laparoscopic surgeons with triple the case volume experience (91 cases), suggesting that fewer robotic cases are needed to achieve reliable results than are required to reach expert level in laparoscopy.

Secondary oncologic end points included circumferential resection margin (CRM) positivity (5.1% for robotic surgeries vs 6.2% in the laparoscopic arm) and odds of achieving the highest standard plane of surgery (mesorectal plane; no significant difference). Compared to the COLOR II, CLASICC, ALaCaRT, and ACOSOG Z6051 trials, however, the ROLARR trial had the lowest rates of CRM positivity. No significant difference was reported in 30-day complication rates (33.1% in robotic arm vs 31.7% in laparoscopic arm), including the anastomotic leak rate (12.2% in robotic arm vs 9.9% in laparoscopic arm), or in postoperative bladder and sexual function.

## **ROBOTIC RIGHT COLECTOMY TECHNIQUE**

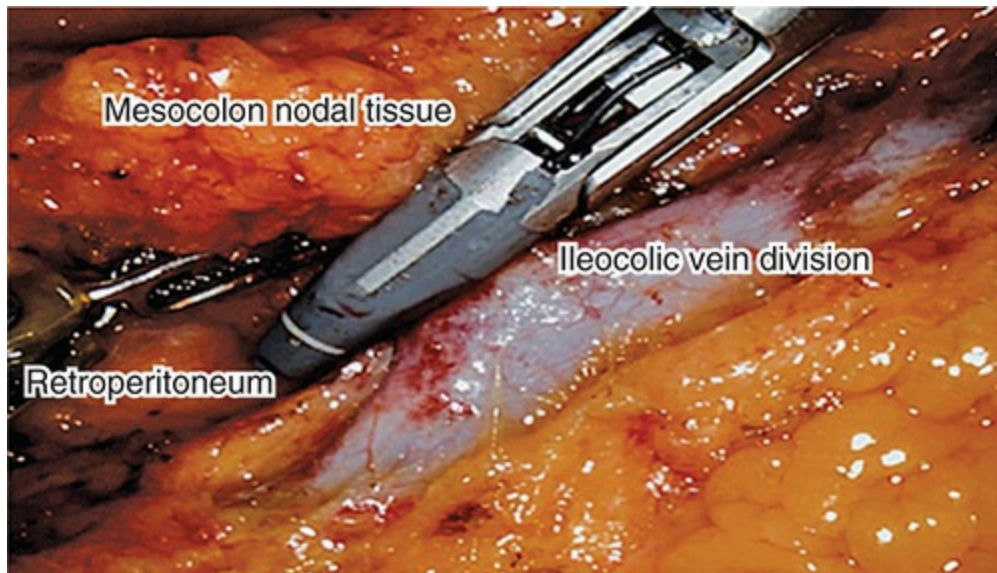

The patient is placed supine on the operating table. The arms are secured by the patient's side, pressure points are protected with padding, and the patient is confirmed to be secure on the table. A Veress needle inserted below the left subcostal margin in the midclavicular line is the preferred method of establishing pneumoperitoneum because it allows rapid access and is

appropriate for all patients. For extracorporeal anastomosis, an 8-mm robotic trocar is placed superior to the umbilicus. Three additional robotic 8-mm ports are placed: left upper quadrant, midline subumbilical, and right lower quadrant. An assistant port for pneumoperitoneum or AirSeal device is placed in the left lateral position (Fig. 51-1). The patient is then placed in a slight Trendelenburg position, with an 8- to 12-degree left-sided downward tilt. The peritoneal cavity is inspected for metastatic disease to confirm the feasibility of resection, and the omentum is then displaced cephalad to allow retraction of the small bowel into the left abdomen. The robotic cart is positioned on the same side as the pathology. The 0-degree robotic camera is inserted into the supraumbilical port, a monopolar scissor is inserted in the left upper quadrant port, a bipolar fenestrated grasper is inserted in the infraumbilical port, and a Cadiere is inserted in the right lower quadrant port.

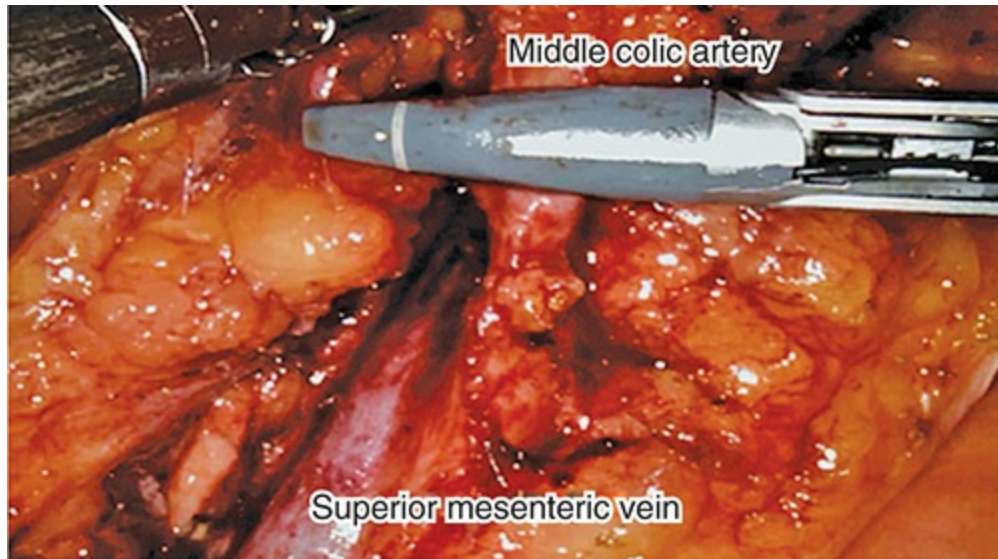

**FIGURE 51-1** Ports for robotic right colectomy.

We routinely perform medial-to-lateral dissection, beginning along the superior mesenteric vein to locate the origin of the ileocolic pedicles, consistent with the principles of complete mesocolic excision. In the right lower quadrant, arm 4 provides lateral and anterior traction to the cecum and terminal ileum to generate tension for lifting the ileocolic vessels. The retroperitoneum is incised along the path of the superior mesenteric vein, and all nodal tissue is cleared with the specimen. The ileocolic pedicle is identified, the retroperitoneal space immediately below the vessels is entered, and a retromesenteric dissection is developed. The duodenum and the head of the pancreas are displaced posteriorly, and the ileocolic artery and vein are ligated and divided using the vessel sealer at their origins (Fig. 51-2). The dissection continues cephalad along the superior mesenteric artery and vein to expose the middle colic vessels and gastrocolic trunk using an infracolic approach. The improved visualization, articulating instruments, and retraction of the robotic platform are particularly useful for ensuring dissection of all nodal disease at the base of the middle colic pedicle (for hepatic flexure or transverse colon lesions) or right branch of the middle colic pedicle (for cecal and ascending colon lesions) (Fig. 51-3).

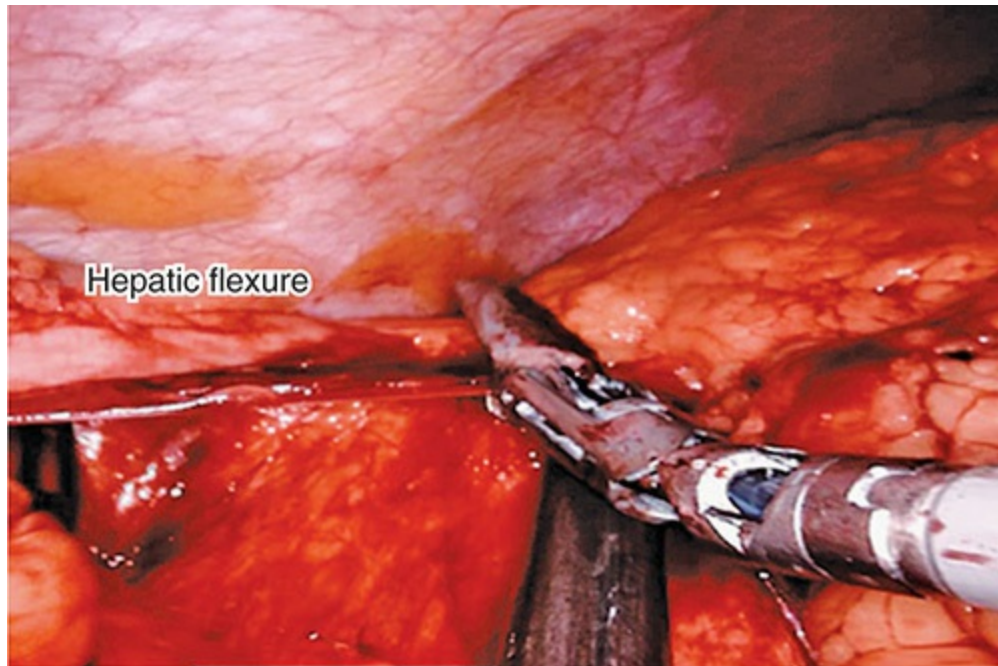

**FIGURE 51-2** Ileocolic vein division after retromesenteric dissection has been developed.

**FIGURE 51-3** Division of the middle colic artery using a vessel sealer.

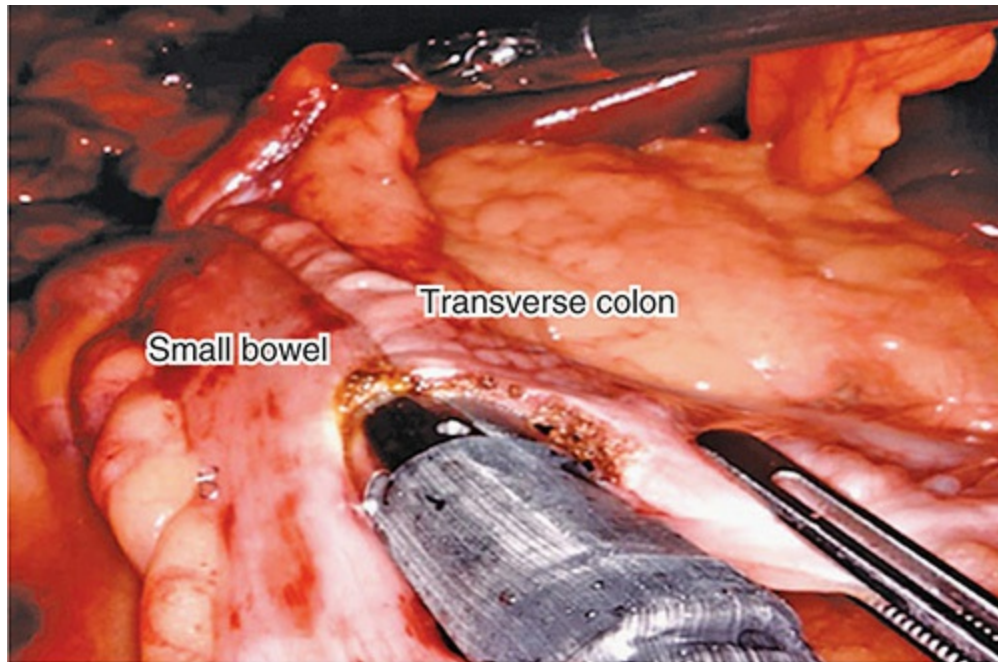

Dissection then continues both laterally and cephalad over the Gerota fascia toward the lateral congenital parietal attachments and underside of the hepatic flexure. The hepatic flexure is next addressed; the assistant retracts the transverse colon caudally using the right lower quadrant and subumbilical arms, and the surgeon dissects using the left upper quadrant arm (Fig. 51-4). The gastrocolic ligament is separated from the transverse colon, beginning at the falciform ligament, entering into the lesser sac, continuing proximally toward the hepatic flexure, and separating the omentum off the superior border of the proximal and mid transverse colon to facilitate later exteriorization.

**FIGURE 51-4** Dissection of the hepatic flexure.

For extracorporeal anastomosis, the mid and distal transverse colon should be mobilized to ensure sufficient laxity to allow exteriorization of the bowel. The mesentery of the terminal ileum is released from the retroperitoneum, and the congenital peritoneal attachments are incised while holding the inferior pole of the cecum and appendix, continuing dissection up the right paracolic gutter to complete the medialization of the right colon. The terminal ileal mesentery should be fully mobilized to the duodenum to ensure a tension-free anastomosis, often facilitated by increasing Trendelenburg positioning. The robot is undocked after a grasper has been placed on the ileocecal junction. The umbilical incision is lengthened to accommodate a wound retractor, and the colon is then delivered through the wound. The resection and anastomosis are completed in the usual fashion, and the colon is then returned into the abdomen.<sup>12,13</sup>

Intracorporeal anastomosis is especially preferred for patients with a high body mass index, shortened transverse colon mesentery, and transverse colon lesions, since transverse colon mobilization is not required and the specimen can be removed via a Pfannenstiel incision. The stapler is generally introduced via a mid-left lateral port, and the anastomosis is created isoperistaltically with suture closure of the common enterotomy/colotomy (Fig. 51-5).

**FIGURE 51-5** Intracorporeal isoperistaltic anastomosis between the terminal ileum and transverse colon.

## **ROBOTIC RECTAL TOTAL MESORECTAL EXCISION TECHNIQUE**

Rectal resections can be divided into 2 major stages: (1) an abdominal stage, which involves mobilization of the left colon and splenic flexure and division of both the inferior mesenteric artery (IMA) and the inferior mesenteric vein (IMV) and (2) a pelvic stage, during which rectal dissection and TME are performed.

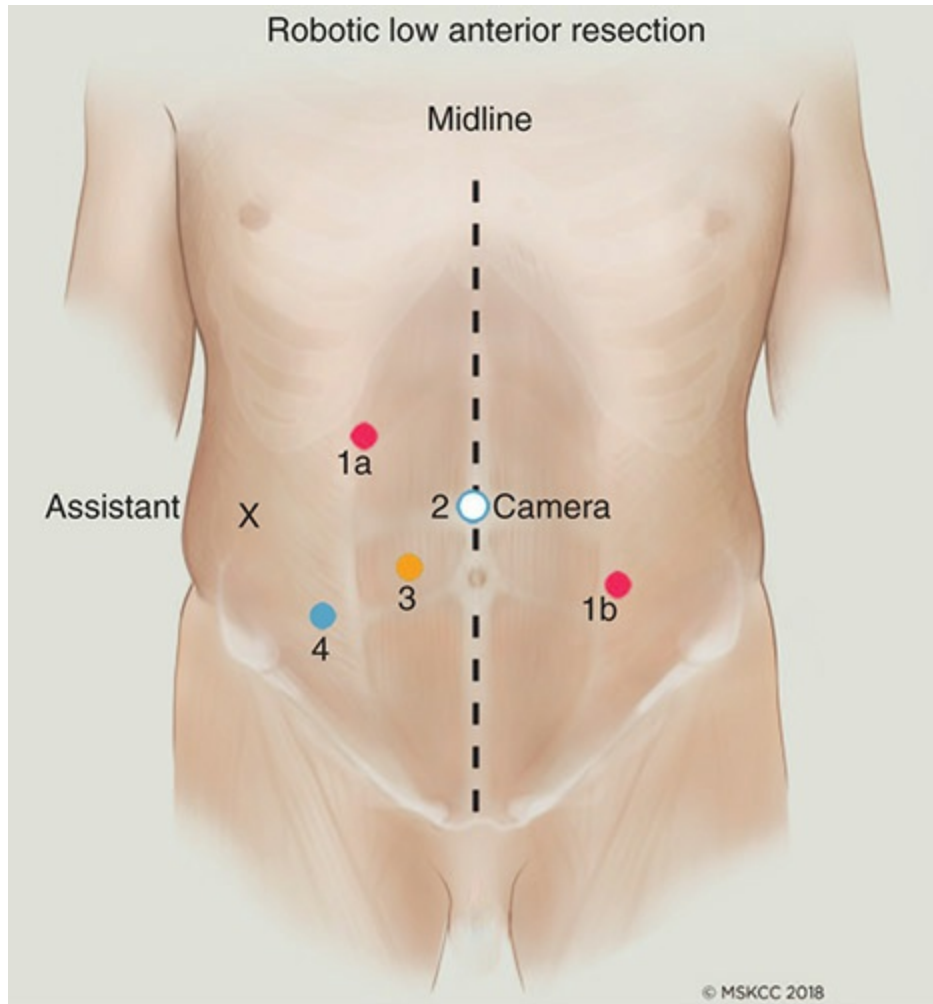

Dissection during the abdominal stage can be accomplished in a number of ways, including medial-to-lateral, lateral-to-medial, and IMV first. A medial-to-lateral approach allows easy visualization and control of the mesenteric vasculature early in the procedure, immediate delineation of the plane between the mesentery and the retroperitoneum, preservation of the autonomic nerves, early identification of the left ureter and other retroperitoneal structures, and quick access to the splenic flexure.

Certain steps in the robotic TME procedure described herein require particular attention to avoid complications. High ligation of the IMA and division of the IMV near the ligament of Treitz facilitate colonic

mobilization. Failure to complete these steps reduces the likelihood of properly connecting the colon to the lower rectum or proximal anal canal and increases the risk of constructing an anastomosis under tension. Vascular division should be performed after the left ureter is clearly identified, as this structure travels lateral to and in very close proximity to the IMA. Avoiding damage to autonomic nerves requires special attention in the following anatomic areas: (1) the superior hypogastric plexus during dissection of the IMA; (2) the hypogastric nerves at the sacral promontory during entry into the retrorectal space; (3) the pelvic plexus during lateral mobilization of the rectum; and (4) below the peritoneal reflection during anterior dissection of the rectum.

The patient is placed in the modified lithotomy position, with the buttocks slightly over the end of the table. The thighs are abducted and aligned with the contralateral shoulder. The hips, particularly on the left side, should be fully extended, and the knees should be flexed at 45 degrees so that the legs are not in the way when the robot is docked at the left hip. Both legs should be gently rotated internally to avoid lateral pressure on the peroneal nerve. The patient's arms are placed alongside the body to lessen the possibility of shoulder injury and to provide sufficient space for the surgeon and assistant as well as the robotic platform. Pressure points and bony prominences are padded, and the body is secured to the operating table. Before proceeding, the patient's secure positioning is confirmed by testing the table in the Trendelenburg position and in a left-sided tilt.

After insufflation via Veress needle placed below the left costal margin in the midclavicular line, the camera port is placed just above the umbilicus, and 8-mm ports are placed in the right upper quadrant, right lower quadrant, and left mid abdomen. A 12-mm trocar is placed roughly halfway between the umbilicus and right anterior superior iliac spine, which corresponds to the midclavicular line, and often can be used as an aperture for a diverting loop ileostomy. An accessory port is also placed lateral in the right mid abdomen (Fig. 51-6).

**FIGURE 51-6** Port placement for robotic low anterior resection. For pedicle ligation and splenic flexure, mobilization ports 1a, 2, and 3 are used. For pelvic dissection, ports 1b, 2, and 3 are used.

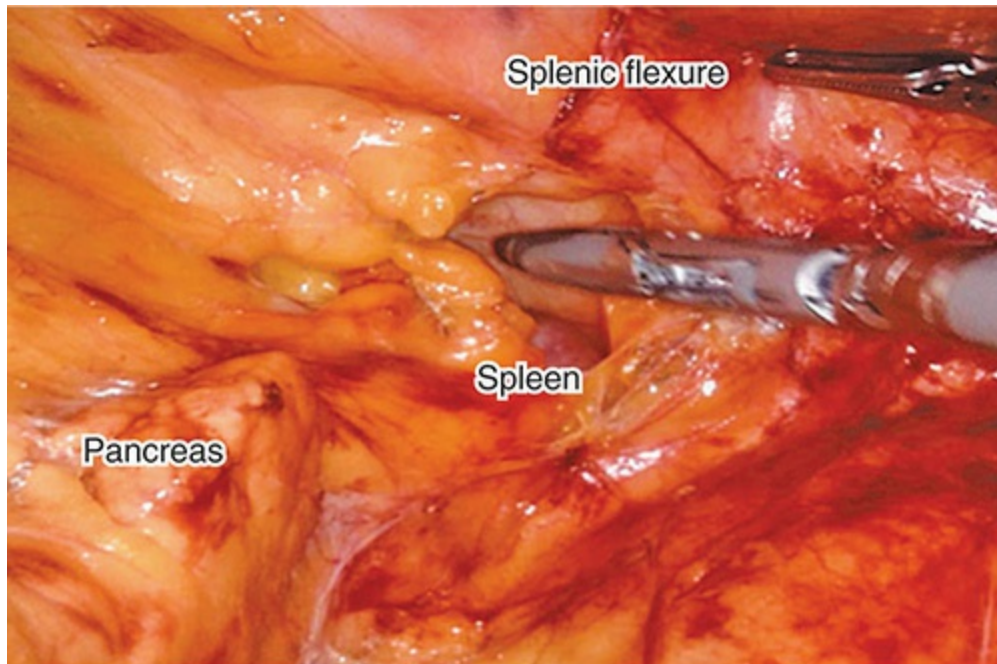

For pedicle ligation and splenic flexure mobilization, the right-side ports are used (see Fig. 51-6), with the patient in a slight Trendelenburg position with a 12- to 15-degree tilt. The small bowel is swept laterally, and the omentum is placed over the liver, exposing the IMA and IMV. A bipolar fenestrated grasper is used in the left upper quadrant port, the monopolar scissor is used in the left lower abdominal port, and the Cadere grasper is used in the lowest left quadrant port. With the Cadere holding tension on the sigmoid mesentery, the peritoneum at the sacral promontory is incised, the autonomic nerve is swept into the retroperitoneum, and the IMA is identified. In a medial-to-lateral dissection, the sigmoid mesentery is dissected off the retroperitoneum in an avascular plane. After identification of the gonadal

vessels laterally, the ureter medially, and the IMV at the ligament of Treitz and just inferior to the pancreas (Fig. 51-7), the left colon is mobilized off the retroperitoneum medially to laterally in an avascular plane. The IMV is divided using the vessel sealer via the left midabdominal port.

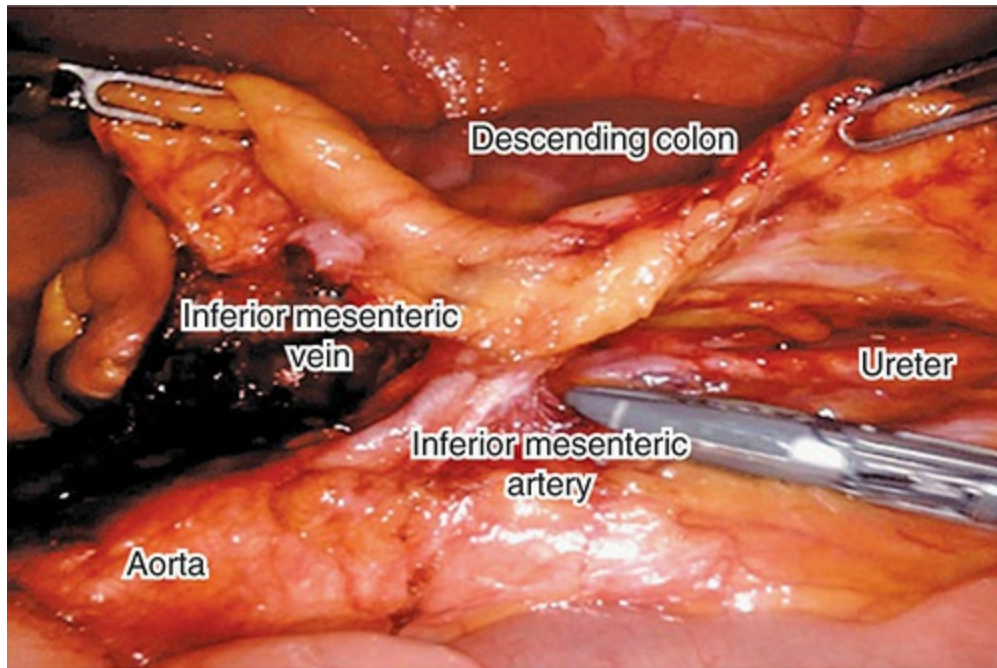

**FIGURE 51-7** Dissection of the inferior mesenteric vein adjacent to ligament of Treitz and inferior to pancreas.

The splenic flexure is then mobilized by further elevating the left colon mesentery off the retroperitoneum and then off the pancreas with entry into the lesser sac. Next, the omentum is dissected off the distal transverse colon, and the left colon lateral wall attachments are divided along with the remaining retroperitoneal attachments of the splenic flexure of the colon (Fig. 51-8).

**FIGURE 51-8** Medial-to-lateral dissection revealing the pancreas, prior to visualization of the spleen. The splenic flexure of the colon is being gently retracted by the grasper.

After the IMV is divided and the left colon is mobilized, the IMA should take on the characteristic T-shaped structure, branching into the cranial left colic artery and caudal superior hemorrhoidal artery (Fig. 51-9). The position of the ureter and gonadal vessels in the retroperitoneal plane is reconfirmed, and the IMA is ligated and divided using the same implement as for the IMV. Because the left ureter travels just lateral to the IMA, the dissection must be adequate to avoid injuring it when attempting to divide the IMA. The medial-to-lateral dissection continues toward the abdominal wall using a blunt dissection to gain entry into the previously developed avascular plane beneath the IMV and advance toward the sacral promontory. As the gonadal vessels and the ureter are encountered, they should be dissected posteriorly toward the retroperitoneum. Visualization of the psoas muscle usually indicates that the dissection is too deep and in the wrong plane.

**FIGURE 51-9** Inferior mesenteric artery (note characteristic T-shaped structure) after division of the inferior mesenteric vein. The ureter and gonadal vessels are visible prior to artery division.

Following division of both the IMA and the IMV, the lateral attachments of the sigmoid and descending colon are divided. These include the line of Toldt, which is divided using monopolar cautery. This dissection, starting at the left lower quadrant, is facilitated by retracting the colon medially and anteriorly. Division of the line of Toldt reveals the medial dissection plane; as dissection progresses toward the left upper quadrant, any omental attachments to the colon should be divided, leaving attachments between the omentum and the abdominal wall in place, unless visualization is impaired.

The entire left colon should now be medialized and mobilized so that attention can be directed at the proposed site of mesenteric ligation and colon transection for future anastomoses. The mesentery of the descending colon is then divided from the stump of the IMA toward the colon to the point of the future division of the bowel, usually at the junction of the descending and sigmoid colon. The mesentery should be divided using an energy source or several firings of a vascular stapler. Dividing the marginal artery at this time avoids tearing vessels during extraction.

After colonic mobilization, pelvic dissection can begin. The robotic arms are detached from the trocars, and the patient is leveled and placed in a

significant Trendelenburg position to keep the small intestines out of the pelvis. The robotic system should be redocked at the patient's left hip, permitting access to the anus and perineum (see Fig. 51-6). As the assistant elevates the rectosigmoid junction (or grasps the divided mesenteric pedicle of the superior rectal artery), dissection begins posteriorly at the sacral promontory, entering the avascular plane between the visceral and parietal layers of the endopelvic fascia.<sup>14</sup>

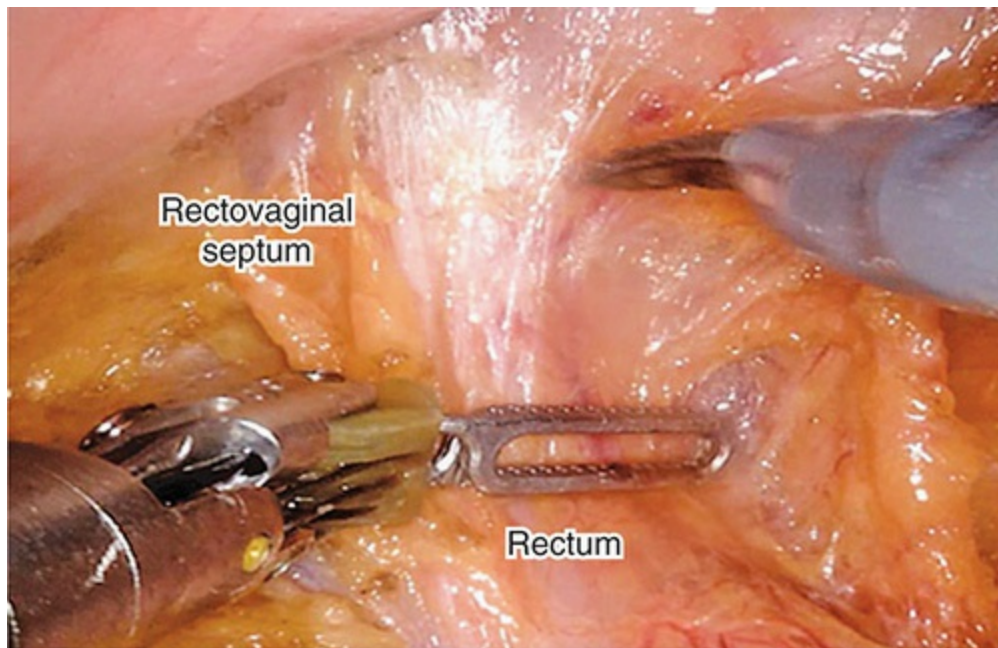

At the beginning of dissection, the hypogastric nerves should remain in the retroperitoneum (Fig. 51-10). As dissection continues distally, the surgeon must keep in mind that the rectum curves upward and anteriorly as the anorectal junction is approached. Just above the levator ani muscles, the endopelvic fascia fuses with the mesorectal fascia. To avoid bleeding and injury to the fascia, the dissection uses monopolar cautery and smooth maneuvers, and the mesorectum is manipulated using a gauze tie rather than robotic graspers. The TME proceeds along the areolar plane down to the rectococcygeal ligament.

**FIGURE 51-10** Posterior mesorectal excision and right lateral dissection.

Anteriorly, the peritoneal reflection is incised, and the dissection is continued along the rectovaginal septum in women or over the rectovesical or rectal prostatic fascia (Denonvilliers fascia) in men (Fig. 51-11). Arm 3 is used to retract the bladder and other anterior structures as dissection proceeds

distally. The articulation of the robotic scissor tips enables the surgeon to perform the dissection using ideal approach angles: as distally as possible in the posterior plane, which facilitates identification of the lateral stalks and dissection in the anterolateral areas. In most cases, the surgeon alternates between the posterior, lateral, and anterior planes to achieve complete circumferential dissection.

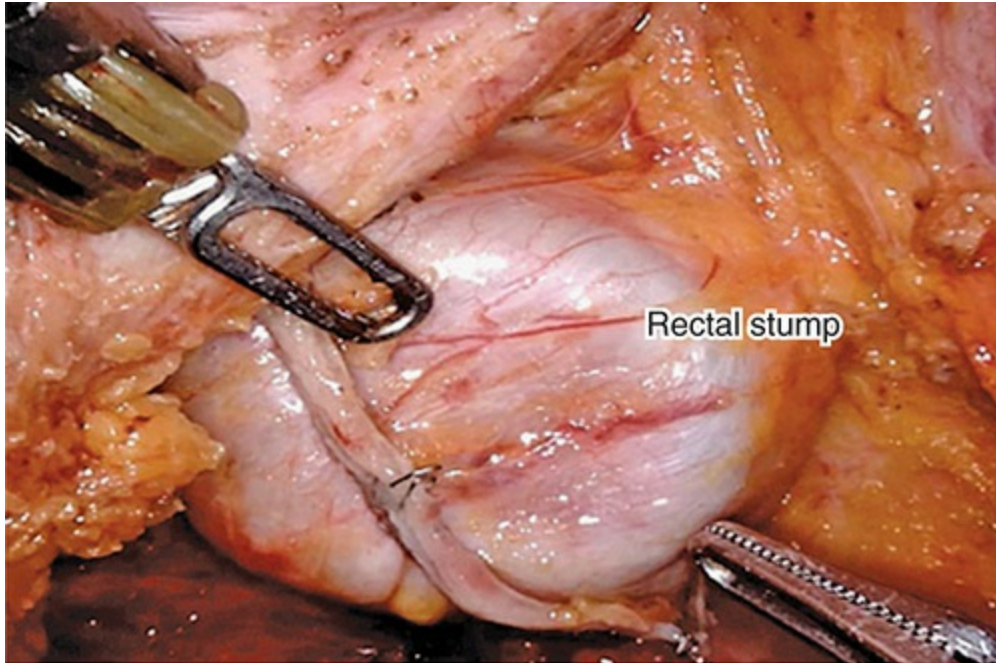

**FIGURE 51-11** After the peritoneal plane is incised, dissection should continue along the rectovaginal septum in women or rectovesical fascia in men.

Laterally, dissection proceeds along the sidewalls medial to both ureters, contouring along the curving mesorectal plane. Injury to the autonomic plexus and generation of excess medial traction on the sidewall, which jeopardize transection of the nervi erigentes, should be avoided. As the lateral stalks are divided, care should be taken to preserve the hypogastric plexus and the pelvic sidewall, lateral to the seminal vesicles in men and the cardinal ligaments in women. The lateral stalks are controlled with bipolar cautery or monopolar cautery using the scissors and divided.

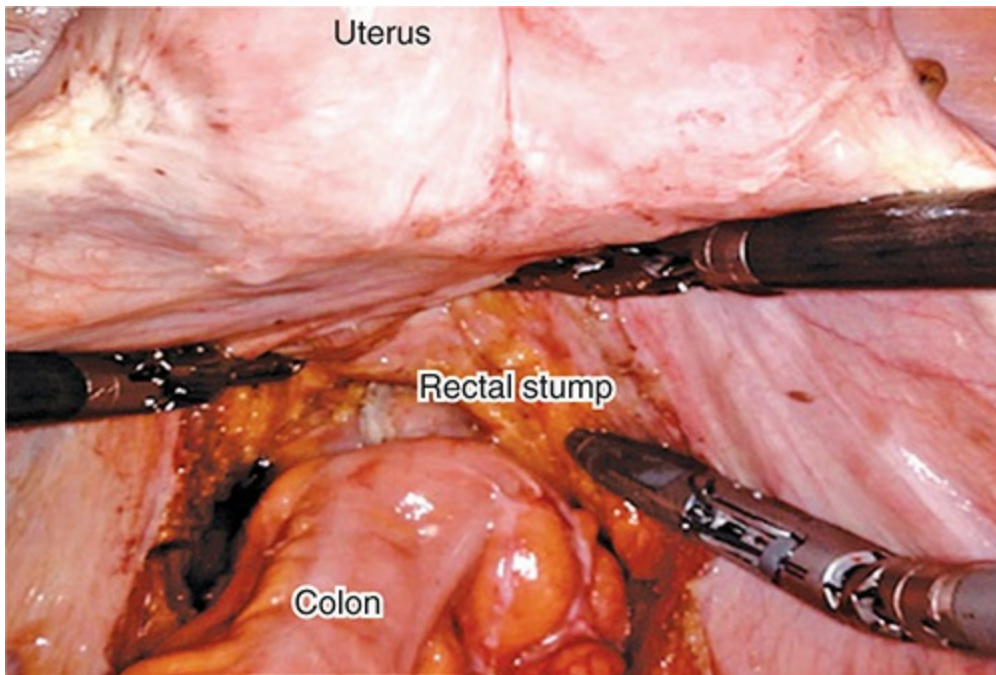

Anteriorly, the peritoneum between the rectum and seminal vesicles or upper vagina is dissected under direct vision by simultaneous retraction of the anterior structures toward the pubis, and the rectum toward the sacrum. During this dissection, the planes are less distinct, and the fat on the anterior

mesorectum can be thin, so the anterior pelvic structures are elevated off the anterior rectal wall. The dissection continues through Denonvilliers fascia, which is separated from the anterior structures and kept with the specimen. The distal point of this dissection matches that of bowel transection, which depends on the level of the tumor. Middle and distal rectal tumors require removal of the entire mesorectum, while an upper rectal tumor requires transection of the rectum and mesorectum 5 cm below the level of the tumor.<sup>15</sup>

Dissection continues down to the pelvic floor, separating the fatty mesorectum from the levator muscle. The rectum is lifted off the muscle and cleared circumferentially for transection. This mobilization of the rectum increases the distance of the tumor from the dentate line, allowing an adequate distal margin and preservation of the sphincters. Continuing dissection further down allows the surgeon to access the intersphincteric plane if necessary for ultralow anterior resection with intersphincteric dissection. In preparation for rectal division, the rectum is examined digitally and by flexible endoscopy to ascertain the level of the tumor. Using the 12-mm trocar port, a 45-mm robotic stapler is used to divide the rectum, after which the robotic cart can be undocked. We routinely extract the specimen through a 3- to 4-cm supraumbilical right lower quadrant (site of future diverting ileostomy) or suprapubic Pfannenstiel incision covered with a wound protector. The proximal bowel is divided, and an anvil is secured to the proximal colon with a purse-string suture. The descending colon conduit is returned to the peritoneal cavity, and the wound protector is twisted to occlude the wound so that pneumoperitoneum can be reestablished. The circular stapler is introduced through the anus, and an end-to-end anastomosis is constructed under robotic vision (Figs 51-12 and 51-13).

**FIGURE 51-12** After rectal stapling, the circular stapler is passed per anus to the stapled end of the rectum.

**FIGURE 51-13** End-to-end intracorporeal stapled anastomosis between the descending colon and the rectal stump, with complete exposition of the pelvic space. The uterus can be retracted using a stitch.

## CONCLUSION

Robotic surgery was developed to overcome the limitations of conventional laparoscopy and to help surgeons perform complex procedures. This technique has demonstrated a range of advantages that could change the way we approach colorectal cancer.

## ACKNOWLEDGMENTS

## **RECTUM AND ANUS**

# **BENIGN DISORDERS OF THE ANORECTUM (PELVIC FLOOR, FISSURES, HEMORRHOIDS, AND FISTULAS)**

James W. Fleshman, Jr. • Anne Y. Lin

Benign diseases of the anorectum range from relatively simple disorders such as hemorrhoids and fissures to extremely complex problems associated with pelvic floor abnormalities.

## **ANATOMY**

The rectum normally lies attached to its mesorectum within the curve of the sacrum, with limited mobility. The junction of the rectosigmoid is usually fixed by the inferior mesenteric artery and peritoneal attachments. The rectum and mesorectum (fat and vessels) follow the curve of the sacrum to the pelvic floor. The rectum exits the pelvis behind the prostate or vagina through a slit in the pelvic floor. The horseshoe-shaped puborectalis muscle

circles from its origin on the pubis around behind the rectum and reinserts on the pubis anteriorly. Contraction of the muscle pulls the rectum forward, creating a more acute angle at the palpable anal-rectal ring. The anal canal is a 3- to 4-cm long funnel-shaped extension of the pelvic floor voluntary musculature called the external sphincter. The pressure generated by contracting this circular muscle prevents egress of rectal contents. The internal sphincter muscle is a thickened continuation of the circular muscle of the rectal wall. As such, it is an autonomic muscle and has no voluntary control. It is innervated by a local plexus of nerves that connects the stretch receptors of the rectal wall to the internal anal sphincter as a sampling reflex (anal inhibitory reflex) which produces relaxation as the rectum fills.

The anorectum receives both sympathetic and parasympathetic nerves. The sympathetic nerves originate from thoracolumbar segments and unite below the inferior mesenteric artery to form the inferior mesenteric plexus. Injury to these nerves results in retrograde ejaculation and infertility in men. These fibers then descend to the superior hypogastric plexus located on the sacral promontory just inferior to the aortic bifurcation. These purely sympathetic fibers bifurcate and descend as the hypogastric nerves. Parasympathetic fibers from S2, S3, and S4 (the *nervi erigentes*) join the hypogastric nerves in the side wall of the low pelvis, anterolateral to the rectum, to form the inferior hypogastric plexuses. Mixed fibers from the plexuses innervate the prostate, rectum, bladder, penis, and internal anal sphincter. These autonomic plexuses of the pelvic nerves run around the lateral aspect of the pelvic rim to enter the prostate and seminal vesicles anteriorly. The sympathetic innervation of the internal sphincter is motor, while the parasympathetic innervation is inhibitory. Injury to the pelvic autonomic nerves during pelvic surgery may result in urinary retention or erectile dysfunction.

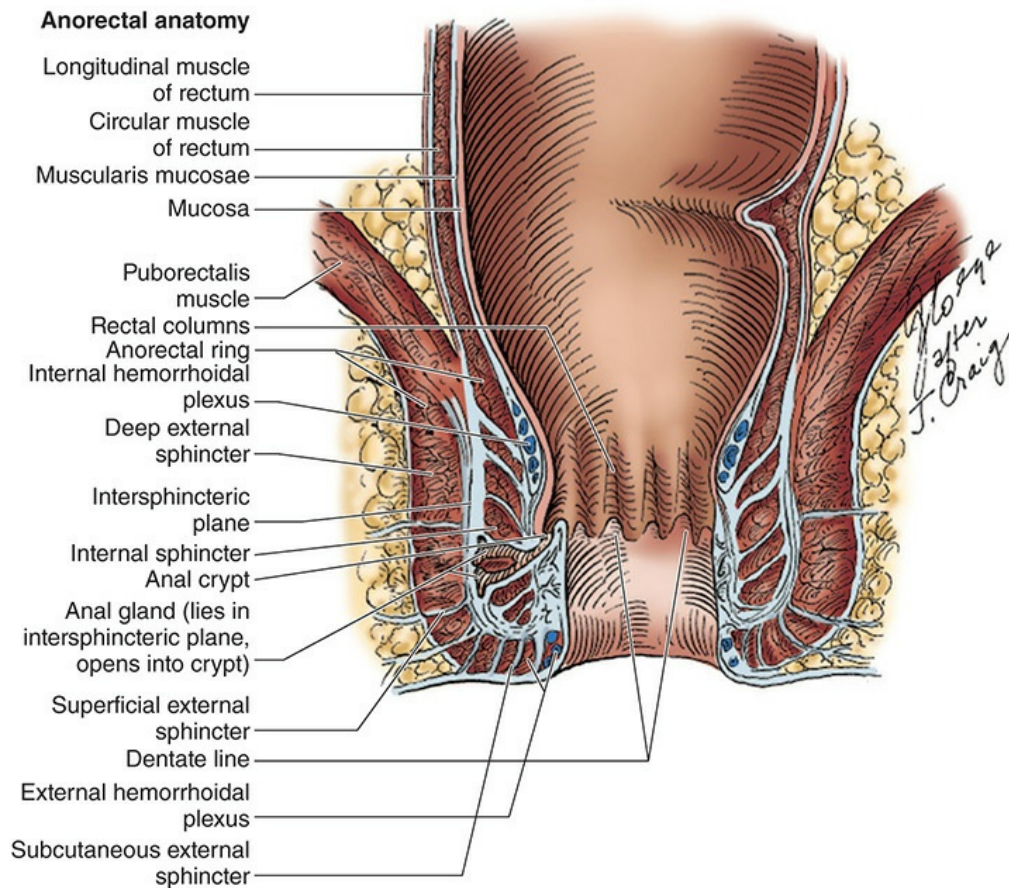

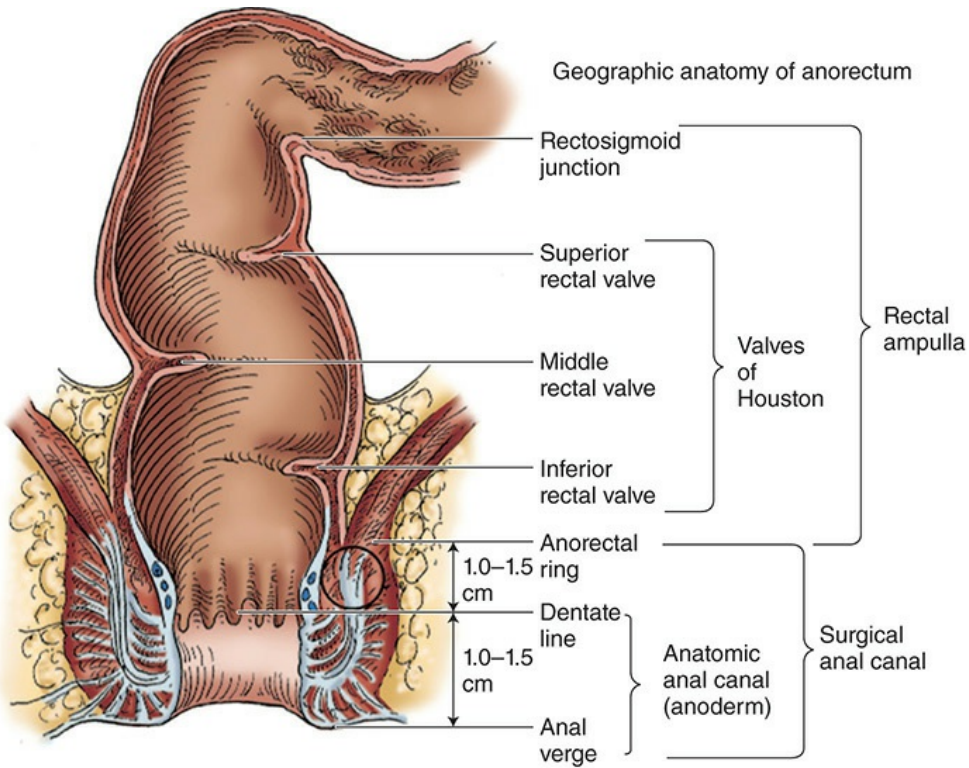

The innervation of the voluntary muscles of the pelvic floor is via direct fibers from S2, S3, and S4 in the pelvis from the sacrum (Fig. 52-1). The motor and sensory nerves of the external sphincter are derived from S2, S3, and S4 nerve roots from the sacral plexus and they arrive at the external sphincter via the pudendal nerve around the ischial spine at Alcock's canal. The vagina is closely approximated to the anterior surface of the rectum and anal canal and separated from the rectum by the embryologic potential space known as Denonvilliers' fascia. Dissection posterior to Denonvilliers' fascia in a male protects the *nervi erigentes* on the posterior surface of the prostate

from injury and preserves erectile function.

**FIGURE 52-1** Diagram of the pudendal nerve. Note the five regions in which it runs and the three divisions into which it divides. (Reproduced with permission from Anderson JE: *Grant's Atlas of Anatomy*, 8th ed. Baltimore, MD: Williams & Wilkins; 1983.)

It is useful to consider the anus and surrounding structures as a single unit: the anorectum (Fig. 52-2). The anorectum includes the perianal skin, the anal canal, the anal sphincters, and the distal rectum. The three main anatomic points of reference are the anal verge, the dentate line, and the anorectal ring. The distal external boundary of the surgical anal canal is the anal verge, which is the palpable intersphincteric groove between the lowest fibers of the internal and external sphincter. At this point the anal epithelium (anoderm) is devoid of hair follicles, sebaceous glands, and apocrine glands that are present in the perianal skin.

**FIGURE 52-2** Anatomy of the anus and rectum: geographic anatomy of the anorectum and anorectal anatomy.

The cephalad border of the anatomic anal canal is a mucocutaneous junction, the dentate line, and a zone of transitional cuboidal cells. This union of the embryonic ectoderm with the endodermal gut resides approximately 1.0 to 1.5 cm above the anal verge. The anal transitional zone (ATZ) is 6 to 12 mm in length and the columnar epithelium of the rectum changes to cuboidal epithelium that joins the squamous epithelium at the dentate line.

The upper border of the surgical anal sphincteric complex is the anorectal ring. It may be palpated by digital examination about 1.0 to 1.5 cm above the dentate line. The anatomic anal canal begins at the dentate line and ends at the anal verge. The surgical anal canal starts at the anorectal ring and terminates at the anal verge. This latter definition of the anal canal is used throughout this chapter.

Just above the dentate line, the rectal mucosa forms 8 to 14 longitudinal folds known as the *rectal columns*. Between each two columns at the dentate line is a small pocket termed an *anal crypt*. Small, rudimentary secretory anal glands open into some, but not all, of these anal crypts. The ducts of the glands extend through the internal sphincter as far as the intersphincteric plane, where the glandular tissue resides.

Below the dentate line, cutaneous sensations of heat, cold, touch, and pain are conveyed by afferent fibers in the inferior rectal nerves. Cephalad to the dentate line, visceral sensitivity to vibration or when the mucosa is pinched, such as when internal hemorrhoids are ligated, are carried by parasympathetic fibers. These fibers participate in the sampling reflex in the continence complex.

The superior rectal artery, the terminal branch of the inferior mesenteric artery, descends to the upper rectum where it divides into lateral branches. Subsequent smaller divisions penetrate the rectal wall. The middle rectal arteries arise from the internal iliac arteries and supply the distal rectum and upper anal canal. The inferior rectal arteries, branches from the internal pudendal arteries, cross the ischiorectal fossae to supply the anal sphincters and the distal rectum (Fig. 52-3). The collateralization between these three sources provides the rectum with an impressive resistance to ischemia.

**FIGURE 52-3** Vascular supply of the anus and rectum. Blood returns from

the anus via two routes. Below the dentate line, the external hemorrhoidal plexus drains into the inferior vena cava via inferior pudendal veins. Above the dentate line, the internal hemorrhoidal plexus drains into the portal system via the superior rectal vein.

There are two paths for venous blood return from the anorectum. Above the dentate line, venous blood flows into the portal system through the superior rectal vein and inferior mesenteric vein. Below the dentate line, the external hemorrhoidal plexus drains into the internal iliac vein via the middle rectal vein or via the pudendal vein, which receives blood from the inferior rectal vein. This can become a source of venous collateralization when portal vein flow is compromised.

## FECAL INCONTINENCE

### Pathophysiology

Injury to the anal sphincter complex and the resulting anal incontinence is usually due to obstetric injury, trauma, or fistula disease in which the external muscle is divided or damaged ([Table 52-1](#)). Neurogenic incontinence is due to stretching of the pudendal nerves during prolonged labor, chronic descent of the perineum and nerve stretch during straining at stool or rectal prolapse, or systemic disease such as multiple sclerosis, scleroderma, or spinal cord injury. Idiopathic incontinence is due to medical disease such as diarrhea in a patient with limited rectal capacity, irritable bowel syndrome, or sedatives that cause poor sensation in the anal canal in patients with no evidence of neurogenic or mechanical incontinence. The subject of anal incontinence is covered in [Chapter 53](#).

**TABLE 52-1: FECAL INCONTINENCE ETIOLOGY**

Mechanical	Neurogenic	Idiopathic
Obstetric injury	Pudendal nerve stretch	No clear etiology
Fistula disease	Strain	Medical illness
Trauma	Prolonged labor	Irradiation
Iatrogenic	Trauma	Irritable bowel syndrome
Systemic disease		Multiple sclerosis, diabetes mellitus, scleroderma
Diarrheal states		

The rectum normally holds between 200 and 250 mL. It distends readily with filling and has limited muscular activity intrinsically. The internal anal sphincter provides 80% of the resting anal sphincter pressure that provides the resistance to gas and mucus at the anal canal. The sampling reflex is a function of rectal distension causing internal anal sphincter relaxation via an intramural reflex to the internal sphincter. The rectal contents can then be sensed in the sensory nerve-rich transitional zone and anoderm to discriminate the true nature of the rectal contents. This sampling reflex occurs frequently throughout the day to provide continence and also serves to initiate the defecation process. The voluntary external sphincter muscle contraction in response to this sampling reflex provides the final active component of fecal continence. The subconscious voluntary contraction of the external sphincter, puborectalis, and pelvic floor muscles provide complete control of rectal contents. The pelvic floor muscles maintain continual activity, even during sleep, to provide fecal continence. This also seems to be a learned response because infants and children require 1 to 2 years to achieve control.

## RECTAL PROLAPSE AND INTERNAL INTUSSUSCEPTION

### Pathophysiology

The true etiology of rectal prolapse and intussusception is unknown. The mechanism is influenced by three components: (1) The rectum and

rectosigmoid junction have increased mobility off the sacrum; (2) descent of the rectosigmoid junction into the pelvis allows a funnel-shaped intussusception into the rectum as the rectum attempts to expel itself; and (3) poor relaxation of the pelvic floor and external sphincter mechanism occurs during straining (Fig. 52-4). Persistent straining against this outlet obstruction may lead to descent of the perineum, expulsion of the rectum, and true rectal prolapse. This sequence of events from progression of internal intussusception (funnel formation) to full rectal prolapse is supported anecdotally. Consequences of rectal prolapse include anal canal injury from stretch of the internal sphincter during rectal prolapse and/or injury to the pudendal nerve during descent of the perineum. The classic defecographic picture of rectal prolapse and severe intussusception is a funnel that descends into the deep pelvis as the rectosigmoid junction descends. A ball valve obstruction occurs at the level of the anal canal before it is pushed through to the outside.

**FIGURE 52-4** Rectum with internal intussusception. (Reproduced with permission

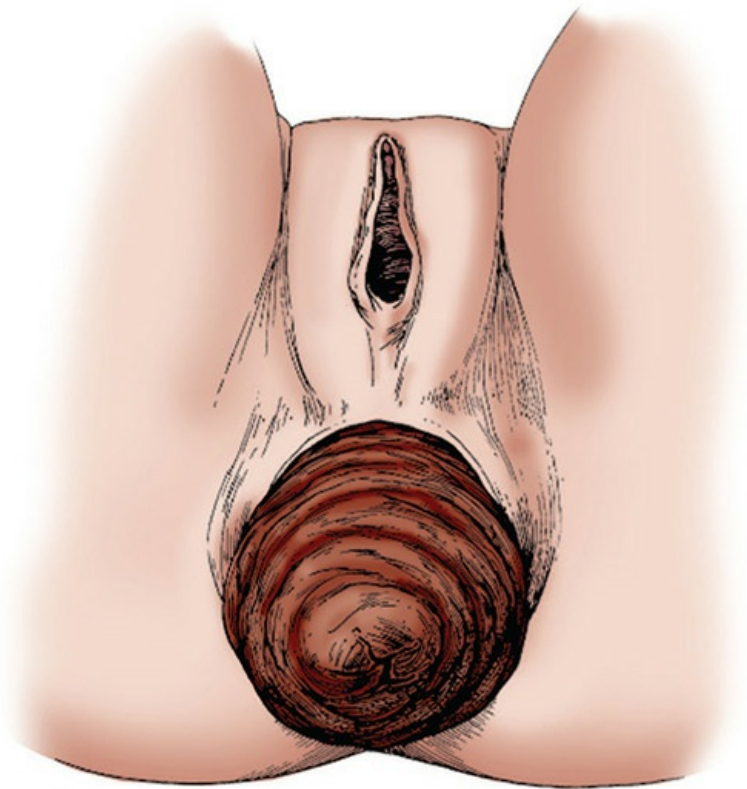

from Hoffman MJ, Kodner IJ, Fry RD: Internal intussusception of the rectum: diagnosis and surgical management, *Dis Colon Rectum* 1984 Jul;27(7):435-441.)

A distal mucosal prolapse is occasionally mistaken for full rectal prolapse. The typical appearance of a mucosal prolapse is that of mucosa separated by radial lines around the anus (Fig. 52-5A). Concentric rings of mucosa are seen in true rectal prolapse (Fig. 52-5B). Defecography is helpful to distinguish between these two entities.

A

B

**FIGURE 52-5** **A.** Radial folds of mucosal prolapse. **B.** Concentric rings of full-thickness rectal prolapse.

## Diagnosis and Evaluation

Signs and symptoms of rectal prolapse include rectal pressure and pain, incomplete evacuation, outlet obstruction, and constipation causing prolonged straining. Mucus discharge and bleeding from the fully prolapsed tissue may also be present. Examination most often reveals concentric rings of rectal tissue with a patulous anal canal, poor voluntary tone, and a very mobile rectum within the vault. Proctosigmoidoscopy reveals descent of tissue during straining and occasionally an ulcer on the anterior wall (caused by ischemia at the lead point of the intussusception). Defecography reveals extreme mobility of the rectum from its point of fixation to the sacrum, redundancy of the mesorectum, and funnel formation as the rectum prepares to descend through the anal canal opening at the pelvic floor. Defecography is most useful in cases that cannot be visualized in an office setting.

Thickened barium simulates stool and cinedefecography allows visualization of the defecating process; this is particularly helpful in cases in which mucosal prolapse is suspected and the intent is to rule out full rectal prolapse. Four-contrast cinedefecography (rectum, vagina, and small bowel and bladder as needed) also helps delineate complex pelvic floor abnormalities. This technique is gradually being replaced, or at least supplemented, by dynamic MRI of the pelvic floor.

A grading system of intussusception has been developed to assist in planning management ([Table 52-2](#)). Mild to moderate intussusception with some mobility, some funnel formation, and descent of the rectum can usually be treated conservatively with biofeedback for poor relaxation of the pelvic floor and high doses of bulk fiber to fill the rectum and limit intussusception. However, grade 4 intussusception with severe outlet obstruction may require operative resection of the redundant rectum or rectopexy to secure the rectum to the sacrum.<sup>1</sup> The most appropriate setting for operative treatment of internal intussusception is the patient who has developed moderate incontinence from the intussusception and straining or the patient who has severe bleeding from the solitary rectal ulcer at the tip of the funnel.

**TABLE 52-2: DEFECOGRAPHY GRADING SYSTEM<sup>a</sup>**

Grade	Description
N	Rectum remains fixed to sacrum, sphincter relaxes, and rectum empties
1	Nonrelaxation of puborectalis
2	Mild intussusception or mobility from sacrum
3	Moderate intussusceptions
4	Severe intussusceptions
5	Prolapse
R	Rectocele

<sup>a</sup> Lateral view on videofluoroscopy unit of patient in sitting position, passing thickened barium.

Anal manometry can be useful to document the preoperative function of the sphincter if there is not an obvious patulous anal canal on examination. Electromyography can provide objective evidence of pudendal nerve injury (pudendal nerve terminal motor latency [PNTML] >2.0 msec/cm) and allow some prediction of continued recovery after repair.

## Management

**Rectal Prolapse.** Numerous techniques exist for management of rectal prolapse; over 100 procedures have been described. The four basic types of procedure include rectopexy, low anterior resection, perineal proctectomy, and anal encirclement.<sup>2</sup>

The low anterior resection technique uses the standard technique for removal of the middle and upper portions of the rectum and redundant sigmoid colon. The left colon is reattached to the upper or middle third of the rectum by using either a double-staple or hand-sewn technique (Fig. 52-6). The rectum is mobilized to the level of the pelvic floor circumferentially, but preserving the anterolateral ligaments carrying the middle rectal arteries and splanchnic nerves. The left colon and rectum (now in continuity) are returned

to the curve of the sacrum and the peritoneal flaps sutured to the sacrum to keep the rectum on stretch. The incidence of fecal incontinence may be higher after this procedure because the rectal capacitance is reduced. Postoperative evacuation difficulties may be noted if the nerves within the anterolateral ligaments have been divided. Preoperative anal physiological testing may assist in the selection of patients who are candidates for low anterior resection (ie, no evidence of sphincter injury or dysfunction).

**FIGURE 52-6** Laparoscopic low anterior resection with colorectal anastomosis—double-staple technique. **A.** Laparoscopic positioning of the patient and surgeon. The patient is secured to the table in modified lithotomy

position. The operating surgeon stands to the right of the patient. Trocar placement is based on use of hand-assisting devices and surgeon preference. **B.** Lateral approach to mobilization of the sigmoid colon and identification of the left ureter. **C.** Laparoscopic mobilization and dissection of the rectum down to the lateral ligaments. **D.** Intracorporeal colorectal anastomosis: a descending colon purse-string suture is tied around the shaft of the anvil. This can also be performed extracorporeally with a hand-assisting device or via a small incision. **E.** Completed anastomosis with stapler still in place.

Suture rectopexy, accomplished by mobilizing the rectum posteriorly to the pelvic floor and placing sutures to the sacrum through the redundant peritoneal attachments to fix the rectum in a straight line to the pelvic floor, results in low recurrence rates in well-selected patients. Laparoscopic suture rectopexy is the method of choice in most hospitals and is associated with fewer complications and a shorter hospital stay.<sup>3,4</sup> The technique of anterior Prolene mesh rectopexy, described by D'Hoore, mobilizes the anterior rectum to the anal canal and suspends the rectum with mesh attached to the sacral promontory. Sutures attach the mesh to the anterior rectum at the level of the rectovaginal septum. The redundant cul-de-sac is excised and the peritoneum is closed over the mesh along its path<sup>5</sup> on the right side of the rectum to the sacral promontory.<sup>6</sup> Results suggest rapid recovery, good control of prolapse, reduction of constipation, and limited morbidity.

A perineal proctectomy with anterior and posterior reefing of the sphincter muscle to restore the pelvic floor opening to its original size can be used in the elderly patient with full rectal prolapse and incontinence. The entire prolapsing rectum and redundant sigmoid are removed through a perineal approach beginning at the top of the transitional zone columns (Fig. 52-7). The left colon or proximal sigmoid is sutured to the transitional zone 1 to 2 cm above the dentate line. The external anal sphincter and pelvic floor muscles can be reefed in the anterior and posterior midline to restore anal tone in patients with incontinence, as described by Prasad et al.<sup>7</sup> The incidence of recurrent prolapse is approximately 10% in patients with good sphincter function. It actually carries a higher risk of complication than laparoscopic rectopexy and has slowly been replaced, even in the highest risk elderly patients, by the laparoscopic or robotic approach.<sup>8</sup> This procedure is not technically possible in patients who have mucosal prolapse alone or patients with high rectal prolapse and an intact anal canal and normal

sphincter.

**FIGURE 52-7** Perineal proctectomy. **A.** Patient in the prone jackknife

position. After gentle traction is applied on the rectal wall, a diluted epinephrine solution is injected into the outer layer of the prolapsed rectal wall. **B.** A circular incision is made through the full thickness of the outer layer of the prolapsed segment just proximal to the everted dentate line. **C.** The rectal prolapse has been completely unfolded. The mesenteric vessels are carefully ligated close to the bowel wall. **D.** The rectum is elevated anteriorly to expose the presacral space. A posterior rectopexy is performed (*arrow*) by approximating the seromuscular layers of the bowel wall to the precoccygeal fascia above the levator anu muscles. **E.** The levator anu muscles are approximated posteriorly (*arrow*). This repair pushes the bowel anteriorly to help recreate the anorectal angle. **F.** One or two sutures are used to approximate the levators anterior to the rectum to reinforce the pelvic floor. **G.** The prolapse is amputated and the colon sutured to the dentate line in a circumferential fashion (*dotted line*). **H.** Completed anastomosis. (Reproduced with permission from Prasad ML, Pearl RK, Abcarian H, et al: Perineal proctectomy, posterior rectopexy, and postanal levator repair for the treatment of rectal prolapse, *Dis Colon Rectum* 1986;Sep;29(9):547-552.)

Anal encirclement procedures have been mostly replaced by the perineal proctectomy. The anal encirclement procedure using synthetic material such as nylon mesh should be limited to the extremely debilitated patient or the elderly patient who cannot withstand perineal proctectomy.<sup>9</sup> It can be effectively performed under local anesthesia in patients with prohibitive surgical risks and decreased life expectancy. A rolled silastic mesh may be adequate to reinforce the sphincter orifice with minimal postoperative recovery period. The risk of erosion increases in the patient with a large amount of scar tissue in the perineum.

## Internal Intussusception of the Rectum

The treatment of internal intussusception of the rectum is primarily conservative with use of a high-fiber diet. High doses of psyllium may prevent formation of the funnel and eliminate the associated outlet obstruction with normalization of bowel function. Patients with pelvic floor outlet obstruction (nonrelaxation of the puborectalis) may benefit from biofeedback. In patients without pelvic floor outlet obstruction and with severe symptoms from the intussusception (ie, bleeding or incontinence), an operation may be considered. A low anterior resection or rectopexy is

appropriate for these patients depending on whether they have constipation or incontinence, respectively. The treatment of a bleeding solitary rectal ulcer by low anterior resection usually requires an ultralow anterior resection and coloanal anastomosis in the setting of an extremely thickened anterior rectal wall that overwhelms even the thickest staple height. Perineal proctectomy is not recommended because the sphincter mechanism is intact and resection of redundant rectum will be extremely difficult in patients with an incomplete prolapse. Colonic transit times are helpful to document normal colonic transit. Defecography will identify the level of the funnel formation within the rectum and mobility of the rectum away from the sacrum. A balloon expulsion test can document or rule out pelvic floor outlet obstruction as a cause of the intussusception.

The use of transanal stapling (STARR [(stapled transanal rectal resection)] or Transtar) procedures has become popular in Europe. Patient selection is important, as those with other abnormalities such as enteroceles, larger rectoceles, or nonrelaxation of the puborectalis were found not to have good response after the STARR procedure.<sup>10</sup> Complications include bleeding, perineal pain, recurrence, or incontinence. In a trial comparing STARR versus biofeedback, the STARR procedure was found to be more effective in improving symptoms of obstructed defecation. It may be performed in unhealthy individuals under local anesthetic by a properly trained individual after failure of biofeedback.<sup>11,12</sup>

## **PELVIC FLOOR OUTLET OBSTRUCTION AND SOLITARY RECTAL ULCER SYNDROME**

### **Pathophysiology**

The presenting complaints of patients with pelvic floor outlet obstruction usually include some form of constipation and straining. Defecation is a learned process and pelvic floor outlet obstruction may be either a change in the defecating mechanism or a failure to learn the appropriate series of events to allow normal function. The muscle of the pelvic floor is completely normal, but the function and control are abnormal. There may be a psychologic influence in this syndrome because patients who have been

sexually abused or who have been psychologically traumatized may develop this outlet obstruction. The need to dominate and control has also been documented in these patients. The syndrome results from obstruction of the anal canal due to anterior displacement of the puborectalis muscle and contraction of the pelvic floor and external sphincter during straining to defecate. Attempts to defecate against a closed pelvic floor result in chronic funnel formation of the rectum and descent of the anterior rectal wall into the anal canal. This chronic trauma and ischemia may lead to the formation of an ulcer on the anterior wall of the rectum. The stimulus to defecate is often neglected. The end result is an uncoordinated effort at defecation with pelvic floor obstruction of the outlet, even as the rectum begins to distend and the autonomic muscles begin to relax.

It is possible that pelvic floor outlet obstruction is etiologically related to rectal prolapse and intussusception. However, no long-term studies have provided conclusive evidence. Patients may also present with megarectum from outlet obstruction, fecal incontinence due to nerve injury from chronic straining, or severe mucosal prolapse or hemorrhoids.

The solitary rectal ulcer is assumed to be due to ischemia of an isolated portion of the mucosa on the anterior rectal wall, approximately 10 cm above the anal verge, which prolapses partially into the anal canal and becomes ischemic during prolonged straining. The healing process may occasionally incorporate functioning mucosal glands beneath the new mucosal surface and form a localized area of colitis cystica profunda. These entrapped glands continue to produce mucus and are occasionally mistaken for an early neoplasm of the rectum. An increase in collagen deposition is also present and helps distinguish this from a neoplasm.

## **Diagnosis and Evaluation**

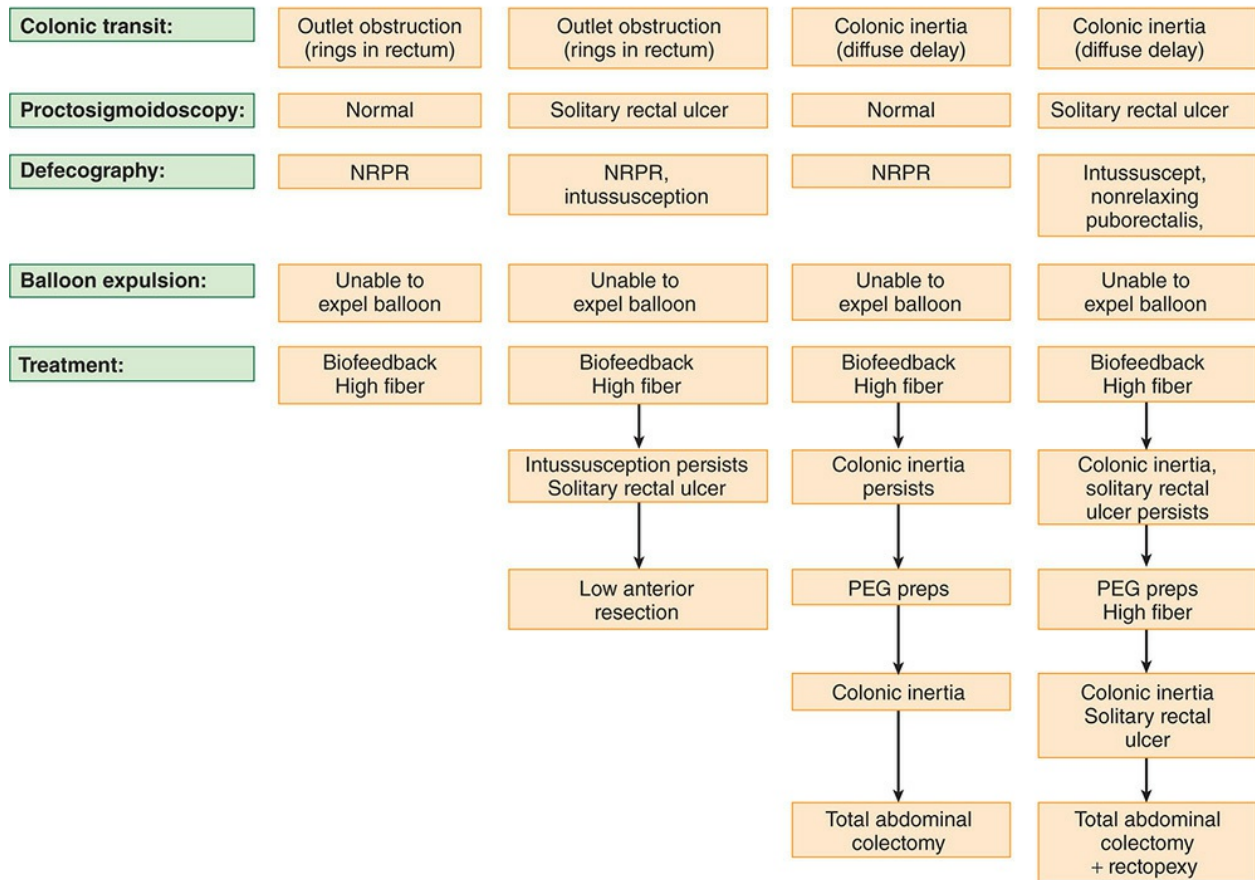

Patients with pelvic floor outlet obstruction may complain of a number of problems that include constipation and straining at defecation, the need for digital maneuvers to evacuate the rectum, bleeding, mucosal prolapse, and hemorrhoids. They occasionally present with chronic pain of the anal canal and symptoms of severe spasm of the anal canal and pelvic floor. In the past this was classified as anismus, proctalgia fugax, or levator ani syndrome. Digital rectal examination may reveal paradoxical motion (tightening instead of relaxing) of the puborectalis muscle during attempts to push the finger out

of the rectum. Defecography generally shows a persistent puborectalis impression on the posterior rectum as the patient attempts to evacuate the rectal contents. Defecography tends to overdiagnose the problem of nonrelaxing puborectalis. This may be due to an unnatural setting in a cold radiology suite or possible patient embarrassment. The presence of nonrelaxing puborectalis muscle must therefore be confirmed using some other technique. The method best suited to our practice has been to have the patient expel a 60-mL air-filled soft latex balloon while sitting in a private bathroom. This simple technique of expulsion of the balloon within the confines of a private bathroom seems to be adequate.<sup>13</sup> Surface electromyography (EMG) is also useful in the diagnosis and treatment of nonrelaxing puborectalis muscle, as it documents decreased pelvic floor electrical activity during proper relaxation of the muscle and an increase during paradoxical contraction. Colonic transit study will demonstrate accumulation of all of the administered radiopaque markers within the rectum after an elapsed period adequate for clearance (>7 days). An algorithm used to deal with pelvic floor disorders is shown in [Figure 52-8](#).

**Symptoms:** Constipation, straining, digital maneuvers, rectal pressure

**Tests:** Colonic transit, defecography, balloon expulsion, proctosigmoidoscopy

**Results:**

**FIGURE 52-8** Algorithm for diagnosis and treatment of pelvic floor outlet obstruction. NRPR, nonrelaxing puborectalis.

## Treatment and Management

The initial steps in the treatment of outlet obstruction problems include high doses of fiber and establishment of a normal bowel routine. Outpatient biofeedback using surface EMG, balloon expulsion, sensation techniques, and a simulated stool are also effective in severe cases of nonrelaxing puborectalis muscle.<sup>14</sup> Psychological counseling and relaxation techniques may be helpful in patients who have a psychological component to their problem.

## RECTOCELE, ENTEROCELE, AND COMPLEX

## PELVIC FLOOR ABNORMALITIES

Outpouching or bulging of the rectum into the vagina (rectocele) can be seen on defecography in patients with pelvic floor disorders. These findings, however, can also be found in patients without any pelvic or bowel complaints. Surgical repair does not always lead to resolution of symptoms. No predictors of successful outcome of surgery are universally accepted from various studies examining characteristics on defecography and symptomatology. Surgical technique is the surgeon's preference and can be performed via a transanal, transvaginal, or perineal approach to bolster, pleat, and reconstruct the muscle in the rectovaginal septum. Fortunately, the majority of patients improve with medical management.<sup>15,16</sup> Rectoceles occurring in patients with rectal prolapse generally resolve after repair of the prolapse as long as the rectum is mobilized all along the rectovaginal septum.

An enterocele is the bulging of small bowel into the rectogenital area during cough or even constantly, causing symptoms of urinary urgency, pain, constipation, and fullness. It is usually part of a complex of pelvic floor defects. This is a common finding in patients who are status post hysterectomy, in patients with symptoms of obstructive defecation, or in asymptomatic patients. A defecography defines the problem. An enterocele can be repaired transabdominally in conjunction with operative management of other pelvic floor abnormalities by reefing or excising and reclosing the redundant pelvic peritoneum to prevent herniation of small bowel into the pelvic floor.

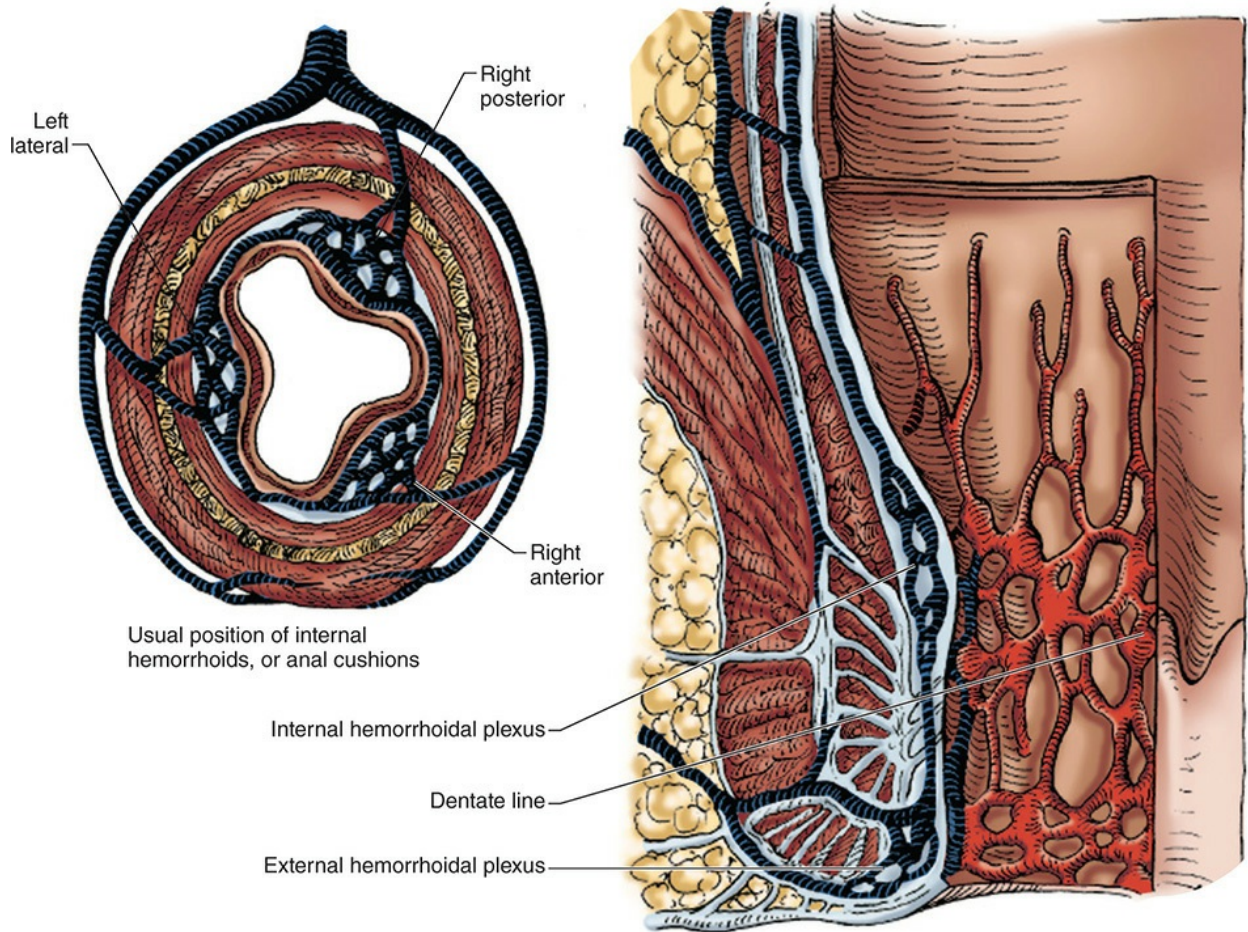

Pelvic floor disorders may also involve bladder or gynecological complaints. A multidisciplinary team approach for evaluation, discussion, recommendation, and operative management of complex pelvic floor abnormalities provides the best care for these patients. A urogynecologist or urologist with experience in bladder or vaginal suspension, a colorectal surgeon with experience in treatment of incontinence and rectopexy/-resection, and pelvic floor suspension as well as physical therapists, psychologists, radiologists, and endoscopists define the "pelvic floor" team. Dynamic MRI is a useful modality for the diagnosis of some of these challenging pelvic floor cases.<sup>17</sup> High-resolution 3D endovaginal and endorectal ultrasonographies are increasingly being used for evaluation of pelvic floor disorders.<sup>18,19</sup>

# HEMORRHOIDS

Current theories about the development of hemorrhoids consider the nature of anal “cushions.” These cushions are aggregations of blood vessels (arterioles, venules, and arteriolar-venular communications), smooth muscle, and elastic connective tissue in the submucosa that normally reside in the left lateral, right posterolateral, and right anterolateral anal canal.<sup>20</sup> Smaller discrete secondary cushions may reside between the main cushions. Hemorrhoids are likely the result of a sliding downward of these anal cushions. Hemorrhoids provide tissue to close the anal canal during rest. It appears that the disintegration of the anchoring and supporting connective tissue and the terminal fibers of the longitudinal muscle above the hemorrhoids allows these structures to slide distally. Chronic straining and repeated thrombosis, or disruption of the vascular complex, result in tissue expansion of the cushions, stretched and redundant overlying mucosa, and visible columns of hemorrhoids.

## Classification

Anal skin tags are discrete folds of skin located at the anal verge. These may be the end result of resolved thrombosed external hemorrhoids or, more rarely, may be associated with inflammatory bowel disease. Internal hemorrhoids reside above the dentate line and are covered by transitional and columnar epithelium (Fig. 52-9). First-degree internal hemorrhoids are not large and are often barely visible but result in painless bleeding during strained defecation. Second-degree hemorrhoids are large enough to protrude through the anal canal at the time of defecation and may bleed, but spontaneously reduce. Third-degree internal hemorrhoids protrude and bleed with defecation, but are large enough and stretched enough that they must be manually reduced. Fourth-degree internal or mixed hemorrhoids are a fusion of internal and external hemorrhoids as the vascular complexes and cushions descend in the submucosa and become permanently fixed below the dentate line and cannot be manually reduced.

**Types of hemorrhoids**

External hemorrhoid

Internal hemorrhoid

Mixed hemorrhoid

## **FIGURE 52-9** Location and types of hemorrhoids.

External hemorrhoids consist of the dilated vascular plexus located below the dentate line and are covered by squamous epithelium. They become symptomatic when the venous plexus becomes thrombosed. This clot may erode and cause pain and bleeding or resolve and leave behind a “tag” of excess skin over the anal verge. External hemorrhoids do not always follow the typical pattern that internal hemorrhoids do and may occur randomly around the anal orifice.

## **Evaluation of Internal Hemorrhoids**

Even though internal hemorrhoids are the most common source of rectal bleeding, it is imperative that other causes be excluded. Because internal hemorrhoids cannot be detected by digital examination, diagnosis can only be made by anoscopy. It is mandatory that colonoscopy be performed in high-risk patients to exclude other sources of bleeding, such as carcinoma or proctitis (eg, for patients aged >40 years and those with a personal or family history of colorectal neoplasia or a change in bowel habits).

## **Treatment**

Regulation of diet and avoidance of prolonged straining at the time of defecation comprise the initial treatment of mild symptoms of bleeding and protrusion. Increasing the fiber content of the diet to at least 25 to 35 g daily with raw vegetables, fruits, whole-grain cereals, and hydrophilic bulk-forming agents can reduce and often alleviate all symptoms. Symptomatic relief is provided by a daily dose of 12 g of psyllium powder in a glass of water by producing adequate bowel fiber and function for most patients complaining of constipation and hemorrhoids. If bleeding and protrusion persist, however, the hemorrhoids should be treated surgically.

Elastic ligation of the friable redundant hemorrhoidal tissue is quite satisfactory for first-, second-, and third-degree hemorrhoids. The procedure is quite simple. The hemorrhoid is visualized with the aid of an anoscope and grasped with forceps. The redundant tissue is pulled into a double-sleeved cylinder on which there are two latex bands. The bands are discharged from the cylinder, and the hemorrhoidal bundle is ligated (Fig. 52-10).

**FIGURE 52-10** Elastic ligation technique.

Certain precautions, however, must be taken with this form of treatment. The ligatures must be placed at least 2 to 3 cm above the dentate line on minimally innervated tissue to avoid extreme discomfort. Ideally, the ligatures should be placed at the top of the hemorrhoidal cushion. About 25% of patients experience mild, dull anorectal discomfort lasting for 2 to 3 days following the procedure. Mild analgesics and warm baths are usually sufficient to relieve the discomfort. In fewer than 1% of patients, brisk bleeding may occur when the necrotic tissue sloughs off at 7 to 10 days. Occasionally this requires suture ligation. Less than 2% of patients treated with ligation of the internal hemorrhoid develop thrombosis of an external hemorrhoid, which may cause considerable discomfort. Necrotizing pelvic or perineal sepsis is the most severe complication of ligation. Fortunately, it is rare and almost always associated with immune compromise. It requires immediate recognition in the setting of increased pain, fever, or urinary dysfunction. Treatment consists of immediate examination under anesthesia for debridement of all necrotic tissue, intravenous broad spectrum antibiotics

covering anaerobes, and observation in the intensive care unit. Patients with poorly functioning neutrophils or reduced numbers of white blood cells for any reason (human immunodeficiency virus [HIV] patients with low CD4 count, patients on chemotherapy, brittle diabetics, patients with leukemia) should be treated with another method of hemorrhoid ablation which does not leave necrotic tissue behind, or at least be warned of and observed for the occurrence of this potentially life-threatening complication.

Hemorrhoidal elastic band ligation is an office procedure, and no special preparation is required. Patients with a bleeding diathesis or with portal hypertension are not good candidates for ligation. Usually only one hemorrhoid is ligated on the first treatment visit to prevent urinary retention, constipation, or severe spasm. Ligations can be performed every 2 to 4 weeks until all symptoms of bleeding or prolapse are alleviated. The second ligation can be multiple if the first treatment is well tolerated. Other minimally invasive procedures such as infrared coagulation and diathermy coagulation cause thrombosis of the internal vascular pedicle and stop bleeding, and may fix the loose tissue within the anal canal. They are primarily indicated for first- and second-degree hemorrhoids and may require multiple treatments. Ultrasound- or Doppler-guided ligation of hemorrhoids has received increased interest because of claims of less pain and ease of the procedure. The technique is based on the use of an ultrasound source to identify the vascular pedicle in the wall of the rectum at the apex of the hemorrhoidal cushion to suture ligate the vessel and pexy the redundant mucosa up to the lower rectal wall.

Although diet, bowel regulation, or elastic ligation will alleviate most symptoms of internal hemorrhoids, occasionally further surgical treatment may be needed. Excisional hemorrhoidectomy is indicated for large, mixed (combined internal/external) hemorrhoids that are not amenable to ligation because the ligature would have to incorporate pain-sensitive tissue at or below the dentate line.

Circular stapled hemorrhoidectomy is a technique occasionally or rarely indicated for the elective treatment of circumferential third- and fourth-degree hemorrhoids (sometimes referred to as distal mucosal prolapse) that are not permanently prolapsed due to scar.<sup>21</sup> This involves placing a purse-string suture incorporating the mucosa of the upper anal canal (not the muscle of the rectal wall) circumferentially at 4 to 5 cm above the dentate line. A stapled circumferential mucosectomy and anopexy is then accomplished with

a 33-mm circular stapler incorporating all of the redundant mucosa of the distal rectum to have a circular staple line at a level 4 to 5 cm above the dentate line. This can be performed under regional anesthesia with minimal morbidity in experienced hands. Potential complications include bleeding if the staple line is incomplete, pain if the staple line is too close to the dentate line, rectovaginal fistula if the purse string captures the rectovaginal septum, complete closure of the rectum if the stapler and purse string are malpositioned, return of symptoms if the purse string is incomplete, and a syndrome of unrelenting pain in some patients if the staples persist in the wall of the rectum. Many colorectal surgeons have abandoned this technique, the author included.

## **THROMBOSED, PROLAPSED, INCARCERATED INTERNAL HEMORRHOIDS**

Occasionally, the internal hemorrhoidal tissue may become thrombosed and incarcerated outside the anal canal, resulting in spasm of the anal sphincter, massive local edema, and severe pain. In such circumstances, the edematous tissue may be injected with a local anesthetic containing epinephrine. Dissipation of the edema by manual compression then can be achieved, allowing reduction of the prolapsed tissue into the rectum. Observation and use of stool softeners with tub soaks usually allow the acute episode to resolve without an operation because the hemorrhoidal vessels have been naturally thrombosed. The thrombosed internal hemorrhoids will sclerose and may not require surgery. If symptoms persist or recur, a three-quadrant excisional hemorrhoidectomy may then be necessary.

## **THROMBOSED, PROLAPSED, INCARCERATED, STRANGULATED, NECROTIC INTERNAL HEMORRHOIDS**

In the circumstance where necrotic tissue is present due to strangulation of tissue at the time of acute thrombosis and incarceration of internal hemorrhoids, emergent excisional hemorrhoidectomy is necessary. Care should be taken to preserve the anoderm. The usual three-quadrant pattern is most often found and normal skin bridges will persist. The patient should be kept in the hospital after the procedure until the pain is minimal and until

spontaneous voiding is possible, and to ensure resolution of any potential infection. Prophylactic broad spectrum antibiotic coverage is recommended in patients with diabetes or immune compromise.

## **MIXED HEMORRHOIDS**

The mucosal component of mixed hemorrhoids occasionally can be treated by elastic ligation above the dentate line to reduce mucus discharge and nuisance tissue prolapse. Large symptomatic, nonreducing mixed hemorrhoids generally are treated by excisional hemorrhoidectomy.

### **Hemorrhoidectomy Technique**

The patient is placed in the prone flexed position with padded rolls under the hips. Local anesthesia with sedation under anesthesia monitoring using a perianal field block with 0.25% bupivacaine with or without epinephrine is usually adequate. If the patient has a history of obstructive sleep apnea, general anesthesia with control of the airway is more appropriate. The apex of the vascular pedicle is ligated first, 4 to 5 cm above the dentate line, with a 2-0 or 3-0 absorbable, soft suture. Long lasting sutures with rigidity will irritate the anal canal. An elliptical incision with cautery or sealing device starting below the apical hemostatic suture should incorporate the internal and external hemorrhoid out onto the perianal skin. The hemorrhoidal tissue is sharply dissected from the underlying internal sphincter without removing any muscle (Fig. 52-11). Hemostasis must be meticulous prior to closing the defect. The entire wound is then closed by running the apex suture to the distal perianal skin edge. A running locking suture guarantees hemostasis of the mucosal edges. The largest hemorrhoid is excised first, with care taken not to excise excessive tissue. If the anoderm bridges are inadequate after complete excision, a stricture is likely to form in the future. If there is any concern of leaving an adequate anal aperture covered by normal anoderm, it is best to modify a planned three-quadrant hemorrhoidectomy and instead perform a two-quadrant hemorrhoidectomy and band the remaining internal component.

**FIGURE 52-11** Excision technique for mixed hemorrhoids.

## THROMBOSED EXTERNAL HEMORRHOIDS

The external venous plexus is located at the anal verge and encircles the anal canal. A segmental thrombus is confined to the anoderm and perianal skin and does not extend above the dentate line. A thrombosed external vein presents as a painful perianal mass. The overlying skin may be stretched to 2 cm or more. Pain usually peaks within 48 hours and generally becomes minimal after the fourth day. If untreated, the thrombus is absorbed within a few weeks. The pressure of the underlying clot will occasionally cause the adjacent skin to become necrotic, and the clot will be extruded through the area of necrosis. This is noted by the patient as rectal bleeding followed by relief of the anal pain. A partially extruded clot can be removed in the office to provide relief.

Treatment of thrombosed hemorrhoids is aimed at relief of the pain. If symptoms are minimal, mild analgesics, sitz baths, proper anal hygiene, and

bulk-producing agents will suffice. However, if necrosis is extensive, excision of the thrombosed hemorrhoid is usually indicated. Numerous vessels are usually involved. It is necessary to excise the entire necrotic mass along with the overlying skin and subcutaneous tissue. The wound is left open without packing. Postoperative care consists of mild analgesics and warm sitz baths or showers and bulk agents to remove the need for straining at defecation.

## **ANAL FISSURE**

An anal fissure is a split in the anoderm over the hypertrophied band of internal sphincter at the anal verge (Fig. 52-12). The fissure is almost always located close to the midline of the anal canal; in men, 95% are near the posterior midline and 5% near the anterior midline, whereas in women, about 80% will be located posteriorly and 20% anteriorly. The unusual event of anterior and posterior anal fissure occurs in less than 5% of patients. The precise cause of an anal fissure has yet to be determined. Increased resting pressure in the internal sphincter must contribute. However, fissures probably are related to tearing of the anoderm at the time of defecation. Anal sphincter hypertonicity and an increase in ultraslow waves on anal manometry characterize typical anal fissures. The increased anal canal pressure that accompanies an anal fissure is associated with ischemia in the area of the fissure and prevents healing, as spasm recurs with each bowel movement.<sup>22</sup> An anal ulcer is the chronic form of an anal fissure with heaped-up edges, sentinel skin tag, and often associated with an internal hypertrophied anal papilla and external sentinel skin tag.

**FIGURE 52-12** Anal fissure.

## Clinical Features and Diagnosis

Most acute fissures are superficial and heal rapidly with no specific treatment. Occasionally, the fissure may extend deeply through the anoderm to expose the fibers of the internal sphincter. Surprisingly, secondary infection rarely occurs.

Fissures that are aberrantly located should alert the surgeon to other causes besides hypertrophied anal sphincter. Individuals with chronic diarrhea may develop anal stenosis associated with a fissure. Anal Crohn's disease is associated with anal fissures, which may be a primary manifestation of the disease. These fissures are associated with the edematous, painless anal skin tags typical of anal Crohn's disease and occur anywhere around the circumference of the anus. These fissures, ulcers, and tags are often accompanied by simultaneous abscesses and fistulas. Isolated anal Crohn's disease occurs in only 2% of patients with Crohn's disease but will eventually occur in some form in over 80% of patients with Crohn's disease.

Patients with anal fissures usually complain of anal pain accompanying and following defecation. Bright red bleeding may accompany a bowel movement, although it is usually minimal. A slight discharge also may be present. It is common for patients to complain of continued spasm for several hours after defecation. This spasm may move down the posterior thigh in severe cases.

An anal fissure is detected by gently separating the buttocks to reveal the lower edge of the fissure at the anal verge, where a sentinel tag also may be seen. A soft touch of a cotton swab to this area will elicit the pain and help with the diagnosis. A deep gluteal cleft or tight spasm of the sphincter may sometimes obscure the fissure, and if the patient can tolerate it, examination with a small anoscope may be required. The fissure/ulcer complex rarely extends above the dentate line. It is also possible for an anal ulcer to develop a posterior subcutaneous abscess and fistula as bacteria accumulate under the outer overhanging lip of the ulcer.

## Treatment

Dietary recommendations and prescription of bulking agents to promote soft stools are beneficial, and warm tub soaks may provide sphincter relaxation

and comfort. The majority of acute fissures will heal with conservative management. The use of 0.2% nifedipine ointment applied to the anoderm of the anal verge relaxes the sphincter and dilates local vessels to promote healing. Most acute fissures will heal with this added therapy.<sup>23</sup>

The injection of 20 to 25 units of botulinum A toxin into the internal anal sphincter at both edges of an anal ulcer and directly into the internal sphincter muscle at the ulcer base (total of 75-100 units) is a simple procedure that has been shown to heal anal fissures.<sup>24</sup> It can be done with local anesthesia as an outpatient procedure, with symptomatic relief by approximately 1 week. The paralysis of the internal sphincter reverses in several months and the fissure may recur. Repeat treatments can be performed if the initial response was adequate, but it is expensive with at best modest complete healing rates. This has been an excellent means of treating difficult-to-heal anal ulcers in a woman who fears incontinence of gas and liquid that may occur after an internal sphincterotomy.

Surgical treatment may be required for deep, chronic fissures associated with a sentinel skin tag, hypertrophied anal papilla, and exposed internal sphincter. Excellent results can be achieved if the internal sphincter is divided laterally rather than in the midline. Furthermore, lateral sphincterotomy is not associated with a “keyhole” deformity. Only the thickened band of the internal sphincter should be divided (ie, partial sphincterotomy). This limits the amount of internal sphincter transection and reduces the potential for fecal incontinence. The sphincter band palpable under the ulcer is the only muscle that needs to be divided and the cut in the sphincter should not be longer than the length of the ulcer.

## **OPEN AND CLOSED SPHINCTEROTOMY**

Sphincterotomy can be performed under local anesthesia, using either an open or closed technique (Fig. 52-13). The open technique consists of a radial incision of the anoderm at the right lateral position over the intersphincteric groove and limited division of the internal sphincter only up to the proximal extent of the fissure under direct vision. The thickened band of autonomic muscle is delivered into the incision over the tip of a curved clamp and divided with electrocautery to reduce bleeding. The incision is left open and the patient is started on warm tub soaks to close secondarily in a few days to

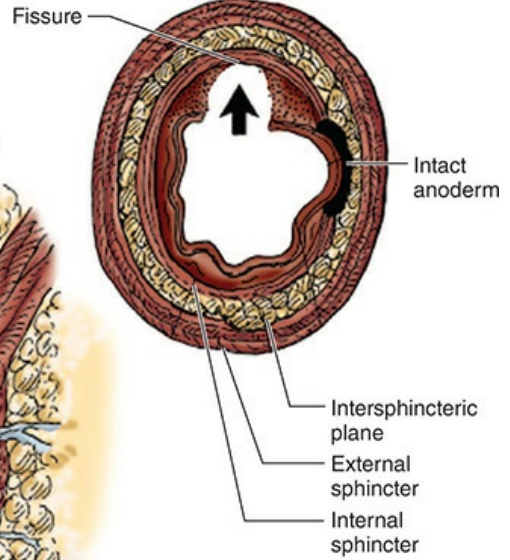

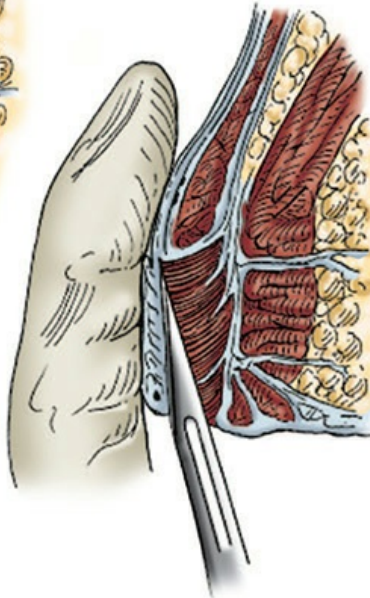

avoid infection.

**Closed technique**

Blade inserted in intersphincteric groove and passed cephalad in intersphincteric plane to level of dentate line

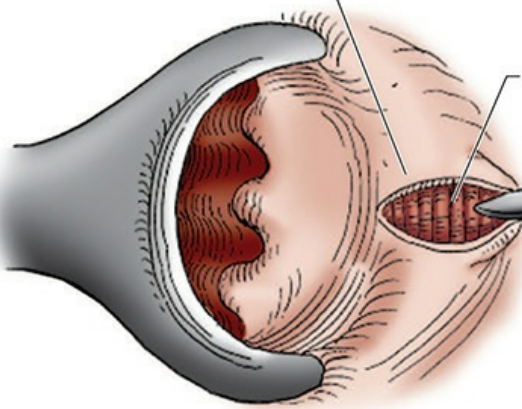

Blade then moved medially, dividing inferior 1/3 to 1/2 of internal sphincter

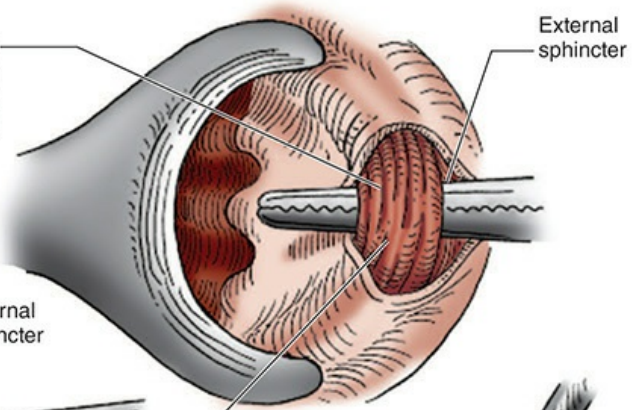

Internal sphincter divided; external sphincter, anoderm, and longitudinal muscle remain intact

**Open technique**

Skin incision made external to anal verge

Hypertrophied band of internal sphincter freed and elevated into incision

Internal sphincter

Internal sphincter divided; wound usually left open for drainage

**FIGURE 52-13** Lateral internal sphincterotomy.

The closed method entails dividing the internal sphincter by a subcutaneous approach. With a Hill-Ferguson retractor in the anal canal, the tip of a #11 blade scalpel is inserted into the right lateral intersphincteric groove and turned toward the lumen of the anus. The gentle sawing motion toward the fingertip in the anus cuts the muscle fibers in a controlled way to avoid injury to the mucosa. Both techniques may be used in the outpatient setting and afford rapid pain relief.<sup>25</sup> Approximately 98% of fissures heal following sphincterotomy. However, there is a small incidence of fecal incontinence following the procedure, so careful patient selection is mandatory. There is a risk of anal fistula if the tip of the scalpel breaks the mucosal surface of the anal canal during a closed sphincterotomy. The open sphincterotomy can also become infected and act like a perianal abscess.

Elderly female patients, with decreased anorectal sensation, are generally not ideal candidates for internal sphincterotomy because of the risk for anal incontinence. Consideration should be given to a diamond skin advancement flap to cover the ulcer bed in women to prevent incontinence. This flap requires isolation of a postage stamp–sized island of skin based on a subcutaneous fat pedicle from the inner aspect of the buttock posteriorly or the perineum anteriorly. The ulcer is excised leaving a defect in the size of the flap. The flap is advanced to the open area in the anoderm and secured to the freshly cut mucosal edges (Figs 52-14 and 52-15).

## ANORECTAL ABSCESS AND ANAL FISTULA

### Diagnosis and Classification

More than 95% of all anorectal abscesses are caused by infections arising in the anal glands that communicate with the anal crypts (cryptoglandular disease). The acute phase of cryptoglandular disease is an anorectal abscess, while the chronic stage is recognized as an anal fistula. The anal glands lie in the intersphincteric space between the internal and external anal sphincters at the level of the dentate line. Obstruction of an anal duct leads to the formation of a glandular abscess in the intersphincteric plane. The clinical presentation, natural history, and proper treatment of anorectal abscess and fistula are understood easily if it is recognized that the disease originates as an intersphincteric abscess.

As the abscess enlarges, it escapes the confines of the intersphincteric plane and spreads in one of several possible directions (Fig. 52-16). The most

common of all anorectal abscesses is a perianal abscess, which presents as a tender, erythematous bulge at the anal verge. An ischiorectal abscess is formed when a growing intersphincteric abscess penetrates the skeletal muscle of the external sphincter below the level of the puborectalis and expands into the fat of the ischiorectal fossa. These abscesses can become quite large, because the levator ani (the upper border of the ischiorectal fossa) serves as the upper extent of the ischiorectal fossa and the fat of the ischiorectal fossa, which encircles the anal sphincter, offers no resistance to expansion of the abscess. An ischiorectal abscess may be palpated as a bulge above the puborectalis, although it actually lies below the levator ani musculature. In contrast to the perianal abscess, this abscess seldom presents as a visible bulge because of the large potential space in the ischiorectal fossa. Patients complain of pain of the inner buttock or low pelvis as the pressure of the abscess increases. Rarely, an intersphincteric abscess may expand upward between the circular internal sphincter and the external sphincter, forming a supralelevator abscess.

**FIGURE 52-16** Anorectal abscess and fistula-in-ano cryptoglandular origin theory.

## Treatment

Perianal abscesses should be drained immediately, before wide fluctuance or cellulitis develops. Antibiotics are not indicated and should be used only in the presence of extensive cellulitis, valvular heart disease, diabetes, or compromised immunity. If the diagnosis is suspected but not readily evident, examination under anesthesia should be performed. This is facilitated by lighted Hill-Ferguson retractors and curved grooved probes to identify internal openings and determine potential fistula formation already present at the time of abscess drainage.

With adequate regional or general anesthesia, the abscess can be detected and localized by digital examination. An intersphincteric abscess is treated definitively by performing an internal sphincterotomy over the length of the abscess cavity, which serves to unroof and drain the abscess into the low rectum and anal canal. However, if the infection has developed into a perianal or an ischiorectal abscess, adequate drainage of the abscess cavity first must be done by making a cruciate incision or removing a disc of the skin overlying the abscess as close to the anal canal as possible. Complete evacuation of the contents of the abscess cavity is essential. In 30% of patients, the internal opening of the abscess will be obviously draining purulent material. In these cases it is appropriate to place a soft silicone seton through the drainage incision on the skin, along the tract to the internal opening, and then around the entire sphincter complex and overlying skin to be tied in a loose circle with a silk suture. The silicone seton allows the fistula tract to mature and a definitive procedure to be planned as the next step.

Incision and drainage alone will result in complete resolution of the infection in about half of patients. An anal fistula occurs in 50% of patients. A fistula is a fibrous, tubular tract with an internal opening located in a crypt at the level of the dentate line and an external opening located at the drainage site of the earlier abscess. The fistula may travel through varying amounts of muscle or fat, depending on the characteristic of the causative abscess or the drainage method applied to the abscess. It is important to allow the fistula tract to become mature, and a soft seton can be placed when the fistula is discovered. The seton is usually left in place for 4 to 8 weeks.

The appropriate treatment for an anal fistula is dependent on the anatomy and the location of the fistula tract. Goodsall's rule states that if the anus is bisected by a line in the frontal plane, an external opening anterior to the line

(within 2 cm of the anal verge) will connect to an internal opening by a short, direct fistula tract (Fig. 52-17). However, if the external opening is located posterior to this imaginary line or anteriorly but outside 2 cm from the anal verge, the fistula tract follows a curved course to the crypt in the posterior midline. This rule, while useful, is not infallible.

**Goodsall's rule**

Fistulas with external openings anterior to midanal line connected to internal opening by short, straight tract. Posterior external openings follow curved course to internal opening in posterior midline

Surgical management of intersphincteric and low (below puborectalis) transsphincteric fistulas involves unroofing the tract. Only internal sphincterotomy in the first case; internal sphincterotomy involving portion of external sphincter in the latter case. Division of puborectalis muscle results in incontinence, so high fistulas are not treated by sphincterotomy.

**FIGURE 52-17** Surgical management of fistula-in-ano.

Occasionally, an external opening located more than 2 cm from the anal verge anterior to the imaginary bisecting line connects to an internal opening in the posterior midline. This is based on the lack of barriers to forward spread for an abscess in the ischioanal fossa. Because of its shape, this fistula is usually called a *horseshoe fistula*. Horseshoe fistulas usually have an internal opening in the posterior midline of the anus and may extend anteriorly and laterally to both ischioanal spaces by way of the deep postanal space. The posterior opening must be incised into the postanal space to deal with the primary cause. The anterior extensions of the horseshoe tracts then can be drained by a secondary opening, avoiding a long skin incision that would unroof the entire tract (Fig. 52-18). This is the Hanley procedure

for a horseshoe abscess/fistula.

Horseshoe fistula with external openings anterior to midanal line and internal opening in posterior midline

**FIGURE 52-18** Surgical management of horseshoe fistula.

If a perianal abscess develops into a fistula that involves a small portion of the internal and very few of the most superficial fibers of the external sphincter muscle, the condition can be treated by simple fistulotomy. This “superficial fistulotomy” divides a portion of the internal sphincter and no meaningful fibers of the external sphincter to unroof the tract.

The fistula that forms after drainage of an ischiorectal fossa abscess is a transsphincteric fistula, which crosses the lower portion of the external sphincter. The fistulotomy required to unroof this tract results in division of a significant portion of the internal sphincter and external sphincter. Only a fistula in the posterior midline can be treated without worry of incontinence. However, the puborectalis must not be divided, or incontinence will invariably ensue. During posterior midline fistulotomy, a finger on the puborectalis muscle will keep the surgeon from this mistake.

The external anal sphincter is much less prominent in the anterior half of the anal canal. Thus, fistulotomy as a treatment for an anterior quadrant anal fistula is associated with an increased risk of anal incontinence, particularly in women. Consequently, treatment of such fistulas often involves eradicating the internal opening of the fistula at the level of the dentate line by advancing a flap of rectal mucosa. It is important to ensure adequate drainage of the fistula through the external opening until the suture line of the advancement flap is well healed; otherwise, an abscess can reform and disrupt the suture line (Fig. 52-19). Injection of Fibrin glue and insertion of collagen plugs into the fistula tract are alternatives with minimal morbidity and mixed success.<sup>26,27</sup>

**FIGURE 52-19** Endorectal advancement flap repair of complex anal-perineal or low rectal-perineal fistula. (Reproduced with permission from Kodner IJ, et al. Endorectal advancement flap repair of rectovaginal and other complicated anorectal fistulas, *Surgery* 1993;Oct;114(4):682–690.)

Ligation of the intersphincteric fistula tract (LIFT) may be used with minimal morbidity and mixed success.<sup>28,29</sup>

Through a radial incision in the intersphincteric groove the fistula can be encircled and divided with double-suture ligation. Healing has been reported for greater than 50% of fistulas treated this way. Minimal damage to the sphincter mechanism and anal canal allows other treatments to be used if the technique fails. The LIFT procedure can also be supplemented with a “postage stamp” piece of biologic mesh to separate the ends of the fistula in the intersphincteric groove. Even if the fistula recurs, the internal sphincter is the only muscle involved in the subsequent fistulotomy to finally cure the fistula.<sup>30</sup>

The patient with a fistula that defies identification, the tract that does not follow the usual path, or the fistula that has been through multiple failed attempts at treatment are candidates for MRI of the pelvis with dilute hydrogen peroxide injected through either the internal or external opening. A 3D ultrasound may provide similar information. Other substances such as dilute povidone iodine, dilute milk, or methylene blue can be used for tracking the fistula through the pelvic tissue. The usual cause for a persistent fistula is an undrained abscess in an area of the sphincter complex which prevents access and maintains a low-grade state of purulence. Rarely extreme measures are required to generate healing, such as proximal diversion and incision and unroofing of the external component of the tract to identify the hidden abscess.

Rectovaginal (RV) fistulas after obstetric injury are best treated with a sliding advancement flap.<sup>31,32</sup> It is important to perform preoperative testing to evaluate for an associated external sphincter defect that may need to be repaired at the time of the advancement flap. If the patient has a history of pelvic malignancy, a biopsy of the fistula tissue is important to rule out cancer as a cause. Transperineal and transvaginal approaches to repair of the RV fistula do not manage the high pressure (rectal) side of the fistula. The advancement flap repair of a high RV fistula requires creation of a full thickness rectal wall flap that has a good blood supply and no tension. The flap should be twice as wide as it is long and the tip of the flap must travel at least 2 cm to reach the distal aspect of the excised fistula. Counterdrainage of the RV septum is helpful to avoid a hematoma of the septum and disruption of the flap. It is helpful to have the patient undergo a bowel preparation to reduce stool passage for the first few days. A diverting ileostomy or

colostomy is recommended when the fistula has been repaired before and failed. In the worst case, the use of an interposition flap of muscle or labial fat may be required to bring new blood supply to the area. This is especially true for patients who have undergone prior radiation. General anesthesia and prone jackknife position are beneficial. A Lone Star retractor provides excellent exposure.

Although most anorectal abscesses originate in the anal crypts, other disease entities must be considered if the pathology appears atypical. Crohn's disease should be suspected if there are numerous complex fistula tracts associated with edematous skin tags, or if there is inflammation of the rectal mucosa. Tuberculosis is now a rare cause of anal abscesses and fistulas but has recently been observed in immigrants to America.

Hidradenitis suppurativa also may mimic cryptoglandular suppurative disease. Hidradenitis may be associated with Crohn's disease. Close examination, however, will reveal that the disease arises from the apocrine glands of the perianal skin and not the anal crypts. Wide excision of the subcutaneous apocrine glands with vacuum-assisted wound closure (VAC) is the best method of treating this problem. Intensive hygiene to reduce levels of skin flora (usually *Staphylococcus aureus*) is needed to prevent recurrence. Mixed flora sometimes cause the problem around the anus, and this will respond to daily chlorhexidine gluconate showers. Actinomycosis should be suspected if typical sulfur-like granules are seen in the abscess cavity or fistula tract.

Pilonidal disease sometimes can be confused with a posterior perianal abscess, but careful examination should reveal that there is no communication with the anus. Hair obtained from the abscess cavity when the pilonidal abscess is drained will indicate the true nature of the disease. Unroofing of the abscess, curetting the debris in the tract, and excision of the gluteal cleft hair follicle "pits" will allow delayed secondary healing. Wound VAC therapy may be useful in particularly large wounds. Shaving of the hirsute gluteal cleft and buttocks will help prevent recurrence. Obsessive hygiene is required to heal and then maintain healing of the area. More complicated cleft transposition procedures are rarely needed to treat routine cases of pilonidal disease. The wound VAC therapy has essentially supplanted the need for large surgical flap procedures in this disease.

## SEXUALLY TRANSMITTED ANAL DISEASE

In recent years, there has been a profound change in the prevalence and types of sexually transmitted diseases. Genital-anal, oral-anal, and other anal-based practices among homosexual or bisexual men and among women who engage in anal receptive intercourse account for the transmission of most of these diseases.

The incidence of other venereal diseases appears to be increasing. Although a detailed discussion of these infections is beyond the scope of this textbook, the surgeon will often be consulted for evaluation of complications of these diseases.<sup>33</sup>

### Human Papillomavirus

Human papillomavirus (HPV) is the etiological agent causing venereal warts. These lesions are most common in homosexual men and can have a varied appearance, including (1) discrete warts: papillary or condyloma acuminata white lesions, usually occurring singly or in clusters at or below the dentate line; (2) circumferential wart ring lesions located at the dentate line and encompassing 60% to 100% of the anal canal; and (3) flat white epithelium: pale areas of smooth opaque epithelium that often extend cephalad to the dentate line. These latter lesions may be detected more easily by using a colposcope to magnify the anal canal. A high prevalence of histologically confirmed dysplasia in these internal lesions can be detected in asymptomatic homosexual men. Dysplasia is found in 70% of HIV-seronegative men and 85% and 90% of nonimmunosuppressed and immunosuppressed HIV-seropositive men, respectively. Dysplasia cannot be predicted by the gross appearance of the warts.

The association of dysplasia with HPV is now well recognized. There are at least 60 different HPV types. Types 6 and 11 are associated with warts and low-grade dysplasia. Types 16 and 18 have been found in cervical cancer and high-grade cervical dysplasia, and type 16 has been found in high-grade anal dysplasia and invasive cancers. HPV types 31, 33, and 35 are thought to pose a lower cancer risk.

While it is clear that HPV is implicated in the pathogenesis of anal cancer in homosexual men, the rates of progression from dysplasia to cancer in the

anal canal are unknown. Anal intraepithelial neoplasia (AIN) is believed to be a precursor of anal neoplasm. Low-grade anal squamous intraepithelial lesion (LSIL) is equivalent to AIN grade I, and high-grade anal squamous intraepithelial lesion (HSIL) is equivalent to AIN grade II or III. AIN III is defined as nuclear abnormalities that have penetrated through the full thickness of the epithelium. AIN III may be found in the pathology specimen after surgery for an unrelated problem such as hemorrhoids. One can apply 4% acetic acid to the low rectal and anal canal mucosa and perianal skin to visualize the lesions under magnification. This technique of high-resolution anoscopy can be used in high-risk individuals to prevent the development of anal cancer. Depending on the size and location of the lesion around the anus, the appropriate therapy for AIN III or HSIL is ablation of the lesions, either by excision, electrocautery, or laser. Medical options include topical 5-fluorouracil (5-FU) cream or imiquimod. Wide local excision may result in morbidity including anal stenosis or incontinence. Thus, high-risk patients should be followed closely, especially those with immunocompromise.<sup>34</sup>

## Chlamydial Infections

Chlamydial infections are now the most common sexually transmitted disease in the United States and they account for increasing numbers of cases of proctitis in patients who practice receptive anal intercourse. There are 15 recognized immunotypes of *Chlamydia trachomatis*, but for practical purposes it should be recognized that there are lymphogranulomatous-causing lymphogranuloma venereum (LGV) and nonlymphogranulomatous (non-LGV) types. The non-LGV organisms are a common cause of urethritis, epididymitis, and pelvic inflammatory disease. At least half of the genital infections previously diagnosed as “nonspecific” or “nongonococcal” are caused by non-LGV *Chlamydia*. Chlamydial proctitis may coexist with other rectal infections, especially gonorrhea. Several serotypes are responsible for proctitis, and serotypes L1, L2, and L3 are responsible for LGV. The pathogen is introduced by either genital-anal or oral-anal intercourse. The non-LGV organisms are obligate intracellular parasites that can penetrate only columnar or transitional epithelium. The LGV organisms also can penetrate mononuclear cells, which may account for the prominent lymphadenopathy in patients with lymphogranuloma venereum.

Infection may be asymptomatic or may consist of nonspecific symptoms

such as anal pain, pruritus, purulent discharge, and bleeding. More severe forms of infection, especially severe proctitis, usually indicate the presence of one of the LGV serotypes. Perianal fistulas and rectovaginal fistulas may develop, with untreated cases progressing to severe rectal stricture. Two weeks after the initial symptoms, inguinal lymphadenopathy becomes predominant and the inguinal nodes may fuse together in a large mass.

The organism is an obligate intracellular organism, and rectal cultures are usually inconclusive. A biopsy of the rectal mucosa is probably the most commonly used method to confirm the diagnosis. The diagnosis of chlamydial infections used to be difficult because satisfactory culture techniques were not widely available. Diagnosis usually required the detection of rising antibody titers. The organism, however, now can be identified by using tissue culture techniques or DNA probes.

Chlamydial infections should be treated as soon as the diagnosis is suspected. The recommended treatment for non-LGV chlamydial infection is doxycycline or, alternatively, erythromycin for 7 to 14 days. LGV chlamydial infection should be treated with tetracycline and sulfonamides for a minimum of 21 days.

Sexual abstinence until eradication with antibiotics, education, testing, and treatment of sexual partners is recommended.

## **Herpes Simplex Virus**

Anorectal herpes is usually caused by the type 2 herpes simplex virus (HSV-2), although the HSV-1 virus is responsible for approximately 10% of anal infections. Patients who have been previously infected have virus-specific antibodies. The first symptoms of infection are perianal pruritus or paresthesia, followed by intense anal pain. Small vesicles surrounded by red areolas may appear. These vesicles subsequently rupture, leaving small ulcers that appear on the perianal skin, in the anal canal, or even on the rectal mucosa. Fever and malaise are frequently present. The ulcerated lesions may become secondarily infected, with increased pain and discharge. The lesions usually heal in about 2 weeks. Unfortunately, a chronic relapsing course is common, although recurrent lesions are usually much less painful.

Scrapings from the base of a ruptured vesicle can be stained to show typical intranuclear inclusion bodies, but the diagnosis is most expeditiously

made by viral HSV culture.

There is no known cure for herpes. Primary or initial infections are treated with oral acyclovir, famciclovir, or valacyclovir for 7 to 10 days.<sup>35</sup> Acyclovir should be taken at the onset of recurrent symptoms, which may reduce the formation of new vesicles. Chronic suppressive therapy or self-initiation of antiviral treatment with recurrent episodes may be helpful in patients with more than six recurrences per year. AIDS patients with perianal herpes resistant to acyclovir may benefit from two newer compounds, foscarnet or vidarabine.<sup>36</sup>

Patients are contagious while the lesions are present and should abstain from sexual activity until all lesions are completely healed. Even after the lesions have completely healed, a condom should be used during sexual intercourse.

## Gonorrhea

Anorectal infections caused by the bacterium *Neisseria gonorrhoeae* are common in the male homosexual population and frequently accompany other venereal diseases. Over half of homosexual men seen in screening clinics have been found to be infected, with the rectum being the only site infected in about half of cases. The majority of these infections are asymptomatic.<sup>37</sup>

Symptoms vary from none to intense anorectal pain and tenesmus accompanied by a viscid, yellow anal discharge. Anoscopy may reveal anositis or distal proctitis. Diagnosis is confirmed by obtaining cultures from the rectal discharge or mucosa, or more recently by DNA probes.

Treatment should be initiated if the disease is suspected. Untreated rectal gonorrhea can lead to septic arthritis, endocarditis, perihepatitis, and meningitis, as well as infection of sexual partners. Several drugs (penicillin, tetracycline, ampicillin, and spectinomycin) may be used for treatment, although increasing numbers of resistant strains are being recognized. Cultures should be repeated after treatment is completed, because antibiotic therapy may fail in as many as one-third of the patients. All sexual contacts also must be treated. All patients with confirmed rectal gonorrhea should have a serologic test for syphilis 3 months after treatment is completed.

## Syphilis

The classic lesion of primary syphilis is a chancre on the genitalia, but in homosexual males the chancre usually presents in the anal canal or at the anal verge.<sup>38</sup> These ulcerated lesions may mimic an anal fissure, but an aberrant location of the lesion (eg, lateral anus instead of midline) should arouse suspicion. Classic descriptions indicate that the syphilitic chancre is a painless lesion, but anal chancres may be extremely painful. The causative organism is the spirochete, *Treponema pallidum*, which may occasionally cause severe proctitis without an accompanying chancre. Inguinal adenopathy is common.

Early syphilis can be diagnosed by examining scrapings from the base of the chancre with dark-field microscopy; these lesions teem with spirochetes that can be seen as corkscrew-shaped motile fluorescent yellowish-green organisms. Serology is also very helpful in establishing the diagnosis. In untreated primary syphilis, the Venereal Disease Research Laboratory assay is reactive in about 75% of cases, in early latent syphilis about 95%, and in the secondary state it is 100% reactive. The fluorescent treponemal antibody absorption test usually becomes positive about 4 to 6 weeks after the initial infection. Rapid plasma reagin and darkfield microscopy are the appropriate tests for suspected early syphilis.

The second stage of anal syphilis appears 6 to 8 weeks after the chancre has healed in untreated patients. It may present as condyloma latum, a pale-brown or flesh-colored flat verrucous lesion, or as a mucocutaneous rash. All three serologic tests for syphilis will be positive at this stage. Skin lesions are highly contagious.

Benzathine penicillin G is the treatment of choice for syphilis. Alternative treatments include doxycycline, tetracycline, or erythromycin. Patients with syphilis must abstain from sexual contact until treatment is complete. All sexual contacts within the preceding 90 days should be prophylactically treated.

# CONSTIPATION AND INCONTINENCE

*Alexander T. Hawkins • Liliana G. Bordeianou*

## INTRODUCTION

Constipation and fecal incontinence are 2 forms of evacuatory dysfunction that cause significant morbidity across ages and populations. Both are end symptoms of a range of etiologies that are often linked. Diagnosis and treatment depend on a detailed examination and careful workup. Some etiologies are easily treated, whereas others require extensive therapy in a multidisciplinary setting.

## CONSTIPATION

Constipation is a broad term used by both patients and practitioners, with variable meaning. The Rome III definition of functional constipation requires 12 weeks of symptoms in the past 6 months, including at least 2 of the following symptoms: straining at defecation on at least 25% of defecations, lumpy or hard stools in at least 25% of defecations, sensation of incomplete evacuation for at least 25% of defecations, sensation of anorectal

obstruction/blockage for at least 25% of defecations, manual maneuvers to facilitate at least 25% of defecations (eg, digital evacuation, support of the pelvic floor), and less than 3 defecations per week (Table 53-1).<sup>1</sup>

**TABLE 53-1: ROME III CRITERIA FOR FUNCTIONAL CONSTIPATION<sup>a</sup>**

Must include 2 or more of the following:

- a. Straining during at least 25% of defecations
- b. Lumpy or hard stools in at least 25% of defecations
- c. Sensation of incomplete evacuation for at least 25% of defecations
- d. Sensation of anorectal obstruction/blockage for at least 25% of defecations
- e. Manual maneuvers to facilitate at least 25% of defecations (eg, digital evacuation, support of the pelvic floor)
- f. Fewer than 3 defecations per week.

Loose stools are rarely present without the use of laxatives

Insufficient criteria for irritable bowel syndrome

---

<sup>a</sup> Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

## Pathophysiology and Etiology

Multiple conditions and medications can result in functional constipation. Colonic motility, rectal sensation, distention, and propulsion aided by pelvic floor relaxation must all work in concert for stool to develop normally and pass through the colon, rectum, and anus. Constipation can be classified into 3 broad subtypes: constipation-predominant irritable bowel syndrome (IBS-C), colonic transit disorder, and obstructed defecation syndrome (ODS). Differentiating between these 3 main etiologies requires a careful history and tailored evaluation.

IBS-C is a functional gastrointestinal disorder characterized by recurring symptoms of abdominal pain, bloating, and altered bowel habits. Irritable bowel syndrome (IBS) is suspected by recurrent abdominal pain or discomfort at least 3 days per month in the past 3 months associated with 2 or

more of the following: improvement with defecation, onset associated with a change in frequency of stool, and onset associated with a change in form (appearance) of stool. IBS symptoms are not treated surgically.

Colonic transit disorder is a gastrointestinal dysmotility syndrome. Symptoms suggestive of slow transits include long intervals between bowel movements, bloating, abdominal distention, megacolon, colonic fecalization, and secondary small bowel obstruction due to constipation.

ODS is associated with a range of symptoms including incomplete and/or painful evacuation, excessive straining, sensation of incomplete evacuation, and the need to insert a finger into the vagina or anus in order to evacuate bowel contents (ie, “splinting”). ODS accounts for 50% of constipation cases and is most commonly seen in women older than age 65years.<sup>2</sup> It has a 60% association with both depression and anxiety.<sup>3</sup>

## **Diagnosis and Evaluation**

The above subtypes of constipation are not mutually exclusive and often coexist. In absence of alarm symptoms, such as new onset of symptoms at 50 years or older, unintentional weight loss, nocturnal diarrhea, anemia, bloody stools, family history of colon cancer, celiac disease, or inflammatory bowel disease, patients can be initiated on an empiric trial of fiber therapy, especially if their symptoms appear consistent with IBS-C.<sup>4</sup> However, if routine medical therapy fails, further diagnostic testing should be considered to further determine the etiology of constipation.

Initially, the evaluation should always be guided by a careful history and a complete perianal and anoscopic examination. This will help rule out alternative pathology such as hemorrhoids, anal stricture, rectal stricture, or rectal prolapse. Laboratory studies for thyroid hormone and calcium levels can exclude metabolic etiologies of constipation. Endoscopy can evaluate for obstructing colonic lesions, diverticular strictures, or inflammatory bowel disease. In absence of obvious obstruction, subsequent workup of constipation should attempt to exclude functional constipation. To accomplish this, patients should undergo anorectal physiology and colonic motility testing.

## **ANORECTAL PHYSIOLOGY TESTING**

Anal manometry is one of the main testing procedures performed with the goal of delineating the etiology of constipation (Fig. 53-1). The test is performed with either air- or water-charged systems. Anal resting and squeeze pressures are calculated at each centimeter starting at 6 cm from the anal verge. The high-pressure zone is identified, and mean resting, maximum resting, and maximum squeeze pressures are calculated using standardized American Society of Colon and Rectal Surgeons definitions.<sup>5</sup> In addition, the test includes a quantification of rectoanal inhibitory reflex (RAIR). The RAIR describes the relaxation of the internal anal sphincter with distension of the rectum. This reflex is thought to be essential for the discrimination between gas and stool and the ability to pass them independently. Notable causes for absence of the reflex include Hirschsprung disease, circumferential myotomy, and overly aggressive lateral sphincterotomy. Other relevant findings on anorectal manometry in a patient with constipation may be the presence of elevated resting and squeeze pressures, which may suggest ODS. However, the absence of elevated sphincter pressures alone does not reliably exclude outlet obstruction, and other testing for pelvic floor dyssynergia (balloon expulsion testing and electromyography) and for intermittent anatomic outlet obstruction (defecography) is recommended when this diagnosis is high on the differential.<sup>6</sup>

**FIGURE 53-1** Anal manometry.

## BALLOON EXPULSION TESTING

Balloon expulsion testing is an easy, inexpensive way to evaluate evacuation. A balloon is inserted in the rectum and inflated to 60 mL. Patients are asked to expel the balloon on a commode, with the expectation that a normal subject should be able to do so within 1 to 5 minutes. Patients unable to expel the balloon are suspected to have outlet obstruction, otherwise not specified. The test does not differentiate between the causes of outlet obstruction

(dyssynergia vs anatomic).

## **ELECTROMYOGRAPHY**

Electromyography (EMG) aids in the diagnosis of pelvic floor dyssynergia due to a nonrelaxing puborectalis. The test can reveal a paradoxical or nonrelaxing puborectalis muscle ([Fig. 53-2](#)). A small EMG sponge containing 2 electrodes is gently positioned into the rectum and then pulled back until the recording electrodes lodge in the anal sphincter. EMG tracings are then obtained at rest, squeeze, and push. The presence of reproducible contractions when the patient attempts to push the sponge out is defined as abnormal.

**FIGURE 53-2** Paradoxical electromyography.

## **DEFECOGRAPHY**

Fluoroscopic defecography allows for evaluation for intermittently occurring, obstructing pathology caused by the shifting of the pelvic organs during the act of defecation. This is a dynamic, real-time study that can reveal the presence of internal intussusception, enteroceles, sigmoidoceles, and rectoceles. It is a useful test to rule out dyssynergy that would otherwise be undiagnosed.<sup>6</sup> Before examination, patients are asked to drink liquid barium or Gastrografin to opacify the small bowel. A scout abdominal radiograph is then done after 1 hour to confirm that the contrast agent has reached the right colon. The patient is then positioned in the left lateral decubitus position on the fluoroscopy table. If the patient is a woman, 10 mL of barium cream is inserted into the vagina using a catheter syringe. Then approximately 400 mL of thick paste with the consistency of stool is inserted into the rectum. In women, a barium pill is taped to the perineal body. The patient is then asked to sit down in an upright position onto a specially designed radiolucent upright commode. A single image is acquired when the patient is sitting on the commode at rest. The patient is then asked to strain but hold in the contrast material while a second image is acquired. Finally, the patient is asked to try to evacuate the rectum. Defecography images are acquired during pulsed fluoroscopy at a rate of 1 per second for 30 seconds or as needed. They can also be videotaped continuously. If contrast material remains in the rectum, the patient is asked to try again, using finger manipulation or another method to aid evacuation if that is what they normally do.

In the absence of defecography equipment, which requires fluoroscopy and a radiolucent commode, dynamic upright magnetic resonance imaging (MRI) in a sitting position can be obtained. However, upright MRI machines are expensive and scarce and have a lower signal-to-noise ratio and soft tissue resolution.<sup>7</sup>

## **COLONIC TRANSIT TESTING**

A number of options are available to assess colonic transit time. The most widely available technique involves ingestion of radiopaque markers and serial abdominal radiography refined by Metcalf et al.<sup>8</sup> Patients must prepare

for the test by refraining from all enemas, laxatives, and nonessential medications 2 days before the test. Capsules containing 24 radiopaque markers are ingested. An abdominal radiograph is obtained at 5 and 7 days, and colonic transit is deemed abnormal if >30% of markers are retained (Fig. 53-3). The pattern of accumulation is also diagnostics. Left-sided or rectal accumulation suggests ODS, whereas right and transverse colon distribution suggests colonic inertia. Cowlam et al<sup>9</sup> challenged this dogma with their study of 108 patients with functional constipation. They found no correlation between the pattern of marker distribution and any of the parameters suggesting ODS.

**FIGURE 53-3** Abnormal sitz markers dispersed throughout the colon, with concentration in the rectum. Interpretation would be concurrent colonic dysmotility and obstructed defecation syndrome.

The SmartPill (SmartPill Corporation, Buffalo, NY) is a new wireless pH and pressure recording capsule that allows for assessment of regional (gastric, small bowel, and colonic) and whole gut transit time without radiation. It reveals hitherto unrecognized sex differences and upper gut dysfunction in constipation. It correlates well with radiopaque markers and offers a standardized method of discriminating normal from slow colonic transit.<sup>10</sup> Although promising, the utility and role of gut transit assessment with a capsule remain to be seen. Utilization may also be decreased by its cost and reluctance of many insurance carriers to cover the expense given lack of proven additional benefit.

## SYNTHESIZING RESULTS

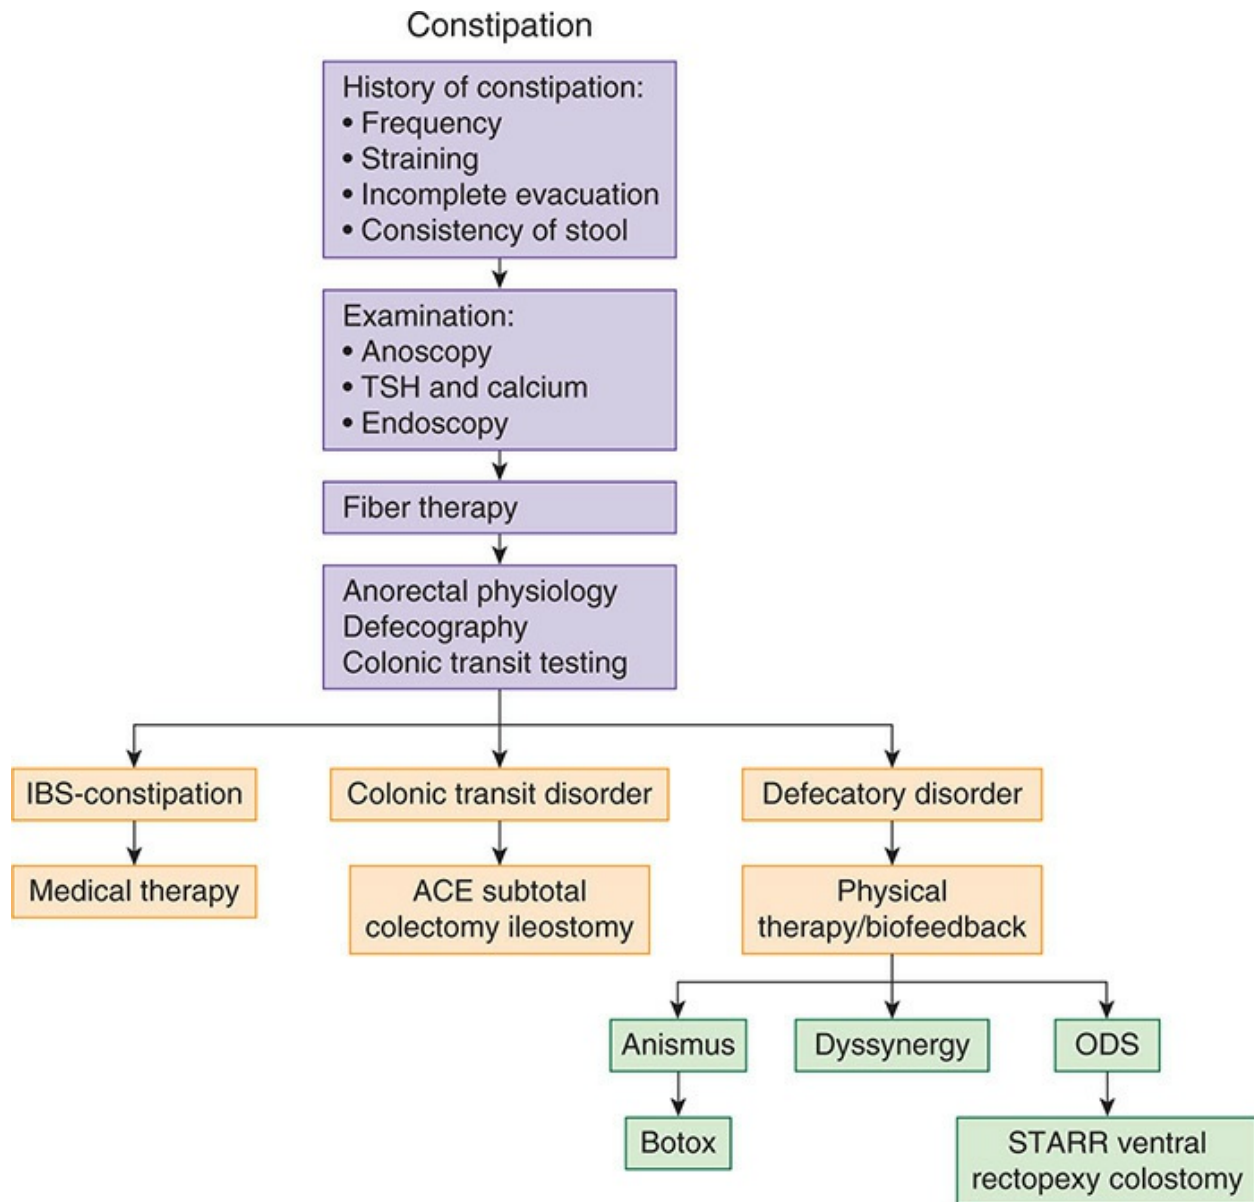

After evaluations guided by history, the clinician should be able to classify the patient into 1 of the following groups. It should be noted that these groups are not mutually exclusive and overlap is common.

1. Normal transit constipation with normal colonic transit and defecation; some patients will have symptoms of IBS
2. Slow transit constipation
3. Defecatory disorder (anismus/dyssynergy/ODS)
4. Combination of 2 and 3 above; clinical observations suggest patients will have features of IBS
5. Organic constipation (mechanical obstruction or adverse drug effect)
6. Secondary constipation (metabolic disorder)<sup>4</sup>

Accurate classification is important because it will dictate management strategy.

## Management

Figure 53-4 provides an algorithm for the evaluation and treatment of constipation.

**FIGURE 53-4** Algorithm for evaluation and treatment of constipation. ACE, antegrade colonic enema; IBS, irritable bowel syndrome; ODS, obstructed defecation syndrome; STARR, stapled transanal rectal resection; TSH, thyroid-stimulating hormone.

## MEDICAL

The hallmark of medical management is increasing fiber in a patient's diet. Fiber can be either soluble (eg, nuts, beans, fruit, lentils, vegetables, barley) or insoluble (eg, whole wheat, whole grain, vegetables, wheat bran). Fiber supplementation can include psyllium-based products such as Metamucil or

non-psyllium-based products such as polycarbophil (FiberCon) or dextran (Benefiber). A randomized study in 275 patients revealed superior results for psyllium (10 g twice daily), but not bran, when compared with placebo at 1 month. At 3 months, bran was better than placebo.<sup>11</sup> Fiber therapy can have side effects, including gas, bloating, decreased motility, and abdominal pain. The key to introducing dietary fiber supplements is to start with a low dose and slowly increase. Patients should be counseled that improvement might not be seen for 2 to 4 weeks.

Recommendations on laxative therapy suffer from a lack of strong data. Osmotic laxatives are first-line therapy and include polyethylene glycol (PEG)-based products as well as milk of magnesia. In a controlled 6-month trial with 304 patients, successful treatment was seen in 52.0% of subjects in the PEG arm and 11% of subjects in the placebo arm.<sup>12</sup> Stimulant laxatives, such as bisacodyl (Dulcolax) and senna (Senocot), should be used with caution due to concern about addiction.

More recently, intestinal secretagogues such as lubiprostone and linaclotide have shown promise in the management of constipation. Secretagogues accelerate transit and facilitate defecation by stimulating efflux of ions and water into the intestinal lumen. Lubiprostone and linaclotide have shown efficacy for both chronic constipation and women with IBS-C.<sup>13-15</sup>

## **BIOFEEDBACK FOR ODS**

For patients with ODS and/or dyssynergy, biofeedback therapy should be first-line therapy. Biofeedback teaches patients to relax the anus and puborectalis during defecation. It appears to be very effective in treating ODS, with 63% of patients with constipation having improvement after  $\geq 5$  training sessions,<sup>16</sup> 71% of patients with pelvic floor dyssynergia having improvement lasting up to 2 years after 5 sessions,<sup>17</sup> and 28% of patients with ODS and internal intussusception having at least partial improvement after 2 sessions.<sup>18</sup> In a systematic review, biofeedback conferred a six fold increase in the odds of treatment success when compared to medical management alone.<sup>19</sup> EMG-assisted biofeedback appears to have the best results. Shim et al<sup>20</sup> described predictors of biofeedback success as harder stools, shorter duration of laxative use, higher straining rectal pressure, and

prolonged balloon expulsion.

## **SURGERY**

Surgery for constipation should be considered only after medical therapy has failed and symptoms severely compromise activities of daily living.

Interventions are divided into procedures for slow transit constipation and those for obstructed defecation. Some patients may need a combination of the 2 based on their individual presentation and testing results.

### **Procedures for Treating Slow Transit Constipation**

***Subtotal Colectomy.*** For patients with documented severe slow transit constipation without ODS, a subtotal colectomy with ileorectal anastomosis should be strongly considered. This procedure has been shown to reliably increase bowel movement frequency in patients with slow transit constipation.<sup>21</sup> Although functional outcomes are generally good, patients may report persistent abdominal pain (41%-52%), postoperative incontinence (21%), diarrhea (46%), and recurrent constipation (0%-33%).<sup>22,23</sup> However, most patients are satisfied with the results and state they would undergo subtotal colectomy again if given a second chance.<sup>24</sup> Proper patient selection is crucial to the success of surgery.

***Sacral Nerve Stimulation.*** First developed for urinary and fecal incontinence, the use of sacral nerve stimulation (SNS) to treat both slow transit and pelvic floor constipation has increased, especially in Europe. In the largest study to date, 39 (87%) of 45 patients who received SNS achieved treatment success. Colonic transit normalized in half of patients with baseline slow transit.<sup>25</sup> However, in the intent-to-treat population of 48 patients, only 14 (29.2%) met the definition of a successful outcome at a median of 25 months.<sup>26</sup> SNS has yet to be approved for use for constipation in the United States by the US Food and Drug Administration (FDA).

***Antegrade Colonic Enema.*** Antegrade colonic enema involves creation of either an appendiceal conduit or an indwelling cecostomy catheter followed by regularly scheduled instillation of either water or PEG solution.<sup>27,28</sup> This procedure is most frequently used in the pediatric population, and adult data

are limited but encouraging.<sup>29</sup>

**Stoma.** For patients with slow transit constipation accompanied by bloating and abdominal pain, an ileostomy can be both destination therapy and a diagnostic tool to determine if symptoms are attributable to the small or large intestine. In general, in these situations, a concomitant colectomy is not recommended.

**Procedures for Treating Constipation due to Intermittent Anatomic Obstructed Defecation.** For patients with ODS, the next step is to decide who needs an operation and who will benefit from other therapy. Regardless of whether or not an anatomic cause of ODS is identified on defecography, surgical intervention is only considered in patients who failed medical management and  $\geq 6$  biofeedback training sessions. This is due to the thought that anatomic ODS may be secondary to inciting dyssynergia, which needs to be treated first.<sup>30</sup> In a prospective cross-sectional cohort study of 270 ODS patients, Hicks et al<sup>31</sup> found that 71.1% of patients with ODS and a coexisting rectocele responded to medical management and biofeedback alone and therefore avoided surgery.

**Botulinum Toxin Type A (Botox).** To augment biofeedback teaching and retraining, botulinum toxin type A (BTX-A; Botox) injections have been proposed as a method to induce chemical denervation of the puborectalis. Results are mixed. Ron et al<sup>32</sup> studied 25 patients who underwent injections. Although 75% achieved manometric relaxing, only 29.2% had symptomatic improvement on a straining index. Faried et al<sup>33</sup> studied 60 patients with anismus and randomized them to either biofeedback, BTX-A, or partial division of puborectalis (PDPR). The groups differed significantly regarding clinical improvement at 1 month (50% for biofeedback, 75% for BTX-A injection, and 95% for PDPR), and differences persisted at 1 year (30% for biofeedback, 35% for BTX-A injection, and 70% for PDPR). Constipation score of the patients significantly improved after PDPR and BTX-A injection.<sup>33</sup>

**Stapled Transanal Rectal Resection (STARR).** STARR was designed to treat the anatomic abnormality of internal intussusception and/or rectocele. Two circular staplers are used sequentially to perform an anterior and posterior

full-thickness rectal wall resection ultimately producing a circumferential transanal resection of the rectum. This eliminates the obstruction caused by the intussuscepting rectum and/or rectocele into the anus and the ODS attributable to these.<sup>34</sup> Functional outcomes are reported as excellent in some studies, with 80% to 90% resolution of symptoms.<sup>35</sup> However, subsequent studies have not been able to replicate that success and describe persistent symptoms in 35% to 44% of patients.<sup>36,37</sup> Large rectoceles, anismus, sense of incomplete evacuation, pelvic floor descent, and digitation predict poor outcomes.

**Ventral Rectopexy.** Ventral rectopexy involves suspension of the anterior rectum to the sacral promontory with mesh. Good results have been reported in the literature. In one study, D'Hoore et al<sup>38</sup> performed ventral rectopexy in 50 patients for both incontinence and ODS. In 28 of 31 patients with incontinence, there was a significant improvement in continence. Symptoms of obstructed defecation resolved in 16 of 19 patients. During follow-up, new onset of mild obstructed defecation was noted in only 2 patients.<sup>38</sup> Follow-up studies have confirmed excellent outcomes. In a study of 100 patients undergoing laparoscopic ventral rectopexy for both fecal incontinence and/or constipation, constipation improved in 82 (92%) of 89 patients.<sup>39</sup>

**Stoma.** For patients with isolated severe outlet obstruction, end colostomy can be considered. As stated earlier, when a slow transit component exists as well, an ileostomy is more appropriate.

## Conclusion

Constipation is a multifactorial disorder. Differentiation between subtypes is essential for accurate diagnosis and can be achieved with careful attention to the reported symptoms and thoughtful approach to testing. Aggressive medical management is always the first, second, and third step. Many patients with ODS symptoms will also benefit from biofeedback. Surgery is an option of last resort with borderline efficacy. Patient collaboration with treatment is essential in ensuring long-lasting success.

## FECAL INCONTINENCE

Fecal incontinence is an emotionally devastating medical disorder that can affect both men and women. Seen in up to 25% of elderly women, it is also common in those who have experienced traumatic or obstetric injury. Although not life threatening, fecal incontinence can result in a serious decrease in quality of life, resulting in depression, agoraphobia, and anxiety, and the effect on quality of life correlates with the severity of the condition.<sup>40</sup> Treatment is guided by a focused workup and can result in lasting improvement. Even incremental improvements in severity are meaningful given the gradient in the impact on the quality of life.

## **Etiology and Pathophysiology**

Normal continence has several components. Rectal capacitance and compliance are essential for normal defecation. The rectum normally holds between 200 and 250 mL. It has limited muscular activity intrinsically and distends readily with filling. The internal anal sphincter provides 80% of the resting anal sphincter pressure that provides the resistance to gas and mucus at the anal canal. The sampling reflex is a function of rectal distension causing internal anal sphincter relaxation via an intermural reflex to the internal sphincter. The contents of the rectum can then be sensed in the sensory nerve-rich transitional zone and anoderm to discriminate the true nature of rectal contents. This sampling reflex occurs throughout the day to provide continence and also serves to initiate the defecation process. The voluntary external sphincter muscle contraction in response to this sampling reflex provides the final active component of fecal continence. The subconscious, voluntary contraction of the external sphincter, puborectalis, and pelvic floor muscles provides complete control of rectal contents. The pelvic floor muscles maintain continuous activity, even during sleep, to provide fecal continence.

Fecal incontinence is defined as the inability to control the passage of gas, liquid, or stool until a socially acceptable time and place for evacuation. The frequency of the incontinence may vary, and the loss of control may involve gas, liquid stool, or solid stool. Frequent episodes of incontinence of gas alone can be just as debilitating as passage of stool. Evaluation of incontinence must include assessment of both severity of disease and impact on quality of life. A number of well-validated, easy-to-use surveys are available for both clinical and research use.<sup>41,42</sup>

The etiology of fecal incontinence is often multifactorial and requires thoughtful evaluation. A review of the 2005–2006 National Health and Nutrition Survey found progressive incidence of fecal incontinence with increasing age from 2.9% in women 20 to 39 years old to 21.6% in women > 80 years old.<sup>43</sup> Anal weakness can be the end result of a multitude of etiologies (Table 53-2). Mechanical disruption due to trauma results in division or damage to the external sphincter muscle. Neurogenic incontinence results from stretching of the pudendal nerves from prolonged labor, descent of the perineum and nerve stretch during straining during defecation, or rectal prolapse. Idiopathic incontinence is seen in patients with medical diseases such as diarrhea or inflammatory bowel disease or patients who use sedatives that cause poor sensation in the anal canal.

## Diagnosis and Evaluation

Evaluation begins with a thorough history, including frequency and duration of incontinence. History of anal trauma, including surgical and obstetric, should be obtained. Patients should also be queried for a history of scleroderma, inflammatory bowel disease, and neurologic disease. After a careful physical exam including a rectal exam and anoscopy, patients may

benefit from manometry, pudendal nerve terminal motor latency, anorectal ultrasound, and potentially defecography.

Keating et al<sup>44</sup> demonstrated the limitations of mere history and physical exam in the diagnosis of fecal incontinence. In his study, 50 patients with fecal incontinence were seen by 2 physicians who diagnosed etiology and suggested treatment based on traditional evaluation alone. Patients then underwent anorectal physiology testing and ultrasound. The plan had to be changed in 20% of patients.<sup>44</sup>

## **MANOMETRY**

Anorectal manometry provides essential functional information about the anal sphincters. Details about manometric evaluation have been discussed earlier in this chapter. In the evaluation of fecal incontinence, a number of different patterns can be recognized in manometric pressures. Normal *mean resting pressure* in an adult ranges from 40 to 70 mm, and a large percentage of this comes from the internal anal sphincter. Patients with fecal incontinence often have low resting pressure. *Mean squeeze pressure* is normally 2 to 3 times the resting value and is mostly provided by the external sphincter. As such, damage to the external sphincter from childbirth or surgery can cause decreased squeeze pressure. *Rectal sensation* is measured by slowly inflating a balloon in the rectum. Normal volunteers normally encounter sensation at 40 mL of air. Patients with overflow incontinence often require higher volumes to generate sensation. Finally, *rectal compliance* is the measured change in pressure in response to change in volume within a water-filled or air-filled balloon within the rectum. Patients with a noncompliant rectum can develop fecal incontinence because their rectum is unable to accommodate the stool bolus.

## **PUDENDAL NERVE TERMINAL MOTOR LATENCY**

Neuropathy of the pudendal nerve is a known etiology of fecal incontinence. Testing of the pudendal nerve terminal motor latency (PNTML) is a necessary component of the evaluation of fecal incontinence. A disposable electrode is attached to the practitioner's finger, inserted into the anus, and directed toward the ischial spines bilaterally. Electrical impulses are then delivered to the pudendal nerve, and the time for response at the external

sphincter is measured.<sup>45</sup> Normal response is within  $2.0 \pm 0.2$  milliseconds. Ricciardi et al<sup>46</sup> showed that the majority of incontinent patients with intact sphincters have abnormal PNTML. Bilateral, but not unilateral, prolonged PNTML is associated with poorer function and physiology in the incontinent patient with an intact sphincter.<sup>46</sup> Loganathan et al<sup>47</sup> related PNTML to manometry and showed that in patients with an intact anal sphincter, either unilateral or bilateral prolonged PNTMLs are associated with significantly decreased resting and squeeze pressures. This suggests that both internal and external sphincter function is impaired with pudendal nerve injury and that the inhibition of internal sphincter function may be due to damage of autonomic, principally sympathetic fibers carried in the pudendal nerve.<sup>47</sup>

## **ANAL ULTRASOUND**

Anal ultrasound is a technique to image the internal and external anal sphincter muscles as well as the puborectalis muscle. After an enema and a digital rectal exam, a rigid rotating probe with a 360-degree radius and an ultrasound frequency of between 5 and 16 MHz is introduced into the rectum. The probe is then slowly withdrawn so that the pelvic floor and sphincter complex are completely visualized. Recent software allows for 3-dimensional reconstruction of the images.

Anal ultrasound assesses muscle thickness and integrity. Scarring, loss of muscle tissue, or other local pathology can all be identified (Fig. 53-5). Internal sphincter defects tend to be identified more reliably than external defects.<sup>48</sup> Like other varieties of ultrasound, the quality of the examination is markedly operator dependent.<sup>49</sup> When relating ultrasound findings to manometry, defects in the internal sphincter are accompanied by lower resting pressures, while defects in the external sphincter are associated with lower maximum anal squeeze pressures.<sup>40,50</sup> In addition, the size of the external anal sphincter defect inversely correlates with the maximum squeeze pressure.

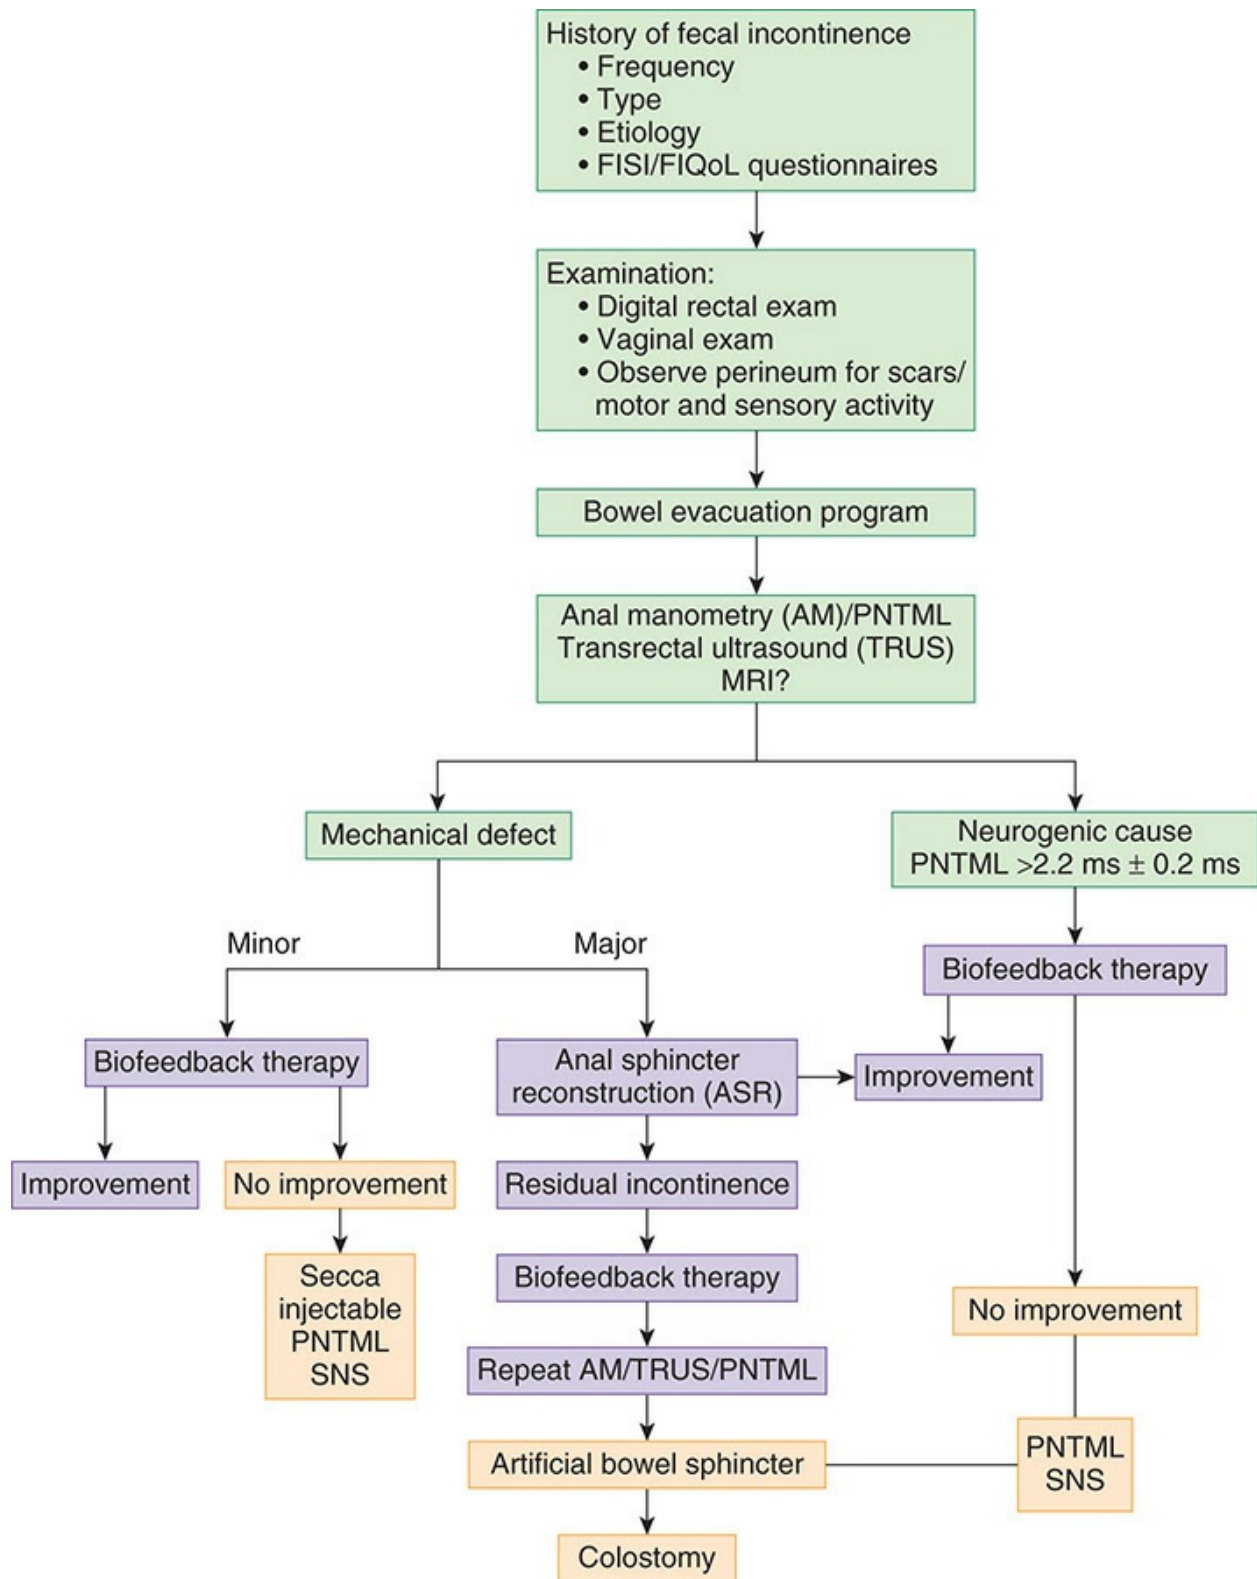

**FIGURE 53-5** External sphincter defect. Note associated internal sphincter tear and retraction.

## DEFECOGRAPHY

With normal results in the above testing, fluoroscopic defecography can be helpful in identifying cryptic causes of fecal incontinence. Internal intussusception or intermittent rectal prolapse may weaken the anal sphincters and result in incontinence. Defecography can also identify incomplete evacuation, which might suggest overflow incontinence as a cause of symptoms. The technique is described above.

## Management

[Figure 53-6](#) provides an algorithm for the evaluation and treatment of fecal incontinence.

**FIGURE 53-6** Algorithm for evaluation and treatment of fecal incontinence. FIQoL, Fecal Incontinence Quality of Life Scale; FIS, Fecal Incontinence Severity Index; MRI, magnetic resonance imaging; PNTML, pudendal nerve

terminal motor latency; SNS, sacral nerve stimulation.

## **MEDICAL**

Before consideration of surgical treatment, management of fecal incontinence should first begin with fiber supplementation to increase stool consistency, loperamide to decrease stool frequency, and amitriptyline to increase rectal sensory thresholds to fecal stimulation. Patients should also be instructed in bowel evacuation protocols using daily evacuation with glycerin suppositories. All patients with diarrhea should have a thorough workup and treatment of diarrhea, with treatment tailored to its etiology.

## **BIOFEEDBACK**

Biofeedback uses visual, auditory, and sensory information to improve a patient's ability to sense rectal fullness and retrain appropriate sphincter contraction. Engel et al<sup>51</sup> published the first report of the technique in 1974, using a Miller-Abbott balloon as a sensor attached to a polygraph to improve the quality of Kegel exercises. Heymen et al<sup>52</sup> assigned 108 patients to either biofeedback or pelvic floor exercises. Biofeedback training increased anal canal squeeze pressure more than pelvic floor exercises. Three months after training, 76% of patients treated with biofeedback versus 41% of patients treated with pelvic floor exercises reported adequate relief.<sup>52</sup> Current treatment is variable and can include weekly or biweekly sessions of 30 to 60 minutes each on a number of different machines. Jodorkovsky et al<sup>53</sup> highlighted the difficulty in biofeedback, with less than half of patients recommended for biofeedback ultimately undergoing therapy. Byrne et al<sup>54</sup> studied 513 patients and found a 70% improvement rate in the short term. Treatment success was more likely in patients who completed 6 training sessions, were female, were older, or had more severe incontinence. Patients were less likely to complete treatment if they were male, were younger, or had milder incontinence.<sup>54</sup> Biofeedback should be considered a first-line option for most patients with fecal incontinence who have not responded to simple dietary modification or medication.<sup>55</sup>

## **SURGERY**

In determining the correct procedure for patients with fecal incontinence, the lack of high-quality data on the surgical treatment for fecal incontinence in adults is striking.<sup>56</sup> In many situations, treatments are offered in a sequence from simple to complex with the goal of minimizing complications while aiming to achieve an improvement in symptoms. Treatments are classified based on 1 of 3 goals: bulking the sphincter complex; reconstruction of the sphincter complex; or rewiring the defecatory neuromuscular pathway. Finally, some patients with fecal incontinence have internal or external rectal prolapse, which needs further evaluation and treatment. Finally, when all else fails, stoma and stoma alternatives can be considered.

### **Bulking or Remodeling the Sphincter Complex**

**Secca.** In patients with mild to moderate fecal incontinence who have failed fiber and biofeedback and do not have an identifiable sphincter defect, the Secca procedure is a therapeutic option. The Secca procedure involves the administration of radiofrequency to the anal canal in an attempt to cause thermal injury to the sphincters. In theory, radiofrequency-induced injury to the internal anal sphincter causes collagen deposition and fibrosis with the potential for tightening of the affected area.<sup>57</sup> It can be performed in the outpatient setting with minimal morbidity. Patients are placed in the jackknife prone position, and the probe is placed in the anal canal so that the electrodes are at the level of the dentate line. Radiofrequency is then delivered to approximately 16 to 20 sites throughout the anal canal. Ruiz et al<sup>58</sup> studied 24 patients and collected 12-month follow-up data on 16 patients. A Fecal Incontinence Score improved from a mean of 15.6 ( $\pm$  3.2) at baseline to 12.9 ( $\pm$  4.6) at 12 months. Takahashi et al<sup>59</sup> provided even longer follow-up when they studied 19 patients for 5 years. At the 5-year follow-up, the mean fecal incontinence score had improved from 14.37 to 8.26, with 16 patients (84.2%) demonstrating >50% improvement. All fecal incontinence–related quality of life scores improved.<sup>59</sup>

**Injectable Bulking Agents.** For patients with minor fecal incontinence due to internal anal dysfunction, injection of various biocompatible bulking agents has been shown to be modestly effective, although so far, only NASHA Dx (non–animal-stabilized hyaluronic acid/dextranomer) is FDA approved for use in the United States. Injection of NASHA Dx is a simple, noninvasive

procedure that can be performed in an outpatient setting. The bulking gel is injected into the anal submucosa, above the dentate line. It is thought that the injection increases the resting anal sphincter pressures by mass effect, as well as by restoring anal symmetry.<sup>60</sup> FDA approval of the agent was granted after Graf et al<sup>61</sup> randomized 206 patients to either NASHA Dx or sham injection. Seventy-one patients who received NASHA Dx (52%) had a 50% or more reduction in the number of incontinence episode, compared with 22 patients who received sham treatment (31%). They recorded 128 treatment-related adverse events, of which 2 were serious (1 rectal abscess and 1 prostate abscess).<sup>61</sup>

In general, patients considered for both Secca and NASHA Dx injections should first undergo Secca. The goal is to avoid subsequent superinfection of NASHA Dx if the Secca radiofrequency needles are deployed through the implant. Though there have been no reports of adverse events with Secca following NASHA Dx injection, this remains a preferred sequence of interventions.

## **Reconstruction of the Sphincter Complex**

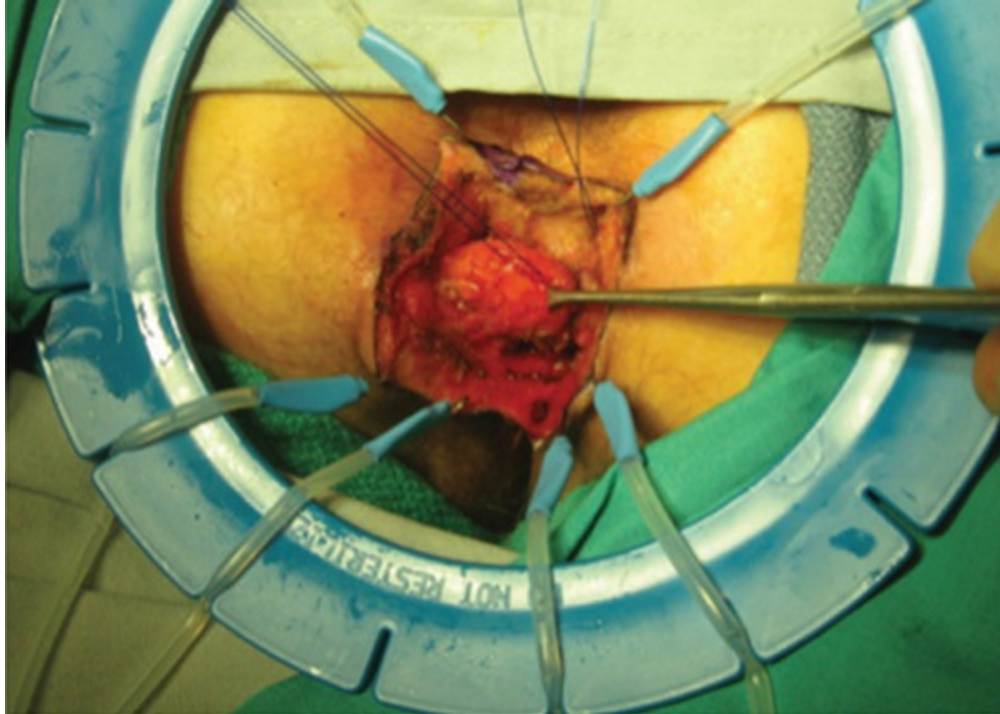

***Sphincteroplasty.*** In the appropriately selected patient, sphincter repair can reduce and even cure fecal incontinence (Fig. 53-7). The overall success rate is around 60%, and patients should be selected based on normal PNTMLs, reduced anal sphincter pressure on manometry, and a sphincter defect on ultrasound. The operation is best performed in the jackknife prone position. An elliptic incision on the perineal body is made, and the rectum is separated from the vagina all the way to the levators. The external anal sphincter is identified and freed to allow for overlap of the edges (Fig. 53-8). Slowly absorbable sutures are then used to approximate the scar and muscles in the overlapped position. The repair is covered with interrupted sutures, and the skin is closed loosely. Barisic et al<sup>62</sup> examined 65 patients undergoing overlapping anal sphincter repair; 72.3% were a result of obstetric trauma. At a mean follow-up of 80 months, 55.5% of patients reported excellent results. Bravo et al<sup>63</sup> followed 191 patients for 10 years and noted that results worsened significantly between the assessments at 3 and 10 years, with only 6% of patients reporting no incontinence at 10 years. Gearhart et al<sup>64</sup> studied 20 women with large sphincter defects (>50%) and noted that overlapping anal sphincter repair improved absolute resting and squeeze pressures and

Fecal Incontinence Severity Index scores. In addition, patients with lower scores had higher increases in their pressures postoperatively.<sup>64</sup>

**FIGURE 53-7** Anal sphincter overlapping muscle repair. **A.** Anterior incision and perineal view of muscles. **B.** Rectal flap is created, and sphincter muscles are isolated. **C.** Muscle flaps are fully mobilized. **D.** Muscle flaps are overlapped around a 15-mm rubber dilator or fingertip. **E.** Muscle flaps are sutured in place, and the perineal body is repaired. **F.** A drain is placed behind the vaginal wall and the wall closed. (Reproduced with permission from Zuidema GD: *Shackelford's Surgery of the Alimentary Tract*, 4th ed. Philadelphia, PA: WB Saunders; 1996.)

**FIGURE 53-8** Overlapping sphincteroplasty.

**Artificial Bowel Sphincter.** For patients who fail all other treatments, an artificial sphincter of silicone with a water-filled circumanal cuff may be implanted. The fluid is shifted from the sphincter-encircling cuff to a balloon implanted in the space of Retzius. The 2 reservoirs are connected via silicone tubing. The artificial bowel sphincter (ABS) has produced good results and has been FDA approved for nearly 2 decades. In patients who can tolerate device implantation without complications, overall results of ABS are excellent, with 85% of patients reporting complete or near-complete continence to solid stool. However, if results are measured on an intent-to-treat basis, the success rate was 53%, mostly due to the need to explant devices that become infected or break.<sup>65</sup> Even with improved experience, the incidence of surgical revision and explantation remains high, highlighting the importance of careful patient selection (Figs. 53-9 and 53-10).<sup>66</sup>

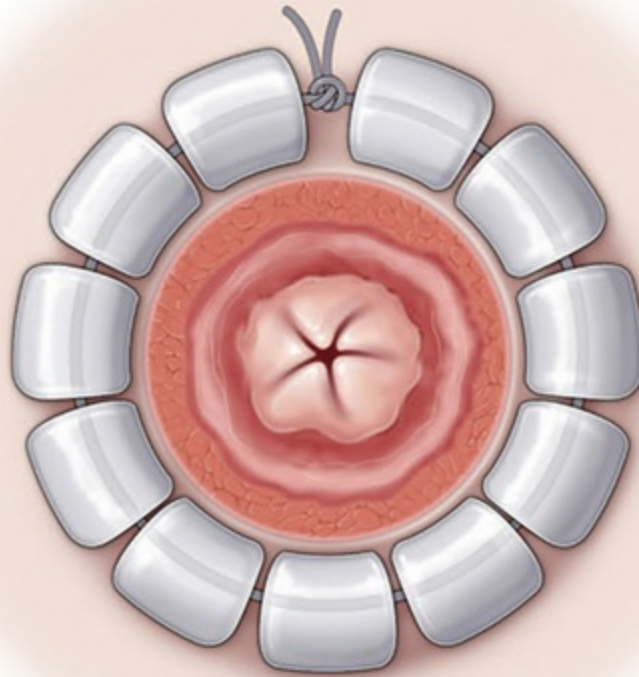

**FIGURE 53-9** Patient needs artificial bowel sphincter revision because anal cuff snapped open and it is not encircling the anus circumferentially.

**FIGURE 53-10** Artificial bowel sphincter can also leak at site of numerous tubing connections between balloon, cuff, and control button.

Magnetic sphincter augmentation, which is currently not FDA approved, may ameliorate some of the concerns regarding the frequent need for device explanation seen with traditional ABS breakage while providing equivalent benefits (Fig. 53-11).<sup>67</sup> In the largest study to date, 18 patients were implanted with the magnetic sphincter augmentation device. Bowel diary results showed that 76% of the patients with implants experienced a  $\geq 50\%$  reduction in the number of fecal incontinence episodes per week.<sup>68</sup> Further study on this device is required.

**FIGURE 53-11** Magnetic sphincter does not have many connections, so likelihood of explant once healed is lower.

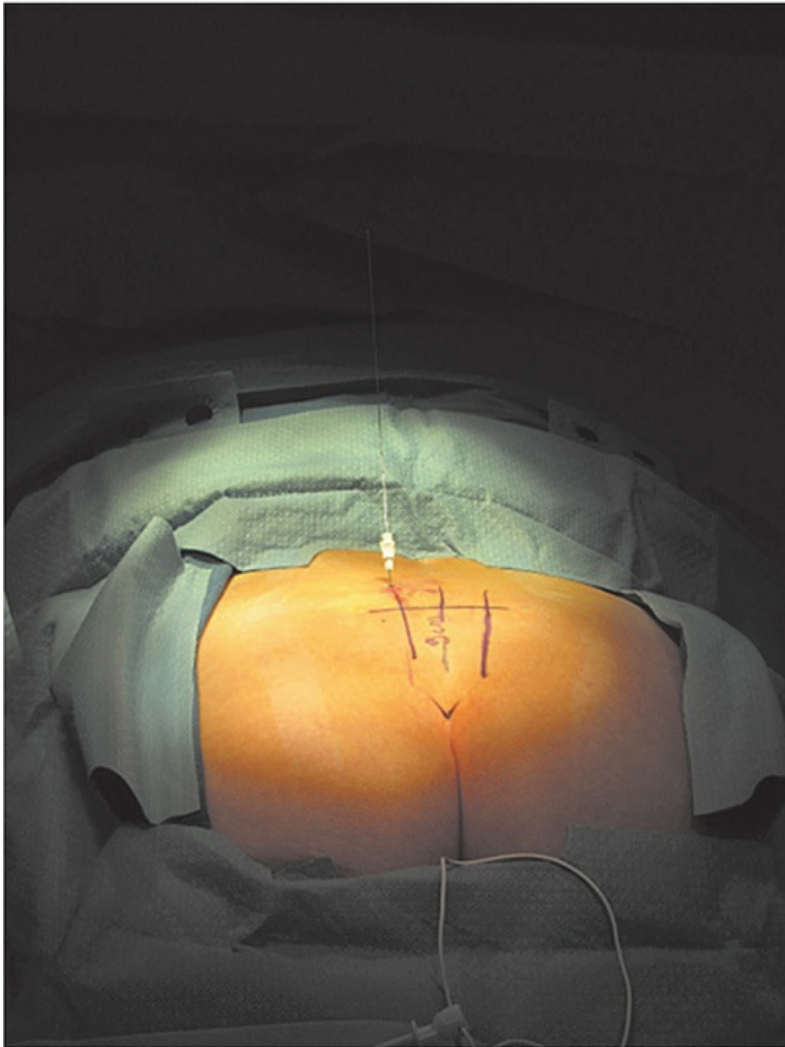

### **Rewiring the Defecatory Neuromuscular Pathway**

**Sacral Nerve Stimulation (SNS).** SNS was initially developed for urinary incontinence before Matzel et al<sup>69</sup> described its use for fecal incontinence. The goal is stimulation of the sacral nerves to recruit additional inactive motor units to improve muscle strength, resulting in an increase in resting anal pressure.<sup>70</sup> SNS is offered to all patients who do not have a large sphincter injury that may be amenable to a simpler sphincter repair and who report loss of a full bowel movement more than twice a week. It is a 2-stage procedure, with the first stage involving percutaneous nerve evaluation, which typically lasts 2 weeks. Patient who experience a 50% or greater decrease in the number of incontinence episodes are then offered placement of a permanent stimulator. The procedure is performed using fluoroscopy

under sterile conditions. (Fig. 53-12). Stimulation of the S4 nerve roots via the sacral foramina is tested, and a permanent stimulator is placed. Results reported in the literature are encouraging. Wexner et al<sup>71</sup> studied 129 patients who underwent a 2-week trial of subchronic test stimulation. One hundred and twenty patients qualified for permanent implant, and 112 patients were implanted. The mean follow-up time was 28 months, and more than 75% of patients noted persistent benefits including a 50% decrease in weekly incontinence episodes, incontinent days, and urgent incontinent episodes.<sup>71</sup> Altomare et al<sup>72</sup> reported even more robust follow-up of 272 patients who underwent SNS placement with a long-term follow-up at a median of 84 months. Significant reductions in the number of fecal incontinence episodes per week and summative symptom scores were recorded after implantation and maintained in long-term follow-up. Risk of long-term failure correlated with minor symptom score improvement during the temporary test phase.<sup>72</sup>

A

B

**FIGURE 53-12 A and B.** Sacral nerve stimulation implantation can be performed under local anesthesia.

**Posterior Tibial Nerve Stimulation.** Posterior tibial nerve stimulation (PTNS) is believed to work by stimulation of the ascending afferent spinal pathways. The tibial nerve contains afferent and efferent fibers originating from the fourth and fifth lumbar nerves and the first, second, and third sacral nerves. Stimulation of the tibial nerve may lead to changes in anorectal neuromuscular function similar to those observed with SNS, but without the need for a surgically implanted device. A recent systematic review found the success rate of PTNS, based on the proportion of patients who achieved a reduction in weekly fecal incontinence episodes of at least 50%, to be 63% to 82%.<sup>73</sup> However, a recent randomized controlled trial of 227 patients assigned to PTNS or placebo questioned these data by showing no statistical significance when accounting for a placebo effect, which was as high as 31%.<sup>74</sup>

**Stoma and Stoma Alternatives.** For patients who fail both medical and surgical therapy, a permanent end colostomy may be appropriate. Assessment of postoperative quality of life shows that patients are generally satisfied. In a series of 69 patients who underwent colostomy for fecal incontinence, 84% indicated they would “probably” or “definitely” choose to have the stoma again.<sup>75</sup>

## CONCLUSION

Fecal incontinence is a common problem and can occur in both men and women. Many forms are treatable surgically. Surgical treatment is ultimately determined by etiology. A careful, tailored workup is essential to providing the best treatment. This field is a dynamic one, and research continues on innovative techniques.

# CANCER OF THE RECTUM

*Joel Goldberg • Ronald Bleday*

## INCIDENCE AND EPIDEMIOLOGY

At the beginning of the 21st century, rectal cancer continues to be a significant medical and social problem. Currently, there are approximately 135,000 cases of colorectal cancer diagnosed in the United States each year and 50,000 deaths. Approximately 60% of all cases occur in patients older than 65 years of age. Cases that occur prior to age 65 this include 45% of men and 39% of all women diagnosed with colorectal cancer. Significant racial disparities also exist in the incidence and mortality for colorectal cancer, with non-Hispanic blacks (NHB) having the highest incidence and mortality. When compared to non-Hispanic whites (NHW), the NHB population has a 20% higher incidence of colorectal cancer and a 40% higher mortality rate. Overall survival is higher for patients with rectal cancer (67%) than colon cancer (64%), with the most likely explanation being that rectal cancer is more often diagnosed at an earlier localized stage.

Overall, 40% of colorectal tumors are in the proximal colon and 60% are in the distal colon and rectum. However, women are more likely to have proximal lesions (46%) when compared to men (37%), and this disparity increases with advancing age. At younger ages (less than 50), both men

(41%) and women (36%) are more likely to be diagnosed with rectal than colon cancer. In fact, there has been a substantial absolute increase in the risk of rectal cancer in patients born after 1970. The reason for the increased risk for rectal cancer in this young population has not been identified but is most likely related to a change in environment, either an exogenous exposure or ingested material in foods such as pesticides or food additives. Increases in the sedentary lifestyle, high-fat diet, and obesity have been suggested etiologic factors as well. As pointed out above, adenocarcinoma of the rectum accounts for nearly 30% of all colorectal cancers. This translates into about 41,000 new diagnoses of rectal cancer each year and greater than 10,000 deaths attributable to this disease within the same time.<sup>1,2</sup>

## HISTORY

The history of modern rectal cancer resection dates to 1884, when Czérny described the first abdominoperineal resection (APR). In 1885, Kraske pioneered the transsacral approach of rectal resection and anastomosis. In 1908, Miles improved on the APR by understanding that there was a “zone of upward spread.”<sup>3</sup> He emphasized the importance of performing a wide perineal excision. Consistent with this, current surgical technique includes a cylindrical resection at the level of the levators to include the entire anal canal such that there is not a “coning in” or “waist” on the specimen at the distalmost aspect of the specimen. Furthermore, Miles advocated removal of the rectum with a high ligation of the superior hemorrhoidal artery as well as excision of the abdominal attachments of the rectum and the iliac lymph nodes. Despite the improvements in oncologic resection, operative mortality in Miles’ first series exceeded 42%. Over the next 80 years through the late 1980s, mortality and morbidity for rectal cancer surgery improved markedly in pace with improvements in intra-, peri-, and postoperative care. Unfortunately, there were few, if any, advancements in oncologic techniques during this period. Then, in the late 1980s, William Heald described and began popularizing total mesorectal excision (TME) for carcinoma of the rectum.<sup>4</sup> In this technique, he advocates using sharp dissection to perform the complete excision of the mesorectum and its associated lymphatics along the subtle fascial planes that encompass the rectum. Moreover, Heald described a “zone of downward spread” within the mesorectum that requires complete

excision to reduce local recurrence. Finally, local excision of small rectal cancers has been used for over 100 years in selected patients. More recently, local excision is being combined with neoadjuvant and adjuvant chemoradiotherapy to maximize local control with a minimally invasive approach.

## ETIOLOGY AND RISK FACTORS

In Western industrialized nations, the average lifetime risk for an individual to develop colorectal cancer is approximately 6%. This risk increases two- to fourfold if the patient has a personal history of a first-degree relative with colorectal cancer. Inflammatory bowel disease (IBD) is another risk factor. In the first 10 years after the initial diagnosis of ulcerative colitis (UC), the incidence of colorectal cancer increases, and in the past was suggested to be as high as 1% per each year of disease. Recent studies, however, have demonstrated that the cumulative risk is about 2% to 7.5% at 25 to 30 years of disease duration and as high as 13.5% at 45 years of disease.<sup>5</sup> Pancolitis is associated with both an earlier and an increased risk for colorectal cancer when compared to left-sided colitis alone. Screening the colon yearly starting at 10 years after the diagnosis with colonoscopy and multiple biopsies in four quadrants every 10 cm from the cecum to the distal rectum is used to predict when a patient is at risk for developing colorectal cancer. If high-grade dysplasia is detected in any of the biopsies, the patient should be advised to have a total proctocolectomy. Some practitioners advocate a surgical resection for low-grade dysplasia as well, whereas some are willing to repeat a colonoscopy with multiple biopsies. If low-grade dysplasia is found on subsequent short-interval colonoscopy, then total proctocolectomy is advised. Ultimately, the most effective method for preventing colon cancer in patients with UC is to remove the colon once any type of dysplasia has been identified. Crohn's colitis is also associated with an increased risk for colorectal cancer. This is often not appreciated by clinicians because patients with severe Crohn's colitis often undergo proctocolectomy before their long-term risk becomes an issue. The cumulative risk for colon and rectal cancer in patients with Crohn's colitis is 2.9% at 10 years, 5.6% at 20 years, and 8.3% at 30 years.<sup>5</sup>

Genetic risk factors also have been implicated in the development of

colorectal cancer. One is familial adenomatous polyposis (FAP), an autosomal dominant syndrome with 100% lifetime risk of developing colorectal cancer. The abnormality is caused by a defect in the *APC* gene located on chromosome 5q21. Patients with FAP develop hundreds or thousands of adenomas by their twenties, and colorectal cancer develops in all patients by age 50 years if untreated. Extraintestinal manifestations of this genetic defect include desmoid tumors, periampullary masses, osteomas, and medulloblastomas. A second genetic abnormality associated with the development of colorectal cancer is related to defects in the mismatch repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Genetic defects in these mismatch repair genes affect the repair of DNA replication errors and spontaneous base repair loss and contribute to hereditary nonpolyposis colorectal cancer (HNPCC) that is also known as *Lynch syndrome*. Despite the name, these cancers arise from adenomas and may account for 5% of all colorectal malignancies. In this autosomal dominant syndrome, cancers occur more often on the right side of the colon. Despite developing at a younger age, there is a better prognosis with these cancers when compared with age-matched controls with a non-HNPCC colorectal cancer. In theory, a patient with HNPCC living to age 80 years would have an 80% risk for developing colorectal cancer; additionally, there is a substantial risk of endometrial cancer (50%), ovarian cancer (15%), urinary tract cancer (10%), and gastric cancer (5%). There is a smaller but substantial risk of small intestinal (1%) and hepatopancreaticobiliary (1%) tumors as well. Family members should be screened initially at age 25 years or 10 years prior to the age at which the first family member was diagnosed with a neoplasm. Screening should include yearly colonoscopy and esophagogastroduodenoscopy (EGD) every 3 years (unless there is a family history of gastric cancer when yearly EGD is advised). If an endoscopically unresectable polyp or cancer is detected, a total abdominal colectomy with an ileorectal anastomosis is recommended. Urine cytology to rule out dysplastic cells in the genitourinary tract (which is at risk for transitional cell carcinoma) is recommended. Women who desire to retain fertility should get at least once-yearly transvaginal pelvic ultrasounds and CA-125 levels. Any affected woman who has finished childbearing should consider having a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO). Any affected woman who requires a colectomy should be advised to undergo simultaneous prophylactic TAH-BSO. Finally, there is MUTYH polyposis, which is an autosomal recessive genetic defect

that predisposes to colon and rectal cancer as well. This is often referred to as the autosomal recessive FAP, as this disease has very similar features to FAP. Patients who are carriers of MYH genetic defects are also at increased risk of colorectal cancer even though they do not carry genetic defects in both alleles. These patients should have colonoscopy every 5 years.

Dietary fats, especially red-meat fats, have been implicated as a risk factor for colon and rectal cancer.<sup>6</sup> People who consume less than 15% of their diet as fat have a lower incidence of colorectal cancer, whereas those who take in 20% of their diet as fat, either as unsaturated animal fat or as highly saturated vegetable oils, have an increased risk of colorectal malignancy.

In the past few decades, several studies have linked alcohol consumption and tobacco use with an increased risk of colorectal neoplasia. Moreover, there appears to be a synergistic effect with an even greater increased risk of adenomatous polyps in people who are both smokers and drinkers.<sup>7</sup>

## POLYPS

The concept that colorectal cancers develop from polyps, or the “adenoma-to-carcinoma sequence,” was first described by Dukes in 1926. Most patients with rectal cancer have no inherited component; instead, there is an initiating genetic mutation, such as of an oncogene like *Kras*, that leads to abnormal cell growth. Subsequently, mutations resulting in inactivation of tumor suppressor genes, such as *p53*, loss of heterozygosity (LOH) on the long arm of chromosome 18 and the APC gene (even in non-FAP patients), allows for progression to cancer. In fact, in sporadic cancers, mutations in the APC gene are the most common initial genetic alteration.<sup>8</sup>

The time course for polyp development and transformation to cancer is thought to be 5 to 10 years. Most adenomas remain benign; however, histologic type, polyp size, and evidence of dysplasia are associated with transformation. Data from the National Polyp Study and St. Mark’s Hospital in London show that approximately 75% to 85% of adenomas are tubular, 8% to 15% are tubulovillous, and 5% to 10% are villous. Tubular adenomas usually form a stalk, whereas villous adenomas have a broad base (Fig. 54-1). Villous histology is associated with an increased risk of cancer development. Only 1% of polyps less than 1 cm in diameter show evidence of malignant transformation, whereas 50% of polyps greater than 2 cm in diameter harbor

areas of carcinoma.

**FIGURE 54-1** Haggitt classification of a pedunculated and sessile polyp, each of which contains an invasive cancer.

Clinically, it is important to diagnose the type, size, and number of polyps to risk-stratify patients for treatment and future surveillance. Endoscopic treatment likely reduces or eliminates the risk of colorectal cancer in patients. Rigid sigmoidoscopy and flexible sigmoidoscopy are all that are necessary to screen the rectum. Sigmoidoscopic screening should be followed by a complete colonoscopy if biopsy of a small rectal or sigmoid polyp shows adenomatous changes. Colonoscopy screening as the first study is indicated in high-risk populations such as those with a family history of colorectal cancer, a personal history of IBD, or a known familial genetic mutation (FAP/HNPCC/MUTYH). Autopsy studies have reported that adenomas are present in 20% to 60% of patients with a colorectal cancer, and synchronous cancers are found in 3% to 9% of patients. In patients who cannot undergo a preoperative colonoscopy, either a virtual colonoscopy or barium enema should be performed. If both procedures are contraindicated in these patients, colonoscopy evaluation should be performed 3 months after resection.

Treatment of the malignant rectal polyp is becoming more common with the increase in colonoscopy screening and the early diagnosis of small distal rectal cancers. Surgical treatment in part depends on the morphology of the polyp and the histologic evaluation of the resected lesion. Pedunculated malignant polyps are classified by Haggitt per the depth of invasion of the cancer within the head of the polyp and stalk<sup>9</sup> (see Fig. 54-1). Malignant polyps completely resected with greater than 2-mm margins and without stalk invasion are considered adequately treated with colonoscopic removal, provided there are no poor prognostic histologic features such as lymphovascular invasion or poor differentiation (high grade). Tumors with poor differentiation and/or lymphatic/venous invasion are associated with an increased incidence of involved lymph nodes.<sup>10</sup>

## ANATOMY

### Anatomic Landmarks

The type of therapy offered to a patient with rectal cancer depends not only on the stage of the tumor but also on its location within the pelvis and its relation to the anal sphincters. Compared with colon cancer, knowledge and appreciation of anatomic landmarks are critical in determining resectability and sphincter preservation.

The rectum, usually 15 to 20 cm in length, extends from the rectosigmoid junction, marked by fusion of the taenia coli into a completely circumferential muscular layer, to the anal canal. In males, the rectum tends to be longer (18 cm) when compared to females (15 cm). The rectum transitions from being intraperitoneal to being completely extraperitoneal 10 to 12 cm from the anus and the root of the sigmoid mesentery is approximately 19 cm from the anal verge on rigid sigmoidoscopy.<sup>11</sup> The rectum is “fixed” posteriorly and laterally by Waldeyer’s fascia and the lateral stalks, respectively. In the male patient, the anterior rectum is fixed to Denonvilliers’ fascia, a fold of two layers of peritoneum that separates the rectum from the posterior prostate and seminal vesicles. In the female patient, the peritoneal cavity descends to the pouch of Douglas, with its most dependent point being adjacent to the cervix anteriorly and mid-rectum posteriorly.<sup>12</sup> When seen endoscopically, the rectum has three valves of

Houston, the middle of which corresponds to the anterior peritoneal reflection ([Fig. 54-2A](#)).

A

B

## FIGURE 54-2 Anatomic landmarks of the rectum and anus.

While many surgical descriptions for rectal cancer refer to the distance of the lesion from the anal verge or the *dentate line*, a more accurate description for distal (palpable lesions) is the distance above the anorectal ring as palpated by the examining surgeon. For nonpalpable lesions, we use a rigid sigmoidoscope to localize the lesion and then ascertain the distance from the anal verge to the mass. At the muscular level, the anal canal starts at the top of the “high-pressure zone” that is at the proximal aspect of the anorectal ring, a muscular structure consisting of the internal sphincter, external sphincter, and puborectalis (Figs 54-2A and B). The high-pressure zone descends beyond the dentate line to the junction of the anal mucosa and the perianal skin; this junction is often referred to as the *anal verge*. To achieve an adequate distal margin ( $\geq 1$  cm) with sphincter preservation, the lower border of a tumor must be located high enough above the top of the anorectal ring. The closer the tumor is to the anorectal ring the less likely the surgeon will be able to get extra length with rectal mobilization. This will often make sphincter preservation more difficult. This caveat even holds true with neoadjuvant chemoradiation, as scarring in the distal rectum after radiation and a lack of mesorectum fixes the tissues posteriorly, making it technically more difficult for the surgeon to gain extra length even with mobilization down to the levator ani complex. Hence, some tumors that are 1 to 2 cm above the anorectal ring and seem at initial exam to be amenable to sphincter preservation are not. Once in the operating room, the surgeon is not able to gain distal mobilization and an adequate margin is difficult to achieve and thereby sphincter preservation can prove challenging or not possible. If curative resection compromises perfect function of the sphincter apparatus, or if an adequate distal margin cannot be obtained while preserving the anorectal ring, an APR with a permanent colostomy should be constructed. Although a patient may assume that a colostomy indicates a hopelessly incurable cancer, we must emphasize that the colostomy is necessary because of the anatomic location, not necessarily the severity of the rectal cancer.

## Vascular Supply

Arteriography demonstrates extensive intramural anastomoses between the superior, middle, and inferior rectal arteries. The superior rectal artery

originates from the inferior mesenteric artery and descends in the mesorectum to supply the upper and middle rectum (Fig. 54-3). The inferior rectal arteries, branches of the internal pudendal arteries, enter posterolateral and provide blood supply to the anal sphincters and epithelium. The middle rectal artery, often depicted in anatomic drawings as a large and significant artery branching off the internal iliac artery on each side, is seldom greater than 1 mm in diameter.<sup>13</sup> In one study, the middle rectal artery was observed in only 22% of cadaver specimens.<sup>12</sup> When present, the middle rectal artery is located near the lateral rectal stalks. These stalks are primarily nerves but have been confused previously with arterial supply.

**FIGURE 54-3** Vasculature of the rectum and anus. **A.** Arterial supply. **B.** Venous drainage.

The superior rectal vein drains the upper and middle thirds of the rectum and empties into the portal system via the inferior mesenteric vein. The middle rectal veins drain the lower rectum and upper anal canal into the internal iliac veins. The inferior rectal veins drain the lower anal canal, emptying into the internal iliac veins via the pudendal veins. Because the

venous systems communicate, low rectal cancers may spread via the portal and systemic circulations.

## Lymphatic Drainage

Local recurrence after resection is common and can occur with and without distant metastatic disease. Rectal cancer can spread locally via lymphatics that follow cranially along the superior hemorrhoidal vessels. This “zone of upward spread” was described initially by Miles in his landmark paper describing the APR. Heald has described a “zone of downward spread” within the mesorectum<sup>4</sup>; this zone can encompass as much as 4 cm beyond the distal mucosal edge of the tumor.<sup>14,15</sup> Although some surgeons and pathologists describe tumor within this zone of downward spread as tumor implants, others believe that these implants are replaced nodes. Appreciation of the zones of upward and downward spread has influenced the extent of dissection surgeons now perform for curative resection of rectal cancers.

Lymph from the upper and middle rectum drains into the inferior mesenteric nodes (Fig. 54-4). Lymph from the lower rectum may drain into the inferior mesenteric system or into the network along the middle and inferior rectal arteries, posteriorly along the middle sacral artery, and anteriorly through the channels to the retrovesical or rectovaginal septum, to the iliac nodes, and ultimately, to the periaortic nodes. In a Japanese study, the obturator nodes, external to the hypogastric nerve plexus, were found to be involved with cancer in 8% of tumors located in the distal rectum, whereas these nodes were rarely, if ever, involved with proximal tumors.<sup>16</sup>

Lymphatics from the anal canal above the dentate line usually drain via the superior rectal lymphatics to the inferior mesenteric lymph nodes and laterally to the obturator and internal iliac nodes. Below the dentate line, lymph drains primarily to the inguinal nodes but may empty into the inferior or superior rectal lymph nodes. In most cases of rectal cancer, spread to the inguinal lymph nodes should be considered stage IV disease. In our experience, however, some patients whose distal rectal adenocarcinoma invades the anal canal can have regional nodal spread to the inguinal lymph nodes. These select few patients may remain curable and their radiation fields should include the involved inguinal lymph node basins.

**FIGURE 54-4** Lymphatic drainage of the rectum and anus. **A.** Nodes at the origin of the inferior mesenteric artery. **B.** Nodes at the origin of sigmoid branches. **C.** Sacral nodes. **D.** Internal iliac nodes. **E.** Inguinal nodes.

## Innervation

The pelvic autonomic nerves consist of the paired hypogastric (sympathetic), sacral (parasympathetic), and inferior hypogastric nerves (Fig. 54-5).

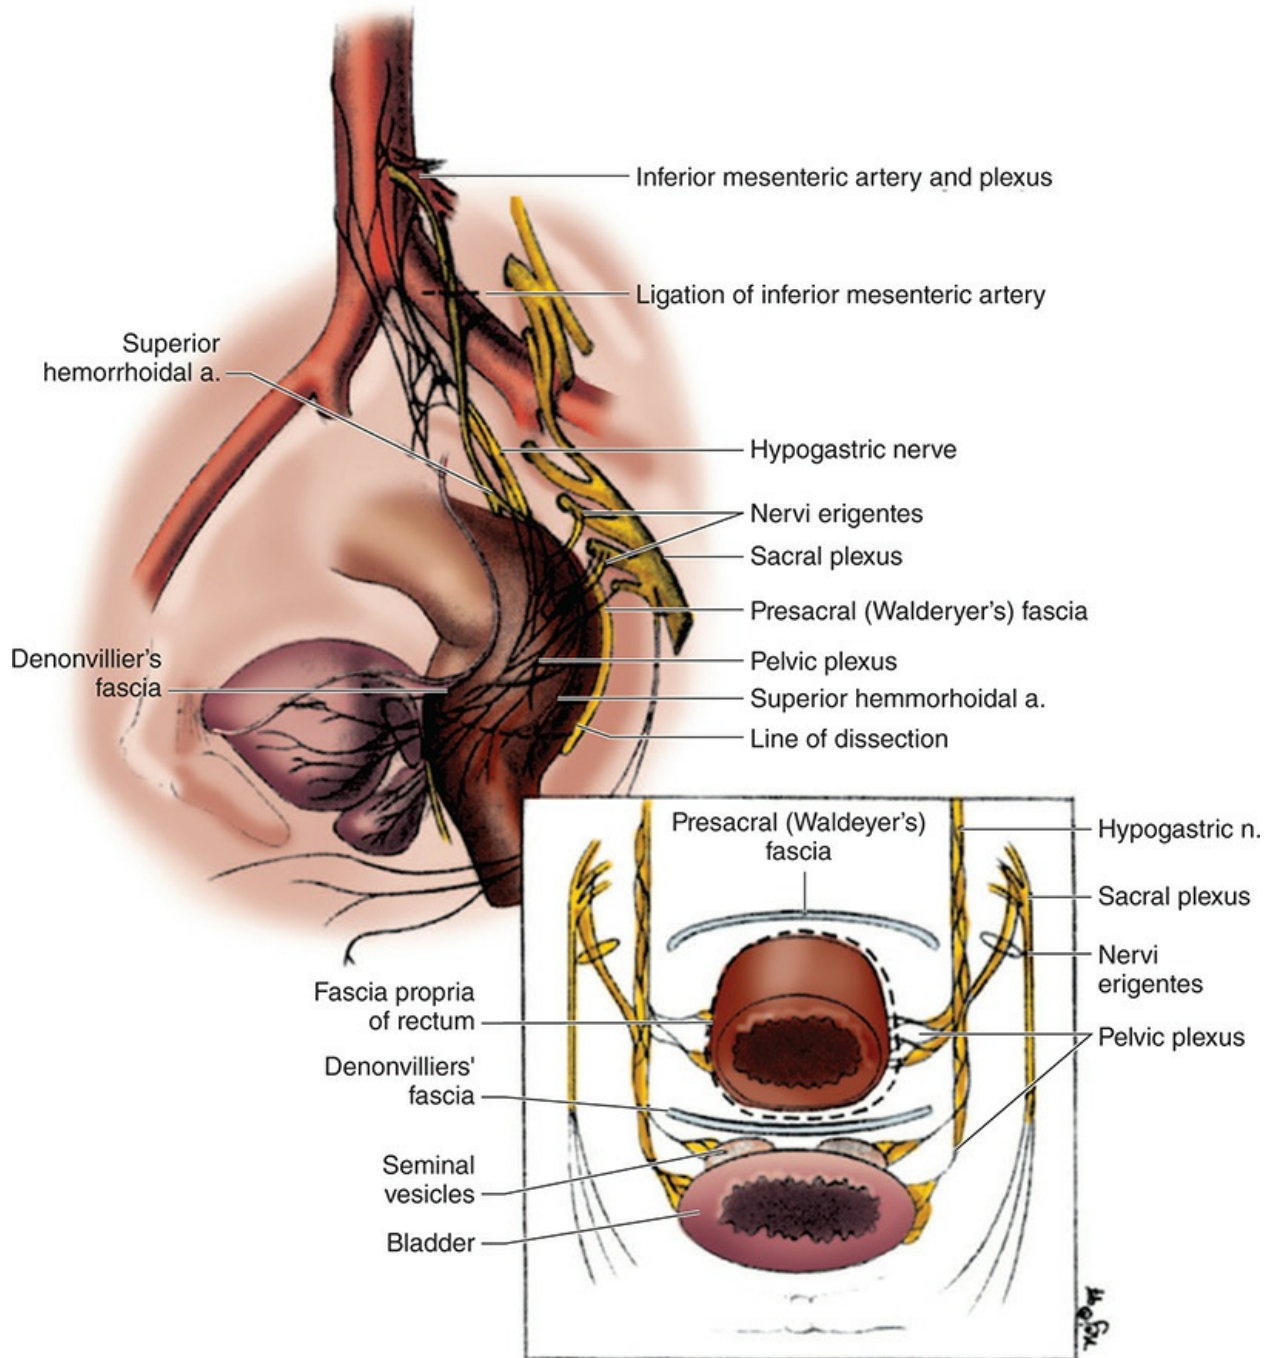

Sympathetic nerves originate from L1 to L3, form the inferior mesenteric plexus, travel through the superior hypogastric plexus, and descend as the hypogastric nerves to the pelvic plexus. The parasympathetic nerves, or nervi erigentes, arise from S2 to S4 and join the hypogastric nerves anterior and lateral to the rectum to form the pelvic plexus and ultimately the periprostatic plexus. The inferior hypogastric nerve plexus arises from interlacing sympathetic and parasympathetic nerve fibers and forms a fenestrated rhomboid plate on the lateral pelvic sidewall. Fibers from this plexus innervate the rectum as well as the bladder, ureter, prostate, seminal vesicles, membranous urethra, and corpora cavernosa. Therefore, injury to these autonomic nerves can lead to impotence, bladder dysfunction, and loss of normal defecatory mechanisms.

**FIGURE 54-5** Nerve supply of pelvic organs.

## Fascial Planes

The walls and floor of the pelvis are covered by the endopelvic, or parietal, fascia (Fig. 54-6). The fascia propria, an extension of the endopelvic fascia, encloses the rectum and its mesorectal fat, lymphatics, and vascular supply as a single unit; forms the lateral stalks of the rectum; and connects to the parietal fascia on the pelvic sidewall. The presacral fascia is the parietal fascia that covers the sacrum and coccyx, presacral plexus, pelvic autonomic nerves, and the middle sacral artery. Posteriorly, a thickening of this fascia, called *Waldeyer's fascia*, is the anteroinferior fascial reflection from the presacral fascia at the level of S4. Anteriorly, *Denonvilliers' fascia* separates the anterior rectal wall from the prostate and seminal vesicles in the male and is thought to be an entrapped extension of the peritoneum.<sup>17</sup>

## DIAGNOSIS AND EVALUATION

The preoperative evaluation is critically important to treat the cancer optimally and achieve sphincter preservation. With this information, surgeons

must individualize the treatment and care of each patient.

## History

The patient with rectal cancer usually presents to the surgeon after a definitive endoscopic diagnosis. The patient's initial complaint may include rectal bleeding, a change in bowel habits or stool caliber, rectal pain, a sense of rectal "fullness," weight loss, nausea, vomiting, fatigue, or anorexia; however, many patients are completely asymptomatic. Specific symptoms may assist the surgeon in deciding on the optimal approach to therapy. Tenesmus, the constant sensation of needing to move one's bowels, usually is indicative of a large and possibly fixed stage II or III cancer. Pain with defecation suggests involvement of the anal sphincters; cancers growing directly into the anal sphincter usually are not amenable to sphincter-sparing procedures. Information pertaining to anal sphincter function is invaluable when one is contemplating a low anastomosis. If patients are incontinent, they are better served with an ostomy. Preoperative sexual function is important to know because one must discuss the risks of the procedure and the likelihood of sexual dysfunction postoperatively. Patients who have preexisting sexual dysfunction are at increased risk for worse postoperative function. Diabetics, smokers, and patients who require neoadjuvant radiation are also at increased risk of postoperative sexual dysfunction.

A comprehensive medical history should be aimed at identifying other medical conditions, such as cardiopulmonary, renal, and nutritional issues that may require additional evaluation before surgical intervention. A comprehensive evaluation allows for more accurate risk stratification. Family history or factors predisposing the patient to rectal cancer, such as FAP, HNPCC, MUTYH, and IBD, are important to consider as one plans the operative procedure. For patients with UC/FAP/MUTYH and rectal cancer, the preferred operation is a total proctocolectomy with ileoanal J-pouch reconstruction or end ileostomy, depending on age and sphincter function. One must carefully consider the role of neoadjuvant chemoradiotherapy in patients with rectal cancer and these diseases because once an ileoanal J-pouch is constructed, if radiation has not been given preoperatively, postoperative radiation will severely damage the reconstruction, resulting in poor function and often in the need to remove the J-pouch. In HNPCC, the subsequent lifetime risk of a metachronous cancer is approximately 10% so

either a low anterior resection or APR or total proctocolectomy with an ileoanal J-pouch reconstruction can be considered. Whenever an ileoanal J-pouch is created, careful consideration of preoperative radiation is necessary due to the difficulty using radiation on a small bowel reconstruction in the pelvis.

## **Physical Examination**

A careful and accurate digital rectal examination (DRE) is critical in determining the clinical stage and any plans for neoadjuvant therapy. Digital exam of a palpable lesion allows for the assessment of tumor size, mobility and fixation, anterior or posterior location, relationship to the sphincter mechanism and top of the anorectal ring, and distance from the anal verge.

Rigid proctoscopy is also essential to the evaluation of patients with rectal cancer because it demonstrates the proximal and distal levels of the mass from anal verge, extent of circumferential involvement, orientation within the lumen, and relationship to the vagina, prostate, or peritoneal reflection. All this information aids in determining the feasibility of local excision if indicated. Rigid proctoscopy also allows one to obtain an adequate tissue biopsy. Flexible sigmoidoscopy is not used routinely because the flexibility of the instrument can give a false distance between the tumor and the dentate line. Furthermore, a mass will often be described as a sigmoid or rectosigmoid tumor on flexible colonoscopy and then when the patient is evaluated in the office with rigid sigmoidoscopy, the lesion is often found to be much lower and in fact is often a true rectal cancer that qualifies for neoadjuvant chemoradiotherapy. Hence, rigid sigmoidoscopy is mandatory for all distal left-sided lesions. A complete colonoscopy to the cecum is essential to rule out synchronous cancers, which occur 2% to 8% of the time. We prefer colonoscopy over virtual colonoscopy so that we may not only diagnose but also excise any amenable polyps. For anterior lesions, women should undergo a complete pelvic examination to determine vaginal invasion.

## **Preoperative Staging**

Following the initial history, DRE, and rigid proctoscopy, additional preoperative staging studies can help to determine the appropriate treatment

for each patient, whether radical resection or local excision is warranted, and whether preoperative chemoradiation is recommended. Accurate preoperative staging is gaining increasing importance as combined-modality therapy and sphincter-preserving surgical approaches are considered.

Abdominal and pelvic computed tomography (CT) scans can demonstrate regional tumor extension, lymphatic and distant metastases, and tumor-related complications such as perforation or fistula formation. Its accuracy in determining the depth of invasion, however, is less than that of endorectal ultrasound (ERUS) or specialized magnetic resonance imaging (MRI). Pelvic CT scan therefore is not recommended as the only modality for evaluation of a patient's primary tumor. For example, the sensitivity of CT scan for detecting distant metastasis is higher (75%-87%) than that for detecting perirectal nodal involvement (45%) or the depth of transmural invasion (70%). If a node is seen on CT scan, it should be presumed to be malignant because benign adenopathy is not normally seen around the rectum.

Intravenous contrast given at the time of a CT scan is important to assess the liver for metastatic disease, as well as to evaluate the size and function of the kidneys. Ureteral involvement by the tumor can be assessed and allows for planning of ureteral stent placement preoperatively. Also, invasion of contiguous structures such as the vagina, prostate, and bladder can be initially evaluated on CT scan. Most importantly, lateral pelvic sidewall invasion must be ascertained as this can be very challenging to resect if the disease burden does not regress substantially with neoadjuvant chemoradiation. All patients should undergo a chest CT scan to exclude pulmonary metastases. Because of newer chemotherapies (Oxaliplatin, Irinotecan, Avastin, and Cetuximab) and multiple treatment regimens, patients with multiple sites of metastatic disease are more likely to receive chemotherapy alone if the pelvic disease is asymptomatic and/or chemoradiation (symptomatic pelvic disease) followed by chemotherapy and may avoid a surgical resection if they have a large burden of distant disease or multiple sites of metastatic disease.

## **LABORATORY STUDIES**

Complete blood count and electrolytes often are obtained. Liver enzymes may be normal in the setting of small hepatic metastases and are not a reliable marker for liver involvement.

Guidelines published by the American Society for Clinical Oncology

(ASCO) recommend that serum carcinoembryonic antigen (CEA) levels be obtained preoperatively in patients with rectal cancer to aid in staging, surgical treatment planning, and assessment of prognosis. Although neither sensitive nor specific enough to serve as a screening method for the detection of colorectal cancer, preoperative CEA levels greater than 5 ng/mL signify a worse prognosis, stage for stage, than those with lower levels. In addition, elevated preoperative CEA levels that do not normalize following surgical resection imply the presence of persistent disease and the need for further evaluation. CEA is most helpful in identifying recurrent disease with an overall sensitivity rate of 70% to 80%.

## ENDOLUMINAL ULTRASOUND

Compared with CT scanning, transrectal endoluminal or endoscopic ultrasound (TRUS) permits a more accurate characterization of the primary tumor and the status of the perirectal lymph nodes. Localized cancers involving only the mucosa and submucosa usually can be distinguished from tumors that penetrate the muscularis propria or extend through the rectal wall into the perirectal fat.

ERUS is an office-based procedure that is well tolerated and can be performed by the surgeon for preoperative planning. [Figure 54-7](#) shows the schematic layers seen in TRUS.

**FIGURE 54-7** Schematic of transrectal endoluminal ultrasonography

illustrates the five layers seen on ultrasound.

**T Stage.** Several studies comparing the accuracy of TRUS with CT scan and MRI suggest that TRUS is superior for T staging of rectal cancer. The range of the accuracy of TRUS is 80% to 95% compared with 65% to 75% for CT scan, 75% to 85% for MRI, and 62% for DRE. In one review, the accuracy of TRUS was greatest (95%) in distinguishing whether a tumor was confined to the rectal wall (T1, T2) versus invading into the perirectal fat (T3 or greater) and less able to distinguish accurately T1 from T2 cancers.<sup>18</sup> It is important to understand that all of the above methods are operator dependent; if an institution regularly utilizes ERUS instead of endorectal coil MRI (ecMRI), then that modality will lead to more accurate staging for that institution, and vice-versa if it more regularly utilizes ecMRI. Sometimes, if the lymph nodes are negative and there is a question of whether the tumor is a T2 or T3 lesion, it can be beneficial to get both an ERUS and an ecMRI. [Figure 54-8](#) demonstrates a uT2 lesion. In addition, in patients who have received prior radiation, the accuracy decreases owing to edema and fibrosis.

**FIGURE 54-8** Transrectal endoluminal ultrasonography of a uT2 lesion. The *arrow* indicates the intact serosa.

Despite these data, there is considerable inter-observer variability and a significant learning curve associated with performing TRUS. For these reasons, TRUS under-stages more frequently than over-stages the primary rectal tumor. However, TRUS under-stages the cancer less often than CT scan (15% vs 39%). A modified tumor-node-metastasis (TNM) classification for rectal cancer has been proposed based on TRUS-derived T stage ([Table 54-1](#)).

**TABLE 54-1: ENDOSCOPIC ULTRASOUND STAGING OF RECTAL TUMORS**

uT1	Invasion confined to the mucosa and submucosa
uT2	Penetration of the muscularis propria but not through to the mesorectal fat
uT3	Invasion into the perirectal fat
uT4	Invasion into the adjacent organ
uN0	No enlargement of lymph nodes
uN1	Perirectal lymph nodes enlarged

---

**N Stage.** TRUS is less useful in predicting the status of perirectal lymph nodes. In several comparative studies, the accuracy of TRUS (70%-75%) was like that of CT scan (55%-65%) and MRI (60%-65%). The accuracy of nodal staging with TRUS requires the nodes to be larger than 5 mm. The contribution of TRUS-guided fine-needle aspiration (FNA) biopsy to N-staging accuracy for rectal cancer is controversial.

## MAGNETIC RESONANCE IMAGING

MRI offers some advantages compared with TRUS when it comes to staging rectal cancer. It permits a larger field of view, it may be less operator- and technique-dependent (although it is reader-dependent), and it allows study of stenotic tumors that may not be even amenable to DRE or passage of the ERUS probe.<sup>19</sup> Figure 54-9 illustrates a T3 lesion. Like TRUS, ecMRI or phased-array MRI can discriminate small-volume nodal disease and subtle transmural invasion. These specialized MRI techniques can identify involved perirectal nodes based on characteristics other than size, with reported accuracy rates of up to 95%. Another advantage over TRUS is identification of foci not only within the mesorectum but also outside the mesorectal fascia, such as the pelvic sidewall. We currently prefer phased-array MRI for staging of rectal cancers because it provides equal accuracy in staging compared to ecMRI but without the intrarectal coil.

**FIGURE 54-9** Endorectal MRI of a T3 lesion. *Arrowhead* indicates the site of the endorectal coil. *Large arrow* demonstrates fingerlike projections of carcinoma invading into the mesorectal fat. *Small arrow* points to the anterior rectal wall. (Used with permission from Koenraad J. Mortele, MD, Beth Israel Deaconess Medical Center, Boston, MA.)

Double-contrast MRI may permit more accurate T staging of rectal cancer by allowing better distinction between normal rectal wall, mucosa, muscularis, and perirectal tissues. In one report, the specificity and sensitivity of ecMRI with combined intravenous and endorectal contrast material to predict infiltration of the anal sphincter were 100% and 90%, respectively. However, N staging was not improved with this approach.

Phased-array surface coil MRI also may be beneficial in predicting the likelihood of a tumor-free resection margin by visualizing tumor involvement of the mesorectal fascia. If confirmed in other series, preoperative MRI may

prove useful in selecting patients at high risk of local recurrence for therapy prior to resection.

## **POSITRON EMISSION TOMOGRAPHY**

Fluorine-18 fluorodeoxyglucose–positron emission tomography (FDG-PET) is effective in assessing the extent of pathologic response of primary rectal cancer to preoperative chemoradiation and may predict long-term outcome.<sup>20</sup> In addition, it has an accuracy of 87% for detecting recurrence of rectal cancer after surgical resection and full-dose external-beam radiation therapy.<sup>21</sup> While PET scans are positive in 90% of primary and recurrent tumors and in distant metastatic disease, they are relatively inaccurate for nodal metastases. Rectal cancer rarely metastasizes to the bones or to the brain, and without symptoms these two areas are not included routinely in surveillance imaging. They will, however, light up on PET scan. Current guidelines recommend that PET scans not be used routinely in the standard workup of a rectal cancer.

## **TNM STAGING**

The purpose of staging any cancer is to describe the anatomic extent of the lesion. Staging by clinical examination, radiology, and pathology aids in planning treatment, evaluating response to treatment, comparing the results of various treatment regimens, and determining prognosis. Currently, the most widely accepted staging system for rectal cancer in the United States is the TNM classification system.

In 1987, the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (IUC) introduced the TNM staging system for colorectal cancer. The seventh edition was published in 2009 (Tables 54-2 and 54-3). The TNM staging system is based on depth of tumor invasion as well as presence of lymph node or distant metastases. In stage I disease, the tumor may invade into the muscularis propria. In stage II disease, the tumor invades completely through this layer into the perirectal fat (T3) or adjacent organs (T4). Any lymph node metastasis represents stage III disease, and metastatic spread denotes stage IV disease. Depth of invasion (T stage) of the primary tumor is an important prognostic variable as increasing depth of invasion is correlated with an increasing chance of lymph node metastases.

For instance, early-stage cancers extending into the muscularis mucosa (T1) will have up to a 10% to 13% incidence of metastasizing to perirectal lymph nodes.<sup>22,23</sup> In 805 pathology specimens, Sitzler noted that 5.7% of T1 lesions, 19.6% of T2 lesions, 65.7% of T3 lesions, and 78.8% of T4 lesions had lymph node metastases.<sup>24</sup>

#### TABLE 54-2: TNM CLASSIFICATION OF RECTAL CANCER

### Primary Tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i> , intramucosal carcinoma (involvement of lamina propria with no extension through muscularis mucosae)
T1	Tumor invades the submucosa (through the muscularis mucosa but not into the muscularis propria)
T2	Tumor invades the muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organ or structure
T4a	Tumor invades through the visceral peritoneum (including gross perforation of the bowel through tumor and continuous invasion of tumor through areas of inflammation to the surface of the visceral peritoneum)
T4b	Tumor directly invades or adheres to adjacent organs or structure

### Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One to three regional lymph nodes are positive (tumor in lymph nodes measuring $\geq 0.2$ mm), or any number of tumor deposits are present and all identifiable lymph nodes are negative
N1a	One regional lymph node is positive
N1b	Two or three regional lymph nodes are positive
N1c	No regional lymph nodes are positive, but there are tumor deposits in the <ul style="list-style-type: none"><li>• subserosa</li><li>• mesentery</li><li>• or nonperitonealized pericolic, or perirectal/mesorectal tissues.</li></ul>
N2	Four or more regional nodes are positive
N2a	Four to six regional lymph nodes are positive
N2b	Seven or more regional lymph nodes are positive

### Distant metastasis (M)

M0	No distant metastasis by imaging, etc.; no evidence of tumor in distant sites or organs (This category is not assigned by pathologists.)
M1	Metastasis to one or more distant sites or organs or peritoneal metastasis is identified
M1a	Metastasis to one site or organ is identified without peritoneal metastasis
M1b	Metastasis to two or more sites or organs is identified without peritoneal metastasis
M1c	Metastasis to the peritoneal surface is identified alone or with other site or organ metastases

**TABLE 54-3: AJCC PROGNOSTIC STAGE GROUPS**

<b>When T is...</b>	<b>And N is...</b>	<b>And M is...</b>	<b>Then the stage group is...</b>
Tis	N0	M0	0
T1, T2	N0	M0	I
T3	N0	M0	IIA
T4a	N0	M0	IIB
T4b	N0	M0	IIC
T1-T2	N1/N1c	M0	IIIA
T1	N2a	M0	IIIA
T3-T4a	N1/N1c	M0	IIIB
T2-T3	N2a	M0	IIIB
T1-T2	N2b	M0	IIIB
T4a	N2a	M0	IIC
T3-T4a	N2b	M0	IIC
T4b	N1-N2	M0	IIC
Any T	Any N	M1a	IVA
Any T	Any N	M1b	IVB
Any T	Any N	M1c	IVC

Generally, the biologic behavior of rectal cancer cannot be predicted by its location or size although there is a consensus among experts that the more distal cancers have a poorer outcome when compared stage for stage with more proximal lesions. Poorly differentiated cancers have a worse long-term prognosis than well or moderately differentiated tumors. Other factors that portend a poor prognosis include direct tumor extension into adjacent structures (T4 lesions), lymph node metastases, lymphatic, vascular, or perineural invasion, and bowel obstruction.

## **PRINCIPLES OF TREATMENT**

Surgical resection is the cornerstone of curative therapy. Following a potentially curative resection, the 5-year survival rate varies per disease extent<sup>25,26</sup> (Table 54-4). However, these survival figures may improve with the increased use of adjuvant therapy.

**TABLE 54-4: SURVIVAL RATES**

Stage I	80-90%
Stage II	62-76%
Stage III	30-40%
Stage IV	4-7%

Surgical and oncologic management varies greatly depending on the stage and location of the tumor within the rectum. Superficially invasive, small cancers may be managed effectively with local excision. However, most patients have more deeply invasive tumors that require major surgery, such as low anterior resection (LAR) or APR. Yet others present with locally advanced tumors adherent to adjoining structures such as the sacrum, pelvic sidewall, vagina, uterus, cervix, prostate, or bladder, requiring an even more extensive operation.

After establishing the diagnosis and completing the staging workup, a decision is made whether to pursue immediate resection or administer preoperative chemoradiotherapy. For patients with stage II and III rectal cancer, the authors advocate for combined preoperative chemoradiotherapy. The authors recommend this for all stage II and III patients with tumors located in the distal two-third of the rectum. For patients with rectal cancer in the proximal one-third of the rectum, the authors use preoperative chemoradiotherapy on a case-by-case basis depending on the size and bulkiness of the tumor and the number of involved lymph nodes as well as the patient's medical and surgical history.

## **Bowel Preparation**

The high bacterial load in the intestinal tract requires preoperative bowel decontamination to reduce the incidence of infectious complications. Prior to

the routine use of mechanical bowel preparation and preoperative antibiotics, the reported rate of infection following colorectal surgery was 60%.<sup>27</sup> A standard bowel preparation includes a clear-liquid diet 24 hours prior to surgery, laxatives and/or enemas, oral antibiotics (erythromycin base and neomycin base) and gastrointestinal tract irrigation with a solution of polyethylene glycol electrolyte lavage (GoLYTELY or Miralax). In two separate surveys of North American colorectal surgeons, almost two-thirds preferred the polyethylene glycol electrolyte solutions because of the reliability of the cleansing results.<sup>28,29</sup> Certain preparations are contraindicated in patients with certain medical conditions. For example, patients with elevated creatinine or congestive heart failure should avoid the magnesium citrate preparation, whereas patients with gastroparesis should not take a large-volume polyethylene glycol preparation.

Recent studies have shown that mechanical bowel preparation in conjunction with oral antibiotics, a chlorhexidine shower, and a clean closure protocol grouped together as an infection protection bundle have reduced the overall surgical site infection (SSI) rate from 19.7% to 8.2%. The chlorhexidine shower, the oral antibiotics, and the mechanical bowel preparation were all associated with decreased SSI. Moreover, patients who received both oral antibiotics and a mechanical bowel prep had an SSI of 2.7% versus 15.8% for all other patients.<sup>30</sup> Furthermore, a mechanical bowel preparation should be performed in large part because it allows for easier manipulation of the colon and rectum with both open and laparoscopic surgery.<sup>31</sup>

Oral antibiotics are also used to further decrease the incidence of postoperative infectious complications. Although mechanical cleansing decreases the total volume of stool in the colon, it does not affect the concentration of bacteria per milliliter of effluent. The most commonly used regimen is the Nichols/Condon preparation: neomycin 1 g and erythromycin base 1 g, both non-absorbable antibiotics, by mouth at 5:00 pm and 10:00 pm on the day prior to surgery. In addition to oral antibiotics, perioperative systemic antibiotics should be given prior to incision time. A typical choice to cover both aerobic and anaerobic intestinal bacteria is a second- or third-generation cephalosporin in combination with metronidazole. Postoperative antibiotic prophylaxis is not indicated.

Perioperative systemic antibiotic coverage is broadened in patients with

high-risk cardiac lesions such as prosthetic heart valves, previous history of endocarditis, or a surgically constructed systemic-pulmonary shunt, and with intermediate-risk cardiac lesions such as mitral valve prolapse, valvular heart disease, or idiopathic hypertrophic subaortic stenosis. Intravenous ampicillin 2 g and gentamycin 1.5 mg/kg are administered 30 to 60 minutes before the procedure, and ampicillin is repeated once 6 hours postoperatively in place of cefazolin; metronidazole is administered as usual. Vancomycin is substituted for ampicillin if the patient is allergic to penicillin or cephalosporin.

## **Enhanced Recovery after Surgery Protocols**

Enhanced recovery after surgery (ERAS) protocols have become popularized in the last several years in colorectal surgery programs across the United States. ERAS protocols have been very successful in decreasing length of stay as well as postoperative surgical complications. These protocols include a preoperative bowel preparation as outlined above while allowing the patient to continue to consume clear liquids up to 2 hours prior to surgery. This aims to limit preoperative dehydration and thereby limit the need for intraoperative fluid administration, which itself leads to third spacing and tissue edema, and as a result, a slower recovery. Patients are also instructed to refrain from taking ACE inhibitors and diuretics the morning of surgery to prevent hypotension and thereby obviate the need for excess intraoperative fluids. In addition to the bowel preparation, a complex carbohydrate load is often given 2 hours prior to the surgery and it is hypothesized that this decreases insulin resistance because it prevents starvation physiology and thereby limits the catabolic effects of starvation generally seen around surgery.

Preoperative pain control is initiated with 1000 mg of Tylenol and a COX-2 inhibitor such as Celebrex and gabapentin (age- and sex-related dosing) in the holding area. Intraoperatively, fluid administration is limited and goal-directed fluid therapy is utilized. Goal-directed fluid therapy is achieved by monitoring urine output (0.25 cc/kg/h) and cardiac stroke volume as monitored with a transesophageal probe. Intraoperative narcotics are minimized. Epidurals and transversus abdominus plane (TAP) blocks and catheters are utilized to further decrease postoperative reliance on narcotics. Exogenous fluid administration is stopped within 6 hours of surgery and patients are immediately started on clear liquids and advanced to regular diet on postoperative day one. This allows for earlier usage and absorption of oral

pain medicines. Liberal use of Tylenol and NSAIDs is recommended as well. ERAS protocols have resulted in a dramatic decrease in length of stay and wound infections, among other complications. An ERAS protocol is an integral part of any program in colon and rectal surgery.

## **Goals of Surgery for Rectal Cancer**

The primary goal of surgical treatment for rectal cancer is complete eradication of the primary tumor along with the adjacent mesorectal tissue and the superior hemorrhoidal artery pedicle. Although reestablishment of bowel continuity at the time of surgery has become routine, cancer removal should not be compromised in an attempt to avoid a permanent colostomy.

For tumors located in the extraperitoneal rectum, resection margins are limited by the bony confines of the pelvis and the proximity of the bladder, prostate, and seminal vesicles in men and vagina in women. Although locoregional recurrence may be inevitable, local recurrence, cure, mortality, anastomotic leaks, and colostomy rates after rectal cancer surgery are related to surgical technique as well as to the experience and volume of the individual surgeon and institution.

## **Resection Margins**

### **DISTAL MARGINS**

The optimal distal resection margin for surgically treated rectal cancer remains controversial. Although the first line of rectal cancer spread is upward along the lymphatics, tumors below the peritoneal reflection can spread distally via intra- or extramural lymphatic and vascular routes.

The use of APR for low rectal cancers traditionally has been based on the need for a 5-cm distal margin of normal tissue. However, in retrospective studies, margins as short as 1 cm have not been associated with an increased risk of local recurrence.<sup>32-34</sup> Distal intramural spread usually is limited to within 2.0 cm of the tumor unless the lesion is poorly differentiated or widely metastatic. Data from a randomized, prospective trial conducted by the National Surgical Adjuvant Breast and Bowel Project demonstrated no significant differences in survival or local recurrence when comparing distal

rectal margins of less than 2, 2 to 2.9, and greater than 3 cm.<sup>32</sup> Therefore, a 1- to 2-cm distal margin is acceptable for resection of rectal carcinoma, although a 5-cm proximal margin is still recommended.<sup>34,35</sup>

## **RADIAL MARGINS**

The importance of obtaining an adequate circumferential or radial margin has been appreciated more in the last 15 years. In fact, the circumferential radial margin (CRM) is more critical than the proximal or distal margin for local control. Tumor involvement of the circumferential margin has been shown to be an independent predictor of both local recurrence and survival. The Norwegian Rectal Cancer group reported on circumferential resection margins with 29-month median follow-up in 686 patients who had curative intent LAR with TME alone (no adjuvant radiotherapy) for rectal adenocarcinoma. The Norwegian group found that the overall local recurrence rate was 7% (22% with positive CRM and 5% with a negative CRM). Moreover, 40% of patients with a positive CRM developed distant metastases whereas only 12% of those with negative CRM developed distant disease.<sup>36</sup> In this study, a positive CRM clearly affected survival. In another report of 90 patients undergoing resection for rectal cancer, when the radial margins were histologically positive, the hazard ratio (HR) for local recurrence was 12.2, and the HR for death was 3.2 when compared with those with clear circumferential margins. Furthermore, the length of mesorectum beyond the primary tumor that needs to be removed is thought to be 5 cm because tumor implants usually are seen no further than 4 cm from the distal edge of the tumor within the mesorectum.<sup>9,15</sup> Therefore, in proximal rectal cancers, distal mesorectal excision 5 cm below the lower border of the tumor should be the goal. There is ample evidence, however, that in more distal tumors where there is less mesorectum, a 1- to 2-cm margin is acceptable to achieve sphincter preservation.<sup>34,35</sup>

## **LOCAL EXCISION**

### **Oncologic Results**

Several retrospective studies of local excision since the 1970s have

demonstrated a local recurrence rate of 7% to 33% and survival rates of 57% to 87%. Many of these reviews are limited, small, single-institution studies, often combining patients with tumors of different depths, including T3 lesions, positive margins, or those who underwent different forms of local therapy, such as fulguration and snare cautery. Despite these limitations, many of these studies have demonstrated that local excision for superficial tumors with negative margins may provide similar survival and local control but without the morbidity of the APR. Major risk factors for local recurrence include positive surgical margins, transmural extension, lymphovascular invasion, and poorly differentiated/high grade histology. These retrospective studies suggest that local excision of selected distal rectal adenocarcinomas may provide adequate oncologic control at considerably less morbidity than APR.

Several prospective studies have been published (Table 54-5). In a study from the MD Anderson Cancer Center, 46 patients underwent transanal excision of small distal rectal cancer followed by postoperative radiation treatment.<sup>37</sup> Patients with T3 lesions also were given chemotherapy. For patients with negative margins, there was only a 6.5% local recurrence rate (all were T3 tumors) with a 93% overall 3-year survival. Local treatments combined with radiation provided similar oncologic control for T1 or T2 small distal rectal adenocarcinomas as compared with APR.

**TABLE 54-5: RECURRENCE RATES AFTER LOCAL EXCISION AND ADJUVANT THERAPY**

	Patients (n)	Treatment	Follow-Up (mo)	Local Recurrence	Survival
Ota et al. <sup>33</sup>	46	LE and post-op XRT and 5-FU for T2, T3	36 (median)	6.5% (3/46) All T3s	Overall 3-y 93%
Bleday et al. <sup>34</sup>	48	LE, post-op XRT and 5-FU for T2, T3	41 (mean)	8% (4/48)	Disease-specific 96%
Steele et al. <sup>35</sup>	110	LE, post-op XRT and 5-FU for T2	48 (mean)	T—5.1% (3/59)	Overall 6-y 85%; disease-specific
Greenberg et al. <sup>36</sup>	110	Same as Steele	85	T2—13.7% (7/51)	Overall 10-y T1 84% T2 66%

Abbreviations: 5-FU, 5-fluorouracil; LE, local excision; post-op, postoperative; XRT, radiation therapy.

From the New England Deaconess Hospital in Boston, patients with small distal cancers (<4 cm in diameter and <10 cm from the dentate line) with no evidence of metastatic disease were entered in a prospective study.<sup>38</sup> Patients

with T1 lesions were observed after local excision. Patients with T2 lesions treated with local excision were given postoperative chemoradiation. Several patients were found to have T3 lesions and all were recommended further radical surgery. Those who refused had adjuvant chemoradiation therapy and were followed. All patients were followed every 3 months for 2 years and then every 6 months for 5 years. The local recurrence rate in this study was 8%, and the cancer-specific mortality rate was 4%. Risk factors associated with recurrence were T3 cancers or lymphatic invasion. Surgery alone was adequate for T1 lesions, and surgery combined with chemoradiation was appropriate for T2 lesions excised with negative margins. Radical resection was and still is appropriate for tumors with positive margins after local excision or for T3 cancers. Patients with lymphovascular invasion deserve further therapy, although that therapy was not defined.

In his initial report, Steele and colleagues published the only large multicenter prospective trial of local excision (CALGB 8984 [Cancer and Leukemia Group B]).<sup>39</sup> Patients were eligible for the study if their cancer was within 10 cm of the dentate line and was less than 4 cm and involved less than 40% of the luminal circumference. All patients preoperatively were thought to have N0M0 disease, as determined clinically and by CT scan. All study patients had negative margins. T1 lesions had no further treatment, and T2 lesions were treated with chemoradiation. After 6 years of follow-up, the overall survival (OS) and the disease-free survival (DFS) were 85% and 78%, respectively. DFS was 84% and 71% for T1 and T2 lesions, respectively. Seven patients recurred with local disease only and underwent APR with a 70% salvage rate. This approach was no worse than that of radical resection. Longer-term follow-up (median 7.1 years) of CALGB 8984 revealed that 10-year overall survival rates were 84% for T1 lesions and 66% for T2 lesions. DFS was reported at 75% in T1 patients and 64% in those with a T2 lesion. Furthermore, local and distant recurrence rates were 8% and 5% versus 18% and 12% in T1 and T2 lesions, respectively. The longer-term follow-up of CALGB 8984 showed that the rates of local recurrence, OS, and DFS did not change significantly for T1 lesions, but that there was a significant decrease in OS and DFS in the T2 lesions even though these patients received adjuvant therapy. Local excision is indicated for appropriately selected patients and that local excision with adjuvant therapy should be used more judiciously especially in medically fit patients.<sup>40</sup>

## Patient Selection and Choice of Operation

Preoperative staging, primarily with ERUS or MRI, is most helpful in identifying appropriate patients for a local excision. Criteria for consideration for local excision are listed in [Table 54-6](#). Patients with T3 or N1 disease are inappropriate for local excision. Given the low probability of microscopic nodal disease in T1 lesions, these patients are the best candidates for local excision. T3 and T4 lesions have a high probability of nodal involvement and therefore should be treated with radical resection. Controversy remains over the best therapy for T2 lesions. Most colorectal surgeons still believe that radical surgery with an LAR or APR remains the standard for T2 lesions. However, local excision combined with postoperative chemoradiation achieves similar rates of survival but not necessarily similar rates of DFS. In patients with a T2 lesion who undergo treatment with local excision and adjuvant chemoradiation, those who have a recurrence ultimately require a salvage APR for cure. The American College of Surgeons Oncology Group (ACOSOG Z6041) was multi-institutional single arm open-label non-randomized trial of patients with T2N0 distal rectal cancer treated with neoadjuvant chemoradiation followed by transanal excision. Preliminary results reported a 44% pathologic complete response rate, 64% pathologic downstaging rate, 5% had ypT3 tumors, and 1% to 2% positive radial margin rate. These preliminary results showed that there was an excellent pathologic complete response and downstaging as well as good surgical outcomes, with nearly all margins being negative.<sup>41</sup> Long-term results of this trial were published in 2015. With median follow-up of 56 months the estimated 3-year DFS was 88.2%, suggesting that preoperative chemoradiation followed by local excision is an acceptable alternative to radical surgery, especially when sphincter preservation cannot be offered with radical surgery or when the patient is not medically fit for radical surgery.<sup>42</sup>

Patients with extensive metastatic disease and poor prognosis who require local control

Adjuvant treatment for patients with lymphatic invasion, T1 with poor prognosis features, T2 lesions

---

Tumors less than 3 cm from the dentate line but not invading the sphincters usually can be resected via a transanal procedure. Tumors 5 cm from the dentate line may need a transcoccygeal approach or transanal endoscopic microsurgery (TEM). Tumors 7 to 10 cm from the dentate line require TEM or should be considered for an LAR. Clearly, tumors tethered to the mesorectum or pelvic floor on physical examination, suggesting transmural involvement, are not amenable to local excision. Patients with such lesions should undergo preoperative radiation followed by a radical resection.

Patients considered medically unfit for a major resection are good candidates for local treatment of most small, mobile tumors, including T2 and T3 lesions, accepting a higher rate of local recurrence. In these circumstances, adjuvant chemoradiation is advocated, and close follow-up is mandatory.

After local excision, if the pathology is unfavorable, the patient should be counseled to have further therapy, including chemoradiation therapy and either an LAR or APR with TME. Local excision in these circumstances can be considered an open biopsy and not the definitive therapy.

## Technique

There are four approaches to local excision: transsphincteric, transanal, transcoccygeal, and TEM. The transsphincteric technique, however, leads to significant dysfunction of the anal sphincters with subsequent moderate to severe fecal incontinence. Therefore, the transanal, transcoccygeal, and TEM approaches are the preferred techniques.

## Transanal Excision

Most small distal rectal cancers can be excised locally via a transanal excision. Tumors amenable to this approach usually range from 6 to 8 cm above the anal verge, which is the same as 3 to 4 cm above the anorectal ring.

Prior to the procedure, all patients should receive a full mechanical and antibiotic bowel preparation. Most patients are placed in the prone jackknife position, and the buttocks are taped apart. For lesions that are directly posterior, the lithotomy position can be used. The surgeon wears a fiberoptic headlight. A pudendal nerve block using 0.5% Marcaine (bupivacaine) with 1:100,000 units of epinephrine is administered to relax the sphincters and facilitate postoperative pain control. A Lone Star retractor (Cooper Surgical, Inc., Trumbull, CT) can be used to expose the dentate line. A Pratt bivalve retractor (Pilling-Weck Instruments, Ft. Washington, PA), a Fansler operating speculum (Hayden Medical, Inc., Santa Clarita, CA) or Parks anal retractor (CS Surgical, Inc., Slidell, LA) should be inserted to dilate the anus and expose the lesion. Once the tumor is viewed adequately, traction sutures using 2-0 Vicryl (Ethicon, Somerville, NJ) are placed 2 cm proximal to the tumor. The circumferential dissection line is outlined on the mucosa using the cautery with a pinpoint Bovie tip approximately 1 cm from the border of the tumor; careful attention should be paid to maintaining a wide proximal margin. If an adequate view of the lesion cannot be obtained initially, serial traction sutures starting distally are used to prolapse the lesion into the field. Additional local anesthetic is injected submucosally circumferentially along the Bovie markings to provide hemostasis. Starting proximally and proceeding circumferentially, a full-thickness incision of bowel wall is made down to perirectal fat using the cautery along the previously marked mucosa (Fig. 54-10). Once fat is reached, the dissection is made through the fat to undercut the specimen. Anteriorly in a female patient, one must not injure the posterior wall of the vagina. In a male patient, one must avoid the prostate. Once the specimen is free, carefully maintain and mark the orientation for the pathologist (eg, proximal, anterior, left, right). Irrigate and check for hemostasis. After excision, the defect in the bowel wall is closed transversely with full-thickness bites using interrupted 2-0 Vicryl sutures on a UR-6 needle. One stitch is placed in the center of the incision. One-half is closed, followed by the other. A rigid sigmoidoscope is inserted to visualize the suture line and to ensure patency of the rectal lumen. The patient then is

placed supine. A pad is applied to the rectal area and secured with mesh rectal shorts. A pack in the anal canal or rectum is not used. These procedures can be done either as an outpatient or with a 23-hour observation status. Potential complications include urinary retention, urinary tract infections, fecal impaction, infections in the perirectal and ischioanal spaces, and delayed hemorrhage. The incidence of these complications is quite low; mortality in most series is zero.

**FIGURE 54-10** Approach to transanal excision of a rectal tumor. **A.** A 1- to 2-cm margin is marked circumferentially with Bovie electrocautery on the rectal mucosa. **B.** Full-thickness excision down to perirectal fat is performed. **C.** The specimen is oriented for the pathologist. ## Transcoccygeal Excision

Originally popularized by Kraske, the transcoccygeal excision is used for larger or more proximal lesions within the middle or distal third of the rectum. Bleday et al. reported that the average distance of the distal margin of an appropriate tumor that was selected for the posterior or Kraske approach was approximately 4.8 cm from the dentate line.<sup>38</sup> This approach is useful for lesions on the posterior wall of the rectum but can be used for anterior lesions.

Patients undergo similar bowel preparation and thrombosis precautions as the transanal excision patients. The patient is placed in the prone jackknife position. The buttocks are taped apart for better exposure, but at closure the tape is released to facilitate approximation of the subcutaneous tissues and skin. After prepping the skin, the rectum is irrigated with a Betadine (povidone/iodine) solution. The incision is made in the intergluteal fold over the sacrum and coccyx down to the upper border of the posterior aspect of the external sphincter. After division of the skin and subcutaneous tissues, one encounters the coccyx and anal coccygeal ligament. To obtain optimal exposure, the coccyx is removed by cauterizing its attachments, including the anal coccygeal ligament, from each side and from its lower edge and then proceeding with the dissection on its undersurface. A cutting wire is used to transect the sacral coccygeal joint. With removal of the coccyx, bleeding from an extension of the middle sacral artery is controlled with electrocautery. The levator ani muscles are separated in the midline, exposing a membrane that is just outside the mesorectal fat. Once this membrane is divided, the rectum can be completely mobilized within the intraperitoneal pelvis. For anterior lesions, a posterior proctotomy is made; the anterior rectum is approached under direct vision, with removal of the tumor along with a 1-cm margin (Fig. 54-11). For posterior-based lesions, after complete mobilization of the mesorectum, the distal margin of the tumor can be palpated via a rectal examination; the mesorectum and rectum are transected approximately 1 cm distal to the tumor (Fig. 54-12). The tumor is excised with a 1-cm margin of normal tissue. The advantage of the posterior approach is that the immediate mesorectal tissue adjacent to the tumor is removed along with perirectal nodes. After removal, the specimen is oriented for the pathologist. The incision is closed in a transverse manner using an absorbable suture such as 3-0 Vicryl or 3-0 PDS (Ethicon, Somerville, NJ). After closure

of the rectum, an air test is performed by insufflating the rectum with air and filling the operative field with sterile saline. After all air leaks are controlled, the levator ani musculature is reapproximated and the anal coccygeal ligament is reattached to the sacrum, followed by closure of the subcutaneous tissues and skin.

**FIGURE 54-11** Kraske approach to an anterior lesion. The coccyx is excised, the levator is split in the midline, and the rectum is mobilized. The posterior rectal wall is opened to expose an anterior lesion. (Reproduced with permission from Bleday R: Local excision of rectal cancer, *World J Surg* 1997;Sept;21(7):706-714.)

**FIGURE 54-12** Kraske approach to a posterior lesion. After the rectum has been exposed, the surgeon may palpate the distal margin of the tumor. The tumor is excised with a 1-cm margin. (Reproduced with permission from Bleday R: Local excision of rectal cancer, *World J Surg* 1997;Sept;21(7):706–714.)

One of the most troubling complications of the transcoccygeal excision is a fecal fistula extending from the rectum to the posterior incision. The incidence of this complication ranges from 5% to 20%.<sup>39</sup> These fistulas usually heal after temporary fecal diversion.

## **Transanal Endoscopic Microsurgery**

The TEM technique was first described by Gerhard Buess of Tübingen, Germany, in 1980. It is especially useful for small benign and malignant lesions in the mid and proximal rectum that are too high for a traditional transanal excision. This technique is widely used in Europe but over the years has been underutilized in North America until recently. It is gradually becoming standard practice for early mid to upper rectal lesions. The specialized instrumentation includes a 4-cm Wolf operating proctoscope (Richard Wolf Company, Frankfurt am Main, Germany) in lengths of 12 and 20 cm with a flat or beveled end. The operating proctoscope is equipped with a binocular microscope and videoscope attachment for viewing on a standard laparoscopy tower. A CO<sub>2</sub> insufflator and long operating surgical instruments are needed as well. The surgeon must be trained in the technique, which follows the same principles as transanal excision described earlier using the pinpoint tip on the Bovie electrocautery. Preoperative localization in the office with a rigid sigmoidoscope is essential so that the patient can be appropriately positioned. The patient is positioned using a beanbag and fixation to the table with tape, which allows the patient to be rotated laterally during the procedure. For an anterior lesion, the patient is placed in the prone jackknife position. For a posterior lesion, the patient is placed in a modified lithotomy position. For lateral lesions, the patient can be placed on the appropriate side so that the lesion is at the inferior quadrant of the visual field. After the patient is appropriately positioned, the operating proctoscope is fixed to the table with a rigid support arm and a glass faceplate. The faceplate is equipped with two operating ports and a suction port. The rectum is distended with carbon dioxide anywhere from 15- to 26-cm water pressure so that the tumor can be visualized and the resection and closure of the rectum can be completed. After full-thickness excision of the lesion is completed, the defect is endoscopically closed with interrupted 3-0 PDS figure-of-eight sutures. If this cannot be performed, the defect may be left open as in a standard transanal excision. The one caveat, however, is that extreme care must be taken to identify the peritoneal reflection, especially anteriorly. If dissection carries into the peritoneal cavity, the defect must be closed. If we enter the peritoneal cavity, after we close the defect our practice is to observe these patients in hospital until they are passing flatus. In selected patients, temporary diversion is needed after entering the peritoneal cavity. Patients in whom TEM is contemplated should be made aware that because of technical considerations (proctoscope won't fit or pass and/or

poor visualization or entry into the peritoneal cavity), an LAR may need to be performed. This is especially true in patients with a known malignancy.

Unfortunately, the literature describing oncologic outcomes for TEM resection of early-stage rectal adenocarcinoma is mainly single-institution, small-series, with short-term follow-up. Most of these studies make a comparison with radical surgery (LAR, APR) but never make a direct comparison with transanal resection. For the most part, the comparison of TEM to traditional transanal excision is made with historical data alone. This is in part because very distal lesions near the sphincter are difficult to excise with the TEM and a traditional transanal excision is easier, whereas the more proximal lesions are not amenable to a traditional approach and a TEM is more likely to succeed in removing these lesions per rectum. Hence only a small number of tumors that are above 8 cm and below 10 cm from the anal verge could ever be enrolled in a trial to make a direct comparison. To address this issue, a multicenter randomized trial comparing TEM to traditional transanal excision for early-stage rectal cancer with and without adjuvant radiotherapy needs to be performed. To date such a trial has not been done.

TEM resection of low-risk T1 rectal adenocarcinoma results in a 0% to 11% local recurrence rate, whereas local recurrence for T2 lesions without adjuvant therapy is approximately 19% to 35%. When T2 and T3 lesions are treated with adjuvant or neoadjuvant therapy and TEM resection, the local recurrence rates decrease to 14% and 3%, respectively. One caveat is that these studies have short-term follow-up, with the longest being 4 years. Indirect comparisons of local excision with TEM for T1 lesions have similar local recurrence rates (7%-18% transcatheter arterial embolization [TAE] vs 0%-11% TEM), and thus the decision to perform traditional transanal excision versus TEM should depend on the location of the tumor and the individual surgeon's expertise. Local recurrence rates without chemoradiotherapy for either TEM or transanal excision, on the other hand, are not satisfactory. Local recurrence rates for T2 lesions excised by TEM range from 19% to 35% versus 26% to 47% for traditional transanal excision (see [Table 54-5](#)). In either case, the results are not adequate, and as a result, medically fit patients with T2 lesions should not have either a TEM or a transanal excision without the addition of radiotherapy.

In summary, the results of TEM resection are as good as or better than traditional transanal resection for early rectal cancer. When deciding whether

to utilize transanal excision or TEM, the surgeon should remember that TEM offers better visualization, almost complete intact excision, and access to lesions that are higher in the rectum and otherwise would need radical surgery. Cataldo's group from the University of Vermont has shown that TEM resection resulted in intact nonfragmented excision 94% of the time, whereas transanal excision only accomplished intact nonfragmented excision 65% of the time ( $p < .001$ ) and tumor-free margins were 98% with TEM versus 78% with TAE when resecting a rectal cancer ( $p = .03$ ). Furthermore, they showed a nonstatistically significant trend to lower recurrence rates (22% for TAE and 3% for TEM).<sup>43</sup>

## LOW ANTERIOR RESECTION WITH TOTAL MESORECTAL EXCISION

### Oncologic Results

Local failures most often result from inadequate surgical clearance of the radial margin. The concept of TME proposed by Heald et al. has been shown to improve both disease-free and overall survival.<sup>4</sup> TME in conjunction with an LAR or APR involves precise dissection and removal of the entire rectal mesentery, including that distal to the tumor, as an intact unit. Unlike conventional blunt dissection, which may leave residual mesorectum in the pelvis, TME involves sharp dissection under direct vision in the avascular, areolar plane between the fascia propria of the rectum, which encompasses the mesorectum, and the parietal fascia overlying the pelvic wall structures. This procedure emphasizes autonomic nerve preservation (ANP) and complete hemostasis and avoids violation of the mesorectal envelope. This results in a characteristic bilobed, smooth, glistening surface of the excised mesorectum.

Because rectal cancer spread appears to be limited to the mesorectal envelope, its total removal should encompass virtually every tumor satellite, thus improving the likelihood of local control. The excellent results with TME may be attributed to improved lateral clearance with removal of potential tumor deposits in the mesentery and decreased risk of tumor spillage from a disrupted mesentery.<sup>44</sup> The completeness of the mesorectal

excision influences local control, even if the surgical margins are uninvolved. In one report, both local (11.4% vs 5.5%) and distant recurrence rates (19.2% vs 12.2%) were higher in patients with an incomplete, as compared with a complete or nearly complete, mesorectal resection. These favorable results have led some to question the need for routine postoperative radiation in patients undergoing complete resection of rectal cancer with TME. However, the Dutch neoadjuvant trial that randomly assigned 1861 patients with resectable rectal cancer to TME alone or a short course of preoperative radiation (5 Gy daily for 5 days, in the “Swedish style”) followed by TME demonstrated a significantly decreased rate of local recurrence 8.2% versus 2.4% at 2 years.<sup>45</sup>

Of greatest importance is that improved local control appears to result in better overall survival. In one of the earliest reports, Heald et al. noted a local recurrence rate of 3.6% and a survival rate of 86% after 9 years of follow-up.<sup>46</sup> In 1994, the Norwegian Rectal Cancer Group was founded to improve the surgical standard by implementing TME on a national level and to evaluate the results; courses were arranged to teach surgeons the technique of TME. Optimized TME reduced the rate of local recurrence (6% TME vs 12% non-TME) and increased overall survival (73% TME vs 60% non-TME) within 2 years.<sup>47</sup> This led to a strategic change in both Norway and the United States to initiate quality assessment in the surgical treatment of rectal cancer.

Guillem et al. recently demonstrated an improved overall and disease-free survival in patients with T3 or N1 tumors who underwent TME after preoperative combined-modality therapy.<sup>48</sup> With a median follow-up of 44 months, the estimated 10-year overall survival was 58% (Fig. 54-13), and 10-year recurrence-free survival was 62% (Fig. 54-14). On multivariate analysis, pathologic response greater than 95%, lack of lymphovascular invasion and/or perineural invasion (PNI), and lack of postoperative positive lymph nodes were significantly associated with improved overall and disease-free survival.

**FIGURE 54-13** Five- and ten-year overall survival with 95% confidence intervals of rectal cancer patients following preoperative combined modality therapy and total mesorectal excision. (Reproduced with permission from Guillem JG, Chessin DB, Cohen AM, et al: Long-term oncologic outcome following preoperative combined modality therapy and total mesorectal excision of locally advanced rectal cancer, *Ann Surg* 2005;May;5;241(5):829-838.)

**FIGURE 54-14** Five- and ten-year recurrence-free survival with 95% confidence intervals of rectal cancer patients following preoperative

combined-modality therapy and total mesorectal excision (TME). ## Lateral Nodal Dissection

Despite the advent of TME and the addition of neoadjuvant chemoradiotherapy to the treatment of patients with rectal cancer, there is still a risk of local pelvic recurrence and the appearance of distant metastatic disease. Lateral nodal spread, especially in distal rectal cancers, is one possible culprit for treatment failures in rectal cancer. It is well established that distal rectal adenocarcinomas have a worse prognosis than more proximally based lesions. Most surgeons attribute this to three factors: (1) distal tumors require a more difficult low dissection in a narrow pelvis; (2) there are probably biologic differences in tumors with the low-lying tumors possibly having a poorer biology; and (3) the more distal tumors have a predilection to more complex lymphatic channels and the possibility of lateral spread into the systemic circulation as well as the portal circulation.

Takahashi et al. performed a retrospective analysis of 764 patients over a 20-year period (1975-1995) who underwent a curative three-space dissection. The three spaces are defined as: (1) the inner space, which is encircled by the visceral pelvic fascia posteriorly and Denonvilliers' fascia anteriorly, and laterally the three spaces unite near the pelvic nerve plexus; (2) the intermediate space, which is defined by the parietal pelvic fascia posteriorly and the internal iliac arteries and branches laterally and anteriorly; and (3) the outer space, which is lateral to the internal iliac arteries. Takahashi found that 66 of 764 patients (8.6%) had lateral nodal spread of their rectal cancer. More importantly, 16.4% of the low-lying rectal cancers had their lower margins less than 5 cm above the dentate line. Lateral nodal spread is outside the traditional TME resection plane but can be encompassed by a three-space lateral nodal dissection in appropriate patients. When this was achieved, they had a 42.4% 5-year survival in their subgroup of patients who had lateral spread and a curative three-space dissection.<sup>49</sup>

A comparative study of Japanese and Dutch patients examined local recurrence in Dutch patients who received TME alone versus TME plus preoperative radiotherapy and Japanese patients who were treated with TME

plus lateral nodal dissection (LAR or APR). Most Japanese patients did not receive neoadjuvant therapy. Local recurrence, lateral pelvic recurrence, and presacral recurrence rates were analyzed and are shown in [Table 54-7](#).

**TABLE 54-7: ANALYSIS OF LOCAL, LATERAL PELVIC, AND PRESACRAL RECURRENCE RATES**

	TME Alone (%)	TME + RT (%)	TME + Lateral Dissection (%)
Local recurrence	12.1	5.8	6.9
Lateral pelvic recurrence	2.7	0.8	2.2
Presacral recurrence	3.2	3.7	0.6

In summary, both TME with radiotherapy and lateral nodal dissection without radiotherapy result in excellent local control and have improved local control over TME alone. The conclusion is that the radiotherapy sterilizes the lateral space that has microscopic tumor extension beyond the traditional TME resection plane.<sup>50</sup> The major caveat is that patients who have TME alone have much better postoperative sexual and urinary function than those who have TME plus lateral nodal dissection.<sup>51</sup>

## Quality of Life

Quality of life has improved with TME and ANP. Conventional rectal surgery is associated with a significant incidence of impotence, retrograde ejaculation, and urinary incontinence/retention, presumably owing to damage to the pelvic autonomic parasympathetic and sympathetic nerves by blunt dissection. Postoperative impotence, retrograde ejaculation, or both are observed in 25% to 75% of conventionally treated patients compared with only 10% to 29% of patients after TME with its careful nerve-sparing dissection.<sup>52</sup>

Erectile capacity and normal ejaculation may be preserved in most male patients, especially those 60 years of age or younger. In one retrospective

study of patients undergoing TME with ANP, 86% of male patients younger than 60 years and 67% of those 60 years or older were able both to engage in postoperative sexual intercourse and to achieve orgasm.<sup>52</sup> In female patients, sexual activity was maintained in 86%, sexual arousal with vaginal lubrication in 98%, and the ability to achieve orgasm in 91%. With the advent of pelvic dissections that preserve autonomic nerves, postoperative sexual dysfunction rates have been reduced from greater than 50% to 10% to 28%.<sup>52</sup>

Isolated urinary dysfunction is uncommon with preservation of the pelvic autonomic nerves. In a prospective study of rectal cancer patients undergoing TME with ANP, only 2 of 35 had difficulty with bladder emptying and possessed evidence of bladder denervation on postoperative studies.<sup>52</sup>

Some studies, however, have demonstrated impaired quality of life owing to LAR with TME in part because of a temporary loop ileostomy or preoperative radiotherapy. However, cost-utility analysis estimates that improved survival outweighs impaired quality of life.<sup>53</sup>

## **Technique of Total Mesorectal Excision**

Prior to the procedure, all patients receive a full mechanical and antibiotic bowel preparation. The patient's abdomen is marked preoperatively by the enterostomal therapy nurse for potential stoma sites. An epidural catheter is placed by the anesthesia team for postoperative pain control. Sequential compression devices are applied to the lower extremities before general anesthesia is induced for deep vein thrombosis (DVT) prophylaxis. One dose of 5000 units of heparin is administered subcutaneously. A second- or third-generation cephalosporin and metronidazole are infused. After anesthesia is induced, the patient is brought down on the table so that the buttocks are at the edge; a gel pad placed under the buttocks facilitates access to the anus. The patient is placed in a modified lithotomy position using Allen or Yellow Fin stirrups (Fig. 54-15). The hips are minimally flexed and abducted. The feet are positioned flat in the stirrups; an imaginary line is visualized keeping the ankle, knee, and contralateral shoulder in a straight line. Care is paid to having no pressure on the peroneal nerve or bony prominences; a hand should be able to be placed easily between the posterolateral aspect of each lower leg and its respective stirrup. If the patient has had previous pelvic surgery or evidence of hydronephrosis on CT scan, consider bilateral ureteral

stent placement. A Foley catheter is placed and is draped over one leg. A nasogastric tube is inserted by the anesthesia team. A DRE is performed. If there is any question regarding the distal or proximal limits of the tumor, rigid proctoscopy may be performed now. Preoperatively, the lesion may have been marked by an injection of India ink. The surgeon should wear a headlight to help with visualization in the lower pelvis. Most surgeons stand on the patient's left, which allows them to operate more efficiently with their right hand in the lower pelvis. A low midline incision is made between the umbilicus and the pubis, keeping in mind potential stoma sites; cephalad extension may be necessary to mobilize the splenic flexure. The abdomen is explored to search for metastatic disease in the liver, pelvic organs (ovaries), or peritoneal surfaces. The rectum is palpated to assess the primary mass. The colon is palpated for any synchronous lesions. A wound protector is then placed and a self-retaining tractor may also be used.

**FIGURE 54-15** Position of patient for surgical treatment of rectal cancer allows access to both the abdomen and the perineum.

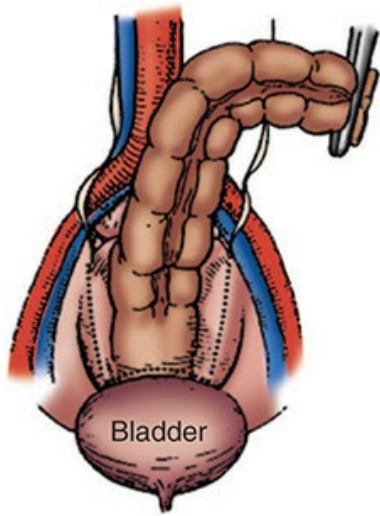

The abdominal self-retractor is set up. The patient is placed in slight Trendelenburg position. The sigmoid colon is mobilized laterally by scoring the white line of Toldt (Fig. 54-16A). The left ureter may be identified by several methods: visualizing it cross over the bifurcation of the common iliac artery, palpating the external iliac artery and pinching the tissue above it, locating it at the level where the sigmoid turns, or incising the peritoneum over the psoas muscle and finding the ureter on the medial aspect of the peritoneum (Fig. 54-16B). In general, the left ureter is found deep and medial to the gonadal vessels. After mobilization of the sigmoid colon and identification of the left ureter, the surgeon should ascertain if much length will be necessary for reconstruction of the rectum. If additional conduit is needed for the reconstruction, then the splenic flexure is mobilized. Tension on the colon should be gentle but firm; too much traction on the colon or omentum can cause splenic injury. The transverse colon is freed from the omentum by sharp dissection along the avascular plane between the two structures. The bowel is packed into the upper abdomen. The sigmoid is held up in the air at the junction between the descending colon and sigmoid. Both sides of the mesentery are scored from this point down to the sacral promontory. The right ureter is identified. The colon usually is divided proximal to the rectosigmoid junction using a linear stapler (or may be divided between two bowel clamps, which would require a hand-sewn anastomosis). The sigmoidal vessels are isolated and divided. The vessels are doubly ligated. The colon is packed cephalad, out of the field. The superior hemorrhoidal artery is then divided at the junction with the left colic artery (Fig. 54-16C). A more proximal ligation of the inferior mesenteric vessel can also be performed if extra length on the colon is needed, but it is not necessary to ligate the IMA flush with the aorta for oncologic reasons. One usually suture-ligates the superior hemorrhoidal vessels to ensure hemostasis. If additional length is still required, then division of the inferior mesenteric vein near the root of the transverse mesocolon just lateral to the fourth portion of the duodenum will give additional length.

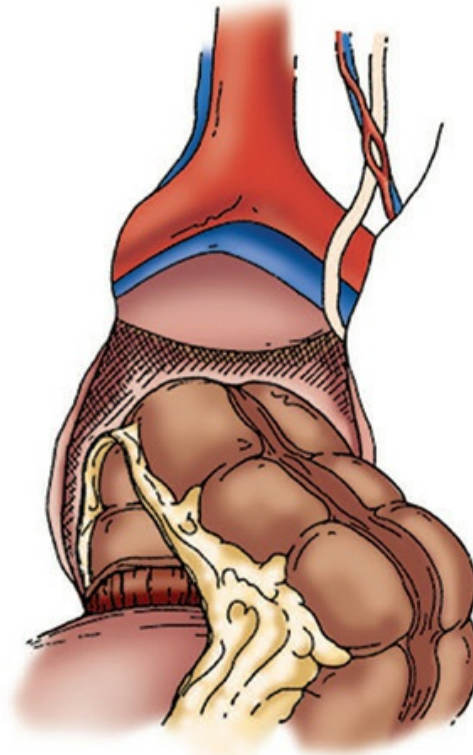

**FIGURE 54-16** Mobilization of the left colon. **A.** Incision line around the left colon. **B.** Left colon reflected medially, exposing the ureter and gonadal vessels. **C.** Superior hemorrhoidal artery is divided close to the aorta to result in a high arterial ligation. The arcade of Riolan is preserved, and the left colon and mesentery are divided at the junction of the descending and sigmoid colon. **D.** Proximal ligation of the inferior mesenteric vein adds extra mobility.

After dividing the superior hemorrhoidal artery, it is important to find the proper plane of dissection at the sacral promontory. One first locates the sympathetic nerves along the pelvic brim. The rectum is retracted anteriorly. Electrocautery with a long Bovie tip is used to develop the loose areolar plane of avascular tissue posteriorly (Fig. 54-17B). The nerves are visualized and kept posterior and lateral to the plane of resection. The presacral fascia is incised down to Waldeyer's fascia, and the dissection is carried inferiorly to the tip of the coccyx. The St. Mark's abdominal retractor facilitates the deep pelvic dissection.

**FIGURE 54-17** Mobilization of the rectum. **A.** Peritoneal incision of the pelvis. **B.** Rectum reflected anteriorly and posterior avascular plane entered between the presacral fascia of Waldeyer and the fascia propria of the rectum. **C.** Division of lateral stalks. **D.** Projected line of dissection in pelvis through Waldeyer's and Denonvilliers' fascia.

The anterior and lateral dissections are then started after the posterior dissection has been partially completed. The peritoneum is incised on each side and then across the anterior midline at the deepest point in the cul-de-sac. The anterior peritoneum is incised in the groove between the rectum and the anterior structures (uterus/vagina in women, seminal vesicles/prostate in men) (Fig. 54-17A). The mesorectum is separated from the pelvic sidewall using the cautery to divide the thin areolar tissue that is found when one is dissecting in the proper plane. The dissection is carried down anterolaterally to the lateral ligaments or "stalks" (Fig. 54-17C). Only 25% of patients have distinct branches of the middle rectal vessels in these ligaments. They can be divided flush with the pelvic sidewall, but care should be taken to preserve the hypogastric plexus that lies on the pelvic sidewall just lateral to the seminal vesicles in men or just lateral to the cardinal ligaments in women. Preservation of the plexus helps with avoiding postoperative erectile dysfunction or urinary problems, and resection of the plexus is rarely helpful for oncologic reasons. Throughout the lateral dissection, one should be aware of the nerves and vessels along the pelvic sidewall. Too lateral a dissection can cause bleeding from the pelvic sidewall.

Anteriorly, the planes are less distinct, and the fat of the mesorectum is thin. The vaginal wall or seminal vesicles are elevated anteriorly using the lipped St. Mark's retractor while the surgeon places posterior traction on the rectum. In the male patient, the dissection is continued through or anterior to Denonvilliers' fascia (Fig. 54-17D). This fascia is often two layers of a thin membrane. When performing a cancer resection, one should take both layers of this membranous fascia off the seminal vesicles and upper prostate if possible.

## **POINT OF TRANSECTION**

For middle to low rectal cancers, TME involves removing the entire mesorectum with its enveloping fascia as an intact unit. For tumors in the

upper rectum (>10 cm from the anal verge), TME is extended to 5 to 6 cm below the level of the tumor, dividing the rectum and mesorectum at the same level. Several pathologic studies demonstrate that tumor spread within the mesorectum rarely extends beyond 4 cm distal to the caudal edge of the tumor; usually most nodes or mesorectal implants are within 3 cm of the distal edge of the tumor.<sup>9,15</sup> However, multiple studies have shown that a 1- to 2-cm margin is adequate on the mucosa. Fewer than 2% to 4% of tumors will have mucosal or submucosal spread beyond 2 cm distally. Rigid sigmoidoscopy may be used to identify the appropriate site for transection if the cancer is not palpable, especially after neoadjuvant therapy.

Once the rectum has been mobilized, a tumor measured at 5 cm by rigid proctoscopy often may be moved to 8 cm from the dentate line, a distance that permits an adequate resection margin and sphincter preservation (Fig. 54-18).

**FIGURE 54-18** Tumor position relative to the dentate line after mobilization

of the rectum. This may permit a sphincter-preserving resection.

When the distal extent of the tumor and the site of transection have been established, electrocautery is used to dissect the mesorectal fat away from the rectum. Vessels require ligation with 2-0 Vicryl ties or an energy device such as the LigaSure (Valleylab: Boulder, CO). It is important to keep the dissection of the mesorectum perpendicular to the site of transection. “Coning in” as one divides the mesorectum prior to transection should be avoided.

Once the bowel has been cleared of mesorectal fat, a 30-, 45-, or 60-mm TA linear stapler or a curved 40-mm contour stapler (Ethicon, USA) is used to staple the rectum ([Fig. 54-19A](#)). This is the first staple line in the “double-stapling technique.” The contour stapler staples on either side and divides between, whereas the linear TA staplers require that the specimen side of the bowel is clamped just proximal to this linear stapler. A no. 10 blade on a long handle is used to transect the bowel. The specimen is handed off the field.

**FIGURE 54-19** Colorectal anastomosis: double-staple technique. **A.** Transection of the distal rectum with a linear stapler. **B.** Stapling instrument introduced through rectum. **C.** Descending colon purse-string suture is tied around shaft of anvil. After the trocar of the circular stapler penetrates behind the staple line, the trocar is removed before reconnecting the anvil to the shaft. **D.** The circular stapler is reconnected, reapproximated, and fired. **E.** The anastomosis is complete. **F.** The proximal and distal staple lines are examined for intact inner “donuts.”

## **RECONSTRUCTION: DOUBLE-STAPLING TECHNIQUE**

The proximal colon is unpacked, and the length required for a tension-free anastomosis is determined. If more colon is needed, the splenic flexure is mobilized further. This may require an extension of the incision cephalad. Proximal ligation of the inferior mesenteric vein also adds extra mobility (see [Fig. 54-16D](#)). The proximal bowel is cleaned by resecting residual fat and small vessels approximately 1 cm proximal to the staple line. The staple line is excised with Bovie electrocautery. We routinely use a 28-mm end-to-end anastomosis (EEA) circular stapler. The anvil is placed within the opened bowel and a 3-0 Prolene is used to take full-thickness, 1- to 2-mm bites to fashion a purse-string stitch around the anvil. The purse-string suture is tied gently but firmly around the shaft so that the shaft is completely encircled by bowel ([Fig. 54-19C](#)). If there are any gaps, an additional 3-0 Prolene suture can be used to take another full-thickness bite, and this suture may be tied around the shaft as well. The serosa of the bowel is cleaned further of fat and small vessels within 1 cm of the shaft of the anvil to optimize bowel-to-bowel contact when the circular stapler is applied. One can also perform a similar placement of the anvil on the antimesenteric side of the colon for a side-to-end anastomosis. The optimal placement of the anvil in this case is such that only a small blind end of colon remains distal to the anastomosis (1-5 cm).

Attention then is turned to the pelvis, which is irrigated and inspected for hemostasis. This is truly the last opportunity to inspect this area because exposure will be compromised once the anastomosis is completed.

One member of the team then stands between the patient’s legs. The circular stapler is coated with lubricant on the outside of the stapler; we do not place lubricant on the staples themselves. The tip is retracted fully. A rectal examination is performed, and the anus is dilated gently with two to

three fingers to accommodate the stapler. The circular stapler is inserted gently following the curve of the sacrum—initially straight in and then the stapler is tilted posteriorly. Using close communication with the surgeon overlooking the abdomen, the assistant positions the circular stapler tip so that the trocar will exit either 2 to 3 mm anterior or posterior (we elect to do this posteriorly in women to avoid the vaginal wall) to the staple line (Fig. 54-19B). The trocar then is advanced slowly; the bowel continues to be adjusted as necessary. When the spiked trocar protrudes through the bowel wall, be sure that the trocar is fully advanced so that its bottom is visualized (see Fig. 54-19C). The surgeon controlling the proximal bowel should at this point ensure that the proximal bowel is not twisted and that the remaining bowel, mesentery, and epiploicae are held away. The anvil is then brought down gently to the stapler and connected to the spiked trocar. The colon is inspected again to verify that no adjacent tissue is entrapped. The stapler is closed slowly until both pieces of colon are fully approximated (Fig. 54-19D). The stapler is fired, opened slightly, and gently removed. This is the second staple line in the double-stapling technique (Fig. 54-19E). The stapler is opened, and the tissues from the proximal and distal bowel are inspected to make sure that the two rings of tissue, or “donuts,” are intact (Fig. 54-19F). If they are not intact, additional sutures are placed if a visible gap is apparent. All anastomoses are checked for integrity. The surgeon fills the pelvis with saline and clamps the bowel proximal to the anastomosis gently with the index and third finger in a scissor fashion. At this point the assistant between the legs introduces a rigid sigmoidoscope into the rectum and insufflates air. If bubbles cannot be detected, one can be confident that the anastomosis is intact. If bubbles are detected, additional sutures are placed in suspected areas, and a diverting loop ileostomy is constructed. If the anastomosis is disrupted completely, it must be refashioned.

## **DIVERTING LOOP ILEOSTOMY**

A diverting loop ileostomy should be considered in any low anastomoses (<5 cm) from the dentate line as these anastomoses are associated with anastomotic leak rates of up to 17%. Other risk factors for anastomotic breakdown include a history of radiation, perioperative steroid use, malnutrition, elderly women with a thin rectovaginal septum, or elderly patients undergoing preoperative combined-modality therapy with planned

postoperative chemotherapy. Additionally, if there is any question regarding the integrity of the anastomosis, an ileostomy should be created.

Ileostomies can be closed within 8 weeks but often are left in place until the patient completes adjuvant chemotherapy. A Gastrografin (diatrizoate meglumine) enema is used to check the patency and integrity of the anastomosis prior to ileostomy reversal.

## **DRAIN PLACEMENT**

Most surgeons continue to advocate routine use of drains after pelvic anastomoses. One prospective, randomized trial of 100 patients to receive either no drains or closed-suction drains demonstrated that the presence or absence of a drain did not influence the rate of morbidity and mortality. Although there is no evidence for the use of drains when an anastomosis has been made outside the pelvis, pelvic drainage may be important after anterior resection. We recommend placing a drain in extremely low resections, especially where the anastomosis was hand-sewn or in patients who undergo an APR. For all other resections, placement of a drain may be determined on a case-by-case basis.

## **CLOSURE**

We prefer to close the abdominal fascia with a looped zero or number 1 PDS suture starting at the cephalad and caudad ends and to run the suture toward the middle. The skin is closed with either staples and a dry sterile dressing consisting of 4 × 8 gauze and Tegaderms (3M, USA) or a 4-0 Vicryl subcuticular suture followed by Dermabond (Ethicon, USA).

## **Postoperative Care**

The orogastric tube is removed at the end of the procedure. Intravenous fluids are stopped 6 hours after surgery and the patient can drink sips of clear liquids. The diet is advanced to low residue on postoperative day 1. Heparin is administered subcutaneously at a dose of 5000 units TID. Sequential compression devices are worn by the patient unless the patient is ambulating well. Most patients ambulate on postoperative day 1. The Foley catheter is kept in place for 2 to 3 days. If an epidural has been used for postoperative

pain control, it is usually left in place until the patient is started on oral pain medication.

## **Coloanal Anastomosis**

Anastomoses at or just above the anorectal ring often result in increased frequency of stool, incontinence or soilage, and impaired quality of life owing to an insufficient reservoir. Diet restrictions, fiber supplementation, and time after surgery usually will improve these symptoms. Two techniques of reconstruction that also help improve these symptoms in the first year are a side-to-end reconstruction or a colon J-pouch reconstruction when compared to a straight end-to-end anastomosis. In the past, a transverse coloplasty was entertained, but this technique has a higher complication rate and no significant improvement in symptoms so it is of historical interest only.

To create a colon J-pouch, a 6-cm limb of sigmoid or descending colon is folded on itself and the apex is brought down to reach the rectal stump without tension. The splenic flexure may require additional mobilization. Once the apex has been identified a colotomy is made at the apex with Bovie electrocautery, and an 80 GIA linear cutting stapler is used to create the colon J-pouch by stapling out the wall between the two loops of bowel turned on itself, thereby creating a common lumen. A second fire of the stapler may be necessary. This pouch now serves as the neorectum. A double-stapled anastomosis as described above or a hand-sewn anastomosis is then performed. A diverting loop ileostomy is used routinely for these ultralow anastomoses.

Multiple prospective, randomized studies have demonstrated superior function of a coloanal J-pouch over a straight coloanal anastomosis, especially in the first 6 months after ileostomy takedown.

## **ABDOMINOPERINEAL RESECTION**

Traditionally, distal rectal cancers have been treated with an abdominoperineal resection (APR), as first described by Miles, who noted high failure rates after local excision.<sup>3</sup> This procedure involves the en bloc resection of the tumor as well as the surrounding lymph nodes and the anal sphincters, resulting in a permanent colostomy.

The APR, although quite successful for early rectal cancers (stage I) in terms of survival, is associated with significant morbidity of 61% and mortality ranging from 0% to 6.3%.<sup>54</sup> Urinary complications can be as high as 50% and perineal wound infections 16%. In addition to these perioperative problems, significant long-term morbidity is associated with a permanent colostomy. In a patient survey, 66% of patients complained of significant leaks from their stoma appliance, 67% experienced sexual dysfunction, and only 40% of patients working preoperatively ultimately returned to work.<sup>55</sup> There is also a significant change in body image when compared with sphincter-saving procedures. The 5-year survival rates following an APR range from 78% to 100% for stage I, 45% to 73% for stage II, and 22% to 66% for stage III disease.<sup>56</sup> Despite radical resection, 20% recur locally. Variations in recurrence rates depend on location of the tumor within the rectum, changes in surgical technique, and the addition of adjuvant therapy.

For patients with cancers that involve the sphincter apparatus or for those who are incontinent of feces, an APR is performed to remove the rectal specimen.

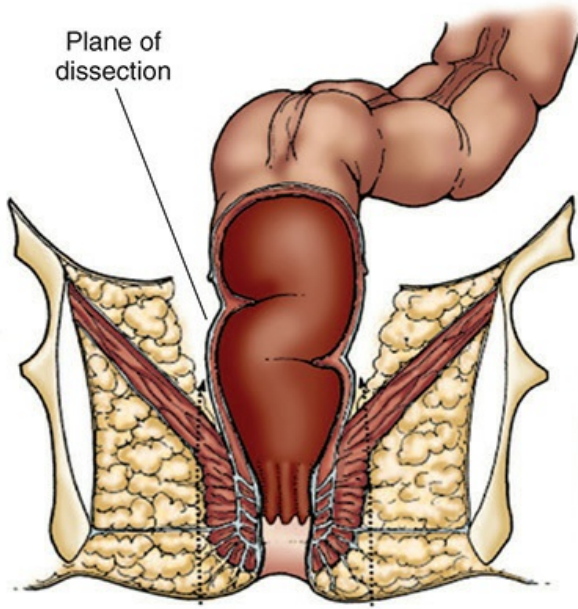

## Technique

The patient is marked preoperatively by the enterostomal nurse for a permanent colostomy. Please see the section Low Anterior Resection with Total Mesorectal Excision for details regarding additional preoperative care, positioning, incision, and rectal mobilization. The dissection proceeds down to the striated muscles of the levator ani; one can confirm muscle contraction by using electrocautery. Once this level is reached, the colostomy is created and the abdominal cavity is closed. The patient is then rolled into the prone position with the buttocks taped apart. The perineal dissection is then performed.

## Perineal Dissection

The anus is closed with a no. 0 silk suture in a purse-string fashion ([Fig. 54-20B](#)). A marking pen is used to draw an ellipse 2 cm outside the superficial external sphincter and extending from the perineal body anteriorly, coccyx posteriorly, and ischial tuberosities laterally. The incision is made with a no.

10 blade and carried down through the dermis into ischiorectal fat (Fig. 54-20C). Two Gelpi retractors are placed at 45 degrees to the anus to facilitate deep dissection. The dissection is carried deep outside the external sphincter toward the tip of the coccyx, keeping in mind the planes of dissection (Figs 54-20A and E). The anococcygeal ligament is palpated just anterior to the tip of the coccyx and it is divided and the retrorectal space is entered. The digit of the surgeon is hooked around the levator complex and this is divided as well. The anterior plane is divided last, taking the specimen off the back wall of the vagina or the prostate. If the two-team technique is used, the perineal incision used is the same as for the prone position. Once the anococcygeal ligament has been divided the palpating finger meets the fingers of a team member working from the abdominal field (Fig. 54-20D). A pair of large scissors is used to poke through the ligament; the scissors are fully spread and, while wide open, are pulled straight back. Hooking the index and middle fingers under the levator muscles and transecting with electrocautery frees the rectum laterally (Figs 54-20F and G).

**FIGURE 54-20** Perineal dissection: two-team synchronous approach. **A.** Projected lines of pelvic floor resection in the vertical plane. **B.** Anal closure. **C.** Perineal incision. **D.** Incision line anterior to coccyx through anococcygeal ligament through which scissors are used to gain entrance to the pelvis. **E.** Planes of pelvic dissection and posterior plane of entry into pelvis through the pelvic floor. **F.** Projected lines of pelvic floor transection. **G.** Lateral transection of levator ani muscle. **H.** Anterior transection of rectourethralis, puborectalis, and pubococcygeus. **I.** Completion of anterior dissection and removal of rectum through perineal wound. **J.** Pelvic floor closed with two drains in place.

The anterior surface is dissected last (Figs 54-20H and I). The rectum is delivered through the perineal opening. An assistant retracts the skin and subcutaneous tissue anteriorly with an Army-Navy retractor. Care is taken to keep the posterior wall of the vagina or the prostate anterior to the plane of dissection. The surgeon cups the hand around the rectum with traction posteriorly and inferiorly and uses cautery between the rectum and the anterior structures, often reassessing the plane of transection. Once freed circumferentially, the specimen is passed off the field.

The pelvic floor is irrigated and checked carefully for hemostasis. A tongue of omentum or omental pedicle flap may be used to cover the pelvis to prevent the small bowel from dropping deep into the pelvis if radiation is contemplated. Omentum also helps healing, especially in an irradiated perineum or when patients also have undergone prostate or vaginal resections. One or two 19 Fr fluted Blake drains are placed in the pelvis and are brought anteriorly out through the abdominal wall and secured to the skin using 3-0 nylon suture (Fig. 54-20J). The abdomen is closed as described under Low Anterior Resection. The colostomy is matured using interrupted 3-0 Vicryl suture.

If using a two-team approach, the perineal wound can be closed after the pelvis has been irrigated and hemostasis achieved. The remnants of the levators are closed with 0 Vicryl figure-of-eight sutures and then the subcutaneous tissues are closed in two layers of interrupted 0 Vicryl. One layer of 3-0 Vicryl in a deep dermal layer is placed and then the skin is closed with a running 3-0 Monocryl and Dermabond. Because this area is often radiated, multiple layers decrease the risk of the wound breakdown extending into the pelvis.

Initially, the APR was performed utilizing an anterior approach and then flipping the patient for the perineal component. In this way, APR was done by completing the abdominal mobilization of the rectum to the levators circumferentially and then creating a colostomy and closing the abdomen and flipping the patient to complete the perineal portion of the operation. In most institutions two teams work simultaneously (as described previously) and two instrument tables are used with separate counts and often requiring additional OR support staff to assist. All of this increases utilization to save operative time. More recently, attention has reverted to the traditional anterior and posterior approach to the APR. In fact, there are recent data that support a better oncologic outcome using an anterior and posterior approach as described previously. This is known as the *cylindrical technique*. West et al. reported more tissue excised in all pathologic resections and better margins from the muscularis to all resection margins. These results translated into a lower rate of positive circumferential resection margin with APE 14.8% versus 40.6% for traditional APR and a decrease in intraoperative perforations 22.8% to 3.7%, respectively.<sup>57</sup> In our experience, we have also found better short-term outcomes with lower perineal wound infections and improved perineal healing.

## Postoperative Care

Postoperative care is like that described under Low Anterior Resection. The patient can sit starting postoperative day 1 for 30 minutes 3 to 4 times daily for meals if there is no muscle flap reconstruction (in which case sitting directly on the flap is usually postponed for about 4 weeks). Over the next several weeks, the patient gradually increases the sitting time, always utilizing a soft pillow; we do not advocate using a “donut” because the perineum is not supported so it sinks into the donut hole, and this puts tension on the perineal closure. The Foley catheter remains in place for 2 to 3 days.

## Complications

Perineal wound complications are common following APR and occur in up to 25% of patients. While most of these wound complications are minor, some may require operative debridement. We demonstrated previously that

preoperative radiation and primary closure were not associated with an increased incidence of wound complications compared with nonirradiated patients following APR for rectal cancer.<sup>58</sup>

Stoma complications include ischemia, retraction, hernia, stenosis, and prolapse. The construction of a good colostomy will provide a patient with a superb quality of life after APR. Early education in the immediate postoperative period allows the patient to adjust to life with a stoma. The stoma shrinks to its final size approximately 6 to 8 weeks postoperatively when the edema has subsided. An end colostomy may be irrigated to establish regularity of bowel movements and further improve the patient's quality of life. The operative mortality for APRs is less than 2%.

## EN BLOC EXCISION WITH RECTUM

### Posterior Vaginectomy

Partial vaginectomy is indicated for locally advanced low rectal cancers involving the vagina. One study demonstrated a 5-year survival of 46% and a median survival of 44 months, with most favorable results from negative surgical margins and node-negative disease.<sup>59</sup>

If the patient undergoes an APR, the posterior wall of the vagina is removed as the anterior margin of the resection (Fig. 54-21). After completing the posterior and lateral dissections, the rectum is delivered through the perineum. The anterior aspect of the perineal incision includes the posterior introitus and is extended around the posterior third to half of the vagina only to avoid denervation of the urethra. To achieve hemostasis during the procedure, one can place interrupted 2-0 absorbable full-thickness sutures through the vagina from either side, starting at the apex of the incision, and tie the sutures as the specimen is being excised.

**FIGURE 54-21** Posterior vaginectomy with APR. **A.** Line of dissection, including posterior wall of vagina for low anterior rectal cancer. **B.** Lines of transection, including posterior wall of vagina.

If the patient undergoes an LAR with a coloanal anastomosis, the partial vaginectomy may be performed through the abdominal approach. The involved area of the vagina is resected with a 1-cm margin and kept en bloc with the rectum. Subsequent closure of the vagina is completed by initially placing Allis clamps on the vaginal edges and then taking full-thickness bites with 2-0 Vicryl sutures in a figure-of-eight fashion.

Before abdominal closure, we recommend placing an omental flap around the vaginal cuff to prevent breakdown of the vaginal suture line. If a coloanal anastomosis is in place, we would position the omentum between the vaginal and the coloanal suture lines.

## Prostatectomy

In locally advanced rectal cancer in which there appears to be possible involvement of the prostate, urethra, bladder, or ureterovesicular junction on

CT scan of the abdomen and pelvis, an MRI of the pelvis should be obtained. Urology consult should be made because one must be prepared for radical prostatectomy and/or cystectomy with ileal conduit diversion. A prostatectomy en bloc with rectal resection is an alternative to total pelvic exenteration in patients whose rectal cancer is fixed only to the prostate. The reasons for involving urology are in part due to the vascularity of the prostate. In addition, one should be concerned about constructing any genitourinary anastomosis (eg, between bladder and urethra) in the presence of previous radiation and a rectal anastomosis. Attention should be paid to potential for autonomic nerve deficit if proximity and effacement of the neurovascular bundle are evident on MRI.

## **Pelvic Exenteration**

Total pelvic exenteration is an alternative for patients with locally advanced rectal cancer in which the tumor is contiguous with adjacent organs, such as the prostate or bladder (Fig. 54-22). Long-term survival rates range from 20% to 70% and are improved in younger patients with no lymph node metastases.<sup>60</sup> Local recurrence rates range from 3% to 8%. An argument against performing total pelvic exenteration is the considerable morbidity (20%-40%) and 0% to 20% mortality associated with this procedure. The most common complications are infection, small bowel obstruction, and problems with urinary diversion.

**FIGURE 54-22** Pelvic exenteration. (Reproduced with permission from Schwartz DI: *Principles of Surgery*, 6th ed. New York, NY: McGraw-Hill; 1993.)

## Prophylactic Bilateral Oophorectomy

Carcinoma of the rectum metastasizes readily to the ovaries. Prophylactic oophorectomy is not routinely advocated for pre- or postmenopausal patients, as prophylactic bilateral oophorectomy does not significantly affect survival. We discuss the potential need for prophylactic oophorectomy if a lesion or nodule is found on the ovary. In postmenopausal women oophorectomy

suffices, and in premenopausal women a biopsy, and if it is positive for invasive cancer then an oophorectomy is performed.

## **PALLIATIVE RESECTION IN STAGE IV DISEASE**

Palliative resection of the primary colorectal tumor in stage IV rectal cancer depends on the degree of symptoms present. In patients who are symptomatic from bleeding, localized perforation, and obstruction, there are several management options that can relieve the symptoms of the primary tumor:

1. Permanent diversion followed by chemotherapy ( $\pm$  radiotherapy depending on local symptoms)
2. Palliative resection with a permanent colostomy followed by chemotherapy (radiotherapy is generally not needed if the primary is successfully resected with negative margins in the stage IV patient)
3. Palliative resection with restoration of GI continuity followed by chemotherapy ( $\pm$  radiation depending on the burden of metastatic disease, the resection margins, and any symptoms the patient may develop later from recurrent disease)

In the symptomatic patient, it is our practice to offer upfront surgical resection/diversion and additional therapy using one of the above three options. The surgical procedure depends on the performance status and the intraoperative findings at the time of exploration. In patients with distant spread to solid organs alone, it is our inclination to perform resection of the primary with restoration of GI continuity. In patients with significant peritoneal and pelvic carcinomatosis, we will offer either resection with end colostomy or just a diversion, depending on the degree of pelvic peritoneal carcinomatosis. In the patient with a large burden of disease, it is better to just divert the patient and start chemotherapy and then offer palliative radiotherapy if the bulky primary continues to bleed or causes pain from infiltration of the sacral nerve roots.

On the other hand, resection in the asymptomatic patient with incurable stage IV disease is controversial. Resections for rectal cancer often have significant morbidity and measurable mortality but at the same time offer the

best palliation of local symptoms. Moreover, in the last decade chemotherapy regimens have significantly extended the life expectancy of patients with colorectal cancer. The advent and widespread use of the FOLFOX (5-fluorouracil [5-FU], leucovorin, and oxaliplatin) and FOLFIRI (folinic acid, fluorouracil, and irinotecan) chemotherapy regimens have extended the median life expectancy of patients with stage IV disease from approximately 8 months to nearly 2 years. Many patients live much longer than this. Hence it is our opinion that upfront palliative resection is warranted in the medically fit patient with a low burden of distant but traditionally incurable disease. In those who have significant distant disease, we prefer systemic therapy with restaging after several courses of chemotherapy. In the medically fit patient with a good performance status that has substantial improvement in the metastatic burden, we will once again offer palliative resection. The choice of operation (see above choices) depends on the intraoperative findings. This approach has never been studied prospectively, and the sparse literature is based solely on retrospective reviews. Despite this, patients who have had asymptomatic primary tumors resected have a substantial survival advantage over those who were never resected. Ruo et al. showed that those who were resected versus the non-resected had a prolonged median survival of 16 versus 9 months and a 2-year survival of 25% versus 6% with both measures reaching statistical significance.<sup>61</sup> Venderbosch et al. in 2011 reviewed all patients enrolled in the CAIRO and CAIRO2 trials who had stage IV incurable metastatic colorectal cancer and they compared patients who had an upfront resection of the primary versus those who did not. In both instances, they found a survival advantage of approximately 6 months for those who were in the resection group.<sup>62</sup>

## LAPAROSCOPIC SURGERY

Minimally invasive laparoscopically assisted surgery was first considered in 1990 for patients undergoing colectomy for cancer. The technical feasibility of performing laparoscopic TME was demonstrated in several prospective studies. Preservation of the autonomic nerves is also possible during laparoscopic TME. Early results confirmed complete resection of the mesorectum with intact visceral fascia in all patients.<sup>63</sup> Because Nelson others showed equivalent outcome, quality of life, and survival in

laparoscopic surgery for colon cancer, there has been renewed interest in laparoscopic LAR for rectal cancer.<sup>64</sup> The Conventional versus Laparoscopic-Assisted Surgery In Colorectal Cancer (CLASSIC) trial group from the United Kingdom published the results of their randomized comparison of laparoscopic versus open LAR for rectal cancer in 794 patients (526 lap vs 268 open) with a median follow-up of 36.8 months and equivalent numbers of patients receiving chemoradiotherapy. The OS (open 66.7% vs lap 74.6%) and DFS (open 70.4% vs lap 70.9%) were similar in both groups and were without statistical significance. The overall local recurrence rates were 7% in open resection and 7.8% in the laparoscopic group. Even though there was a trend (not statistically significant) toward the laparoscopic group having a higher positive CRM, there was no difference in local recurrence at 3-year follow-up. Long-term follow-up of the CLASSIC trial was published in 2010 and this showed no statistically significant difference in distant recurrence, local recurrence, DFS, or OS.<sup>65</sup> Initially, the increased positive CRM was concerning with only 3-year follow-up. However, with longer-term follow-up the initial increase in positive CRM did not translate into worse outcomes with higher rates of locoregional recurrence.<sup>66,67</sup> The CLASSIC trial did report overall worse sexual function in men (not women) undergoing laparoscopic rectal cancer resection.<sup>68</sup> Hence patients need to be made aware of the potential for worse sexual dysfunction with laparoscopic surgery for rectal cancer. Finally, the CLASSIC trial measured quality-of-life outcomes for patients undergoing laparoscopic versus open surgery and there were no significant differences between laparoscopic resection and open surgery.

In 2015, the COLOR II trial was published in *The New England Journal of Medicine*, and the results showed that laparoscopic surgery when compared to open surgery for rectal cancer had similar rates of locoregional recurrence as well as disease-free and overall survival. Three-year results showed that the locoregional recurrence rate was 5% in both groups and that the DFS was 74.8% and 70.8% in the laparoscopic versus open groups, respectively. The OS was 86.7% versus 83.6% in the laparoscopic versus open group again. None of these comparisons was statistically significant.<sup>69</sup> Furthermore, in 2015 both Stevenson and Fleshman published trials in *JAMA* looking at the efficacy of laparoscopic rectal cancer surgery versus open surgery to establish the noninferiority of laparoscopic resection by examining pathologic specimens. Neither trial yet demonstrates noninferiority because there is no

long-term data for local recurrence, disease free survival and overall survival rates; both authors suggest that laparoscopy should not be considered equivalent to open surgery until long-term clinical outcomes have been established. This has stirred controversy since noninferiority was not proven and all metrics examined were within the established confidence intervals.<sup>70,71</sup> In summary, nearly all the evidence supports equivalent outcomes with respect to locoregional recurrence, DFS and OS when comparing laparoscopic to open surgery for rectal cancer. There is equivalent quality of life and the potential for worse sexual function with laparoscopy in men. Pending adverse reports of worse clinical outcomes in the long-term follow-up on the two *JAMA* noninferiority trials (Fleshman and Stevenson), laparoscopic surgery for rectal cancer should be considered equivalent with the above-mentioned caveats regarding sexual function.

## **ROBOTIC SURGERY**

In recent years, robotic rectal cancer surgery has begun to take hold. The ROLLAR clinical trial published in 2017 showed that robotic surgery had equivalent results and clinical outcomes when compared to laparoscopic surgery. The primary endpoint of the study was to show that robotic surgery had a lower conversion rate to an open procedure but this was not shown. The conversion rate to open surgery and the rate of positive CRM were equivalent between robotic surgery and laparoscopic surgery. Moreover, there was no difference in the secondary endpoints of urinary dysfunction, sexual dysfunction, intra/postoperative complications, 30-day mortality, and length of stay. Hence it is safe to conclude that robotic surgery offers no advantage when compared to laparoscopic surgery for rectal cancer.<sup>72</sup> Since laparoscopic and robotic surgery have equivalent results in outcomes, the choice between types of minimally invasive rectal cancer surgery depends on the institution, the surgeon, and patient preference. The main obstacles to robotic rectal cancer surgery (and even laparoscopic when compared to open technique) are the learning curve, time constraints, and the cost of the procedure. Operative time is longer and cost is more substantial in both minimally invasive approaches.

## **OTHER TREATMENT OPTIONS**

Besides surgical resection for rectal cancer, there are other options for patients who may not be candidates for surgery owing to their comorbidities, extent of disease, or preference. Endocavitary radiation may be delivered at doses of 50 cGy for palliation and for curative intent. Performed as an outpatient and well tolerated by patients, endocavitary radiation is delivered with sedation and local perineal block.

Electrocoagulation may be used via a transanal approach after administering general anesthesia and placing the patient in the lithotomy position. The rectal lesion and a 1-cm margin are fulgurated. Recurrence rates approach 50% to 80%; therefore, patients may require repeat treatments.

Cryotherapy, another alternative modality, results in a large amount of foul-smelling discharge. Photodynamic therapy has limited availability. Laser vaporization using neodymium: yttrium-aluminum-garnet laser provides palliation but is associated with a 14% recurrence rate and is costly.

## COMPLICATIONS

Complications of surgical management of rectal cancer may include those common to any major intra-abdominal operation, such as infection, bleeding, wound problems, deep venous thrombosis/pulmonary embolism, myocardial infarction, pneumonia, and renal failure. There are, however, several complications specifically related to rectal cancer. There is a 50% incidence of impotence in men following resection for rectal cancer. Therefore, it is critical to discuss this situation with the patient before the resection and to record the preoperative status of his sexual function. If a man is impotent after surgery, it is advisable to wait 1 year before undergoing implantation of a penile prosthetic device. This delay is recommended not only to ensure that the malignancy has been cleared but also to allow the patient sufficient time to overcome psychological impediments such as a change in body image from pelvic surgery or from a colostomy. Women may also suffer from impaired sexual function, especially if the vagina is distorted during the rectal resection.

A possible permanent colostomy is often not preferred by patients. Its placement, however, must be explained in a way that the patient understands that he or she may be left with this if reconstruction is not technically possible.

Anastomotic leak, which occurs in up to 20% of patients, can be avoided by constructing the anastomosis with well-vascularized tissue without tension. Interestingly, young, muscular men have a higher incidence of anastomotic leaks, which may result from the technical challenge of operating in a narrow pelvis or from strong sphincters that may stress the anastomosis. The latter may be addressed by dilating the anal sphincter in the operating room at the end of the procedure. Anastomotic leaks usually present between 4 and 7 days postoperatively. Symptoms may include fever, tachycardia, arrhythmias, tachypnea, enterocutaneous fistula, or diffuse peritonitis. When a leak is suspected, the patient should be made NPO and blood should be sent for a complete blood count, electrolytes, and type and cross-match. An upright chest x-ray will diagnose pneumoperitoneum. Abdominal series may demonstrate extraluminal air. CT scan of the abdomen and pelvis with water-soluble contrast material may demonstrate abscess formation, extraluminal air, and the actual leak. Barium should be avoided because leakage of barium creates a destructive peritonitis. A leak may be managed with intravenous antibiotics and bowel rest in a patient without peritonitis. An abscess may be drained percutaneously. An enterocutaneous fistula may be treated with total parenteral nutrition and local wound care. If a large leak is demonstrated or the patient experiences peritonitis, exploratory laparotomy with diverting ileostomy or colostomy should be performed. The anastomosis is rarely taken down and should not be reconstructed in the presence of sepsis.

Massive venous bleeding from the presacral space may result intraoperatively from lateral dissection onto the pelvic sidewall or sacrum. Ligation of the iliac vessels is discouraged and may be hazardous. If massive bleeding is encountered, a surgical titanium “tack” may be driven into the sacrum to compress the venous space. Additionally, the pelvis may be packed for 24 to 48 hours, at which time the patient is returned to the operating room for pack removal and closure.

Urinary dysfunction may occur after rectal resection. Many men have coexisting prostatic hypertrophy. Because low rectal dissection approaches the membranous urethra, Foley catheters usually are kept in place for 2 to 3 days. Patients may be discharged with indwelling catheters, especially if they have undergone partial prostatectomies or seminal vesiculectomies. Women may experience urinary incontinence if the anterior aspect of the vagina, which contains the neurologic control of the urethra, is transected.

# OBSTRUCTING, METASTATIC, AND RECURRENT RECTAL CANCER

## Obstructing Cancer of the Rectum

For obstructing cancers of the rectum, a loop ileostomy, performed as an open or a laparoscopic procedure, is constructed for diversion. Staging of the tumor with ERUS or ecMRI usually reveals locally advanced disease and the patient is then treated with neoadjuvant chemoradiation and considered for subsequent surgical resection.

## Metastatic Rectal Cancer

The management of hepatic and pulmonary metastases is not described in this chapter. Nonetheless, if a patient presents with incurable metastatic disease and life expectancy is greater than 6 months, it is reasonable to consider a palliative rectal resection. If the rectal lesion is staged as T3 or N1, we recommend neoadjuvant chemoradiation because this addresses both the primary lesion and the metastasis and may provide some palliation of obstruction, bleeding, or pain. Other options include rectal stents or laser destruction of the tumor to maintain an adequate lumen. It is important to understand the patient, his or her desires, and general state of health when recommending treatment at this stage of cancer.

## Recurrent Rectal Cancer

Historically, local recurrence of rectal adenocarcinoma can be seen in up to 30% of patients depending on whether the patient had neoadjuvant or adjuvant chemoradiotherapy in addition to adequate surgery with TME by an experienced surgeon. A good TME in combination with neoadjuvant chemoradiotherapy should yield a local recurrence in the 9% to 13% range. Although recurrence may be seen at the distal margin of the anastomosis, most develop from residual cancer on the pelvic sidewall or inadequate TME with mesorectal nodes that are not excised as part of the endopelvic envelope. The time course for recurrences to present through the anastomosis is

approximately 18 months. By their nature, these tumors are fixed to the pelvic wall and surrounding viscera. They cause significant symptoms, such as intractable pelvic pain, bleeding, cramping or constipation, urinary tract dysfunction, and chronic pelvic sepsis.

When patients present with these symptoms or with a rising CEA level, a workup including CT scan of the abdomen and pelvis, ERUS, MRI of the pelvis, and PET scan may be helpful. A careful pelvic examination is mandatory. A biopsy, either via sigmoidoscopy or CT-guided, should be used to confirm the diagnosis pathologically. If external radiation has not been used before, it should be considered. The surgeon should review the imaging studies and determine which organs are involved, such as the vagina, uterus, prostate, bladder, sacrum, and small intestine, which will require en bloc resection. Urology consult should be obtained if there is any question of prostate or bladder involvement; ureteral stents should be placed preoperatively. Removal of the rectum and urinary bladder with surrounding lymphatic tissue results in a permanent colostomy and ileal conduit.

## **INTRAOPERATIVE RADIATION THERAPY**

Intraoperative radiation therapy (IORT) may be considered in patients with pelvic sidewall recurrence. This is performed in an operating room–radiation therapy suite. Resection with negative microscopic margins and absence of vascular invasion independently predicts improved local control and survival after resection and IORT.<sup>73</sup> The major morbidities of IORT include peripheral neuropathy and ureteral stenosis.

## **PALLIATION**

These tumors are difficult to palliate, let alone cure. Surgical resection combined with aggressive multimodality therapy is advocated to avert the morbidity of pelvic disease and to prolong survival in a subset of patients, with survival rates up to 30%.<sup>74</sup> Most patients, however, will not be offered curative surgery depending on their comorbidities, poor performance status, distant metastases, or locally unresectable disease on preoperative imaging. These patients may be offered palliative intervention. Miner and colleagues demonstrated that in patients who underwent surgery with palliative intent, improvement was noted in 40% with bleeding, 70% with obstruction, and

20% with pain.<sup>75</sup> When considering the effective use of surgery for these patients, decision-making is complex because one must balance palliation of symptoms, comorbidities, and patient desires and goals. Seeking the input of a multidisciplinary treatment group, including medical oncologists and radiation oncologists, is invaluable.

## CHEMORADIATION

Patients with rectal cancer who undergo surgery with intention to cure and without evidence of gross disease postoperatively may still develop local recurrence or distant metastases. Up to 10% of patients who undergo TME with tumor-free radial and distal margins may develop local failure. The goal of adjuvant therapy is to eliminate the micrometastatic disease present at the time of surgery.

### Adjuvant Chemoradiation

In 1990, the National Institutes of Health consensus statement concluded that “combined postoperative chemotherapy and radiotherapy improves local control and survival in stages II and III patients and is recommended.” Most of the information regarding chemotherapy for colorectal cancer comes from trials of colon cancer rather than for rectal cancer. The NSABP C-04 (National Surgical Adjuvant Breast and Bowel Project C-04) trial studied stages II and III colon cancer patients and demonstrated that 5-fluorouracil (5-FU) and leucovorin treatment had a significantly better 5-year survival rate (74% vs 69%) compared with 5-FU and levamisole.<sup>76</sup>

Several trials have suggested a benefit for adjuvant chemoradiation for rectal cancer in patients with resected stage II or III cancers. The GITSG (Gastrointestinal Tumor Study Group) trial demonstrated that combined chemoradiation resulted in an improvement in overall survival as well as a decrease in local recurrence.<sup>77</sup> The NCCTG (North Central Cancer Treatment Group) trial demonstrated that the addition of chemotherapy to radiation reduced both local recurrence (13% vs 25%) and distant metastases (28% vs 46%) and improved survival.<sup>78</sup>

Radiation therapy used alone as adjuvant therapy may improve local recurrence but not survival rates. A theoretical reason to use postoperative

radiation therapy is that more appropriate patient selection can be achieved because pathologic staging is performed prior to radiation. Disadvantages include radiating the neorectum and small bowel and a lower tendency of patients to complete their radiation. While none of the trials in the 1980s and 1990s demonstrated increased survival, one study did show a decrease in local recurrence.

## **Neoadjuvant Chemoradiation**

There are several potential advantages for using neoadjuvant chemoradiation. One is the ability to deliver higher doses of chemotherapy with radiation. Another advantage is tumor downstaging, which has been noted in up to 80% of patients. Moreover, a pathologic complete response occurs in 15% to 30% of patients. The ability to “shrink” the tumor facilitates surgical resection, thereby allowing one to achieve negative margins and perform a sphincter-preserving operation in patients who otherwise would require an APR. Additional advantages include radiating tissues with a greater oxygen supply and then resecting this area and reconstructing and creating the neorectum with nonirradiated colon. Another benefit of neoadjuvant chemoradiation is that the small intestine has not fallen into the pelvis as it will in the postoperative patient; hence there is a decreased likelihood of developing radiation enteritis. Also, patients are more likely to complete the course of radiation therapy because it precedes their surgical resection. Finally, for complete responders it is not uncommon for the oncologist to consider a shorter duration and a less toxic chemotherapy regimen (5-FU/LV vs FOLFOX).

The Dutch Colorectal Cancer Group demonstrated a significantly decreased rate of local recurrence at 2 years in patients who received preoperative radiotherapy (20 Gy over 5 days) followed by TME compared with TME alone (2.4% vs 8%).<sup>45</sup> The Swedish trial was the first and only study to demonstrate a survival benefit (58%) for stage III rectal cancer patients receiving preoperative radiation (short course of 5 Gy over 5 days) followed by surgery compared with patients who underwent surgery alone (48%).<sup>79</sup> The Swedish trial also demonstrated a decreased rate of local recurrence in the radiation-treated group (11%) compared with 27% in the surgery-alone group. Furthermore, a meta-analysis published in *JAMA* in 2000 concluded that preoperative radiation therapy plus surgery compared

with surgery alone significantly reduced the 5-year overall mortality rate, cancer-related mortality rate, and local recurrence rate.<sup>80</sup>

In the German Rectal Cancer Trial published in *The New England Journal of Medicine*, Sauer et al. randomly assigned patients with clinical stage II or III rectal cancer to preoperative (421 patients) or postoperative (402 patients) chemoradiotherapy based on a concurrent long course of radiotherapy (5040 cGy delivered in fractions of 180 cGy per day, 5 days per week) and 5-FU (120-hour continuous intravenous infusion during the first and fifth weeks).<sup>81</sup> Six weeks later, TME was performed, followed by four cycles of 5-FU 1 month postoperatively. In this study the median follow-up was 46 months. There was no difference in 5-year overall survival with preoperative versus postoperative chemoradiation (76% vs 74%), which was not statistically significant ( $p = .80$ ). Moreover, the patients who received preoperative chemoradiotherapy had a 6% local recurrence rate as compared to a 13% local recurrence rate in those receiving postoperative chemoradiotherapy ( $p = .006$ ). Likewise, of the 194 patients who were determined preoperatively by the surgeon to need an APR, 39% of this group treated with preoperative chemoradiotherapy could have sphincter preservation compared with only 19% of those patients in the postoperative treatment group ( $p = .004$ ). The neoadjuvant treatment group had less short- and long-term treatment-related toxicity. These differences in local recurrence, sphincter preservation, and treatment toxicities were all statistically significant.<sup>81</sup> An intention-to-treat analysis of long-term median follow-up of 11 years (134 months) of this cohort of patients revealed that overall survival at 10 years was 59.6% in the preoperative treatment group and 59.9% in the postoperative treatment group ( $p = .85$ ). Likewise, the local recurrence rate was 7.1% versus 10.1% in the two treatment arms, respectively ( $p = .048$ ) Finally, there were no differences in the incidence of distant metastases or disease-free survival.<sup>82</sup>

A Polish rectal cancer trial from 2004 compared preoperative short-course radiotherapy (5 days of 5 Gy) versus conventional radiotherapy (28 fractions of 1.8 Gy for a total of 50.4 Gy) to ascertain whether there was a difference in sphincter preservation. The surgical resection was based on the tumor status at the time of surgery not before the radiotherapy. This allowed for the surgical decision to be made after tumor shrinkage for patients who received the longer course of radiotherapy. Between 1999 and 2002 the study enrolled 316 patients. Tumor shrinkage was on average 1.9 cm greater in the long-course group and this was statistically significant. However, sphincter

preservation in the short-course group was 61% and in the long-course group 58%. In other words, whether the patient received short- or long-course radiotherapy, it did not impact sphincter preservation.<sup>83</sup> There was also no difference in survival, local control, or late complications. Furthermore, this Polish trial reported no differences in anorectal or sexual function between the short- or long-course radiotherapy.<sup>84</sup>

A French group in conjunction with the EORTC (European Organization for Research and Treatment of Cancer) group studied “the addition of chemotherapy to preoperative radiotherapy and the use of postoperative chemotherapy in the treatment of rectal cancer.” Patients with clinical stage T3 or T4 rectal adenocarcinoma were randomized to four groups: preoperative radiotherapy, preoperative chemoradiotherapy, preoperative radiotherapy with postoperative chemotherapy, and preoperative chemoradiotherapy with postoperative chemotherapy. This study enrolled 1011 patients; the primary end-point was overall survival and the secondary end-point was local recurrence. The results showed that there was no difference in overall survival between the groups that received chemotherapy preoperatively or those that received it postoperatively. There was, however, a difference in local recurrence. In the patients who received preop, postop, or preop and postop chemotherapy, the local recurrence rates were 8.7%, 9.6%, and 7.6%, respectively, whereas the radiotherapy-alone group had a local recurrence rate of 17.1%. This was statistically significant and it suggests that there is a benefit to local control by adding preoperative chemotherapy to the regimen. It is not clear whether the addition of postoperative chemotherapy to a patient who has already received preoperative chemotherapy with the radiation treatment has any survival benefit.<sup>85</sup>

Our current practice is to recommend preoperative staging with ERUS or MRI to all patients with rectal adenocarcinoma and then to offer chemoradiation to medically fit patients with curative intent who have T3-T4 or node-positive rectal carcinoma. Some patients with bulky T2 lesions near the sphincters should also be considered for neoadjuvant chemoradiotherapy to improve sphincter preservation (Table 54-8). Neoadjuvant therapy then is followed by TME with APR or TME with an end-to-side or colonic J-pouch reconstruction. Postoperatively, patients who have had involved lymph nodes either by preoperative staging or on the final pathology report are encouraged to have additional postoperative chemotherapy. Postoperative chemotherapy

in node-negative patients or patients who have had a complete response is determined on a case-by-case basis.

**TABLE 54-8: CURRENT RECOMMENDATIONS FOR CHEMORADIATION IN RECTAL CANCER PATIENTS AFTER RADICAL RESECTION**

Stage I	No adjuvant therapy
Stage II or III	Neoadjuvant chemoradiation
Low/mid lesion	5-FU-based chemotherapy or other investigational agents with XRT (180 cGy 5 d/wk × 30 treatments) Rest for 4–8 wk Total mesorectal excision Rest for 4 wk Chemotherapy in appropriate patients for 4–6 mo
High lesion	Pre- or post-op chemoradiation therapy Total mesorectal excision
Stage IV	LAR or APR for palliation/prevention of obstruction or bleeding Adjuvant chemotherapy 5-FU + leucovorin ± irinotecan or oxaliplatin with individualized XRT

Abbreviations: APR, abdominoperineal resection; 5-FU, 5-fluorouracil; LAR, low anterior resection; XRT, radiation therapy.

There are several in-progress trials that address new and evolving trends in rectal cancer therapy. The Alliance cooperative cancer trial group has the PROSPECT trial, which compares standard therapy of preoperative neoadjuvant chemoradiotherapy for locally advanced rectal cancer to an experimental arm of FOLFOX preop and postop with the elimination of radiation. The primary endpoint is local recurrence, with secondary endpoints being disease-free and overall survival.

A wait-and-watch approach has been advocated for several years by Habr-Gama and colleagues from Sao Paulo. In 2004, they reported on a cohort of patients who were observed after chemoradiation. They initially looked at 265 patients with distal rectal adenocarcinoma who received standard chemoradiation. After 8 weeks, all patients were examined with radiologic and endoscopic means and biopsies. Patients who had negative biopsies and no appreciable ulcer were defined as complete responders and then entered a surveillance program and were designated the observation group ( $n = 71$ ). This was 26.8% of the original cohort of 265 patients. Patients who had positive biopsies or a large remaining ulcer were considered incomplete responders and were referred for surgery ( $n = 194$ ). After resection, 22 patients who had a resection were pathologic complete responders. This group was designated the resection group (mean follow-up 48 months) and was compared to the observation group (mean follow-up 57.3 months). Five-

year overall and disease-free survival rates were 88% and 83% in the resection group and 100% and 92% in the observation group.<sup>86</sup>

Finally, protocols incorporating total neoadjuvant chemoradiotherapy and chemotherapy (total neoadjuvant therapy [TNT]) have been developed and are being utilized in the treatment of locally advanced rectal cancer. The rationale for this approach is twofold. First, the use of neoadjuvant chemoradiation and TME surgery have markedly reduced local recurrence and increased sphincter preservation but distant metastases remain a problem. The benefit of postoperative chemotherapy is not as well documented and understood. In fact, most of the data are extrapolated from colon cancer survival data for adjuvant chemotherapy. Moreover, compliance is not as good as chemotherapy in the adjuvant setting that is not as well tolerated. Hence TNT is being evaluated in phase II and III trials for compliance and efficacy. The goal is to increase completion rates of therapy with decreased toxicity and hopefully decrease distant recurrences.<sup>87</sup>

## SURVEILLANCE

After curative resection, long-term follow-up includes routine screening for rectal recurrence and metachronous colorectal neoplasms. Between 60% and 84% of recurrences are seen in the first 24 months and 90% within 48 months. Median time to recurrence is 11 to 22 months. Local recurrence rates range between 4% and 50%. Survival rates vary per stage (see [Table 54-4](#)). Median survival after recurrences are detected is 40 months.

Patients are seen postoperatively at 2 weeks and then every 3 months for 2 years. At each visit, the patient undergoes DRE and sigmoidoscopy, and a CEA level is obtained. As per the National Comprehensive Cancer Network (NCCN) guidelines, we recommend at 1 year post-resection a colonoscopy and CT scans of the chest, abdomen, and pelvis. A CT scan is performed annually until 3 to 5 years postoperatively. Colonoscopy frequency is determined by the findings at 1 year. If there are no polyps and no recurrence, the follow-up interval colonoscopy can be lengthened to 3 years, and then if normal even up to a 5-year interval after that. Certainly, in patients who have polyps, Lynch syndrome, or are younger at the initial age of diagnosis, a shorter interval such as every 3 years is recommended. After the initial 2 years of surveillance, patients continue to be followed every 6 months with

CEA levels and physical examinations until 5 years after the surgery. At 5 years, if the patient has had no recurrence, he or she may be followed yearly with clinic visits and may undergo colonoscopy every 3 to 5 years as outlined above. Of course, closer observation is indicated for patients at high risk for subsequent cancer formation, such as patients with IBD, polyposis syndromes, or a strong family history of colorectal cancer.

# CANCER OF THE ANUS

*Najjia N. Mahmoud*

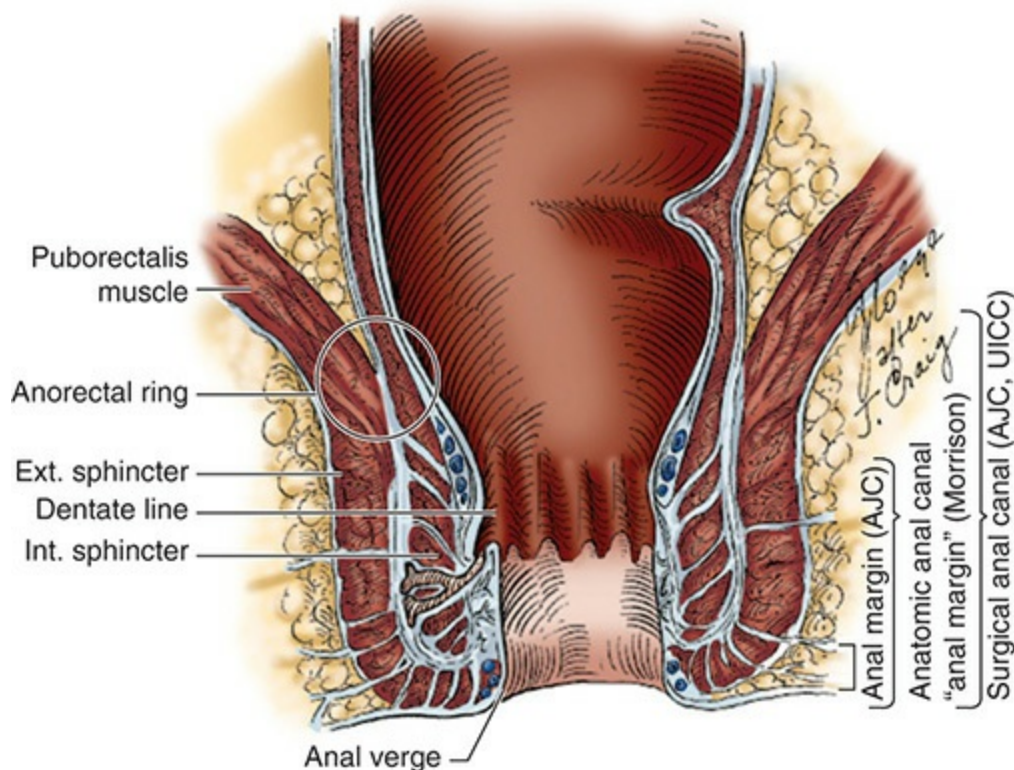

## INTRODUCTION

Cancers of the anus are rare problems with diverse histology. While squamous cell carcinoma (SCC) of the anal canal remains by far the most common of these neoplasms and the main focus of the chapter, the anus may also harbor tumors such as adenocarcinoma, melanoma, and basal cell carcinoma. The treatment of anal cancer has undergone dramatic changes in the last 25 years. Multimodality treatment consisting of radiation and chemotherapy has replaced abdominoperineal resection or wide local excision as the mainstay of therapy. Five-year survival rates now exceed 80% and radical surgery is reserved for cancers of the anal canal that do not respond to chemoradiation or that recur locally. Our understanding of the etiology and epidemiology of anal SCC and its precursor lesions has also profoundly changed in the past few decades yielding new initiatives in both therapy and prevention that may further alter the future treatment of this disease. Anal cancer is clearly a disease that benefits from multispecialty intervention. Because of this, the treatment of anal cancer serves as a paradigm for the multimodality treatment of cancer.

## ANAL CANAL ANATOMY AND HISTOLOGY

Until recently, discrepancies in anatomic definitions and tumor locations in the anorectal region have made comparisons of therapeutic outcomes difficult. In addition, the evolution of anal canal cancer treatment has resulted in management differences between anal canal and margin tumors that make precise anatomic localization important. In 2000, the World Health Organization refined their definitions of “anal canal” and “anal margin” in the context of histology, the American Joint Committee on Cancer (AJCC)/Union Internationale Contre le Cancer (UICC) staging system, and traditional anatomic landmarks. This standardized definition is currently used and endorsed by surgeons, pathologists, and radiologists.<sup>1</sup>

The anal canal extends from the top of the anorectal ring (a palpable convergence of the internal sphincter, deep external sphincter, and puborectalis muscle) to the anal verge (the junction of the anal canal and the hair-bearing keratinized skin of the perineum). The lining of the anal canal is comprised of transitional epithelium as well as non-hair-bearing squamous epithelium. Tumors distal or beyond the verge are termed anal margin or perianal tumors (Fig. 55-1).

## **FIGURE 55-1** Anatomy of the anal canal and margin.

The anal canal is divided by the anal transition zone (ATZ) into three histologically distinct areas. The ATZ is a circumferential band that extends above and below the dentate line in fingerlike projections that vary in length. Fenger defined the relationship of the ATZ to the dentate line by staining surgically excised specimens with alcian blue—a dye that renders mucin-rich columnar epithelium dark blue, mucin-poor transitional epithelium light blue, and squamous mucosa colorless.<sup>2</sup> He found that the dentate line ranges from 5 to 19 mm above the distal end of the anal canal. The width of the ATZ is generally 1 to 2 cm, projecting 3 to 6 mm below the dentate line.<sup>2</sup> Columnar cells line the anal canal above the ATZ, and squamous epithelium resides below. The ATZ is an area of mixed histology where cuboidal cell types are prevalent. Tumors arising in the anal canal above and within the ATZ are typically nonkeratinizing SCCs. Those originating below this level are generally keratinizing.<sup>2</sup>

Because of the complex gross and histologic anatomy of this region, classification of anal neoplasms has been confusing and inconsistent. According to the World Health Organization classification, anal canal lesions consist of squamous cell (cloacogenic) variants, including keratinizing, nonkeratinizing, and “basaloid” tumors. Other anal canal neoplasms include adenocarcinoma, carcinoid, lymphoma, and melanoma.<sup>3</sup> Anal margin tumors include SCC, giant condyloma (verrucous carcinoma), and basal cell carcinoma.<sup>3</sup>

The dentate line provides an anatomic reference point for lymphatic drainage of the anal canal and margin. Above the dentate line, drainage is primarily via the superior rectal lymphatics to the inferior mesenteric nodes and laterally along the middle and inferior rectal vessels to the internal iliac nodal basin. Lesions distal to the line drain to the inguinal and femoral lymphatics. Tumors in the ATZ may follow both lymphatic routes. Patients with unexplained inguinal lymphadenopathy should undergo a careful examination of the anal canal.

## **ANAL SQUAMOUS CELL CARCINOMA**

## Incidence and Epidemiology

The rate of anal cancer has increased from 19/100,000 person-years in 1995 to 78.2/100,000 person-years in 2003. Although this number represents only 1% to 2% of all hindgut cancers, the rise in incidence underscores a significant and serious change in the epidemiology of the problem.<sup>4</sup>

Squamous cell cancers of the anus have a viral etiology similar to that of cervical cancer. In the year 2000, approximately 3400 new cases were reported in the United States, but this figure rose to 8080 in 2015, reflecting a trend that mirrors increases in human papilloma virus (HPV) infection.<sup>4,5</sup>

Until the past decade, the highest rates of anal SCC were described in women, with numbers increasing after 30 years of age to plateau at an incidence of 5.0/100,000 after age 85.<sup>5</sup> The ratio of females to males affected was approximately two to one.<sup>6</sup> However, in the past 10 years, men under the age of 45 who have sex with men (MSM) have constituted the group with the greatest number of reported cases as well as the greatest increase in disease incidence.

Considered as a group, men who practice anal receptive intercourse have an incidence of anal SCC of 35/100,000—a rate identical to that of cervical cancer prior to routine cervical cytological screening.<sup>7</sup> Although not listed as an acquired immune deficiency syndrome (AIDS)-defining illness like cervical cancer, the argument has been made that anal SCC should have similar emphasis. The United States AIDS-Cancer registry is a survey that linked AIDS-related cancer registries in 11 states or metropolitan areas for the period of time between 1995 and 1998 and included over 309,000 HIV-infected patients.<sup>7</sup> The relative risk of SCC-type anogenital cancers in this population was much higher than that of the general population. The relative risks for cervical, vulvar/vaginal, and penile cancers were 5.4, 5.8, and 3.7, respectively, while the risk for anal cancer in women was 6.8 and for men 37.9.<sup>8</sup> Subset analysis of affected individuals revealed that those less than 30 years of age had dramatically elevated relative risks of anal cancer of 134 for women and 162.7 for men. Analyzing the data by HIV exposure history showed that homosexual contact resulted in the highest relative risk of anal SCC, with other categories such as intravenous drug abuse, heterosexual contact among women, and blood transfusion somewhat less.<sup>8</sup>

# Etiology, Pathogenesis, and Risk Factors

## HUMAN PAPILLOMAVIRUS

Striking evidence, both circumstantial and direct, links HPV infection with the development of both anal SCC and cervical cancer, and it is accepted that these cancers have not only the same etiology and natural history, but a common mode of transmission.<sup>9</sup> Both anal SCC and cervical SCC arise in mucoepithelial histological transformation zones; both are associated with the same oncogenic HPV strains and both have noninvasive precursor lesions. Sexual contact is the mode of transmission of HPV. Women with multiple sexual partners, other venereal diseases, or human immunodeficiency virus (HIV) have a significantly increased risk of developing cervical cancer.<sup>10</sup> Women with a prior history of cervical cancer have a relative risk of developing anal SCC of 4.6.<sup>11</sup>

HPV is a double-stranded DNA virus with a predilection for mucoepithelial tissues. More than 100 HPV strains have been identified, but only approximately 30 have been isolated in cancers of the anogenital region.<sup>11</sup> HPV infection results in either anogenital warts (condyloma accuminata) or squamous intraepithelial lesions (SILs).<sup>12</sup> Condyloma are generally associated with HPV 6 and 11 and their subtypes, and consist of fleshy growths that harbor and generate infectious viruses and have virtually no malignant potential.<sup>12</sup> SILs are graded on the degree to which they exhibit cytologic atypia. In the United States, the Bethesda criteria for anal intraepithelial lesions (AINs) list two dominant categories—high-grade squamous epithelial lesions (HSILs) and low-grade squamous epithelial lesions (LSILs).<sup>12</sup> In the European literature, HSIL is known as AIN 3, whereas LSIL consists of AIN 1 and 2.<sup>13</sup>

The most commonly isolated oncogenic HPV viruses are HPV 16 and 18, which are strongly associated with invasive cancer and are commonly found in both anal and cervical cancer.<sup>13</sup> In a case-control study of 388 patients with anal cancer from Denmark and Sweden, 88% of anal cancers harbored HPV DNA.<sup>13</sup> HPV 16 was detected in 84% of these specimens, whereas no HPV DNA was found in the rectal cancer controls.<sup>14</sup> These investigations have been repeated in SIL with similar results.<sup>14</sup> Studies such as these provide good evidence to support a viral etiology for SIL and anal SCC.

Further characterization of specific viral/cytologic changes have focused on defining the differences between LSIL (AIN 1,2) and HSIL (AIN 3). LSILs can be associated with both low- and high-risk HPV types, although there is a predominance of high-risk types.<sup>13</sup> It is likely that HSIL contains exclusively high-risk viruses.<sup>13</sup> It may be possible to base pharmacologic prevention and intervention in SIL and cancer on the genetic differences between these viruses. Therapies may exploit the fact that on the cellular level, LSILs and condyloma support and tightly regulate the viral infectious cycle, resulting in completion of viral replication and production of intact virus.<sup>13</sup> In contrast, in HSIL, certain genes essential to viral expression are lost, thereby facilitating integration into the host genome and producing incomplete viral replication and genetic instability leading to tumorigenesis.<sup>13</sup> It is unclear whether persistent viral infection produces increasing cellular atypia that supports this dysregulation, or whether there is something intrinsic and permissive about the anal epithelium itself that allows oncogenic viruses to exploit the cell cycle.

## **HUMAN IMMUNODEFICIENCY VIRUS INFECTION**

There is an increased incidence of both anal SCC as well as its precursor lesion HSIL in patients with HIV infection. Data collected in case control studies among homosexual men and heterosexual women with high-risk behaviors show a direct correlation between HIV seropositivity, HPV prevalence, and anal cancer and its precursors. Epidemiologic evidence among homosexual men in the San Francisco Bay area documents a dramatic rise in anal SCC between 1973 and 1999 when the relative risk increased from 3.7 to 20.6.<sup>15</sup> Similar studies conducted in New York City between the years 1979 to 1985 show a tenfold increase in anal SCC in men 20 to 49 years of age coinciding with the explosion of HIV in this population at this time.<sup>11</sup> However, HPV, HSIL, and anal cancer are not phenomena linked exclusively to homosexuality. Similar findings occur in HIV-infected male heterosexual IV drug users who deny anal receptive sex. In this cohort, a high rate of HPV infection coincides with an elevated rate of HSIL as well as anal cancer.<sup>16</sup> Heterosexual women who are HIV positive or have progressed to AIDS have high rates of HSIL as well.<sup>8</sup> When HIV-positive and -negative cohorts (both male and female) with similar HPV risk factors are compared, the rates of both HSIL and anal cancer are dramatically increased in the HIV-

positive groups.<sup>8-11</sup>

Although the resultant decline in cell-mediated immunity in HIV-infected patients seems to correlate with HPV infection, the exact mechanism of potentiation is unknown. In fact, there is evidence to support the hypothesis that HPV may represent an opportunistic infection assisted by retroviral preinfection.<sup>8</sup> It is uncertain whether the level of immunity and the severity of HIV infection as measured by CD4 counts directly correlate with HSIL or SCC rates in cervical or anal cancer. However, several studies done in the past 10 years have demonstrated an inverse relationship between CD4 counts and progression from LSIL to HSIL, supporting a causal relationship between cell-mediated immunosuppression and high-risk phenotypes.<sup>12</sup> Conversely, a recent subgroup analysis of a 202 member HIV+ cohort receiving highly active antiretroviral therapy (HAART) for 6 months indicates that the rates of HPV infection, HPV levels, and progression of anal dysplasia remained unchanged in spite of significant improvement in CD4 counts.<sup>4,8</sup> Longer follow-up is needed to determine whether advances in the treatment of HIV will correlate with lower rates of HPV positivity, anal dysplasia, and anal cancer.

Persistence of high-risk HPV types 16 and 18 in HIV infected individuals is a well-documented problem. Lingering infection, immunosuppression, and the presence of the HIV virus may all be factors contributing to a lack of viral cell-cycle regulation, increased proliferation, diminished apoptosis, and faulty DNA repair. These individuals have a twofold increase risk over non-HIV infected patients of progression from LSIL to HSIL within 2 years of diagnosis, and have a relative risk of anal cancer of 63.4 over the general population.<sup>13</sup>

## **SMOKING**

Cigarette smoking is a well-known risk factor for anal SCC that is independent of sexual practices. The risk increases two- fivefold over that of the general population.<sup>11,17</sup> It is speculated based on data demonstrating an increased incidence in premenopausal women of 5.6 with a 6.7% linear increase per pack-year that smoking may have an antiestrogenic effect permissive for the disease in the estrogen-sensitive tissues of the anal canal.<sup>18</sup> This hypothesis is supported by the finding that no risk increase was

demonstrated by this study in either male or postmenopausal female smokers.

## **CHRONIC INFLAMMATION**

At one time, benign anorectal conditions such as hemorrhoids, fissures, and fistulas were thought to predispose to the development of SCC. The etiology or common mechanism was presumed to be prolonged exposure of the anal canal epithelium and margin to chronic inflammatory conditions. Patients with inflammatory bowel disease (IBD) were believed to be at increased risk, particularly when anal fistulas were present. In 1994, Frisch examined this issue in a large population and found no evidence to support a causal relationship between benign anorectal conditions and anal cancer up to 13 years after resolution of the benign condition.<sup>19</sup> In another large population study, Frisch identified 9602 Danish patients with a diagnosis of either Crohn's disease or ulcerative colitis with a mean follow-up time of 10 years.<sup>20</sup> Only two patients developed anal SCC during this time. Both patients had the disease longer than 15 years. Although long-term IBD patients may be at slightly increased risk of anal SCC, short- and mid-term risk is not significantly different from that of the general population.<sup>21</sup>

## **Anal Intraepithelial Neoplasia**

No discussion of anal SCC would be complete without a consideration of its precursor lesion, AIN. The term HSIL is synonymous with AIN 3 (European designation), "carcinoma-in situ," and "Bowen's disease." Bowen's disease is still a term often used to describe this entity and may refer to scaly, pruritic low-profile inflammatory perianal manifestations of AIN. Until recently, wide local excision had been the treatment of choice for HSIL (Bowen's disease). It was assumed, based on anecdotal evidence, that a percentage of patients with HSIL progress to invasive cancer. This led to attempts to surgically clear patients of the disease. Recent advances in the understanding of the natural history of LSIL, HSIL, and anal cancer have more clearly defined the risk of dysplasia, leading many to adopt a policy of either very specific "high-risk" ablative therapy or close and frequent observation.

The incidence of anal cancer among HIV-positive homosexual men is 75 to 80/100,000 (a rate of .8/100,000 in the general population), more than

twice the incidence of cervical cancer in women (35/100,000) prior to the introduction of routine cervical Pap smear cytology evaluations.<sup>8,16</sup> Because of the dramatic reduction in cervical cancer (8/100,000 currently) attributed to the detection of dysplasia, it is widely believed that the same result could be seen in high-risk anal cancer populations if similar detection and ablation methods are used. A predicate to this hypothesis, however, is to better establish the role of equivalent potential precursor lesions in the development of invasive anal cancer.

There is a very high incidence of HSIL in the same population affected by high rates of anal cancer. In a study of 67 HIV-positive homosexual men (MSM) and 50 HIV-positive IV drug users who denied anal intercourse, HSIL was present in 85% of the MSM group and 46% of the IV drug users.<sup>21</sup> In a large group of HIV-positive women followed by the Women's Interagency HIV Study, 6% of HIV-positive and 2% of HIV-negative women had HSIL.<sup>22</sup> Seventy-nine percent of HIV positive women in this study were HPV positive.<sup>23</sup> A similar result was documented in the University of California San Francisco (UCSF) Anal Neoplasia Registry, where the vast majority of HIV-positive (93%) and -negative (61%) homosexual men had HPV infection whereas only 5% of the HIV-positive and only one HIV-negative man had HSIL.<sup>23</sup> Cytologic testing (anal Pap smears) in this group was abnormal in 60% of the HIV-positive and 21% of the HIV-negative men.<sup>24</sup> Clearly, abnormal anal cytology does not necessarily correlate with HSIL. Furthermore, it is clear that not all patients with HSIL progress to invasive cancer. Not enough longitudinal studies have been conducted, however, to specifically quantify the risk associated with either the presence of HPV or HSIL. The 4-year projected incidence of HSIL in HIV-positive men in the study mentioned is 49% and in HIV negative homosexual men it is 17%.<sup>24</sup> Ongoing studies will help establish actual rates of conversion to invasion, associated risk factors, and high-risk populations.

## **DIAGNOSIS AND TREATMENT OF HSIL**

A growing awareness of the natural history of anal cancer has resulted in an increase in diagnosis of the problem in high-risk populations. Anal cytology (similar to cervical Pap smears) is currently being used by some as a screening tool for the detection of anal dysplasia in high-risk populations. Prior to the present understanding of the pathogenesis of anal cancer, HSIL

was most commonly (25%-40% of cases) discovered as an incidental finding after hemorrhoidectomy.<sup>24</sup> Other patients came to attention with scaly, raised, lesions at the anal margin. Because the majority of patients diagnosed are asymptomatic, the true incidence of HSIL is not known presently. Future studies following patients with abnormal anal cytology may clarify this number.

Anal screening (Pap smears) was first described in the 1990s as a direct corollary of cervical Pap smears and has since been promoted as a diagnostic and screening tool in high-risk populations.<sup>25</sup> However, evidence demonstrating a resulting decrease in incidence of anal cancer similar to that of cervical cancer has not been forthcoming. The use of anal cytology as a screening technique has not gained the recognition afforded cervical Pap smears. Lack of recognition by clinicians of the increased incidence of anal cancer, limitation of the problem to high-risk populations, lack of knowledge of techniques, cost, and a dearth of supporting outcomes data may all conspire to limit the perceived usefulness of the tool. Ongoing outcome studies may clarify the role of anal Pap smear for high-risk patients.

A 1999 survey of the practice patterns of members of the American Society of Colon and Rectal Surgeons revealed that 86% to 95% surgeons treated HSIL with wide local excision.<sup>26</sup> A distinction was made between “microscopic” disease and other manifestations. Most HSIL found incidentally in hemorrhoidectomy specimens were considered microscopic asymptomatic disease were and simply followed without re-excision (74%).<sup>27</sup> This survey coincided with other investigations highlighting the multifocal nature of HSIL and the difficulty presented by wide local excision under these circumstances. In one review, of 34 patients undergoing wide local excision for macroscopically evident HSIL, 19 had positive margins at the time of initial resection, and 12 of the 19 had recurrent HSIL within one year.<sup>27</sup> Even with a microscopically complete initial resection, 2 of 15 patients eventually developed HSIL. Although none of these individuals subsequently developed anal cancer, five developed significant surgical complications of resection including anal stenosis and incontinence.<sup>28</sup>

A growing recognition of the morbidity of surgery for HSIL, particularly asymptomatic microscopic disease, in light of the uncertain natural history of anal neoplasia and dysplasia, has resulted in uncertainty concerning appropriate treatment. In the early 1990s, high-resolution anoscopy (HRA)

was developed at the UCSF. Like anal Pap cytology, HRA is a direct application of the technology for cervical intraepithelial detection and ablation to anal dysplasia. The technique can be done in either the office or, for anal margin involvement or more extensive disease, in the operating room. After obtaining a Pap smear, a digital rectal exam is performed followed by placement of a cotton swab covered in gauze soaked in 3% acetic acid. The swab is held in place for 1 minute, after which an anoscope is inserted permitting examination of the anal canal by a colposcope providing 6× to 25× magnification. Special attention is directed to the area surrounding the ATZ. Applying acetic acid causes these often unapparent lesions to become opaque or “acetowhite.” Lugol’s iodine solution is then placed in the anal canal to further highlight these areas. HSILs fail to take up Lugol’s, rendering the area yellow to tan, whereas normal tissue or LSILs stain dark brown or black.<sup>26</sup> This approach, combined with the magnification, allows visualization of vascular changes such as punctation, mosaicism, and atypical vessels characteristic of dysplastic change.<sup>26</sup> Suspicious lesions are then destroyed by electrocautery or laser. Over 400 patients have been prospectively evaluated at UCSF with HRA. Patients with findings of HSIL have gone on to HRA with ablation. Over 75% of HIV-positive patients with “extensive” circumferential disease have had recurrent HSIL on follow-up (2.5 years). None of these patients have thus far developed anal cancer.<sup>26</sup>

There are no prospective studies or published reports documenting the rate of progression of HSIL to invasive cancer. While treatment strategies for anal HSIL vary widely, no approach has been conclusively shown to reduce anal cancer incidence. The rate of HSIL progression to anal cancer has, based on clinical models, been proposed as 1% per year.<sup>12</sup> Because the rate is so low and the natural history of HSIL as yet unknown, chemotherapy and radiation is unwarranted. Wide local excisional techniques that compromise form and function may also be too drastic given the apparent low malignant potential of HSIL. HRA with ablation may specifically eradicate early invasive lesions and aggressive precursors, but data supporting that position does not yet exist. Furthermore, HRA ablative therapy does not eliminate the need for follow-up.

While many clinicians advocate a program of close follow-up consisting of digital rectal exams and unmagnified anoscopy at regular intervals, this approach, too, is unvalidated. HRA may provide objective evidence of the presence of disease that office examination alone does not. Whether ablative

therapies should follow documentation of HSIL by any method remains unknown and controversial. ANCHOR (ANal Cancer/HSIL Outcomes Research) is a randomized clinical trial that started accruing in 2015 and is designed to definitively address the question of utility of anal pap smears and HRA by randomizing more than 5000 HIV-positive persons with HSIL to either treatment or close monitoring without treatment. The outcome of this study will hopefully answer this question.<sup>83</sup>

## **HUMAN PAPPILOMAVIRUS VACCINES**

Administration of the HPV vaccine is considered primary prevention in the treatment of cervical cancer and is very effective in prevention of both high-grade lesions and cancer as well as condyloma. A similar strategy is employed in the prevention of anal cancer. In a randomized, blinded trial, 602 sexually active MSM were randomized to receive three doses of the quadrivalent HPV (qHPV against serotypes 6, 11, 16, 18) vaccine or placebo and evaluated every 6 months by HRA and HPV testing over 3 years. Significant reduction of anal HSIL associated with any type of HPV occurred in those who received the qHPV compared with placebo. Another study evaluated 112 HIV-positive men (ages 27 or older with no evidence of anal HSIL) with the three-dose course of qHPV vaccine and found seroconversion in all of these subjects. The quadrivalent HPV vaccine has been demonstrated to be effective and safe in HIV-infected men. When incidence of anal cancer is used as an endpoint, it has been found that qHPV vaccination of HIV-negative MSM treated for anal HSIL reduced the lifetime risk of cancer by 60.77%. When costs of vaccination were balanced against costs of treatment, vaccination compared very favorably. The 9-valent (9v) HPV vaccine became available in 2015 and proved efficacious and safe in a large randomized trial of over 14,000 women. It provided protection against serotypes 6, 11, 16, 18 that was noninferior to that of the quadrivalent vaccine with additional extended coverage. Although no current data exist, it is assumed that the 9v HPV vaccine would provide a similar response to the quadrivalent vaccine in high risk populations.<sup>13</sup>

## **Pathology, Diagnosis, and Staging of Anal Squamous Cell Cancer**

## **PATHOLOGY**

Nearly 80% of anal canal tumors are either SCCs or histologic variants of SCC (Fig. 55-2). The great variation in terminology results from the histologically diverse microscopic anatomy and the fact that many tumors, especially in the ATZ, have a mixed histologic appearance including squamous, basaloid, and rarely, glandular elements. The World Health Organization designates all squamous carcinoma variants in this location as “cloacogenic.”<sup>3</sup> Tumors of the distal anal canal, and particularly of the anal margin, are generally comprised predominately of squamous cells, with fewer basaloid and no glandular characteristics.<sup>28</sup> The more distal in the anal canal the squamous tumor arises, generally, the more likely it is to contain keratinizing cells. Tumors of the proximal anal canal and ATZ are usually composed of nonkeratinizing cells.<sup>29</sup> It is important to note that the difference in the cellular characteristics of these anal canal cancers does not result in a different mode of treatment. There are no data to suggest differences in outcome between squamous and basaloid histologic types in anal canal cancers. Anal margin tumors, however, are typically treated like skin cancers by local excision.

**FIGURE 55-2** Anal squamous cell carcinoma.

The treatment of anal canal cancer has undergone major changes within the past 25 years. Currently, chemotherapy and radiation is usually the sole treatment for patients with localized disease. Prior to 1974, standard-of-care was either wide local excision if the tumor was judged to be superficial or abdominoperineal excision for tumors invading the sphincter. Outcomes were poor, with overall survival rates after abdominoperineal resection (APR)

ranging from 30% to 70%, depending on tumor grade, stage, and size.<sup>29</sup> The local recurrence rate after wide resection or APR was reported to be 25% to 35% with a 100% local recurrence rate for tumors invading through the submucosa in a series from Singh and associates at Roswell Park Memorial Institute.<sup>30</sup> Perineal or pelvic recurrence occurs in 50% to 70% of patients undergoing APR, with less than 10% dying of distant disseminated disease.<sup>7</sup> In 1974, Norman Nigro, at Wayne State University, used radiation and fluoropyrimidines in anal canal cancer as a way to reduce local recurrence.<sup>31</sup> He observed that often there was no residual cancer in the resected specimen. Thus began an exciting and revolutionary time in the treatment of this disease that resulted in a radical shift in treatment.

## DIAGNOSIS AND STAGING

Over 50% of patients present with a complaint of rectal bleeding. Delays in diagnosis are common because the tumor is often mistaken by both patients and physicians for benign conditions such as hemorrhoids or fissures. Pain, tenesmus, and pruritis may be present. The initial physical examination should include a digital rectal exam, proctoscopy, and palpation of the inguinal lymph nodes. A biopsy of the anal mass is necessary to confirm the diagnosis. Inguinal masses should be aspirated with a fine needle for diagnosis and staging. Because the current nonoperative approach to anal cancer management is highly effective, excisional biopsy of suspected anal squamous cell cancers and inguinal node dissection for adenopathy should be avoided. The staging process is completed by computed tomography of the chest, abdomen, and pelvis and an MRI of the pelvis to assess depth of invasion and aid in establishing the size of the tumor.

The International Union Against Cancer (IUCC) staging system for anal cancer was updated in 2010 and adopted by the AJCC ([Table 55-1](#)). In contrast to staging parameters for other gastrointestinal lesions, it is based upon size rather than depth of invasion. Anal margin tumors are staged the same as skin cancers.

**TABLE 55-1: AJCC STAGING SYSTEM FOR ANAL CANAL CARCINOMA**

### Primary Tumor (T)

TX	Primary tumor not assessed
T0	No evidence of primary tumor
Tis	High-grade squamous intraepithelial lesion (previously termed carcinoma <i>in situ</i> , Bowen disease, anal intraepithelial neoplasia II-III, high-grade anal intraepithelial neoplasia)
T1	Tumor $\leq 2$ cm
T2	Tumor $> 2$ cm but $\leq 5$ cm
T3	Tumor $> 5$ cm
T4	Tumor of any size invading adjacent organ(s), such as the vagina, urethra, or bladder

### Regional Lymph Node (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in inguinal, mesorectal, internal iliac, or external iliac nodes
N1a	Metastasis in inguinal, mesorectal, or internal iliac lymph nodes
N1b	Metastasis in external iliac lymph nodes
N1c	Metastasis in external iliac with any N1a nodes

### Distant Metastasis (M)

M0	No distant metastasis
M1	Distant metastasis

### AJCC PROGNOSTIC STAGE GROUPS

When T is...	And N is...	And M is...	Then the stage group is...
Tis	N0	M0	0
T1	N0	M0	I
T1	N1	M0	IIIA
T2	N0	M0	IIA
T2	N1	M0	IIIA
T3	N0	M0	IIB
T3	N1	M0	IIIC
T4	N0	M0	IIIB
T4	N1	M0	IIIC
Any T	Any N	M1	IV

### HISTOLOGIC GRADE (G)

GX	Grade cannot be determined
G1	Well differentiated (low grade)
G2	Moderately differentiated (low grade)
G3	Poorly differentiated (high grade)
G4	Undifferentiated (high grade)

<sup>a</sup>Direct invasion of the rectal wall, perirectal skin, subcutaneous tissue, or the sphincter muscle(s) is not classified as T4.

Used with the permission of the American College of Surgeons. Amin MB, Edge SB, Greene FL, et al. (Eds.) *AJCC Cancer Staging Manual*, 8th Ed. Springer New York, 2017.

A number of reviews in the literature prior to and during the introduction of chemoradiotherapy for anal SCC document the strong correlation between tumor size, lymphatic spread, and prognosis.<sup>32</sup> In a 1984 report from MD Anderson Cancer Center, 132 patients treated by abdominoperineal resection for anal SCC were studied. For patients with tumors 1 to 2 cm in size, survival was 78%, 3- to 5-cm tumors had survival of 55%, and patients with tumors >6 cm experienced survival of only 40%.<sup>33</sup> Other reviews suggest that survival for large tumors is considerably worse, at less than 20%, and that generally, overall survival is diminished when tumor size is greater than 5 cm, whether the tumor is treated by excision or chemoradiotherapy.<sup>33,34,35,36</sup>

The presence of regional nodal metastases is a poor prognostic indicator regardless of treatment modality. Although survival in the face of nodal metastases has improved significantly with the use of chemoradiation, patients who present with metastatic disease have a significant survival disadvantage.<sup>34,33</sup> Prior to the routine use of chemoradiotherapy, a report in which surgery was done with and without preoperative radiation demonstrated a 5-year survival rate of 44% for node-positive patients compared to 74% for node-negative patients.<sup>33</sup> Other studies confirm comparatively poor survival for patients with nodal metastases.<sup>34</sup>

## **Surgical Management**

Operative therapy for anal canal SCC has largely been supplanted by chemoradiation and is now the exception rather than the rule. Historically, the failure rate for APR has depended rather predictably on the size of the primary tumor. This procedure was often accompanied by prophylactic inguinal node dissection, but the morbidity and lack of efficacy caused routine inguinal lymphadenectomy to be abandoned. Failure rates for APR range from 40% to 70%, with local failure rates of 40% and median survival time after recurrence of only 1 year.<sup>30</sup>

Although chemotherapy and radiation have been shown to result in higher disease-free survival rates, there may still be a role for local excision in some cases of anal canal carcinoma. A retrospective analysis of local excision at University of Minnesota revealed a direct correlation between survival and tumor size. For tumors greater than 2.5 cm, 5-year survival rates were 60%.<sup>37</sup>

Although the sample size was small, the authors advocated local resection with curative intent only for small (<1 cm) well-differentiated tumors confined to the submucosa, for which survival rates were greater than 90%.<sup>38</sup> Corman and Haggitt reported a similar experience, with all tumors confined to the submucosa being cured by local excision or APR, and those invading more deeply suffering eventual local recurrence.<sup>38</sup> Longo recorded a 62% failure rate in Stage I to III tumors undergoing solely local excision in which all patients with Stage II and III tumors recurred.<sup>39</sup> Tumor accessibility, full-thickness excision, depth of invasion, and negative margins seem imperative technical considerations when considering local resection. Even so, very few candidates are suitable for this approach.

## NEOADJUVANT MULTIMODALITY THERAPY

National Comprehensive Cancer Center (NCCN) guidelines specify concurrent chemoradiotherapy with 5-FU and mitomycin C (MMC) as the optimum regimen for the treatment of anal SCC. Phase III trials of radiation in doses of 50 to 60 GY with either MMC or cisplatin as single agents have been confirmed to prove the best overall survival, disease-free survival, and colostomy-free survival with the least toxicity when compared to either radiation alone or radiation with combination MMC and cisplatin together.<sup>1</sup> Chemoradiotherapy is highly successful in early stage (T1 and T2) cancers, with complete tumor regression in 80% to 90% of patients. Any therapy or combination of therapies is less successful in T3 and T4 tumors or those with locoregional nodal metastases at diagnosis. Intensity-modulated radiotherapy (IMRT) seems to offer better local control with less toxicity to surrounding organs when compared to 3D conformational radiation.<sup>45</sup>

The treatment of anal canal carcinoma has changed radically since the late 1970s. In 1974, Norman Nigro, a colorectal surgeon at Wayne State University, defined a treatment protocol involving the administration of 5-FU, MMC, and preoperative radiation to shrink anal canal tumors.<sup>32</sup> Fluoropyrimidines were known at the time to enhance the effect of radiation, and there was some evidence that MMC had an antineoplastic effect on squamous cell tumors. Nigro's protocol was neoadjuvant, and the radiation (30 Gy total) was given in 15 sessions over a 3-week period. The 5-FU was administered at a dose of 1000 mg/m<sup>2</sup>/day for 4 days, starting on the first day

of radiation therapy, as a continuous infusion. It was then repeated on days 29 through 32. MMC (15 mg/m<sup>2</sup>) was administered as a single dose on treatment day one.<sup>32</sup> Of the three patients in the initial report, two underwent APR 6 weeks after treatment. The third refused surgery and remained disease free. No evidence of tumor was found in the specimens of the two patients who underwent surgery.<sup>32</sup>

Following the dramatic results reported by Nigro's group, others followed suit, treating patients with radiation alone and with multimodality therapy followed by surgical excision. In 1983, Michaelson et al. at Memorial Sloan Kettering Cancer Center (MSKCC) reported that 52% of patients treated with both chemotherapy and radiation had a complete pathologic response and another 22% had only microscopic disease at operation.<sup>40</sup> All of these patients had undergone APR or wide local excision following treatment. After Nigro's 1974 publication, a number of other investigators examined the effects of multimodality therapy. Most used 5-FU and MMC as the chemotherapeutic regimen, although several made dose and infusion modifications, and nearly all increased the radiation dose. Maximal doses were in the range of 50 Gy. Because of such variability among therapies, meta-analysis is difficult. Even now, variability in dosing, both for chemotherapy and radiation, and variability in outcome metrics make comparing existing phase III data difficult.

Preliminary studies done by Nigro and others set the stage for prospective phase II studies. Because MMC was observed to contribute significant toxicity to the regimen, RTOG 8704 was designed to randomly compare 5-FU+radiation versus 5-FU+MMC+radiation directly.<sup>41</sup> The oncologic benefits of the MMC were immediately obvious, resulting, in spite of higher toxicity, in significantly higher disease-free survival. Similarly, radiation alone was tested on the theory that chemotherapy-related toxicity could be spared, but the stage-for-stage local control rates dropped to 45% to 55% of study subjects. A series of randomized trials in both Europe and the US followed, all confirming that multimodality therapy significantly improved both disease-free survival as well as endpoints such as colostomy free survival. All except the small Action Clinique Coordonnees en Cancerologie Digestive (ACCORD-03) used concurrent 5-FU+MMC. ACCORD-03 used 5-FU+cisplatin.<sup>42</sup>

The current recommendation of chemotherapy and radiation resulted in

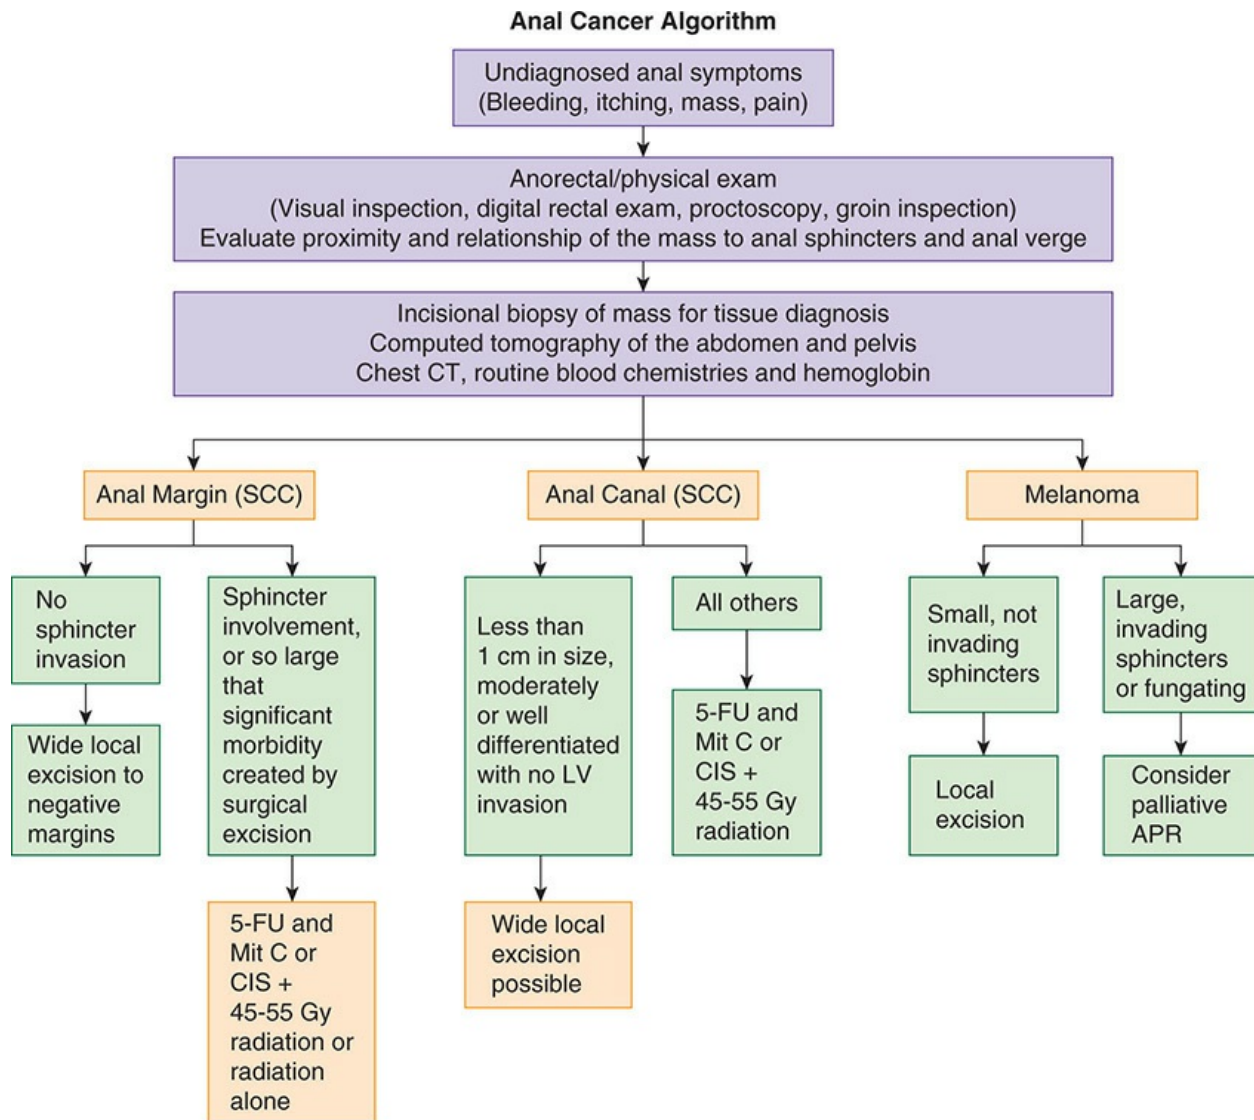

overall survival rates of 78% in the MMC arm of the RTOG 9811 trial, 79% in the MMC arm of the Anal Cancer Trial II (ACT II), and 71% in the cisplatin arm of ACCORD-03.<sup>42,43,44</sup> Because these studies were designed to compare radiation regimens as well, optimal ranges of radiation were able to be determined. Higher doses of radiation were not found to be beneficial to achieve local control; indeed, doses of 50 to 60 Gy were found to promote fecal incontinence. Also, these studies failed to demonstrate any benefit in the use of cisplatin over MMC in terms of disease-free or progression-free survival (Table 55-2).

**TABLE 55-2: RANDOMIZED PHASE III TRIALS OF RADIATION AND CHEMOTHERAPY FOR ANAL CANAL CANCER**

	Median Follow-Up	Number of Eligible Patients	Colostomy Rate	Local Failure Rate	Overall Survival
RTOG 9811 2008	2.5 y	644	10% with 5-FU, MMC vs 19% with 5-FU, cisplatin, $p = .02$ at 5 y	25% MMC, 5-FU vs 33% cisplatin, 5-FU	75% with 5-FU, MMC vs 70% with 5-FU, cisplatin, $p = .1$ at 5 y
ACT II 2013	2.5 y	940	5% vs 4%	Overall 11% with MM, 13% with cisplatin	85% vs 84% at 3 y
ACCORD-03 2012	4 y	307	19%-30% depending on arm	Overall 19% at 5 y	76%-89% 5 y

Abbreviations: 5-FU, 5-fluorouracil; MMC, mitomycin C

Radiation dose and type have been particularly difficult to analyze because of variability of techniques, doses, and boosts to both the primary site as well as the inguinal lymph nodes. However, some conclusions can be drawn based on existing recent phase III evidence. In general, small, early-stage tumors localized to the anal canal respond well to lower doses of radiation (in the 30-50 Gy range). Larger, more advanced T3 and T4 tumors and those >5 cm are notoriously difficult to control with any technique and generally higher doses have been used to treat. Minimum total doses of 45 Gy for early tumors with increased doses to 54 Gy for larger tumors is a guideline. Higher rates of radiation beyond 54 to 56 Gy seem to result in higher colostomy rates. The colostomy rates associated with multimodality therapy reached 14.5% in the ACCORD-03 study, 5% in the RTOG 9811 trial, and 12.5% in ACT II. Both colostomy and fecal incontinence rates are both probably directly attributable to the late effects of radiation<sup>45</sup> (Fig. 55-3).

**FIGURE 55-3** Basic treatment algorithm for most common anal neoplasms.

## Treatment of Inguinal Nodal Metastases

Palpable inguinal lymph nodes should be evaluated by fine needle aspiration at the onset of treatment for staging. Several reviews have confirmed the poor prognostic outlook conferred by inguinal lymph node (LN) metastases. In 1970, Stearns reviewed the MSKCC experience with anal canal cancer and noted that only 14% of patients with synchronous nodal metastases survived for 5 years.<sup>46</sup> Similarly, O'Brien reported in 1982 that none of the 52% of patients presenting with synchronous LN involvement survived more than 3 years after diagnosis.<sup>42</sup> Both Stearns and O'Brien observed independently

that patients presenting with metachronous LN metastases had better survival following therapeutic inguinal LN dissection.<sup>47</sup> In the MSKCC review, 75% of patients survived longer than 5 years after groin dissection.

The use of radiation to the inguinal lymph nodes, both prophylactically and for treatment was explored by Papillon.<sup>48</sup> In 1974, he reported on 19 patients with synchronous inguinal nodal involvement who underwent groin irradiation for disease control. Eleven of the 19 had no evidence of disease at 3 years. Cummings group treated nodal disease in a similar fashion and showed that 87% of patients had good disease control or cure without groin dissection.<sup>49</sup>

With the use of radiation fields expanded to include inguinal, internal, and external iliac nodes, the current treatment paradigm is to treat synchronous inguinal nodal metastases with chemotherapy and radiation along with the primary tumor. Metachronous LN involvement is treated with salvage chemotherapy and radiation if dose limits have not been exceeded as well as groin dissection if warranted.

## **Management of HIV-Positive Patients**

Treatment for anal cancer does not differ in the HIV-positive population. Combined chemotherapy and radiation is the best approach to this disease in the setting of HIV/AIDS. Studies have consistently documented responses to standard therapy that equal those in the HIV negative population.<sup>16</sup> However, experience with treatment in this population is limited, confined mostly to retrospective reviews with historic comparisons. Although the time period of treatment is often only 6 weeks in duration, it can be complicated by moist desquamation, diarrhea, perineal pain and tenderness, and severe anal pain. Late effects include anal stenosis, necrosis, chronic ulcer formation, and compromised continence in both the HIV-positive and -negative populations. Severe toxicity may require diverting stomas in 6% to 12% of HIV-negative patients with an even greater rate in the HIV-positive population.<sup>8</sup> Symptoms of acute toxicity are generally manageable with good skin care, antidiarrheals, and narcotic analgesics. Even so, there is widespread concern regarding the degree and management of these toxicities in the HIV-positive patient and some evidence to suggest that they are significantly more severe, resulting in treatment delays or dose reductions. At the UCSF, toxicity

requiring hospitalization, dose reduction, or treatment delays occurred in 82% of patients undergoing standard high-dose therapy.<sup>8</sup> For patients with a baseline CD4 count under 200, the rates of toxicity were especially severe: 50% of these patients required fecal diversion.<sup>8</sup> A review of patients treated from 1985 to 1998 by Orkin's group compared treatment toxicity and tolerance of 13 HIV-positive with 60 HIV-negative patients.<sup>50</sup> Although demographics of the HIV-positive patients were different from that of the comparison group, there was no difference in treatment or stage at diagnosis. Acute toxicity occurred in 80% of the HIV-positive patients versus 30% of those who were HIV negative. Late toxicity (40% vs 16%) and rates of local control (38.5% vs 15%) were also compromised in the HIV-positive cohort.

The impact of HAART on the treatment of anal cancer in the HIV population is not well understood at this time. Several small series have published reports suggesting that HAART improves tolerance to anal cancer therapy. Stadler et al. at the University of Texas Southwestern Medical Center examined the effects of treatment in HIV-positive patients before and after the advent of HAART.<sup>46</sup> The group found the average CD4 count of the HAART patients was significantly higher, and that this seemed to correlate with better disease-free survival. All six pre-HAART patients died with active disease, with a 2-year survival rate of 17%. Of those on HAART, the 2-year survival rate was 67% with 4/8 patients remaining free of disease.

A preliminary review of 11 HIV-positive patients at UCSF receiving both HAART and chemoradiation with baseline mean CD4 counts above 300 further delineates the difficulties treating this population.<sup>8</sup> Although ten patients completed therapy, eight of ten developed severe acute toxicity and two had chronic complications requiring colostomy. Three of the eleven died of disease within 13 months of diagnosis, and two have undergone APR for local recurrence.<sup>8</sup> It is clear that although HAART has extended and improved the lives of those infected with HIV, it has not necessarily provided protection against the toxicities of anal cancer treatment in those patients.<sup>51</sup> At this time, however, it seems prudent to deliver standard therapy (4500-5400 Gy, MMC, and 5-FU) to those HIV-positive patients in good health, and to monitor closely for side effects. HIV patients with very low CD4 counts (<200) and significant comorbidities may require individualized regimens, closer monitoring, or treatment breaks.

## Recurrent Disease and Salvage Therapy

The goal of early detection of local post-treatment recurrence is to prevent lymphatic spread of disease and maximize salvage. Most clinicians advocate a thorough physical exam including a digital rectal exam and anoscopy every 3 to 4 months for at least 2 years. Suspicious lesions are then sampled either in the office or operating room should they arise.

There is some evidence that local regression of disease following radiation therapy can occur up to 6 to 9 months following chemoradiation. Routine biopsy of the anal canal following treatment is no longer recommended within this time period. Rousseau et al. advise allowing the anal canal to heal completely, reserving biopsy for nonhealing ulcers and recurrent or enlarging anal canal masses after a period of at least 6 months following therapy.<sup>52</sup> After this point, any disease detected is “residual,” and salvage therapy is warranted.

In spite of success with nonoperative anal canal cancer management, depending upon the stage of disease, 10% to 30% of patients will recur—most locally. The treatment of recurrent or persistent disease is APR with negative margins. In a retrospective analysis of salvage therapy for recurrent disease following chemotherapy with radiation, Allal and colleagues found that APR results in a 53% actuarial 5-year survival rate versus 28% in those who didn’t receive additional treatment.<sup>53</sup> Pocard’s data from St. Antoine University Hospital examined salvage APR in 21 patients who had either residual disease after sphincter conservation or recurrence. The group found an actuarial 5-year survival benefit of 30%.<sup>54</sup> Factors resulting in failure were lymphadenopathy, positive margins, and distant disease. Longo et al. compared salvage with chemoradiation versus APR and found that only 27% of patients treated with additional combined therapy survived long-term, whereas 57% of those in the APR group did<sup>55</sup> (Table 55-3).<sup>39,54,56,57,58,59,60</sup>

**TABLE 55-3: ABDOMINOPERINEAL RESECTION (APR) AFTER FAILURE OF RADIATION (WITH OR WITHOUT CHEMOTHERAPY) FOR ANAL CANCER**

Review	Number of Patients	Median Follow-Up (Months)	Alive (%)	5-Year Survival Rate (%)
Zelnick 1992 <sup>56</sup>	9	20	<10	–
Tanum 1993 <sup>57</sup>	9	36	67	–
Lasser 1993 <sup>58</sup>	14	36	50	–
Ellenhorn 1994 <sup>59</sup>	38	47	–	44
Longo 1994 <sup>39</sup>	11	25	18	–
Hill 1996 <sup>60</sup>	11	25	18	–
Pocard 1997 <sup>54</sup>	21	40	48	33

Patients with recurrence die of locoregional complications including ureteral obstruction, perineal sepsis and necrosis, bowel obstruction, and venous thrombosis. Contraindications for salvage surgery include medical debilitation, known distant metastases, invasion of the pelvic sidewalls, and obvious inguinal lymphadenopathy. The preoperative assessment should include a chest CT or positron emission scan and an MRI or CT scan of the abdomen and pelvis with oral and intravenous contrast. A multidisciplinary approach is appropriate for local invasion of resectable structures such as the urinary bladder, cervix, vagina, or the sacrum. A team including a urologist, neurosurgeon, orthopedic surgeon, and plastic surgeon may be required. Recurrences close to the pelvic sidewall may be indistinguishable intraoperatively from fibrosis and scarring from prior radiation or surgery. An intraoperative frozen section may be useful if considering placing after-loading catheters or delivering intraoperative brachytherapy to these areas. The role and long-term outcomes of brachytherapy as a treatment adjunct for salvage surgery have not yet been validated.

The complications of salvage pelvic surgery may be severe and debilitating and include perineal wound dehiscence and necrosis. Tissue coverage in previously irradiated fields improves wound healing, and many consider it essential for post-exenteration reconstruction. Pedicle and rotational flaps may be fashioned from the gluteus, gracilis, or rectus abdominus muscles.

Data documenting long-term follow-up in patients salvaged with radiation or chemoradiation following local excision are lacking. The patients who undergo primary excision for anal canal carcinoma do so for a number of reasons including polypectomy, hemorrhoidectomy, or excisional biopsy as well as local excision with intent-to-cure. Although it is unclear at this point whether further treatment for completely excised, early-stage lesions is appropriate, patients with positive margins, or those with tumors harboring vascular or lymphatic invasion with poorly differentiated characteristics are

candidates for further therapy. A retrospective analysis from MSKCC in 1999 reviewed 14 patients who received postoperative chemoradiation (either 30 or 45-50 Gy) after local excision.<sup>61</sup> Actuarial 5-year local control rates were 93% with no differences between outcomes in the higher and lower dose groups. Longo published the largest single retrospective analysis of outcomes in 1994 reviewing chemoradiation following local excision.<sup>39</sup> The overall local control rate at 5 years was 79% in 109 patients receiving a median dose of 42 Gy. Stratification of the data by stage revealed 90% local control rate with Stage I, 54% Stage II, and 100% Stage III (6/6 patients).<sup>39</sup> There have been no prospective studies comparing local excision alone versus chemoradiation for T1 favorable-histology tumors. However, current studies suggest that tumors that are incompletely excised, have poor histologic characteristics, or are Stage II and above are candidates for chemoradiation following excision.<sup>65,68,74</sup> As with primary therapy, giving chemotherapy (principally infusional 5-FU with mitomycin-C or cisplatin) seems to promote effective local control at lower radiation doses.

Anal canal carcinoma metastasizes in 10% to 20% of patients late in the course of disease and prognosis is exceedingly poor.<sup>7</sup> Liver and lung metastases predominate and cisplatin-based chemotherapy is the only strategy shown to be somewhat effective.<sup>65</sup>

## ANAL MARGIN CANCER

SCC of the anal margin is at least five times less common than anal canal carcinoma, and for the most part is treated by primary surgical excision similar to skin cancers. These tumors arise on the perianal skin beyond the anal verge (Fig. 55-4). They are usually well or moderately differentiated keratinized SCCs and generally have a favorable prognosis.<sup>7</sup> Metastases are late and rare, and recurrences are typically locoregional. Symptoms include pain, bleeding, itching, and palpable mass. In a study from Denmark, Jensen noted a 6-month median duration of symptoms prior to diagnosis with an erroneous initial diagnosis made in 29% of cases.<sup>62</sup> Because these tumors are fairly slow-growing and uncommon, they are frequently mistaken for hemorrhoids or other benign conditions at initial presentation.

**FIGURE 55-4** Anal margin tumor.

Diagnosis is often suspected by the experienced clinician on inspection, but biopsy prior to definitive treatment is imperative. If the lesion is small, excisional biopsy can be accomplished with adequate margins (1 cm). If the tumor is larger, a small incisional biopsy allows accurate classification of the tumor and appropriate preoperative counseling.

Metastases to the inguinal lymph nodes occur in 15% to 25% of patients. The rate of nodal metastases is directly proportional to the size of the tumor. Papillon and Chassard reported that for tumors less than 2 cm in size, the rate of nodal metastasis was 0%; 2 to 5 cm (24%); greater than 5 cm (67%).<sup>63</sup> Cummings found that those with tumors less than 5 cm in size had 0% rate of nodal metastases, whereas metastases occurred in 25% of those with tumors 5 cm or larger.<sup>64</sup>

## **Surgery**

Although surgical excision (either local excision or APR depending upon location) is considered standard-of-care for anal margin tumors, outcomes data for this rare neoplasm are primarily retrospective. In most studies, overall and disease-specific survival are considered for all stages together, and subgroup analysis for large numbers of patients is not available.

Unfortunately, evaluation of local recurrence data is similarly limited by the small numbers of patients affected; however, in general, a trend toward increased recurrence in larger tumors is apparent.<sup>65</sup> Surgical treatment of the primary anal margin tumor is accomplished by wide local excision with 1 cm margins. At MSKCC, Greenall et al. reported a series of 51 patients with SCC of the anal margin.<sup>66</sup> Five-year survival was 88% although local recurrence was 46%. Local recurrences were amenable to re-excision. Inguinal nodal dissection was employed for metachronous inguinal nodal metastases. Thirteen patients in this series underwent APR as initial treatment. The local recurrence rates for these patients was identical to that of the local excision group. Tumor size was the most important factor for local control and survival (Fig. 55-5). In 1979, Cleveland Clinic reviewed their experience with surgery for anal margin tumors over a 20-year period.<sup>67</sup> Eight patients were identified for whom follow-up was available. A disease-specific survival rate of 70% was noted after 8 years, with a local recurrence rate of 30%. At the University of Chicago, a 19% local recurrence rate was noted in 16 patients undergoing surgical therapy alone.<sup>68</sup> Two of eleven patients recurred following local excision, and one of three recurred after APR. Of 27 patients with either Stage I anal margin cancer or carcinoma-in-situ treated at Mayo Clinic between 1950 and 1970, 5-year survival rates were 100%, although local recurrence rates were unavailable.<sup>69</sup>

**FIGURE 55-5** Deeply ulcerating anal margin tumor. (Used with permission from Charles Friel, MD.)

After surgery alone (local excision or APR), the overall survival rate for all stages is 60% to 90% with a local recurrence rate of approximately 30%. Survival rates after surgery for recurrence are unknown.<sup>70</sup>

## **Radiotherapy**

The optimal treatment of anal margin tumors is dependent upon location. Significant challenges and functional problems may result when the anal

sphincters are present within the boundaries of optimal surgery. If adequate excision compromises the sphincters, abdominoperineal resection is an option. However, many surgeons and oncologists would advocate a more conservative approach and use radiotherapy. Cummings et al. demonstrated local control rates of 100% for anal margin tumors less than 5 cm in size with a dose of 50 Gy over 4 weeks.<sup>64</sup> Local control rates were inversely proportional to the size of the tumor. For those tumors 5 to 10 cm, 70% local control was achieved, but for tumors greater than 10 cm, only 40% sustained a durable response. Similar results were reported by Papillon and Chassard at Centre Leon Berard in France.<sup>63</sup> In this review, a 78% overall survival rate was achieved using external beam (40 Gy cobalt 60 source) with a perineal field. Again, those with tumors greater than 5 cm in size fared considerably worse, with overall survival rates less than 50%.<sup>63</sup>

There have been numerous retrospective reviews of the response of anal margin tumors to radiation in the past 40 years documenting stage-specific local recurrence rates, disease-specific survival rates, and overall survival rates. Overall, local control rates of 52% to 87% are typical, with 5-year overall survival rates ranging from 52% to 90%.<sup>70</sup> T1 and T2 tumors have better local control rates and overall and disease-specific survival rates ranging from 82% to 100%.<sup>70</sup>

It is difficult to evaluate the sphincter preservation rate from these reviews. Small numbers and retrospective design limits direct comparison of this technique to surgery alone. There are no prospective studies comparing surgery alone to radiotherapy. Although the addition of chemotherapy (5-FU and MMC or cisplatin) seems logical, there are few data to support that approach. The rationale for these agents is extrapolated from the prospective trials of chemoradiation in the setting of anal canal carcinoma. Even so, it is reasonable to believe that primary radiotherapy with or without chemotherapy for anal margin tumors in close proximity to the anal sphincters, where adequate excision may compromise function, will result in both sphincter preservation and good local control. It is also reasonable to expect that surgical salvage for recurrence after primary radiotherapy is a possibility, with rates of local control of approximately 50%. Long-term disease-specific survival following this scenario is unknown.

## **ANAL MELANOMA**

Melanoma of the anus and rectum is a rare malignancy accounting for less than 1% of all colorectal and anal neoplasms.<sup>65</sup> After the skin and eye, the anorectum is the third most common site of melanoma. Although there is a female predominance with an almost 1:2 ratio, there is evidence that the median age of affected males is significantly less (57 vs 71 years of age).<sup>66</sup> Cagir et al. examined the epidemiology and demographics of anorectal melanoma using the Surveillance, Epidemiology, and End Results (SEER) database. These investigators note a recent emergence of a bimodal age distribution of anorectal melanoma for all patients, with males occupying the younger aspect of the curve. Survival rates were slightly better in this group (63% vs 51% at 1 year and 41% vs 27%  $p < 0.01$  at 2 years).<sup>71</sup>

Most common symptoms include bleeding, itching, presence of a mass, pain, tenesmus, or changes in bowel habits. Like anal SCC, misidentification of the tumor as a hemorrhoid is a common mistake. Diagnosis is frequently made following hemorrhoidectomy or local excision of the perianal mass. The tumor can appear small and polypoid, or large and ulcerating. About 30% of these tumors are amelanotic and unpigmented, making immediate recognition of the problem difficult.<sup>70</sup> On pathology, 70% of lesions show some evidence of melanin production either grossly or microscopically.<sup>70</sup> Commonly, anal melanoma arises at the mucocutaneous junction. Occasionally, the lesion arises more proximally, within the rectal mucosa. Although the origin of these tumors is speculative, they are believed to arise in areas of heterotopic anal canal epithelium in the rectum or to start from proximal microscopic mucosal spread from a small lesion located more distally.<sup>70</sup>

## Staging and Prognosis

Like melanoma of the skin, anorectal melanoma is staged by depth or thickness of the lesion. Lymphatic metastases can occur in the inguinal, mesorectal, and internal iliac nodal distribution. Mesorectal LN metastases are found in 40% to 60% of patients at initial presentation and inguinal adenopathy is present in at least 20%.<sup>73,74</sup> Distant spread occurs to the bone, lung, and liver.

Regardless of stage, 5-year survival rates for patients diagnosed with anorectal melanoma are very poor, averaging about 6%. The median survival

time following diagnosis is 12 to 18 months.<sup>70</sup>

## Surgery

In recent years, local excision has replaced APR for the treatment of anal melanoma. Outcomes data comparing local recurrence rates and survival do not demonstrate a survival difference between the two approaches; therefore, the preservation of fecal continence is a priority when possible. A number of retrospective series published from 1985 to 1990 reviewing institutional experience with local excision and APR found that 5-year survival rates range from 0% to 29% for those undergoing wide local excision and from 0% to 26% for those undergoing APR.<sup>72,73,74</sup>

Even though survival differences are minimal between local and radical approaches, local recurrence rates may be higher after local excision. A study from MD Anderson Cancer Center found that recurrence after local excision was significantly higher than recurrence after APR (58% vs 29%), and that median survival times were the same (approximately 19 months for both groups).<sup>74</sup> Patients in this study with local recurrence developed synchronous regional and distant disease. Roumen's group in the Netherlands also reported an increased rate of local recurrence with local excision, but no overall survival disadvantage.<sup>75</sup> Based on these data, wide local excision with negative margins is the treatment of choice for those patients without anal sphincter involvement.<sup>78</sup>

Inguinal LN dissection in anorectal melanoma is usually reserved for those with clinically positive nodes and is a palliative intervention. Prophylactic nodal dissection does not seem to provide a survival benefit and there currently is no clear indication for it. The role of sentinel LN mapping in this disease is not clear. The benefits of the technique are now well established in cutaneous melanoma, but it has not been investigated in anorectal melanoma and is not currently routinely performed.

## Adjuvant Therapy

Checkpoint inhibitors are currently used in the treatment of cutaneous melanoma. It confers a survival benefit in this group, improving disease-free survival rates, sometimes dramatically. There are scant data demonstrating its

efficacy in anorectal melanoma, however, and current reports of adjuvant chemotherapy in this setting are not robust. External beam radiation for symptomatic pelvic and local recurrences and metachronous inguinal nodal disease has been incorporated into the palliative treatment of anorectal melanoma, but again, no data are available to assess overall efficacy. It seems reasonable, however, to extrapolate treatment paradigms from cutaneous melanoma to anorectal melanoma in Stage IV disease.

The surgical treatment of anorectal melanoma has changed over time, evolving from radical to local excision. No survival benefit is conferred by APR in most studies, and in most reviews survival is quite poor in spite of surgical excision, with median survival less than 20 months from the time of diagnosis. Although adjuvant chemotherapy and immunotherapy is shown to be effective in cutaneous melanoma, lack of data hinders acceptance of this therapy in anorectal melanoma.

## **ANAL ADENOCARCINOMA**

Anal adenocarcinomas are uncommon, comprising 10% of all anal canal carcinomas.<sup>76</sup> Symptoms of bleeding, pain, and change in bowel habits are nonspecific and similar to other anal canal and distal rectal neoplasms. Anal adenocarcinomas may occasionally be found in chronic anal fistulas.

Although outcomes data are few, anal adenocarcinoma has a poor prognosis when compared to rectal cancers or anal SCC. In small series, 5-year survival rates range from 64% to less than 5%.<sup>76</sup> These neoplasms have a high rate of both local and distant failure.<sup>77</sup>

Treatment is similar to therapy for adenocarcinoma of the rectum. Neoadjuvant chemoradiation followed by surgical excision is recommended. Postoperative adjuvant chemotherapy may be prudent, as it is in rectal adenocarcinoma, to reduce the risk of distant spread.

## **PAGET DISEASE**

Paget disease was first described in 1874 by Sir James Paget who reported 15 cases involving the nipple.<sup>78</sup> Paget's has a female predominance (1.5:1) with a median presentation age of 65 years.<sup>78</sup> The disease is usually present for an extended period of time prior to diagnosis because the symptoms are

nonspecific and often mistaken for a benign dermatitis. Paget's occurs in apocrine, hair-bearing areas. Erythematous, pruritic, scaling plaques with well-defined serpiginous borders are a typical feature of the disease. These lesions may also appear ulcerated and crusty with a serous discharge. The disease can be found in both the anal canal and margin.<sup>78</sup> Histologically, Paget disease is defined by the presence of large intraepidermal anaplastic tumor cells lying separately or in small clusters. Perianal Paget cells are foamy and vacuolar in appearance and stain light blue with hematoxylin and eosin. They are positive for PAS, mucicarmine, alcian blue, and cytokeratin 7.<sup>78</sup>

The pathogenesis of Paget disease is still somewhat unclear. Because it can be associated with the presence of rectal adenocarcinoma, it is speculated that Paget's represents a downward extension of the tumor or that a "neoplastic milieu" may create an environment hospitable to the presence of multiple gastrointestinal primary tumors. Another hypothesis holds that it is a primary tumor of the apocrine glandular elements of the distal anal canal and margin. Others have suggested that Paget's may arise from a neoplastic pluripotent epidermis basal cell.<sup>78</sup>

Perianal Paget's is associated with an underlying visceral malignancy in 20% to 86% of cases.<sup>78</sup> Colorectal adenocarcinoma is the most common synchronous tumor, but urogenital, breast, and bile duct carcinomas have also been reported. Screening for other malignancies is imperative. A colonoscopy and prostate exam are basic preventive and diagnostic tests that can be helpful. Some authors recommend CT of the abdomen and pelvis as well.

Complete excision is the treatment for Paget disease. The extent of the disease is usually determined by taking circumferential biopsies of the anal canal and margin. After the disease is mapped, wide local excision is performed. Often, the procedure creates large defects that may require skin grafts or flaps (rotational, island, or myocutaneous). Because excision to negative margins is critical to cure, techniques to ensure this may be required. Surgeons may obtain frozen sections of the margins of the specimen in the operating room prior to reconstruction. Some surgeons prefer to cover the wound with saline-soaked gauze, admit the patient to the hospital, and await permanent pathology results for up to 2 to 3 days prior to reconstruction. If a large flap reconstruction is placed in the anal canal, some recommend diversion with a colostomy or ileostomy at the time of the perineal excision.

Recurrence rates as high as 61% have been reported following excision of perianal Paget disease.<sup>79,80</sup> Re-excision is the usual recommendation, although in cases where underlying rectal or anal adenocarcinoma exist, radiation followed by abdominoperineal resection is advisable. Although recurrence rates are high, the prognosis of Paget's limited to the perianal area with no concomitant neoplasm is very good.<sup>80</sup> Because of the association with additional visceral neoplasms, continued surveillance is required for patients with perianal Paget disease. Physical examination, including a prostate and pelvic examination, and periodic colonoscopy are probably prudent. Biopsies of new lesions at the edges of the flap or graft may reveal residual disease. Local excision of these recurrences and continued surveillance is required.

## BUSCHKE-LÖWENSTEIN TUMORS

Buschke-Löwenstein tumors are also referred to as “giant condylomas” and were first described in 1925 by Buschke and Löwenstein as “carcinomalike condyloma acuminata.”<sup>81</sup> They are rare entities belonging to a wider group of lesions called “verrucous carcinomas,” which includes oral and cutaneous fungating condylomas. The key feature of giant condyloma that differentiates it from benign anal condyloma is the presence of local invasion.

Although the natural history of these lesions is poorly understood, the etiology is assumed to be similar to that of condyloma. HPV has been isolated from the tumors. Histologically, the lesions are benign in appearance and do not invade the basement membrane as carcinomas do. Instead, they destroy surrounding tissue by expansion rather than direct invasion. The tumor does not metastasize. Deaths from untreated Buschke-Löwenstein tumors have occurred following deep invasion into unresectable pelvic structures followed by superinfection and recurrent sepsis. Overall mortality rate from this rare entity is 20%.<sup>82</sup>

Because there are so few cases reported, there are no consistent treatment guidelines. Primary treatment consists of surgical resection to clear margins.<sup>82</sup> However, adequate surgery may be impossible when the tumor deeply invades the pelvis. There have been several case reports demonstrating the efficacy of intralesional injection of interferon- $\alpha$  2b.<sup>81</sup> At least three reported cases of deeply infiltrating giant condyloma have

completely responded to long-term therapy including one patient who would have required hemipelvectomy with limb amputation to achieve negative margins. Interferon- $\alpha$  2b may be a good alternative or supplement to radical resection in select cases. Long-term outcomes are not available.

**LIVER**

# HEPATIC ABSCESS AND CYSTIC DISEASE OF THE LIVER

*Nikolaos A. Chatzizacharias • Kathleen K. Christians • Henry A. Pitt*

## INTRODUCTION

The differential diagnosis of cystic lesions of the liver includes bilomas, abscesses, parasitic disease, simple cysts, polycystic liver disease, biliary cystadenoma, and cystadenocarcinoma.<sup>1</sup> The disease spectrum includes infectious, traumatic, congenital, and neoplastic hepatic lesions, which are relatively uncommon. Although significant improvements have been made in the diagnosis, treatment, and outcome of many of these cystic hepatic lesions, controversy continues regarding the best treatment option. Many classification systems exist for these lesions; however, the one used in this chapter is presented in [Table 56-1](#).

- I. Infectious hepatic cysts
    - A. Pyogenic liver abscess
    - B. Amebic liver abscess
    - C. Hydatid liver cysts
  - II. Congenital hepatic cysts
    - A. Simple cysts
    - B. Polycystic liver disease
  - III. Neoplastic hepatic cysts
    - A. Cystadenoma
    - B. Cystadenocarcinoma
  - IV. Traumatic hepatic cysts
- 

## PYOGENIC LIVER ABSCESS

The first description of a hepatic abscess is credited to Hippocrates in the year 4000 BC. Ochsner's classic 1938 paper<sup>2</sup> described this disease as one that occurred in young males with pylephlebitis, usually due to appendicitis, and resulting in liver abscess. At that time, pyogenic liver abscesses carried a case-fatality rate of 77%,<sup>2</sup> and open surgical drainage remained the treatment of choice for many years. In 1953, McFadzean and associates<sup>3</sup> in Hong Kong advocated closed aspiration and antibiotics for treatment of solitary pyogenic liver abscess; however, this treatment did not gain widespread acceptance until imaging advancements in the 1980s allowed for precise localization and a percutaneous approach to treatment. In recent decades, the predominant etiology of pyogenic liver abscess has changed from pylephlebitis to a biliary origin, and more recent reports from Asia and the United States have noted an increase in incidence of cryptogenic liver abscesses. Fortunately, advanced imaging techniques and improved therapeutic modalities have decreased the case-fatality rate for this disease to 6% to 26%.<sup>4,5</sup>

### Etiology

Kupffer cells act as a filter for the clearance of microorganisms in the liver. These organisms reach the liver through the bloodstream, biliary tree, or direct extension. Abscesses occur when normal hepatic clearance

mechanisms fail or the system is overwhelmed. Parenchymal necrosis and hematoma secondary to trauma, obstructive biliary processes, ischemia, and malignancy also promote invasion of microorganisms.

In order to appropriately treat the abscess, source control is required. Six distinct categories have been identified as potential sources: (1) bile ducts, causing ascending cholangitis; (2) portal vein, causing pylephlebitis from appendicitis or diverticulitis; (3) direct extension from a contiguous disease; (4) trauma due to blunt or penetrating injuries; (5) hepatic artery, due to septicemia; and (6) cryptogenic<sup>6,7</sup> (Fig. 56-1).

**FIGURE 56-1** Comparison of etiology of pyogenic liver abscesses treated from 1952 to 1972 and 1973 to 1993 at the Johns Hopkins Hospital.

(Reproduced with permission from Huang CJ, Pitt HA, Lipsett PA, et al: Pyogenic hepatic abscess: Changing trends over 42 years, *Ann Surg* 1996;May;223(5):600–609.)

Biliary disease accounts for 35% to 40% of all pyogenic liver abscesses, and 40% of pyogenic liver abscesses of biliary origin are related to an underlying malignancy.<sup>8</sup> Obstruction of the biliary tree is the norm, and

cholangitis is present in up to one-half of these patients.<sup>9</sup> Intrahepatic stones and related biliary stricture are predominant in Eastern series, whereas malignant biliary obstruction is more common in the West.<sup>7</sup> Any manipulation of the biliary tree—namely cholangiography, percutaneous transhepatic stents, endoscopic stent placement, and biliary-enteric anastomoses—also predisposes patients to cholangitis and pyogenic liver abscess. Malignancy contributes to poor nutrition and immunosuppression, potentiating the whole process.

Intestinal pathology is responsible for 20% of all pyogenic liver abscesses. Transient bacteremia due to bacterial translocation or frank gastrointestinal perforation causes overwhelming numbers of microorganisms to spread via the portal venous system to the liver. In the preantibiotic era, 43% of Ochsner's 622 patients seeded the liver through the portal vein, and appendicitis was the most common source (34%).<sup>2</sup> Today, appendicitis accounts for only 2% of all pyogenic liver abscesses. Diverticulitis, perforated colon cancers, and abscesses elsewhere in the abdomen and pelvis remain common causes of pyogenic liver abscesses. Primary and metastatic liver tumors may also become colonized with enteric flora.

Contiguous extension of gangrenous cholecystitis, perforated ulcers, and subphrenic abscesses also is a reported source for pyogenic liver abscess. In addition, liver trauma causes parenchymal necrosis and clot, which creates an ideal milieu for the seeding and proliferation of microorganisms and subsequent abscess formation. Microorganisms can then seed these areas of necrosis through intraoperative contamination, biliary-enteric anastomoses, external drains involving the biliary tree, or percutaneous drains placed near the site of trauma or ablation.

Arterial embolization of bacteria via the hepatic artery causes approximately 12% of pyogenic liver abscesses. Intravenous drug abuse accounts for most of these cases, but hepatic artery chemoembolization or particle embolization as well as umbilical artery catheterization also have been cited. Liver abscess formation has been described as a complication in less than 5% of hepatic transarterial embolizations and less than 1% of tumor ablations. Arterial embolization also can occur from distant infection in the heart, lungs, kidneys, bones, ears, and teeth.<sup>8</sup>

Cryptogenic abscesses occur in 10% to 45% of patients, depending on the aggressiveness of investigation used to define the source.<sup>8,10</sup> Patients with

cryptogenic abscesses usually have comorbidities such as diabetes, immunosuppression, or malignancy. Abscesses in these patients tend to be solitary and usually contain a single anaerobe.

## Incidence

Pyogenic liver abscess affected 5 to 13 patients per 100,000 admissions prior to 1970 and accounts for approximately 15 cases per 100,000 admissions today. Seeto and Rocky<sup>11</sup> reported an incidence nearly two fold that of earlier reports (22 per 100,000). This rising incidence is attributed to a more aggressive management approach to hepatobiliary and pancreatic cancers as well as major improvements in diagnostic imaging.<sup>7,12</sup>

## Predisposing Factors

Pyogenic liver abscesses occur more frequently in adults with comorbid conditions including diabetes mellitus, cirrhosis, pancreatitis, inflammatory bowel disease, pyelonephritis, and peptic ulcer disease. Solid organ cancers, as well as lymphoma and leukemia, are present in 17% to 36% of patients with liver abscesses.<sup>8</sup> Branum and associates<sup>13</sup> reported an increased incidence in patients with underlying malignancy and immunosuppression. Civardi and colleagues<sup>14</sup> and Lambiase and coworkers<sup>15</sup> have reported series of patients with liver abscesses and underlying acquired immune deficiency. The combination of chemotherapy and steroid use is thought to be responsible in these cases.

In addition to comorbidities, age plays a role in the development of pyogenic liver abscess. The age of patients with pyogenic liver abscess has increased since 1938. This disease has now become a disease of the middle-aged and elderly, with a reported mean age of 47 to 65 years. Older patients are more likely to have a biliary etiology or underlying malignancy, whereas younger patients are more likely to be alcoholic males with a cryptogenic origin. Polymicrobial or anaerobic infections with multidrug-resistant organisms, a pleural effusion, inappropriate initial antibiotic selection, and a greater severity of illness on admission occur more frequently in older patients. Underlying malignancy is more prevalent in older patients and is a risk factor for developing anaerobic infections. Age and an Acute Physiology

and Chronic Health Evaluation II (APACHE II) score  $\geq 15$  on admission are risk factors for case fatality in older patients. The case-fatality rate in older patients is related to host conditions, rather than characteristics of the abscess itself. Clinicians should apply an aggressive approach for older patients exhibiting a poor response to primary treatment, particularly in those with a greater severity of illness on admission.<sup>16</sup>

In children, pyogenic liver abscesses tend to occur in the setting of host-defense abnormalities or immune disorders. Complement deficiencies, chronic granulomatous disease, leukemia, and other malignancies place these children at increased risk for liver abscess. Hepatic abscesses also are seen in sickle cell anemia, congenital hepatic fibrosis, polycystic liver disease, and after liver transplantation (Table 56-2).<sup>8</sup>

 **TABLE 56-2: PREDISPOSING FACTORS FOR PYOGENIC LIVER ABSCESSES**

Children	Adults
Chronic granulomatous disease	Diabetes mellitus
Complement deficiencies	Cirrhosis
Leukemia	Chronic pancreatitis
Malignancy	Peptic ulcer disease
Sickle cell anemia	Inflammatory bowel disease
Polycystic liver disease	Jaundice
Congenital hepatic fibrosis	Pyelonephritis
Posttransplant liver failure	Malignancy
Necrotizing enterocolitis	Leukemia and lymphoma
Chemotherapy and steroid therapy	Chemotherapy and steroid therapy
Acquired immunodeficiency syndrome	Acquired immunodeficiency syndrome

## Pathology

The source of the liver abscess is predictive of the number, location, and size of the abscess affecting a given patient. In general, portal, traumatic, and

cryptogenic hepatic abscesses are solitary and large, whereas biliary and arterial abscesses are multiple and small. Huang and associates<sup>7</sup> reported that 63% of patients had abscesses involving the right lobe, 14% had abscesses involving the left lobe, and 22% had bilobar disease. The number of bilateral and multiple abscesses has increased as more patients present with a biliary etiology. Bilateral disease may be seen in 90% of patients with an arterial or biliary source. In contrast, those with intra-abdominal infections frequently present with right lobe abscesses due to preferential flow from the superior mesenteric vein. Fungal abscesses are usually multiple, bilateral, and miliary.<sup>8</sup>

## Bacteriology

Diagnostic confirmation of a pyogenic liver abscess involves aspiration of the abscess itself and obtaining blood cultures that are positive. Abscess cultures are positive for growth in the majority of cases (80%-97%), whereas blood cultures are positive in only 50% to 60% of cases.<sup>11,14</sup> *Escherichia coli*, *Klebsiella* species, enterococci, and *Pseudomonas* species are the most common aerobic organisms cultured, whereas *Bacteroides* species, anaerobic streptococci, and *Fusobacterium* species are the most common anaerobes.<sup>12</sup> Huang and colleagues<sup>7</sup> cited the increased use of indwelling biliary stents as the cause of an increasing incidence of *Klebsiella*, streptococcal, staphylococcal, and pseudomonal species in liver abscesses. They also noted the presence of fungi in 22% of cultures taken between 1973 and 1993 compared to only 1% between 1952 and 1972. Broad-spectrum antibiotic use in the treatment of cholangitis was thought to be the causative factor. *Candida* fungal abscesses also are found in cancer patients who have undergone cytotoxic chemotherapy. *Mycobacterium tuberculosis* is a common infecting organism in acquired immunodeficiency syndrome<sup>9</sup> (Table 56-3).

TABLE 56-3: ORGANISMS ISOLATED FROM PYOGENIC LIVER ABSCESSES

Category of Organism	% of Patients
Gram-negative aerobes	50-70
<i>Escherichia coli</i>	35-45
<i>Klebsiella</i>	18
<i>Proteus</i>	10
<i>Enterobacter</i>	15
<i>Serratia</i>	Rare
<i>Morganella</i>	Rare
<i>Acinetobacter</i>	Rare
Gram-positive aerobes	55
Streptococcal species	20
<i>Enterococcus faecalis</i>	10
$\beta$ -Streptococci	5
$\alpha$ -Streptococci	5
Staphylococcal species	15
Anaerobes	40-50
<i>Bacteroides</i> species	24
<i>Bacteroides fragilis</i>	15
<i>Fusobacterium</i>	10
<i>Peptostreptococcus</i>	10
<i>Clostridium</i>	5
<i>Actinomyces</i>	Rare
Fungal	26
Sterile	7

The species of microorganism found in a hepatic abscess is related to the source. The biliary tree gives rise to abscesses predominantly comprised of *E coli* and *Klebsiella*. *E coli*, enterococci, and anaerobes are the main organisms recovered from abscesses related to the intestinal tract. Anaerobes are the usual microorganisms found in cryptogenic liver abscesses in Western countries. Negative cultures may relate to poor anaerobic culture technique or the use of broad-spectrum antibiotics prior to abscess drainage. In series where careful attention is paid to anaerobic organism recovery, anaerobes may be detected in 10% to 17%, most often *Bacteroides fragilis*.<sup>17</sup> If suspected bacterial cultures are repeatedly negative, amebic and parasitic

organisms must be considered because they are difficult to identify by routine staining and culture techniques.<sup>8</sup>

*Klebsiella pneumoniae* is the number 1 pathogen found in pyogenic liver abscesses in Taiwan and Korea and usually occurs in a monobacterial, as opposed to mixed bacterial, setting. Investigation into the K antigen serotype revealed that the K1 serotype accounts for 60% of *K pneumoniae* strains causing liver abscess in these countries. In contrast, this particular serotype is rarely found in clinical isolates from Western countries. In Taiwan and Korea, the average age to develop a *K pneumoniae* liver abscess is 55 to 60 years. These abscesses are twice as likely to be diagnosed in men than in women and are much more likely to be cryptogenic in origin (64%). Diabetes is a known risk factor for developing *K pneumoniae* liver abscess and is a significant risk factor for embolic complications, especially endophthalmitis.<sup>17,18</sup>

## Diagnosis

The clinical presentation of pyogenic liver abscess is usually subacute and nonspecific, leading to delays in presentation, diagnosis, and treatment. In Seeto and Rocky's review<sup>11</sup> of 142 patients with pyogenic liver abscesses, the classic triad of fever, jaundice, and right upper quadrant tenderness was present in less than 10% of patients overall.

## Clinical Presentation

Most patients have fever (92%), and 50% have abdominal pain, but only half have pain in the right upper quadrant. Diarrhea occurs in less than 10% of patients. The liver may be tender (65%) and enlarged (48%), and the patient may appear jaundiced (54%). Other nonspecific complaints include malaise, anorexia, and nausea. If the diaphragm is involved, pleuritic chest pain, cough, or dyspnea may occur. If the abscess ruptures, peritonitis and sepsis may be presenting features<sup>7,9,11</sup> (Table 56-4).

**TABLE 56-4: SYMPTOMS, SIGNS, AND LABORATORY DATA OF PYOGENIC LIVER ABSCESSSES**

	<b>% of Pyogenic Abscesses</b>
<b>Symptom</b>	
Fever	83
Weight loss	60
Pain	55
Nausea and vomiting	50
Malaise	50
Chills	37
Anorexia	34
Cough or pleurisy	30
Pruritus	17
Diarrhea	12
<b>Sign</b>	
Right upper quadrant tenderness	52
Hepatomegaly	40
Jaundice	31
Right upper quadrant mass	25
Ascites	25
Pleural effusion or rub	20
<b>Laboratory data</b>	
Increased alkaline phosphatase	87
WBC count >10,000/ $\mu$ L	71
Albumin <3 g/dL	55
Hematocrit <36%	53
Bilirubin >2 mg/dL	24

Abbreviation: WBC, white blood cell.

## Laboratory Evaluation

Leukocytosis is present in 70% to 90%, an elevated alkaline phosphatase in 80%, and an elevated bilirubin and transaminases in 50% to 67% of patients. Anemia, hypoalbuminemia, and prolonged prothrombin time are seen in 60%

to 75% of patients.<sup>7,9,11,12</sup>

## Radiology

Plain films such as chest radiographs are abnormal in 50% of patients. Findings may include an elevated right hemidiaphragm, a right pleural effusion, and/or right lower lobe atelectasis. Abdominal films may show hepatomegaly, air-fluid levels in the presence of gas-forming organisms, or portal venous gas if pylephlebitis is the source (Fig. 56-2). Ultrasound will distinguish solid from cystic lesions and is cost-effective and portable. Ultrasound (US) is 80% to 95% sensitive but has limited utility in the morbidly obese and in lesions that are located under the ribs or located in an inhomogeneous liver.

**FIGURE 56-2** Plain film of a barium enema performed on a patient with a large gas-filled abscess located in the right hepatic lobe. (Reproduced with permission from Zuidema GD: *Shackelford's Surgery of the Alimentary Tract*, 4th ed. Philadelphia, PA: WB Saunders; 1996.)

Computed tomography (CT) is more sensitive (95%-100%) than US in detecting hepatic abscesses. On CT examination, an abscess is of lower attenuation than the surrounding liver, and the wall of the abscess may enhance with intravenous contrast administration. Lesions are detectable to around 0.5 cm with CT and are not limited by shadowing from ribs or air. CT and US may be used to evaluate and potentially treat the source of infection by percutaneous drainage (Figs 56-3 and 56-4). Radionuclide scanning with technetium-99m is no longer used and has been completely replaced by CT and US. However, cholangiography, usually through an indwelling biliary stent, may visualize the abscess (Fig. 56-5).

A

B

**FIGURE 56-3** **A.** Abdominal ultrasound demonstrating a pyogenic liver abscess. The lesion appears as a low-density collection with small internal echos. **B.** Duplex ultrasound of pyogenic liver abscess with intervening portal vessels blocking safe access to percutaneous drainage.

**FIGURE 56-4** **A.** Abdominal CT demonstrating a large pyogenic abscess that is of low density. **B.** Percutaneous drainage of posterior liver abscess. **C.** MRI of liver abscesses. CT, computed tomography; MRI, magnetic resonance imaging.

**FIGURE 56-5** Cholangiogram via a transhepatic stent in a patient with biliary obstruction secondary to recurrent gastric cancer. It shows a communicating liver abscess.

## **Treatment**

The appropriate treatment for pyogenic liver abscesses requires treatment of the abscess itself and concomitant treatment of the source. Drainage of a pyogenic abscess is essential for cure in most cases. Although antibiotics alone may be curative, these patients have a higher risk of failure and complications such as abscess rupture. Percutaneous transhepatic drainage is

a relatively low-risk and successful treatment method for both polymicrobial liver abscesses and *K pneumoniae* liver abscesses.<sup>17</sup> Steps in management include antibiotic administration, radiologic confirmation by US or CT, and drainage. Exceptions to this strategy include multiple small abscesses and miliary fungal abscesses. These abscesses are treated with intravenous antibiotics and antifungals, respectively, without a drainage procedure.

## ANTIBIOTICS

After confirmatory imaging with US or CT, abscesses are aspirated, blood cultures are drawn, and broad-spectrum intravenous antibiotics are administered until sensitivities allow a more selective antibiotic choice. Serologic testing also should be performed if an amebic abscess is suspected.<sup>9</sup>

Classic antibiotic regimens include an aminoglycoside, clindamycin, and either ampicillin or vancomycin. However, *E coli*, *K pneumoniae*, and other Enterobacteriaceae have developed up to 30% resistance to these antibiotics. Fluoroquinolones can replace aminoglycosides, and metronidazole can be used instead of clindamycin, especially if an amebic source is suspected. Single-agent therapy with ticarcillin-clavulanate, imipenem-cilastatin, or piperacillin-tazobactam also is acceptable.<sup>12</sup> Recent reports advise a third-generation cephalosporin and metronidazole or piperacillin-tazobactam as the initial regimen of choice. Carbapenems are recommended when extended-spectrum  $\beta$ -lactamase-producing strains are isolated. Treatment used to be given for 4 to 6 weeks; however, many studies now document success with only 2 weeks of antibiotic therapy.<sup>8</sup> Empiric antibiotics should include anaerobic coverage in older pyogenic liver abscess patients, particularly in the setting of malignancy.<sup>16</sup>

For patients with a *K pneumoniae* liver abscess, ampicillin alone is not recommended. In addition, metronidazole is ineffective against aerobic organisms, and regimens containing first-generation cephalosporins have been shown to be inferior in treatment of *K pneumoniae* liver abscess. Thus, a broad-spectrum penicillin, such as piperacillin-tazobactam, or a second- or third-generation cephalosporin is preferred for patients with *K pneumoniae* liver abscess.<sup>17</sup>

Antibiotics alone have an 80% success rate for solitary abscesses with a

diameter <5 cm.<sup>19</sup> In a series of 107 patients with unilocular hepatic abscesses of <3 cm, treatment with antibiotics alone had a 100% success rate. In the setting of multiple abscesses <1.5 cm in size and no concurrent surgical disease, patients may be treated with intravenous antibiotics alone. However, multiple small abscesses frequently imply biliary tract disease and may require biliary drainage for source control. Similarly, fungal abscesses are miliary in nature and not amenable to percutaneous or surgical drainage.

## **ANTIFUNGALS**

Candidal liver abscess is a rare disease reported most commonly in patients with hematologic malignancies during periods of neutropenia resolution. Most of the candidal liver abscesses in patients with hematologic malignancies are a manifestation of disseminated candidiasis and have high mortality rates. They also can be acquired by fungemia from the portal vein or an ascending retrograde infection from the biliary tree. In patients with hematologic malignancies, the yield of positive culture is often less than 50%, with the diagnosis usually based on microscopic examination or histopathology from deep tissues. Higher doses of amphotericin B (2-9 g) are recommended by most experts because a cumulative dose of <2 g correlated with residual lesions at autopsy. Cases of hepatosplenic candidiasis have been successfully treated with fluconazole. Symptoms improved at 3 to 8 weeks, but resolution of the lesions on CT scan was noted after at least 1 month of fluconazole.<sup>20</sup>

*Candida glabrata* often has reduced susceptibility to both azoles and amphotericin B, and opinions on best therapy are divided. Both *Candida krusei* and *C glabrata* appear susceptible to caspofungin, and this agent may be a good alternative. Although fungemia due to *C glabrata* has been treated successfully with fluconazole (6 mg/kg/d), many experts prefer amphotericin B deoxycholate (>0.7 mg/kg/d). On the basis of pharmacokinetics predictions, fluconazole (12 mg/kg/d; 800 mg/d for the 70-kg patient) may be a suitable alternative, particularly in less critically ill patients.<sup>21</sup>

## **ASPIRATION AND PERCUTANEOUS CATHETER DRAINAGE**

Needle aspiration and percutaneous catheter drainage of liver abscesses have

similar mortality rates; however, recurrence rates and the requirement for surgical intervention may be greater in those who undergo aspiration alone.<sup>11</sup> Needle aspiration is less invasive, less expensive, and avoids all of the complications associated with catheter care. Giorgio and colleagues<sup>22</sup> reported a series of 115 patients with a 98.3% success rate for needle aspiration, no mortality, and no procedure-related morbidity. A randomized controlled trial by Rajak et al<sup>23</sup> in 1998 compared percutaneous needle aspiration to catheter drainage and also found no major complications and no deaths. They did, however, report only 60% success with needle aspiration versus a 100% success rate with catheter drainage.<sup>23</sup> The highest rate of recurrence (15%) occurred in patients with biliary tract disease and obstructive lesions, whereas the recurrence rate with cryptogenic abscesses was less than 2%. This observation suggests that the underlying lesion should influence the type of therapy chosen. Another option that is infrequently employed is repeated aspiration.

Patients in whom percutaneous drainage is not appropriate include those with (1) multiple large abscesses; (2) a known intra-abdominal source that requires surgery; (3) an abscess of unknown etiology; (4) ascites; and (5) abscesses that would require transpleural drainage.<sup>6</sup> An example of a patient managed by percutaneous drainage is provided in [Figure 56-6](#).

## SURGICAL DRAINAGE

Surgical drainage was the widely accepted treatment for liver abscesses for many years following Ochsner's 1938 report.<sup>2</sup> Right-sided abscesses were drained extraperitoneally via a 12th rib resection to avoid contamination of the peritoneal cavity. With the advent of systemic antibiotics, transperitoneal surgical exploration also was considered a safe surgical approach.

Advantages of the transperitoneal approach include the ability to: (1) treat the inciting pathology in the remainder of the abdomen/pelvis; (2) gain access and exposure of the entire liver for evaluation and treatment; and (3) access the biliary tree for cholangiography and bile duct exploration.

Since the 1980s, treatment has shifted to a less invasive approach utilizing percutaneous needle aspiration or catheter drainage to treat pyogenic abscesses. Surgical drainage is currently reserved for patients who have failed nonoperative therapy, those who need surgical treatment of the underlying source, those with multiple macroscopic abscesses, those on steroids, or those patients with concomitant ascites.<sup>7</sup>

## Complications

Up to 40% of patients develop complications from pyogenic liver abscesses, with the most common being generalized sepsis. In addition to sepsis, morbidity can include pleural effusions, empyema, and pneumonia. Abscesses also may rupture intraperitoneally, which is frequently fatal. Usually, however, the abscess does not rupture, but develops a controlled leak resulting in a perihepatic abscess. Pyogenic abscesses also may cause hemobilia and hepatic vein thrombosis.<sup>8</sup>

Bacteremia is extremely common (95%) in *K pneumoniae* liver abscesses as opposed to other types of pyogenic liver abscesses (50%). As a result, end-organ seeding and distant abscesses are common. Extrahepatic abscesses occur in 7% to 12% of patient with *K pneumoniae* liver abscesses, with the most commonly reported organ being the eye. Endophthalmitis occurs in 6% to 61% of cases and commonly occurs after liver abscess drainage. Disseminated intravascular coagulation, septic pulmonary emboli, and acute renal failure are also well-documented complications of *K pneumoniae* liver abscess.<sup>17</sup>

## Outcome

Between the 1950s and 1990, mortality rates varied from as low as 11% to as high as 88%.<sup>6</sup> High mortality rates came from delay or failure to diagnose the abscess, failure to detect smaller intrahepatic abscesses, ineffective surgical drainage, lack of source control, associated malignancy, immune insufficiency, or other major comorbid conditions. No general consensus has been reached regarding risk factors due to the variability of the patient population being studied (Table 56-5).

**TABLE 56-5: FACTORS ASSOCIATED WITH A POOR OUTCOME IN PATIENTS WITH PYOGENIC LIVER ABSCESSSES**

Age >70 years	WBC count >20,000/ $\mu$ L
Diabetes mellitus	Increasing bilirubin
Associated malignancy	Increasing aspartate aminotransferase
Biliary etiology	Albumin <2 g/dL
Multiple abscesses	Aerobic abscess
Septicemia	Significant complication
Polymicrobial bacteremia	

Abbreviation: WBC, white blood cell.

The prognosis for *K pneumoniae* is better than for other pyogenic liver abscesses with respect to mortality (6%-17%) and disease relapse. Prognosticators for mortality in *K pneumoniae* liver abscess are abscess >5 cm, concomitant sepsis, intrahepatic gas formation, APACHE III score >40, delayed/inadequate abscess drainage, use of antimicrobials alone, thrombocytopenia, and diabetes.<sup>17</sup> The main concern in this type of liver abscess is no longer mortality, but catastrophic disability due to irreversible ocular or neurologic complications. The *K pneumoniae* genotype K1 is a pathogen capable of causing septic ocular or central nervous system complications from pyogenic liver abscess independent of host underlying diseases.<sup>18</sup> The outcome for patients who develop endophthalmitis is grim because despite rapid intervention, visual acuity outcome is poor.<sup>17</sup>

## AMEBIC LIVER ABSCESS

Amebic liver abscess is caused by the parasitic protozoan *Entamoeba histolytica*. The disease was described in association with blood and mucus diarrheal stools in the 5th century BC by Hippocrates and other practitioners. In 1890, Sir William Osier described the first North American case when, after an attack of dysentery while in Panama, a physician's stool and abscess fluid were both found to contain amebae. Councilman and LaFleur of Johns Hopkins Hospital went on to detail the pathogenic role of amebae and coined the terms "amebic dysentery" and "amebic liver abscess" in 1891.<sup>24</sup> Amebic liver abscess is the most common extraintestinal form of invasive amebiasis, and an estimated 100,000 people succumb to this disease each year.<sup>25</sup>

### Etiology

Three species of ameba mainly infect humans. *Entamoeba dispar* is associated with an asymptomatic carrier state and not with disease. *Entamoeba moshkovskii* has been associated with mild gastrointestinal discomfort. *E histolytica* is responsible for all forms of invasive disease. The life cycle involves cysts, invasive trophozoites, and fecally contaminated food or water to initiate the infection.<sup>26,27</sup> Fecal-oral transmission occurs; the cyst passes through the stomach into the intestine unscathed, and pancreatic enzymes start to digest the outer cyst wall. The trophozoite is then released into the intestine and multiplies there. Normally, no invasion occurs, and the patient develops amebic dysentery or becomes an asymptomatic carrier. In a small number of cases, the trophozoite invades through the intestinal mucosa, travels through the mesenteric lymphatics and veins, and begins to accumulate in the hepatic parenchyma, forming an abscess cavity. Liquefied hepatic parenchyma with blood and debris gives a characteristic "anchovy paste" appearance to the abscess.<sup>12</sup>

### Incidence

Worldwide, an estimated 500 million people are carriers of *E histolytica* or *E dispar*, 50 million people have active disease, and 50,000 to 100,000 die annually. The vast majority of these infections are acquired in the developing

world. Amebiasis is common in Africa, Indochina, and Central and South America. Up to 5% of diarrheal illness in Mexico is due to *Entamoeba* disease.<sup>26</sup> The overall prevalence in the United States is 4% per year. High-risk groups in the United States include sexually active homosexual men, immigrants, tourists who travel to endemic areas, institutionalized people, and those with HIV.<sup>28</sup> Children also have been known to infect entire families. Amebiasis follows a bimodal age distribution. One peak is at age 2 to 3 years, with a case-fatality rate of 20%, and the second peak is at >40 years, with a case-fatality rate of 70%.<sup>26</sup> Those living in developing countries have a greater risk and an earlier age of infection than do those in developed regions. Low socioeconomic status and unsanitary conditions are significant independent risk factors for infection.<sup>28</sup> Amebic liver abscess is 10 times as common in men as in women and is a rare disease in children.<sup>27</sup> The reason for this vast difference between the sexes is not clear. Greater alcohol consumption among men, which may impair Kupffer cellular function as well as cellular and humoral immune response, and the potentially protective effects of hormones and iron deficiency anemia in menstruating women have been proposed to play a role.

## Pathology

Roughly 90% of people who become infected with *E histolytica* are asymptotically colonized, and factors that control the invasiveness of this organism are not completely understood. *E histolytica* cysts can last for days in a dried state at temperatures of 30°C. These cysts are resistant to the effects of gastric acid pH, but become stimulated to form trophozoites in the alkaline pH of the bowel. Trophozoites are found in the colon and in the feces of humans and mammals. Humans become reservoirs, and transmission occurs by ingesting food and water contaminated with amebic cysts, or occasionally through person-to-person contact. Incubation takes 1 to 4 weeks. Left untreated, asymptomatic individuals may shed cysts for many years.

The reasons why only a small portion of the colonized people will develop invasive disease are not fully understood. Virulence factors of the parasite (eg, the amount of secreted cysteine proteinases, phospholipases, hemolysins, and amebapores) and the host's immune status are the most likely factors. Invasive amebiasis can include anything from amebic dysentery to metastatic

abscesses. The most common form of the invasive disease is colitis. The majority (70%-80%) of patients experience a gradual onset of symptoms with worsening diarrhea, abdominal pain, weight loss, and stools containing blood and mucus. Trophozoites invade and induce apoptosis in colonic mucosa, resulting in “buttonhole” ulcers with undermined edges. Trophozoites are actually found in the edge of the ulcers.

The most common extraintestinal site of amebiasis is the liver, occurring in 1% to 7% of children and 50% of adults (usually males) with invasive disease.<sup>26</sup> Trophozoites reach the liver through the portal system, causing focal necrosis of hepatocytes and multiple microabscesses that coalesce into a single abscess. The central cavity of the lesion contains a homogenous thick liquid that is typically red/brown and yellow in color and similar to anchovy paste in consistency.<sup>29</sup>

## Diagnosis

The definitive diagnosis of amebic liver abscess is by detection of *E histolytica* trophozoites in the pus and by finding serum antibodies to the ameba.<sup>29</sup> The differential diagnosis should include pyogenic liver abscess, necrotic adenoma, and echinococcal cyst.

## CLINICAL PRESENTATION

Ninety percent of amebic liver abscesses occur in young adult males. The presentation may be acute, with fever and right upper quadrant (RUQ) pain, or subacute, with weight loss and, less frequently, fever and abdominal pain. The usual case of amebic liver abscess does not present with concurrent colitis, but patients may have had dysentery within the past year. Alcohol abuse is common.<sup>30</sup> Eighty percent of patients with amebic liver abscess present with symptoms that develop within 2 to 4 weeks, including fever, cough, and a dull aching pain in the RUQ or epigastrium. Diaphragmatic involvement causes right-sided pleural pain or pain referred to the shoulder. Gastrointestinal symptoms of nausea, vomiting, abdominal cramping, abdominal distention, diarrhea, and constipation occur in 10% to 35%. Hepatomegaly with point tenderness over the liver or subcostal region is common<sup>27</sup> (Table 56-6). In contrast to pyogenic liver abscesses, amebic liver

abscesses are more likely to occur in males under 50 years old who have immigrated or traveled to a country where the disease is endemic. The patient also will not be jaundiced or have biliary disease or diabetes mellitus<sup>27</sup> (Table 56-7).

**TABLE 56-6: SYMPTOMS, SIGNS, AND LABORATORY DATA OF AMEBIC LIVER ABSCESES**

	<b>% of Amebic Abscesses</b>
<b>Symptom</b>	
Pain	90
Fever	87
Nausea and vomiting	85
Anorexia	50
Weight loss	45
Malaise	25
Diarrhea	25
Cough or pleurisy	25
Pruritus	<1
<b>Sign</b>	
Hepatomegaly	85
Right upper quadrant tenderness	84
Pleural effusion or rub	40
Right upper quadrant mass	12
Ascites	10
Jaundice	5
<b>Laboratory data</b>	
Increased alkaline phosphatase	80
WBC count >10,000/ $\mu$ L	70
Hematocrit <36%	49
Albumin <3 g/dL	44
Bilirubin >2 mg/dL	10

Abbreviation: WBC, white blood cell.

**TABLE 56-7: DISTINGUISHING CLINICAL CHARACTERISTICS OF PATIENTS WITH HEPATIC ABSCESES**

Amebic	Pyogenic
Age <50 years	Age >50 years
Male-to-female ratio 10:1	Male-to-female ratio 1:1
Hispanic descent	No ethnic predisposition
Recent travel to endemic area	Malignancy
Pulmonary dysfunction	High fevers
Abdominal pain	Pruritus
Diarrhea	Jaundice
Abdominal tenderness	Septic shock
Hepatomegaly	Palpable mass

## LABORATORY EVALUATION

Patients may present with a mild to moderate elevation of the white blood cell count and anemia. Acutely, alkaline phosphatase will be normal and alanine aminotransferase levels will be elevated. The opposite is true in patients with chronic disease.<sup>27</sup> Jaundice is rare. Because amebic abscesses involve destruction of liver parenchyma and are often larger than pyogenic liver abscesses, patients may have an elevated prothrombin time.<sup>8</sup> If colitis is present, wet mount preps of stool samples contain trophozoites 30% of the time in 1 sample and 70% of the time if 3 samples are tested. Patients with an amebic liver abscess have positive stool samples in 40% to 50% of cases.<sup>26</sup>

## RADIOLOGY

Chest radiographs are abnormal in two-thirds of patients with amebic liver abscess and frequently show pleural effusion, infiltrates, or an elevated hemidiaphragm.<sup>8</sup> US, CT, and magnetic resonance imaging (MRI) are all excellent methods for detecting amebic liver abscesses but are nonspecific.<sup>27</sup>

In 75% to 80% of cases, only a single abscess is present and located in the right lobe. Ten percent are in the left lobe, and the rest are multiple. Six percent may present as a caudate lobe abscess. Only 40% have typical sonographic features of amebic liver abscess, and serial scanning shows no change in the US features despite adequate treatment. The mean time to resolution is 7 months, and 70% have findings that persist for more than 6 months. Eventually, resolution may be complete or result in a small residual

cystic cavity that resembles a simple cyst of the liver.<sup>31</sup>

## SEROLOGY

Serum antibodies are positive in 85% of patients with invasive colitis and 99% of patients with liver abscesses.<sup>32</sup> Countries with a high prevalence of amebiasis also have a high prevalence of positive serologies in asymptomatic individuals. Therefore, serologies help exclude the diagnosis only in appropriately chosen populations. Patients with *E dispar* infection will have negative serologies. Biopsies of the edge of an ulcer or the wall of an abscess reveal trophozoites with periodic acid-Schiff stain.<sup>26</sup>

## DIAGNOSTIC ASPIRATION

Serologic data are usually available within 24 to 48 hours; therefore, the need to aspirate a suspected amebic abscess is questionable. Diagnostic aspirations usually are done when amebic serologies are negative and a pyogenic cause needs to be ruled out. The fluid of an amebic abscess is odorless, and Gram stain and cultures are negative. Amebae are recovered in 33% to 90% of aspirates, and wall scrapings increase the yield. Aspiration should not be done if an echinococcal cyst or a cancer is suspected. The former may result in anaphylactic shock, and the latter has the potential to seed the tract with malignant cells.<sup>8</sup>

The diagnosis of invasive amebiasis is most commonly attempted by a combination of stool testing for ova and parasites (O&P) and serologic testing, possibly coupled with colonoscopy and biopsy of intestinal lesions or drainage of liver abscesses. Numerous studies have demonstrated the inadequacies of microscopic examination for *E histolytica* for the diagnosis of both amebic colitis and liver abscess. Antigen detection or polymerase chain reaction (PCR) to detect *E histolytica* in the stool is a better approach than O&P, but requires fresh or frozen stool specimens (versus preserved), and PCR is impractical in the developing world. The detection of amebic markers in the sera of patients with amebic colitis and liver abscess remains only a research tool.<sup>28</sup>

## Treatment

Since the introduction of metronidazole in the 1960s, surgical drainage of amebic liver abscesses has become virtually unnecessary. Drainage procedures, regardless of the approach, are reserved for patients in whom the diagnosis is questionable or when complications occur.

## **ANTIBIOTICS**

Noninvasive infections can be treated with paromomycin. Nitroimidazoles, especially metronidazole, are the mainstays of treatment for invasive amebiasis. Nitroimidazoles with longer half-lives (secnidazole, tinidazole, and ornidazole) are better tolerated and can be given for shorter periods of time but are not available in the United States.<sup>27</sup> Metronidazole reaches high concentrations in the liver, stomach, intestine, and kidney. This antibiotic crosses the placenta and blood-brain barrier and is contraindicated in the first trimester of pregnancy. The drug also is excreted in milk; thus, breastfeeding should be discontinued during use. Serious side effects are rare. Positive responses to metronidazole should be seen by the third day of treatment. At 5 days, an 85% cure rate is achieved, and this response may be increased to 95% by 10 days. Five to 15% of patients with amebic liver abscess may be resistant to metronidazole.<sup>31</sup> Parasites persist in the intestine in up to 40% to 60% of patients who receive a nitroimidazole; thus, nitroimidazole treatment should be followed with paromomycin or diloxanide furoate to cure luminal infection or risk relapse from residual infection in the intestine.<sup>27</sup> Chloroquine also is effective and has an excellent dose distribution in the liver. Chloroquine use is recommended as an adjunct to standard antimicrobial therapy in cases of large or multiple abscesses.

In summary, amebic liver abscess is usually managed by the administration of metronidazole or tinidazole, followed by treatment with a luminal amebicide (paromomycin or diloxanide furoate).<sup>25</sup>

## **THERAPEUTIC ASPIRATION**

Blessmann and colleagues<sup>33</sup> reported a prospective, randomized trial of patients with amebic abscesses who were treated with metronidazole alone or with US-guided aspiration of the fluid plus medication. Fever, RUQ pain, liver tenderness, and laboratory studies such as erythrocyte sedimentation rate, white blood cell count, hemoglobin, C-reactive protein, and abscess size

were obtained on admission and daily thereafter. Abscess aspiration resulted in improved liver tenderness within the first 3 days, but no other difference was demonstrable between the 2 groups. The authors concluded that this minor benefit was insufficient to justify routine needle aspiration. They advocated drug treatment alone for uncomplicated abscesses with a diameter up to 10 cm and located in the right lobe of the liver. However, aspiration may be considered in patients with pleuropulmonary extension and in pregnancy when metronidazole is contraindicated.

Therapeutic aspiration may occasionally be required as an adjunct to antiparasitic treatment. Drainage should be considered in patients who have no clinical response to drug therapy within 5 to 7 days or those with a high risk of abscess rupture defined as having a cavity diameter >5 cm or lesions located in the left lobe.<sup>34</sup> A 2009 Cochrane review<sup>35</sup> attempted to lay to rest the controversy surrounding percutaneous needle aspiration of uncomplicated amebic liver abscesses. The authors found that percutaneous needle aspiration did not help patients with uncomplicated amebic liver abscess. Benefits were observed in resolution time of pain and tenderness, but no additional benefit was found with percutaneous needle aspiration plus metronidazole versus metronidazole alone for uncomplicated amebic liver abscesses.<sup>35</sup> Bacterial coinfection of amebic liver abscess has been observed; therefore, addition of antibiotics, drainage, or a combination of both to nitroimidazole therapy may be necessary.<sup>27</sup>

## **DRAINAGE**

Percutaneous or surgical drainage should be reserved for cases in which the diagnosis of amebic liver abscess is in question or when complications occur.

**Percutaneous.** Image-guided percutaneous catheter drainage has replaced surgical intervention as the procedure of choice for decreasing the size of an abscess. Percutaneous drainage remains most useful for treating pulmonary, peritoneal, and pericardial complications. The high viscosity of amebic abscess fluid, however, requires a large-diameter catheter for adequate drainage, and these catheters may cause more discomfort for the patient. Secondary infections related to the indwelling catheter are always a risk of this intervention.<sup>8</sup>

**Surgical.** Surgical drainage of amebic liver abscesses has largely been replaced by antibiotic therapy. The most common indication for surgical intervention is to manage abscesses that have failed to respond to more conservative therapy. Laparotomy is indicated for life-threatening hemorrhage that may or may not be related to abscess rupture, or when the amebic abscess erodes into a neighboring viscus and control of the involved viscus is necessary. Sepsis due to a secondarily infected amebic abscess also warrants operative intervention if percutaneous treatment fails.<sup>8</sup>

## Complications

Complications from amebic abscesses occur secondary to rupture of the abscess into the peritoneum, pleural cavity, or pericardium (Fig. 56-7). Extrahepatic sites also have been described in the lung, brain, skin, and genitourinary tract, presumably from hematogenous spread.<sup>27</sup> Ruptured amebic liver abscesses occur in 2% to 17% of patients and are associated with mortality rates between 12% and 50%.<sup>31</sup>

**FIGURE 56-7** Paths of extension of amebic liver abscesses located within (A) the right hepatic lobe (labels 1-7) and (B) the left hepatic lobe (labels 8 and 9).

Peritonitis associated with amebiasis is due to rupture in the majority (78%) of cases and, less commonly, secondary to necrotizing or perforated amebic colitis (22%). The liver abscess usually adheres to the diaphragm and the anterior abdominal wall, or the omentum and bowel tend to wall it off. Rupture into the colon or stomach also may occur. Free rupture into the peritoneal cavity is uncommon and occurs in moribund patients or those with poor nutrition.<sup>31</sup>

Thoracic amebiasis (empyema, bronchohepatic fistulas, and pleuropulmonary abscess) is the most common complication, followed by

pericardial amebiasis (acute pericarditis with tamponade).<sup>26</sup>

Transdiaphragmatic involvement manifests as dyspnea and dry cough. On exam, right basilar crackles and a pleural rub may be heard. Plain films show atelectasis and blunting of the costophrenic angle. If the abscess ruptures into the pleural cavity, it usually occurs suddenly, collapsing the lung, filling up the pleural space, and whiting out the lung on chest x-ray. Treatment requires drainage of the pleural cavity with tube thoracostomy. If the abscess ruptures into the bronchi, this complication causes sudden onset of coughing with expectoration of copious brown sputum. Surgical intervention is not required, as the abscess is usually walled off from the pleural and peritoneal cavities. Postural drainage, bronchodilators, and antiamebic drugs may suffice.

Left lobe abscesses are more likely to involve the pericardium.

Complications range from asymptomatic effusions, to cardiac tamponade, to intrapericardial rupture. If pericardial thickening or effusion is noted on imaging, some experts believe that this is an indication for aspiration of a left lobe liver abscess. When tamponade develops, aspiration of the pericardium, drainage of the liver abscess, and antiamebic drugs are indicated.<sup>31</sup> Cerebral amebiasis is seen in up to 8% of autopsies. These patients are severely ill from sepsis and may experience seizures.<sup>26</sup>

## Outcome

The majority of patients with amebic liver abscess defervesce within 3 to 4 days of treatment<sup>30</sup>; however, left untreated, amebic liver abscesses may be fatal. Mortality rates of 0% to 18% are reported, with higher rates occurring secondary to a delay in diagnosis, or when secondary bacterial infection or complications (abscess rupture) occur. Independent risk factors for mortality include serum bilirubin >3.5 mg/dL, encephalopathy, hypoalbuminemia defined as <2.0 g/dL, and the presence of multiple abscess cavities.<sup>36</sup> Abscess aspiration is a risk factor for secondary bacterial infection; however, in recent reports, secondary bacterial infection rates have decreased from 10% to 20% to 0% to 4% (Table 56-8).

## HYDATID LIVER CYST

Echinococcosis (hydatid disease) is a zoonosis caused by the larval stage of *Echinococcus granulosus* (also known as *Taenia echinococcus*). Humans are accidental intermediate hosts, whereas animals can be both intermediate and definitive hosts. The 2 main types of hydatid disease are caused by *E granulosus* and *Echinococcus multilocularis*. The former is commonly seen in the Mediterranean, South America, the Middle East, Australia, and New Zealand, and is the most common type of hydatid disease.<sup>37</sup> In humans, 50% to 75% of the cysts occur in the liver, 25% are located in the lungs, and 5% to 10% distribute along the arterial system. Infection with echinococcal organisms is the most common cause of liver cysts in the world.<sup>38</sup>

### Etiology

The life cycle of *E granulosus* has 2 hosts. The definitive host is usually a dog or some other carnivore. The adult worm of the parasite lives in the proximal small bowel of the definitive host attached by hooklets to the mucosa. Eggs are released into the host's intestine and excreted in the feces. Sheep are the most common intermediate host, and these animals ingest the ovum while grazing. The ovum loses the protective chitinous layer and is digested in the duodenum. The released hexacanth embryo (oncosphere) passes through the intestinal wall into the portal circulation and develops into cysts within the liver. The definitive host eats the viscera of the intermediate host to complete the cycle (Fig. 56-8).

**FIGURE 56-8** Life cycle of *Echinococcus granulosus*. (Modified with permission from Melvin DM et al: Common Blood and Tissue Parasites of Man. Life Cycle Charts. Atlanta, Georgia, Center for Disease Control, 1979.)

Humans may become intermediate hosts through contact with the definitive host (usually a dog) or by ingestion of contaminated water or vegetables. Once in the liver, cysts grow to 1 cm in the first 6 months and 2 to 3 cm annually thereafter. Once the parasite passes through the intestinal wall into the portal venous or lymphatic system, the liver is the first line of defense, and thus is the most frequently involved organ.

## Incidence

The incidence of hydatid liver cysts in the United States is approximately 200 cases per year, with an increased frequency in immigrant populations. Hydatid liver disease affects all age groups and both sexes equally, and no predisposing pathologic conditions are associated with infection. Public education about the life cycle and transmission of the disease has helped decrease the incidence. Washing hands after contact with canines, eliminating the consumption of vegetables grown at ground level from the diet, and stopping the practice of feeding entrails of slaughtered animals to dogs have all aided in decreasing the incidence of the disease.<sup>8</sup>

## Pathology

Hydatid liver cysts tend to expand slowly and without symptoms and are thus frequently very large on presentation. Single lesions are noted in 75% of patients and are predominantly located within the right lobe (80%).<sup>37</sup> Even though the lesion is single, half contain daughter cysts and are multilocular.

The typical hydatid cyst has a 3-layer wall surrounding a fluid cavity. The outer layer is the pericyst, a thin, indistinct fibrous tissue layer representing an adventitial reaction to the parasitic infection. The pericyst acts as a mechanical support for the hydatid cyst and is the metabolic interface between the host and the parasite. As the cyst grows, bile ducts and blood vessels stretch and become incorporated within this structure. This process explains the biliary and hemorrhagic complications of cyst growth and difficulties with resection. Over time, the pericyst calcifies.<sup>8</sup>

The outer layer of the cyst itself is the ectocyst or laminated membrane and is bluish-white, gelatinous, and about 0.5 cm thick. This membrane is a cuticular chitinous structure without nuclei and acts as a barrier for bacteria and an ultrafilter for protein molecules.

The inner layer or endocyst is the germinal membrane, responsible for the production of clear hydatid fluid, the ectocyst, brood capsules, scoleces, and daughter cysts. The endocyst is 10 to 25  $\mu\text{m}$  thick and attached tenuously to the laminated membrane. The absorptive function of the inner layer is important for cyst nutrition. The inner layer also has a proliferative function producing the ectocyst and scoleces.<sup>39</sup> This germinal layer forms small

cellular masses that give rise to brood capsules, in which future worm heads develop. They enlarge and develop into invaginated protoscolexes with 4 suckers and a double row of hooks—a protoscolex. The protoscolex fully differentiates and matures attached by a pedicle to the capsule wall. Brood capsules and freed protoscolexes are released into the fluid of the original cyst and, together with calcareous bodies, form hydatid sand.

Hydatid sand is made up of around 400,000 scolexes per milliliter of fluid. The protoscolex can differentiate in 2 directions. In the definitive host, the scolex becomes an adult tapeworm. In the intermediate host, including humans, each of the released protoscolexes is capable of differentiating into a new hydatid cyst. Development of brood capsules from the germinal layer indicates complete biologic development of the cyst, which occurs after 6 months of growth.

Daughter cyst formation is a defense reaction. Hydatid cysts in humans are long-standing, large, and liable to injury. Any injury may cause daughter cyst formation. Daughter cysts are replicas of the mother cyst, and their size and number are variable. In uncomplicated cysts, the cyst cavity is filled with sterile, colorless, antigenic fluid containing salt, enzymes, proteins, and toxic substances.<sup>39</sup> The formation of daughter cysts is called endogenic vesiculation.

Ectogenic vesiculation occurs when a small rupture or defect in the laminated membrane occurs and the germinal layer passes through and creates a satellite hydatid cyst. This process is uncommon in *E granulosus*, but is characteristic for the larval stage of *E multilocularis*. Because the liver parenchyma in humans cannot sequester *E multilocularis* and the process of ectogenic vesiculation is fulminant, multiple vesicles are formed in all directions. The infected parenchyma has a multilocular appearance, and the center becomes necrotic, spongy, and filled with a gelatinous fluid similar to that of a mucoid liver carcinoma. Hepatic insufficiency is common, and the disease is often lethal.<sup>39</sup>

## Diagnosis

The diagnosis of uncomplicated hydatid liver cyst depends on the index of clinical suspicion. Most uncomplicated cysts are asymptomatic. Symptoms may arise due to a toxic reaction from the presence of the parasite or local

mechanical effects.

## CLINICAL PRESENTATION

The clinical features of hydatid liver disease depend on the site, size, stage of development, whether the cyst is alive or dead, and whether the cyst is infected.<sup>39</sup> Pain in the RUQ or epigastrium is the most common symptom, whereas hepatomegaly and a palpable mass are the most common signs. Nonspecific fever, fatigue, nausea, and dyspepsia may also be present<sup>40</sup> (Table 56-9). Approximately one-third of patients will have eosinophilia, and only 20% will present with jaundice and hyperbilirubinemia.

**TABLE 56-9: SYMPTOMS, SIGNS, AND LABORATORY DATA OF HYDATID LIVER CYSTS**

	% of Hydatid Cysts
<b>Symptoms</b>	
Asymptomatic	75
Abdominal pain	20
Dyspepsia	13
Fever and chills	8
Jaundice	6
<b>Signs</b>	
Right upper quadrant mass	70
Right upper quadrant tenderness	20
<b>Laboratory data</b>	
Eosinophilia	35
Bilirubin >2 mg/dL	20
WBC count <10,000/ $\mu$ L	10

Abbreviation: WBC, white blood cell.

## SEROLOGY

No single biochemical test definitively establishes the diagnosis. The Casoni and Weinberg tests are no longer used due to their low sensitivities. Determination of specific antigens and immune complexes of the cyst with enzyme-linked immunosorbent assay (ELISA) gives a positive result in more than 90% of patients. Specific IgE antibodies are demonstrated with ELISA and radioallergosorbent test (RAST) if active disease is present. The arc 5 antibody test involves precipitation during immunoelectrophoresis of the blood of patients with the antigen. Positivity for this test is 91%. Sbihi and colleagues<sup>41</sup> reported that purified fractions enriched in antigens 5 and B and glycoproteins from hydatid fluid yielded a sensitivity of 95% with a specificity of 100%.

## **RADIOLOGY**

Chest radiographs may show an elevated diaphragm and concentric calcifications in the cyst wall but are of limited value. US and CT are considered the first choice for imaging (Fig. 56-9). Classic findings of hydatid cysts are calcified thick walls, often with daughter cysts.<sup>42</sup> US defines the internal structure, number, and location of the cysts and the presence of complications. The specificity of US in hydatid disease is around 90%.<sup>40</sup> The classification proposed by Gharbi and associates<sup>43</sup> provides a morphologic description. Type I has a pure fluid collection. Type II has a fluid collection with a split wall (floating membrane). Type III reveals a fluid collection with septa (honeycomb image). Type IV has heterogenous echographic patterns, and type V has reflecting thick walls. An updated classification system has been proposed by the World Health Organization (Table 56-10). Differential imaging characteristics of hepatic cysts are presented in Table 56-11.

**TABLE 56-10: CLASSIFICATION OF HYDATID LIVER CYSTS**

Gharbi's Classification	WHO Classification
—	Type CL: cystic lesions, anechoic, without visible wall
Type I	Type CE1: cystic lesions, active, fertile, unilocular, anechoic, with visible wall
Type II	Type CE2: cystic lesions, active, fertile, multilocular, with multiple daughter vesicles
Type III	Type CE3: transitional cyst, with germinate membrane detached
Type IV	Type CE4: inactive cyst, scratchy aspect
Type V	Type CE5: inactive cyst, calcified wall

Abbreviation: WHO, World Health Organization.

**TABLE 56-11: DIFFERENTIAL IMAGING AND CHARACTER OF HEPATIC CYSTS**

	Pyogenic	Amebic	Hydatid	Congenital	Cystadenoma
Number	Single or multiple	1 or few	Usually single	Single or multiple	Single with loculations
Wall thickness	Thick	Thick	Thick	Thin	Variable
Wall character	Uniform or multiloculated	Usually uniform	Uniform, daughter cysts; 50% calcified	Uniform	Septations common may be irregular
Cyst contents	Usually pus with blood	Red-brown; like anchovy paste	Clear or bilious; gelatinous	Usually clear water density	Usually green-brown mucinous
Computed tomography	Central hypodensity and peripheral contrast enhancement	Central hypodensity and peripheral contrast enhancement	Daughter cysts in rosette pattern	Water dense, smooth, avascular	Well-defined, contrast-enhancing wall, often nodularity
Magnetic resonance imaging	T1 hypointense T2 hyperintense with enhancing rim	T1 hypointense T2 hyperintense with enhancing rim	T2 low-intensity rim Daughter cysts hypointense to intracystic fluid on T1 and hyperintense on T2	T1 hypointense T2 very hyperintense	T1 hypo- or isointense T2 hyperintense Wall and septations enhance with contrast

CT gives similar information to US, but more specific information about the location and depth of the cyst within the liver. Daughter cysts and exogenous cysts also are clearly visualized, and cyst volume can be

estimated. CT is imperative for operative management, especially when a laparoscopic approach is used.<sup>40</sup> MRI provides structural details of the hydatid cyst, but adds little more than US or CT and is more expensive. Magnetic resonance cholangiopancreatography (MRCP) may show communication with the biliary system as well as provide detailed information on the biliary anatomy. Endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiogram (PTC) may show communication between the cysts and bile ducts and can be used to drain the biliary tree before surgery. The routine use of ERCP is advocated by some to completely define the bile duct anatomy and to visualize any clinically silent connections between the bile ducts and cysts.<sup>42</sup>

## Treatment

Most echinococcal cysts are asymptomatic on presentation, but potential complications such as pulmonary infection, cholangitis, rupture, and anaphylaxis give good reason to consider treatment for all. Medical, surgical, and percutaneous approaches may be part of the treatment armamentarium.<sup>42</sup> Small cysts (<4 cm) located deep in the parenchyma of the liver, if uncomplicated, can be managed conservatively.<sup>40</sup> Basic principles include: (1) eradication of the parasite within the cyst, (2) protection of the host against spillage of scoleces, and (3) management of complications.<sup>42</sup>

## ANTIHELMINTHICS

Medical therapy for echinococcosis is based on the benzimidazoles (mebendazole and albendazole) and, used alone, is only 30% successful. Albendazole is readily absorbed from the intestine and metabolized by the liver to an active form. Mebendazole is poorly absorbed and is inactivated by the liver. Albendazole is thus the drug of choice for medical therapy. Greater success rates may be observed in patients with extrahepatic manifestations of the disease and with the alveolar form caused by *E multilocularis*. Given for at least 3 months preoperatively, albendazole reduces the recurrence rate when cyst spillage, partial cyst removal, or biliary rupture has occurred. Duration of therapy in these instances is at least 1 month.<sup>42</sup> Monitoring with

complete blood count and liver function tests throughout the duration of treatment is advised, as benzimidazoles are known to cause neutropenia and hepatotoxicity. Other side effects include nausea and occasionally alopecia. Pregnancy, chronic liver disease and myelosuppression are contraindications for their use. Combination therapy with praziquantel 40 mg/kg once weekly may be advisable in refractory disease.

## **PERCUTANEOUS ASPIRATION AND DRAINAGE**

Historical surgical dictum stated that percutaneous puncture of a hydatid cyst is a dangerous and contraindicated activity. Potential risks including anaphylaxis, communication with the biliary tree, and spillage may outweigh possible advantages. In 1983, Fornage<sup>44</sup> challenged this axiom and reported an accidental puncture of a hydatid cyst by US that had no clinical consequences. Many successful reports followed thereafter.<sup>39,45</sup> The most frequently used protoscolicidal agents used for percutaneous treatment are 15% to 20% saline, 95% ethanol, a combination of 30% saline and 95% ethanol, and mebendazole solution.

PAIR technique stands for: *p*uncture of the cyst wall, *a*spirations of cyst content, *i*njection, and *r*easpiration of a scolecidal agent. PAIR involves initial puncture of the cyst under US or CT guidance, aspiration of cyst content, injection of contrast material to opacify the cyst, and infusion of scolecidal drug, followed by povidone-iodine infusion. The catheter stays clamped for 30 minutes, then povidone-iodine is infused again. The catheter is preserved for drainage. Except in the case of povidone-iodine infusion, aspiration can be followed by sclerotherapy or infusion of alcohol or a scolecidal such as albendazole. Recently, a modified PAIR technique was created to introduce concomitant evacuation of cyst contents while infusing scolecidal agent via a specially designed coaxial catheter system. The simultaneous aspiration/infusion process allows almost complete washout of cyst content, reducing chances of any scolices surviving, and maintenance of the intracystic pressure minimizes risk of biliary fistula formation.<sup>46</sup> The PAIR technique has been combined with albendazole therapy with 70% success rates and a low rate of recurrence. In 1997, Filice and Brunetti<sup>47</sup> reported a series of 163 patients with 231 cysts treated percutaneously. No complications were reported, and long-term results were good.

Indications for percutaneous treatment of liver hydatid cysts are type I and

II cysts, type III and IV cysts with drainable material, suspected fluid collections, infected hydatid cysts, inoperable patients, pregnant women, and patients with multiple, disseminated, or symptomatic cysts. Contraindications include subgroups of type III and IV cysts (hydatid cysts with heterogeneous echo pattern), liver cysts that have ruptured into the biliary system or peritoneum, cysts inaccessible to puncture, and children <3 years old. Type V cysts are not eligible for any intervention other than simple follow-up. Recurrence rates vary between 0% and 4%. Overall complication rates in percutaneous drainage range from 15% to 40%. Major complications (anaphylactic shock) are rare (0.1%-0.2%). Minor complications (urticaria, itching, hypotension, fever, infection, fistula, rupture into the biliary system) range from 10% to 30%. Cyst-biliary complications after PAIR and caused by cyst decompression can be handled endoscopically or by cyanoacrylate infusion. In one of the largest recently published series on the management of liver hydatid cysts, PAIR technique yielded good results in cystic lesions and cystic echinococcosis types 1 (CE1) and 2 (CE2) disease with low complication rates (1% biliary fistula, 1% abscess formation, 3.8% allergic reaction). Only 2.8% of patients required repeat procedure to achieve results.<sup>48</sup> Cholangiography or ERCP is recommended before any attempt for percutaneous drainage to inject contrast material and make any communication visible. Overall mortality rates are as low as 0.1%.<sup>46</sup>

## **SURGERY**

Surgery remains the treatment of choice for uncomplicated hydatid disease of the liver, although much debate exists about the most appropriate surgical technique that can offer total extirpation of the parasites with minimal postoperative complications.<sup>46</sup> The objectives of surgical treatment are to: (1) inactivate the scoleces, (2) prevent spillage of cyst contents, (3) eliminate all viable elements of the cyst, and (4) manage the residual cyst cavity. The surgical procedure varies from a radical resective open approach (pericystectomy or hepatic resection) to a conservative approach (drainage or obliteration of the cavity or both), which can potentially even be done laparoscopically<sup>40</sup> (Fig. 56-10). One of the most important end points of hydatid cyst surgery may be recurrence. Dissemination of protoscolices-rich fluid during surgery and incomplete removal of the germinative membrane from the cyst cavity are major causes of recurrence (8.5%-25%) in

postoperative cases.<sup>49</sup>

**FIGURE 56-10** **A.** Open cyst evacuation demonstrating cyst aspiration (*upper left*), removal of daughter cysts (*upper right*), resection of active cyst lining (*lower left*), and packing with omentum (*lower right*). **B.** Pericystectomy demonstrating removal of a calcified pericyst (*top right*), closure of a small bile duct (*middle left*), and closure of the cavity over a drain (*lower right*). (Reproduced with permission from Cameron JL, Sandove C: *Atlas of Surgery*. Philadelphia, PA: BC Decker; 1990.)

**Scolecidal Agents.** Early on, surgical management of hydatid cysts via cyst evacuation resulted in a high rate of peritoneal implantation. This problem

prompted the use of scolecidal agents for injection into the cyst and for use in the surrounding peritoneum. Formalin, hypertonic saline, chlorhexidine, cetrimide, hydrogen peroxide, polyvinylpyrrolidone-iodine, silver nitrate, and ethyl alcohol are among some of the many agents that have been used.<sup>40,42,46</sup> However, formalin caused sclerosing cholangitis when it entered the biliary tract. Hypertonic saline has to be used carefully to avoid biliary injection and hypernatremia. The safety of the other agents in the biliary tree has not been established. No agent should be injected pre-evacuation due to high intracyst pressure. The World Health Organization (WHO) regards the use of scolecidal agents for intraoperative killing of infectious material as questionable, because no agent is both effective and safe. According to WHO, ethanol (70%-95%), hypertonic saline (15%-20%), and cetrimide solution (0.5%) are deemed substances with relatively low risk.<sup>49</sup> Chlorhexidine gluconate 0.04% (Chx-Glu) is relatively nontoxic, without harmful effects on the biliary tract, and is not affected by dilution in the cyst fluid. In addition, Chx-Glu is commonly available, easily prepared, and inexpensive and was 100% effective on protoscolices and the germinative membrane and may be the preferred scolecidal agent.<sup>49</sup>

**Open Cyst Evacuation.** The safest surgical approach is open cyst evacuation. Peripherally located cysts are the most easily treated, and either abdominal or flank approaches may be used depending on cyst location. Prior to opening the cyst, the field is lined with hypertonic (20%) saline-soaked gauze to guard against spillage. The cyst is then opened, and the contents are aspirated with a suction device that is capable of generating high negative pressures. The cyst is then opened completely, and any remaining debris is meticulously cleared. The cavity may then be irrigated with a scolecidal agent.<sup>42</sup> The recurrence rate of this procedure is 10% to 30%.<sup>46</sup>

**Laparoscopic Cyst Evacuation.** Peripherally located echinococcal hepatic cysts may be safely managed by laparoscopic cyst evacuation.<sup>50</sup> The lesions best suited for this approach are situated anteriorly and do not have thick calcified walls. A right lateral approach also works for cysts in segments VI and VII. A trocar (11 mm) is inserted just above the cyst, and 10% povidone-iodine-soaked sponges are placed as the scolecidal agent. The cyst is aspirated with a 14-gauge needle. The endocyst then shrinks back from the wall and rests at the bottom of the cyst. The 11-mm trocar is then exchanged

for an 18-mm trocar, and the germinal membrane is aspirated. The laparoscopic camera is inserted directly into the cyst to explore for residual daughter cysts or biliary fistulae. The remaining cavity is irrigated with a 20% saline solution, and the cyst wall is excised. The cavity may be plugged with omentum or closed over a closed suction drain.<sup>50</sup>

The most difficult part of the laparoscopic approach is the initial cyst puncture and aspiration of the cyst fluid. Indications for laparoscopic excision of liver echinococcosis have changed over the years. Currently, the only excluding criteria for laparoscopic intervention are deep intraparenchymal cysts or posteriorly situated cysts, more than 3 cysts, and cysts with thick and calcified walls. Postoperative morbidity ranges from 8% to 25%, and mortality in most series is 0% with recurrence rates of 0% to 9% (vs 12%-63% morbidity, 0%-3% mortality, and 0%-30% recurrence in open series). However, major complications (eg, anaphylaxis) are more common in laparoscopic interventions as a result of peritoneal spillage during debridement and removal of cyst contents. Major drawbacks to the comparison of laparoscopic versus open procedures are the small studies, lack of randomization, and bias related to careful selection of laparoscopic candidates.<sup>46</sup>

**Pericystectomy.** Pericystectomy involves complete resection of the cyst wall without entering the cyst cavity. This procedure is done through a plane outside of the pericyst or along the cyst wall itself. Preoperative localization of the bile ducts and vascular system is imperative. If a bile duct connection is suspected, preoperative ERCP should be obtained. Intraoperative US should be used. Pericystectomy decreases the risk of spillage of cyst contents into the peritoneal cavity and also lowers the risk of recurrence. The disadvantage to this approach is the potential for bleeding and/or damage to bile ducts in proximity to the cyst wall.<sup>42</sup> Gunay and associates<sup>38</sup> reported 0% recurrence rates, a lower incidence of biliary fistulae, and shorter hospitalization compared with more conservative procedures. The procedure also precludes management of the cavity and facilitates detection of recurrence.

One of the largest recently published cohorts, including 359 patients, suggested that open pericystectomy should remain the method of choice for complicated liver hydatid cysts. However, a laparoscopic approach may be implemented in simple disease with good results.<sup>48</sup> In their review of

published literature on laparoscopic management of liver hydatid cysts, Tuxun et al<sup>51</sup> reported a 0.22% mortality and 15% overall complication rate. Most procedures were cystectomies (60%) of disease types CE1-2 (46%), whereas more advanced types were also treated by some groups (CE3 14%, CE4 4%, CE5 16%). Conversion rate to open surgery was about 5%, and recurrence was 1%, occurring 3 to 68 months after the procedure.<sup>51</sup>

**Liver Resection/Transplantation.** Some experts have argued that formal resection for benign disease is excessive and unnecessary, whereas others have stressed that resection is very safe. Multiple cysts within proximity to a major blood supply or to each other or cysts in a relatively safe location (ie, segments II and III) are candidates for resection provided a complete resection can be achieved. *E multilocularis* infection also may lead to fulminant hepatic failure from sclerosing cholangitis, biliary sclerosis, or Budd-Chiari syndrome, and in these rare cases, orthotopic liver transplantation may be necessary.<sup>42</sup> Among these various treatment options, criteria for uncomplicated and complicated patients are presented in [Table 56-12](#). A recent study also discovered lymphatic spread of larval *E multilocularis* from the liver to regional lymph nodes and suggests the routine removal of regional nodes to reduce the risk of persistent infection.<sup>52</sup>

**TABLE 56-12: TREATMENT OPTIONS FOR HYDATID LIVER CYSTS**

## UNCOMPLICATED PATIENTS

Percutaneous or Laparoscopic Evacuation	Open Evacuation or Resection
Gharbi type I or II	Gharbi type IV or V
Anterior cysts	Posterior cysts
Peripheral cysts	Central cysts
1 to 3 cysts	>3 cysts
Small cysts	Large cysts
No or minimal calcification	Heavy calcification

## COMPLICATED PATIENTS

Percutaneous or Laparoscopic Evacuation	Open Evacuation or Resection
Infected cysts meeting above criteria	Infected cysts meeting above criteria
Biliary communication—not indicated	Biliary communication—indicated
Pulmonary communication—not indicated	Pulmonary communication—indicated
Peritoneal rupture—not indicated	Peritoneal rupture—indicated

## Complications

Complications from hydatid cysts are seen in one-third of patients. Most commonly, the cyst ruptures internally or externally, followed by secondary infection, anaphylactic shock, and liver failure, in order of decreasing frequency.<sup>38</sup> Viable hydatid cysts are space-occupying lesions with a tendency to grow. In confined areas such as the central nervous system, even small cysts can cause severe symptoms. In less confined areas, symptoms depend on the site and size of the cyst. Symptoms result from direct pressure or distortion of neighboring structures or viscera. Compressive atrophy of the surrounding hepatocytes and fibrosis occurs, and these cysts may grow to such an enormous size that they replace an entire lobe.

As the cysts enlarge, they may also rupture. If rupture of only the endocyst occurs, the content is retained within the pericyst. A communicating rupture is a rupture into the biliary or bronchial tree.<sup>39</sup> Hydatid liver cysts cause compression of the biliary system, leading to decubiti-like lesions and biliary communication in up to 80% of cases. This communication may be very difficult to find and result in biliary leakage/fistulae postoperatively. Bile leakage is the main source of cavity-related complications in conservative surgery. If not properly drained, a bile leak may result in an abscess or bile peritonitis. If drained effectively, an external biliary fistula may develop. Twelve to 33.3% of patients with biliary fistulae require biliary drainage postoperatively, and rates are higher in conservative versus radical surgery. The complication rates for radical surgery range from 17% to 20%. Retention cysts in conservative surgery may lead to misdiagnosis of early recurrence and result in unnecessary operations.<sup>53</sup>

A free rupture occurs when hydatid contents rupture throughout the peritoneal, pleural, or pericardial cavity. Acute symptomatic rupture into the peritoneal cavity occurs in 1% to 4% of patients and may precipitate anaphylactic shock.<sup>39</sup>

## Outcome

Medical therapy alone results in recurrence rates of 70% to 80% and is not recommended. Medical treatment is used in combination with a drainage procedure or in patients who are not surgical candidates. Uncomplicated cases that undergo open surgical, laparoscopic, or percutaneous drainage have recurrence rates of approximately 10%. Early local recurrence and cavity-related complications are the main problems affecting the success of the surgical management of hydatid liver disease. These problems are rare for complete resections due to complete removal of the cyst wall containing the germinal epithelium and daughter cyst. Conservative operations are easier and safer but are associated with a high incidence of local recurrence (10%) and cavity-related complications (37%). Older cysts have an increased risk of exogenic daughter cyst formation, which is an important risk factor for early local recurrence. Another important risk factor for early local recurrence, especially in conservative surgery, is pre- and intraoperative undetected satellite cysts, which exist around pericysts or exogenic vesiculations. Since

the disease is endemic to many locations, the potential for reinfestation remains, so long-term serologic and imaging studies are necessary. Rupture into the pleural or peritoneal cavity portends a recurrence rate of up to 25%.<sup>42</sup>

Uncomplicated cases undergoing elective procedures such as laparoscopic or percutaneous cyst aspiration should have morbidity rates between 15% and 30% and essentially no mortality. In patients with complicated disease that requires open evacuation, pericystectomy, or resection, morbidity is as high as 50%; however, mortality should still remain less than 5%. Septic shock, peritoneal rupture, and comorbid conditions (ie, malnutrition) play a major role in increasing mortality rates.

## CONGENITAL LIVER CYSTS

### Simple

The incidence of simple hepatic cysts in 1695 patients referred for abdominal or pelvic US was 2.5%, with a sharp increase noted at >60 years old.<sup>54</sup> In a separate European study<sup>55</sup> of more than 26,000 patients undergoing upper abdominal US, simple cysts were found in 2.8%, and most patients (>92%) were over the age of 40. The female-to-male ratio was 1.5:1.

Solitary benign cysts are believed to be congenital and thought to arise from abnormal development of intrahepatic bile ducts in utero. The aberrant ducts enlarge slowly and may result in symptoms later in life. In a study from the Mayo Clinic<sup>56</sup> from 1907 to 1971, only 24% of simple cysts were symptomatic, and they usually became symptomatic in the fourth or fifth decade of life. Abdominal pain or a mass was noted most frequently and was present in more than 50% of patients. Less commonly, symptoms were related to mass effect resulting in nausea, vomiting, early satiety, and jaundice. Physical exam revealed hepatomegaly or a palpable abdominal mass. Laboratory values should be normal, but occasionally, hyperbilirubinemia may be seen. Simple solitary cysts are bluish in color and contain clear, straw-colored fluid. Echinococcal disease should be ruled out by serology.<sup>57</sup>

US is the most accurate imaging modality, with greater than 90% sensitivity and specificity. On US, the cysts appear as anechoic masses with

smooth margins and thin, imperceptible walls. US also differentiates between cystic and solid lesions and can assess for intra- and extrahepatic biliary dilatation in the jaundiced patient. CT imaging reveals nonenhancing, fluid (water) density lesions with a thin, uniform wall (Fig. 56-11). On MRI, simple cysts are well-circumscribed lesions that are hypointense on T1-weighted images and hyperintense on T2-weighted images.<sup>55</sup>

**FIGURE 56-11** CT demonstrating a large simple cyst compressing the hepatic veins and inferior vena cava and abutting the left portal venous system. CT, computed tomography.

Most simple cysts are found incidentally and are asymptomatic, and 80% to 95% remain asymptomatic. In the setting of symptoms, percutaneous aspiration can aid in diagnosis but is associated with 100% recurrence within a 2-year period. If sclerosants are added, a 17% recurrence rate can be achieved.<sup>57</sup>

Success of surgical treatment for cystic liver disease is judged by relief of

symptoms rather than by complete disappearance of the cystic lesion on imaging studies. Once the benign nature of the cyst is established, a permanent internal cyst “drain” is the mainstay of surgical therapy, and complete cyst excision is not necessary.<sup>58</sup> If the cyst protrudes from the liver and no biliary connection is demonstrated, the accessible wall on the liver surface may be excised and the remaining cyst lining allowed to drain freely into the peritoneal cavity. If the cyst has a biliary connection, suspicion should be high that the lesion is a biliary cystadenoma rather than a simple cyst. In general, cyst excision or unroofing and resection have a 0% to 20% recurrence rate and a mortality rate of 0% to 5%<sup>54</sup> (Table 56-13).

---

In recent years, laparoscopy has become the most common approach and has an overall success rate of more than 90% with a 10% rate of symptomatic cyst recurrence. Proponents of the laparoscopic approach report excellent exposure, less postoperative pain, and success rates similar to those of cases done open.<sup>57</sup> The laparoscopic approach has also been associated with a longer time interval to symptom recurrence compared to both open unroofing and resection. Gamblin et al<sup>59</sup> reported the largest series of laparoscopic liver

resections for cystic lesions, which included 51 patients. The authors routinely left the back wall of the cyst behind and untreated. Patients experienced minimal postoperative pain, short hospital stays (median, 2 days; range, 1-11 days), and resolution of symptoms (pain resolved in all) and had a low recurrence rate (2 of 51 patients required reoperation), and there were no 90-day mortalities. Median follow-up was 13 months. A growing body of literature supports the equivalency of many laparoscopic and open procedures with regard to outcomes and advantages in avoiding a laparotomy, especially in benign disease. These authors proposed minimally invasive cyst excision as the standard of care for management of benign hepatic cysts.<sup>59</sup>

## Polycystic

Polycystic liver disease (PCLD) is an autosomal dominant disorder often found in association with polycystic renal disease (40%).<sup>60</sup> PCLD is the most frequent extrarenal manifestation of autosomal dominant polycystic kidney disease. PCLD also exists in an autosomal dominant pattern that is not associated with polycystic renal disease, but may have cysts that develop in other organs in addition to the kidneys.

Cysts in PCLD are epithelial-lined growths arising from biliary epithelium that usually do not communicate with the biliary tree. The majority of patients are asymptomatic and do not require treatment. Their prognosis is directly related to the severity of the accompanying renal disease.<sup>61</sup>

If PCLD becomes symptomatic, the cause usually is hepatomegaly. Symptoms may include abdominal fullness, distention and pain, or bowel and biliary obstruction. Complications such as bleeding, infection, rupture, portal hypertension, and Budd-Chiari syndrome have been reported but are rare. Malignant transformation also has been reported but occurs infrequently. Hepatic function is typically preserved, so progression to liver failure is uncommon.<sup>61</sup>

Routine imaging of cysts in PCLD is similar to that of simple cysts. Unenhanced CTs show multiple, homogenous, hypoattenuating lesions with a regular outline (Fig. 56-12). Contrast-enhanced CT images have no cyst wall or enhancement of cyst contents. MRI demonstrates very low signal intensity on T1-weighted images and does not enhance after administration of gadolinium. Since the cyst content is purely fluid and homogenous, high

signal intensity is demonstrated on T2-weighted images.<sup>60</sup> Based on CT imaging, adult polycystic liver disease can be categorized as follows: type I, limited number (<10) of large cysts with large areas of noncystic parenchyma; type II, diffuse involvement of liver parenchyma by medium-sized cysts with remaining large areas of noncystic parenchyma; and type III, diffuse involvement of liver parenchyma by small- and medium-sized liver cysts with only a few areas of normal liver parenchyma.

**FIGURE 56-12** CT demonstrating polycystic liver disease. CT, computed tomography.

Development of symptoms in PCLD is most often due to hepatomegaly; and therefore, treatment needs to result in a reduction of liver size. Percutaneous aspiration with sclerotherapy may be used in patients who are not surgical candidates or in lesions that are not surgically accessible, but long-term results of this approach are poor.

If a small number of large cysts exist, laparoscopic unroofing with the aid of intraoperative US may be successful. Deeper cysts may be accessed and unroofed through the back wall of more superficially located cysts. However,

due to the rigid architecture found in PCLD, unroofing alone may not be enough to provide hepatic collapse and relief of symptoms. In addition, if too many cysts are unroofed, the peritoneum's absorptive capacity may be exceeded and cause ascites. Unroofing is not useful in patients with a large number of smaller cysts because it cannot be adequately performed.

In PCLD, recurrence of symptoms is common and has been reported in up to 57% of patients after open and 72% after laparoscopic approaches. In a comparative study between open unroofing, laparoscopic unroofing, and resection in patients with liver cysts, in the polycystic liver disease subset, laparoscopic unroofing was associated with the highest recurrence of symptoms (85%). However, symptoms were less severe. Time to symptom recurrence was longer compared to open unroofing and comparable to resection. No difference was identified in quality of life by type of surgical approach. However, the quality of life in patients with recurrence of symptoms was better after laparoscopic unroofing compared to resection.

A combination of cyst unroofing and liver resection may achieve the best results in terms of reducing liver volume. Resection should include the most cysts with the least loss of hepatic function. Morbidity for this approach is greater, but long-term results are improved. Orthotopic liver transplant is occasionally indicated if symptoms are disabling or hepatic function is compromised. If patients have associated renal failure, the liver transplant may be combined with renal transplantation.<sup>61</sup>

## NEOPLASTIC CYSTS

Neoplastic cysts are acquired cysts that occur less commonly than simple cysts, usually in females, in the fifth decade of life. Their etiology is unknown. Cystic neoplasms are frequently large, resulting in abdominal discomfort and a palpable mass on examination. Cystic neoplasms appear as multiloculated lesions with papillary projections inside the cyst cavity. Invasion of the surrounding tissue suggests malignancy, as does the presence of a predominantly solid (vs cystic) component. Ten percent of neoplastic cysts are malignant. Definitive diagnosis requires intraoperative biopsy of the cyst wall. Incomplete resection will result in nearly 100% recurrence.<sup>57</sup>

Laboratory investigation is normal in most, although some patients present with elevated liver enzymes. Serum  $\alpha$ -fetoprotein (AFP) and

carcinoembryonic antigen (CEA) levels are usually normal. In some patients, CA 19-9 has been found to be elevated five fold. In general, hemorrhagic cyst fluid suggests cystadenocarcinoma, whereas bilious or mucinous fluid suggests cystadenoma.<sup>62</sup>

## Cystadenoma

Cystadenomas comprise less than 5% of all intrahepatic cysts of biliary origin.<sup>63</sup> Hepatobiliary cystadenoma with mesenchymal stroma occurs exclusively in young- and middle-aged women and has potential to transform into cystadenocarcinoma. In contrast, hepatobiliary cystadenoma without mesenchymal stroma occurs in both sexes equally, at a mean age of 50 years, and has no clear association with cystadenocarcinoma.<sup>62</sup> These tumors are lined with columnar epithelium and frequently have papillary infoldings.<sup>63</sup> If symptoms are present, they may include abdominal pain (60%-80%), jaundice, cholangitis, fullness, or bloating.<sup>1</sup>

Cystadenomas have a septated, multilocular appearance on US and CT (Fig. 56-13).<sup>57</sup> CT will reveal well-demarcated cystic lesions, usually with internal septations; the walls are rarely calcified, and the presence of polypoid protrusions or wall excrescences should trigger the concern for cystadenocarcinoma.<sup>1</sup> MRI shows typical features for a fluid-containing loculated mass with homogeneous low signal intensity on T1-weighted images and homogeneous high signal intensity on T2-weighted images. However, signal intensity of mucinous fluids vary depending on protein concentration. On T1-weighted images, the signal intensity may change from hypointense to hyperintense as protein concentration increases. On T2-weighted images, signal intensity of mucinous fluids can decrease from hyperintense to highly hypointense with increasing protein concentration and viscosity. Blood products also have different signal characteristics on MRI. The distinction between cystadenoma and cystadenocarcinoma remains difficult based on imaging findings alone, as the presence or absence of septae, mural nodules, and papillary projections is variable between lesions. MRCP does, however, appear helpful in evaluating the relationship of the lesion to the bile ducts.<sup>64</sup> ERCP will usually demonstrate communication with the biliary tree, often at the proximal left hepatic duct.

A

B

C

**FIGURE 56-13** **A.** Ultrasound demonstrating a septated cystic liver tumor. **B.** Intraoperative photograph of segment IV liver cystadenoma. **C.** Gross photograph of liver cystadenoma after enucleation.

Serum CEA and CA 19-9 levels are usually within normal ranges and cannot be considered as significant parameters to discriminate between malignant and benign liver tumors.<sup>64</sup> The diagnosis of intrahepatic biliary cystadenoma can be suggested on the basis of cyst fluid analysis (CFA), but this relies on adequate sampling and correlation with clinical and radiologic findings. CA 19-9 and CEA have been shown to be elevated in intrahepatic biliary cystadenoma and normal in simple cysts. Immunohistochemical analysis of intrahepatic biliary cystadenoma has shown the presence of CA 19-9 and CEA in the epithelium; however, the premalignant progression is based on the histologic presence of intestinal metaplasia characterized by the presence of numerous goblet cells. This observation has led to the recommendation that patients with suspected intrahepatic biliary cystadenoma based on CFA should undergo cyst wall sampling to determine whether a premalignant (intestinal metaplasia plus atypia) or malignant diagnosis requiring resection exists.<sup>65</sup> Other authors, however, believe that percutaneous biopsy for preoperative diagnosis rarely produces a definitive diagnosis and the risk of peritoneal dissemination in the case of malignancy is prohibitive.

Neoplastic cysts with no signs of malignancy may be enucleated. This technique requires removal of the entire cyst, the cyst's surrounding wall, and a small rim of liver parenchyma.<sup>57</sup> Formal hepatic resection also is an appropriate treatment. Aspiration, sclerosis, marsupialization, and internal drainage must be avoided. Inadequate excision leads to recurrence in all cases<sup>63</sup> (Table 56-14).

## Cystadenocarcinoma

Devaney and colleagues<sup>66</sup> divided cystadenocarcinoma (Fig. 56-14) into 3 subtypes: (1) cystadenocarcinoma with mesenchymal stroma arising from cystadenoma with mesenchymal stroma, occurring exclusively in females and following a relatively indolent course; (2) cystadenocarcinoma without mesenchymal stroma not associated with cystadenoma, occurring in males and following an extremely aggressive course; and (3) cystadenocarcinoma without mesenchymal stroma, occurring in females and with a poorly understood clinical course.<sup>67</sup> Resection is the only appropriate treatment for malignant biliary cystadenocarcinoma.<sup>57</sup> With complete resection, the clinical course for cystadenocarcinoma is better than that for hepatocellular carcinoma or cholangiocarcinoma,<sup>67</sup> with a reported 65% to 70% 5-year survival after complete resection.

**FIGURE 56-14** CT scan demonstrating a cystadenocarcinoma. CT, computed tomography.

On the contrary, partial excision predisposes to local recurrence and a significantly worse 5-year survival of 36%. Extrahepatic recurrence is rare but may be observed in up to 20% of patients. A recently published multicenter retrospective cohort review reported an overall survival of 8.4 years.<sup>68</sup> Worse survival was associated with the presence of spindle cell/ovarian stroma. The available evidence on the role of other treatment modalities, such as chemotherapy and radiation, is limited to few single-center reports. Definitive chemotherapy and radiation for unresectable disease has previously been reported to confer a 33% 5-year survival. In the rare patient with a symptomatic cystadenocarcinoma with peritoneal metastases, palliative unroofing of the cyst may be indicated.

## **TRAUMATIC CYSTS**

In recent years, the management of hepatic trauma has undergone major changes. The frequent use of dual-phase CT imaging to assess patients with

abdominal trauma has resulted in the detection of even the most minor of liver injuries. In the hemodynamically unstable patient, damage control laparotomy—the control of bleeding and contamination with packing off of the abdomen to postpone definitive treatment—has gained popularity, while formal anatomic hepatic resection has fallen out of favor. More American Association for the Surgery of Trauma grade IV and V liver injuries also are being managed nonoperatively. Mortality rates have fallen to 7% to 12%,<sup>69</sup> but a different set of management problems is being created. One such problem is the traumatic liver cyst.

Traumatic hepatic cysts are acquired cysts that occur from continued bile leakage from an injured intrahepatic bile duct after abdominal trauma. When an injured biliary structure continues to leak into a hematoma cavity, a cyst containing bile and blood may form.<sup>57</sup> These cysts lack a true epithelial lining and are considered pseudocysts (Fig. 56-15). Some traumatic cysts may resolve spontaneously,<sup>61</sup> while others may grow until compressive symptoms develop. Presentation is typically delayed, and abdominal pain or fullness may occur months or sometimes years after the trauma.<sup>57</sup>

B

**FIGURE 56-15** **A.** CT scan demonstrating a traumatic hepatic cyst 4 months after blunt liver trauma. **B.** Ultrasound in the same patient demonstrating a thickened cyst wall. CT, computed tomography.

## Treatment

Treatment is reserved for patients who are symptomatic. Options include aspiration, unroofing, and excision. Bile leaks must be sought and controlled.<sup>61</sup> Small bilomas may be observed, whereas larger collections usually require percutaneous drainage at the time of diagnosis. Once the cavity is collapsed, spontaneous closure of the fistula is the rule.

# BENIGN LIVER NEOPLASMS

*Kevin C. Soares • Timothy M. Pawlik*

Benign liver neoplasms encompass a variety of liver lesions, each with distinct pathologic, radiographic, and molecular characteristics. These include hemangioma, focal nodular hyperplasia, hepatocellular adenoma, and other less commonly seen lesions ([Table 57-1](#)). Benign liver lesions occur in up to 20% of the population and far surpass the incidence of malignant liver lesions. With the increased utilization of cross-sectional imaging, these tumors are being identified more frequently. Benign liver lesions are usually asymptomatic and are generally observed. Surgical intervention is warranted in symptomatic patients, cases where malignancy cannot be excluded, or if there is a potential for malignant transformation or associated complications ([Fig. 57-1](#)). Liver lesions with equivocal imaging characteristics can lead to diagnostic uncertainty resulting in important therapeutic ramifications. As a result, a thorough understanding of benign liver neoplasms is necessary to more accurately and appropriately screen patients for expectant management versus surgical intervention.

# HEMANGIOMA

## Epidemiology and Etiology

Hepatic hemangiomas are the most common benign tumor of the liver, affecting up to 20% of the population.<sup>1,2</sup> Hemangiomas occur predominantly in females (60%-80%) and typically present in the third to fifth decades of life.<sup>3-5</sup> Hemangiomas may be isolated to the liver or associated with systemic syndromes.<sup>6</sup> In nearly 50% of patients, hepatic hemangiomas are multifocal.<sup>7</sup>

The etiology of hepatic hemangiomas is poorly defined. They are thought to arise either as congenital lesions that enlarge due to vascular ectasia or as vascular enlargement from previously normal hepatic vasculature. The blood supply of hepatic hemangiomas is derived from the hepatic artery. Commonly seen characteristics suggest a role of estrogens in their pathogenesis. These include female predominance, increase in size during pregnancy, and change in size while taking oral contraceptive pills (OCPs), as well as association of estrogen replacement therapy with hemangioma recurrence.<sup>8-10</sup> The association of hormones and hemangioma does, however, remains controversial. For example, a case-control study showed no association between liver hemangioma and a history of OCP use.<sup>11</sup> However, Glinkova et al. performed a prospective evaluation of 94 women with 181 hemangiomas and concluded that hormone therapy increased the risk of hemangioma enlargement.<sup>7</sup> Although the association of hormone therapy and hepatic hemangioma pathogenesis remains poorly understood, hepatic hemangioma patients with nonphysiologic exposure to sex hormones warrant serial close observation.

## Pathology

Grossly, cavernous hemangiomas are soft, compressible, blood filled, and well-defined tumors. Hemangiomas can be multifocal and of variable size. Hemangiomas greater than 5 cm in size are typically considered “giant” hemangiomas. Microscopically, hemangiomas consist of a single layer of benign endothelium along vascular channels separated by thin connective tissue. Cystic degeneration, thrombosis, fibrosis, and calcifications may be

present. Estrogen and progesterone receptors are not typically seen.<sup>12</sup>

Hepatic hemangiomas are generally not encapsulated and the liver parenchyma–hemangioma interface varies (Fig. 57-2). Zimmerman and Baer described this variation and its clinical implications.<sup>13</sup> Most commonly, the liver parenchyma–hemangioma interface consists of capsule-like, avascular fibrous lamellae, making hemangiomas more amenable to enucleation. The second pattern, known as the interdigitating interface, has components of the hemangioma projecting into the associated liver parenchyma without fibrous lamellae. A third pattern is characteristic of highly irregular borders without clear delineation of liver parenchyma versus the hemangioma. The fourth and final interface lacks fibrous tissue between the hemangioma and liver parenchyma. In this case, the hemangioma is in direct contact with the liver parenchyma leading to a smooth, regular interface that includes dilated portal vein branches and microhemangiomas. The lack of a fibrous capsule in the latter three patterns complicates attempts at enucleation.

**FIGURE 57-2** High magnification microscopic appearance of hepatic hemangioma with multiple blood-filled vascular channels lined by a single layer of flat epithelium. (Used with permission from Dr. Robert Anders, MD, PhD.)

## Clinical Presentation and Diagnosis

Hepatic hemangiomas are typically asymptomatic and found incidentally during imaging studies obtained for other reasons. Symptomatic hemangiomas occur in 10% to 50% of cases. Not unexpectedly, larger lesions are more likely to produce symptoms.<sup>3,14</sup> Associated symptoms include right upper quadrant pain, general abdominal pain, nausea, and early satiety as a result of compression of adjacent structures. Potential life-threatening complications may include hemorrhage, hemobilia, rupture, and hemangioma-associated heart failure; however, each of these complications is very uncommon. In fact, less than 5% of hemangiomas will present after spontaneous rupture. However, if a patient does present with rupture, disseminated intravascular coagulation, hemodynamic instability, and hypovolemic shock are seen in up to one-third of these cases.<sup>4,15</sup> Spontaneous rupture of a liver hemangioma has an estimated mortality of approximately 35%.<sup>16</sup> Kasabach–Merritt syndrome is a life-threatening complication often triggered by a dental or surgical procedure in patients with giant hemangiomas. It consists of thrombocytopenia and disseminated intravascular coagulopathy, and patients present with acute right upper quadrant pain and bleeding.

Diagnosis of a hepatic hemangioma is typically accomplished via imaging (Table 57-2). On ultrasound, hemangiomas appear as a well-defined, hyperechoic mass (Fig. 57-3A). The echogenicity can vary secondary to internal fibrosis, thrombosis, and necrosis.<sup>2</sup> Unenhanced abdominal computed tomography (CT) depicts a hypodense or isodense lesion within the liver parenchyma, and an unenhanced scan can often miss hemangioma lesions. Multiphasic CT and magnetic resonance imaging (MRI) are highly sensitive and are most useful in differentiating hemangiomas from other hepatic lesions. Early peripheral enhancement that proceeds toward central enhancement is generally diagnostic. MRI has a better sensitivity (91%) and specificity (92%) than CT<sup>2</sup> (Fig. 57-3B-F). MRIs with heavily weighted T2 imaging typically show delayed relaxation times and can reliably differentiate hemangioma from metastatic disease with an accuracy of 97%.<sup>17</sup> Positron emission tomography scans may be helpful in differentiating hemangiomas from metastatic disease given that hemangiomas are not <sup>18</sup>F-fluorodeoxyglucose (FDG)-avid—although this is rarely necessary.

Technetium-99m-labeled red blood cell scans can also be used in instances where CT and MRI are nondiagnostic, although this test is also seldom needed.

**TABLE 57-2: IMAGING CHARACTERISTICS OF HEPATIC HEMANGIOMA, FOCAL NODULAR HYPERPLASIA, AND HEPATIC ADENOMA**

	Ultrasound	CT	MRI	Other
Hepatic hemangioma	Well-defined, hyperechoic	Hypoattenuating on noncontrast CT  Arterial phase shows peripheral, discontinuous enhancement  Portal venous phase shows centripetal filling and hyperattenuating lesion	T1: hypointense, T2: hyperintense with respect to the liver  T1+ Gadolinium: peripheral, discontinuous nodular enhancement with centripetal filling on delayed images  T1 + Eovist: variable appearance	Tagged red blood cell scan with larger lesions can show increased activity on delayed images
FNH	Variable echogenicity and difficult to visualize	Hypo or isoattenuating lesion with hypoattenuating central scar on noncontrast CT  Arterial phase shows hyperattenuating lesion with hypoattenuated central scar  Enhanced on delayed phases in 80% of cases	T1: isointense with hypointense central scar T2: isointense with hyperintense central scar  T1 + Gadolinium: intense arterial phase, isointense to liver on portal venous phase  T1 + Eovist: early arterial enhancement, persists in delayed phases, remaining slightly enhanced on hepatobiliary phase	Technetium 99 m sulfur colloid scan positive (80% of cases)
Hepatic adenoma	Well-defined, typically solitary lesion with variable echogenicity depending on fat and blood content	Well demarcated with variable attenuation depending on blood (hyperattenuating) and fat (hypoattenuating) content	T2: hyperintense  T1+ Gadolinium: early arterial enhancement followed by rapid isointensity to liver on delayed images  T1 + Eovist: hypointense on hepatobiliary phase	

Abbreviations: CT, computed tomography; FNH, focal nodular hyperplasia; MRI, magnetic resonance imaging.

B

C

D

**FIGURE 57-3** Hemangioma in a 42-year-old female. (A) Ultrasound image in the sagittal plane showing a large echogenic lesion (*arrows*), which is a feature of hemangioma. (B) Axial T2-weighted image shows the lesion to be very bright (*arrow*), known as the “light bulb” sign, and compatible with hemangioma. Axial T1-weighted images in the hepatic arterial phase (C), portal venous phase (D), and delayed phase (E) show peripheral nodular enhancement increasing centrally (*arrowheads*), characteristic of hemangioma. (F) Coronal T1-weighted image better demonstrates enhancing nodules (*arrows*) at the periphery of the lesion. (Used with permission from Ihab Kamel MD and Sepideh Besharati MD.)

Invasive diagnostic procedures are unnecessary and are typically contraindicated given the high likelihood of complications. Liver function tests are generally normal except in cases of obstructive jaundice secondary to parenchymal compression or in cases of Kasabach-Merritt syndrome. Biopsy of hepatic hemangioma is highly unreliable and is associated with a high risk of bleeding, and therefore is contraindicated when hepatic hemangioma is suspected.<sup>3</sup>

## Treatment

Hepatic hemangiomas typically remain stable in size, and radiographic changes are unlikely.<sup>18</sup> As a result, observation is warranted in both

asymptomatic and minimally symptomatic patients.<sup>3</sup> Gestational hepatic hemangiomas behave similarly to lesions in nonpregnant patients. Accordingly, asymptomatic lesions may be followed in both pregnant patients and patients taking hormone replacement therapy.

Indications for surgical resection include severely symptomatic lesions, patients with hemangioma-related complications (ie, rupture or Kasabach–Merritt syndrome), and patients with indeterminate liver lesions where malignancy cannot be ruled out. Of note, size is not a criterion for operative intervention. In a retrospective series of 492 patients with giant hemangiomas, long-term outcomes were available in 289 survey responders. Clinical observation resulted in a similar incidence of hemangioma-related complications/symptoms versus operatively managed patients<sup>19</sup> (Table 57-3).

**TABLE 57-3: COMPARISON OF ADVERSE OUTCOMES DURING FOLLOW-UP BETWEEN NONOPERATIVELY AND OPERATIVELY MANAGED HEPATIC HEMANGIOMAS**

Type of Adverse Event <sup>a</sup>	Nonoperative Group (n = 233)		Operative Group (n = 56)		p Value
	n	%	n	%	
Perioperative morbidity	–		8	14	
Persistence of symptoms or complications	26	11	0	0	<0.001
New onset of symptoms or complications	20	9	0	0	0.02
Need for intervention or reoperation	14	6	0	0	0.08
Total patients with adverse events	46	20	8	14	0.45

<sup>a</sup> More than one type of adverse outcomes per patient possible

Operative approaches for hepatic hemangiomas include enucleation and formal anatomic or nonanatomic liver resection. Hemangioma enucleation is associated with reduced loss of functional hepatic parenchyma, less perioperative blood loss, and fewer complications compared with formal liver resection.<sup>3,20</sup> As a result, enucleation is the most commonly employed surgical technique. Peripheral lesions are particularly amenable to this approach. Enucleation typically begins with control of hepatic artery inflow via a Pringle maneuver. The ipsilateral hepatic artery is identified. For larger lesions, ligation of the ipsilateral hepatic artery may be necessary, whereas in smaller hemangiomas, hepatic artery inflow can be controlled with ligation of more distal branches. Division of hepatic parenchyma is then performed via gross identification of the hemangioma to normal parenchyma border. Control of bile ducts and small blood vessels is obtained while transecting through the compressed sheath of liver tissue representing the hemangioma–normal liver parenchyma interface.

## **Prognosis**

Follow-up imaging as suggested by Mezhir et al. is recommended.<sup>21</sup> This consists of follow-up MRI 3 months after diagnosis along with a repeat MRI in 3 to 6 months for atypical lesions with low suspicion for malignancy. More infrequent follow-up is appropriate once the diagnosis and stability of the lesion have been documented. Recurrence is rare after definitive treatment. These instances are commonly associated with estrogen therapy.<sup>9</sup> As noted above, hemangiomas in pregnant patients or patients receiving exogenous estrogen may have a higher likelihood to increase in size.<sup>7</sup> As a result, these patients warrant careful observation.<sup>7,22</sup>

## **FOCAL NODULAR HYPERPLASIA**

### **Epidemiology and Etiology**

Focal nodular hyperplasia (FNH) is the second most common benign solid liver tumor. Its prevalence is estimated to be between 0.3% to 3% based on autopsy analysis.<sup>23</sup> FNH occurs predominantly in females (8:1 female-to-

male ratio). The average age of presentation is 35 years old. FNH tumors are composed of a cluster of benign-appearing hepatocytes within the background of normal-appearing hepatic parenchyma.<sup>24</sup>

FNH is thought to arise from a vascular malformation or a vascular injury and subsequent expansion of proliferative hepatocytes.<sup>25</sup> Its association with vascular abnormalities is further supported by studies demonstrating a higher prevalence of FNH in families with hereditary hemorrhage telangiectasia.<sup>26</sup> Furthermore, in a series of 148 patients with FNH, 20% of patients had concomitant hepatic hemangiomas.<sup>27</sup> An association with dysregulation of angiopoietin genes *ANGPT1* and *ANGPT2* has also been suggested.<sup>28</sup>

FNH and its association with oral contraceptives remains controversial. Approximately 50% to 75% of patients with FNH report a history of oral contraceptive use. Moreover, estrogen receptor expression within FNH specimens has been reported.<sup>29,30</sup> However, other studies indicate that there is no direct association between FNH and oral contraceptives or sex hormones.<sup>31-33</sup> For example, in their analysis of 216 patients, Mathieu and colleagues concluded that neither the size nor the number of FNH lesions was influenced by OCP use.<sup>31</sup> Size changes during follow-up were rare and were not associated with OCP use.

## Pathology

FNH lesions are benign lesions without malignant potential. They grossly appear as brown or tan nodules composed of proliferative, polyclonal hepatocytes and lack the presence of a true capsule<sup>24</sup> (Fig. 57-4A). Approximately 80% of patients present with solitary lesions that are variable in size (1 mm-20 cm).<sup>25,34</sup> A central scar (80%) and bile duct proliferation (100%) are characteristics of FNH lesions<sup>34</sup> (Fig. 57-4B,C).

A

B

**FIGURE 57-4 (A)** Surgical specimen of focal nodular hyperplasia showing a globular, lobulated mass with a prominent central scar. Microscopic appearance of focal nodular hyperplasia at high magnification showing **(B)** hepatocytes with a central fibrous septum and proliferating bile ductules at the interface between the hepatocytes and fibrous tissue. (Used with permission from Dr. Robert Anders, MD, PhD.)

Focal nodular hyperplasia falls into one of two categories: typical or atypical. Typical or classic FNHs comprise 80% of all FNH cases and contain all of the classic features: lesion with normal appearing hepatocytes, proliferative bile ducts, and a central scar containing abnormal arteries but limited portal veins. Atypical FNH lacks at least one of these classic features. Atypical FNH lesions are further classified into three categories: telangiectatic, FNH with cytological atypia, and mixed hyperplastic or adenomatous FNH. More recently, telangiectatic FNH has been reclassified as a hepatic adenoma subtype as a result of molecular analysis; surgical resection is warranted in the case of telangiectatic FNH/hepatic adenoma.<sup>28</sup>

Microscopically, nodular hyperplastic parenchyma is characteristic. Although hepatocytes are normal in appearance, the surrounding hepatic parenchyma is distorted and portal triads are sometimes lacking. Unlike hepatic adenoma, Kupffer cells and sinusoids are also present. Overall, FNH appears as a hyperplastic process containing components of normal liver but in a disorganized fashion.<sup>2</sup>

## Clinical Presentation and Diagnosis

FNH is typically discovered incidentally in young females of reproductive age. Approximately 80% of FNH lesions are asymptomatic, and abnormal liver functions tests are rare (12%-13%).<sup>26</sup> Definitive diagnosis is essential to avoid unwarranted interventions, and this can typically be accomplished through multimodality imaging. On ultrasound, FNH is isoechoic to the liver and can be difficult to identify. Noncontrast CT shows an isointense lesion within the liver background. Contrast-enhanced imaging is generally diagnostic. FNH enhances on arterial phase CT, but unlike hemangioma, there is no centripetal progression. Moreover, the central scar is visualized as hypointense with respect to the rest of the lesion and the normal liver.

Dedicated liver protocol MRI is highly sensitive (70%) and specific (98%) for FNH. FNH is iso/hypointense to normal liver on T1 weighted imaging, including the central scar (Fig. 57-5). These lesions are iso/hypointense on T2 weighted imaging; however, the central scar in this case will be hyperintense. The addition of gadolinium contrast to MRI produces a similar pattern to contrast-enhanced CT, where there is a global, rapid enhancement of the lesion with respect to the rest of the liver. The introduction of gadolinium-based hepatobiliary-excreted contrast agents such as Eovist and Gd-EOB-DTOPA has significantly improved the ability to radiographically diagnose FNH.<sup>35</sup> These are particularly helpful in differentiating FNH from hepatic adenoma given that adenomas will not have any contrast uptake on delayed phases.<sup>36</sup> In a recent systematic review and meta-analysis, high/isointensity signal intensity on hepatobiliary imaging was highly accurate in distinguishing FNH from hepatic adenomas with a reported sensitivity of 93.9% and specificity of 95.3%<sup>37</sup> (Fig. 57-5E).

A

B

C

D

**E**

**FIGURE 57-5** Focal nodular hyperplasia in a 48-year-old male. Axial unenhanced T1-weighted (**A**) and T2-weighted (**B**) images show subtle isointense lesion (*arrow*) in the right lobe. T1-weighted image in the hepatic arterial phase shows homogeneous enhancement of the mass (**C**) which becomes isointense to the liver parenchyma in the portal venous phase (**D**). (**E**) Delayed (10-minute) phase of enhancement using a hepatobiliary contrast agent demonstrates increased uptake within the lesion (*arrow*). These findings are consistent with focal nodular hyperplasia. (Used with permission from Ihab Kamel MD and Sepideh Besharati MD.)

Technetium-99m sulfur colloid scintigraphy depicts Kupffer cell activity and therefore can be used in cases of suspected FNH. Eighty percent of these lesions demonstrate uptake of the sulfur colloid.<sup>2</sup> This scan can be helpful in distinguishing FNH from other liver lesions such as hepatic adenomas,

hepatocellular carcinoma (HCC), and hepatic metastases, which typically contain minimal to no Kupffer cells. The sensitivity and specificity of MRI, however, has led to a dramatic decrease in the need for technetium-99m scans.

In cases of imaging discrepancy or uncertainty, biopsy prior to definitive therapy is appropriate. Biopsy should be done, however, only after appropriate imaging modalities have been performed, particularly MRI with gadolinium-based hepatobiliary-excreted lesions, which reduce unnecessary interventions.<sup>37</sup>

## Treatment

FNH is benign and not premalignant. The natural history of these lesions is one of limited to no growth, and FNH lesions rarely cause symptoms. Therefore, operative intervention for FNH is seldom required. The standard therapy of FNH is observation. For patients taking OCPs, cessation of OCPs remains a warranted recommendation.<sup>29,38</sup> Surgical resection is indicated when there is an inability to rule out malignancy or in the rare instances of rapid growth (particularly with increasing symptoms).<sup>39-41</sup> When necessary, surgery generally involves enucleation, as it is associated with fewer complications than a formal liver resection and preserves normal hepatic parenchyma. Liver resection is appropriate when enucleation is unsafe or in instances where malignancy cannot be excluded. The authors prefer nonanatomic liver resections for FNH given the indolent nature of these lesions and the desire to preserve as much normal hepatic parenchyma as possible. In addition, minimally invasive approaches deserve consideration.<sup>42</sup>

## Prognosis and Follow-Up

As noted above, FNH rarely causes symptoms and the likelihood of complications is low. As a result, serial observation is safe and is warranted for most cases.<sup>21</sup> There are a lack of data describing the appropriate timeline for follow-up. We have adopted the approach described by Mezhir et al. that consists of follow-up MRI 3 months after diagnosis along with a repeat MRI in 3 to 6 months for atypical lesions with low suspicion of malignancy.<sup>21</sup>

# HEPATOCELLULAR ADENOMA

## Epidemiology and Etiology

Similar to FNH, hepatic adenomas occur predominantly in young females, with a female-to-male ratio of 11:1.<sup>1</sup> Although their etiology is poorly understood, the association with oral contraceptives is well established. The overall incidence of hepatic adenomas is approximately 1/1,000,000 in the general population; however, the incidence can range from 0.1 to 4 per 100,000 among users of OCPs.<sup>1,43</sup> The duration of OCP use directly correlates with the risk of developing hepatic adenomas. Moreover, OCP users are more likely to present with larger tumors and incur adenoma-associated complications.<sup>44</sup>

In addition to OCPs, hepatic adenomas are associated with androgenic steroid use, glycogen storage diseases, familial diabetes mellitus, and galactosemia.<sup>45,46</sup> Recent data have noted the higher incidence of multifocal adenoma disease, adenomas in men, and non-OCP associated adenomas in females.<sup>47</sup> Furthermore, the increased utilization of cross-sectional imaging has led to a higher incidence of incidentally discovered hepatic adenomas.<sup>47</sup>

Malignant transformation is rare and adenomas often regress with discontinuation of the stimulus (ie, OCPs). The understanding of hepatic adenoma etiology and its malignant risk has been strengthened by the pathomolecular classification of these lesions introduced in 2006. Based on this classification, hepatic adenomas are broken down into four subtypes: hepatocyte nuclear factor-1- $\alpha$  (HNF1- $\alpha$ ),  $\beta$ -catenin-mutated hepatic adenomas, inflammatory (telangiectatic), and unclassified.<sup>48-50</sup> This classification separates these lesions into subtypes with specific imaging characteristics, natural history, and clinical behavior such as higher malignant potential (ie,  $\beta$ -catenin-mutated subtype).

## Pathology

Hepatic adenomas are well-circumscribed tumors of epithelial origin. Although they lack a true capsule, adenomas are soft, light-colored lesions with identifiable borders against the normal parenchyma (Fig. 57-6A).

Hepatic adenomas are generally solitary (75%), although multiple adenomas are commonly seen with glycogen storage disease or hepatic adenomatosis. Hepatic adenomatosis is defined as multiple adenomas, typically greater than 10 adenomas, and is associated with a germline mutation of HNF1- $\alpha$ .<sup>51</sup> Adenomas can range in size from 1 to 20 cm. Patients with OCP-related adenomas typically have a single large adenoma, while those with glycogen storage disease have numerous, small, poorly circumscribed adenomas dispersed throughout the liver.

A

B

**FIGURE 57-6** (A) Gross sectioned pathological specimen of a resected hepatic adenoma represented as single tan globular mass which bulges from the cut surface and is well demarcated from the surrounding liver. (B) Light microscopy view of hepatic adenoma with cords of uniform hepatocytes without an acinar architecture. (Used with permission from Dr. Robert Anders, MD, PhD.)

Microscopically, hepatic adenomas appear similar to normal liver parenchyma. Hepatic adenomas consist of benign-appearing hepatocytes organized into sheets or cords (Fig. 57-6B). Characteristic features that can facilitate differentiation from normal parenchyma include an absence of portal tracts, minimal central veins, and hepatocytes with large amounts of glycogen and lipid. In addition, the absence of bile ducts in adenomas differentiates these lesions from FNH. Given the prognostic implications of the  $\beta$ -catenin-mutated subtype, glutamine synthase staining is now recommended.

Malignancy in:	1993-1995	1997-2000	2001-2004	2005-2008
Single HCA male	1	0	5	10
Single HCA female	0	2	1	1
Multiple HCA female	1	1	0	1

**FIGURE 57-7** Hepatic adenoma incidence and malignancy risk by gender over time. Evolution of the numbers of female and male patients with benign and malignant hepatocellular adenoma divided into several time intervals. Numbers in the table refer to patients with malignancy occurring in single and multiple hepatocellular adenomas. (Reproduced with permission from Farges O, Ferreira N, Dokmak S, et al: Changing trends in malignant transformation of hepatocellular adenoma, *Gut* 2011 Jan;60(1):85-89.)

## Clinical Presentation and Diagnosis

The majority of hepatic adenoma patients present after an incidental finding on imaging or for other reasons such as nonspecific abdominal discomfort. Hepatic adenoma is generally a solitary lesion in the setting of normal liver function tests and no elevation in  $\alpha$ -fetoprotein levels. Symptomatic adenomas can be due to large lesions that stretch the capsule of the liver or present in the setting of rupture with acute abdominal pain or hemodynamic instability.<sup>52</sup> In cases of hepatic adenomatosis, approximately 40% of patients

present with acute abdominal pain, and the bleeding rate is nearly 50%.<sup>53</sup> The risk of hepatic adenoma rupture is associated with lesion size greater than 5 to 7 cm and is typically higher among patients taking OCPs.<sup>54,55</sup> Risk factors for bleeding include exophytic growth, adenomas greater than 4 to 5 cm in size, peripheral liver location, and visualization of lesion-associated arteries.<sup>56</sup>

Approximately 5% to 10% of all hepatic adenomas will progress to hepatocellular cancer.<sup>57,58</sup> Risk factors associated with malignant risk include male sex, steroid use, size greater than 5 cm, glycogen storage disease, history of steroid intake, and hepatic adenoma molecular classification<sup>59,60</sup> (Fig. 57-7).  $\beta$ -catenin-mutated adenomas have the highest risk of developing into HCC.<sup>57</sup> Inflammatory hepatic adenomas have only a 10% malignancy risk, while HNF1- $\alpha$  subtypes have a negligible risk. The association of adenoma subtype and bleeding risk remains controversial. Despite earlier studies reporting a higher risk of bleeding in inflammatory subtypes, a recent systematic review by Van Aalten et al. found no difference in the bleeding or rupture risk among the adenoma subgroups.<sup>61</sup>

Adenomas are commonly first identified via ultrasound for right upper quadrant pain. The lesion typically appears as hyperechoic given the high lipid content. Intratumoral hemorrhage results in increased echogenicity, and Doppler view can demonstrate active hemorrhage or intralesional vessels. On noncontrast CT, hepatic adenomas are isoattenuating. Increased fat content or intratumoral hemorrhage leads to hypo- or hyperattenuation, respectively. Contrast-enhanced CT demonstrates a well-demarcated lesion on the arterial phase. This enhancement is short-lived and serves to differentiate these lesions from FNH, which typically have delayed washout.

The best imaging modality to diagnose hepatic adenomas is MRI (Fig. 57-8). In general, adenomas may be hyper- or hypoattenuated depending on the blood and/or fat content, respectively. Gadolinium-enhanced MRI demonstrates arterial enhancement with immediate washout and isointensity of the liver on the portal phase. Although their appearance can be variable and nonspecific, some adenoma subtypes have specific MRI characteristics. Inflammatory hepatic adenoma lesions are diffusely hyperintense on T2 images while gadolinium-enhanced T1 images show intense enhancement in the arterial phase and persistent enhancement in the delayed phase. HNF1- $\alpha$ -mutated hepatic adenoma, on the other hand, lack the persistent enhancement

on the delayed phase.  $\beta$ -catenin-mutated hepatic adenoma does not have a specific MRI pattern.

**FIGURE 57-8** Hepatocellular adenoma in a 43-year-old female with history of adenomatosis. Axial T-1 weighted-in phase image of the liver (**A**) shows a mass that is slightly hyperintense (*arrow*) with significant signal loss on the out of phase image (**B**). These findings are consistent with a lipid-containing lesion. T1-weighted MR image in the hepatic arterial phase (**C**) shows a hypervascular mass that washes out in the portal venous phase (**D**). These

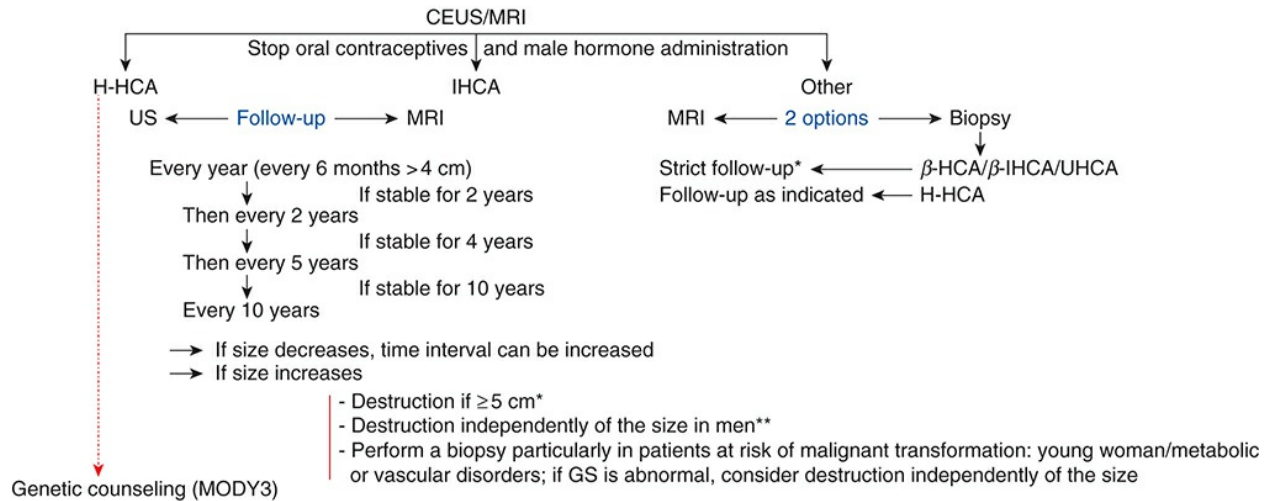

findings are suspicious for hepatocellular adenoma in this patient with pathologically proven adenomatosis. (Used with permission from Ihab Kamel MD and Sepideh Besharati MD.)

In cases of uncertainty after diagnostic imaging, biopsy is warranted. Both fine needle aspiration and core needle biopsy are appropriate. Core needle biopsy remains, however, the gold standard for the diagnosis of hepatic adenoma subtype.<sup>62</sup> The combination of MRI and biopsy is highly reliable in identifying adenoma subtype.<sup>63</sup>

## Treatment

The propensity for malignant transformation and hemorrhage make many hepatic adenomas a surgical disease. Surgical resection is offered to patients with symptoms, as well as those patients deemed to be at risk for bleeding or malignant transformation. These risk factors include lesions greater than 5 cm in size, history of bleeding, imaging characteristics concerning for hepatocellular cancer, and  $\beta$ -catenin-mutated subtype. The number of lesions does not dictate therapeutic interventions. Surgical resection consists of complete resection with negative margins. Wide resection margins and lymphadenectomy are not indicated. Acceptable approaches include enucleation, nonanatomic liver resection, and formal liver resection. When feasible, a laparoscopic approach is safe and appropriate. In patients presenting with acute hemorrhage, aggressive resuscitation and interventional radiology-guided selective hepatic artery embolization is the standard of care as initial therapy. Elective surgical resection should then be offered once the patient is stabilized and the hematoma has regressed, which is generally 6 weeks later. Radiofrequency ablation is indicated in unresectable patients with centrally located adenomas or those with severe underlying liver disease.

Careful observation and cessation of OCPs is warranted in women taking OCPs with hepatic adenomas less than 5 cm in size (Fig. 57-9).<sup>64,65</sup> Although some groups have reported adenoma regression with cessation of OCPs, regression does not eliminate the risk of malignant transformation or hemorrhage.<sup>66</sup> Therefore, reimaging should be performed within 6 to 12 months, and close observation is necessary.

Patients overweight/obese/with metabolic syndrome (the majority with IHCA) should be followed

In presence of multiple HCA nodules: generally all nodules are of the same subtype (i.e., H-HCA, IHCA). Among IHCA some may be  $\beta$ -catenin mutated, others not. Association of H-HCA and IHCA has been rarely observed in a same liver. In glycogenosis, different types of nodules may exist ( $\beta$ -HCA, IHCA,  $\beta$ -IHCA, and UHCA). The destruction (resection, radio frequency) of nodules depends on the size, on the presence of  $\beta$ -catenin mutation, and on the disease background. OLT is exceptional and should not be considered just on the number criteria.

\*Destruction should be considered for nodules <5 cm (in the 3–4 cm range)

\*\*In men, destruction is planned well before the size of the nodule reached 5 cm

**FIGURE 57-9** Management of hepatic adenomas less than 5 cm. (Adapted with permission from Balabaud C, Al-Rabih WR, Chen PJ, et al: Focal Nodular Hyperplasia and Hepatocellular Adenoma around the World Viewed through the Scope of the Immunopathological Classification, *Int J Hepatol* 2013;2013:268625.)

The management of liver adenomatosis is primarily conservative. Close follow-up with either CT or MRI imaging and  $\alpha$ -fetoprotein levels is indicated. Surgical resection should be reserved for nodules greater than 5 cm, large severely symptomatic nodules, or when malignancy cannot be excluded.<sup>53</sup> In rare cases of large unresectable hepatic adenomas, liver transplantation may be indicated.

## Prognosis and Follow-Up

Surgical resection can be performed safely and outcomes are excellent. Optimal surveillance and follow-up of hepatic adenomas remains controversial. For all adenomas, subtype classification should be attempted. Balabaud and colleagues have proposed a comprehensive algorithm for nodules less than 5 cm which addresses imaging, follow-up, and appropriate indications for resection.<sup>65</sup>

## MISCELLANEOUS BENIGN SOLID TUMORS

### **Nodular Regenerative Hyperplasia**

Nodular regenerative hyperplasia (NRH) is a rare condition consisting of diffusely distributed hyperplastic hepatocyte lesions. NRH lesions are often associated with portal hypertension; however, these tumors lack a fibrous rim, thus differentiating them from liver cirrhosis.<sup>67</sup> These lesions have no malignant potential and tumor growth is rare. NRH is typically multifocal and diffuse, which helps differentiate this lesion from hepatic adenomas, which are generally solitary lesions. With regard to FNH, NRH is similar in radiographic appearance; however, on portal venous phase CT scan, NRH typically has complete contrast washout, unlike FNH. Nonoperative management of NRH is indicated. In cases of diagnostic uncertainty, a tissue biopsy is warranted.

### **Bile Duct Adenoma**

Bile duct adenomas are well-demarcated benign subcapsular lesions. Histologically, bile duct adenomas are lined by irregularly arranged cuboidal epithelium and mixed with variable amounts of stroma and inflammatory cells.<sup>68,69</sup> Bile duct adenomas typically measure between 0.5 and 1 cm and are grossly well delineated with a gray-white appearance.<sup>67</sup> These lesions are classically encountered incidentally, either radiologically, during exploration of the abdomen at the time of surgery for an unrelated reason, or at autopsy. Bile duct adenomas are considered proliferative/reactive lesions rather than neoplastic.<sup>68,69</sup> Operative resection is seldom required and expectant management is justified.

### **Hepatic Hamartomas**

Hepatic hamartomas are rare liver tumors of infancy, typically discovered before 2 years of age. Hepatic hamartomas comprise 8% of all pediatric tumors and consist of irregularly arranged and dysmorphic bile ducts mixed with myxomatous mesenchyme.<sup>70</sup> Continued tumor growth results in

compression of adjacent structures that can lead to significant complications such as biliary obstruction, portal hypertension, and death. Although some hepatic hamartomas may involute spontaneously, malignant transformation is possible. Complete resection or enucleation is the standard of care. Fenestration or marsupialization is contraindicated given the propensity for local recurrence and malignant potential. Close observation may be warranted in specialized cases, particularly in patients whose hamartomas contain a dominant vascular component.<sup>71</sup>

## **Peliosis Hepatis**

Peliosis hepatis consists of multiple blood-filled sacs within the hepatic parenchyma. Peliosis hepatis lacks an epithelial lining, and recanalization and fibrosis are common.<sup>67</sup> It occurs in immunocompromised patients, including patients taking anabolic steroids, AIDS patients, and transplant recipients.<sup>72,73</sup> Tumor rupture and massive intraabdominal hemorrhage have rarely been reported.<sup>74</sup> In these instances, angioembolization is the preferred treatment modality. Surgical resection is rarely indicated, and optimal management consists of minimizing identifiable etiologies, ie, steroid therapy.

## **CONCLUSION**

With increasing utilization of cross-sectional imaging, benign liver lesions are increasingly encountered. As a result, it is imperative that clinicians gain an understanding of these lesions in order to appropriately manage these patients. The natural history and etiology of these lesions remains poorly defined; however, improved imaging technologies and renewed research interests have contributed significantly to our understanding of these lesions. For example, recent studies describing molecular pathogenesis have directly impacted diagnostic and management protocols, ie, hepatic adenoma subtype classification. Although management of most benign liver lesions typically consists of observation, certain lesions or characteristics are more prone to malignant transformation and/or complications and therefore warrant surgical resection. Future research should continue to elucidate the natural history of these lesions to better understand appropriate therapies and surveillance in

order to optimize patient outcomes.

## ACKNOWLEDGMENTS

The authors wish to thank Drs. Ihab Kamel, Robert Anders, and Sepideh Bessharati for their invaluable contributions to this chapter.

# MALIGNANT LIVER NEOPLASMS

*Sameer H. Patel • Guillaume Passot • Jean-Nicolas Vauthey*

## INTRODUCTION

In 2018, primary liver tumors will be diagnosed in approximately 42,220 new patients in the United States, and approximately 30,200 individuals will die from this disease.<sup>1</sup> Worldwide, primary liver tumors remain the second leading cause of death from cancer in males and the sixth leading cause of death from cancer in females.<sup>2</sup> Malignant lesions can arise from any of the various cell types that comprise the organ, which include hepatocytes, endothelial cells, and the cells of the intrahepatic bile ducts. The 2 most common hepatic neoplasms are hepatocellular carcinoma (HCC), which accounts for more than 75% of primary liver tumors, and intrahepatic cholangiocarcinoma (ICC), which accounts for 10% to 15%. The remaining primary hepatic neoplasms are hepatic angiosarcoma, epithelioid hemangioendothelioma, and hepatic lymphoma. The focus of this chapter will be on HCC and ICC.

In patients with primary hepatic malignancies, the malignancy itself and any underlying liver disease must be considered as 2 separate but

interconnected pathologic processes. The extent of abnormalities associated with each pathologic process directly affects the clinical impact and treatment options.

## HEPATOCELLULAR CARCINOMA

### Epidemiology

The incidence of HCC is greatest in areas where exposure to factors that cause chronic HCC injury is heaviest. The incidence of HCC is greatest in sub-Saharan Africa and East Asia, where the incidence is more than 20 cases per 100,000 individuals per year.<sup>2</sup> In the United States, the overall incidence of HCC is 6 cases per 100,000 individuals per year; the incidence is highest among Asian, African American, and Hispanic individuals.<sup>3</sup> Globally, males have up to 5.7 times the HCC incidence observed in females.<sup>2</sup>

### Risk Factors

There are several risk factors for development of HCC, many of them related to the development of chronic hepatocellular injury (Table 58-1). Some risk factors are independent, while others have potentiating effects. The risk factors most commonly observed in individuals with HCC are the hepatitis viruses: worldwide, 75% to 80% of primary liver tumors are associated with persistent liver infections, particularly hepatitis B (seen in 50%-55% of patients with HCC) or hepatitis C (25%-30%).<sup>4</sup> The degree of liver change that results from hepatitis before development of HCC differs between hepatitis B and C. Among patients with hepatitis B, 20% of HCC cases develop before cirrhosis develops, whereas among patients with hepatitis C, HCC almost always arises in the background of significant cirrhosis and fibrosis. The mechanism proposed to explain this difference is that hepatitis B virus directly modulates oncogenes, whereas hepatitis C virus-induced HCC is related to the degree of inflammation.<sup>5</sup>

TABLE 58-1: RISK FACTORS FOR DEVELOPMENT OF HEPATOCELLULAR

**CARCINOMA AND INTRAHEPATIC CHOLANGIOCARCINOMA (LISTED FROM GREATEST TO SMALLEST)**

<b>Hepatocellular Carcinoma</b>	<b>Intrahepatic Cholangiocarcinoma</b>
Hepatitis B	Primary sclerosing cholangitis
Hepatitis C	Cholelithiasis or hepatolithiasis
Alcohol consumption	Cholecystitis
Smoking	Choledochal cysts/Caroli disease
Aflatoxin exposure	Thorotrast contrast agent exposure
Vinyl chloride exposure	Hepatitis B
Oral contraceptive pill use	Hepatitis C
Diabetes	Diabetes
Nonalcoholic fatty liver disease (nonalcoholic steatohepatitis)	HIV infection
Hereditary hemochromatosis	<i>Opisthorchis sinensis</i> infection
$\alpha_1$ -Antitrypsin deficiency	<i>Opisthorchis viverrini</i> infection
Wilson disease	Lynch syndrome

Today, with vaccination against hepatitis B and better detection of hepatitis B and C, approximately 60% of patients with HCC are not infected with hepatitis virus. Other risk factors for HCC include environmental exposures, chronic disease processes, and genetic conditions that predispose patients to development of cirrhosis and/or chronic liver inflammation.

Alcohol consumption is a major risk factor for the development of HCC. Metabolism of alcohol occurs through oxidative processes, resulting in lipogenesis and fatty liver development that can progress to cirrhosis.<sup>6</sup> Additionally, reactive oxygen species are created in hepatocytes during alcohol metabolism and can lead to further liver damage.<sup>6</sup> The degree of alcohol-induced liver damage and related risk of HCC development are dose dependent. Studies have found that exposure to 60 g of alcohol per day for more than 25 years increases the risk of HCC by almost 6 times (odds ratio [OR], 5.7; 95% confidence interval [CI], 2.4-13.7).<sup>7</sup>

Aflatoxin is a hepatic carcinogen produced by *Aspergillus flavus* and *Aspergillus parasiticus* that contaminates foods stored in warm and damp environments, such as corn, soybeans, and peanuts. The mycotoxin is thought to act by creating mutations in the *TP53* gene.<sup>8</sup> Regions of the world where

aflatoxin exposure is highest coincide with regions of high hepatitis B prevalence, and the effects are potentiative. A study has found that individuals in Shanghai with concomitant hepatitis and aflatoxin exposure had 59.4 times the risk of developing HCC of the normal population. Hepatitis B alone was associated with only a seven-fold increase in risk, whereas aflatoxin exposure alone was associated with a four-fold increase in risk.<sup>9</sup>

Higher body mass index (BMI) has been associated with increased death rates from multiple malignances, including esophagus, colorectal, pancreas, and liver cancers. Women with a BMI of 35 to 40 kg/m<sup>2</sup> had almost twice the mortality rate from liver cancer of women with a lower BMI, and men with a BMI of 35 to 40 kg/m<sup>2</sup> had almost 5 times the liver cancer mortality rate of men with a lower BMI.<sup>10</sup> Obesity can lead to the development of chronic liver changes, such as steatosis and steatohepatitis.<sup>11</sup> Obesity in the United States affects over 1 in 3 adults.<sup>10</sup>

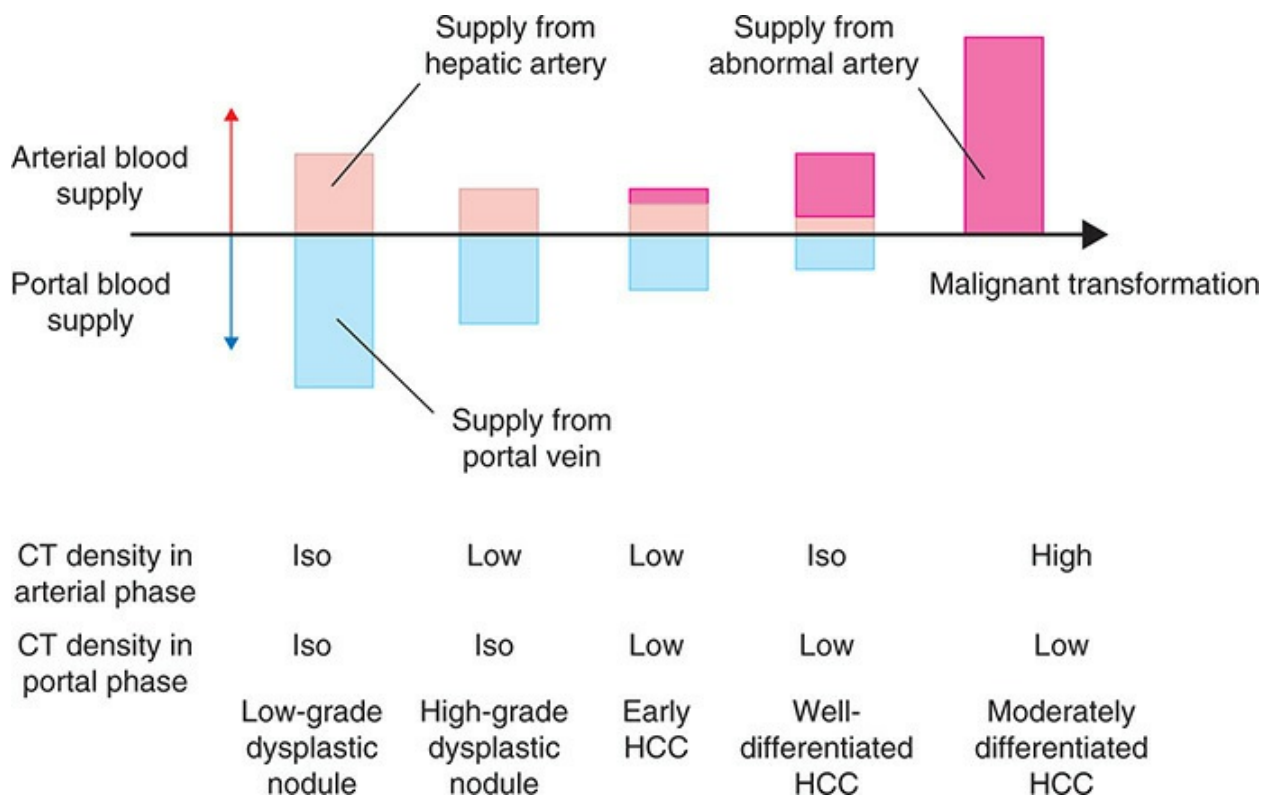

## Protective Factors

Statin use has been found to protect against the development of HCC. A meta-analysis of 10 studies with 1.46 million patients found that statin use was associated with an adjusted OR of 0.63 (95% CI, 0.52-0.76).<sup>12</sup> Despite the heterogeneity of the studies analyzed in this meta-analysis, this protective affect was seen not only in Asian but also in Western populations. Statins are thought to inactivate pro-growth pathways and activate apoptotic pathways through hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase-dependent and -independent pathways.<sup>12</sup>

Prevention of HCC is based on reduced exposure to the risk factors such as environmental exposures and hepatitis viruses. Vaccination against hepatitis B has reduced HCC rates in high-risk countries such as Taiwan.<sup>13</sup> In patients with hepatitis B or C, close surveillance and treatment to prevent development of cirrhosis are of paramount importance and have been shown to improve outcomes associated with HCC.<sup>14</sup>

## Pathology

HCC is thought to develop in a multistep progression from normal hepatocytes to malignancy (Fig. 58-1) through alterations in various molecular pathways. A consensus on the nomenclature for precancerous lesions and early HCC has been developed to standardized pathologic assessment of specimens.<sup>15</sup> Dysplastic nodules are defined as nodular lesions larger than 5 mm. These are divided into low-grade and high-grade dysplastic nodules. Low-grade nodules have no cytologic atypia and often have a peripheral fibrous scar. High-grade nodules have architectural and/or cytologic atypia, increased cell density, and an irregular trabecular pattern.<sup>15</sup> These lesions precede the development of HCC.

**FIGURE 58-1** Vascular and radiographic findings associated with progression from precancerous lesions to hepatocellular carcinoma (HCC). CT, computed tomography; Iso, isodense. (Used with permission from J. Shindoh, MD, Toranomon Hospital, Tokyo, Japan.)

Early HCCs are larger than dysplastic nodules and characterized by 5 parameters: (1) cell density more than twice that of the surrounding tissue, with an increased nuclear/cytoplasm ratio and irregular thin-trabecular pattern; (2) portal tracts within the nodule (intratumoral portal tracts); (3) a

pseudoglandular pattern; (4) diffuse fatty changes; and (5) unpaired arteries within the nodule.<sup>15</sup> Despite these defining criteria, differentiation between high-grade dysplastic nodules and early HCC is challenging. One of the key distinguishing findings is the presence of stromal invasion in HCC.<sup>15</sup>

## Gross Features

HCC can exhibit any of several growth patterns and was eloquently categorized by Eggle in 1901 into 3 separate types.<sup>16,17</sup> The *nodular* type is characterized by well-circumscribed nodules and the absence of extranodal extension or multinodularity and has the lowest frequency of spread.<sup>17</sup> Large HCCs that occupy the majority of the liver parenchyma are defined as *massive* and are often seen in livers that do not have cirrhosis (Fig. 58-2). Massive HCCs have a higher propensity for lymph node and intrahepatic metastases than nodular HCCs.<sup>17</sup> Finally, *diffuse* HCCs are characterized by multiple small lesions covering the liver and are almost always associated with hematogenous extrahepatic metastases.<sup>17</sup> Additional poor prognostic features often seen in patients with HCC are invasion of the portal and hepatic vein or bile duct.<sup>18,19</sup>

**FIGURE 58-2** Gross pathologic specimen of a massive hepatocellular carcinoma. (Used with permission from J. Shindoh, MD, Toranomon Hospital, Tokyo, Japan.)

## **Fibrolamellar HCC**

Fibrolamellar carcinoma is a distinctive variant of HCC, accounting for less than 5% of all HCC cases. Unlike traditional HCCs, fibrolamellar carcinomas are seen in younger patients, affect males and females equally, and are not associated with chronic liver inflammation such as hepatitis or cirrhosis.<sup>20</sup> Fibrolamellar carcinomas are slow growing, present with abdominal pain or an abdominal mass, are often resectable, and consequently have a better prognosis; the 5-year overall survival after resection is 76%.<sup>21</sup>

## **Combined HCC and Cholangiocarcinoma**

Combined HCC and cholangiocarcinoma is a type of liver tumor that contains elements of both HCC and cholangiocarcinoma and accounts for less than 1% of all primary liver tumors. The pathogenesis is malignant transformation of hepatic progenitor cells with dual differentiation leading to formation of a lesion capable of bile production, trabecular growth, glandular structures, and intracellular mucin production.<sup>22,23</sup> Five-year overall and disease-specific survival rates for patients with combined HCC and cholangiocarcinoma fall in between those for patients with HCC and those for patients with cholangiocarcinoma.<sup>24</sup>

## **Clinical Presentation and Diagnosis**

Unlike other malignancies, HCC often presents incidentally as patients are being followed for underlying liver disease or when there is enough tumor progression to cause a mass effect. Direct obstruction of the bile ducts can lead to obstructive jaundice; compression of the liver capsule can cause right upper quadrant pain; and bleeding from the tumor can cause anemia if the bleeding is minimal or severe hemorrhagic shock if the bleeding is major. Additional generalized constitutional symptoms of HCC include anorexia, weight loss, and malaise. In patients with cirrhosis in whom HCC is discovered incidentally, general physical examination findings caused by portal hypertension include ascites, jaundice, varices, and splenomegaly. Other, rarer presentations include development of fevers secondary to tumor necrosis and paraneoplastic syndromes such as hypoglycemia,

hypercalcemia, hypercholesterolemia, watery diarrhea, erythrocytosis, and cutaneous manifestations, which are present in multiple gastrointestinal malignancies but not necessarily specific for HCC (Table 58-2).<sup>25-28</sup>

**TABLE 58-2: PARANEOPLASTIC SYNDROMES ASSOCIATED WITH HEPATOCELLULAR CARCINOMA<sup>25-28</sup>**

Clinical Manifestation	Underlying Mechanism
Hypoglycemia	Increased metabolic activity Insulin-like growth factor II secretion
Hypercalcemia	Parathyroid hormone–related protein secretion
Watery diarrhea	Vasoactive intestinal polypeptide, gastrin, or prostaglandin activity
Hypercholesterolemia	Cholesterol dysregulation
Erythrocytosis	Erythropoietin secretion
Thrombocytopenia	Portal hypertension
Cutaneous	Cytokines secretion
Seborrheic keratoses	
Pityriasis rotunda	
Dermatomyositis	
Pemphigus foliaceus	
Porphyria cutanea tarda	

One of the unique features of HCC is its hypervascularity. HCC derives the majority of its blood supply from the hepatic artery as opposed to the portal vein.<sup>29</sup> This feature allows accurate identification of HCC on imaging, particularly on high-quality multiphase (unenhanced, arterial phase, portal venous phase, and delayed venous phase) cross-sectional imaging. The pathognomonic radiographic profile is enhancement in the arterial phase followed by washout in the delayed venous phase (Fig. 58-3). Additional common findings are delayed enhancement of the fibrous pseudocapsule, presence of septations, and an internal mosaic pattern.

C

**FIGURE 58-3** Scans from multiphase computed tomography of hepatocellular carcinoma. **A.** Arterial phase. **B.** Portal venous phase. **C.** Delayed venous phase. (Used with permission from J. Shindoh, MD, Toranomon Hospital, Tokyo, Japan.)

The decision whether to use computed tomography (CT) or magnetic resonance imaging (MRI) for diagnosis of HCC is largely dependent on the institution and the physician's level of comfort with interpreting the results. A meta-analysis of 15 studies comparing CT to MRI found that MRI was associated with better sensitivity (91% vs 81%) and specificity (95% vs 93%), especially for smaller HCC lesions.<sup>30</sup> Regardless of the modality used, if the lesion is larger than 1 cm and exhibits the classic appearance of HCC on radiographs, no additional workup or biopsy is needed for diagnosis. If the imaging findings are not definitive, the next step is repeat imaging with another modality (CT if MRI was used and vice versa). If the imaging findings remain ambiguous after repeat imaging, a needle biopsy can be performed unless the patient is a candidate for liver transplant. In candidates for liver transplant, biopsy should be avoided until evaluation by a transplant team to avoid peritoneal seeding even though the risk of seeding is low when needle biopsy is performed by a physician with appropriate experience. For lesions smaller than 1 cm, hepatic ultrasonography should be performed every 3 months.<sup>31</sup> If there are concerning changes or findings, further investigation is warranted (Fig. 58-4).

**FIGURE 58-4** American Association for the Study of Liver Diseases algorithm for workup of suspected hepatocellular carcinoma. CT, computed tomography; MDCT, multidetector computed tomography; MRI, magnetic resonance imaging; US, ultrasonography. (Reproduced with permission from Bruix J, Sherman M; American Association for the Study of Liver Diseases: Management of hepatocellular carcinoma: an update, *Hepatology* 2011 Mar;53(3):1020-1022.)

## Screening

Screening for HCC should be reserved for patients at high risk for development of HCC and should not be performed in the general population. Individuals with cirrhosis of the liver should undergo evaluation with liver sonography every 6 to 12 months according to the American Association for

the Study of Liver Diseases.<sup>32</sup>

The tumor marker most commonly used for monitoring and diagnosis of patients at high risk for HCC is  $\alpha$ -fetoprotein (AFP). AFP is a glycoprotein produced by the fetal liver and yolk sac. AFP can be elevated in a variety of disease processes and other malignancies, including tumors of gonadal origin, gastric cancer, pregnancy, acute or chronic hepatitis, and cirrhosis.<sup>33-36</sup> Typically an AFP value of greater than 20  $\mu\text{g/L}$  is considered abnormal, but with this cutoff value, there are significant variations in the sensitivity and specificity of AFP level according to the population examined (patients with cirrhosis or chronic hepatitis vs patients with normal livers).<sup>37</sup> Therefore, the status of the underlying liver must be taken into account in interpreting the AFP level. Furthermore, up to 40% of patients with small HCCs have normal AFP levels.<sup>38</sup>

Because AFP measurements alone have variable sensitivity and specificity in the diagnosis of HCC, imaging remains the mainstay of surveillance.<sup>31,39</sup> The combination of characteristic imaging findings with an elevated AFP level does have high positive predictive value.<sup>40,41</sup> In Japan, where the prevalence of HCC is much higher than in the United States, the Japanese Society of Hepatology recommends liver sonography and serum AFP and plasma des-gamma-carboxy prothrombin measurement every 3 to 4 months and CT or MRI every 6 to 12 months for patients with cirrhosis related to hepatitis B or C.<sup>42</sup> For patients with chronic hepatitis B or C or with cirrhosis not due to hepatitis B or C, the Japanese Society of Hepatology recommends liver sonography and serum AFP and plasma des-gamma-carboxy prothrombin measurement every 6 months with or without cross-sectional imaging when such imaging would be appropriate.<sup>42</sup>

## Staging

The treatment of HCC involves consideration of 2 separate pathologic processes, the primary liver tumor and any underlying liver disease. To help stratify patients for treatment, there are 2 general systems of staging, pathologic and clinical. The pathologic staging systems are based on surgical outcomes and include the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) TNM staging system, Liver Cancer Study Group of Japan staging system, Japanese Integrated Staging score, and

Chinese University Prognostic Index.<sup>43-46</sup> The clinical systems include the Okuda system, Cancer of the Liver Italian Program (CLIP) scoring system, and Barcelona Clinic Liver Cancer (BCLC) staging system.

The seventh edition of the AJCC/UICC staging system ([Table 58-3](#)) takes into account prognostic factors after resection of HCC, including tumor size (cutoff 5 cm), solitary versus multiple tumors, and presence or absence of vascular invasion. The most important prognostic factor is vascular invasion. Tumors without vascular invasion are defined as T1; those with vascular invasion as at least T2; and those with major vascular invasion, defined as invasion of a major branch of the portal or hepatic vein, as T3. Five-year overall survival rates after liver resection for patients with stages I, II, and III HCC are 55%, 37%, and 16%, respectively ([Fig. 58-5](#)).<sup>47</sup>

**TABLE 58-3: AMERICAN JOINT COMMITTEE ON CANCER/INTERNATIONAL UNION AGAINST CANCER STAGING SYSTEM FOR HEPATOCELLULAR CARCINOMA**

<b>T Category</b>	<b>T Criteria</b>
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Solitary tumor $\leq 2$ cm, or $> 2$ cm without vascular invasion
T1a	Solitary tumor $\leq 2$ cm
T1b	Solitary tumor $> 2$ cm without vascular invasion
T2	Solitary tumor $> 2$ cm with vascular invasion, or multiple tumors, none $> 5$ cm
T3	Multiple tumors, at least one of which is $> 5$ cm
T4	Single tumor or multiple tumors of any size involving a major branch of the portal vein or hepatic vein, or tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of visceral peritoneum

<b>N Category</b>	<b>N Criteria</b>
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

<b>M Category</b>	<b>M Criteria</b>
M0	No distant metastasis
M1	Distant metastasis

<b>When T is ...</b>	<b>And N is ...</b>	<b>And M is ...</b>	<b>Then the stage group is ...</b>
T1a	N0	M0	IA
T1b	N0	M0	IB
T2	N0	M0	II
T3	N0	M0	IIIA
T4	N0	M0	IIIB
Any T	N1	M0	IVA
Any T	Any N	M1	IVB

**FIGURE 58-5** Survival after liver resection for hepatocellular carcinoma according to stage. Stage I, single tumor without vascular invasion. Stage II, single tumor with vascular invasion or multiple tumors, none >5 cm. Stage III, multiple tumors, any >5 cm, or single tumor or multiple tumors of any size involving a major branch of the portal vein or hepatic vein. (Reproduced with permission from Vauthey JN, Lauwers GY, Esnaola NF, et al: Simplified staging for hepatocellular carcinoma, *J Clin Oncol* 2002 Mar 15;20(6):1527-1536.)

Although there were significant improvements between the sixth and seventh editions of the AJCC/UICC staging system, additional stratification of the current stage categories may lead to better assessment of patient prognosis. An international multicenter study showed that neither microvascular invasion nor tumor differentiation affects surgical outcomes in patients with HCCs smaller than 2 cm. This subset of patients can be reclassified into a separate group that is associated with improved prognosis.<sup>48</sup> Evaluation of the underlying liver disease is assessed through a fibrosis score, which is stratified into 2 tiers. Although this score is not incorporated into the overall staging, it does provide prognostic value with respect to overall survival, as patients with associated liver disease have a worse prognosis.<sup>49</sup>

Clinical staging systems are more useful than pathologic staging systems for choosing the appropriate treatment regimen, particularly when surgery is not feasible. The Okuda system (Table 58-4) is based on tumor size, presence of ascites, albumin level, and bilirubin level and categorizes patients into 3 stages.<sup>50</sup> Unfortunately, the Okuda system was derived from a cohort with primarily advanced HCC and used limited tumor-specific factors. As a result, it has little validity in patients with early HCC and groups patients with vascular invasion and multifocal disease into a single group.

**TABLE 58-4: OKUDA STAGING SYSTEM FOR HEPATOCELLULAR CARCINOMA<sup>50</sup>**

Criterion	Positive	Negative
Tumor size	≥50% of liver	<50% of liver
Ascites	Clinically detectable	Clinically absent
Albumin level	≤30 g/L	>30 g/L
Bilirubin level	>3 mg/dL	<3 mg/dL

Stage Definition	
I	No criterion positive
II	1 or 2 criteria positive
III	3 or 4 criteria positive

Data from Okuda K, Ohtsuki T, Obata H, et al: Natural history of hepatocellular carcinoma and prognosis in relation to treatment. Study of 850 patients, *Cancer* 1985 Aug 15;56(4):918-928.

The CLIP scoring system (Table 58-5) is based on the Child-Turcotte-Pugh (CTP) score (Table 58-6), tumor morphology, serum AFP level, and presence or absence of portal vein thrombosis.<sup>51</sup> Although the CLIP system stratifies patients with respect to prognosis better than the Okuda system does, the CLIP system still groups a wide range of patients with heterogeneous outcomes together and does not accurately account for vascular invasion.<sup>43</sup>

**TABLE 58-5: CANCER OF THE LIVER ITALIAN PROGRAM SCORING SYSTEM FOR HEPATOCELLULAR CANCER<sup>43,51</sup>**

Variable	Score
<b>Child-Turcotte-Pugh Stage</b>	
A	0
B	1
C	2
<b>Tumor Morphology</b>	
Uninodular and extension $\leq 50\%$	0
Multinodular and extension $\leq 50\%$	1
Massive or extension $> 50\%$	2
<b><math>\alpha</math>-Fetoprotein Level, units ng/mL</b>	
<400	0
$\geq 400$	1
<b>Portal Vein Thrombosis</b>	
Absent	0
Present	1

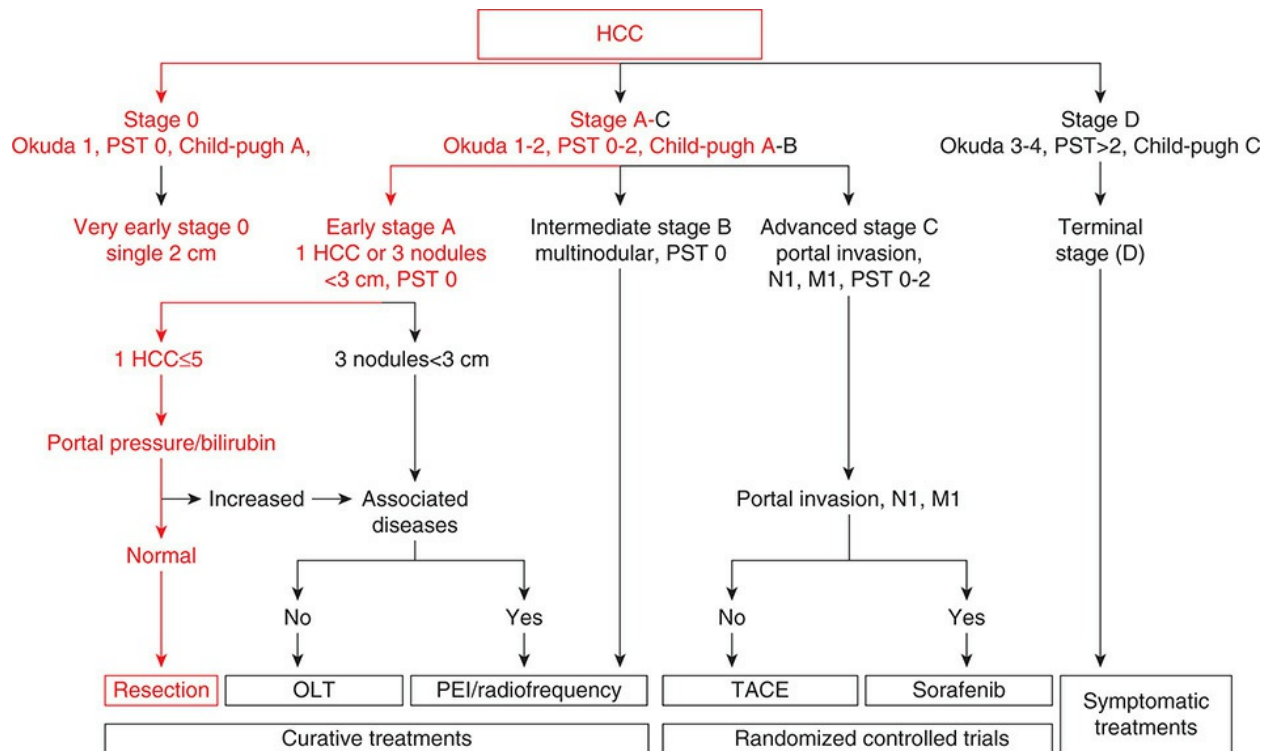

Overall score is the sum of the scores for the 4 individual variables. Median survival for scores of 0, 1, 2, 3, and 4-6 was 36, 22, 9, 7, and 3 months, respectively.<sup>124</sup> Adapted with permission from Daniele B, Annunziata M, Barletta E, et al: Cancer of the Liver Italian Program (CLIP) score for staging hepatocellular carcinoma, *Hepatology Res* 2007 Sep;37 Suppl 2:S206-S209.

Class C	10-15 points		

The BCLC staging system (Fig. 58-6) was designed to incorporate more prognostic factors and better stratify patients with early HCC.<sup>52</sup> The system created 5 stages based on the primary tumor size and number of nodules, liver function, performance status, presence of constitutional symptoms, vascular invasion, and extrahepatic spread. Limitations of this system include lack of a patient-centered approach, failure to outperform other systems in larger studies, and relatively few patients judged to be candidates for resection or interventional therapy.<sup>52,53</sup> In Figure 58-6, candidates for resection according to the BCLC staging system are highlighted in red.<sup>54</sup>

**FIGURE 58-6** Barcelona Clinic Liver Cancer algorithm for treatment of patients with hepatocellular carcinoma (HCC). Red indicates patients who are potentially candidates for resection. OLT, orthotopic liver transplant; PEI, percutaneous ethanol injection; PST, performance status; TACE, transarterial chemoembolization. (Reproduced with permission from Bruix J, Llovet JM: Prognostic prediction and treatment strategy in hepatocellular carcinoma, *Hepatology* 2002 Mar;35(3):519-524.)

In selecting among the multitude of available HCC staging systems, physicians should take a patient-centered approach. The AJCC/UICC pathologic staging system should be used for patients who undergo resection. It remains the only system validated in independent cohorts of patients undergoing either hepatic resection or transplant.<sup>7</sup> In contrast, patients with advanced HCC with poor liver function have a better assessment of prognosis with clinical staging systems, particularly the BCLC system.<sup>47</sup>

## CTP Score

Hepatic functional reserve, the most important predictor of mortality risk, is determined by using the CTP score (Table 58-6). This score is based on the grade of encephalopathy, presence or absence of ascites, serum bilirubin level, serum albumin level, and prothrombin time and is used to stratify

patients into 3 groups with different risk. The CTP score has been validated in multiple studies and is incorporated into various treatment algorithms for hepatic neoplasms.<sup>32</sup> Early studies showed that the perioperative mortality rates associated with abdominal operations in patients with CTP class A, B, and C disease were 10%, 30%, and 82%, respectively.<sup>55</sup> In light of these risks, patients with CTP class A HCC and selected patients with class B HCC can undergo liver resection without significant complications. In contrast, patients with HCC with CTP class C disease have extremely high perioperative mortality rates and should not undergo resection if it can be avoided.<sup>56</sup>

## Treatment

Determining the appropriate therapy for patients with HCC can be challenging. Multiple factors need to be taken into account, including patient performance status, liver quality, and tumor burden. With appropriate patient selection, studies have demonstrated 5-year overall survival rates of up to 70%.<sup>57,58</sup>

For patients without underlying liver disease and resectable disease, liver resection offers the best survival, and for patients with underlying liver disease, liver transplant offers the best prognosis. Patients with poor liver function who are not candidates for transplant should proceed with supportive care, systemic therapy, or liver-directed therapies.

## SURGERY

The first decision is to decide whether the lesion is resectable, which depends on the extent of extrahepatic disease. Many would consider vascular invasion, involvement of adjacent organs besides the gallbladder, extension beyond the visceral peritoneum, or disease in multiple nodes (AJCC seventh edition stage IIIb or greater) to render HCC unresectable. However, exceptions can be made for selected patients when care is undertaken by a multidisciplinary team at a high-volume center.

If HCC is judged resectable, the status of the underlying liver needs to be assessed. Patients with poor liver quality should be referred for transplant, while those with acceptable liver quality (CTP class A or B) should be

optimized medically. [Table 58-7](#) summarizes criteria for resection in patients with chronic liver disease at the University of Texas MD Anderson Cancer Center.<sup>59</sup>

**TABLE 58-7: THE UNIVERSITY OF TEXAS MD ANDERSON CANCER CENTER  
CRITERIA FOR RESECTION IN CHRONIC LIVER DISEASE**

Type of Resection	Criteria
Minor ( $\leq 3$ liver segments)	Child-Turcotte-Pugh class A Bilirubin level $\leq 20$ g/L Absence of ascites Platelet count $> 1 \times 10^6$ /L
Major ( $> 3$ liver segments)	Criteria for minor resection plus: Bilirubin level $\leq 1$ mg/dL Absence of portal hypertension Portal vein embolization in patients with future liver remnant $< 40\%$

Reproduced with permission from Truty MJ, Vauthey JN: Surgical resection of high-risk hepatocellular carcinoma: patient selection, preoperative considerations, and operative technique, *Ann Surg Oncol* 2010 May;17(5):1219-1225.

Patients with an inadequate future liver remnant should undergo portal vein embolization (PVE). PVE in patients with HCC can increase the future liver remnant ([Fig. 58-7](#)), thereby increasing the number of patients eligible for resection, reducing liver failure–related complications, and increasing the safety of liver resection.<sup>60-62</sup> Generally, for safe liver resection, patients without liver disease need a minimum future liver remnant of at least 20%, patients who underwent chemotherapy need a future liver remnant of at least 30%, and patients with cirrhosis or fibrosis require a future liver remnant of at least 40%.<sup>63-65</sup> PVE, similar to functional liver tests such as indocyanine green clearance and technetium-99m-galactosyl human serum albumin scintigraphy, is able to provide information about the severity of liver disease. Degree of liver hypertrophy less than 5% at 3 weeks after PVE is associated with increased risk of liver-related complications, hepatic dysfunction or insufficiency, prolonged hospital stay, and 90-day mortality.<sup>66</sup> [Table 58-8](#) summarizes indications and contraindications for PVE.<sup>60</sup>

**FIGURE 58-7** Right portal vein embolization (PVE) and segment IV embolization for a large hepatocellular carcinoma. **A.** Pre-PVE computed tomography (CT) scan. Standardized future liver remnant (sFLR) (segments I, II, and III, outlined in blue) = 12%. **B.** CT scan 3 weeks after right PVE and segment IV embolization. sFLR = 22%, and degree of hypertrophy = 10%. **C.** CT scan 8 years after extended right hepatectomy. sFLR = standardized future liver volume measured on CT/standardized total liver volume.<sup>125</sup> Standardized total liver volume =  $-794.41 + 1267.28 \times \text{body surface area (m}^2\text{)}$ .

**TABLE 58-8: INDICATIONS AND CONTRAINDICATIONS FOR PORTAL VEIN EMBOLIZATION (PVE) IN PERIOPERATIVE MANAGEMENT OF HEPATOCELLULAR CARCINOMA**

## Indications for PVE

To increase the safety of major resection  
FLR <20% in absence of underlying liver disease  
FLR <40% if underlying liver disease  
In combination with transarterial chemoembolization  
Segment IV embolization for extended right hepatectomy

## Contraindications for PVE

Vascular invasion or thrombosis of portal vein  
Tumor extension to FLR  
Uncorrectable coagulopathy  
Renal failure  
Portal hypertension

Abbreviation: FLR, future liver remnant.

Data from Truty MJ, Vauthey JN: Uses and limitations of portal vein embolization for improving perioperative outcomes in hepatocellular carcinoma, *Semin Oncol* 2010 Apr;37(2):102-109.

## TRANSPLANT

For patients with HCC who have significant underlying liver dysfunction that precludes resection because of the risk of liver-related complications, liver transplant is an option. To determine who is a candidate for liver transplant, the United Network for Organ Sharing (UNOS) uses the Milan criteria, proposed by Mazzaferro and colleagues: solitary lesion smaller than 5 cm or up to 3 lesions all smaller than 3 cm with absence of extrahepatic disease or vascular invasion.<sup>67</sup> Patients meeting these criteria achieved 4-year survival rates of 75%. Patients with CTP class B or C disease who meet the Milan criteria are best treated with transplant, while patients with CTP class A disease often go straight to resection. However, the recurrence rate after liver resection has been reported to be up to 70%.<sup>61</sup>

A group at the University of California San Francisco (UCSF) proposed expansion of the UNOS criteria to single tumors no larger than 6.5 cm or a maximum of 3 tumors, none larger than 4.5 cm and with the sum of the maximum diameters of the tumors no greater than 8 cm.<sup>68</sup> This proposed expansion is controversial because 5-year overall survival rates of patients who met these criteria and underwent transplant ranged from 38% to 93%.<sup>68-</sup>

<sup>73</sup> The data remain unclear regarding the suitability of the UCSF criteria. Proponents of the UCSF criteria state that patients with larger HCCs can be cured with transplant, while critics cite higher rates of vascular invasion and recurrence. Given the relative shortage of livers, the UNOS criteria remain the standard in the United States.<sup>67,69,71</sup>

## **LOCOREGIONAL THERAPIES**

Several locoregional therapies exist for patients with HCC who are not candidates for resection or transplant. These include radiofrequency ablation (RFA), percutaneous ethanol injection, and transarterial chemoembolization (TACE). RFA uses application of radiofrequency energy with an alternating current to cause thermal damage to tissues. The range of tissue damage from RFA suggests that the optimal candidates for RFA are those with tumors smaller than 2 cm if RFA is delivered with curative intent and tumors smaller than 4 cm if RFA is delivered with palliative intent. Randomized controlled trials comparing RFA and percutaneous ethanol injection found that RFA was associated with better overall survival.<sup>74</sup>

Characteristically, HCC derives its blood supply from the hepatic artery. TACE capitalizes on this fact and involves injection of chemotherapeutic agents with a procoagulant material into the hepatic artery branch supplying the tumor. TACE has been proven to be more effective than supportive care.<sup>75,76</sup> Drug-eluting polyvinyl alcohol microspheres or beads can also be injected into the tumor, resulting in embolization and local administration of chemotherapy to the lesion and limiting the escape of chemotherapeutic agents.

TACE is often used for large HCCs that are not amenable to resection or ablation. Chemotherapeutic agents commonly used for TACE are doxorubicin, cisplatin, epirubicin, and doxorubicin-eluting beads. Randomized controlled trials comparing various chemotherapeutic agents have found no differences in outcomes, and the benefit of drug-eluting beads remains controversial.<sup>77,78</sup> Locoregional therapies are often used as a bridge to transplant, particularly when patients are on the waiting list and their HCC lesion or lesions are close to exceeding the tumor size criteria. Many of the studies showing survival benefits from locoregional therapies had small numbers of patients, but use of such therapies is increasing at transplant centers throughout the United States.<sup>79</sup>

## SYSTEMIC THERAPY

For patients with unresectable or metastatic HCC, systemic therapy is the primary treatment. HCC is notoriously resistant to cytotoxic chemotherapies given its overexpression of drug-resistance genes. Furthermore, patients with HCC often have underlying liver dysfunction that causes cytotoxic chemotherapies to be poorly tolerated. Sorafenib has emerged as the standard systemic therapy option for advanced HCC. Sorafenib is a multikinase inhibitor acting on vascular endothelial growth factor receptor 2, platelet-derived growth factor receptor, FLT3, Raf-1, Ret, and c-Kit. Two randomized phase III trials, the Sorafenib Hepatocellular Carcinoma Assessment Randomized Protocol (SHARP) trial and the Asia-Pacific trial, demonstrated statistically significant improvements in overall survival, of 2.8 months and 2.3 months, respectively, for patients with advanced HCC treated with sorafenib.<sup>80,81</sup>

Despite the limitations of cytotoxic chemotherapy for HCC, modest effects are seen with combinations of different cytotoxic agents, particularly in patients with minimal underlying liver disease. The combination of cisplatin, interferon  $\alpha$ -2b, doxorubicin, and fluorouracil (PIAF) showed an improvement of the objective response rate.<sup>82</sup> The objective response rate increased with the number of cycles (Fig. 58-8), and for patients amenable to surgery after treatment with PIAF, survival was significantly improved compared to the survival of patients who were not able to undergo surgery after treatment with PIAF (Fig. 58-9)<sup>83</sup>.

**FIGURE 58-8** Objective response rate according to number of cycles of cisplatin, interferon  $\alpha$ -2b, doxorubicin, and fluorouracil (PIAF). (Reproduced with permission from Kaseb AO, Shindoh J, Patt YZ, et al: Modified cisplatin/interferon alpha-2b/doxorubicin/5-fluorouracil (PIAF) chemotherapy in patients with no hepatitis or cirrhosis is associated with improved response rate, resectability, and survival of initially unresectable hepatocellular carcinoma, *Cancer* 2013 Sep 15;119(18):3334-3342.)

**FIGURE 58-9** Overall survival for patients with initially unresectable hepatocellular carcinoma according to whether patients received conventional or modified cisplatin, interferon  $\alpha$ -2b, doxorubicin, and fluorouracil (FU) (PIAF) regimen and whether patients underwent surgery. Conventional PIAF:

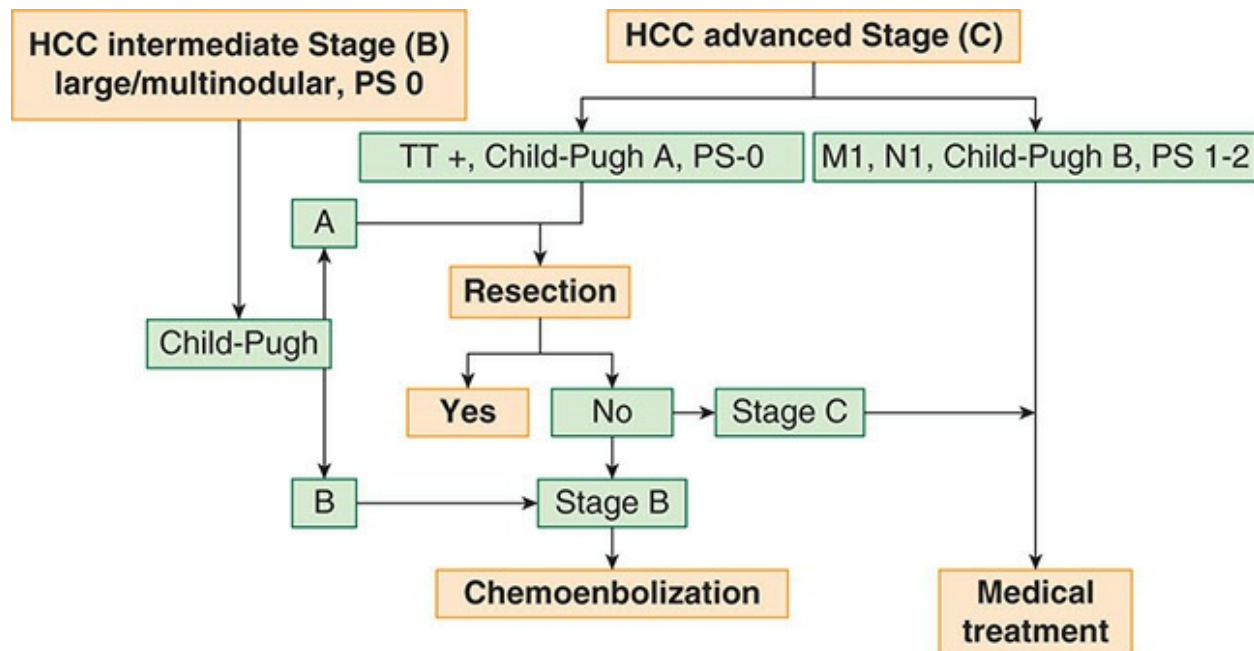

cisplatin 80 mg/m<sup>2</sup> day 1, interferon α-2b 5 MU/m<sup>2</sup> days 1-4, doxorubicin 40 mg/m<sup>2</sup> day 1, and FU 500 mg/m<sup>2</sup> over 24 hours days 1-4. Modified PIAF: cisplatin 20 mg/m<sup>2</sup> days 1-4, interferon α-2b 4 MU/m<sup>2</sup> days 1-4, doxorubicin 40 mg/m<sup>2</sup> day 1, and FU 400 mg/m<sup>2</sup> as a bolus infusion on days 1-4. (Reproduced with permission from Kaseb AO, Shindoh J, Patt YZ, et al: Modified cisplatin/interferon alpha-2b/doxorubicin/5-fluorouracil (PIAF) chemotherapy in patients with no hepatitis or cirrhosis is associated with improved response rate, resectability, and survival of initially unresectable hepatocellular carcinoma, *Cancer* 2013 Sep 15;119(18):3334-3342.)

## METHODS TO INCREASE RESECTABILITY OF LARGE HCC

Treatment of patients with good liver function, good performance status, and large HCCs who do not meet the criteria for transplant is challenging. For resectable HCC, recent series indicate that surgery performed by experienced surgical teams is associated with improved long-term survival (Fig. 58-10).<sup>84</sup> Furthermore, for selected patients with BCLC stage B or C disease, resection can be proposed (Fig. 58-11).<sup>61,85</sup> However, most patients with large HCCs have borderline resectable tumors at the time of diagnosis because of either a small future liver remnant or major vascular invasion.

**FIGURE 58-10** Improvement in overall survival (OS) after major hepatectomy (resection of >3 liver segments) for hepatocellular carcinoma over time (n = 630). (Reproduced with permission from Andreou A, Vauthey JN, Cherqui D, et al. Improved long-term survival after major resection for hepatocellular carcinoma: a multicenter analysis based on a new definition of major hepatectomy, *J Gastrointest Surg* 2013 Jan;17(1):66-77.)

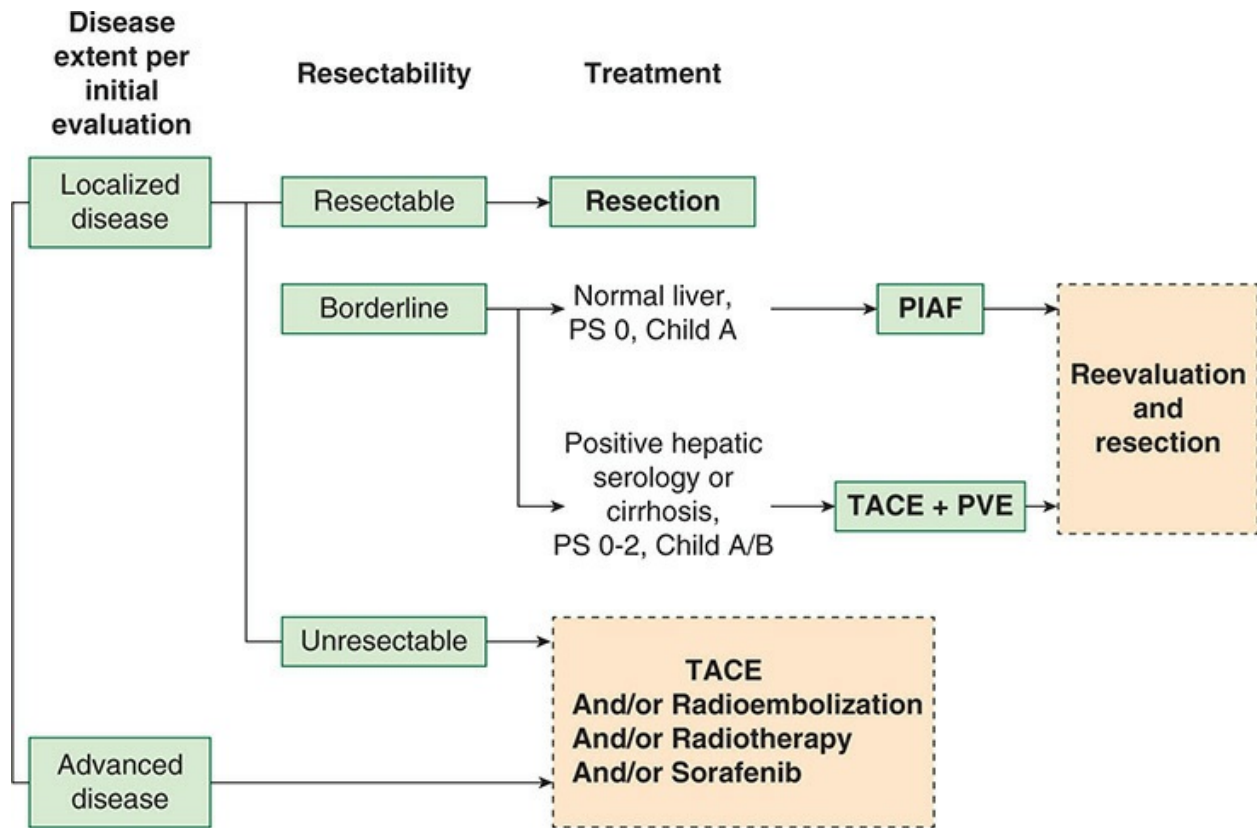

**FIGURE 58-11** Revised Barcelona Clinic Liver Cancer algorithm for treatment of patients with intermediate and advanced hepatocellular carcinoma (HCC). N1 and M1 are defined according to the American Joint Committee on Cancer/International Union Against Cancer staging system for HCC, seventh edition. PS, performance status; TT, Tumor Thrombus. (Reproduced with permission from Torzilli G, Belghiti J, Kokudo N, et al: Reply to Letter: “A Snapshot of the Effective Indications and Results of Surgery for Hepatocellular Carcinoma in Tertiary Referral Centers: Is It Adherent to the EASL/AASLD Recommendations? An Observational Study of the HCC East-West Study Group”: When the Study Setting “Ignores” the Patients, *Ann Surg* 2015 Jul;262(1):e30-e31.)

For patients with a small future liver remnant, PVE can be considered to increase resectability.<sup>62</sup> The combination of PVE with TACE has been suggested to increase the rate of hypertrophy, especially for patients with underlying liver disease, by suppressing arterioportal shunts and increasing parenchymal damage in the embolized liver (Fig. 58-12).<sup>86</sup> A sequential approach, with TACE completed 3 to 4 weeks before PVE, was associated with an increase of future liver remnant size and longer recurrence-free and overall survival compared to PVE alone.<sup>87,88</sup> In patients without hepatitis or cirrhosis with tumors that were borderline resectable because of locoregional extension, PIAF also increased resectability.<sup>83</sup> Figure 58-13 summarizes the treatment strategy for large HCCs advocated at MD Anderson Cancer Center. Treatment of patients by an expert multidisciplinary team optimizes the strategy and improves the outcome of patients with HCC (Fig. 58-14).

**FIGURE 58-12** Intraoperative view of the liver in a patient with cirrhosis secondary to chronic hepatitis B and hepatitis C before right hepatectomy for hepatocellular carcinoma. After ligation of the right artery, the liver is demarcated along the main plane (Cantlie line). The patient underwent sequential transarterial chemoembolization followed by portal vein embolization prior to resection, and major hypertrophy of the left liver is clearly noticeable. The patient had a recurrence 4 years after liver resection and underwent salvage liver transplant. At this writing, the patient is alive 10 years after liver transplant.

## INTRAHEPATIC CHOLANGIOCARCINOMA

## Epidemiology

Intrahepatic cholangiocarcinoma (ICC) is the second most common primary liver tumor following HCC and accounts for approximately 10% to 15% of primary liver malignancies. ICCs arise from the intrahepatic biliary tree and behave differently than extrahepatic cholangiocarcinomas (perihilar and distal cholangiocarcinomas). The incidence of ICC in the United States from 2000 through 2009 was 0.88 cases per 100,000 individuals per year, and the incidence continues to rise.<sup>89-91</sup> The reason for this increase is unclear, but it is thought to be due to increased detection as a result of better diagnostic modalities and increases in the risk factors associated with ICC development.<sup>92,93</sup> Unfortunately, most patients with ICC present with advanced disease, and the 5-year overall survival rate is only 5% to 10%; even with resection, the 5-year overall survival rate is a dismal 20% to 35%.<sup>94</sup> Given the rarity of ICC, routine screening is not currently recommended.

## Risk Factors

Risk factors for the development of ICC include conditions that lead to increased inflammation of the biliary tract ([Table 58-1](#)). Primary sclerosing cholangitis is an inflammatory condition of the biliary tract that leads to fibrosis and strictures. Almost 1 in 3 patients with cholangiocarcinoma are diagnosed with primary sclerosing cholangitis, and the lifetime risk of developing cancer in patients with primary sclerosing cholangitis is up to 15%.<sup>95,96</sup> Congenital abnormalities of the biliary tree, such as choledochal cysts and Caroli disease, are associated with a 15% risk of developing cholangiocarcinoma.<sup>97-99</sup> Infection with the liver flukes *Opisthorchis viverrini* and *Opisthorchis sinensis*, which are found in Asia, leads to chronic inflammation of the biliary system after the worms lay eggs in the biliary tree.<sup>97</sup> Additional risk factors for ICC include cholelithiasis, hepatolithiasis, cholecystitis, exposure to Thorotrast contrast agent, hepatitis B and hepatitis C, and Lynch syndrome.<sup>94,97</sup>

## Clinical Presentation and Diagnosis

Unlike extrahepatic cholangiocarcinomas, ICCs often present as an incidental mass on imaging rather than as a biliary obstruction. If the mass is large or pushing on the liver capsule, it can cause vague right upper quadrant pain or constitutional symptoms.

The workup begins with liver function studies, tumor marker studies, and cross-sectional imaging. Carcinoembryonic antigen and carbohydrate antigen 19-9 (CA 19-9) are the tumor markers most often used, and of these, CA 19-9 has the higher specificity. Studies have found that CA 19-9 level greater than 100 U/mL has a sensitivity of 53% and a specificity of up to 90% in the detection of ICC.<sup>100</sup> Care must be taken when interpreting CA 19-9 levels in a patient with hyperbilirubinemia as the results can be falsely elevated. Unlike HCC, ICC has no pathognomonic radiologic characteristics; therefore, biopsy of the mass is required.

Early surgical evaluation is essential to determine whether the mass is a resectable and whether the patient is a candidate for transplant. No delay should be taken to refer the patient, even to acquire a biopsy. Care must be taken to ensure that the lesion is not a metastasis from another malignancy and that there is no disease outside the liver. The surgical workup entails performing an esophagogastroduodenoscopy and colonoscopy to rule out the presence of primary tumor outside the liver.

## Pathology

The Liver Cancer Study Group of Japan classified ICC into 3 subtypes based on gross appearance: mass forming, periductal infiltrating, and intraductal growth (Fig. 58-15).<sup>101</sup> The mass-forming type is the most common type, accounting for 85% of ICCs. On CT, mass-forming cholangiocarcinomas are homogeneous with low attenuation and peripheral enhancement (Fig. 58-16). On MRI, they are hypointense on T1-weighted images and hyperintense in the T2 phase.<sup>102</sup> Periductal-infiltrating ICCs grow along the bile duct without forming a mass. Intraductal growth ICCs, as the name implies, grow within the bile duct and can appear as duct ectasia with or without a mass, a polypoid mass, an intraductal cast, or an intraductal stricture.<sup>102</sup>

## Staging

Like staging for HCC, staging for ICC changed with the seventh edition of the AJCC/UICC staging system. ICCs, hilar cholangiocarcinomas, and distal cholangiocarcinomas were separated into different staging and are now able to better predict survival. For ICC, the system focuses on the number of tumors (1 or >1) and the presence or absence of vascular invasion and lymph node involvement ([Table 58-9](#)). The staging system was externally validated by the French Surgical Association ICC 2009 study group. After a mean follow-up interval of 34 months, median survival for patients with stage I ICC had not been reached; median survival was 53 months ( $P = .01$ ) for patients with stage II disease and 16 months ( $P < .0001$ ) for patients with stage III disease.<sup>103</sup>

# Treatment

## SURGERY

Surgery remains the only curative option for patients with ICC. Unfortunately, the majority of patients present with advanced disease that precludes resection. Depending on the location of the lesion, surgery involves resection of the liver involving the mass with negative margins, possibly resection of a portion of the extrahepatic bile ducts, and resection of regional lymph nodes. A multi-institutional study from the Italian Intrahepatic Cholangiocarcinoma Study Group found improved 5-year overall survival and recurrence-free survival when margins were negative.<sup>104</sup> The size of the margin, however, did not predict outcome. In another international multi-institutional study, lymph node involvement was found in 30% of patients undergoing a formal lymphadenectomy and was associated with poor prognosis.<sup>105</sup> In light of these findings, a portal lymph node dissection is warranted as it provides staging and prognostic information.

## TRANSPLANT

Liver transplant for ICC remains controversial. The Mayo Clinic published their experience using neoadjuvant chemoradiotherapy followed by orthotopic liver transplant for unresectable cholangiocarcinoma arising in patients with primary sclerosing cholangitis and found a 5-year overall survival rate of 82%.<sup>106</sup> In an intent-to-treat analysis from the Mayo Clinic and other centers, 5-year overall survival rates after orthotopic liver transplant were 53% to 55% with a high recurrence rate.<sup>107,108</sup> Given these data, orthotopic liver transplant for ICC is currently performed only in highly selected patients at specialized transplant centers and should be done under a research protocol.

## SYSTEMIC THERAPY

Systemic cytotoxic chemotherapy plays a greater role in the treatment of ICC than in the treatment of HCC. The Advanced Biliary Cancer Trial 02 was a phase III randomized controlled trial comparing gemcitabine plus cisplatin

versus gemcitabine alone in patients with advanced biliary tract cancers (ICCs, hilar cholangiocarcinomas, distal cholangiocarcinomas, ampullary adenocarcinomas, and gallbladder carcinomas). The results showed an improvement in overall survival (11.7 months vs 8.1 months) and progression-free survival (8 months vs 5 months) with the combination regimen.<sup>109</sup> Consequently, gemcitabine with cisplatin is considered the standard of care for patients with advanced cholangiocarcinoma. Patients who undergo surgery and who have positive margins, node-positive disease, or adverse prognostic markers are offered fluoropyrimidine- or gemcitabine-based chemotherapy as adjuvant chemotherapy after surgery.

## HEPATIC ANGIOSARCOMA

Hepatic angiosarcoma is the most common primary sarcoma arising from the liver.<sup>110</sup> Hepatic angiosarcoma is a high-grade vascular neoplasm arising from malignant transformation of hepatic endothelial cells.<sup>110,111</sup> About 200 cases are diagnosed annually worldwide, incidence is highest in patients older than 60 years, and most affected patients are male (male-to-female ratio, 3:1 to 4:1).<sup>112</sup> Known risk factors for the development of hepatic angiosarcoma are exposure to vinyl chloride, thorotrast contrast agent, arsenic, and radium.<sup>112</sup> Patients present with vague abdominal pain, malaise, nausea/vomiting, and abdominal distention from hepatomegaly or development of ascites. A rare presentation is tumor rupture leading to hemoperitoneum, which is associated with high morbidity and mortality.<sup>113</sup> Treatment is centered around hepatic resection; however, over half of patients present with metastatic disease. For patients with unresectable disease, hepatic artery embolization can be employed for palliation.<sup>113,114</sup> The prognosis for patients with hepatic angiosarcoma is dismal: in the absence of treatment, the majority of patients die within 6 months of diagnosis, and with treatment, only 3% of patients survive to 2 years.<sup>115,116</sup>

## EPITHELIOD HEMANGIOENDOTHELIOMA

Epithelioid hemangioendothelioma (EHE) is another rare tumor of mesenchymal origin. Classified as a low-grade malignant neoplasm, it arises from endothelial cells like hepatic angiosarcoma does. EHE is a disease of

middle-aged patients, and two-thirds of affected patients are females.<sup>117,118</sup> Patients present with abdominal pain and malaise, and if there is involvement of the hepatic veins, this can lead to Budd-Chiari syndrome.<sup>119</sup> Vinyl chloride exposure is thought to be one of the risk factors associated with development of EHE.<sup>120</sup> Resection remains the optimal treatment for EHE and is associated with 5-year overall survival rates of 75%.<sup>121</sup> Unfortunately, the majority of patients present with multifocal, diffuse disease that is not amenable to a hepatectomy. Orthotopic liver transplant is an option for patients with diffuse disease and is associated with 5- and 10-year survival rates of 83% and 74%, respectively.<sup>122</sup> Because EHE is indolent, patients can be followed to determine the biology of the tumor. Those who remain candidates for resection or orthotopic liver transplant can be stratified from patients with progression.<sup>123</sup> As with all rare diseases, large randomized studies of EHE are lacking. Multicenter investigations should be undertaken to better understand the biology and treatment options for patients with this disease.

## CONCLUSION

Primary malignancies of the liver are difficult to treat because they are frequently advanced at diagnosis and frequently associated with chronic liver disease. With the recent expansion of therapeutic options, treatment algorithms are becoming increasingly complex. In-depth knowledge of the disease in combination with treatment by a multidisciplinary team allows for patient-centered therapeutic approaches and contributes to optimal outcomes.

# TREATMENT OF HEPATIC METASTASIS

*Sean M. Ronnekleiv-Kelly • Sharon M. Weber*

## OVERVIEW

Hepatic metastases to the liver are significantly more common than primary liver malignancy and comprise approximately 90% of hepatic malignancies. Each year, approximately 140,000 new cases of colorectal cancer (CRC) are diagnosed in the United States, with hepatic metastases complicating 10% to 25% of cases.<sup>1,2</sup> Two-thirds of these patients die from their disease as a result of liver involvement.<sup>2</sup> In addition, numerous other malignancies metastasize to the liver. For instance, approximately 50% of patients with uveal melanoma develop liver metastases within 2 to 5 years after initial diagnosis, and 90% of metastatic uveal melanoma patients die with disease burden in the liver due to inefficacious systemic chemotherapy.<sup>3</sup> Neuroendocrine tumors (NETs) also have propensity to metastasize to the liver as well as breast cancer, esophageal cancer, gastric cancer, gastrointestinal stromal tumors (GISTs), sarcoma, gynecologic and urologic malignancies, and melanoma.<sup>4</sup> Therefore, because of the significant number of patients impacted by either primary or secondary liver malignancy, there is an

increasing need for effective locoregional therapy. Surgical resection as a part of multimodal therapy is generally considered the gold standard.<sup>5-8</sup> However, resection is often not a reasonable option secondary to disease burden, tumor location, insufficient estimated future liver remnant, extrahepatic disease, and medical comorbidities. In fact, surgical resection for metastatic disease to the liver is only feasible in approximately 20% of patients.<sup>9</sup> Therefore, alternative options are necessary in the 60% to 80% of patients with metastatic disease to the liver in whom surgery is not possible.<sup>9</sup> These nonresective techniques are the focus of this chapter.

## **ARTERIAL-DIRECTED THERAPY**

Malignant tumors confined to the liver that cannot be addressed with curative intent are best treated with locoregional therapy. Primary liver lesions such as hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma as well as metastatic liver lesions such as colorectal, neuroendocrine, breast, melanoma, and renal can be palliated or down-staged with arterial-directed therapy. Transarterial directed therapy includes bland embolization, chemoembolization, drug-eluting beads (DEBs), and radioembolization. Bland embolization induces tumor ischemia by arterial disruption but does not use chemotherapeutic agents; therefore, tumor necrosis is simply accomplished by restricted blood supply. Chemoembolization, DEB, and radioembolization deliver toxic agents via the arterial system which preferentially supplies the tumor, in contrast to normal hepatocytes which derive much of their blood supply from the portal venous system.<sup>10</sup> The latter three techniques are the focus of the arterial-directed therapy section.

### **Transcatheter Arterial Chemoembolization**

#### **TECHNIQUE**

Transcatheter arterial chemoembolization also known as transarterial chemoembolization (TACE) was first introduced in 1980 for treatment of unresectable liver tumors, and since that time has expanded to include treatment of numerous malignant processes (HCC, neuroendocrine metastases, cholangiocarcinoma, melanoma, colorectal metastases).<sup>11</sup>

Conceptually, liver tumors preferentially utilize hepatic arterial supply, and therefore chemotherapeutic agents with subsequent embolization can selectively target malignant cells while preserving surrounding liver parenchyma. Specific delivery of chemotherapeutic agents reduces systemic toxicity as the agents remain in the tumor bed; in addition, ischemia induced by arterial embolization can increase tumor cell lethality. However, preservation of proximal hepatic arterial inflow is essential to allow repeated treatments and the optimal number of treatments is based upon tumor response and hepatic reserve. Tumor response is characterized by reductions in size or lack of enhancement on CT/MRI indicating tumor necrosis.<sup>11</sup>

After meticulous patient evaluation and characterization of tumor extent, femoral catheter insertion and subsequent angiography is utilized to delineate the vascular anatomy in the region of the tumor (Fig. 59-1A,B). The chemotherapeutic agent is then introduced into segmental or subsegmental vessels feeding the tumor(s). Variability in technique is common, including altering chemotherapeutic agents and embolic material, as well as inclusion of lipiodol, and also the technical selectivity of catheter positioning. Lipiodol is an iodinated ester from poppy seed oil that is combined with the chemotherapeutic mixture which allows emulsification of the drugs as well as directed targeting of liver tumors because the compound is selectively retained by liver tumors (Fig. 59-1C).<sup>11</sup> The most common cytotoxic agents used include doxorubicin, gemcitabine, cisplatin, and mitomycin C (MMC). After delivery of chemotherapy agents, embolization is performed. Commonly used embolic agents include polyvinyl alcohol particles, starch microspheres, or gelfoam.<sup>11,12</sup> Following embolization, angiography is performed, and subsequently cross-sectional imaging is obtained to confirm the interruption of blood supply.<sup>12</sup> Patients generally require a short hospital stay post-procedure for intravenous hydration and pain control, as well as to monitor for post-embolization syndrome (discussed below). Additional TACE procedures can be performed at 4-week intervals until the specified tumor volume has been treated. Follow-up cross-sectional imaging is generally obtained at 1 month after completion of treatment to assess response; imaging is then obtained at 3-month intervals thereafter.<sup>13</sup>

(A) Contrast-enhanced CT images demonstrate a  $9.1 \times 8.8$  cm heterogeneously enhancing mass in the right lobe of the liver in a female patient with metastatic leiomyosarcoma. (B) Digital subtraction angiography (DSA) anteroposterior view of a segmental right branch off the replaced right hepatic artery showing the hypervascular lesion. (C) Spot fluoroscopic image following conventional TACE demonstrates lipiodol deposition in the treated lesion.

## OUTCOMES

Early randomized studies focused on TACE for unresectable HCC. Many did not demonstrate survival benefit of hepatic arterial chemoembolization versus more conservative treatment.<sup>14-19</sup> However, more recent studies have identified a benefit in patients with unresectable HCC confined to the liver, and therefore TACE has emerged as a safe therapeutic option.<sup>20-22</sup> Subsequently, metastatic disease to the liver has also been evaluated. Vogl and associates identified 463 patients with unresectable colorectal liver metastases (CRLM) that demonstrated no response or disease progression on systemic chemotherapy (two or more lines of chemotherapy), or developed toxicity precluding further systemic treatment. Therefore, all of the patients in the study received no further systemic chemotherapy. Patients received TACE comprised of MMC, MMC with gemcitabine, or MMC with irinotecan followed by embolization. The mean number of sessions was 5.3 per patient, and the TACE was tolerated quite well with minimal toxicity. Partial response (PR) was demonstrated in 14.7%, stable disease in 48.2%, and disease progression in 37.1% of patients according to the Response Evaluation Criteria in Solid Tumors (RECIST). Approximately 13% of patients achieved downstaging which allowed percutaneous ablative procedures to be performed. Median overall survival (OS) duration was 38 months from diagnosis of liver metastases and 14 months from initiation of chemoembolization; these survival times did not differ among the three TACE groups.<sup>23</sup>

Albert and colleagues investigated TACE in 121 patients with metastatic CRC, most of whom had failed systemic chemotherapy for nonresectable CRLM. Chemoembolization consisted of MMC, doxorubicin, and cisplatin and was provided in 4-week intervals until the entirety of tumor volume had been treated (one cycle). Most procedure-related toxicity consisted of pain, fever, nausea, and emesis; serious complications occurred in 11% and included hepatic infarction, hematoma, pulmonary edema, myocardial infarction (MI), and venous thromboembolism (VTE). Overall, 2% had PR, 41% had disease stability, and 57% had disease progression (RECIST). Median time to progression was 5 months and median OS was 9 months after initiation of TACE. Median OS after diagnosis of liver metastases was 27 months, and the authors suggested that given the median survival was greater than historical survival of patients receiving systemic chemotherapy alone (ie, 20 months), chemoembolization provided an additive benefit to systemic chemotherapy.<sup>13</sup>

Vogl and colleagues evaluated TACE followed by MR-guided laser-induced thermotherapy (LITT) for patients with CRLM (unresectable, inoperable, contraindications for surgery, or refusal of surgery). The mean number of TACE treatments was 3.7 and patients received MMC, MMC with gemcitabine, or MMC with irinotecan. PR was seen in 31% of patients with stable disease in 69%; overall mean reduction in tumor size was 21.4%. Reduction in tumor size was sufficient to allow LITT for all of the patients. Median time to progression was 8 months and median OS was 23 months. There was no difference between the treatment groups with respect to reduction in tumor size, response rate, time to progression, and OS. In addition, the treatments were well tolerated, with no mortalities or major complications.<sup>12</sup> The authors concluded that the OS was favorable compared to previous studies demonstrating median survival between 10 and 20 months in patients with nonresectable CRLM receiving systemic or regional chemotherapy.<sup>24,25</sup>

Use in liver metastases from noncolorectal primaries has also been demonstrated. Dong and Carr performed a retrospective study of TACE (doxorubicin or streptozotocin) in the treatment of unresectable metastatic NETs to the liver. An average of seven cycles was provided and PR was found in 62%, while 24% had minor response or disease stability. Median survival was about 3½ years, and the treatment was well tolerated.<sup>26</sup> A recent analysis of therapeutic options for patients with gastro-enteric-pancreatic (GEP) NET identified TACE as a treatment modality for those with unresectable disease. However, the level of evidence presented was low and studies have failed to demonstrate an advantage of TACE over bland embolization.<sup>27</sup>

Taken together, these investigations demonstrate marginal benefit at best for patients with CLRM undergoing TACE versus systemic chemotherapy. In addition, there have not been any robust studies demonstrating improvement in outcome utilizing TACE for CRLM.<sup>28</sup> For these reasons, TACE is not currently recommended for treatment of colorectal liver metastases except as part of a clinical trial.<sup>29</sup> Coincident with this, the European Neuroendocrine Tumor Society (ENETS) consensus guidelines for patients with GEP NET liver metastases stated that although symptom improvement occurs in 73% to 100% (duration 14-22 months) and CR/PR occur in approximately 33% to 50% of patients undergoing TACE for liver metastases from GEP NET, there

remains uncertainty whether TACE provides a survival advantage over systemic therapy.<sup>30</sup>

## INDICATIONS

Patients with good performance status and tumor suitable for resection, ablation, or transplantation should pursue curative measures. In patients with unresectable liver malignancy (primary or metastatic) and disease primarily confined to the liver, TACE can be utilized as salvage monotherapy when patients are unresponsive to systemic chemotherapy.<sup>12,13</sup> TACE can also be used concordantly (neoadjuvant) with other treatment modalities such as LITT, radiofrequency ablation (RFA), microwave ablation (MWA), and resection. However, currently TACE appears to be best suited for treatment in patients with HCC (intermediate stage) as opposed to patients with liver metastases.<sup>31</sup>

Congruent with the exclusion criteria for many of the above studies, contraindications to chemoembolization are absence of hepato-pedal flow and lack of compensatory collaterals, poor hepatic function (encephalopathy or ascites not controlled with diuretics), and biliary obstruction. Relative contraindications include poor hepatic synthesis (serum albumin <2 mg/dL), hepatic compromise (serum bilirubin >2 mg/dL, lactate dehydrogenase >425 U/L, aspartate aminotransferase >100 U/L), bleeding varices, ascites, thrombocytopenia, extensive tumor burden (>50% of liver), cardiac insufficiency, or renal insufficiency.<sup>10</sup>

## COMPLICATIONS

While TACE is generally well tolerated, complications include liver abscess (1%), tumor rupture (1%), acute liver failure, gastrointestinal bleeding (1%-4%), pulmonary embolism, renal dysfunction, cardiac toxicity, bile duct injury, bleeding from femoral puncture site (1%-2%), and post-embolization syndrome. This syndrome, which occurs in 4% to 10% of patients, is characterized by right upper quadrant pain, nausea, emesis, fever, and liver enzyme elevation.<sup>10,11</sup> Although common, the syndrome typically resolves spontaneously within 7 to 10 days.

# Drug-Eluting Bead Transarterial Chemoembolization

## TECHNIQUE

Transcatheter delivery of agents such as doxorubicin and cisplatin has less systemic toxicity compared to standard systemic chemotherapy.<sup>32</sup> Despite this, adverse effects such as acute liver failure, encephalopathy, ascites, upper GI bleeding, marrow suppression, alopecia, and renal failure still occur.<sup>10,11</sup> Although TACE has demonstrated benefit for unresectable HCC, there remains a necessity for improved response rates and decreased complications which may allow expansion of indications. Localization of drugs specifically to the tumor with subsequent sustained release of the specific drug may result in decreased systemic effects and longer tumor exposure to the chemotherapeutic agent. By loading various chemotherapy agents onto polyvinyl alcohol-based hydrogel (DC-Beads, Biocompatibles, Surrey, UK) or a sodium acrylate and vinyl alcohol copolymer (HepaSphere, BioSphere Medical, Rockland, MA) and catheter delivery similar to standard TACE, drug-eluting bead transarterial chemoembolization (DEB-TACE) achieves directed delivery to the tumor microvasculature where the small compounds (100-300  $\mu\text{m}$  and 300-500  $\mu\text{m}$ , respectively) obstruct the vasculature.<sup>33</sup> The lodged DEBs allow slow elution of chemotherapeutic agent in a sustained manner with prolonged exposure compared to TACE and lower systemic plasma levels of chemotherapeutic agent, resulting in reduced adverse effects.<sup>34,35</sup> The technique is quite similar to TACE with the exception of the deployment of DEB microspheres impregnated with chemotherapeutic agent as opposed to chemotherapeutic agent with emulsificant and embolic agent.<sup>36</sup> Additional considerations include presence of replaced or aberrant vessels, avoidance of embolization of cystic artery, and evaluation of phrenic artery if suspected to supply the target tumor.<sup>37</sup>

## OUTCOMES

In the setting of CRLM, a phase III multi-institutional prospective randomized trial evaluated DEB loaded with irinotecan (DEBIRI) compared to systemic chemotherapy including folinic acid, 5-FU and irinotecan (FOLFIRI) in patients presenting with unresectable liver metastases from

CRC (<50% liver parenchyma and no extrahepatic disease) who had undergone prior chemotherapy. Complete or partial response occurred in 69% of patients receiving DEBIRI compared to 20% of the systemic chemotherapy patients. At 2 years, survival was 56% in the DEBIRI group compared to 32% in the FOLFIRI group, and median OS was significantly higher in the DEBIRI group (22 months vs 15 months,  $p = .03$ ). Furthermore, neutropenia greater than or equal to grade III occurred in 4% of the DEBIRI population compared to 44% of the systemic population with fewer rates of diarrhea (6% vs 18%), alopecia (5% vs 35%), asthenia (20% vs 50%), and mucositis (1% vs 20%), indicating a superior safety profile. Supplementary data revealed improved quality of life scores and significant reduction in cost in the DEB-TACE patients compared to the patients receiving FOLFIRI.<sup>32</sup> This study emphasized the importance of consideration of arterially directed therapy in select patients with metastatic disease to the liver.

## **INDICATIONS**

The indications for DEB-TACE fall into the same category as for standard TACE; most studies have evaluated its use in HCC.<sup>37,38</sup> DEB-TACE may provide survival benefit compared to systemic chemotherapy for CRLM; however, further studies are necessary to clarify this potential role.<sup>39</sup>

## **COMPLICATIONS**

Prajapati and colleagues sought to evaluate the safety and efficacy profile of small (100 to 300 mm) and large (300-500 mm) DEBs. DEB TACE with doxorubicin was performed in 94 patients (mean 2.8 per patient). Each group experienced similar mild complications (approximately 30%) consisting of abdominal pain (18%-26%), nausea (13%-17%), fever (3%-4%), and groin pain (3%-4%). The larger bead group had significantly more severe complications, including femoral artery pseudoaneurysm (1.7 vs 2.9%), prolonged hospitalization due to severe abdominal pain (1.7% vs 8.6%), and encephalopathy (0% vs 8.6%). Other complications included bradycardia (1.7%) and gastric ulceration/bleed (1.7%). In addition, mortality was 0% in the small bead group and 4% in the large bead group, leading the authors to conclude that 100 to 300 mm DEB may have an improved safety profile compared to larger beads.<sup>36</sup>

# Selective Internal Radiation Therapy

## TECHNIQUE

Yttrium-90 ( $^{90}\text{Y}$ ) radioembolization is a transarterial treatment for locoregional disease with demonstration of a clear palliative role by achieving delayed progression of hepatic lesions.<sup>40</sup> Selective internal radiation therapy (SIRT) exploits the preferential arterial perfusion of hepatic malignant disease in order to expose liver lesions to radioactive microspheres. There are two microsphere forms that are commonly used including nonbiodegradable glass microspheres (TheraSphere™, MDS Nordion, Ottawa, Canada) of diameter 20 to 30  $\mu\text{m}$ , and biodegradable resin microspheres (SIR-Spheres™, Sirtex, Lane Cove, Australia).<sup>10</sup> As opposed to chemoembolization that combines chemotherapy and ischemia to achieve desired antitumor effect,  $^{90}\text{Y}$  radioembolization relies upon intravascular brachytherapy radiation effect to the targeted segment or lobe. The goal pulmonary exposure (pulmonary shunting) is less than 30 Gy while optimizing exposure to tumor.<sup>41</sup> Prior to radioembolization of hepatic tumor, a simulation angiographic injection of 20 to 100  $\mu\text{Ci}$  technetium-99m labeled albumin followed by single photon emission computed tomography (SPECT) imaging allows estimate of  $^{90}\text{Y}$  deposition (Fig. 59-2 A-D).<sup>40,41</sup> The pretreatment simulation allows for projected tumor delivery as well as to evaluate for gastrointestinal (aberrant vessels) or pulmonary shunting (Fig. 59-2 E-G).<sup>41,42</sup> Consequently, a tumor delivery dose can be estimated; however, tumor dose and resultant objective response is dependent upon tumor type, vascularity of the tumor (ie, intratumoral shunting), and use of previous systemic or intra-arterial agents.<sup>42</sup> In addition, the targeted liver volume with associated feeding vessels can greatly influence the delivery dose. For instance, localized tumors confined within a specific segment can be targeted with the entire planned infusion of  $^{90}\text{Y}$  resulting in a “radiation segmentectomy” in which substantial doses are achieved (>1000 Gy).<sup>42</sup> However, indications are not limited to segmental infusions, as lobar and whole-liver treatments are also routine and can be performed safely.<sup>33</sup>

**FIGURE 59-2**  $^{90}\text{Y}$  radioembolization in a patient with multifocal hypervascular carcinoid metastases. (A) Early arterial and (B) delayed arterial phase digital subtraction angiography (DSA) images following selective right hepatic arterial injection. *Note:* The gastroduodenal artery has been prophylactically embolized to avoid non-target embolization of glass microspheres to the pancreaticoduodenal arcade. (C) Early arterial and (D) delayed-phase DSA images following selective left hepatic arterial injection in the same patient. *Note* arterial supply to segments II-IV as well as a small caudate artery coursing inferiorly off of the left hepatic artery (*arrow*). (E) 3D volumetric data is obtained from CT imaging performed during mapping angiography and used to facilitate dosimetric calculations for each lobar treatment. (F,G) Here, segmentation of the right hepatic lobe is used to calculate the volume of liver parenchyma perfused by the right hepatic artery.

Radioembolization is accomplished 1 to 2 weeks following the simulation. Femoral catheter cannulation and subsequent angiography is utilized to delineate the vascular anatomy in the region of the tumor. The selective

internal radiation therapy then consists of infusion of  $^{90}\text{Y}$  loaded onto resin or glass microspheres.  $^{90}\text{Y}$  is pure  $\beta$ -emission radiation and has a mean tissue penetration of 2.5 mm (maximum 10 mm) with a relatively short half-life of 64.1 hours.<sup>42</sup> For this reason, isolation for radiation precaution is not required and the majority of radiation energy (97%) is emitted within the first 2 weeks. Although the absorbed dose is heterogeneous based on hemodynamics and tumor vasculature, the majority of the  $^{90}\text{Y}$  is absorbed into the tumor compared to the normal liver parenchyma (3:1 to 20:1 ratio). The consequence of radiation exposure to tumor cells is irreversible cell damage. Patients are either observed in the hospital setting for a period of less than 24 hours or the procedure is performed on an outpatient basis. Follow-up imaging is then obtained at specified intervals in order to determine the response to therapy by RECIST criteria, World Health Organization (WHO) criteria, or European Association for the Study of Liver (EASL) criteria (Fig. 59-3). In the setting of downstaging or identifying tumor response based on size criteria alone, imaging can inadequately predict response as a result of discordance between residual size and cell viability. For example, in a study by Kulik et al. in patients with liver tumors treated with  $^{90}\text{Y}$  who had tumor response allowing subsequent liver transplant, there was radiologic-pathologic discordance in five of seven patients receiving liver transplant. Imaging suggested viable tumor in each of the seven patients, while pathologic analysis demonstrated complete pathologic necrosis in five patients.<sup>42</sup> Therefore, additional characteristics such as enhancement on CT or MRI, or PET imaging can be utilized to estimate tumor volume as defined by the modified RECIST assessment or the EASL guidelines assessing percent change in enhancing tissue.<sup>43</sup>

(A) Contrast-enhanced CT demonstrates a  $2.5 \times 2.7$  cm homogeneously enhancing NET metastasis in segment VIII. (B) Three-month and (C) 6-month post-contrast T1WI following  $^{90}\text{Y}$  radioembolization confirm significant post- $^{90}\text{Y}$  necrosis and volume reduction.

## OUTCOMES

$^{90}\text{Y}$  radioembolization has been evaluated in numerous studies and is currently recognized as a treatment option for unresectable Barcelona Clinic Liver Cancer (BCLC) intermediate stage HCC in the National Comprehensive Cancer Network guidelines.<sup>40,42-44</sup> Metastatic disease to the liver has also been demonstrated to respond to  $^{90}\text{Y}$  therapy and is currently a category 3 recommendation for CRLM due to limited data in a highly select patient population.<sup>29</sup>

In a single-institution analysis, Cianni et al. evaluated 110 patients with liver metastases (colorectal, breast, gastric, pancreatic, esophageal, melanoma, cholangiocarcinoma, and pharyngeal) unresponsive to systemic chemotherapy and not amenable to local therapy. Approximately 60% received whole-liver SIRT ( $^{90}\text{Y}$ ), 20% sequential, and the remainder lobar. Among CRC patients, CR or PR was seen in 46%, while in breast cancer patients CR/PR was 44%.  $^{90}\text{Y}$  achieved clinically relevant response rates and was well tolerated, indicating a potential therapy for patients with metastatic disease to the liver.<sup>45</sup>

The same Italian group performed a study to evaluate  $^{90}\text{Y}$  SIRT in 52 patients with metastatic breast cancer. The motivation arose from the fact that only 10% to 20% of patients with hepatic metastases from breast cancer can undergo attempted resection and therefore additional therapies require evaluation. The selected patients were inoperable with chemotherapy-unresponsive hepatic metastases. Patients with less than 25% liver involvement had 54% PR and median survival of 14.3 months, while patients with 26% to 50% liver involvement had 60% PR and median survival of 8.2 months. Considering these patients were receiving salvage therapy, the authors suggested studies investigating earlier use of SIRT (potentially in combination with standard therapies) in metastatic disease to the liver.<sup>46</sup>

In 2012, a group of experts in the management of patients with liver

metastases from NET convened to determine appropriate treatment in patients who are not candidates for surgery or RFA. They examined 18 reports on utilization of transarterial embolization (TAE) and TACE (11 publications), or radioembolization (7 publications). In the studies evaluating  $^{90}\text{Y}$  treatment, there were response rates ranging from 22.5% to 71.4% and median survival ranging from 22 to 70 months, highlighting the heterogeneity of the studies and populations. In a representative study, Memon et al. investigated  $^{90}\text{Y}$  in 40 patients with unresectable liver metastases from NET. Median liver dose was 113 Gy and lung dose 3.81 Gy. Complete or partial response was noted in 64% with stable disease in 32.5% and median OS was 34 months. Symptom control was achieved in 84%.<sup>10</sup> These response rates and median OS were similar to the wide array observed in TAE/TACE. The panel concluded that future studies are required for direct comparison of the intra-arterial therapies, use of intra-arterial therapy versus systemic therapy, and concomitant use of intra-arterial therapy with systemic therapy in order to optimally define the role of  $^{90}\text{Y}$  in NET metastases the liver.<sup>47</sup> Unfortunately, the broad heterogeneity and rarity of this tumor will make future studies difficult to interpret, since it is unlikely an RCT will be performed.

From these studies, it is apparent that  $^{90}\text{Y}$  treatment for liver tumors is a useful adjunct, but its specific capacity remains to be established. Therefore, due to the necessity of additional studies evaluating SIRT in metastatic disease to the liver, investigations have been established that will help clarify its role. For instance, patients with unresectable CRLM will be randomized to FOLFOX ± bevacizumab versus single-session SIRT + FOLFOX ± bevacizumab (SIRFLOX study) to determine effect on progression-free survival (PFS) and OS.<sup>48</sup> The premise of this study (and another similar study, FOXFIRE) is the increased PFS observed in patients with CRLM that received 5-FU/LV and SIRT (18.6 months) versus 5-FU/LV (3.6 months).<sup>49</sup> These, along with additional ongoing studies, will better delineate the optimal patient selection for  $^{90}\text{Y}$ -SIRT, either as monotherapy or in combination with other modalities.

## INDICATIONS

In general, patients with Eastern Cooperative Oncology Group (ECOG)

performance status of 0 to 2 without extrahepatic life-limiting disease, and adequate hematologic parameters with appropriate pulmonary, renal (creatinine <2 mg/dL), and liver function (bilirubin <2.0 mg/dL) are candidates for SIRT. Multiple malignant tumors (primary and secondary) of the liver have been treated with <sup>90</sup>Y radioembolization, allowing for broad application. In addition, patients with disease not amenable to resection or ablation, and who are poor candidates for TACE due to extensive tumor burden or portal vein invasion, or patients who had disease progression following TACE can be treated with SIRT.

When considering transarterial therapy, a noteworthy characteristic of SIRT is the microembolic nature of the <sup>90</sup>Y-microspheres. Sato et al. evaluated 30 patients undergoing SIRT for unresectable HCC or liver metastases and found that pretreatment arteriography and post-treatment arteriography (1-3 months) revealed 100% patency of first- through third-order vessels and inability of experienced radiologists to correctly determine pre- versus post-treatment imaging based on arterial flow, emphasizing the microembolic character of <sup>90</sup>Y.<sup>50</sup> In addition, given the microembolic nature of SIRT (as opposed to macroembolic phenomena in TACE), use in patients with portal venous thrombosis has proven safe and effective without the risk of ischemic hepatitis and hepatic decompensation seen with chemoembolization.<sup>51</sup> Furthermore, <sup>90</sup>Y radioembolization is equally well tolerated in young patients compared to those greater than age 70, indicating an appropriate treatment option for the elderly patient population whose frailty may limit alternative treatment methods.<sup>52</sup>

Contraindications include excessive estimated radiation doses to the lungs (>30 Gy single dose or >50 Gy multiple doses), uncorrectable flow to the gastrointestinal tract on angiography (ie, inability to occlude aberrant vessels), poor hepatic synthetic function (albumin <3 mg/dL), signs of limited hepatic reserve (bilirubin >3 mg/dL in absence of reversible cause, ascites, encephalopathy, recent variceal hemorrhage), or significant extrahepatic disease that is life-limiting.<sup>33</sup>

## COMPLICATIONS

Radioembolization-induced liver disease (REILD) is a syndrome manifest from sinusoidal obstruction that occurs 4 to 8 weeks after treatment. Patients developed jaundice, ascites, and moderate increase in canalicular enzymes;

this occurs in 8% to 15% of patients undergoing partial liver radioembolization and is mostly transient but can be severe in approximately 3.1%.<sup>53</sup> Other adverse effects from SIRT include fatigue (50%), nausea or emesis (30%), abdominal pain (20%-30%), fever (10%-15%), pneumonitis (rare), and gastrointestinal ulcers (1%-3%)—the overwhelming majority of which are grade I or II adverse events.<sup>52</sup>

## **ABLATION**

Ablative techniques achieve local control of tumor cells with minimal impact to adjacent, healthy liver tissue. In comparison to surgical resection, image-guided local control modalities offer reduced morbidity and mortality. Ablative therapy, either as monotherapy or adjunct to surgical resection, has allowed treatment of bilobar disease as well as treatment of patients who are unsuitable for liver resection due to underlying medical comorbidity. There is a vast array of ablative techniques including percutaneous ethanol injection (PEI), cryoablation, irreversible electroporation (IRE), percutaneous laser ablation (PLA; or LITT), high-intensity focused ultrasound (HIFU), stereotactic body radiation therapy (SBRT), MWA, and RFA. While many of these therapies have been used for local ablation, the most commonly used modality is RFA, with growing enthusiasm for and increasing use of MWA. In addition, SBRT is a noninvasive ablative modality that has generated much interest due to potential applications. Finally, IRE is the newest ablative technique, which offers a unique alternative, and its use has been emphasized in certain patient populations. Therefore, the focus of the ensuing section includes RFA, MWA, SBRT, and IRE.

## **Radiofrequency Ablation**

### **TECHNIQUE**

Although other ablative methods have become increasingly common, RFA is currently the most frequently used thermoablative technique. First utilized in 1990 for treatment of hepatic tumors, RFA consists of high-frequency oscillating electrical currents (460-500 kHz) delivered from one or more electrodes that produces resistive heating surrounding the electrode(s) (generally 2- or 3-cm exposed tip), ultimately causing tissue hyperthermia

(>100°C) and coagulative necrosis (Fig. 59-4).<sup>11</sup> The frictional heat arises from ion movement due to the alternating current, and the localized tissue hyperthermia occurs immediately adjacent to the electrode centered within the tumor. Upon reaching temperatures >60°C, microvascular thrombosis, ischemia, tissue hypoxia, and protein denaturation occur.

C

**FIGURE 59-4** Radiofrequency ablation (RFA) for hepatic metastasis. (A) RFA electrode tips with approximately 2 to 3 cm of exposed electrode. RFA consists of high-frequency oscillating electrical currents (460-500 kHz)

delivered from one or more electrodes from the exposed portion of the tip, ultimately causing tissue hyperthermia ( $>100^{\circ}\text{C}$ ) and coagulative necrosis. **(B)** A target hepatic metastasis is demonstrated in segment VI/VII of the liver prior to ablation. **(C)** Cross-sectional imaging obtained during the ablation procedure demonstrating RFA electrode tips within the lesion.

For percutaneous RFA, patients undergo general anesthesia with placement of grounding pads and ultrasound guidance of electrode insertion into the tumor. In general, the ablation is performed with a total ablative area encompassing the tumor and 0.5 to 1.0 cm margin ([Fig. 59-5](#)).

(B) Cross-sectional imaging demonstrates an area of coagulative necrosis encompassing the entirety of the hepatic lesion, 3 days post-ablation. (C) Cross-sectional imaging demonstrates the completely ablated lesion 2 months following RFA.

## OUTCOMES

There have not been any randomized studies comparing surgical resection with RFA in hepatic CRLM. However, a compilation of studies investigating RFA versus surgical resection for liver metastases demonstrated that surgical resection provided superior OS compared to RFA.<sup>54</sup>

A retrospective review by Schiffman et al. sought to evaluate the impact on OS of local treatment choice (thermal ablation [ $n = 46$ ] vs hepatectomy [ $n = 94$ ]) in solitary CRLM. While disease-free survival (DFS) was not significantly different between the two treatment modalities (42.6 months vs 55.2 months,  $p = .073$ ), median OS was substantially different (50.2 months vs 112.7 months,  $p = .005$ ), indicating that even for solitary lesions, hepatic resection should be considered first-line treatment.<sup>55</sup>

McKay and colleagues performed a retrospective study of RFA versus hepatic resection for CRLM. Patients undergoing hepatic resection had increased operative time (269 vs 204 minutes,  $p < .005$ ), blood loss (1400 mL vs 150 mL,  $p < .005$ ), and transfusion requirements (44% of patients vs 5%,  $p < .005$ ). There was no difference in median length of stay (7 days) or complications (59% vs 43%). Multivariate analysis revealed procedure (hepatic resection vs RFA), size of metastasis ( $>5$  cm vs  $<5$  cm), number of lesions ( $<5$  vs 5 or more), and timing of lesion (synchronous vs metachronous) were associated with survival. Patients undergoing hepatic resection had a median OS of 3.8 years versus 2.6 years in patients undergoing RFA, and 5-year OS was 43% versus 23% ( $p = .02$ ), indicating hepatic resection was superior to RFA. However, these data are immensely flawed by the selection bias that exists in the absence of a randomized controlled trial (RCT), reflected by the fact that patients who underwent RFA were considered poor surgical candidates as a consequence of insufficient projected liver remnant, proximity to critical structures, comorbid conditions precluding resection, or patient refusal of hepatic resection. Therefore, a substantive comparison could not be accomplished, and RFA appeared to be a safe and efficacious modality in these high-risk patients.<sup>56</sup>

A similar investigation by Kim and colleagues demonstrated comparable outcomes for RFA versus resection in patients with metastatic lesions less than 3 cm. They evaluated 482 patients undergoing RFA (177), hepatic resection (278), or both (27) for synchronous or metachronous CRLM. In this study, RFA was performed for patients with prohibitive comorbidities for surgical resection (cardiovascular or pulmonary disease), for difficult anatomical site, or if there were more than four hepatic metastases. Patients treated by hepatic resection mostly underwent subsegmentectomy/wedge resection ( $n = 222$ ), segmentectomy ( $n = 42$ ), or lobectomy ( $n = 14$ ). Both groups received postoperative chemotherapy (93% RFA vs 89% surgery). In subgroup analysis, 5-year OS was equivalent in hepatic resection and RFA (51.1% vs 51.2%) for solitary liver metastasis less than 3 cm in size. For patients with solitary lesions greater than 3 cm, 5-year DFS was significantly lower in the RFA group (23.1% vs 36.6%,  $p = .01$ ). Multiple liver lesions also proved to be associated, with worse 5-year DFS in patients undergoing RFA compared to surgical resection (6.4% vs 16.2%,  $p = .037$ ), although 5-year OS was not statistically significantly different (22.9% vs 34.6%,  $p = .330$ ). Hospital length of stay was greater for the surgery group (13.4 days vs 4.2 days,  $p < .001$ ), and complication rate was significantly higher (21.2% vs 6.2%,  $p < .001$ ). In contrast to the previous study which demonstrated high rates of transfusion requirement, bleeding necessitating transfusion occurred in 1% of patients undergoing RFA versus 5% in the resection group (more concordant with expected rates of transfusion requirement). Importantly, in patients with liver metastases less than 3 cm in size (solitary), RFA was not inferior to surgical resection. Furthermore, the authors suggested that despite less robust 5-year DFS in patients with lesions greater than 3 cm or multiple lesions treated with RFA, these results demonstrate that RFA is an effective alternative to surgery, especially in the higher-risk selected population with comorbid conditions or prohibitive location of lesions.<sup>57</sup>

Although the heterogeneity in patient populations creates difficulty for direct comparison, the improved DFS and OS establishes surgical resection as the standard, while RFA is an effective and potentially equivalent alternative in appropriately selected patients.

## INDICATIONS

In addition to RFA for primary liver tumors (HCC), RFA can be utilized for

unresectable metastases to the liver including colorectal and neuroendocrine tumors. In addition, RFA is an accepted alternative to surgical resection in selected patients with contraindication to hepatic resection.<sup>11</sup> Furthermore, RFA can be combined with hepatic resection for curative intent in patients with multisegment or bilobed metastatic liver disease.

While RFA has demonstrated efficacy against tumors <3 cm, with potential application in tumors 3 to 5 cm, there is limited effectiveness in tumors above this size. RFA should be used with caution in tumors with proximity to large vessels (distance <0.5 cm) such as primary or secondary branches of the portal vein, the insertion of hepatic veins, inferior vena cava, or less than 0.5 cm from extrahepatic organs.<sup>54</sup> In addition, a heat dissipation effect as a result of blood flow can be seen near large vessels, such as near the liver hilum, in which proximity to the bile duct and the thermal energy required to produce adequate ablation can result in bile duct injury.<sup>54</sup>

## COMPLICATIONS

Aside from pain, potential complications following RFA occur in 8% to 35% of patients and include fever, cutaneous burns (up to 8%), viscus perforation, bleeding, abscess formation, and biliary injury; the rate of mortality is approximately 0.5%.<sup>5,11</sup> Needle track seeding has also been documented, occurring in approximately 0.9% of cases.<sup>58</sup>

## Microwave Ablation

### TECHNIQUE

One of the limiting factors of RFA is penetrance through tissues with high impedance such as lung or charred tissue, which occurs with essentially every RFA-treated tumor. As temperatures increase greater than 100°C (adjacent to probes), water vapor formation and tissue dehydration occur, which limits flow of electrical current.<sup>59</sup> For this reason, RFA is temperature controlled such that gradual heating occurs to a maximum temperature not greater than 100°C. In contrast, MWA creates local tissue hyperthermia via an electromagnetic field that causes polar molecules (eg, water) to continuously attempt to align with the oscillating field. The resultant rapidly oscillating molecules produce tissue hyperthermia and can achieve temperatures greater

than 100°C with cell death by coagulation necrosis.<sup>60</sup> MWA antennas operate at a frequency of 915 MHz or 2.45 GHz and a power between 60 and 100 W for duration of 60 to 300 seconds. MWA fields can overlap in tissue, allowing multiple applicators for larger ablation zone compared to RFA. In addition, given the ability to penetrate through high-impedance tissues with poor electrical conduction such as pulmonary parenchyma and ablated tissue, ablation times are faster than RFA.<sup>59,61,62</sup> The goal ablation zone encompasses the liver lesion and a 0.5 to 1.0 cm rim of adjacent liver tissue (Fig. 59-6). An additional benefit includes a less pronounced heat-sink effect as is seen in RFA.<sup>60</sup> Inside the antenna shaft, chilled saline (4°C) or gas (CO<sub>2</sub>) is circulated continuously in order to prevent burn injury at the skin entry site. Following the ablation procedure, contrast-enhanced CT or MRI is obtained (1 month post-treatment) to evaluate for residual tumor. Incomplete ablation is identified as any irregular contrast enhancement within or adjacent to the ablation zone, while complete ablation produces a non-enhancing region encompassing the location of the tumor.<sup>62</sup>

**FIGURE 59-6** Microwave ablation (MWA) in a patient with metastatic colorectal cancer. (A,B) Cross-sectional imaging demonstrates small 1-cm lesions adjacent to each other in the right lobe of the liver, preablation. (C,D) Intraprocedural ultrasound of MWA of the same colorectal liver metastases. (E) Cross-sectional imaging after the first ablation demonstrates successful ablation of peripheral most lesion. (F) Cross-sectional imaging after second ablation demonstrating successful ablation of more central lesion; the short, thick arrow identifies the first ablation zone and the long, thin arrows reveal the second ablation zone.

## OUTCOMES

Although MWA is a relatively more recent technology than RFA, it has been studied in both primary liver tumors and metastatic disease and has been found to have equivalent ablation rates, median survival, and OS compared to patients undergoing RFA.<sup>61-63</sup> In a study investigating 879 patients with liver tumors (HCC [ $n = 770$ ], metastatic tumors [ $n = 85$ ], cholangiocarcinoma [ $n = 24$ ]), the safety profile of RFA ( $n = 323$ ) was compared to that of MWA ( $n = 556$ ). Both percutaneous and open ablation was performed and ablation was utilized because of unsuitability for surgical resection or patient refusal.

Based on follow-up imaging obtained at 1 month, complete ablation was achieved in 98.6% after RFA and 99.1% after MWA. Major complications (3.5% vs 3.1%), minor complications (5.9% vs 5.7%), and mortality (0.31% vs 0.36%) were not different between RFA and MWA, indicating MWA has a comparable safety profile.<sup>63</sup>

Stattner et al. recently performed a comprehensive review of the literature for microwave ablation of CRLM, and additionally reported their single-institutional experience. The institutional experience included 28 patients undergoing simultaneous MWA and hepatic resection for unresectable CRLM ( $n = 28$ ). Complications occurred in 39% (6% major complications) and mortality was 0%. Only one recurrence in an ablated tumor occurred and 1-, 3-, and 5-year OS was 82%, 45%, and 18%, respectively, highlighting the importance of MWA as an adjunct to surgical resection. These authors noted that in the literature, a common application of MWA was during concomitant hepatic resection. However, they also reviewed the comparison to RFA and identified potential advantages such as decreased local recurrence (LR).<sup>64</sup> For instance, Martin et al. compared MWA to a matched RFA group and complete ablation rate was higher in patients receiving MWA versus RFA (98% vs 92%) with shorter ablation times (13 min vs 40 min) and operative times (57 min vs 126 min). LR was 6% in patients undergoing MWA versus 17% in those undergoing RFA.<sup>65</sup>

Stattner and colleagues proposed that in the setting of CRLM, MWA is a safe and efficacious modality with reduced local recurrence compared to RFA. This was thought to be secondary to lack of a heat-sink effect such that lesions adjacent to large vessels received complete ablation; additionally, they noted that the desiccation and impedance that limit effectiveness of RFA in lesions >3 cm does not occur with MWA. Although similar 1-year and 3-year survival were seen in patients undergoing MWA versus hepatectomy for CRLM (71% and 14% vs 69% and 23%),<sup>66</sup> the authors concluded that MWA should be used concomitantly with surgery or instead of surgery when surgical resection is not feasible (tumor size, location, bilobar disease, number of lesions, or patient comorbid conditions). In addition, studies focusing on comparison of MWA versus RFA as well as MWA versus surgical resection would clarify the role of MWA in liver tumors.<sup>64</sup>

## **INDICATIONS**

Considering the efficacy of MWA with shorter ablation times compared to RFA, MWA is increasingly being employed for primary liver tumors and hepatic metastases. Many of the indications are similar to those of RFA with the potential benefit of lesion ablation near vascular structures. MWA can be used when surgical resection is not suitable due to tumor (ie, location, distribution, or number) or patient characteristics. In addition, MWA should also be considered an adjunct to surgery and can potentially transform a two-stage resection into a single resection with ablation.<sup>64</sup>

## COMPLICATIONS

Although grounding pads are not used, burn complications can occur along the microwave applicator shaft (entry site), which should be alleviated by the cooling system of the shaft. Post-procedural pain is a fairly common occurrence (60%), as is fever (80%) and asymptomatic pleural effusion (10%-15%). Major complications occur in approximately 2% to 4% and include hemothorax, diaphragmatic hernia, liver decompensation, intrahepatic hematoma, liver abscess, bile leak, biloma, bile duct injury, portal vein thrombosis, and peritoneal hemorrhage. Mortality (30-day) after MWA in the larger series is approximately 0.3% to 0.4%.<sup>63</sup>

## Stereotactic Body Radiation Therapy

Historically, radiotherapy has not been utilized for liver tumors due to the radiosensitivity of liver tissue; doses sufficient to achieve tumor cell death would result in unacceptable toxicity and collateral cell damage.<sup>67</sup> Whole-liver radiation can result in radiation-induced liver disease (RILD) in up to 50% at doses of 36 Gy in 2-Gy fractions.<sup>68</sup> RILD is characterized by ascites accompanied by elevation of alkaline phosphatase and transaminases, and can potentially result in liver failure and mortality.<sup>69</sup> However, with the advent of highly conformal dosimetry and steep dose gradient seen with SBRT, tumor targeting can be achieved with relative sparing of the adjacent normal tissue. SBRT developed from intracranial single-fraction stereotactic radiotherapy and is generally performed in five or fewer fractions with doses up to 30 Gy when delivering a single fraction and doses up to 75 Gy over multiple fractions.<sup>70</sup> In contrast to conventional external beam radiation

therapy, which delivers fractions ranging from 1.5 to 3.0 Gy to a larger treatment volume, SBRT delivers doses ranging from 30 to 75 Gy in 1 to 5 fractions to achieve local control.<sup>67</sup> In addition, although toxicity of SBRT with concurrent chemotherapy has not been well studied, chemotherapy should be stopped 2 weeks prior to planned treatment and can be resumed 2 weeks following completion of treatment, with the exception of clinical trial or endocrine therapy.<sup>67</sup>

Many of the alternative therapies for locoregional control such as RFA, MWA, cryotherapy, IRE, TACE, and SIRT require some level of invasiveness and are accompanied by certain restrictions. In patients who are not candidates for surgical extirpation, SBRT may be preferable over transarterial (SIRT or TACE) and ablative therapies (RFA or MWA) in patients who have poor blood flow or centrally located tumors and in those with peripherally located lesions or tumors adjacent to major vessels.<sup>68</sup> Therefore, SBRT is a noninvasive additional therapeutic option that can be utilized to treat liver metastases in selective patient populations; the noninvasive aspect allows for delivery on an outpatient basis.

## **TECHNIQUE**

The safe delivery of high-dose radiation therapy to specific locations mandates effective patient immobilization combined with precise targeting and steep isodose gradient outside the projected treatment volume. In contrast to treatment of brain lesions, extracranial tumor sites move between and during each delivered fraction of radiotherapy.<sup>70</sup> Therefore, subsequent to patient evaluation and multidisciplinary discussion, SBRT requires significant preparation to optimize control of liver tumors. Patients often undergo multimodal imaging including three-phase contrast-enhanced CT, which is accompanied by MRI and/or PET/CT to improve target definition. Four-dimensional CT scan is also acquired in order to delineate organ movement during respiration. The clinical target volume (CTV) equates to the gross tumor volume (GTV) and internal target volume (ITV) is comprised of GTV throughout the respiratory phases; planned target volume (PTV) encompasses ITV with an additional 5-mm margin.<sup>9</sup> Through the use of respiratory techniques (eg, controlled breath holds or shallow breathing) and abdominal compression devices (eg, corsets or plates) to limit abdominal movement, displacement of tumor during respiration can be minimized. In

addition, the patient may undergo placement of radiopaque fiducial markers within the lesion to assist in image guidance. An ablative dose prescription is then determined with multiple beams using coplanar and non-coplanar geometries; the nominal doses prescribed are a reflection of the isodose lines that encompass the ITV with steep dose gradients as distance from tumor increases.<sup>4</sup> Since a dose-response for local control appears evident, a total prescription of 48 Gy or higher in 3 fractions is recommended.<sup>4</sup> In addition, constraints for organs at risk apply: greater than 700 mL of liver volume should receive <15 Gy, a maximum volume of 0.1 cm<sup>3</sup> of spinal cord receive <18 Gy, a maximum of 35% of the kidneys receive <15 Gy, a maximum of 5 cm<sup>3</sup> of duodenum, small bowel, esophagus, and stomach receive <21 Gy and a maximum of 5 cm<sup>3</sup> of the heart receives <30 Gy.<sup>71</sup> The radiotherapy systems most commonly utilized are linear accelerators (linacs) with on-board imaging capabilities to deliver image-guided SBRT.<sup>70</sup>

Response is determined by follow-up imaging and can pose a challenge due to radiation-induced changes in tumor and surrounding liver tissue. Patterns of contrast enhancement, changes in hypodensity, and displacement of vessels seen on CT or MRI indicate local control.<sup>4</sup>

## OUTCOMES

Expected local control rates vary from 70% to 100% at 1 year and 60% to 90% at 2 years depending on tumor volume, prior therapy, and dose delivered.<sup>4</sup> Median OS after SBRT is on the order of 10 to 34 months, with the majority of patients experiencing metastatic spread outside the treatment field; thus, SBRT is often combined with systemic treatment in order to achieve improved OS.<sup>4</sup>

In a single-institution experience of SBRT for 74 patients ineligible for surgery (local tumor extension or patient comorbidities) and lesions not amenable to other local or systemic therapy, median local recurrence-free interval was 23 months, with 75% local control rate at 1 year; median OS was 27 months. Previous treatments had included systemic chemotherapy, resection, or other local ablative procedures, and primary sites consisted of mostly colon cancer ( $n = 37$ ) and breast cancer ( $n = 12$ ), with the remainder comprised of esophageal, stomach, pancreas, biliary, and other ( $n = 25$ ). Median dose was 35 Gy over 5 fractions and median tumor volume was 45

mL.<sup>72</sup>

A pooled analysis of SBRT in CRLM performed by Chang et al. identified 65 patients with one to four unresectable liver lesions who underwent a median dose of 41.7 Gy over 6 fractions. The majority of patients had received pretreatment chemotherapy (73%). The 12-month and 24-month OS was 72% and 38% with nearly 70% of patients experiencing progression outside the liver; the in-field local recurrence was 29% at 16-month follow-up. The authors found that 12-month and 24-month local control was 84% and 66%, respectively, for patients receiving >42 Gy versus 48% and 43%, respectively, for patients receiving <42 Gy. From the data, the authors used tumor control probability curves and suggested that 12-month local control could be achieved in 90% if delivering 46 to 52 Gy in 3 fractions; total dose, dose per fraction, and biologically effective dose correlated with local control.<sup>73</sup>

In congruence with the suggested dose of 46 to 52 Gy, a multi-institutional phase I/II study evaluated patients with one to three liver metastases (CRC and non-CRC) less than 6 cm in size and appropriate underlying liver function who underwent SBRT. Chemotherapy (in 41/47 patients) was stopped at least 14 days prior to radiation therapy and low-burden, potentially treatable extrahepatic disease was present in 21/47 patients. The phase I aspect of the study identified no toxicity when escalating from 36 Gy to 60 Gy, and the phase II study evaluated 47 patients receiving 60 Gy in 3 fractions. The majority of patients had a single lesion (28/47) while the remaining had two (7/47) or three (12/47) lesions; local control was 95% and 92% at 1 and 2 years, respectively. Lesions less than 3 cm (60% of lesions) had 2-year control of 100% versus 77% for lesions greater than 3 cm (40% of lesions). Despite the achieved local control, distant progression (distant intrahepatic and extrahepatic) occurred in 83% of patients at a median of 6 months. Median and 2-yr OS was 20.5 months and 30%, respectively, and primary tumor site was predictive of survival; lung, ovarian, and noncolorectal gastrointestinal malignancies had median OS of 12 months versus breast, colorectal, renal, carcinoid, GIST, and sarcoma, which had 32-month median OS ( $p < 0.001$ ). The SBRT was well tolerated, with one instance of grade III soft tissue toxicity. These authors emphasized the importance of higher dose and low fraction number for achieving adequate local control.<sup>74</sup>

A more recent study by Scorsetti and colleagues evaluated 61 patients

with liver metastases (colorectal [ $n = 29$ ], breast [ $n = 11$ ], gynecologic [ $n = 7$ ], melanoma/pancreatic/RCC/biliary [ $n = 14$ ]) who were not suitable for surgery, with tumor diameter less than 6 cm and number less than 3 lesions; additionally, there was no evidence of progressive disease or untreated disease outside the liver. Prescription dose was 75 Gy in 3 fractions, although this was not possible in 18% of patients due to organs at risk (received 52.5-67.5 Gy). Local control rates were 90.6% at 2 years with no difference between patients with lesions  $<3$  cm versus  $>3$  cm. These authors concluded that at higher doses, effective treatment can be accomplished in lesions 3 to 6 cm in size, which provides an advantage for local control over many other ablative techniques.<sup>71</sup>

Although there are numerous additional retrospective and prospective analyses of SBRT in liver metastases, there is significant heterogeneity in primary tumor sites, extent of extrahepatic disease burden, prior treatments received, and dose/fractions of SBRT.<sup>75-82</sup> Furthermore, there is a paucity of investigations comparing SBRT to alternative modalities. Currently, there is a multicenter randomized phase III trial evaluating patients with one to four inoperable colorectal liver metastases no larger than 4 cm in size who are randomized to RFA or SBRT (The International Liver Tumor Group RAS-Trial Radiofrequency Ablation versus Stereotactic Body Radiation Therapy for Colorectal Liver Metastases: A Randomized Trial [RAS01 Clinical Trials.gov, available at <https://clinicaltrials.gov/ct2/show/NCT01233544?term=ras01&rank=1>]). The primary endpoint is local PFS, and this trial should provide additional information regarding the therapeutic role of SBRT in liver metastases. Currently, SBRT appears to be a safe and effective modality for local control, even to lesions of 6 cm in size.

## INDICATIONS

Similar to other modalities used to treat liver metastases, the determination of SBRT treatment of liver tumors should be made in a multidisciplinary tumor board discussion. Patients suitable for treatment include those with four or fewer lesions, diameter up to 6 cm (advantage of this modality over RFA and MWA), and greater than 8 mm from organs at risk. Patients generally have a good performance status with absent or stable extrahepatic disease as well as healthy underlying liver function (total bilirubin  $<1.5 \times$  upper limit normal, albumin  $>3$  g/dL, transaminases  $<1.5 \times$  upper limit normal, normal INR) and

adequate hepatic volume.<sup>9</sup> Those with five or more lesions, lesions greater than 6 cm diameter, poor underlying liver function (Child C), insufficient liver volume, or tumor location less than 5 mm from organs at risk are not candidates for SBRT.<sup>9</sup> SBRT has been utilized for numerous primary tumors metastatic to the liver including colorectal, breast, carcinoid, lung, melanoma, gallbladder, ovarian, esophageal, and pancreatic cancer.<sup>9</sup> While OS varies between the primary sites, effective local control has been demonstrated irrespective of malignant primary.<sup>74</sup> In general, smaller tumor volumes are associated with improved local control; additional positive prognostic factors include higher delivered dose, longer disease-free interval, absence of chemotherapy, and adenocarcinoma histology.<sup>67</sup>

## COMPLICATIONS

Most series report Common Terminology Criteria for Adverse Events (CTCAE) grade III or IV toxicity complicating approximately 1% to 10% of liver SBRT.<sup>67</sup> Tumor size and treatment dose are important considerations in order to avoid RILD, which is a result of injury to surrounding healthy liver parenchyma when radiating the hepatic metastases. This complication more commonly occurs in patients with HCC due to the diffusely dysfunctional state of liver parenchyma. In the setting of liver metastases, RILD is rare (<1%), although most series reporting complications have performed SBRT on single metastases.<sup>67</sup> In addition, it has been shown that grade II or higher hepatobiliary toxicity can be avoided when at least 700 mL of liver volume receives less than 21 Gy; therefore, to avoid hepatobiliary toxicity, mean recommended liver radiation dose is 15 Gy with at least 700 mL of liver receiving less than 15 Gy over 3 to 5 fractions.<sup>68</sup>

Other known complications include duodenal ulceration and intestinal perforation; for this reason, ideal locations of SBRT-treated lesions are greater than 8 mm away from visceral organs at risk.<sup>9</sup> In addition, soft tissue toxicity and nontraumatic rib fractures can occur for lesions close to subcutaneous tissue and ribs.<sup>9</sup> Grade I to II toxicity can include fatigue (up to 20%), nausea/vomiting (15%-20%), fever (5%-10%), abdominal pain (5%-10%), skin reaction (5%), and pneumonitis (1%-2%).<sup>72</sup>

## Irreversible Electroporation

Electroporation is characterized by increasing cell permeability achieved through the application of electrical fields across cells, with consequent cell membrane defects that are either temporary (reversible electroporation) or permanent (irreversible electroporation).<sup>83</sup> Reversible electroporation has been utilized extensively as a method to introduce genetic material into cells in vitro.<sup>84</sup> By employing larger electrical fields for longer duration, the cell membrane pores do not reseal and thus the process becomes irreversible, ultimately resulting in disruption of cell homeostasis and cell death.<sup>85</sup> Early studies in animal models focusing on liver ablation identified a well-demarcated nonthermal ablation zone (very narrow transition) confined between the electroporation electrodes; this zone consisted of discriminate cell death and sinusoidal blood vessel congestion while larger vascular structures and bile ducts remained intact.<sup>85</sup> When considering IRE protocols, multiple parameters may be manipulated to achieve optimal cell death including pulse shape, duration, number, polarity, electrode configuration, and geometry.<sup>85</sup> In addition, although IRE was first described for patients with prostate cancer, subsequent studies have evaluated its efficacy in pancreatic cancer, renal cell carcinoma, lung malignancies, and hepatic malignancies.<sup>86</sup>

## **TECHNIQUE**

Meticulous treatment planning is an essential aspect for delivery of successful IRE therapy. Factors such as electrode position and number, electric field amplitude, and pulse duration, number, and frequency are evaluated for nonthermal ablation of target tissue.<sup>86</sup> Treatment planning is based upon preoperative imaging (CT) to determine tumor dimensions and morphology. This will allow calculation of number and spacing of probes.<sup>87</sup> IRE image guidance (US, CT, and MRI) can be used for electrode positioning as well as to monitor the ablation procedure and the ablation zone.<sup>84</sup> In the liver, the ablated region is sharply demarcated on imaging which has excellent correlation to the histologic actual ablation zone (initially hypoechoic on ultrasound with transition to hyperechoic in 24 hours; hypoattenuating core with hyperattenuating rim on CT at 48 hours).<sup>86</sup>

Patients undergo general anesthesia with deep sedation and complete muscle relaxation; additionally, monitors and synchronization devices are

used in order to synchronize the pulse delivery with simultaneous electrocardiography.<sup>88</sup> Delivery of the pulses from the IRE device occur during the refractory period (approximately 50 msec after R-wave) to avoid arrhythmia genesis. Image guidance is generally achieved with CT guidance or ultrasound, either transabdominal if performing percutaneous ablation or intraoperative ultrasound when performing laparoscopic or open ablation. The radiopaque insulated needle electrodes (20 mm exposure length) are 15 cm or 25 cm in length and are placed around the periphery of the tumor in parallel configuration (they must be placed within 10° of parallel to avoid treatment failure) with approximately 20 mm distance between each electrode.<sup>89</sup> Pulsatile electric fields (1000-3000 V/cm) with variable pulse number (typically 90-100) and duration (approximately 20-100 msec) are applied; these parameters are determined by a standard algorithm incorporating factors such as size of ablation zone, number of probes, and distance between probes.<sup>89,90</sup> For larger tumors, the electrodes are pulled back 1.5 cm to continue ablation of the superficial component after ablating the deep aspect of the tumor, and an additional margin of 1 cm around the tumor is generally included.<sup>89</sup>

Follow-up imaging is obtained within 2 weeks in order to evaluate for changes associated with treatment as well as potential complications such as portal vein thrombosis. Subsequently, cross-sectional imaging is obtained at 3-month intervals.

## **OUTCOMES**

The COLDFIRE-1 ablate-and-resect study evaluated ten patients with at least one resectable CRLM smaller than 3.5 cm who underwent open IRE followed by resection of the treated lesion. Patients were excluded if they had cardiac arrhythmias, pacemaker in place, epilepsy, or previous treatment of the lesion(s). At least 1 hour after IRE, the lesion was resected and evaluated. Median lesion size was 2.4 cm and mean ablation time was 25 minutes with IRE delivery time of 182 seconds. One IRE-related adverse event occurred (ventricular extrasystole), which resolved without issue. Histologic evaluation revealed a well-demarcated ablation zone encompassing tumor with preservation of traversing larger portal and arterial and venous vasculature as well as bile ducts. Complete ablation occurred in 9/10 tumors and ultrasound correlated well with ablation margin.<sup>89</sup>

Eisele and colleagues reported the feasibility and success of ultrasound-guided IRE in 13 patients with 14 unresectable liver tumors (colorectal liver metastases [ $n = 6$ ], HCC [ $n = 5$ ] or cholangiocarcinoma [ $n = 2$ ]) and small centrally located tumors. IRE was performed instead of RFA or MWA in cases of tumor proximity to major vessels (portal or hepatic veins; average tumor size 1.5 cm). Seven patients underwent percutaneous ablation, four patients had laparoscopic ablation, and two patients had concomitant open ablation with hepatic resection. There were no treatment-related complications, and local recurrence related to incomplete ablation occurred in 3/14 tumors (all failures in percutaneous) at a median of 6 months follow-up. The authors commented on the difficult location of tumors (adjacent to major vessels), which provided hesitancy to employ MWA or RFA and therefore IRE was advantageous. They suggested adjunct cross-sectional imaging for needle placement to avoid failures during percutaneous IRE ablation.<sup>88</sup>

Kingham et al. retrospectively evaluated 28 patients undergoing IRE to treat 65 tumors (CRLM 75%, HCC 7%, NET 7%, other 11%) in which the majority were located within 1 cm of a major hepatic vein or major portal pedicle. Median tumor size was 1 cm and percutaneous approach was used in 6/28 patients while laparotomy was used in 22/28 patients. There were three local recurrences and one persistent tumor for a consequent 7.5% local failure rate. The authors concluded that the low treatment failure rate given the tumor location was encouraging.<sup>90</sup>

One of the larger series on IRE was performed by Cannon and colleagues. Forty-four patients underwent 48 IRE procedures for centrally located tumors (CRLM [ $n = 20$ ], HCC [ $n = 14$ ], non-small cell lung carcinoma (NSCLC) [ $n = 2$ ], breast [ $n = 2$ ], NET [ $n = 3$ ], other [ $n = 3$ ]) adjacent to major vascular or biliary structures or nearby organs. Percutaneous approach was used in 63% with laparoscopic in 5% and laparotomy in 32%; complete ablation was achieved in 100% of patients. A total of nine adverse events occurred but no treatment-related deaths or biliary stricture/portal vein thrombosis. Local recurrence-free survival was 94.6% and 59.5% at 6 months and 12 months, respectively, while local recurrence-free survival for lesions <3 cm was 100% and 98% at 6 months and 12 months, respectively. Although 72% of patients had received prior treatment (chemotherapy in 60%, liver-directed therapy in 55%), IRE was quite effective for lesions less than 3 cm. The authors concluded that IRE appears best suited for salvage therapy or for tumor location precluding alternative therapies in tumors <3 to 4 cm in diameter.

With accumulating experience, factors such as patient selection, technique (probe number and placement), and image guidance improvement will allow further delineation of the role of IRE.<sup>87</sup>

## **INDICATIONS**

One of the putative benefits of IRE is the ability to produce tissue ablation even in proximity of large vessels (or traversing the ablation zone) without a heat-sink effect.<sup>85</sup> IRE-ablation of liver tissue adjacent to structures such as hepatic arteries, hepatic veins, portal veins, and intrahepatic bile ducts results in preservation of these critical structures.<sup>84,86</sup> Therefore, IRE can be utilized for local ablation of unresectable tumors adjacent to major vascular or biliary structures and has even been used as an adjunct to facilitate extended resection (margin ablation) when location adjacent to vasculature precludes R0 resection.<sup>91</sup> However, IRE has only recently been utilized (since 2007) for treatment of malignant disease, and therefore specific indications remain in evolution.

## **COMPLICATIONS**

IRE requires general anesthesia with paralysis due to prominent muscle contraction from the electrical field. In addition, IRE can produce cardiac arrhythmias, and therefore patients with structural or functional cardiac disease would be highly susceptible; this can be offset by utilization of a cardiac synchronization device such that IRE can only be performed during the non-vulnerable period of the cardiac cycle.<sup>84</sup> Incomplete ablation can arise in the setting of difficult electrode placement. The distance between the electrodes must remain precise and the parallel configuration must also be maintained in order to accomplish the projected ablation zone.<sup>88</sup> Additional considerations include abdominal pain, hemorrhage, hematoma, and infection.<sup>90</sup>

## **CONCLUSIONS**

Treatment of hepatic tumors and metastatic liver disease has evolved significantly due to the various therapeutic options currently available. While

resection (or transplantation) is generally considered the standard, there are many tumor features and patient characteristics that prohibit these options. Therefore, in the setting of local disease, RFA, MWA, and SBRT can achieve local control, with potential applications for IRE. With locoregional disease, transarterial-directed therapy including chemoembolization and radioembolization have gained recognition as treatment options even in patients with severe comorbidities or advanced stage disease. Although investigations are attempting to better delineate the role of each of these modalities in primary and secondary liver tumors, the variability in patient and tumor characteristics highlights the necessity for careful patient and treatment selection in a multidisciplinary setting.

# PERSPECTIVE ON LIVER RESECTION

*Jordan M. Cloyd • Timothy M. Pawlik*

## INTRODUCTION

Liver resection for benign and malignant conditions has evolved significantly over the past 2 decades. Moreover, considerable interest in the field of liver surgery has led to an increase in the number of surgeons subspecializing in hepatobiliary surgery. This interest has brought significant innovation and evolution to the field including new technologies in minimally invasive approaches, expanded indications for patients with liver metastases, and the ability to plan and perform more complex resections. At the same time, improvements in patient selection, liver function assessment, and perioperative care have significantly improved the safety of liver resection at experienced tertiary centers. The concepts and principles of liver surgery are expertly reviewed in [Chapters 56](#) (Hepatic Abscess and Cystic Disease of the Liver) and [57](#) (Benign Liver Neoplasms). Herein, we provide a perspective on recent advances in the field of liver resection, their impact on patient outcomes, and where future developments are anticipated.

# PATIENT SELECTION AND OPTIMIZATION

## Indications for Resection

Although the majority of liver resections today are performed for malignant indications, hepatobiliary surgeons should be familiar with the management of benign conditions as well (Table 60-1). Benign simple cysts can typically be characterized with cross-sectional imaging and do not require resection unless they are symptomatic (unusual unless >10 cm) or contain features worrisome for biliary cystadenoma or cystadenocarcinoma. In the former (simple cyst), laparoscopic fenestration is the preferred treatment, whereas in the latter, formal resection or enucleation should be performed. One notable and frequent cause of liver cystic disease globally is echinococcal or hydatid cyst. Surgical resection of the cyst-bearing area of the liver or operative drainage of the cyst (to ensure prevention of spillage and potential anaphylactic shock) is occasionally required. Despite improvements in antimicrobial therapy and percutaneous aspiration and drainage techniques, the need for occasional surgical management of nonechinococcal hepatic abscesses remains. Finally, hepatic adenomas are benign tumors of the liver that have a low rate of malignant transformation and risk of rupture that increases with size, pregnancy, and location of the tumor. Most authors therefore recommend resection of lesions >5 cm or in women of childbearing age with tumors at risk for rupture. Hemangiomas and focal nodular hyperplasias are benign conditions that do not require resection (or surveillance) unless they are symptomatic, which, in general, is rare.

**TABLE 60-1: INDICATIONS FOR LIVER RESECTION**

	Common	Uncommon
Infectious		Pyogenic abscess Echinococcal abscess Parasitic abscess Chronic hepatolithiasis
Benign	Living-related transplantation Trauma	Simple cyst, <sup>a</sup> biliary cystadenoma Strictures/fistulae, choledochal cyst Focal nodular hyperplasia, <sup>a</sup> hemangioma, <sup>a</sup> hepatic adenoma
Malignant-primary	Hepatocellular carcinoma Cholangiocarcinoma Gallbladder cancer	Hepatoblastoma Angiosarcoma Epithelioid hemangioendothelioma Biliary cystadenocarcinoma
Malignant-secondary	Colorectal liver metastases Neuroendocrine liver metastases	Other liver metastases (eg, breast, sarcoma, genitourinary, gastrointestinal) Tumors directly invading liver (eg, adrenal, retroperitoneal sarcoma)

<sup>a</sup>Symptomatic only.

However, the vast majority of liver resections performed by experienced hepatobiliary surgeons are for malignant indications. Although hepatocellular carcinoma (HCC) is one of the most common solid tumors worldwide, only a minority of patients are candidates for resection because of either poor underlying liver function or advanced disease (eg, multifocality, extrahepatic disease, macrovascular invasion). Unlike HCC, cholangiocarcinoma more commonly develops in patients with normal liver function. Resection of cholangiocarcinomas often requires extended resections with or without biliary reconstruction but is nevertheless recommended in patients with adequate liver function and absence of metastatic disease. Similarly, most liver metastases occur in patients with normal liver function, and colorectal liver metastases (CRLM) are now the most common indication for liver resection among Western hepatobiliary surgeons. Largely based on nonrandomized prospective and retrospective data, liver resection for CRLM when feasible has become largely accepted as standard of care given its association with improved survival rates. Other liver metastases from various histologies, for example, neuroendocrine liver metastases, are also regularly considered for surgical resection.

## Patient Selection

Although advances in perioperative anesthesia, minimally invasive surgery, parenchymal transection techniques, and enhanced recovery protocols have been instrumental, patient selection is paramount to optimizing postoperative outcomes following liver resection. In general, patient selection for liver surgery should be conducted along 3 domains: physiologic, oncologic, and

technical. Physiologic resectability refers to the patient's capacity to safely tolerate major abdominal surgery. Multiple risk calculators, frailty indices, and other measures have recently been developed to identify patients at highest risk for major complications.<sup>1,2</sup> Next, oncologic resectability refers to the indications for resection based on the underlying tumor biology. Consideration should be given to the presence of extrahepatic disease, the histopathologic features, disease-free interval (for liver metastases), response to previous therapies (if applicable), and, increasingly, the molecular features of the tumor. Finally, technical resectability should be evaluated based on high-quality cross-sectional imaging. In general, resectability requires retention of 2 contiguous liver segments with adequate vascular inflow, outflow, and biliary drainage as well as sufficient future liver remnant (FLR) volume and function to prevent postoperative hepatic insufficiency (PHI).

Accurate preoperative assessment of the FLR has been one of the most important advances over the past 2 decades, leading to improved risk stratification as well as prevention of PHI and postoperative mortality. Since FLR volume correlates with function and the risk of PHI, a systematic analysis of liver volumetry is imperative in patients undergoing extended hepatectomies or those with compromised liver function. Previous studies have identified FLR size thresholds at which the risk of PHI is prohibitively high: <20% in chemotherapy-naïve patients, <30% in chemotherapy-treated patients, and <40% to 50% in patients with cirrhosis.<sup>3</sup> In addition to volumetry, several modalities now aim to directly estimate liver function. For example, since indocyanine green (ICG) is exclusively cleared by the liver, the ICG clearance test is useful because the retention rate at 15 minutes has been correlated with postoperative mortality.<sup>4</sup> In addition, <sup>99m</sup>Tc-galactosyl human serum albumin (GSA) scintigraphy, which uses an analogue ligand of asialoglycoprotein that binds to asialoglycoprotein receptors on the hepatocyte cell membrane, has recently been introduced as a more sensitive indicator of liver function and, when combined with single-photon emission computed tomography (SPECT)/computed tomography (CT), can directly estimate function of the FLR.<sup>5</sup>

## **EXPANDING INDICATIONS FOR LIVER RESECTION**

## FLR Augmentation

Limiting liver resection to patients with adequate FLR volume and function is essential to minimizing postoperative morbidity and mortality. Nevertheless, for patients with inadequate FLR by volumetric analysis, advances in FLR augmentation strategies have expanded the proportion of patients eligible for complex liver resection. Portal vein embolization (PVE) diverts portal blood flow and its inherent growth factors preferentially to the FLR, resulting in 30% to 40% hypertrophic response in most patients.<sup>6</sup> PVE is most frequently used among patients undergoing extended right hepatectomy or as part of a 2-stage hepatectomy (TSH) strategy.<sup>7</sup> While various techniques have been described, PVE should be performed in a transhepatic, ipsilateral fashion using microsphere particles and can be extended to segment IV when extended hemihepatectomy is planned.<sup>8</sup> Among patients who do not achieve an adequate degree of hypertrophy (DH), hepatic vein embolization has been described as a method of promoting additional hypertrophy.<sup>9</sup>

TSH allows for the resection of bilobar CRLM that would otherwise be unresectable using a single-stage technique. In the first stage, the FLR (typically the left lateral section) is cleared of metastatic disease. One to 4 weeks after surgery, a right PVE is performed, which leads to hypertrophy of the FLR. In patients who demonstrate adequate hypertrophy on CT volumetry 3 to 4 weeks after PVE, as well as absence of disease progression, a second-stage operation (typically right or extended right hepatectomy) is performed. TSH with PVE has consistently demonstrated high completion rates, low perioperative morbidity and mortality rates, and excellent overall survival outcomes in experienced centers.<sup>10</sup>

The associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) procedure has been introduced as an alternative to traditional TSH.<sup>11</sup> In the first stage of ALPPS, right portal vein ligation is combined with parenchymal transection and clearance of the FLR of metastatic disease. The second stage is performed during the same hospital admission 1 to 2 weeks after the first stage and involves completion hemihepatectomy. Although ALPPS results in rapid FLR hypertrophy and higher completion rates compared to traditional TSH, concerns remain over the relatively high postoperative morbidity and mortality as well as uncertain long-term oncologic outcomes.<sup>12</sup>

It is also important to recognize that the liver's response to PVE provides an estimation of the FLR's regenerative capacity. For example, patients who experience an absolute DH of <5% have significantly elevated risks of PHI and postoperative mortality.<sup>13</sup> In addition, a kinetic growth rate (KGR), measured as the DH divided by the number of weeks since PVE, less than 2% is one of the strongest predictors of PHI.<sup>14</sup> Using a traditional TSH approach, the response of the liver to PVE can be measured and second-stage surgery (and its inherent morbidity) avoided in patients with inadequate FLR and/or demonstrated regenerative capacity. Given the high rates of PHI and postoperative mortality following second-stage ALPPS, mostly among patients with an FLR >30%, better predictors of PHI are urgently needed. Recent evidence suggests that KGR<sup>15</sup> and hepatobiliary scintigraphy with SPECT/CT<sup>16</sup> can accurately identify patients at higher risk for PHI following second-stage ALPPS.

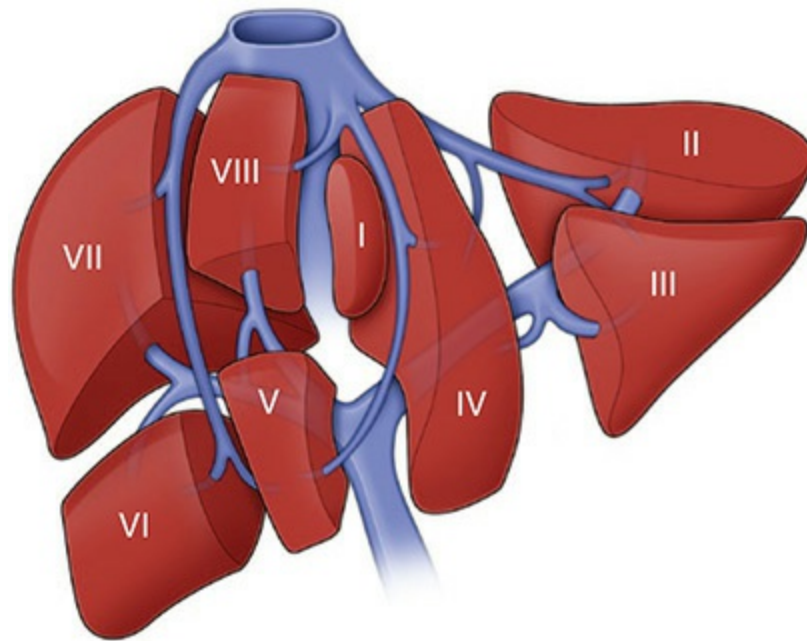

## **Repeat Hepatectomy**

As systemic therapies improve and survival durations increase, the proportion of patients who develop hepatic recurrence will only increase. This is especially true among patients with CRLM in whom the recurrence rate following liver resection approaches 50%. However, multiple retrospective series have demonstrated the feasibility, safety, and oncologic outcomes of patients undergoing repeat hepatectomy.<sup>17</sup> In general, similar outcomes can be expected in these situations as long as a similar approach to patient selection, optimization, and resection techniques is employed. A trend in recent years has been an emphasis on parenchymal sparing approaches—that is, performing nonanatomic resections or minor anatomic resections (eg, segmentectomy, bisegmentectomy) rather than hemihepatectomies. Indeed, parenchymal sparing hepatectomy allows for the opportunity for repeat hepatectomy in the case of future liver recurrence without compromising margin-negative rates or oncologic outcomes compared to traditional approaches.<sup>18</sup>

## **ADVANCES IN RESECTIONAL TECHNIQUES**

## Definitions and Terminology

Advances in hepatobiliary techniques have permitted complex liver resections to be performed at experienced centers while minimizing the risk of perioperative complications. Much of this advancement can be attributed to an improved understanding of segmental liver anatomy. Couinaud<sup>19</sup> originally described the 8 segments of the liver, each with its own segmental portal pedicle, separated into 4 sectors based on 3 portal scissura marked along the path of the hepatic veins (Fig. 60-1). Since the left hepatic vein divides segments II and III, this partitions the left liver into a left paramedian sector (IV, III) and left lateral sector (II). The Brisbane terminology reclassified the liver into more surgically relevant *sections*,<sup>20</sup> which is important given that en bloc resection of segments IV and III cannot be technically performed while leaving segment II in situ. In this description, the left medial section (IVa and IVb) is distinct from the left lateral section (segment II and III), whereas the right liver sectors and sections are concordant. This standardized classification informs the terminology used today to describe common partial liver resections (Table 60-2).

**FIGURE 60-1** The functional division of the liver and the segments according to Couinaud's nomenclature.

**TABLE 60-2: COMMON DEFINITIONS OF LIVER RESECTIONS BASED ON BRISBANE TERMINOLOGY<sup>20</sup>**

<b>Definition</b>	<b>Couinaud's Segments Removed</b>
Extended resections (trisectionectomy)	
Extended right hepatectomy	VIII, VII, VI, V, IV
Extended left hepatectomy	II, III, IV, V, VI
Hemihepatectomy	
Right hepatectomy	VIII, VII, VI, V
Left hepatectomy	II, III, IV
Bisegmentectomy	
Right posterior sectorectomy	VI, VII
Right anterior sectorectomy	V, VIII
Left lateral sectionectomy	II, III
Segmentectomy	Any (I-VIII)
Other	
Central hepatectomy	IV, V, VIII
Wedge resection	Any (nonanatomic)

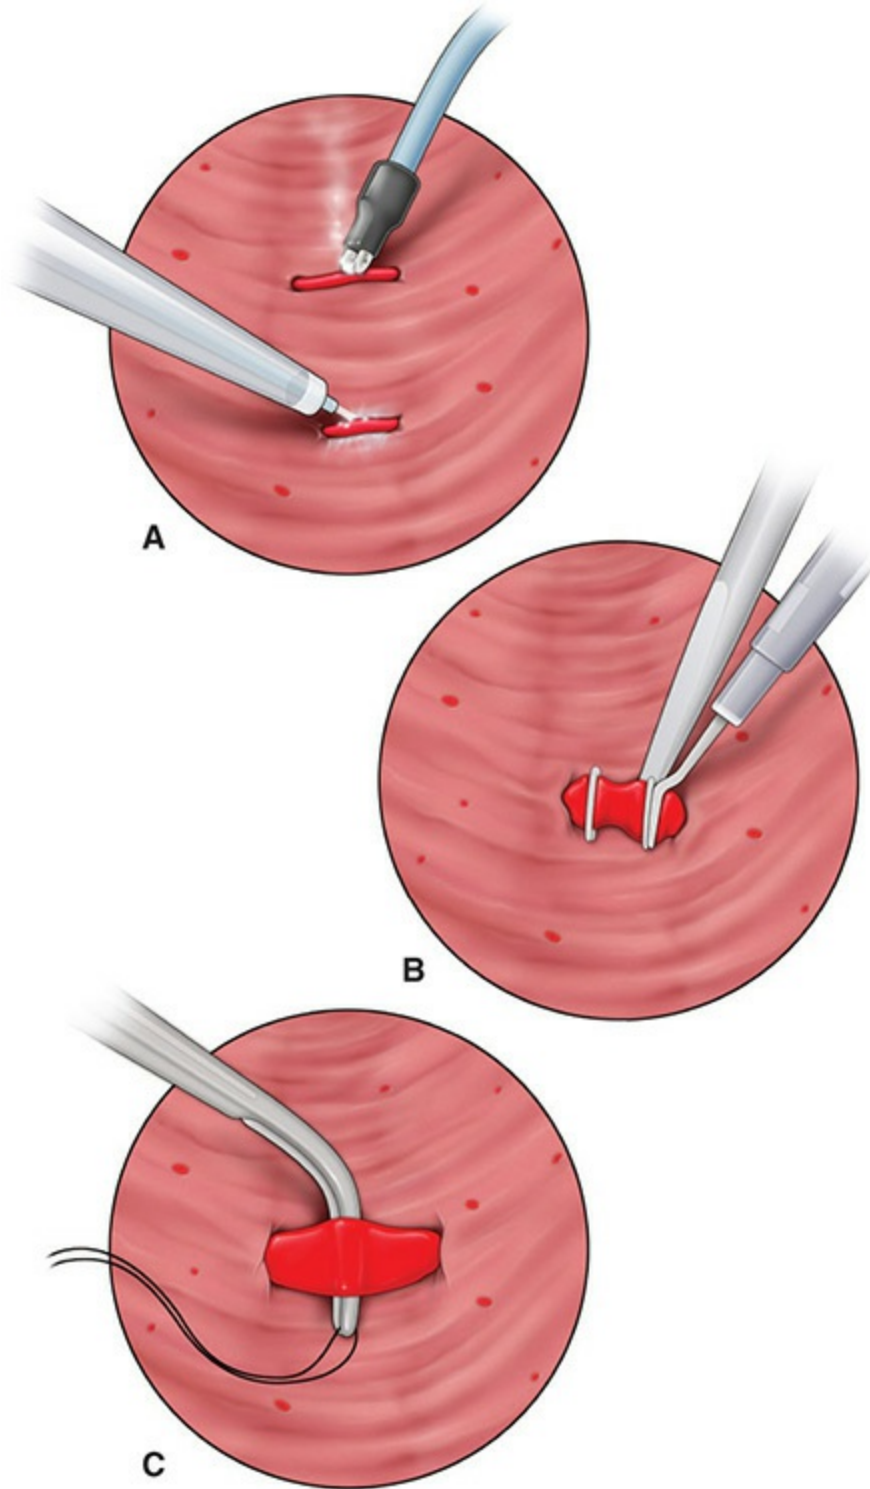

Additional confusion occasionally ensues regarding the terminology used in classifying major and minor resections. By definition, major resections include  $\geq 3$  segments, whereas minor resections involve  $< 3$  segments. This designation does not imply complexity, however, as most would argue that a left hepatectomy (major) is technically less demanding than a right posterior sectorectomy (minor). The term *parenchymal-sparing hepatectomy* (PSH) refers to the concept of preserving noninvolved liver tissue. Whereas the term *wedge resection* connotes a nonanatomic minor resection, the term PSH does not imply whether the resection was anatomically based or not.

## **Surgical Technique**

With this knowledge and consistent with an emphasis on parenchymal-sparing techniques, most minor anatomic resections can be performed with early ultrasound-guided control of the intraparenchymal segmental pedicle

(eg, Glissonian method). This maneuver allows for parenchymal transection along the line of demarcation, as is typically done for major hepatectomy following extrahepatic inflow division. Alternatively, the segmental pedicle(s) can be injected with dye (eg, ICG or blue dye) for counterstaining followed by parenchymal transection and division of the portal pedicle(s). Regardless of methods, parenchymal-sparing anatomic resections result in less blood loss compared to nonanatomic wedge resections and may be associated with reduced recurrence rates in HCC<sup>21</sup> and CRLM.<sup>22</sup>

Randomized controlled trials have suggested no difference between methods of parenchymal transection, which, in general, should be determined by the expertise of the surgeon.<sup>23</sup> While some prefer a traditional crush-clamp technique, it is the authors' preference to use a "2-surgeon" technique where the surgeon dissects using the Cavitron Ultrasonic Surgical Aspirator and an assistant provides exposure and divides vessels.<sup>24</sup> In general, small vessels <3 mm can be divided using electrocautery, medium vessels are controlled with titanium clips, and larger vessels >5 mm are divided between suture (Fig. 60-2). Caution should be given to overuse of linear staplers for parenchymal transection because, although simple and efficient, the technique is relatively "blind" and may lead to inadvertent biliary or vascular injury.

**FIGURE 60-2** The technique for vascular control during parenchymal transection is based on vessel size. **A.** Vessels less than 3 mm are coagulated and divided using saline-linked cautery. **B.** Vessels from 3 to 5 mm are controlled with titanium clips and sharply divided. **C.** Vascular structures

larger than 5 mm are controlled with 3-0 silk ties and sharply divided.

Controversy continues regarding the role of perioperative drains following liver resection. In general, the routine use of surgical drains following liver resection is not warranted and may be associated with increased complications.<sup>25</sup> Awareness of risk factors for biliary fistula (eg, biliary anastomosis, major liver resection, increased blood loss) may allow for more selective use of drains. It should be noted, however, that in randomized controlled trials, the use of a surgical drain does not decrease the need for subsequent percutaneous drainage. One recent advance in the prevention of postoperative biliary fistula is the performance of an air leak test following parenchymal transection.<sup>26</sup> With the resection surface immersed under water and the surgeon's hand manually compressing the duodenum, a transcystic cholangiogram catheter introduces air into the biliary system. Bubbles along the cut surface identify the location of biliary leaks, which can be controlled with suture.

## Minimally Invasive Surgery

Advances in minimally invasive techniques have permitted the extension of many of the benefits of minimally invasive surgery to be applied to patients undergoing liver resection. Although randomized controlled trials have not been performed, multiple retrospective case-control studies suggest that minimally invasive approaches are associated with similar margin-negative resection rates and oncologic outcomes.<sup>27</sup> Moreover, laparoscopic liver resection is associated with less intraoperative blood loss, lower transfusion rates, and less opioid use as well as shorter length of hospital stay.<sup>28</sup> Nevertheless, a significant learning curve exists as surgeons must be proficient in both open hepatobiliary surgery as well as advanced minimally invasive skills. Surgeons early in their learning curve will likely select patients with tumors in more favorable segments (II, III, IVb, V, and VI). As their experience progresses and skills improve, major hepatectomies and minor hepatectomies located in the posterosuperior segments (I, IVa, VII, and VIII) can be undertaken (Fig. 60-3). Minimally invasive liver resection can be performed either laparoscopically or robotically depending on the comfort and experience of the surgical team.

**FIGURE 60-3** Favorable and unfavorable liver segments for minimally invasive hepatectomy. (Reproduced with permission from Guro H, Cho JY, Han HS, et al: Current status of laparoscopic liver resection for hepatocellular carcinoma, *Clin Mol Hepatol*. 2016 Jun;22(2):212-218.)

## IMPROVEMENTS IN PERIOPERATIVE OUTCOMES

Several recent reports have demonstrated significant improvements in perioperative outcomes over time at experienced hepatobiliary centers. For example, at the Memorial Sloan-Kettering Cancer Center, the 90-day mortality rate decreased from 5.0% to 1.6% and morbidity rates decreased from 53% to 20% over the past 2 decades.<sup>29</sup> The authors considered much of this improvement to be the result of a decrease in the proportion of patients undergoing major hepatectomy. On the other hand, a similar decrease in postoperative morbidity and mortality has been observed over time at the University of Texas MD Anderson Cancer Center but with concomitant increases in case complexity (unpublished data). Emerging evidence suggests that minimizing postoperative complications is important for optimizing patient-centered outcomes, returning patients expeditiously to intended

oncologic therapy, and potentially reducing recurrence rates.<sup>30-32</sup> Significant volume-outcomes relationships have been observed in hepatobiliary surgery, and in general, major liver resections should be performed at high-volume experienced centers.

The factors contributing to improved perioperative outcomes are multifactorial. Patient selection and optimization, as discussed earlier in the chapter, are paramount. Anesthetic considerations are also important. Low central venous pressure (CVP) anesthesia is a central tenet for performing safe liver resection. Efforts at reducing intraoperative blood loss and perioperative transfusions are imperative as both are associated with increased complications and higher recurrence rates. In general, among patients with normal liver function who are receiving low-CVP anesthesia and meticulous surgical technique, the need for blood transfusion should be relatively rare. The quality of surgery is also important because remnant liver ischemia (RLI), which can occur via inadvertent vascular injury or imprecise surgery that leaves nonperfused liver tissue, is associated with perioperative complications as well as worse recurrence-free survival.<sup>33-35</sup> Finally, established postoperative care pathways, including enhanced recovery protocols, are associated with high patient satisfaction and reductions in hospital length of stay.<sup>36</sup> Multimodal analgesia is an important component of postoperative pathways because good pain control is associated with improved pulmonary function and reduced complications after hepatectomy.<sup>37</sup>

## MULTIDISCIPLINARY CARE

A major emphasis in the management of patients with benign and malignant liver diseases is the implementation of specialized multidisciplinary care. Patients with liver pathology and those under consideration for liver resection are best served by multidisciplinary evaluation from dedicated hepatobiliary surgeons, transplant surgeons, hepatologists, medical oncologists, radiation oncologists, radiologists, pathologists, and interventional radiologists. Advances in these fields have accompanied the myriad improvements observed in liver resection over the past several decades.

## Chemotherapy

Improvements in survival for patients with CRLM are largely due to advances in systemic chemotherapy effective at treating colorectal cancer. Modern-day chemotherapy regimens using fluorouracil with either oxaliplatin or irinotecan are effective at downstaging some unresectable liver metastases to resectable.<sup>38</sup> Newer targeted agents, such as the EGFR inhibitors cetuximab and panitumumab, may facilitate an even greater response among patients with *KRAS* wild-type tumors.<sup>39,40</sup> Effective chemotherapy is critical for ensuring that systemic control of disease has been achieved (or is at least achievable) prior to performing major liver surgery. In addition, maintenance chemotherapy may allow relatively indolent stages of metastatic disease (eg, low volume lung or nodal metastases) to be controlled such that aggressive surgical resection can be focused on CRLM, which tends to be the most dominant factor in patient prognosis.

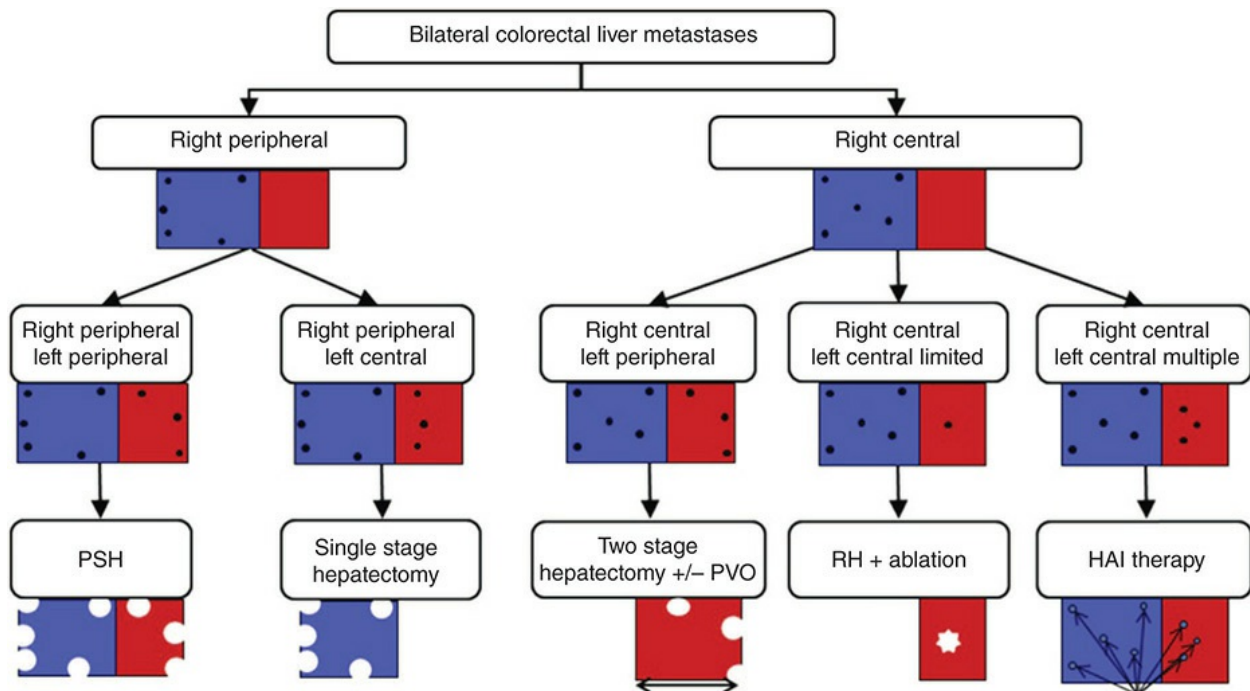

The routine use of preoperative systemic chemotherapy for *resectable* CRLM remains somewhat controversial. Although the European Organization for Research and Treatment of Cancer (EORTC) 49083 randomized controlled trial demonstrated a 9% improvement in progression-free survival among patients with resectable CRLM who received perioperative chemotherapy,<sup>41</sup> given the absence of an overall survival benefit, many centers continue to recommend surgery alone, especially for patients with favorable prognostic features (eg, *KRAS* wild type, solitary lesion, metachronous). Two important principles regarding liver resection following chemotherapy are worthy of mention. First, rates of chemotherapy-associated liver injury (CALI) and PHI significantly increase after 6 cycles (ie, 12 weeks) of chemotherapy, so direct and frequent communication among surgeons and medical oncologists is imperative.<sup>42</sup> Second, a subset of patients who receive preoperative chemotherapy will have a complete radiographic response leading to the so-called “disappearing liver metastasis.” Since a significant proportion of these lesions still harbor occult microscopic disease and many will eventually recur, surgical resection of disappearing metastases is typically recommended when feasible.<sup>43</sup>

Given the lack of effective systemic options, the routine use of preoperative chemotherapy is not indicated for primary liver cancers, although combination gemcitabine/cisplatin can downstage unresectable cholangiocarcinoma to resectable in a minority of cases. Regarding

noncolorectal liver metastases (eg, breast, genitourinary, sarcoma), the demonstration of favorable tumor biology via a positive radiographic response in the metastasis or at least stability of disease will identify patients most likely to benefit from liver resection. Ultimately, the long-term outcomes of liver resection will depend on availability of effective nonsurgical therapies.

## **Liver-Directed Therapies**

A surge in the availability and efficacy of liver-directed therapies has improved the multidisciplinary care of patients with primary and metastatic liver cancers, resulting in improved outcomes for patients with both resectable and unresectable liver tumors. For example, transarterial chemoembolization (TACE) is now commonly employed for downstaging and bridging patients with HCC to liver transplantation,<sup>44</sup> whereas hepatic arterial infusion therapy with implantable pumps can successfully downstage patients with initially unresectable CRLMs.<sup>45</sup> In addition, nonsurgical techniques (eg, ablation) are frequently combined with surgical resection as part of a comprehensive multidisciplinary treatment strategy for bilobar CRLM (Fig. 60-4). At the same time, the availability of effective nonsurgical options, such as TACE, ablation, or radioembolization with yttrium-90, has permitted the careful selection of patients with HCC most likely to benefit from safe surgical resection (eg, Child A with preserved liver function or Barcelona Clinic Liver Cancer stage 0). Finally, liver-directed therapies are critical for treating recurrent liver tumors not amenable to repeat hepatectomy. Combined with effective systemic chemotherapy, these therapies can contribute to extended overall survival durations even for patients with recurrent unresectable disease.

**FIGURE 60-4** A systematic algorithm for assessing the distribution and extent of bilateral colorectal liver metastases that informs operative treatment strategy. Each scenario is modeled with the right liver in blue (representing approximately 65% of total liver volume) and the left liver in red (representing approximately 35% of total liver volume). Tumors are represented as closed circles, parenchymal sparing resections as open circles, and ablations as open stars. HAI, hepatic arterial infusion; PSH, parenchymal sparing hepatectomy; PVO, Portal vein occlusion; RH, right hepatectomy. (Reproduced with permission from Cloyd JM, Aloia TA: Hammer versus Swiss Army knife: Developing a strategy for the management of bilobar colorectal liver metastases, *Surgery* 2017 Jul;162(1):12-17.)

Hepatobiliary surgeons should be abreast of the indications for, the technical aspects of, and the expected outcomes of various liver-directed therapies for primary and metastatic liver tumors. As part of a comprehensive multidisciplinary program that includes expertise in hepatic surgery, improvements in liver-directed therapies have greatly improved the outcomes of patients with complex liver pathology. These patients are therefore best evaluated and managed at tertiary care centers with multidisciplinary specialization and access to the latest knowledge, techniques, and clinical trials.

## **FUTURE DEVELOPMENTS**

At the same time as an improved understanding of tumor biology has led to more effective systemic and liver-directed therapies, simultaneous advances in our knowledge of liver anatomy, FLR assessment and augmentation, liver resectional techniques, and perioperative care have enabled the application of safe, oncologically sound hepatic resection to an increasing number of patients. Due to ongoing translational research, further practice-changing advances are expected. An improved understanding of the molecular biology of liver cancers should not only result in new targeted therapies, but also an opportunity to personalize therapy according to specific molecular features. Already, certain somatic mutations are known to affect prognosis in CRLM and may influence the therapeutic strategy accordingly. Improvements in systemic and liver-directed therapies should aim to more effectively downstage patients such that liver resection can be applied more broadly. An understanding of which patients who develop a complete radiographic response require surgical resection would also be instructive.

Advances in diagnostic imaging will assist not only in tumor identification and diagnosis, but also in accurate assessment of the FLR. At the same time, improvements in augmentation strategies or even bioartificial liver replacement strategies (eg, xenotransplantation, liver tissue engineering, cell transplantation) may afford an opportunity to offer surgical resection to patients who currently have inadequate FLR volume or function. Real-time image guidance technologies are currently available, but future improvements in registration and tracking techniques as well as the development of state-of-the-art operating rooms with upgraded imaging technology will be needed before image navigation is routinely used. Similarly, advances in minimally invasive technology beyond current laparoscopic and robotic systems should enable a faster learning curve and allow the benefits of minimally invasive hepatic surgery to be applied more broadly.

## **SUMMARY**

The field of liver surgery is rapidly changing. Evolving indications for resection, enhanced FLR assessment tools, advances in surgical technique and perioperative care, new systemic and liver-directed therapies, and an improved molecular and biological understanding of liver tumors suggest that

patients are best managed in experienced multidisciplinary centers. In this evolving landscape, surgeons should continue to lead efforts at identifying the optimal treatment strategies for patients with both primary and metastatic tumors of the liver.

# PORTAL HYPERTENSION

*Douglas W. Hanto • Sunil K. Geevarghese • Christopher Baron*

## INTRODUCTION

Portal hypertension (PHTN) can occur in cirrhotic and noncirrhotic patients and can be classified as presinusoidal or prehepatic (extrahepatic or intrahepatic), sinusoidal or hepatic, or post-sinusoidal or post-hepatic (Fig. 61-1). Portal pressure can be measured directly, or more commonly indirectly, by calculating the hepatic vein pressure gradient (HVPG) by subtracting the measured free hepatic vein pressure (FHVP) from the wedged hepatic vein pressure (WHVP). Portal pressure is normally <6 mm Hg and clinically significant PHTN is defined as an HVPG greater than 10 to 12 mm Hg (Table 61-1).

**FIGURE 61-1** Portal hypertension and sites of obstruction.

**TABLE 61-1: PORTAL HYPERTENSION**

Hepatic vein pressure gradient (HVPG) = Wedged hepatic vein pressure (WHVP) – Free hepatic vein pressure (FHVP)

Normal: HVPG <6 mm Hg

Clinically significant portal hypertension: HVPG >10-12 mm Hg

The most common complications of PHTN include gastroesophageal varices, portal hypertensive gastropathy, splenomegaly and hypersplenism, ascites, hepatic hydrothorax, hepatic encephalopathy, hepatorenal syndrome, hepatopulmonary syndrome, portopulmonary hypertension, and cirrhotic

cardiomyopathy (Table 61-2). The management of PHTN has changed dramatically over the past two decades and has been the subject of several clinical practice guideline publications.<sup>1</sup> Medical, endoscopic, and radiologic management strategies have largely replaced many surgical procedures such as selective and nonselective shunts, devascularization procedures, and peritoneovenous shunts. This chapter emphasizes the role of current therapies in the management of patients with PHTN and its complications.

**TABLE 61-2: COMPLICATIONS OF PORTAL HYPERTENSION**

Gastric varices	Hepatic encephalopathy
Esophageal varices	Hepatorenal syndrome
Portal hypertensive gastropathy	Hepatopulmonary syndrome
Splenomegaly and hypersplenism	Portopulmonary hypertension
Ascites	Cirrhotic cardiomyopathy
Hepatic hydrothorax	

## HISTORY

Although descriptions of PHTN and its complications go back over four centuries, surgical therapy was pioneered by Nicolai Eck, who first performed an end-to-side portacaval shunt in an animal model in 1883.<sup>2</sup> Pavlov described hepatic encephalopathy, referred to as meat intoxication at the time, as a consequence of diverting portal flow, which he believed was due to nitrogenous compounds that were not being cleared by the liver. The first portosystemic shunt in a human was performed by Vidal in 1903, but Whipple and colleagues pioneered the era of surgical decompression of portal hypertension in the 1940s. In the 1960s and 1970s, Drapanas developed the mesocaval shunt, Warren and Inokuchi developed selective variceal bed decompression with the distal splenorenal and coronary vein-caval shunts, respectively, Sarfeh studied and popularized small diameter H-grafts, and Sugiura pioneered gastroesophageal devascularization and splenectomy. In the 1980s, endoscopic sclerotherapy and band ligation were introduced for control of variceal hemorrhage. The subsequent development of

pharmacologic therapy, transjugular intrahepatic portosystemic shunts (TIPS), and the pioneering work of Starzl and Calne in the 1960s and 1970s, making liver transplantation a viable alternative for patients with end-stage liver disease, have all radically transformed the care of these patients.

## PATHOPHYSIOLOGY

Portal hypertension results from increased resistance to portal flow in association with increased portal collateral flow. The increased resistance occurs most commonly within the liver due to cirrhosis, but it can occur prehepatic as in portal vein thrombosis (PVT) or post-hepatic due to obstruction of hepatic venous flow (Budd–Chiari syndrome or veno-occlusive disease) (Fig. 61-1). Rarely, a hepatic arterial-portal venous fistula can cause PHTN.

As Bleibel et al. have noted,<sup>3</sup> resistance to portal flow is the result of structural as well as physiologic derangements. Under normal physiologic conditions there is little resistance to portal venous flow and there is little intrinsic regulation of portal flow. In cirrhosis, however, collagen deposition and fibrosis, along with the contractile properties of stellate cells and myofibroblasts that surround the hepatic sinusoids and reside in fibrous septa along with vascular smooth muscle cells, lead to an increased resistance to portal flow. Initially, the splanchnic vascular bed response is vasoconstriction due to the release of thromboxane A<sub>2</sub>, norepinephrine, endothelins, and angiotensin-II, along with decreased nitric oxide–mediated vasodilatation. With progression of portal hypertension, the release of splanchnic vasodilators such as nitric oxide and vascular endothelial growth factor predominates, resulting in increased splanchnic inflow.

These changes result in the development of collaterals between the portal and systemic circulations (Fig. 61-2), plasma volume expansion, increased cardiac output, systemic vasodilatation, and hypotension. The development of a systemic hyperdynamic circulation results in systemic blood pressures of 100 to 110 mm Hg, cardiac outputs ranging from 10 to 15 L/min, and low calculated systemic vascular resistance of 250 to 500 dynes/cm<sup>5</sup> that can impact fluid resuscitation and patient management.

**FIGURE 61-2** Collaterals in portal hypertension. (Reproduced with permission from Sangster GP, Previgliano CH, Nader M, et al. MDCT Imaging Findings of Liver Cirrhosis: Spectrum of Hepatic and Extrahepatic Abdominal Complications, *HPB Surg* 2013;2013:129396.)

## ETIOLOGY AND CLINICAL PRESENTATION

In developed countries, 90% of patients with PHTN have cirrhosis most often caused by chronic viral hepatitis (hepatitis B, C), alcoholic liver disease, hemochromatosis, and nonalcoholic steatohepatitis. Less common causes include autoimmune hepatitis, primary and secondary biliary cirrhosis, primary sclerosing cholangitis, medications (eg, methotrexate), Wilson disease,  $\alpha$ -1 antitrypsin deficiency, celiac disease, idiopathic adulthood ductopenia, granulomatous liver disease, idiopathic portal fibrosis, polycystic

liver disease, right-sided heart failure, Budd–Chiari syndrome, and veno-occlusive disease (Table 61-3). A smaller percentage of patients will have noncirrhotic PHTN usually caused by PVT or hepatic fibrosis. In other parts of the world, noncirrhotic PHTN is much more common and is most often caused hepatic schistosomiasis or PVT.

**TABLE 61-3: CAUSES OF PORTAL HYPERTENSION**

Prehepatic	Prehepatic	Hepatocellular	Post-Hepatic	High-Flow
Extrahepatic	Intrahepatic			
Portal vein thrombosis	Schistosomiasis	Post-infectious cirrhosis (HCV, HBV)	Budd-Chiari syndrome	Arteriovenous communication— intrahepatic or extrahepatic Congenital Acquired
Splenic vein thrombosis Superior mesenteric vein thrombosis	Sarcoidosis	Alcoholic liver disease Nonalcoholic steatohepatitis (NASH) Biliary atresia Congenital disorders of bile acid metabolism Congenital hepatic fibrosis Nodular regenerative hyperplasia Primary sclerosing cholangitis Primary biliary cirrhosis Autoimmune hepatitis Drug toxicity (eg, methotrexate) Metabolic diseases (eg, $\alpha$ -1-antitrypsin) Hemochromatosis Wilson disease	Veno-occlusive disease Congestive heart failure Constrictive pericarditis Vena caval webs	

Patients with cirrhosis are often asymptomatic even though 80% have an elevated HVPG and nearly 50% will have esophageal varices. Patients with PHTN and no varices will develop varices at a rate of about 8% per year.<sup>4</sup> Patients come to the attention of their physician as the complications noted in the introduction develop (Table 61-2). Briefly, the clinical manifestations of bleeding gastroesophageal varices are usually hematemesis and/or melena, but can present with shock and vascular collapse from exsanguinating hemorrhage. Portal hypertensive gastropathy is manifest as diffuse mucosal oozing and may present with anemia from chronic blood loss. Splenomegaly and hypersplenism may present with leukopenia, thrombocytopenia, and sometimes anemia. Ascites, the buildup of fluid in the peritoneal cavity, may

present with abdominal distention, weight gain, and shortness of breath from the increased fluid and intra-abdominal pressure. Patients can also develop hydrothorax (pleural effusion) from movement of fluid from the abdominal cavity into the pleural space, usually on the right side. They can also present with spontaneous bacterial peritonitis with fever, pain, and tenderness. Patients often first present with confusion or hepatic encephalopathy that can be precipitated by many factors including bleeding, infection, renal failure, and other manifestations of liver failure. Hepatorenal syndrome is the development of renal insufficiency in patients with cirrhosis. Patients with hepatopulmonary syndrome may be asymptomatic in its early stages, but may present with oxygen desaturation, shortness of breath, and dyspnea on exertion caused by intrapulmonary shunting. Patients with portopulmonary hypertension may have similar symptoms related to elevated pulmonary artery pressures.

The severity of liver decompensation can be characterized by the Pugh-modified Child-Turcotte (Child-Turcotte-Pugh [CTP]) classification scheme (Table 61-4)<sup>5</sup> or the Model for End-Stage Liver Disease (MELD) score (Table 61-5) (discussed later). The CTP score, which uses clinical assessment and laboratory values, has been used to determine the functional status of the liver and estimate liver reserve as well as predict morbidity and mortality after shunt surgery and other general surgical procedures in cirrhotic patients.<sup>6,7</sup> Patients with Child A cirrhosis have adequate liver reserve and tolerate shunt and general surgery with survival rates similar to noncirrhotic patients. On the other hand, Child C patients have a high mortality, often exceeding 50%, and in general are not candidates for shunt or general surgical procedures, but are candidates for liver transplantation. The CTP has been largely replaced with the MELD score that was originally developed to predict the mortality for cirrhotic patients undergoing TIPS and has been adapted to predict the mortality of patients on the liver transplant waiting list and to prioritize liver allocation to the sickest patients.<sup>8</sup>

**TABLE 61-4: PUGH MODIFIED CHILD-TURCOTTE CLASSIFICATION**

	One Point	Two Points	Three Points
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy (grade)	None	1 or 2	3 or 4
Prothrombin time (sec prolonged) or INR	1-4 <1.7	4-6 1.7-2.3	>6 >2.3
For primary biliary cirrhosis: bilirubin (mg/dL)	1-4	4-10	>10

Abbreviation: INR, international normalized ratio.

For each of five items a score of 1, 2, or 3 is assigned. Total score is summed.

Child's A = 5-6, B = 7-9, C = 10-15.

Reproduced with permission from Pugh RNH, Murray-Lyon IM, Dawson JL, et al: Transection of the oesophagus for bleeding oesophageal varices, *Br J Surg* 1973 Aug;60(8):646-649.

**TABLE 61-5: MODEL FOR END-STAGE LIVER DISEASE (MELD)**

$$\text{MELD} = 3.78 \times \ln[\text{serum bilirubin (mg/dL)}] + 11.2 \times \ln[\text{INR}] + 9.57 \times \ln[\text{serum creatinine (mg/dL)}] + 6.43$$

The 3-month mortality for a patient undergoing a TIPS with a MELD score of 40 or more is 71.3%, 30-39 is 52.6%, 20-29 is 19.6%, 10-19 is 6.0%, and <9 is 1.9%.

## DIAGNOSTIC EVALUATION

The goals of diagnostic studies in initially evaluating patients with PHTN and its complications are to determine the presence of hepatic disease, the level of obstruction to flow, the presence and extent of intra-abdominal portosystemic collaterals, the direction of blood flow in the portal vein (PV) (hepatopetal, toward the liver; hepatofugal, away from the liver), as well as the presence of thrombosis. The imaging is typically multimodality, including duplex ultrasound (US) and multiphase computed tomography (CT) as well as multiphase magnetic resonance imaging (MRI), and conventional angiography. CT arteriography (CTA), CT venography (CTV), MR

angiography (MRA), and MR venography (MRV) can also be useful in certain circumstances.

## Duplex Ultrasound

Duplex US, which includes both gray scale and color Doppler sonography, is a noninvasive, portable, and inexpensive technique that does not use ionizing radiation and is frequently used as the first-line examination in the diagnosis and follow-up of patients with liver disease and PHTN.

Grayscale interrogation of the liver is used to evaluate overall morphology as well as to locate focal lesions suggestive of hepatocellular carcinoma. Color Doppler US is useful in evaluation of the portal, splenic, hepatic, and superior mesenteric veins, the vena cava, and the hepatic artery, including flow direction, flow velocity, and large vessel thrombosis. Portosystemic collaterals are readily identified, and findings such as paraumbilical veins, spontaneous splenorenal circulation, dilated left and short gastric veins, and hepatofugal flow within in the portal system are 100% specific US signs of clinically significant PHTN.<sup>9</sup> Duplex US is also useful in identifying causes of PHTN other than cirrhosis, such as portal or hepatic vein thrombosis.<sup>10</sup> In a recent prospective study, a PV average maximum velocity of <15 cm/s was the only variable independently associated with a high risk of nonmalignant PVT.<sup>11</sup> Splenomegaly (diameter >12 cm and/or area >45 cm<sup>2</sup>) is the most commonly associated and sensitive sign of the presence of PHTN, is an independent predictor of esophageal varices, and is associated with clinically significant PHTN in compensated cirrhotic patients.<sup>12</sup>

Other US signs of clinically significant PHTN include dilatation of the PV (diameter >13 mm), lack of or reduced respiratory variations of splenic and superior mesenteric vein (SMV) diameter,<sup>13</sup> lack of respiratory caliber variations in one of the major portal tributaries (splenic vein [SV] and/or SMV),<sup>14</sup> reduced PV velocity (maximal and mean velocity of PV flow, respectively <16 cm/s and <10 to 12 cm/s),<sup>15</sup> increased congestion index of PV (ratio between the cross-sectional area and blood flow velocity),<sup>16</sup> altered hepatic venous Doppler pattern,<sup>17</sup> increased intraparenchymal hepatic and renal artery impedance,<sup>18</sup> and reduced mesenteric artery impedance.<sup>19</sup>

Finally, Duplex US is useful in the surveillance of patients who have been decompressed by TIPS. Doppler US evaluation can diagnose TIPS

dysfunction by demonstrating in-stent velocities  $>250$  cm/s or  $<50$  cm/s with greater than 90% sensitivity and specificity.<sup>20</sup>

## **Multiple-Detector Computed Tomography, CT arteriography, CT venography**

Multiple-detector computed tomography (MDCT) uses ionizing radiation to acquire a volumetric data set that allows three-dimensional multiplanar reconstructions. Noncontrast images are acquired, intravenous contrast administered, and dynamic images are acquired in the hepatic arterial phase (12 sec following injection), portal venous phase (55 sec following injection), and finally in the late venous phase (120 sec following injection).<sup>21</sup>

MDCT can identify morphologic changes including hepatomegaly in the early stages of cirrhosis. In the later stages, there is frequent atrophy of the right lobe and medial segment of the left lobe with hypertrophy of the left lateral segment. MDCT can also characterize regenerative nodules, dysplastic nodules, and hepatocellular carcinoma (HCC), determine the patency of the venous and arterial systems, and measure liver volumes, which can be useful in preoperative planning for liver transplantation.

Portosystemic collaterals (varices) develop as portal pressures rise above 10 mm Hg, are a hallmark of PHTN, and appear as enhancing, well-defined tubular or serpentine structures that follow the enhancement characteristics of the PV. The left gastric (coronary) vein (LGV) is the most commonly seen portosystemic collateral and is dilated in up to 80% of cirrhotic patients. It normally drains the anterior and posterior surfaces of the stomach and ascends the lesser curvature to the gastroesophageal junction, where it receives the esophageal vein and supplies esophageal and paraesophageal varices that drain into the azygous/hemizygous venous systems.<sup>22</sup> The LGV drains into the PV at the superior border of the duodenum. Dilated left gastric veins are visible between the anterior wall of the stomach and the posterior surface of the left hepatic lobe. A left gastric vein size larger than 5 to 6 mm or multiple veins 4 to 6 mm in diameter are indicative of PHTN. A left gastric vein greater than 7 mm has been shown to correspond to a HVP of 10 mm Hg.<sup>23</sup> Approximately 30% to 70% of patients with PHTN develop varices and 9% to 36% are considered “high risk.”<sup>24</sup>

Paraumbilical venous collaterals are found in 43% of patients with PHTN.

They appear as tubular enhancing structures in the falciform ligament and are supplied by the left PV via a recanalized umbilical vein. They connect with the superior epigastric vein and/or internal thoracic veins which drain into the superior vena cava or connect with the inferior epigastric vein that drains into the external iliac vein. These abdominal wall varices form the caput medusae that are seen on physical exam as dilated subcutaneous veins at the umbilicus.

Gastric varices form in the face of PHTN and decreased drainage through the left gastric, posterior gastric, and short gastric veins. In this setting, portosystemic shunting can be through the left inferior phrenic or left adrenal veins forming a gastrorenal shunt. The incidence of gastric varices in patients with PHTN is approximately 30%.<sup>20</sup> Retroperitoneal varices are commonly seen collaterals and form between intestinal or retroperitoneal tributaries of the SMV or IMV and the systemic circulation.

PVT may be present in 1% of patients with early cirrhosis, in 30% of patients with advanced cirrhosis who are candidates for liver transplantation, and in 10% to 40% of patients with HCC,<sup>25</sup> as well in patients with no cirrhosis but who may have a hypercoagulable state. PVT is demonstrated by an intraluminal filling defect on US (Fig. 61-3A) and on CTA after the administration of IV contrast (Fig. 61-3B, C), and can be associated with bowel ischemia (Fig. 61-3D). After PVT, there is rapid development of numerous enhancing venous collaterals in the porta hepatitis that bypass the obstruction, referred to as cavernous transformation.<sup>25</sup>

**FIGURE 61-3** Acute portal and mesenteric venous thrombosis with associated bowel ischemia in 43-year-old man with the onset of abdominal pain, nausea and vomiting one-week prior. Protein S deficiency and lupus anticoagulant were found. **A.** Gray scale sagittal US image of the right hepatic lobe demonstrates echogenic material filling the right PV indicating PVT (*arrows*). **B.** Axial contrast-enhanced multidetector CT shows non-enhancement of the right portal venous branches (*arrows*) consistent with thrombosis as well as perihepatic ascites (*arrowheads*). **C.** Coronal reformatted multidetector CT images depicts extension of thrombosis into superior mesenteric (*arrows*) and inferior mesenteric (*arrowhead*) veins.

Thrombotic extension into the splenic vein is also present (*black arrow*). **D.** Axial contrast-enhanced multidetector CT shows diffuse hyperattenuating small bowel wall thickening (*white arrows*), with mesenteric fat stranding (*black arrows*) and free fluid (*arrowheads*) corresponding to small bowel ischemia.

## **Magnetic Resonance Imaging, MR Angiography, MR Venography**

MRI uses a high field-strength magnet in combination with radiofrequency energy to create three-dimensional images that can be viewed in multiple planes. Gadolinium chelates are used as contrast agents to improve tissue contrast and to perform angiography. Newer, liver-specific contrast agents such Eovist have been developed, with up to 50% of the injected dose of these liver-specific agents taken up by functioning hepatocytes and excreted in the bile. As with MDCT, MR imaging of patients with diffuse liver disease and PHTN is a dynamic process; T1 in-phase and out-of-phase, T2, and diffusion-weighted sequences are performed. Post-contrast studies are acquired in the arterial phase (20-35 sec), portal phase (70 sec), and equilibrium phase (3 min). A fourth phase is added with liver-specific agents and a delayed hepatobiliary phase at 20 minutes.<sup>26</sup>

MRA can be performed using multiple techniques both with and without the administration of gadolinium contrast agents, and has an added benefit over MDCT in that it can provide information on both flow direction and flow velocity. MRI/MRV has proven useful in the evaluation of the portosystemic collaterals and the vena cava and evaluation of PVT, and compares equally to MDCT. MRI performs equally as well as MDCT in the diagnosis of HCC, but has increased accuracy in detecting smaller lesions.<sup>26</sup>

## **Endoscopy**

Esophagogastroduodenoscopy (EGD) is the gold standard for the diagnosis of esophageal and gastric varices and variceal hemorrhage<sup>4</sup> (Fig. 61-4A-D). It is recommended that esophageal varices be classified as small (<5 mm in diameter) or large (>5 mm in diameter), with the large varices including medium-sized varices when three grades are used (small, medium, and large).

Care should be taken to document the presence or absence of red signs (red wale marks or red spots) on varices that identify high-risk varices. Because therapy with  $\beta$ -blockers prevents bleeding in more than half of patients with medium or large varices, it is recommended that newly diagnosed patients with cirrhosis undergo screening EGD for varices. The prevalence of medium/large varices is about 15% to 25%, so most patients will have a negative EGD or have varices that do not warrant prophylactic treatment. Other noninvasive markers of varices such as platelet count, FibroTest, spleen size, PV diameter, and transient elastography have so far been inaccurate and cannot substitute for screening EGD. It is recommended that patients with no varices and compensated cirrhosis should undergo repeat EGD in 2 to 3 years. Patients with small varices should undergo repeat EGD in 1 to 2 years. Patients with decompensated cirrhosis should have yearly EGD. Esophageal capsule endoscopy may play a role in the future in screening for esophageal varices, although it is still not as sensitive as EGD.<sup>27</sup>

## Angiography and Measurement of Hepatic Venous Pressure Gradient

Historically, angiography played a larger role in the evaluation of patients with PHTN. The portal venous system was indirectly evaluated in the venous phase of celiac or superior mesenteric artery angiography or directly imaged through splenoportography or through transhepatic or transjugular portal venography (Fig. 61-5). However, with the advent of cross-sectional imaging, these diagnostic techniques are now rarely used.

**FIGURE 61-5** Superior mesenteric arteriography with delayed images demonstrating enlarged splenic vein (SV), superior mesenteric vein (SMV), portal vein (PV), and extensive portosystemic collaterals.

Angiography still plays an important role in measurements of the HVPG that is an indirect measurement of portal venous pressure. The procedure is usually performed from a jugular vein access. The inferior vena cava (IVC) is cannulated with a diagnostic catheter and the right hepatic vein is subselected. If using a straight, end hole catheter, it is advanced peripherally into the hepatic vein until wedged, rendering the WHVP. Pressure measurements are obtained with the transducer at the right atrial level (mid-axillary line). A subsequent injection of contrast confirms the location by visualization of a characteristic sinusoidal pattern. The catheter is then withdrawn into the hepatic vein, and an FHVP is obtained. Alternatively, a balloon-tipped catheter is advanced into the middle third of the right hepatic vein and inflated to occlude the vein, which allows measurement of the WHVP. Again, injection of contrast with the balloon inflated confirms balloon occlusion of the hepatic vein. The FHVP is obtained after deflating the balloon. A prospective trial compared these two techniques against direct portal pressure measurements and found that that the balloon occlusion

method is more reproducible and more accurately reflects the direct portal pressure.<sup>28</sup>

The HVPG is calculated by subtracting the FHVP from the WHVP, which eliminates the changes in the pressure measurements caused by changes in intra-abdominal pressure. At the time of pressure measurements, transjugular liver biopsy can also be safely performed and is particularly advantageous in patients who do not meet criteria for percutaneous or open liver biopsy because of uncorrectable coagulopathy or ascites.<sup>29</sup>

A normal HVPG is less than 6 mm Hg, and clinically significant PHTN develops at pressures of 10 to 12 mm Hg with the development of varices. Significant complications such as variceal bleeding and ascites usually arise at pressures greater than 12 mm Hg.<sup>30</sup>

## COMPLICATIONS OF PORTAL HYPERTENSION

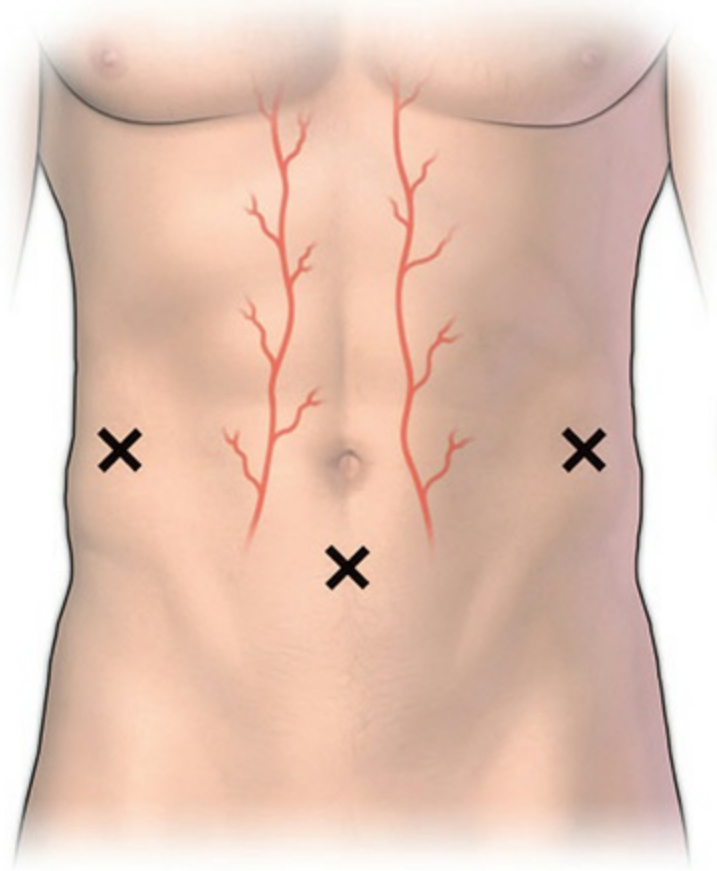

### Ascites

Approximately 85% of patients in the United States with ascites have cirrhosis, and 15% have nonhepatic etiologies including cancer, heart failure, tuberculosis, or nephrotic syndrome.<sup>31</sup> Ascites is usually suspected on the basis of the history and physical examination and confirmed by ultrasound and by paracentesis. Ascites from PHTN can easily be differentiated from other causes by straightforward fluid analysis. The diagnosis of spontaneous bacterial peritonitis (SBP) can be made by determining the absolute number of PMNs in the fluid (>250 PMNs per mm<sup>3</sup>).

### MEDICAL MANAGEMENT

Recommendations for medical management of ascites include abstinence from alcohol if this is the cause of liver disease. Additional recommendations include sodium restriction and diuretics (spironolactone and furosemide), fluid restriction if the serum sodium is less than 120 to 125 mmol/L, and an initial therapeutic paracentesis in patients with tense ascites (Fig. 61-6). Patients who respond to diuretics are preferentially treated with sodium

restriction and diuretics rather than serial paracentesis.<sup>31</sup> Patients with cirrhosis and ascites should be considered for liver transplantation.

**FIGURE 61-6** Sites for paracentesis.

Patients have refractory ascites if they have fluid overload that is unresponsive to sodium restriction and high-dose diuretics or recurs quickly after undergoing therapeutic paracentesis. Treatment options include serial therapeutic paracentesis, TIPS, peritoneovenous shunt, or liver transplantation.

Controlled trials of serial large volume (5-10 liters) therapeutic paracentesis demonstrating its effectiveness and safety have been published<sup>32</sup> and may be performed as often as biweekly or weekly. Although the administration of albumin after large-volume paracentesis is of uncertain value, it is recommended that an albumin infusion of 6 to 8 g/L of fluid be considered, particularly for volumes greater than 5 liters.<sup>31</sup>

## SURGICAL MANAGEMENT

Patients with refractory ascites should be referred for liver transplantation unless there are other surgical or medical contraindications, because 21% die within 6 months.<sup>33</sup> Peritoneovenous shunts (LeVeen or Denver shunts) currently have few indications because of their poor long-term patency due to a high incidence of thrombotic, infectious, and technical complications. Furthermore, controlled trials have demonstrated no survival advantage compared to medical management.<sup>34</sup> Peritoneovenous shunts are now reserved for patients who are not candidates for serial paracentesis (eg, distance from a physician able to perform the procedure) and for patients who are not candidates for liver transplantation or TIPS.

## RADIOLOGIC MANAGEMENT

**Ultrasound.** Although paracentesis in patients with massive ascites can be safely and easily performed without US guidance, in patients who are obese or otherwise have fluid that is difficult to localize by physical examination, paracentesis can be aided by performance under US guidance.

**Transjugular Intrahepatic Portosystemic Shunt.** The development of refractory ascites, which occurs in 5% to 10% of patients with ascites, is associated with a 1-year mortality of 50% to 90% and is a common indication for liver transplantation.<sup>32,33</sup> By reducing portal pressure, TIPS (discussed in more detail in the section on varices) has been shown to be effective in managing patients with refractory ascites.

A meta-analysis of five randomized control trials by D'Amico et al.<sup>35</sup> demonstrated a 7.1-fold reduction in the risk of recurrence of tense ascites after TIPS. Rates of improvement ranged from 38% to 84% after TIPS compared to 0% to 43% after large volume paracentesis. There was a trend toward a reduction in mortality in the TIPS group. Rates of hepatic encephalopathy were 2.2-fold higher in TIPS patients compared to repeated large-volume paracentesis. A meta-analysis by Salerno et al.<sup>36</sup> and review by Eesa et al.<sup>37</sup> also demonstrated TIPS to be superior to repeated large-volume paracentesis in controlling ascites and was associated with a significantly better transplant-free survival at 12 and 24 months.

The threshold portosystemic gradient (PSPG) (see section on TIPS for

treatment of variceal hemorrhage) in the treatment of patients with refractory ascites has been a subject of some debate. The Society of Interventional Radiology (SIR) and American Association for the Study of Liver Disease (AASLD) guidelines recommended reducing the PSPG to less than 8 mm Hg.<sup>38</sup>

## Hepatic Hydrothorax

Hepatic hydrothorax develops in patients with cirrhosis and ascites when there is direct communication between the abdominal and thoracic cavities. It may develop in patients without clinically evident ascites. In most patients the defect is over the dome of the liver.<sup>38</sup> The use of TIPS in the treatment of hepatic hydrothorax is supported by several retrospective case series describing the outcomes of more than 150 patients.<sup>39</sup> At least partial improvement in clinical symptoms (dyspnea and decrease in frequency of thoracentesis) has been reported in 68% to 82% of patients, whereas complete resolution of hydrothorax was observed in 57% to 71% of patients.

## Gastric and Esophageal Varices

Gastroesophageal varices occur in patients with cirrhosis and PHTN with an HVPG of at least 10 to 12 mm Hg. They are present in 50% of patients with cirrhosis, but their incidence is associated with the severity of the liver disease, ranging from 40% in patients with compensated cirrhosis to 85% in patients with decompensated cirrhosis. Varices develop at a rate of 8% per year in patients without varices, and the HVPG is the strongest predictor for their development.<sup>4</sup>

Variceal hemorrhage is the most life-threatening complication of portal hypertension and occurs at a yearly rate of 5% to 15% and at an overall rate of 25% to 70%<sup>4</sup> (Fig. 61-7). Large varices on EGD and the presence of cherry red spots and red wale marks—linear, dilated venules that endoscopically look like whip marks on the variceal surface—are associated with a higher risk of hemorrhage (Fig. 61-4B, C), as is the degree of elevation of the HVPG. In spite of improvements in care, the mortality of esophageal variceal hemorrhage is still about 20%, but exceeds 60% in patients with HVPG >20 mm Hg.<sup>40,41</sup> This is in part related to the fact that patients with an

HVPG >20 mm Hg are at increased risk for early rebleeding or inability to control bleeding. Overall for survivors of a first bleed, 30% will rebleed within 6 weeks, and by 1 to 2 years nearly 60% will have rebled.<sup>42,43</sup> Gastric varices are less common (5%-33%) than esophageal varices in patients with PHTN and about 25% will bleed over 2 years.

**FIGURE 61-7** Bleeding esophageal varix seen on EGD in a patient with hematemesis.

## MEDICAL MANAGEMENT

**Prophylaxis.** Preventive management of variceal hemorrhage includes pharmacologic and endoscopic therapy. Nonselective  $\beta$ -blockade involves  $\beta_1$  and  $\beta_2$  adrenergic blockades, which are known to decrease cardiac output ( $\beta_1$ ) and increase splanchnic arteriolar vasoconstriction ( $\beta_2$ ), reducing portal flow (eg, propranolol and nadolol) (Table 61-6). Vasopressin also has splanchnic vasoconstrictive properties and decreases portal venous collateral flow and portal pressure. Somatostatin decreases splanchnic flow, but does so indirectly by reducing glucagon, substance P, and vasoactive intestinal

peptide.

**TABLE 61-6: EFFECT ON PORTAL FLOW, RESISTANCE AND PRESSURE WITH THE DIFFERENT THERAPIES FOR VARICES/VARICEAL HEMORRHAGE**

Treatment	Portal Flow	Portal Resistance	Portal Pressure
Vasoconstrictors (eg, $\beta$ -blockers)	↓↓	↑	↓
Venodilators (eg, nitrates)	↓	↓ <sup>a</sup>	↓
Endoscopic therapy	—	—	—
TIPS/shunt	↑	↓↓↓	↓↓↓

<sup>a</sup>Although theoretically nitrates act by decreasing resistance, they actually act by decreasing portal flow through a decrease in mean arterial pressure.

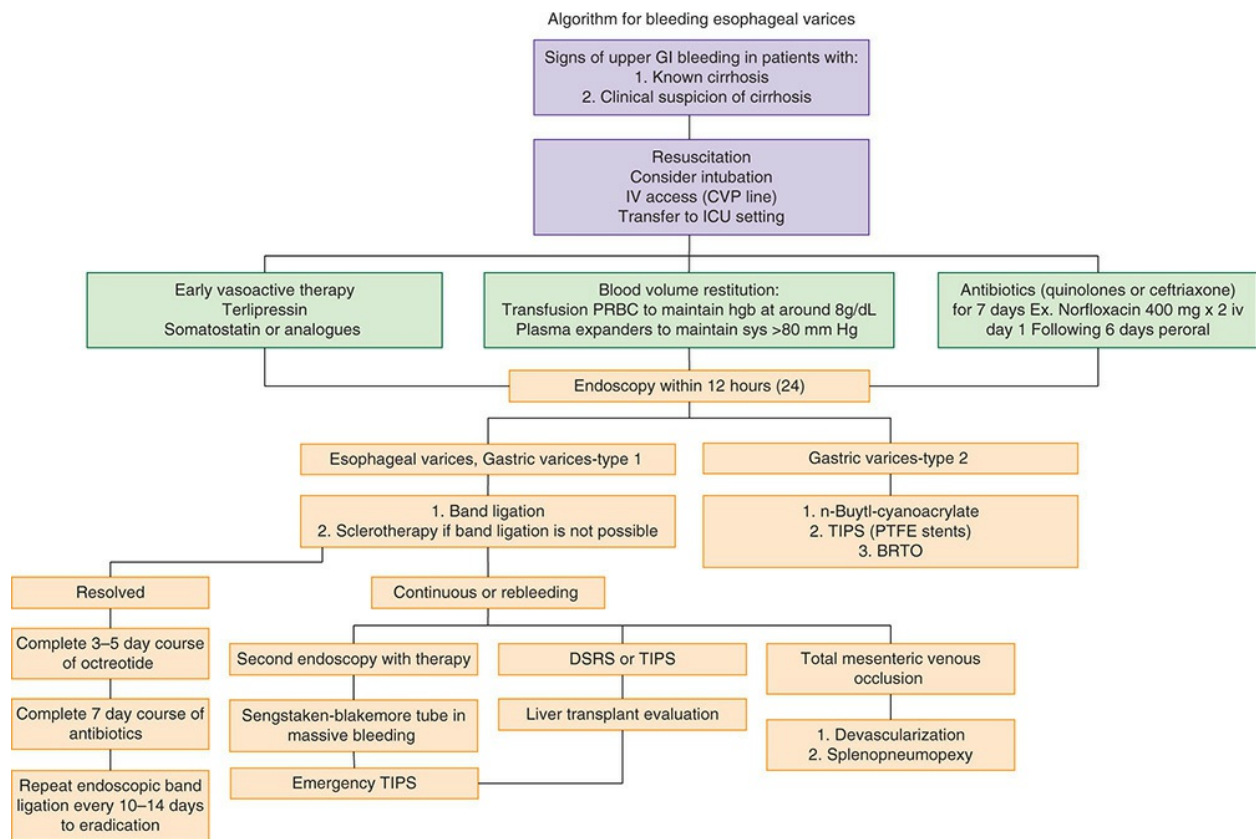

Reproduced with permission from Garcia-Tsao G, Sanyal AJ, Grace ND, et al: Prevention and management of gastroesophageal varices and variceal hemorrhage in cirrhosis, *Hepatology* 2007 Sep;46(3):922-938.

Recommendations for patients with small varices that have not bled are that they be treated prophylactically with  $\beta$ -blockers if they have advanced cirrhosis and red wale marks, indicative of a higher risk of bleeding, and undergo EGD every 2 years, even though the data is inconclusive as to whether  $\beta$ -blockade prevents growth of the varices or reduces the risk of bleeding.<sup>4</sup> Patients with medium/large varices that have not bled should be treated with  $\beta$ -blockers since data has shown that bleeding is reduced from 30% in control patients to 14% in treated patients, there is a lower mortality in treated patients, and prophylaxis is most cost-effective.<sup>4,42</sup> Side effects include fatigue, lightheadedness, and shortness of breath.

Endoscopic therapy is an effective means of preventing and controlling variceal bleeding. Endoscopic variceal band ligation (EVL) can be performed at the bedside and has largely replaced endoscopic sclerotherapy (ES), which can be associated with fever, chest pain, dysphagia, and perforation. EVL has been compared to nonselective beta blockade in several randomized trials. Two meta-analyses have confirmed that it is associated with lower incidence of first variceal bleed without differences in mortality.<sup>43,44</sup> EVL can be

performed regularly to manage the variceal burden in patients when combined with pharmacologic therapy. Per AASLD Practice Guidelines, it can be repeated every 1 to 2 weeks until obliteration.<sup>4</sup> Surveillance EGD can then follow every 6 to 12 months.

**Variceal Hemorrhage.** The first-line treatment of variceal hemorrhage (Fig. 61-7), in addition to volume resuscitation with fluid and blood, and replacement of clotting factors and platelets, is pharmacologic therapy with intravenous vasopressin and nitroglycerin, terlipressin, somatostatin, or octreotide prior to EGD and continued for 3 to 5 days. Patients should also be started on antibiotic prophylaxis with ciprofloxacin or ceftriaxone (Fig. 61-8).

**FIGURE 61-8** Algorithm for bleeding esophageal varices. (Reproduced with permission from Bendtsen F, Krag A, Møller S: Treatment of acute variceal bleeding, *Dig Liver Dis.* 2008 May;40(5):328-336.)

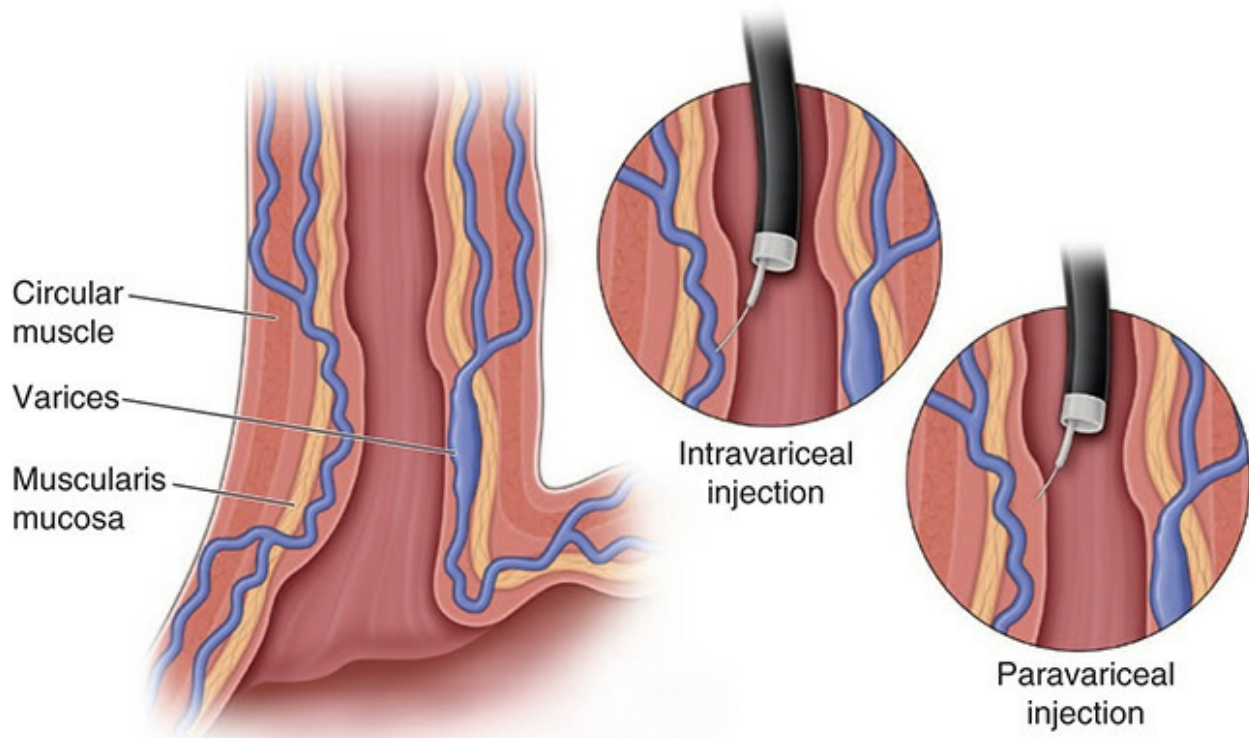

EGD should be performed within 12 hours, and EVL performed to control bleeding (Fig. 61-9). EVL controls bleeding in approximately 80% to 100% of patients and has the same or better results than ES.<sup>45,46</sup> Multiple follow-up sessions are required to eliminate the varices, and are generally performed

every 1 to 2 weeks until obliteration. Rebleeding is less after EVL compared to ES<sup>46</sup> (Fig. 61-10) and mortality is lower, so EVL is preferred.

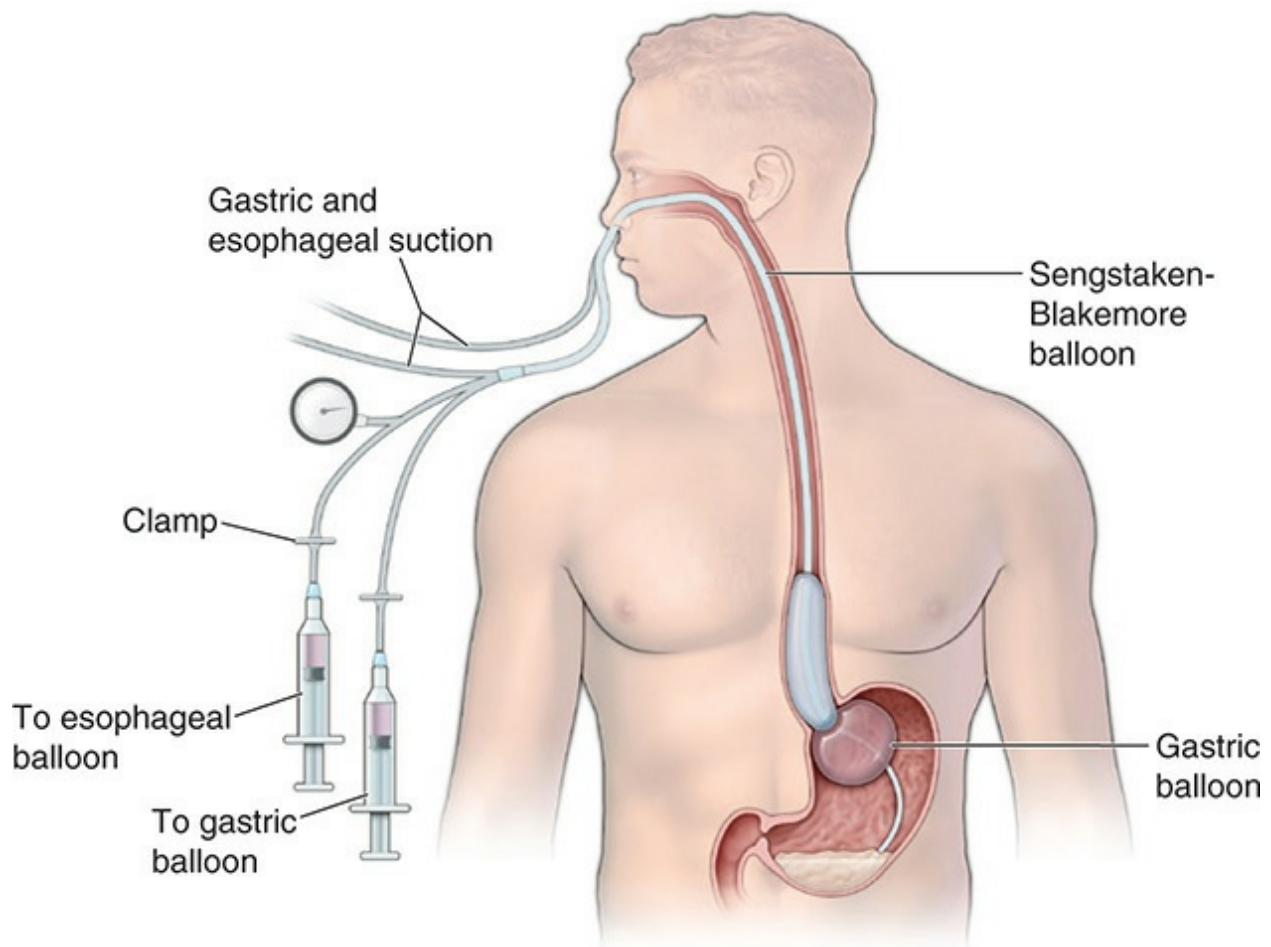

**FIGURE 61-9** Endoscopic sclerotherapy (ES). Intravariceal injection (A) and paravariceal injection (B).

**FIGURE 61-10** Endoscopic variceal band ligation (EVL). The esophageal varix is suctioned into the device (**A**) and the base of the varix is banded (**B**).

Balloon tamponade with a Sengstaken-Blakemore or Minnesota tube can be used for control of variceal hemorrhage in patients who are unresponsive to pharmacologic therapy and EVL.<sup>47</sup> These tubes use two balloons—a gastric balloon and an esophageal balloon—to tamponade the submucosal veins. Initial control of bleeding is accomplished in 80% of patients, but over 50% rebleed after the balloons are deflated. However, these tubes can be used as a temporizing measure while preparing the patient for an emergent TIPS or surgical shunt (Fig. 61-11).

**FIGURE 61-11** The Sengstaken-Blakemore tube for tamponade of distal esophagus and gastric fundus. A nasogastric tube is used to aspirate secretions from the esophagus above the balloon. Other tubes (eg, Minnesota tube) have a proximal esophageal drainage port so that a nasogastric tube is

not required.

Gastric varices occur in 5% to 30% of patients with PHTN. Type 1 gastric varices are an extension of esophageal varices along the lesser curvature of the stomach, and management should be the same as for esophageal varices. The bleeding rate of gastric fundal varices has been reported to be up to 45% at 3 years.<sup>4,48,49</sup> Gastric varices can be difficult to treat and there are few clinical trials to guide therapy. Treatment options include intravariceal injections of a number of sclerosants and “glues” including alcohol, thrombin, and *N*-butyl-cyanoacrylate (with *N*-butyl-cyanoacrylate preferred), EVL, TIPS, and balloon retrograde transvenous obliteration (BRTO). The threshold for TIPS placement is lower than for esophageal variceal hemorrhage and should be considered if EVL or sclerosis are not options or have failed on one occasion.

## **SURGICAL MANAGEMENT**

The surgical management of PHTN has a storied past and at one time was the primary treatment modality. However, innovations in medical management, endoscopic therapies, percutaneous radiologic procedures such as TIPS, and the success of liver transplantation<sup>50</sup> have nearly eliminated the need for surgical shunts except in very limited circumstances. These include symptomatic PHTN in the noncirrhotic patient with preserved liver function (eg, schistosomiasis), patients with Budd–Chiari syndrome, and patients with total mesenteric venous occlusion who may be candidates for splenopneumopexy or a devascularization procedure.

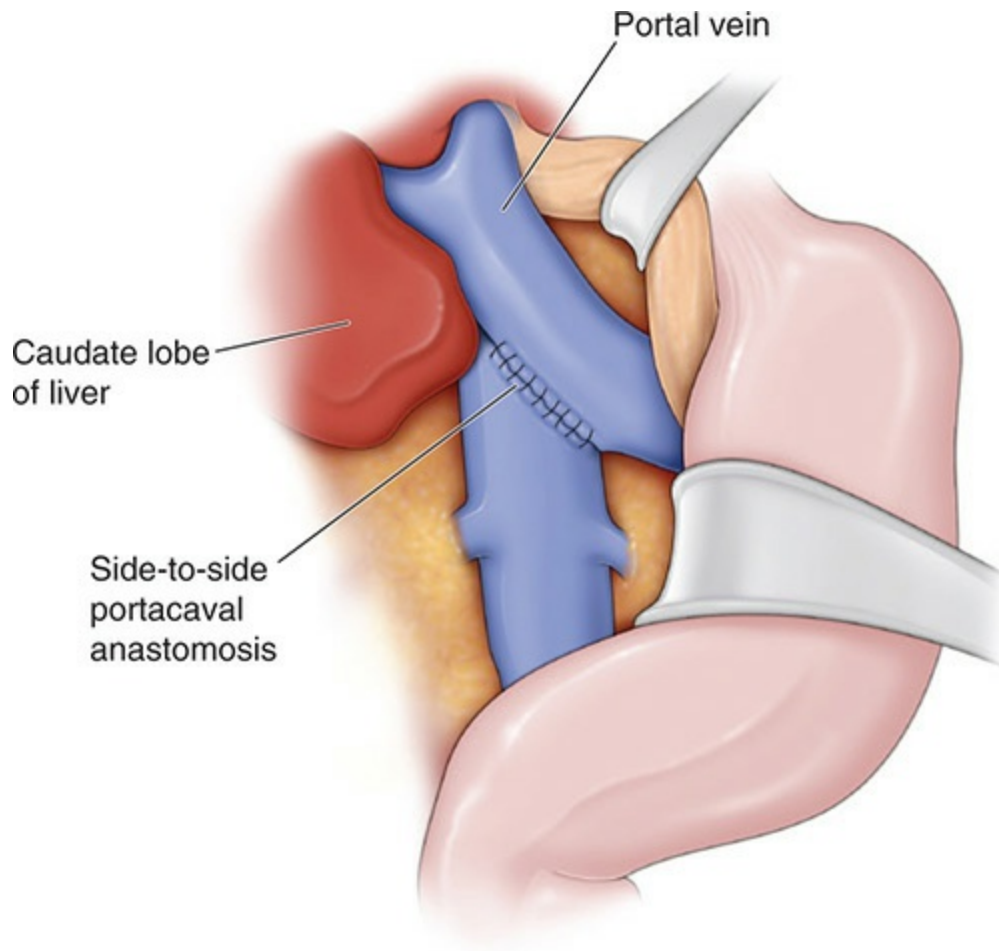

Two major groups of procedures are discussed below: decompressive operations, which can be divided into nonselective and selective shunts,<sup>2,51</sup> and devascularization procedures. *Nonselective shunts* result in the diversion of portal venous blood from the liver into the systemic circulation without passing through the liver. *Selective shunts* theoretically decompress only part of the portal venous system while maintaining portal pressure and portal flow to the liver, even though late studies have revealed a loss of prograde flow to the liver. *Devascularization procedures* do not involve shunting of portal blood, but rather involve the devascularization of the stomach and esophagus that separates their venous drainage from the liver and portal system. *Splenopneumopexy* is an unusual but effective procedure for decompressing

patients with total mesenteric venous occlusion via the pulmonary veins. *Liver transplantation* is now more commonly used for treating patients with portal hypertension.

**Nonselective Shunts.** Nonselective shunts can be divided into total shunts or partial shunts. Examples of total nonselective shunts include the end-to-side portacaval shunt, large side-to-side portacaval shunt (>10 mm), mesocaval shunts, and central splenorenal shunts. The end-to-side portacaval shunt is performed by dividing the PV in the porta hepatis and performing an end-to-side anastomosis to the IVC with the proximal (splanchnic) end of the PV. This effectively decompresses the splanchnic bed and will nearly always control variceal hemorrhage because the portal pressure is markedly reduced. However, the obstructed sinusoids remain under high pressure, and ascites is not usually controlled. Depending on hepatic reserve, there is an increased risk of hepatic decompensation that manifests as worsening hepatic encephalopathy or even liver failure requiring liver transplantation. Patients with well-preserved synthetic function (eg, schistosomiasis) may tolerate an end-to-side shunt without complication.

A side-to-side portacaval shunt is performed by mobilizing a length of the PV (from the head of the pancreas to its bifurcation) and the IVC (from the inferior edge of the liver to the renal veins) and performing a side-to-side anastomosis (Fig. 61-12). In some cases a portion of the caudate lobe needs to be resected to allow a direct anastomosis between the PV and IVC, or a short interposition graft may be required. Because portal pressure is much greater than the central venous pressure in the vena cava and because there is greater resistance to flow through the cirrhotic liver, large side-to-side portacaval shunts are physiologically nearly equivalent to an end-to-side shunt, with effectively all the portal flow being diverted into the vena cava with reversal of flow (hepatofugal flow) to the liver and reduced portal venous perfusion. Although ascites can be effectively decreased by this method because the sinusoidal and splanchnic beds are both decompressed, encephalopathy is often heightened as a consequence and there is again a risk of liver failure. This can accelerate the need for liver transplantation. A side-to-side portacaval shunt is still the treatment of choice for patients with Budd–Chiari syndrome and if performed early enough after the diagnosis can lead to preservation of liver function and prevent the development of cirrhosis.<sup>52</sup> Orloff's series demonstrated 94% long-term survival with well-preserved

liver function and no ascites or encephalopathy.

**FIGURE 61-12** Side-to-side portacaval shunt.

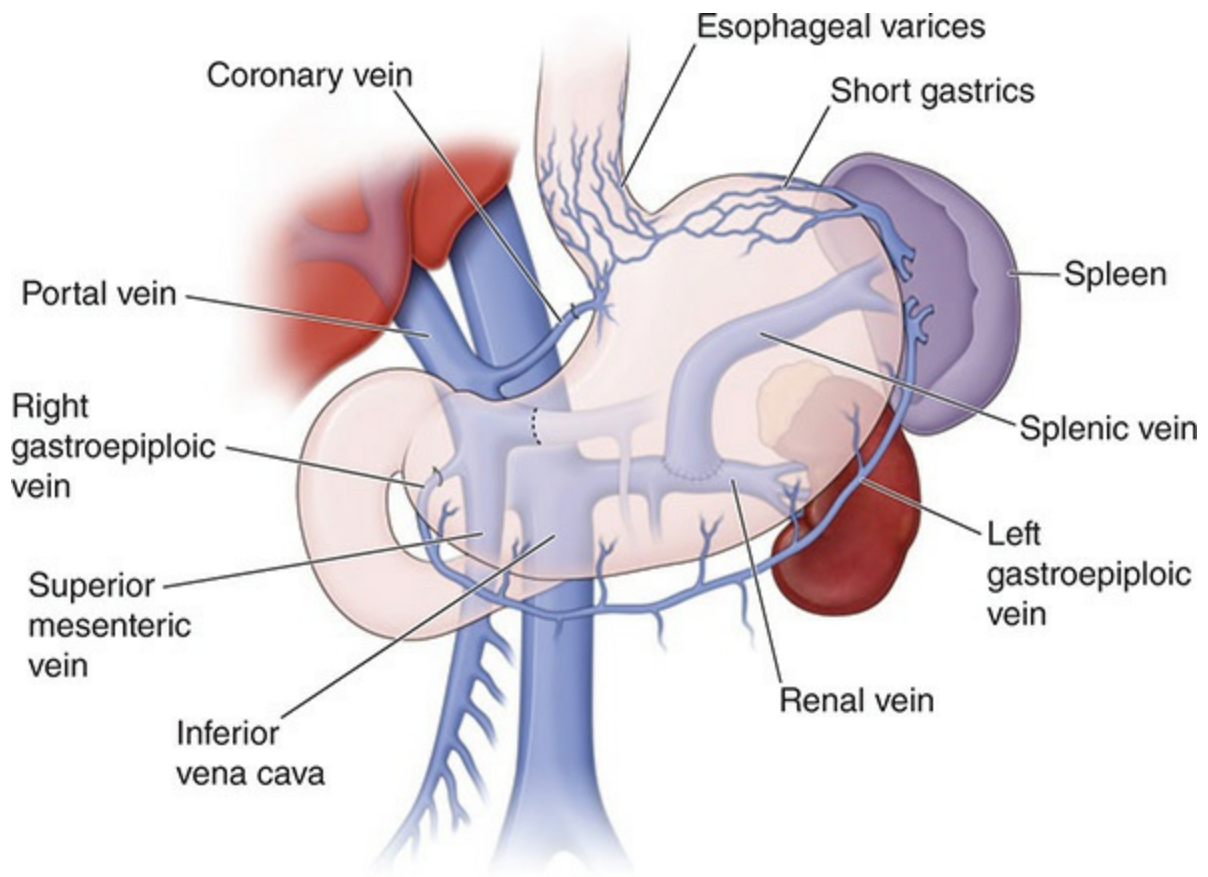

Mesocaval shunts are performed using an interposition graft (usually ribbed polytetrafluoroethylene [PTFE]) between the SMV and the IVC, and are associated with a high rate of thrombosis. The central splenorenal shunt is performed by dividing the distal SV, splenectomy, and performing an anastomosis between the SV and the left renal vein. Both these shunts are physiologically similar to an end-to-side portacaval shunt with hepatofugal flow and all the attendant risks.

**Selective Shunts.** Selective shunts are partially decompressive and include the Sarfeh mesocaval shunt (Fig. 61-13) and the distal splenorenal shunt (DSRS) (Figs 61-14 and 61-15). They are referred to as selective because they have the potential to preserve portal flow (Sarfeh and DSRS) and decompress the splanchnic beds separately, such as the gastroesophageal

network in the case of the DSRS. The Sarfeh shunt is a side-to-side shunt from the SMV to the IVC that can maintain forward portal flow, but also decreases portal pressure via small, 8 mm Dacron or PTFE grafts (Fig. 61-13). Since it is prosthetic, it does not expand like side-to-side portacaval shunts can, which can lead to them becoming complete shunts. This does not involve portal dissection and can thus render less complicated a subsequent transplant. It also has a lower rate of postoperative encephalopathy while providing improved ascites control and variceal decompression.<sup>53</sup>

**FIGURE 61-13** Sarfeh mesocaval shunt.

**FIGURE 61-14** Distal splenorenal shunt demonstrating an anastomosis between the mobilized splenic vein and the left renal vein. The splenic vein is oversewn at the junction with the superior mesenteric/portal vein confluence.

**FIGURE 61-15** The distal splenorenal shunt venous flow from the splenic vein through the renal vein into the inferior vena cava thus bypassing venous blood flow away from the portal vein.

The DSRS was developed by Dean Warren in 1967 as a means of achieving selective gastroesophageal variceal decompression and preservation of portal flow, thus mitigating the risk of postoperative hepatic decompensation.<sup>54</sup> It is performed by mobilizing the SV along the inferior border of the pancreas and disconnecting all the small branches to the pancreas, preserving the spleen, performing an anastomosis between the SV and the left renal vein, and dividing other collaterals between the PV and the shunt including the coronary (left gastric) vein (Figs 61-14 through 61-17). Benefits include control of variceal hemorrhage in 94% of patients, avoidance of portal dissection, maintenance of antegrade portal flow in 90% of patients, and a lower incidence (15%) of hepatic encephalopathy. Durable variceal decompression, however, comes at the cost of increased ascites. The “ascitogenic” nature of the operation originates from the extensive retropancreatic dissection required to mobilize the distal SV from the

pancreas in order to perform the anastomosis to the left renal vein. Another important consideration is the need to perform a splenopancreatic disconnection by discrete ligation and division of numerous SV branches.<sup>55</sup> If not divided, they can enlarge in the months to years that follow and lead to hepatofugal flow and loss of selectivity of the shunt, particularly in patients with alcoholic liver disease. This disconnection, however, further heightens the risk of ascites. As such, DSRS is relatively contraindicated in patients with medically refractory ascites.

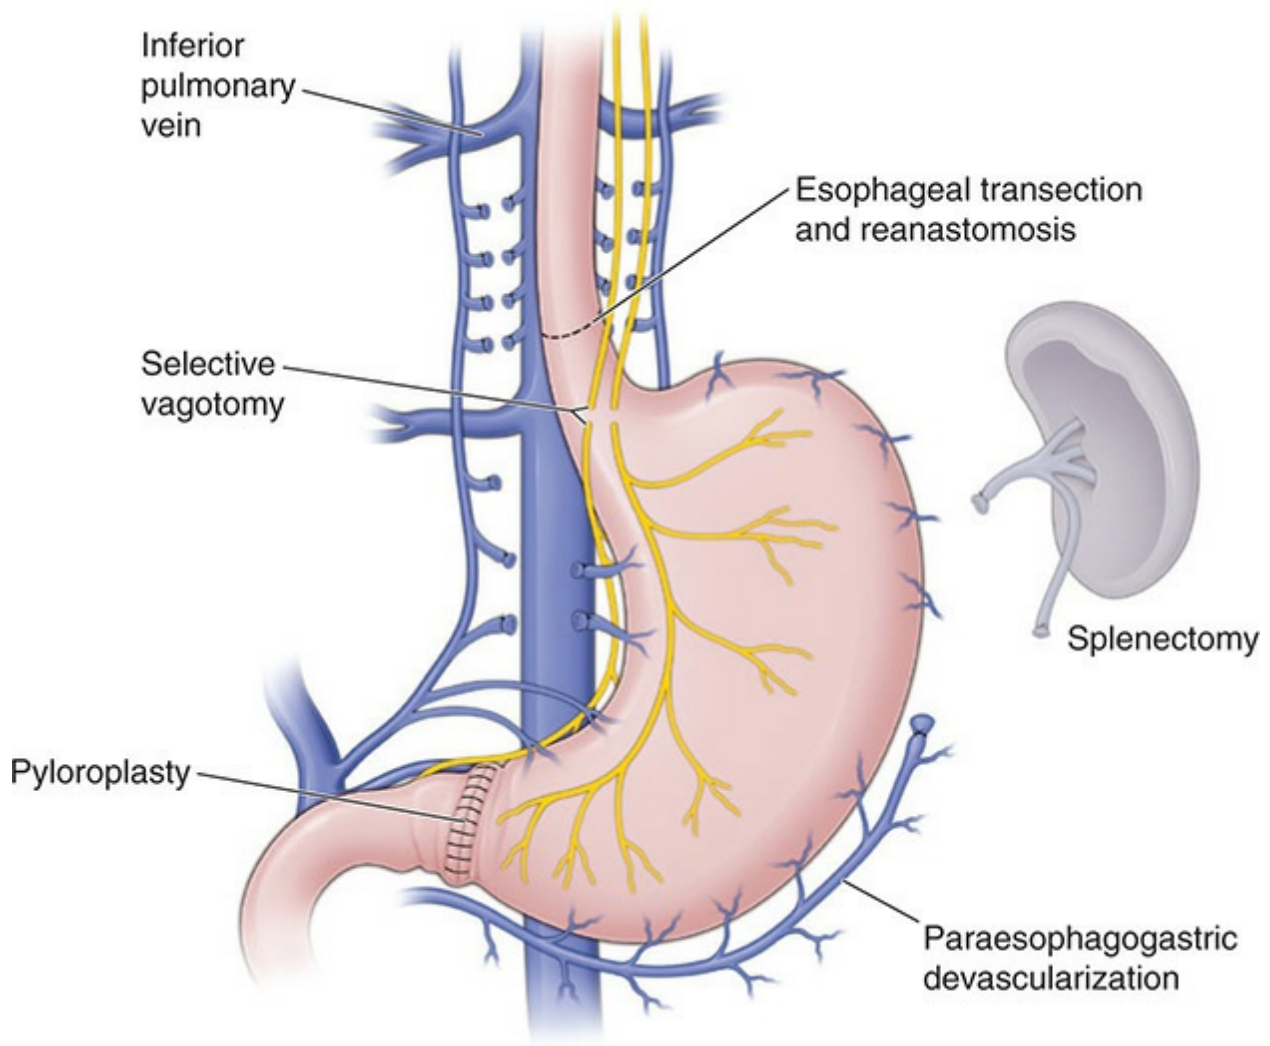

**FIGURE 61-16** Intraoperative photo of anastomosis (*arrow*) of splenic vein (SV) to the left renal vein (RV).

**FIGURE 61-17** Duplex of distal splenorenal shunt demonstrating flow from the splenic vein (SV) to the renal vein (RV) and the SV-RV anastomosis (*arrow*).

**Devascularization.** Devascularization is an approach to portal hypertensive varices that involves direct surgical ligation of esophageal veins, short gastric veins, the lesser and greater curve veins of the stomach. It preserves hepatopetal flow. Sugiura in 1973 championed this approach and added to the above components esophageal transection and anastomosis and splenectomy.<sup>56</sup> He reported rebleeding rates as low as 2% in Japan and a 7-year survival rate of 83%, but in other countries the bleeding rate ranges from 10% to 54% and survival is lower.<sup>57</sup> It may be best reserved as a last resort in the case of endoscopically refractory variceal hemorrhage and extensive portal and mesenteric venous thrombosis, when other approaches are not available. Others have achieved better results with a 10% incidence of rebleeding.<sup>58</sup> Jin and Rikkers described a modified Sugiura procedure performed only transabdominally with division of the esophageal plexus up to the level of the inferior pulmonary ligament through the hiatus and splenectomy without division of the esophagus, along with a selective

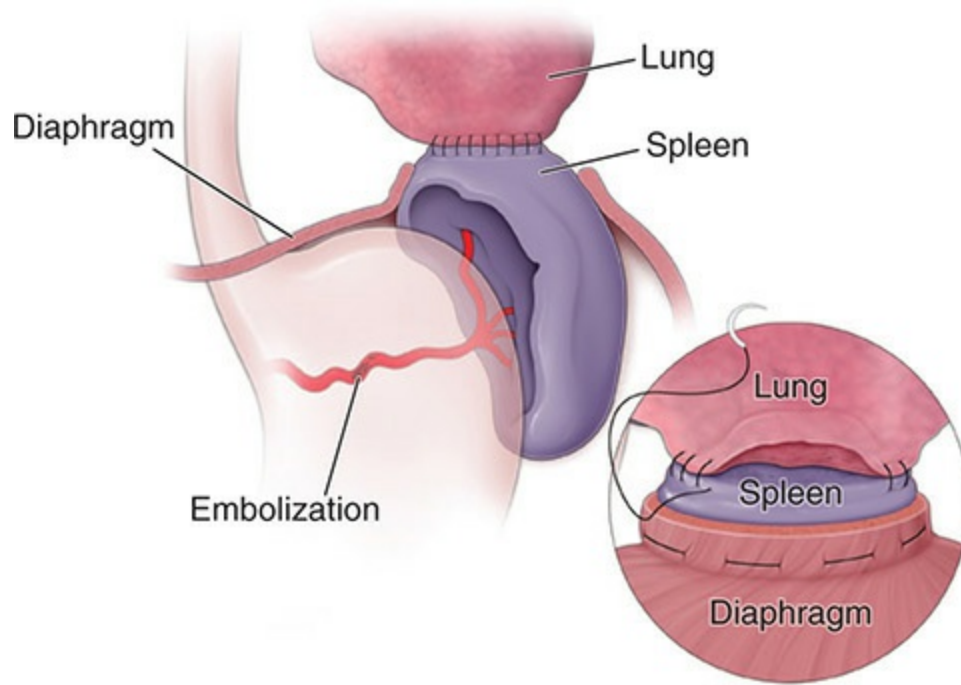

vagotomy and pyloroplasty with good results in selected patients<sup>59</sup> (Fig. 61-18). It is important that the left gastric vein (coronary vein) and paraesophageal collateral veins are preserved so that collaterals between the portal and azygous systems can develop and thereby reduce the chance of reformation of varices.

**FIGURE 61-18** Modified Sugiura devascularization procedure for total mesenteric venous thrombosis.

**Splenopneumopexy.** Splenopneumopexy is designed to lead to collateral circulation between the portal system and the pulmonary veins.<sup>60</sup> An anastomosis between the parenchyma of the transected superior pole of the spleen and the left lower lobe of the lung after removal of the pleura from the lung surface is performed through the left hemidiaphragm. Preoperative

splenic artery embolization is usually performed. This procedure is most commonly applied in patients with total mesenteric venous occlusion and is an alternative to devascularization procedures (Fig. 61-19).

**FIGURE 61-19** Splenopneumopexy for total mesenteric venous thrombosis.

**Liver Transplantation.** Liver transplantation is now frequently used to treat patients with advanced cirrhosis and complications of their cirrhosis including portal hypertension, as outcomes have improved.<sup>56</sup> Patient selection and evaluation are key aspects of the care of cirrhotic patients. The most common disease indications for liver transplantation include acute liver failure (1%), hepatitis C virus (HCV) (29%), alcoholic liver disease (25%), cholestatic disease including nonalcoholic steatohepatitis (8%), malignancy (8%), and other/unknown (29%). However, it is usually the complications of cirrhosis and portal hypertension that lead to liver transplantation, some of which have been discussed above (eg, ascites, hepatic hydrothorax, gastric and esophageal varices and hemorrhage, hyponatremia, malnutrition, jaundice, hepatorenal syndrome, hepatopulmonary syndrome, portopulmonary hypertension, cirrhotic cardiomyopathy). Patient selection requires careful attention to the risk:benefit and outcomes of medical or surgical management of their disease versus liver transplantation. This is greatly informed by the MELD score, which predicts mortality on the waiting

list. Patient selection must consider other medical and surgical comorbidities and risk factors, psychosocial factors (particularly for those with a drug or alcohol problem in the past), and technical factors. Once a patient is on the waiting list, organs are prioritized and allocated by MELD scores, with the sickest patients with the highest MELD score being transplanted first. The outcomes of liver transplantation have continued to improve with 1-, 3-, and 5-year patient survival being 86%, 78%, and 70%, respectively.<sup>61</sup>

## RADIOLOGIC MANAGEMENT

**Transjugular Intrahepatic Portosystemic Shunt.** TIPS was developed by Josef Rosch in 1969 in a canine model in which an intrahepatic channel was created radiologically between the hepatic vein (HV) and PV in order to reduce portal pressure. In 1982, TIPS was first used clinically by Ronald Colapinto. In the mid-1980s, Julio Palmaz was the first to use a stent in a canine model in order to improve patency. In 1988, the first TIPS with stenting in a human was performed by Goetz Richter. PTFE-covered stents have been adopted during the last decade, resulting in marked improvement in long-term shunt patency.

**Indications.** TIPS is most commonly indicated in bleeding patients in whom endoscopic and pharmacological therapy have failed or in patients with recurrent bleeding after EVL (Table 61-7). A randomized control trial by Garcia-Pagan et al.<sup>62</sup> concluded that the early use of TIPS in patients with acute variceal bleeding led to a significant reductions in both treatment failure and mortality. It is frequently used as a bridge to transplantation in patients with advanced liver disease and severe PHTN. As with any procedure, balancing the risks and benefits is important in these critically ill patients who are at risk for progressive liver failure and death. The MELD score was introduced and uses the patient's serum bilirubin, serum creatinine, and the international normalized ration (INR) for prothrombin time to predict survival after TIPS according to the following formula:

**TABLE 61-7: INDICATIONS FOR TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)**

Refractory acute variceal bleeding (gastric or esophageal)  
Secondary prevention of variceal bleeding (gastric or esophageal)  
Portal hypertensive gastropathy  
Refractory ascites  
Hepatorenal syndrome  
Hepatic hydrothorax  
Budd-Chiari syndrome  
Hepatic venoocclusive disease  
Hepatopulmonary syndrome

---

$$\text{MELD} = 3.78 \times \ln [\text{serum bilirubin (mg/dL)}] + 11.2 \times \ln [\text{INR}] + 9.57 \times \ln [\text{serum creatinine (mg/dL)}] + 6.43$$

The MELD score was found to be superior to the CTP score at predicting post TIPS mortality.<sup>63</sup> The 3-month mortality for a patient undergoing a TIPS with a MELD score of 40 or more is 71.3%, 30 to 39 is 52.6%, 20 to 29 is 19.6%, 10 to 19 is 6.0%, and <9 is 1.9%<sup>58</sup> (Table 61-5).

Relative contraindications include hepatic encephalopathy, congestive heart failure, tricuspid regurgitation, cardiomyopathy, pulmonary hypertension, and renal vein (RV) diastolic dysfunction (Table 61-8).

**TABLE 61-8: CONTRAINDICATIONS FOR TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)**

### **Absolute**

Primary prevention of variceal bleeding  
Congestive heart failure  
Multiple hepatic cysts  
Uncontrolled systemic infection or sepsis  
Unrelieved biliary obstruction  
Severe pulmonary hypertension (mean pulmonary artery pressure >45 mm Hg)  
Severe tricuspid regurgitation

### **Relative**

HCC especially if central

Obstruction of all hepatic veins  
Portal vein thrombosis  
Severe coagulopathy (INR >5)  
Thrombocytopenia of <20,000/cm<sup>3</sup>  
Right ventricular diastolic dysfunction  
Moderate pulmonary hypertension  
Hepatic encephalopathy

---

**Procedure.** Cross-sectional imaging of the abdomen should be obtained in all patients undergoing TIPS to define the hepatic vascular anatomy and patency of the PV, identify any anatomic variants that could influence the ability to perform the procedure, and to assess for evidence of malignancy.

There are three main HVs: the right (RHV), middle (MHV), and left (LHV). All usually enter the inferior vena cava (IVC) within 2 cm of the right atrium (RA). In most cases, the MHV and LHV form a common trunk and enter the IVC anteriorly while the RHV enters the IVC posterolaterally and more cephalad. HV size and morphology are variable and can be dramatically altered by cirrhosis. Anomalous HV and PV anatomy are seen in up to 30% of patients. In 3% to 5% of patients, a large inferior RHV may drain directly to the IVC well below the level of the RA. In this situation, the superior RHV may be atretic or absent. Occasionally, none of the HVs are accessible (such as in Budd–Chiari syndrome) and a direct IVC-to-PV-shunt (DIPS) may be considered.

PV anatomic variants are common as well. In 90% of patients, a right portal vein (RPV) trunk is present, bifurcating into anterior and posterior branches. The trunk is located between the 10th and 12th ribs approximately 0.5 to 1.5 vertebral widths to the right of the lateral margin of the spine. This information is important when using landmarks to target the PV. In 11% of patients, there is no RPV trunk and instead there is a trifurcation of the main portal vein (MPV) into anterior and posterior RPV branches and the left portal vein (LPV). Other common variants include the right posterior segment coming directly from the MPV (5%) and the right anterior segment arising from the LPV (4%). The RHV separates the anterior and posterior segments of the right hepatic lobe, originating cephalad and posterior to the RPV trunk. The MHV separates the right and left hepatic lobes and originates cephalad and anterior to the RPV.<sup>64</sup>

Most interventional radiologists prefer to create the shunt from an RHV approach. The right internal jugular (IJ) is accessed, and right atrial, free hepatic, and wedged hepatic venous pressures are measured. A suitable branch of the right hepatic vein is then cannulated (Fig. 61-20A). Using a balloon occlusion catheter or end-hole catheter, wedged hepatic venography is performed with either dilute contrast or carbon dioxide (CO<sub>2</sub>) to gently opacify the hepatic sinusoids and ultimately the PV in a retrograde fashion, allowing for direct visualization of the PV (Fig. 61-20B). CO<sub>2</sub> is preferred because of its low viscosity, low cost, lack of toxicity, and free reflux across the sinusoids, resulting in excellent filling of the PV.<sup>64</sup>

**FIGURE 61-20** Images from a 54-year-old man with recurrent esophageal variceal bleeding despite maximal endoscopic banding and medical management caused by hepatitis C cirrhosis. **A.** Right hepatic venogram demonstrates patency and course of the vein (*arrow*) as well as location of the hepatic vein/IVC junction (*arrowhead*). **B.** A wedge hepatic venogram using carbon dioxide shows the course and location of the portal veins. **C.** Iodinated contrast venogram after successful cannulation of the right portal vein through the TIPS cannula before portal passage of the guidewire. **D.** Simultaneous portovenogram and hepatic venogram using a marker pigtail catheter allow for accurate measurement of the TIPS shunt (portosystemic gradient, 22 mm Hg). Notice hepatofugal flow in the inferior mesenteric vein (*arrow*) as well as filling of esophageal varices via the coronary (*arrowhead*) and posterior gastric veins (\*). **E.** Portogram obtained after TIPS insertion shows flow through the polytetrafluoroethylene-covered (PTFE) Viatorr stent (WL Gore, Flagstaff, AZ). The peripheral portal branches no longer fill due to reversal of flow; however, the coronary and posterior gastric veins persist supplying the esophageal varices. **F.** Completion portovenogram following successful coil occlusion of the coronary and posterior gastric veins. The portosystemic gradient fell to 8 mm Hg.

Once the location of the PV is known, needle passes are made from the HV through the hepatic parenchyma under fluoroscopic guidance. The needle is slowly withdrawn with gentle aspiration using a contrast-filled syringe. Brisk blood return into the aspiration syringe signals access into a vascular

structure, ideally the PV. Injection of a small volume of contrast material fluoroscopically confirms appropriate positioning in the PV (Fig. 61-20C).

A guidewire is then passed through the access needle into the PV and ultimately manipulated into either the SV or SMV and exchanged for a catheter to directly measure portal pressures that are compared to the right atrial pressure to establish the pre-shunt PSPG. Digital subtraction angiography is then performed outlining the portal and hepatic venous systems and the presence and location of portosystemic collaterals (Fig. 61-20D). The length of the parenchymal tract is measured from the PV access site to the HV/IVC confluence. The outflow of the stent should be within 1 cm of the of the HV/IVC confluence to reduce shunt outflow stenosis. Usually 1 cm is added to the measurement to account for the arc of the tissue track once the stiff wire is removed.

Catheterization of the PV with the 10 Fr TIPS sheath is necessary to facilitate placement of the PTFE-covered stent graft. The tissue track is predilated to the intended diameter of the shunt and to ease the advancement of the TIPS sheath. The sheath must be advanced several centimeters into the MPV beyond the PV access to ensure placement of the uncovered caudal portion of the stent in the PV. The covered portion of the stent is placed across the parenchymal track to the HV/IVC confluence. The covered portion was devised to reduce bile contact from crossed biliary radicles and reduce pseudointimal hyperplasia, the leading cause of in-stent stenosis and thrombosis in TIPS performed with bare metal stents. A 10- or 12-mm stent diameter is typically chosen for adults, while 8-mm stents are typically used in the pediatric population.

Once the stent is deployed, it is molded using the same balloon that was used for the initial track dilation, usually an 8-mm balloon. If a 10- or 12-mm stent was placed, this allows additional dilation if the post-TIPS gradient has not been sufficiently reduced.

Following placement of the shunt, post-TIPS pressures are measured. A post-TIPS PSPG of <12 mm Hg in patients with a history of variceal bleeding should be achieved to prevent further bleeding episodes.<sup>65</sup> Following pressure measurements, the pigtail catheter is repositioned in the PV and a repeat portogram is performed from the same position as the original with the same injection rate to assess flow through the shunt as well as to evaluate persistent filling of portosystemic collaterals (Fig. 61-20E).

**Outcomes.** Success rates with TIPS for decompression of the portal system are >90% of cases in most series. SIR consensus guidelines state that a technically successful outcome that includes both creation of the shunt and a decrease in portal pressure to <12 mm Hg should be achieved in 95% of patients, and clinical success (resolution of the complication of portal hypertension) should be achieved in 90% of cases.<sup>66</sup>

A longitudinal pharmacological study demonstrated the risk of bleeding was zero when the HVPG was lowered to  $\leq 12$  mm Hg. Subsequent studies have shown that an overall reduction of the HVPG of >20% confers a significant reduction in the risk of bleeding.<sup>67</sup> Therefore, a reduction in the HVPG >20% or an absolute value <12 mm Hg are the accepted therapeutic targets of therapy.<sup>68</sup>

Numerous randomized controlled trials as well as two recent meta-analyses found more than a threefold decrease in the risk of recurrent bleeding after TIPS placement compared with endoscopic therapy with similar all-cause mortality rates. Rebleeding after TIPS ranged from 9% to 40.6% compared to 20.5% to 60.65 with endoscopic therapy. There was a more than twofold increase in the rate of development of hepatic encephalopathy after TIPS, but hepatic encephalopathy can usually be easily controlled with medical therapy.<sup>69</sup>

TIPS is now the most widely used method for decompressing PHTN in patients with variceal bleeding who have failed EVL, replacing most surgical shunts, and is often used in patients with intractable ascites and hepatic hydrothorax.

**Embolization of Varices Post-TIPS.** A recent case control study suggested that even patients with target PSPGs following TIPS placement for variceal bleeding can benefit from variceal embolization.<sup>70</sup> Coil embolization is the most widely used method to occlude varices and should be performed post TIPS in patients with recent variceal hemorrhage even when a target PSPG is achieved (Fig. 61-20F).

**PTFE-Covered Stents.** The development of PTFE-covered stent grafts has significantly reduced the occurrence of TIPS dysfunction, according to two large studies. The first series included 71 patients in a nonrandomized, non-controlled study. In those enrolled, eight shunt revisions were performed for an incidence of 11.3%. Primary patency rates at 6 and 12 months were 87%

and 81%, respectively.<sup>71</sup> The second was a randomized controlled trial comparing bare metal stents with PTFE stent-graft.<sup>72</sup> Eighty patients with cirrhosis and either refractory ascites or recurrent variceal bleeding were enrolled. Patients were followed with Doppler US and venography was performed at 6, 12, and 24 months post-TIPS. Only 13% of the patients receiving stent grafts had shunt dysfunction, whereas 44% of those receiving bare stents had dysfunction. Also, early thrombosis was seen in three patients receiving bare metal stents. The actuarial rates of primary patency in the covered and bare metal stent groups were 86% and 47%, respectively at 1 year, and 80% and 19% at 2 years. On the basis of this data, PTFE-covered stents have become the standard of care device for de novo TIPS, and patients who have bare metal stents and need repeat intervention should undergo shunt revision with a PTFE-covered stent graft.

**TIPS Maintenance.** A baseline Doppler US is performed 1 to 4 weeks following TIPS placement and usually every 3 to 6 months thereafter. Immediate US is hampered by microbubbles retained in the PTFE-covered stent grafts. Shunt velocities of 250 cm/s or greater or 50 cm/s or less are associated with high sensitivity (>90%) and specificity for shunt dysfunction.<sup>20</sup> The best indicator of TIPS dysfunction is recurrence of the clinical symptoms for which the shunt was originally placed and should prompt a Doppler US for evaluation.

Patients suspected of TIPS dysfunction should undergo TIPS venography. If the original TIPS was created with a bare metal stent, it should be covered with a PTFE-covered stent graft. Other commonly used interventions include balloon angioplasty for stenosis or stent extension for shunts that are too short either cranially or caudally.

**Complications (Table 61-9).** TIPS dysfunction is defined as  $\geq 50\%$  stenosis of the shunt, an increase in the HVPG to  $>12$  mm Hg, or recurrence of the problem for which the shunt was placed (eg, bleeding varices) and is usually caused by pseudointimal hyperplasia within the stent. As discussed above, 13% of the patients receiving covered stent grafts had shunt dysfunction over 2 years, compared to 44% in those with bare metal stents. Close monitoring with Duplex US is important for long-term patency, and if shunt dysfunction is suspected hepatic venography should be performed. Shunt thrombosis typically occurs in 10% to 15% of patients with bare metal stents within 24

hours of placement.<sup>37,73</sup> If early shunt thrombosis is suspected, CT or MR venography can be performed to assess shunt dysfunction.

**TABLE 61-9: TIPS COMPLICATIONS**

TIPS dysfunction	
Bare metal	13%
Covered	44%
Transcapsular puncture	33%
Intraperitoneal bleed	1-2%
Hepatic infarction	~1%
Fistulae	Rare
Hemobilia	<5%
Sepsis	2-10%
Infection of TIPS	<1%
Hemolysis	10-15%
Encephalopathy	
New/worse	20-31%
Chronic	5-20%
Stent migration or placement into IVC or too far into PV	20%

The incidence of new or worsening encephalopathy following TIPS is 20% to 31%. Pre-TIPS factors associated with an increased risk of encephalopathy include etiology of liver disease other than alcohol, female gender, and hypoalbuminemia as well as increasing age, past history of encephalopathy, and evidence of encephalopathy at the time of TIPS. Only if hepatic encephalopathy is uncontrolled is TIPS contraindicated. In most cases, encephalopathy responds well to standard therapies, and only rarely (~5%) does the TIPS need to be occluded to control the encephalopathy.<sup>37,69</sup>

The incidence of fatal complications (intra-abdominal hemorrhage, laceration of the HA or PV, and right heart failure) is less than 1.5%. Technical complications include transcapsular puncture in up to 33% of cases, although capsular perforation leads to significant hemorrhage in only 1% to 2% of cases. Clinically significant hemobilia is rarely seen. The stent

can be placed too far cranially into the IVC or RA or too deep caudally into the PV in up to 20% of cases.<sup>35</sup> The stent outflow should be placed to the junction of the HV and the IVC. Stents that are left short will ultimately lead to stenosis at the stent/hepatic vein interface and TIPS dysfunction, and should be extended at the time of initial placement.<sup>37</sup>

**Direct Intrahepatic Portacaval Shunt.** DIPS is a modification of the TIPS procedure. It consists of direct access of the PV from the IVC via the caudate lobe, typically using intravascular US guidance. Once portal access is obtained, the shunt is created using a PTFE-covered stent graft in a similar fashion as a standard TIPS access. Physiologically this shunt is a side-to-side portacaval shunt from the IVC to the MPV through the caudate lobe of the liver. The DIPS procedure can be extremely helpful in patients with challenging anatomy, such as Budd–Chiari syndrome, patients with PVT, or hepatocellular carcinoma.<sup>74</sup> In the right hands, DIPS may have added benefits over the standard TIPS technique including decreased fluoroscopy times, increased patency, and to extend the spectrum of patients with portal hypertension for whom endovascular portosystemic shunting can be performed.<sup>37,74</sup>

**Balloon-Occluded Retrograde Transvenous Occlusion.** BRTO of gastric varices is an emerging technique that can be performed as an adjunct or alternative to TIPS for the management of isolated gastric varices.<sup>75,76</sup> BRTO is indicated in patients who are not candidates for TIPS because of coagulopathy, high MELD score, or severe hepatic encephalopathy, as well as for the prophylaxis of high-risk gastric varices.<sup>77,78</sup>

BRTO is performed by accessing the portosystemic gastrosplenic shunt via the left renal vein from either a transfemoral or transjugular vein approach. A balloon catheter is advanced into the outflow shunt, inflated, and a retrograde digital subtraction venogram is performed to identify the gastric varices, their inflow and outflow vessels, and collaterals (Fig. 61-21A). Gastric collateral vessels can be occluded first with coils, glue, or gelatin sponge particles to decrease non-target embolization (Fig. 61-21B). The gastric varix can then be embolized under fluoroscopic control in a retrograde fashion either through the occlusion balloon catheter or through a microcatheter placed within the gastric varix (Fig. 61-21C). A foamed mixture of 3% sodium tetradecyl sulfate (STS) is used as the sclerosant. The endpoint of embolization is

minimal filling of the feeding portal branch (Fig. 61-21D). In addition, cone beam CT (performed on the angiography table) can be a valuable adjunct to the procedure to document complete filling of the varix. The balloon is left in place inflated for 4 hours post embolization to allow stabilization of the thrombus within the varix, and is removed under fluoroscopic guidance.<sup>79</sup>

D

**FIGURE 61-21** 55-year-old male with HCV cirrhosis and high-risk gastric varices presenting for balloon-occluded retrograde transvenous obliteration of gastric varices (BRTO). **A.** Retrograde venogram via the gastroduodenal vein

shows partial filling of the gastric varix (*arrowhead*) as well as collateral systemic outflow through the inferior phrenic vein (*arrow*). **B.** Successful coil occlusion of the inferior phrenic vein outflow. **C.** Retrograde venogram shows occlusion balloon (*arrowhead*) in the proximal gastrosplenic shunt, with filling of the gastric variceal complex (*arrows*). **D.** Fluoroscopic image after administration of the sclerosant mixture with complete filling of the gastric variceal complex (*arrows*), the end point of embolization is minimal filling of the afferent portal branch (*arrowhead*).

Technical success, defined as successful filling of gastric varices with sclerosant, is reported to occur in 77% to 100% of cases. Complete obliteration of the gastric varices is reported in 82% to 100% of patients (Fig. 61-22A, B). In some studies, repeat BRTO is necessary to achieve these outcomes. Rebleeding rates are reported as high as 15%, but are typically much lower, with most studies showing rebleeding rates lower than 5%.<sup>77,78</sup>

A

B

**FIGURE 61-22** 55-year-old male with HCV cirrhosis and high risk gastric varices. **A.** Axial contrast-enhanced CT prior to BRTO demonstrates high-risk gastric varices (*arrows*). **B.** Axial contrast-enhanced CT 1 year after BRTO demonstrates complete obliteration of the previously seen varices (*arrows*).

Complications are uncommon but can include epigastric and back pain, fever and hematuria, bacterial peritonitis, worsening ascites and hydrothorax, PV and renal vein thrombosis, pulmonary embolism, ventricular fibrillation, pulmonary edema, and anaphylaxis to ethanolamine oleate.<sup>78</sup> Another complication of BRTO is the aggravation of nongastric (esophageal or duodenal) varices caused by an increase in portal pressure after occlusion of a large gastorenal shunt. Therefore, follow-up endoscopy is necessary after the procedure. Studies have shown an increase in esophageal varices at 1, 2, and 3 years of 27% to 35%, 45% to 66%, and 45% to 91%, respectively.<sup>80</sup> Typically these varices can be managed endoscopically.

## Portal Hypertensive Gastropathy

Portal hypertensive gastropathy refers to changes in the gastric mucosa including friability, dilatation of the venules, and capillaries that have a characteristic mosaic or “snakeskin” appearance. Portal hypertensive gastropathy is often associated with bleeding, which can be slow chronic blood loss requiring intermittent transfusion or can be massive hemorrhage.  $\beta$ -blockade and octreotide have been used along with endoscopic therapy with fibrin or argon beam coagulation. TIPS is the most effective in controlling bleeding from portal hypertensive gastropathy.

## Portal Vein Thrombosis and Total Mesenteric Venous Occlusion

PVT causes presinusoidal portal hypertension, may involve the intrahepatic branches, and may extend to involve the superior mesenteric or splenic veins.<sup>81-83</sup> The prevalence of chronic PVT in cirrhotic patients is 10% to 25% and is even more common in patients with decompensated cirrhosis and a history of splenectomy.<sup>84</sup>

As portal hypertension progresses, portal flow can become stagnant to the point of thrombosis. This can of course become complete and thus exacerbate ascites and variceal bleeding. It can also occur slowly over time. In this case it is often not associated with any identifiable perturbation in liver function or symptoms. However, newly diagnosed PVT in a cirrhotic mandates an assessment for hepatocellular carcinoma. About 25% of PVT is related to an underlying hepatocellular carcinoma or pancreatic carcinoma.<sup>85</sup> Although it may be worth considering anticoagulation in the case of cirrhotic patients with partial PVT, these patients often have varices, and anticoagulation should not precede adequate bleeding prophylaxis and management.

In symptomatic patients with acute PVT, the choice of treatment is determined by the severity of the symptoms. Anticoagulation should be started immediately unless otherwise contraindicated. Bowel ischemia and infarction from total mesenteric venous occlusion necessitate surgical resection, but ischemia may respond to percutaneous therapies, and thrombolysis can be considered.<sup>86</sup>

A number of case reports describe approaches to the treatment of portal and mesenteric venous thrombosis. The portal venous system can be accessed directly from transjugular, trans-hepatic, or trans-splenic routes, or indirectly via a transarterial approach for catheter-directed thrombolysis. A transjugular approach may be most appropriate in patients with preexisting cirrhosis when a TIPS is needed to decompress the portal system. The transjugular approach has additional advantages in patients with severe coagulopathy and massive ascites, whereas transhepatic or trans-splenic approaches pose a high risk of bleeding.

With these direct approaches the portal venous system is accessed, a multiside hole infusion catheter is placed across the thrombus, and thrombolytic therapy is initiated while the patient is monitored for signs of bleeding in the intensive care unit. Agents used include rTPA, urokinase, and streptokinase. In the transarterial (indirect) approach, a catheter is directed into the superior mesenteric artery, and thrombolytic infusion is delivered to the portal venous system across the capillary bed. Thrombolytic therapy is continued until either the thrombus resolves or there is no further improvement in the appearance of the thrombus, worsening clinical symptoms, evidence of systemic fibrinolysis, or bleeding complication.<sup>87</sup>

In addition, catheter-directed mechanical thrombectomy (MT) can be

performed concomitantly to hasten clot removal. A commonly used device is the AngioJet, which is an over-the-wire device that can be easily manipulated through the thrombosed PV segment and utilizes a complex mixture of rapid fluid streaming and hydrodynamic forces to fracture thrombus, allowing extraction at the catheter tip using negative pressure (Bernoulli/Venturi principle).<sup>83</sup> The catheter can also be used in “power pulse spray” mode to deliver a bolus dose of the thrombolytic of choice through the extent of the thrombus prior to MT. Other alternative techniques for clot removal have been described and include balloon embolectomy, suction catheter embolectomy, and basket extraction of thrombus. Following thrombus removal, it is necessary to identify the presence of an underlying “fixed” stenosis in the PV that can be corrected with balloon angioplasty and stent placement.<sup>83</sup>

## **Hepatic Encephalopathy**

Hepatic encephalopathy is one of the most frequent and debilitating aspects of cirrhosis and PHTN.<sup>69</sup> The cognitive impairment can be manifest in various neurologic or psychiatric abnormalities from subclinical disease to coma. These abnormalities can include extrapyramidal dysfunction, asterixis, myelopathy, apathy, and disinhibition. Poor synthetic function and TIPS or surgical portosystemic shunting for PHTN are the main etiologies in the cirrhotic patient. The prevalence of overt encephalopathy in decompensated cirrhosis is 16% to 21%, and post-TIPS 10% to 50%. Lactulose is the initial treatment strategy and is titrated to effect to achieve two to three bowel movements per day. Among other effects, it creates an acidic prebiotic colonic milieu that favors growth of beneficial microorganisms. This is thought to be the reason that laxatives alone are not effective treatments for overt encephalopathy. Rifaximin has been shown in clinical trials to be well tolerated and equivalent or superior in effect. It is often coupled with lactulose for overt encephalopathy refractory to lactulose alone. Although neomycin and metronidazole have been used for short-term therapy, they are not ideal as a part of chronic management due to morbidities including ototoxicity, nephrotoxicity, and neurotoxicity.

## **Hepatorenal Syndrome**

Hepatorenal syndrome is characterized by a progressive rise in serum creatinine, normal urine sediment in most cases, absence of proteinuria (<500 mg per day), low rate of sodium excretion (urine sodium concentration <10 meq/L), and oliguria in patients with severe liver disease, and is a diagnosis of exclusion.<sup>88</sup> There are two forms: Type 1 hepatorenal syndrome, defined as at least a twofold increase in serum creatinine to >2.5 mg/dL over less than 2 weeks, and Type 2, defined as renal dysfunction that is less severe than Type 1 and is often associated with diuretic resistant ascites. The ideal therapy is recovery of liver function. Other treatments include volume expansion, norepinephrine (or vasopressin) in combination with albumin, terlipressin plus albumin, or midodrine, octreotide, and albumin if terlipressin is not available, TIPS, dialysis, and ultimately liver transplantation. Most patients with hepatorenal syndrome die within weeks without therapy. Patients can be maintained on dialysis, but usually die of their liver disease without transplantation. After successful liver transplantation, renal function recovers with the restoration of normal liver function.

## **Hepatopulmonary Syndrome**

Hepatopulmonary syndrome (HPS) is manifest as a defect in oxygenation associated with pulmonary vascular dilatation and arteriovenous communications that occur in patients with liver disease.<sup>89</sup> The clinical manifestations usually occur only after many years of liver disease and include dyspnea on exertion, at rest, or both, digital clubbing, facial telangiectasia, wheezing, and syncope. Patients with chronic liver disease should have screening pulse oximetry and if it is less than 97% on room air in a standing or sitting position, further evaluation should be performed including an arterial blood gas. The prevalence of HPS in cirrhotic patients is between 15% and 20%.<sup>90</sup> The best next test (chest radiograph is usually normal) is a contrast-enhanced transthoracic echocardiogram, which should be performed with saline that has been shaken to produce microbubbles and is then injected into a peripheral vein in the arm. Microbubbles (>10 µm in diameter) do not pass through normal capillaries (<8 to 15 µm in diameter), so the detection of microbubbles in the left atrium within three to six cardiac cycles indicates their passage through dilated pulmonary capillaries or through arteriovenous communications. An intracardiac shunt can also give a positive bubble echo result. Only pulmonary angiography can tell the

difference between the first two entities, and transesophageal contrast-enhanced echocardiography can detect intracardiac shunts.<sup>89</sup> A 99m Technetium-macroaggregated (MAA) perfusion lung scan can be used to quantify and follow the degree of intrapulmonary shunting (27.8% highly specific for intrapulmonary shunting with hypoxia).

It is important to determine the severity of the HPS because it determines survival and aids in determining the timing for liver transplantation. The degree of severity is defined by an alveolar-arterial oxygen gradient  $\geq 15$  mm Hg and  $P_aO_2 \geq 80$  mm Hg (mild),  $\geq 60$  to  $< 80$  mm Hg (moderate),  $\geq 50$  to  $< 60$  mm Hg (severe), and  $< 50$  mm Hg (very severe). The median survival of patients who are not candidates for liver transplantation is 24 months, with a 5-year survival of 23%; survival is significantly worse for patients with a  $P_aO_2 < 50$  mm Hg.<sup>91</sup>

There are no effective medical treatments for HPS and the only option is liver transplantation. Patients should be treated with supplemental  $O_2$  to relieve symptoms. The indications for liver transplantation are a  $P_aO_2 < 60$  mm Hg on RA while sitting and a positive bubble echo. Patients are given priority on the waiting list by the granting of HPS MELD exception points.<sup>85</sup> A recent review of patients transplanted for HPS showed that there was no association between pre-transplantation  $P_aO_2$  and waitlist survival, but a pretransplant  $P_aO_2 \leq 44$  mm Hg was associated with an increased mortality post-transplant compared to patient with a  $P_aO_2$  44.1 to 54.0 mm Hg (hazard ratio = 1.58).<sup>92</sup>

## Portopulmonary Hypertension

Portopulmonary hypertension (POPH) is often confused with hepatopulmonary syndrome because the initial clinical manifestations are similar. POPH, however, can be associated with mild hypoxemia, but not with the severe hypoxemia seen with HPS. Its prevalence is thought to be about 8.5% in patients with liver disease and it is recommended that all patients should be screened for POPH by transthoracic echo. In portopulmonary hypertension, vasoconstriction of the pulmonary arterial bed leads to obstruction of flow. There is also endothelial and smooth muscle cell proliferation, in situ thrombosis, and arteriopathy.<sup>89,93</sup> Chest radiograph and

EKG may reveal a prominent pulmonary artery and right ventricular hypertrophy, but both can be normal. An echocardiogram may show elevations in right ventricular systolic pressures (>50 mm Hg). The diagnosis should be confirmed by a right heart catheterization and measurement of pulmonary hemodynamics that show a mean pulmonary artery pressure >25 mm Hg, pulmonary vascular resistance >240 dyn·s/cm<sup>5</sup>, and a normal or decreased pulmonary capillary wedge pressure <15 mm Hg. Mild portopulmonary hypertension is defined by a mean PAP 25 to 35 mm Hg, moderate 35 to 45 mm Hg, and severe >45 mm Hg.

The treatment of POPH includes supplemental oxygen for hypoxemia (which can worsen POPH via vasoconstriction), prostanoids such as epoprostenol, combination therapy with endothelin receptor antagonists such as intravenous Iloprost and oral Bosentan, and phosphodiesterase inhibitors such as sildenafil.<sup>94</sup> The survival of untreated POPH is poor, and the aforementioned medical therapies are associated with improved survival rates.<sup>95</sup> However, the best survival is with liver transplantation (67% at 5 years), although this depends on the severity of the POPH. For example, the mortality rate of liver transplantation is 35% in patients with a mean PAP >35 mm Hg. Medical therapy should first be implemented to bring the mean PAP down below 35 mm Hg before attempting a liver transplant to maximize outcomes.

## PORTAL HYPERTENSION IN CHILDREN

The management of portal hypertension in children has changed just as it has in adults with improvements in outcomes related primarily to better medical therapy, better endoscopic and radiologic variceal control, and liver transplantation. Emergency shunts are rarely required and TIPS can be used as a bridge to transplant, although the experience in children is limited. It is important to note that the approach to children who have normal parenchyma and well-preserved synthetic function is different than for those with cirrhosis and hepatic dysfunction just as it is in adults.

An interesting aspect of the treatment of children with PHTN are patients with extrahepatic PVT, the management of which has changed significantly since the development of the mesenteric vein-to-LPV bypass for post-transplant PVT.<sup>96</sup> The operation, referred to as a Rex shunt, involves

shunting blood from the patent but obstructed mesenteric vein to the still patent LPV (Fig. 61-23). The criteria for the procedure include no intrinsic liver disease, a patent intrahepatic portal venous system, and a suitable vein in the mesenteric venous system to provide inflow. The procedure is started by dissecting out the intrahepatic LPV in the recessus of Rex where the round ligament enters the liver between segments III and IVB.<sup>96</sup> This requires some excision of liver parenchyma (segments III and IVB) and all the branches to segments II, III, and IV are ligated and divided. The SMV or alternatively the splenic, inferior mesenteric, or coronary veins are dissected out and prepared for anastomosis. The IJ vein is then removed and anastomosed to the intrahepatic PV and then to the SMV. The vein graft usually tracks through the transverse mesocolon and the lesser sac behind the stomach and to the liver. This shunt can restore portal flow to the liver and relieve the portal hypertension resulting from PVT. Patency rates exceed 90% in properly selected patients.

## **GALLBLADDER AND BILE DUCTS**

# CHOLELITHIASIS AND CHOLECYSTITIS

*Ezra N. Teitelbaum • Nathaniel J. Soper*

## HISTORY AND BACKGROUND

Cholecystectomy is one of the most common surgical procedures performed in the United States, with over 700,000 procedures performed each year.<sup>1</sup> Open cholecystectomy, first performed by Carl Langenbuch in 1882, had been the primary treatment of gallbladder disease through the early 1990s.<sup>2</sup> In 1985, the first endoscopic cholecystectomy was performed by Erich Mühe of Böblingen, Germany. Shortly thereafter, pioneers in France and the United States coupled a video camera with a laparoscope to allow the surgeon and the entire surgical team to more easily view the operative field and performed cholecystectomies with laparoscopic equipment. Since then, laparoscopic cholecystectomy has been adopted around the world, and subsequently been recognized as the gold standard for the treatment of gallstone disease.<sup>3,4</sup> The first laparoscopic cholecystectomy in the United States was performed in 1988, and by 1992, the National Institutes of Health (NIH) Consensus Development Conference stated that laparoscopic cholecystectomy provides a safe and effective treatment for most patients with symptomatic gallstones.<sup>5</sup>

Currently, it is estimated that approximately 90% of cholecystectomies in the United States are performed using a laparoscopic approach.<sup>6</sup>

The advantages of laparoscopic over open cholecystectomy have been well documented. These advantages include earlier return of bowel function, less postoperative pain, improved cosmesis, shorter length of hospital stay, earlier return to full activity, decreased wound infections and incision hernia formation, and decreased overall cost.<sup>4,5,7,8</sup> There has been an increase in the rate of cholecystectomies subsequent to the introduction of laparoscopic cholecystectomy accompanied by evidence of lower clinical thresholds for operative therapy of gallbladder disease.<sup>9,10</sup>

## INDICATIONS FOR CHOLECYSTECTOMY

### Symptomatic Cholelithiasis

There are multiple indications for cholecystectomy, with the most common being symptomatic cholelithiasis, also termed “biliary colic” (Table 62-1). Biliary colic typically presents as a severe and episodic right upper abdominal or epigastric pain that can radiate to the back. Attacks frequently occur within 1 to 2 hours postprandially or awaken the patient from sleep. Most often, the postprandial pain will be associated with meals that are high in fat content. These episodes typically last between 30 minutes and 6 hours and can be associated with nausea and vomiting.

TABLE 62-1: INDICATIONS FOR LAPAROSCOPIC CHOLECYSTECTOMY

#### **Symptomatic cholelithiasis**

Biliary colic

Acute cholecystitis

#### **Choledocholithiasis**

Obstructive jaundice or cholangitis

Gallstone pancreatitis

#### **Asymptomatic cholelithiasis**

Sickle cell disease

Chronic immunosuppression

No immediate access to health care

Incidental cholecystectomy for patients undergoing intra-abdominal operations for other reasons

**Acalculous cholecystitis**

**Functional gallbladder disorder**

**Gallbladder polyps >10 mm**

**Porcelain gallbladder**

---

Once a patient begins to experience symptoms, there is a greater than 80% chance that he or she will continue to have symptoms in the future or develop a complication. These complications may result from obstruction of the gallbladder outlet, causing acute cholecystitis, or migration of a stone into the common bile duct, causing cholangitis or pancreatitis. Because there are no effective medical therapies for cholelithiasis, any patient who develops symptoms from gallstone disease should be offered laparoscopic cholecystectomy, given their medical comorbidities do not pose a prohibitive operative risk.

Patients being considered for laparoscopic cholecystectomy should undergo a complete medical history and physical examination. The history should focus on confirming that the patient's symptoms are consistent with biliary colic and determining whether they have symptoms indicative of complications of gallstone disease, such as acute cholecystitis, choledocholithiasis, or gallstone pancreatitis. Additionally, a complete medical history is required to determine the patient's overall surgical risk. Patients with symptomatic cholelithiasis do not typically manifest any signs on physical exam, even when they are in the midst of a pain episode. This is because their pain is visceral in nature, without associated inflammation that would cause local peritonitis and somatic pain. As a result, if a patient has significant right upper quadrant tenderness on exam, it should be suspected that they have acute cholecystitis or another inflammatory process.

Patients being evaluated for gallstone disease should have a complete metabolic panel, including liver function tests (LFTs), and a complete blood count (CBC). Elevations in the LFTs, especially direct bilirubin, may suggest biliary obstruction from choledocholithiasis. Elevations in amylase and, more

specifically, lipase may indicate gallstone pancreatitis. A leukocytosis is suggestive of acute cholecystitis.

In a patient with typical biliary colic, the only diagnostic imaging study necessary prior to laparoscopic cholecystectomy is an abdominal ultrasound revealing gallstones. Ultrasound demonstrates the size and number of stones, the thickness of the gallbladder wall, the presence or absence of pericholecystic fluid, the diameter of the common bile duct (CBD), and other components of the biliary ductal system. Gallstones are seen as rounded hyperechoic echogenic shapes on ultrasound that cause hypoechoic “shadowing” deep to their location on the ultrasonic image (Fig. 62-1). Other nonbiliary disorders such as hepatic lesions or steatosis, masses in the pancreas, or renal tumors may also be diagnosed. If a patient with gallstones has atypical symptoms, however, a more extensive workup including upper gastrointestinal contrast radiography or endoscopy, computed tomography, or cardiac and pulmonary evaluation may be appropriate to rule out significant nonbiliary disease processes.

**FIGURE 62-1** Transabdominal ultrasound showing a gallstone within the gallbladder. The hyperechoic gallstone (GS) creates a hypoechoic “shadow”

(S) deep to its position in the sonographic view.

## Acute Cholecystitis

Acute cholecystitis occurs when a gallstone or sludge becomes lodged in the gallbladder-cyst duct junction, creating bile stasis in the gallbladder, which in turn leads to inflammation and infection. In contrast to biliary colic, patients with acute cholecystitis usually present to the emergency department with unremitting right upper quadrant or epigastric pain, and can additionally have fevers and more severe nausea and vomiting. On physical exam, they can be febrile and tachycardic, but the most consistent exam finding is right upper quadrant tenderness, which is not typically present with biliary colic. Murphy sign is the traditional physical exam test for evaluating for acute cholecystitis. To elicit it, the examiner palpates the right upper quadrant immediately below the costal margin and asks the patient to inspire deeply. This maneuver moves the diaphragm inferiorly and brings the gallbladder into contact with the anterior abdominal wall under the examiner's hand, which causes pain in the setting of cholecystitis. Thus, if the patient abruptly ceases inspiration due to pain, he or she is found to have a positive Murphy sign. A positive Murphy sign has been shown to have a sensitive of 97% and a specificity of 48% in diagnosing acute cholecystitis, with cholescintigraphy used as the "gold standard."<sup>11</sup>

Laboratory evaluation can reveal an elevated white blood cell count in patients with acute cholecystitis, although their liver function tests, especially the direct bilirubin, should be relatively normal given there is no biliary obstruction. Abdominal ultrasound should reveal the presence of gallstones and can additionally show 2 signs that are specific to cholecystitis: thickening of the gallbladder wall to greater than 4 mm and pericholecystic fluid. When combined, these findings have a sensitivity of 88% and specificity of 80% in diagnosing acute cholecystitis.<sup>12</sup> However, in our experience, the presence or absence of these ultrasound findings does not correlate well with the degree of inflammation found at the time of subsequent operation.

A thorough history and physical examination, combined with findings on abdominal ultrasound, should be sufficient to confirm a diagnosis of acute cholecystitis in almost all instances; however, if doubt exists, cholescintigraphy (also known as a HIDA scan) can be used.

Cholescintigraphy is a nuclear medicine study in which a radiotracer,  $^{99m}\text{Tc}$ -hepatic iminodiacetic acid (HIDA), is injected intravenously and selectively taken up by the liver. The tracer is then excreted into the biliary tree, and a lack of uptake into the gallbladder signifies an obstruction of the cystic duct and thus a diagnosis of cholecystitis. Cholescintigraphy has a sensitivity of greater than 95% and a specificity of 90% in diagnosing acute cholecystitis.<sup>13</sup>

Patients with acute cholecystitis should be admitted to the hospital, placed on bowel rest, volume resuscitated with isotonic intravenous fluid, and treated with intravenous antibiotics that cover gram-negative and anaerobic bacteria. Although some patients may improve with this conservative treatment, recurrence rates are high, and if the patients have acceptable operative risk, almost all patients with acute cholecystitis should undergo cholecystectomy for definitive treatment. This timing of this operation has long been a topic of considerable debate, with some advocating initial treatment with antibiotics and then performing a cholecystectomy on an elective basis several weeks later after the acute inflammation has abated. However, as more data have emerged during the laparoscopic era, it is becoming clear that a strategy of early cholecystectomy during the initial hospitalization for acute cholecystitis is safe and carries significant benefits. A randomized trial involving over 600 patients compared a strategy of early laparoscopic cholecystectomy (within 24 hours) with one of initial antibiotic therapy and interval cholecystectomy between 7 and 45 days later and found that the early surgery group had fewer complications (12% vs 34%), a shorter overall hospital length of stay, and lower hospital costs.<sup>14</sup> A meta-analysis of 15 randomized controlled trials showed that early surgery for cholecystitis resulted in short hospital stays with lower costs and higher patient satisfaction and quality of life, while perioperative mortality and morbidity were similar between the early and delayed surgery groups.<sup>15</sup>

Patients who are too high risk for surgery based on either their underlying medical comorbidities or sepsis due to severe cholecystitis can be treated with gallbladder decompression. This is generally done using a transabdominal cholecystostomy tube, placed under ultrasound or computed tomography (CT) guidance. Other options include endoscopic drainage with a transpapillary tube inserted during endoscopic retrograde cholangiopancreatography (ERCP) or a transduodenal tube inserted under endoscopic ultrasound (EUS) guidance. These drainage modalities are

generally effective in resolving the acute inflammatory process<sup>16</sup>; however, they are temporary solutions, and if the tube is subsequently removed, patients are at a high risk of developing recurrent symptoms due to gallstones. For this reason, gallbladder decompression should be reserved for the sickest patients in whom early surgery would pose a prohibitive risk.

## **Asymptomatic Cholelithiasis**

Patients with asymptomatic (ie, incidentally discovered) gallstones have a less than 20% chance of ever developing symptoms, and the risks associated with prophylactic operation outweigh the potential benefit of surgery in almost all patients.<sup>17</sup> Prophylactic cholecystectomy for asymptomatic cholelithiasis can be justified in certain circumstances, such as in patients with sickle cell disease, those undergoing open bariatric surgery, those requiring long-term total parental nutrition, or possibly patients who are therapeutically immunosuppressed after solid organ transplantation. Patients with sickle cell disease often have hepatic or vaso-occlusive crises that can be difficult to differentiate from acute cholecystitis.<sup>18</sup> In patients who have undergone bariatric surgery, the development of gallstones is markedly increased during the period of rapid weight loss, with an incidence of approximately 30%.<sup>19,20</sup> Removing the gallbladder at the time of bariatric surgery can abolish gallstone-related morbidity relatively easily. This approach was adopted by many bariatric surgeons during open bariatric procedures, but this practice has largely been abandoned with the advent of laparoscopic bariatric surgery, because the potential morbidity of an added laparoscopic cholecystectomy in the patient with morbid obesity appears greater than the potential later risk of cholelithiasis-related complications.<sup>21,22</sup> In transplant patients, there is concern that immunosuppression may mask the signs and symptoms of inflammation until overwhelming infection has occurred.<sup>23</sup> Recommendations in the literature range from mandatory screening and treatment of biliary disease before transplantation, to prophylactic cholecystectomy 6 months after transplantation, to expectant management of all asymptomatic patients.<sup>24,25</sup> Other possible indications for prophylactic laparoscopic cholecystectomy include individuals who may not have access to modern health care facilities for an extended time period, such as missionaries and military personnel, and patients who are already

undergoing an abdominal operation for other reasons. Prophylactic cholecystectomy has been occasionally advocated in diabetics. There is no evidence to support this policy but good evidence to support a strategy of early cholecystectomy in the symptomatic patient. Diabetics tend to present with acute cholecystitis more frequently once they become symptomatic and withstand complications less well.

## Functional Gallbladder Disorder

Functional gallbladder disorder (FGD) refers to patients who experience symptoms typical of biliary colic in the absence of gallstones and, in the past, has been referred to as gallbladder dyskinesia, biliary dyskinesia, gallbladder spasm, and/or acalculous biliary disease. The exact etiology of FGD is unknown, but it is thought to be a result of gallbladder dysmotility. FGD is often a diagnosis of exclusion, after evaluating for other common causes of upper abdominal and lower chest pain such as peptic ulcer disease, gastroesophageal reflux disease, pancreatitis, irritable bowel syndrome, musculoskeletal causes, and angina. Consensus guidelines developed by the Rome Committee have established criteria for the diagnosis of FGD.<sup>26</sup> The most recent Rome III guidelines require that the patient's pain must be located in the epigastrium and/or right upper quadrant and additionally meet all of the 8 criteria listed in [Table 62-2](#). Additionally, patients must have normal LFTs and no gallstones on abdominal ultrasound. The strict list of inclusion criteria based on symptoms is meant to limit the number of cholecystectomies performed for FGD and increase the likelihood that such an operation will result in a resolution of said symptoms. The diagnosis of FGD is confirmed with cholescintigraphy. After the radiotracer is observed at maximal levels in the gallbladder, an infusion of cholecystokinin (CCK) is given to stimulate gallbladder contraction. The percentage of tracer ejected from the gallbladder in response to CCK is then measured, with an ejection fraction less than 35% to 40% being indicative of FGD. Patients with gallbladder ejection fractions below this threshold have markedly better symptomatic outcomes after cholecystectomy.<sup>27</sup> According to the Rome III consensus, patients with an ejection fraction greater than 40% should be more carefully evaluated for alternative etiologies of their pain.

**TABLE 62-2: CRITERIA FOR FUNCTIONAL GALLBLADDER DISORDER  
UNDER THE ROME III GUIDELINES<sup>26</sup>**

Episodes of pain must be located in the epigastrium and/or right upper quadrant and meet *all* of the following:

1. Episodes lasting 30 minutes or longer
2. Recurrent symptoms occurring at different intervals (not daily)
3. The pain builds up to a steady level
4. The pain is moderate to severe enough to interrupt the patient's daily activities or lead to an emergency department visit
5. The pain is not relieved by bowel movements
6. The pain is not relieved by postural change
7. The pain is not relieved by antacids
8. Exclusion of other structural disease that would explain the symptoms

## **Gallbladder Polyps and Porcelain Gallbladder**

Other indications for cholecystectomy include the radiographic findings of gallbladder polyps and porcelain gallbladder. Gallbladder polyps are typically an incidental finding that affects approximately 5% of the population, with a higher percentage in Asian populations.<sup>28</sup> Polyps can be cancer (adenocarcinoma), benign neoplasia (typically adenomas), or cholesterosis (a clinically insignificant accumulation of cholesterol on the wall of the gallbladder). Polyps that are larger than 20 mm almost always represent a malignancy. Such patients should undergo radical cholecystectomy and lymph node dissection, an operation that is discussed elsewhere in this text. Polyps between 10 and 20 mm in size are at higher risk of malignancy, but when present, such cancers are usually in an early stage. As such, these patients are typically treated with laparoscopic cholecystectomy without liver resection. Polyps less than 10 mm in size have a low risk of cancer and can be observed with surveillance ultrasound to monitor for growth, which can be done on a yearly basis initially. Multiple small polyps usually signify cholesterosis, and the gallbladder should be removed only if the patient complains of biliary colic symptoms.

Porcelain gallbladder refers to a calcification of the entire gallbladder wall

and has an associated risk of gallbladder cancer. Earlier studies estimated the incidence of gallbladder cancer to be between 12% and 60%, but recent studies suggest that the overall risk is lower, at 7% or less in more recent series.<sup>28,29</sup> Traditionally, radiographic evidence of porcelain gallbladder was seen as an indication for cholecystectomy, but this algorithm has been challenged by some recent authors who recommend a strategy of surveillance imaging in the absence of another indication for cholecystectomy, such as biliary colic.<sup>29</sup> Early in the era of minimally invasive surgery, porcelain gallbladder was seen as a contraindication to the use of a laparoscopy,<sup>30</sup> but this dogma has also largely been abandoned, and it is now viewed as a perfectly safe initial approach to such patients.<sup>31</sup>

## **Choledocholithiasis and Gallstone Pancreatitis**

Although covered in further detail elsewhere in this text, choledocholithiasis and gallstone pancreatitis are important additional indications for laparoscopic cholecystectomy. It is important to understand that in the setting of these diseases, cholecystectomy is a prophylactic operation, rather than a therapeutic one, performed to prevent further migration of gallstones into the CBD. Therefore, when treating patients with choledocholithiasis, the surgeon must come up with a separate plan for dealing with the CBD stone. There are 3 options: either via laparoscopic CBD exploration at the time of cholecystectomy, or with ERCP before or after cholecystectomy. In patients with gallstone pancreatitis, cholecystectomy should be delayed until after the patient's pancreatic inflammation resolves, although in most cases, the gallbladder should be removed during the same hospitalization in order to prevent early recurrences.

## **CONTRAINDICATIONS TO LAPAROSCOPIC CHOLECYSTECTOMY**

The number of absolute and relative contraindications to performing laparoscopic cholecystectomy has decreased over the past 20 years as minimally invasive surgical instrumentation and skills have improved ([Table 62-3](#)). Absolute contraindications include the inability to tolerate general anesthesia or laparotomy, refractory coagulopathy, and diffuse peritonitis

with hemodynamic compromise. Diffuse peritonitis with hemodynamic compromise represents a surgical emergency in which attempted laparoscopic cholecystectomy is not prudent, because the etiology is not clear or secure and the pneumoperitoneum may lead to vascular collapse. Standard open laparotomy allows rapid determination of the etiology and more expeditious management of the disorder. Suspicion of gallbladder malignancy mandates that standard open resection be undertaken. This is because of persistent concerns regarding adequacy of resection and the possibility of gallbladder perforation (occurring in 20%-30% of laparoscopic cholecystectomies) with intraperitoneal dissemination of cancer.

### TABLE 62-3: CONTRAINDICATIONS TO LAPAROSCOPIC CHOLECYSTECTOMY

#### **Absolute**

Unable to tolerate general anesthesia

Refractory coagulopathy

Gallbladder carcinoma

#### **Relative**

Cholangitis

Diffuse peritonitis

Cirrhosis and/or portal hypertension

Cholecystoenteric fistula

Relative contraindications are dictated primarily by the surgeon's philosophy and experience. These include previous upper abdominal surgery with extensive adhesions, cirrhosis, portal hypertension, severe cardiopulmonary disease, morbid obesity, and pregnancy. In most patients, little is lost by initiating a laparoscopic cholecystectomy with conversion to laparotomy if the laparoscopic approach is deemed too risky.

Pregnancy is a controversial relative contraindication to laparoscopic cholecystectomy because of the unknown effects of prolonged carbon dioxide (CO<sub>2</sub>) pneumoperitoneum on the fetus. Laparoscopic cholecystectomy can be performed safely during pregnancy but only with great care.<sup>32</sup> The timing of cholecystectomy during pregnancy is a topic of controversy and was

traditionally limited to the second trimester of gestation after organogenesis is complete and prior to the uterine fundus reaching a size and height that encroaches on the operative field. However, there are no data to suggest that laparoscopy during the first trimester is more dangerous, and current society recommendations are generally in favor of performing laparoscopic cholecystectomy at any point during pregnancy as soon as symptoms arise.<sup>33</sup> Open insertion of the initial port in a supraumbilical or right upper quadrant position should be used to avoid injury to the gravid uterus, and the insufflation pressure should be limited to less than 12 mm Hg to avoid respiratory embarrassment and decreased vena caval return. Also, maternal hyperventilation with close monitoring of end-tidal CO<sub>2</sub> should be undertaken to prevent fetal acidosis. When visualization of the biliary tree is required, laparoscopic ultrasound is used in place of cholangiography in order to limit fetal radiation exposure. Finally, perioperative consultation with an experienced obstetrician is advisable, as is perioperative fetal heart monitoring.

Early experience suggested that acute cholecystitis was a relative contraindication to performing laparoscopic cholecystectomy. However, as general surgeons have gained more experience with laparoscopic cholecystectomy and laparoscopy in general, it has uniformly become the preferred initial approach to patients with cholecystitis. There is clearly a higher rate of conversion in the setting of acute cholecystitis. In particular, after 72 hours, the rate of conversion increases significantly. One should not hesitate to convert to an open cholecystectomy if significant adhesions or inflammation precludes safe dissection during laparoscopy.

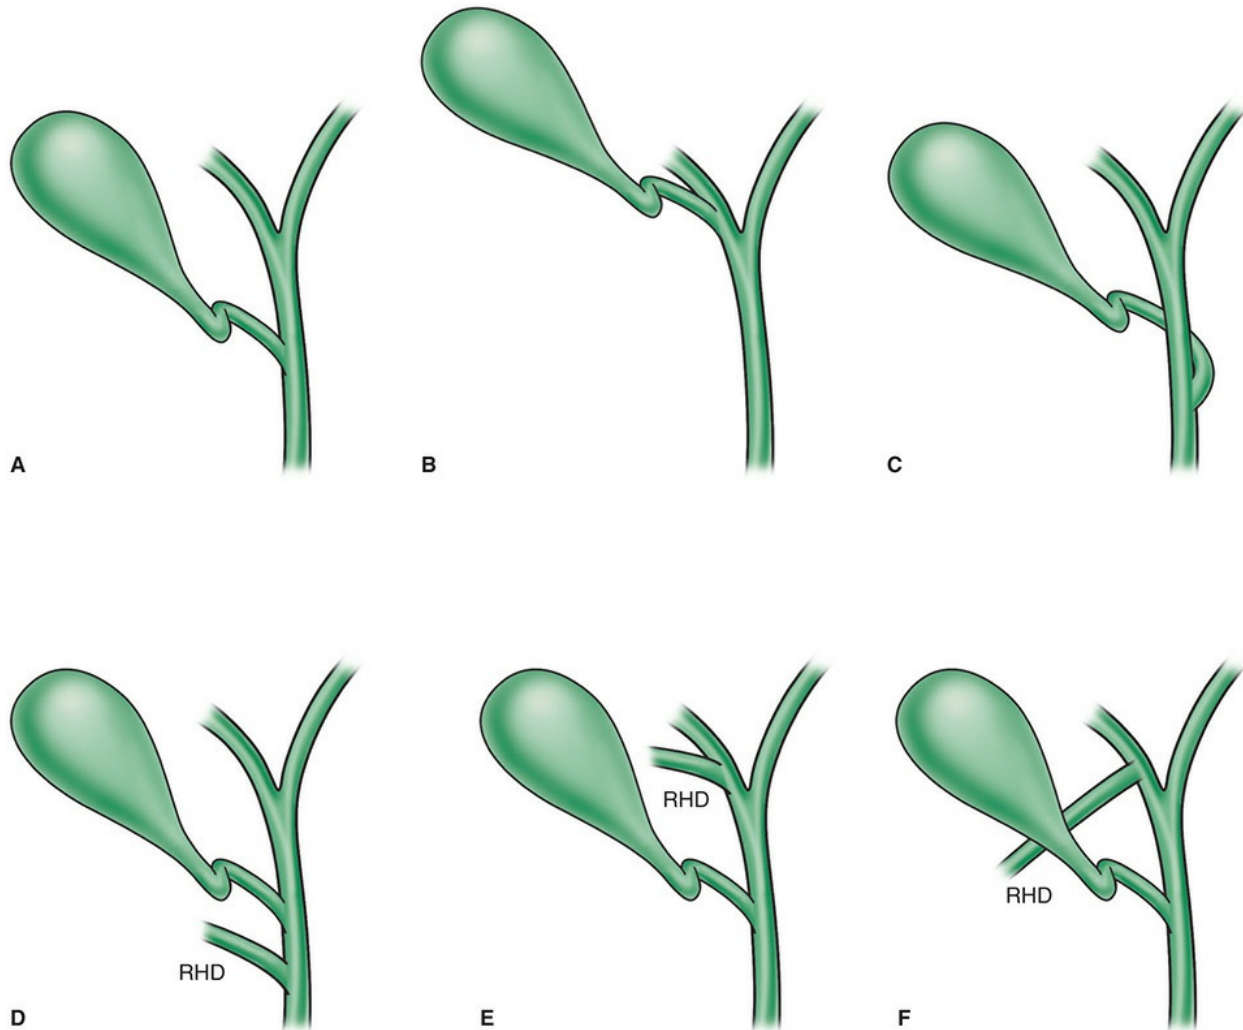

## OPERATIVE TECHNIQUE

### Anatomy

The classic anatomy of the biliary tree is present in only 30% of individuals, so it may be said that anomalies are the rule, not the exception. As with any procedure, the knowledge of normal anatomy and common variants is critical to the success of surgical intervention. The cystic duct may join the CBD at an acute angle, travel parallel to the common duct for several centimeters prior to insertion, insert into the right hepatic duct, or be congenitally absent.

The cystic artery usually arises from the right hepatic artery, but one must be absolutely sure that the cystic artery is visualized entering the gallbladder wall. Occasionally the right hepatic artery will loop up onto the surface of the gallbladder, and a very short cystic artery will arise. Furthermore, there can often be a posterior cystic artery, which can easily be injured if not recognized. The CBD begins at the junction of the cystic duct and the common hepatic duct and passes inferiorly to the ampulla of Vater. Its normal diameter is less than 6 mm, although it may be larger in elderly patients and those with biliary obstruction.

It is important to clearly identify the structures within the hepatocystic triangle, which is the ventral aspect of the area bounded by the gallbladder wall and cystic duct, the liver edge, and the common hepatic duct. Contained within the hepatocystic triangle is the eponymic Calot triangle: The boundaries of the Calot triangle include the cystic duct, cystic artery, and common hepatic duct. Aberrant anatomy is a well-recognized risk factor for biliary injury. An aberrant right hepatic duct is the most common anomaly causing problems during laparoscopic cholecystectomies. The most dangerous variant is when the cystic duct joins a low-lying aberrant right sectoral duct. Injuries to these ducts are underreported since occlusion of an aberrant duct may be asymptomatic and even unrecognized ([Fig. 62-2](#)).

**FIGURE 62-2** Biliary anatomy variations. **A.** Normal anatomy. **B.** Cystic duct insertion on right hepatic duct. **C.** Anterior or posterior spiral insertion of cystic duct. **D, E, and F.** Common variants of accessory right hepatic duct (RHD).

## Patient Preparation

As with any abdominal operation, patients are fasted for a minimum of 8 hours prior to the operation. Patients without major comorbidities are generally scheduled as outpatient procedures. Prophylactic antibiotics are up to the surgeon's discretion; evidence suggests that most patients have a very low risk of perioperative infection, and perioperative antibiotics have not been shown to significantly decrease this risk.<sup>34</sup> Antiembolic stockings and sequential compression devices are placed on both legs to avoid pooling of

blood in the lower extremities by the reverse Trendelenburg position generally used during this operation. Patients at higher risk for lower extremity deep vein thrombosis (DVT) are additionally given prophylactic-dose subcutaneous unfractionated or low-molecular-weight heparin. Following induction of general endotracheal anesthesia, an orogastric tube should be placed to decompress the stomach. The abdomen is shaved and prepared in standard sterile fashion with particular care taken to rid the umbilicus of all debris.

## Laparoscopic Cholecystectomy

### OPERATING ROOM SETUP

Most surgeons use 2 video monitors, 1 on each side of the operating table above the patient's shoulders to facilitate visualization by both the surgeon and assistant. Using the American technique, the surgeon stands to the left of the patient and the first assistant stands to the patient's right (Fig. 62-3). If a laparoscopic video camera operator is used, he or she stands to the left of the surgeon. In the French technique, the patient's legs are abducted and the surgeon stands between the legs.

**FIGURE 62-3** Operating room setup.

## **PNEUMOPERITONEUM**

A working space, provided by a pneumoperitoneum, is essential for the surgeon to see and to operate within the abdominal cavity. CO<sub>2</sub> has the advantage of being noncombustible and rapidly absorbed from the peritoneal cavity. It may, however, lead to hypercarbia in patients with significant cardiopulmonary disease.<sup>35</sup> The most common location for initial peritoneal entry is at the midline near the umbilicus. Supraumbilical or infraumbilical incisions may be made in vertical, horizontal, or curvilinear orientations based on surgeon's preference. Pneumoperitoneum can be established by either a closed or an open technique. In the closed technique, CO<sub>2</sub> is insufflated into the peritoneal cavity through a Veress needle, which is subsequently replaced with a laparoscopic port placed blindly into the abdominal cavity. In the open technique, a laparoscopic port is inserted under direct vision into the peritoneal cavity via a small incision; only after ensuring definitive and safe peritoneal entry is the pneumoperitoneum established. There are advantages and disadvantages to both techniques. Surgeons performing laparoscopic cholecystectomy should learn both and use them selectively based on the patient's body habitus and previous surgical history.

## **PORT PLACEMENT AND EXPOSURE**

Depending on the surgeon's preference, a 5- or 10-mm laparoscope is inserted into the abdomen through the periumbilical port and the abdominal cavity is visually explored. It is generally advantageous to use an angled (30- or 45-degree) laparoscope rather than a 0-degree scope, because the angled scopes enable obtaining multiple views of the same operative field. The patient is then placed in a reverse Trendelenburg position of 30 degrees while rotating the table to the left by 15 degrees. This maneuver allows the colon and duodenum to fall away from the liver edge. The falciform ligament and both lobes of the liver are examined closely for abnormalities. The gallbladder can usually be seen protruding beyond the edge of the liver, and the degree of inflammation surrounding the gallbladder can be gauged.

Two small accessory subcostal ports are then placed under direct vision.

The first 5-mm trocar is placed along the right anterior axillary line between the 12th rib and the iliac crest. This trocar should be at least 2 finger breadths inferior to the costal margin and as lateral as possible while remaining anterior to the ascending colon. A second 5-mm port is inserted in the right subcostal area in the midclavicular line. Grasping forceps are placed through these 2 ports to secure the gallbladder. The assistant manipulates the lateral grasping forceps, which are used to grasp the fundus and elevate the liver. The fourth working port is then inserted through an incision in the midline of the epigastrium (Fig. 62-4). This trocar is usually inserted approximately 5 cm below the xiphoid process, but the precise position and angle depend on the location of the gallbladder as well as the size of the medial segment of the left lobe of the liver. It should be placed so that the trocar enters the peritoneum to the right of the falciform ligament.

**FIGURE 62-4** Port placement.

Dissecting forceps are then inserted and directed toward the gallbladder neck. One should note that the orientation of the laparoscope is generally parallel to that of the cystic duct when the fundus is elevated, whereas the instruments placed through the other 3 ports enter the abdomen at right angles to this plane. The surgeon uses a dissecting forceps to raise a serosal

fold of the most dependent portion of the fundus. The assistant's heavy grasping forceps are then locked onto this fold using either a spring or ratchet device. With these axillary grasping forceps, the fundus of the gallbladder is then pushed in a lateral and cephalad direction, rolling the entire right lobe of the liver cranially.

This maneuver is complicated in patients with a fixed, cirrhotic liver or a heavy, friable liver because of fatty infiltration. In patients with few adhesions to the gallbladder, pushing the fundus cephalad exposes the entire gallbladder, cystic duct, and porta hepatis. Most patients, however, have adhesions between the gallbladder and the omentum, hepatic flexure, and/or duodenum. These adhesions are generally avascular and may be lysed bluntly by grasping them with dissecting forceps at their site of attachment to the gallbladder wall and gently *stripping* them down toward the infundibulum. Extreme caution should be taken to avoid damage to surrounding structures. Use of electrocautery may accidentally damage the unvisualized CBD or proximally located duodenum. After exposing the infundibulum, blunt grasping forceps held in the surgeon's left hand and placed through the midclavicular trocar are used to grasp and place traction on the neck of the gallbladder.

## **DISSECTION**

The infundibulum is grasped, placing traction on the gallbladder in a lateral direction to distract the cystic duct from the CBD (Fig. 62-5). Fine-tipped dissecting forceps (Maryland) are used to dissect away the overlying fibroareolar structures from the infundibulum of the gallbladder. The dissection should begin from a known structure, for example, the gallbladder, rather than in an unknown area, to avoid damage to the underlying structures such as a bile duct or hepatic artery. The dissection initially commences 4 or 5 cm proximal to the neck of the gallbladder and proceeds distally, such that a modified "top-down" technique is employed. The objective of the initial dissection is to free the gallbladder from its bed such that there is a window beneath it through which the liver substance can be seen. This dissection is typically initiated on the lateral (ie, anatomic right) side of the gallbladder to avoid approaching the cystic duct and artery until the anatomy, including the true edge of the gallbladder, has been more clearly defined. During this portion of the dissection, the infundibulum should be retracted medially and

superiorly. Blunt dissection is used to create a “window” in the lateral edge of the peritoneum overlying the gallbladder. Once this window has been opened, it is safe to use an L-shaped electrocautery hook to open the rest of the lateral peritoneal edge, heading toward the gallbladder fundus, away from the cystic duct and portal structures. When applying electrocautery, it is important to pull the instrument away from the gallbladder to avoid a perforation or other injury to underlying structures. We then retract the infundibulum laterally and inferiorly and repeat this process to open the medial peritoneal edge of the gallbladder.

**FIGURE 62-5** Retraction of the gallbladder.

After both peritoneal edges have been opened high up onto the gallbladder fundus, the hepatocystic triangle is maximally opened and converted into a trapezoid shape by retracting the infundibulum of the gallbladder inferiorly and laterally while maintaining the fundus under traction in a superior and medial direction. A lymph node usually lies on the surface of the cystic artery, and occasionally it is necessary to use a brief application of low-wattage electrosurgical coagulation to obtain hemostasis as the lymph node is bluntly swept away. To expose the reverse of the Calot triangle, the

infundibulum of the gallbladder is pulled in a superior and medial direction. The use of an angled laparoscope facilitates viewing both sides of the hepatocystic triangle when used in combination with these retraction techniques. After clearing the structures from the apex of the triangle, the junction between the infundibulum and the origin of the proximal cystic duct can be tentatively identified. The strands of peritoneal, lymphatic, and neurovascular tissue are stripped away from the cystic duct to clear a segment from the surrounding tissue. Curved dissecting forceps are helpful in creating a window around the posterior aspect of the cystic duct to skeletonize the duct itself. Alternatively, the tip of the hook cautery can be used to encircle and expose the duct. It is generally unnecessary and potentially harmful to dissect the cystic duct down to its junction with the CBD. The cystic artery is separated from the surrounding tissue by similar blunt dissection at this time. If the cystic artery crosses anterior to the duct, the artery may require dissection and division prior to approaching the cystic duct, although if at all possible, this should be avoided until all relevant anatomy has been clearly identified.

The neck of the gallbladder is thus dissected away from its liver bed, leaving a large window at its base through which the liver parenchyma is visualized. At least one-third of the cystic plate (ie, gallbladder bed) should be exposed in this manner. At this point, there should be 2, and only 2, structures (the cystic duct and artery) crossing this window—this is the “critical view of safety,” which should be demonstrated prior to clipping or cutting any tubular structures.<sup>36</sup> To reiterate, no structure should be divided until the cystic duct and cystic artery are unequivocally identified. Developing this critical view of safety is an essential step to minimize the chance of bile duct injury during laparoscopic cholecystectomy (Fig. 62-6).<sup>36</sup>

**FIGURE 62-6** Critical view of safety.

## **INTRAOPERATIVE EVALUATION FOR CHOLEDOCHOLITHIASIS**

After initially dissecting the proximal cystic duct, the CBD should be imaged if there is any concern for choledocholithiasis or questions regarding the biliary anatomy. Indications for intraoperative imaging of the CBD include any indication of choledocholithiasis based on the patient's history, physical examination, laboratory tests, preoperative imaging, or intraoperative findings. Imaging can be achieved by intraoperative cholangiography (IOC) or intracorporeal laparoscopic ultrasonography (LUS). Prior to either procedure, a clip is applied high on the cystic duct at its junction with the gallbladder to prevent stones migrating down the duct during subsequent manipulation. To perform IOC, the anterolateral wall of the cystic duct is incised and dissecting forceps are used to gently compress the cystic duct systematically back toward the gallbladder, thereby milking stones away from the CBD and out of the ductotomy. A 4- or 5-Fr catheter is inserted into the duct through a hollow, 5-mm metal tube that has an appropriate gasket to

prevent carbon dioxide leakage around the catheter itself. The cholangiography catheter is inserted into the cystic duct, and a clip is applied loosely to secure the catheter in place. If the introducer has grasping jaws (ie, an Olsen clamp), it can be used to secure the catheter into the duct. Alternatively, catheters equipped with balloons proximal to the tip may be used for fixation. Cholangiography is performed by real-time fluoroscopy after injecting 10 to 20 mL of water-soluble contrast medium. We typically mix the contrast at half-strength (50%/50% contrast-saline mix) to avoid obscuring small stones in the CBD and use digital subtraction fluoroscopy to help eliminate other radiopaque elements, such as the vertebrae, and thus define the biliary anatomy more clearly. The fluoroscopy images should be inspected for the following: (1) the length of cystic duct and location of its junction with the CBD; (2) the diameter of the CBD; (3) the presence of luminal filling defects within the CBD; (4) free flow of contrast into the duodenum; and (5) anatomy of the extrahepatic and intrahepatic biliary tree (Fig. 62-7). After the cholangiocatheter is removed, the cystic duct is doubly clipped below the ductotomy with care to avoid the wall of the CBD and then divided. The posterior jaw of the clip applicator must be visualized beyond the duct or artery prior to applying each clip in order to avoid injuring the surrounding structures. Great care should be taken so that the CBD is not tented up into the clip. If the cystic duct is particularly large or friable, it may be preferable to replace one of the clips with a suture, either hand-tied or a preformed loop with slip knot.

**FIGURE 62-7** Intraoperative cholangiogram images. **A.** A normal cholangiogram. **B.** A cholangiogram revealing a meniscus sign (*arrow*) and lack of duodenal filling resulting from choledocholithiasis.

Evaluation of the CBD by LUS is an alternative to cholangiography. Several studies performed at open cholecystectomy reported intracorporeal ultrasonography to be more accurate than operative cholangiography in assessing the CBD for stones (97%-99% vs 89%-94%).<sup>37-39</sup> With LUS, the transducer has a higher frequency with improved resolution compared to those used with transabdominal ultrasonography. In experienced hands, LUS appears to be as accurate as cholangiography for demonstrating choledocholithiasis but can be performed more rapidly. In a recent prospective multicenter trial with 209 laparoscopic cholecystectomy patients, the time to perform LUS ( $7 \pm 3$  minutes) was significantly less than that of IOC ( $13 \pm 6$  minutes).<sup>40</sup> The study showed that LUS was more sensitive for detecting stones but that IOC was better in delineating intrahepatic anatomy and defining anatomic anomalies of the ductal system. The authors concluded that the 2 methods of duct imaging were complementary. Despite these promising data, more clinical experience will be necessary to establish the appropriate role of LUS for the detection of choledocholithiasis during laparoscopic cholecystectomy.

## COMPLETION OF CHOLECYSTECTOMY

The cystic duct is clipped using an endoscopic clip applier and divided using scissors. Two clips are placed distally on the cystic duct, and 1 clip is placed toward the gallbladder (Fig. 62-8). For cystic ducts that are large or friable, a preformed endoloop is preferable for ligating the distal cystic duct. After the duct is divided, the cystic artery is dissected from the surrounding tissue for an adequate distance to permit placement of 3 clips. The surgeon must determine that the structure is indeed the cystic artery and not the right hepatic artery looping up onto the neck of the gallbladder or an accessory or replaced right hepatic artery. After an appropriate length of cystic artery has been dissected free, it is clipped proximally and distally prior to transection (Fig. 62-9). Electrocautery should not be used for this division, as the current may be transmitted to the proximal clips, leading to subsequent necrosis and hemorrhage.

**FIGURE 62-8** Clipping the cystic duct.

**FIGURE 62-9** Clipping the cystic artery.

The ligated stumps of the cystic duct and the artery are then examined to ensure that there is no leakage of either bile or blood and that the clips are placed securely and compress the entire lumen of the structures without scissoring or impinging on adjacent tissues. A suction-irrigation catheter is used to remove any debris or blood that has accumulated during the dissection. Separation of the gallbladder away from its hepatic bed is then initiated using an electro-surgical probe to coagulate small blood vessels and lymphatics. While maintaining cephalad traction on the fundus of the gallbladder with the axillary forceps, the midclavicular forceps pulls the neck of the gallbladder anterosuperiorly and then alternatively medially and laterally to expose and place the tissue connecting the gallbladder to its fossa under tension. An electrocautery spatula or hook is used to coagulate and divide the tissue. Intermittent blunt dissection will facilitate exposure of the proper plane (Fig. 62-10).

**FIGURE 62-10** Dissecting the gallbladder off the liver.

Dissection of the gallbladder fossa continues from the infundibulum to the fundus, progressively moving the midclavicular grasping forceps cephalad to allow maximal countertraction. The dissection proceeds until the gallbladder is attached by only a thin bridge of tissue. At this point, prior to completely detaching the gallbladder, the hepatic fossa and porta hepatis are once again inspected for hemostasis and bile leakage. Small bleeding points are coagulated, and the right upper quadrant is liberally irrigated and then aspirated dry while checking for any residual bleeding or bile leakage. The final attachments of the gallbladder are divided, and the liver edge is again examined for hemostasis.

After the cholecystectomy has been performed, the gallbladder must be removed from the abdominal cavity. The gallbladder may be placed within an entrapment sac prior to extracting it through the abdominal wall ([Fig. 62-11](#)). This is recommended particularly if the gallbladder has been perforated intraoperatively or if the specimen is large. If the stone burden is small, the gallbladder can be extracted at the subxiphoid port site. Usually, the gallbladder is most easily removed at the umbilical port site where there are no muscle layers anterior to the fascial plane. Also, if the fascial opening needs to be enlarged because of large or numerous stones, extension of the

umbilical incision causes less postoperative pain and has better cosmesis than does enlarging the subxiphoid incision. The laparoscope is removed from the umbilical port and placed through the epigastric port. Large “claw” grasping forceps are introduced through the umbilical port to grasp the infundibulum of the gallbladder. The forceps, trocar, and gallbladder neck are then retracted as a unit through the umbilical incision. The neck of the gallbladder is thus exteriorized through the anterior abdominal wall with the fundus remaining within the abdominal cavity. If the gallbladder is not distended with bile or stones, it can be simply withdrawn with gentle traction. In many cases, a suction catheter introduced through an incision in the gallbladder neck is used to aspirate bile and small stones. Stone forceps can also be placed into the gallbladder to extract or crush calculi if necessary. Occasionally, the fascial incision must be extended to extract larger stones or thick-walled gallbladders.

**FIGURE 62-11** Placing gallbladder in entrapment bag.

Each incision is infiltrated with bupivacaine for postoperative analgesia. The fascia of the umbilical incision is closed with 1 or 2 large absorbable sutures in an interrupted or figure-of-8 fashion. Closure of the subxiphoid

fascia is optional, as visceral herniation is unlikely to occur because of the oblique entry angle of the trocar into the abdominal cavity and its location anterior to the falciform ligament. The skin of the subxiphoid and umbilical incisions is closed with subcuticular absorbable sutures. The skin incisions at both 5-mm port sites can be closed with absorbable sutures, adhesive strips, or skin closure adhesives. The orogastric tube is removed in the operating room, and the patient is transferred to the postanesthesia care unit. Patients are allowed out of bed as soon as they are fit enough to walk, and more than 90% of patients are discharged from the hospital within 24 hours. Fit patients who have been preoperatively selected may be safely discharged within 6 hours following surgery.<sup>37</sup> Patients are evaluated 1 week following surgery. At this time, more than 95% of patients are back to a normal routine, and most return to work immediately following their clinic visit.

## ADVANTAGES AND DISADVANTAGES

The advantages of laparoscopic cholecystectomy over other therapies for gallstone disease are multiple (Table 62-4). Unlike nonresective techniques for gallstone ablation, laparoscopic cholecystectomy removes the diseased gallbladder along with its stones. Relative to traditional open cholecystectomy, postoperative pain and intestinal ileus are diminished with laparoscopic cholecystectomy. The small size of the fascial incisions allows rapid return to heavy physical activities. The small incisions are also cosmetically more appealing than is the large incision used during traditional cholecystectomy. The patient can usually be discharged from the hospital either on the same day or the day following operation and can return to full activity within a few days.<sup>7,11</sup> These factors lead to overall decreased cost of laparoscopic cholecystectomy compared to its traditional open counterpart.<sup>8</sup>

**TABLE 62-4: ADVANTAGES AND DISADVANTAGES OF LAPAROSCOPIC CHOLECYSTECTOMY COMPARED WITH OPEN CHOLECYSTECTOMY**

<b>Advantages</b>	<b>Disadvantages</b>
Less pain	Lack of depth perception
Shorter hospitalization	Difficult in setting of dense adhesions/inflammation
Early return to full activity	More difficult to control hemorrhage
Decreased wound complications (infection and hernia)	Potential CO <sub>2</sub> insufflation complications
Decreased total costs	Slight increase in bile duct injuries

There are, however, several potential disadvantages of laparoscopic cholecystectomy. As opposed to nonresective treatments for gallstones, patients must be acceptable candidates for general anesthesia and possible laparotomy. Three-dimensional depth perception is limited by the 2-dimensional monocular image of the videoscope. It is more difficult to control significant hemorrhage using laparoscopic technology than in an open surgical field. There is also less haptic discrimination of structures using laparoscopic instruments as opposed to direct digital palpation during open cholecystectomy. CO<sub>2</sub> insufflation to create the pneumoperitoneum is associated with a number of potential risks, including reduction of vena caval flow and systemic hypercarbia with acidosis.

## **SPECIAL CONSIDERATIONS**

### **Conversion to Open Operation**

Surgeons performing laparoscopic cholecystectomy should not think of conversion to open operation as a complication, but rather a sound clinical judgment, and hence not hesitate to convert to a traditional open cholecystectomy if the anatomy is unclear, if complications arise, or if there is failure to make reasonable progress in a timely manner. Some complications requiring laparotomy are obvious, such as massive hemorrhage or major injury to the bile duct. Open laparotomy allows the additional tool of manual palpation and haptic sensation and should be performed when the

anatomy cannot be delineated because of inflammation, adhesions, or anomalies. Fistulae between the biliary system and bowel are rare, but may require laparotomy for optimal management. The demonstration of potentially resectable gallbladder carcinoma also dictates an open exploration. Finally, CBD stones that cannot be removed laparoscopically and are unlikely to be extracted endoscopically because of Billroth II anastomosis, previously failed ERCP, should be converted to open operation without hesitation.

## Open Cholecystectomy

The technical aspects of performing an open cholecystectomy have not changed significantly since Langenbuch's description of this procedure more than 100 years ago. Although this operation can be performed safely through a midline, paramedian, or right subcostal incision, most surgeons prefer the right subcostal (Kocher) incision. Adequate exposure of the gallbladder and the hepatoduodenal ligament is the key to performing a safe cholecystectomy. Laparotomy sponges may be packed temporarily between the dome of the liver and the diaphragm, and appropriate self-retaining retractors should be inserted to optimize visualization of the hepatoduodenal ligament and its structures. The hepatic flexure of the colon is packed or retracted inferiorly, and the medial segment of the left liver lobe is retracted superiorly. When a large distended gallbladder is encountered, removal can be facilitated by decompressing the gallbladder. Adhesions of omentum or viscera adjacent to the gallbladder are divided with sharp dissection or electrocautery.

Meticulous dissection and positive identification of the cystic duct, its entry into the CBD, and the cystic artery are mandatory and significantly reduce the likelihood of bile duct injury. Most experienced surgeons prefer to identify these important structures before beginning dissection of the gallbladder from the hepatic bed. The fundus and infundibulum of the gallbladder are grasped with curved clamps. The fundus is retracted anteriorly and superiorly and the infundibulum inferiorly and laterally, exposing the structures of the Calot triangle. Caudal counter-retraction of the hepatoduodenal ligament stretches and exposes the porta hepatis, placing the peritoneum overlying the cystic duct and artery on tension. This maneuver may be accomplished with a retractor, although the left hand of the first assistant effectively retracts the duodenum. The surgeon introduces the left

index finger into the foramen of Winslow and palpates for calculi in the CBD. Acute inflammation or chronic scarring may preclude approaching the infundibulum first; many surgeons prefer to dissect the fundus initially (ie, a fundus first or top-down technique), and the ductal and vascular structures subsequently, only after the organ has been separated from the liver. Careful ligation of the cystic duct is essential not only in preventing a biliary leak, but also in reducing the possibility of bile duct injury and stricture. Ligation of the cystic duct in close proximity to its junction with the CBD has long been considered an essential component of open cholecystectomy. Experience with laparoscopic cholecystectomy suggests that the length of the cystic duct stump is not a critical factor and probably does not significantly contribute to postcholecystectomy syndrome, a poorly defined clinical entity characterized by pain after gallbladder removal. Therefore, it is safer to divide the cystic duct closer to the gallbladder infundibulum once a “critical view of safety” has been obtained and to avoid dissection in proximity to the CBD altogether. The cystic artery should be dissected, secured, and divided near the surface of the gallbladder. This will reduce bleeding associated with division of the peritoneum investing the gallbladder and separation of areolar tissue between the gallbladder and the liver. Intraoperative cholangiography can be performed at the discretion of the surgeon.

Throughout the procedure, care should be exercised to minimize spillage of bile into the peritoneal cavity. Drains are not mandatory and are indicated only if the surgeon is concerned about identifying or controlling a possible bile leak. Common pitfalls are usually related to inadequate exposure, severe inflammation, bleeding, and anatomic variants, which can lead to injury of portal structures, including the CBD and the hepatic artery or its branches. With a short cystic artery, the right hepatic artery must be carefully identified. Similarly with a short cystic duct, careful dissection and high ligation of the cystic duct near the gallbladder should be employed to avoid injury to the CBD. In fact, in the face of severe inflammation with obliteration of normal tissue planes, it may be safest to perform a subtotal cholecystectomy, leaving a portion of the infundibulum in situ (after removing all stones) and suture ligating the mucosal side of the cystic duct origin. If there is unintentional gallbladder puncture, a second clamp or purse string suture can be applied to prevent gallbladder bile and stone spillage. Before closing the abdominal incision, bleeding and bilious drainage must be controlled. Structures in the porta hepatis are reexamined, with special attention to the cystic duct stump.

The subhepatic space is irrigated with warm saline and all irrigants are evacuated. The incision is usually closed in 1 or 2 layers. The skin can be closed with sutures or staples.

## **Acute Cholecystitis**

Acute cholecystitis may be treated successfully by laparoscopic cholecystectomy. Intervention during the early phase often reveals an inflamed, edematous, thick-walled, and tensely distended organ. To gain adequate traction on the gallbladder with the grasping forceps, it may be necessary to decompress the gallbladder by aspirating its contents with a large-gauge needle or suction irrigator. As long as the inflammation is limited to the gallbladder, laparoscopic cholecystectomy is usually technically feasible. However, if inflammation extends to the porta hepatis, great care must be taken in proceeding with the operation. The normally thin, minimally adherent tissue that invests the cystic duct and artery is markedly thickened and edematous and may not readily separate from these structures with the usual blunt dissection techniques. The duct wall also may be edematous, thus making its external diameter similar to the gallbladder neck and CBD. If the anatomy is unclear, cholangiography must be performed before clipping or dividing tissue. When acute inflammation has been present for several days or weeks before operation, the pericholecystic tissue planes may be obliterated by thick, woody tissue that is difficult to dissect bluntly. The surgeon may therefore need to convert to open cholecystectomy if the minimal access approach is initially attempted during this subacute phase. There is no harm in inserting the laparoscope and assessing the right upper quadrant. The decision to convert to an open operation is a matter of judgment, based on the existing anatomy, local conditions, and the surgeon's experience and confidence in his or her ability to complete the procedure using minimal access techniques.

Several authors have reported performing laparoscopic cholecystectomy in the face of acute inflammation with success but with a higher conversion rate than for elective laparoscopic cholecystectomy.<sup>41-43</sup> In a prospective study of 105 patients randomized to early laparoscopic cholecystectomy (within 24 hours of diagnosis of acute cholecystitis) versus delayed laparoscopic cholecystectomy (6-8 weeks later), there was no significant difference in conversion rate (early 21% vs delayed 24%), postoperative analgesic

requirement, or number of postoperative complications. The early group did have a longer operative time (123 vs 107 minutes;  $p = .04$ ), but total hospitalization was shorter (8 vs 12 days;  $p = .001$ ).<sup>44</sup> Rattner and associates retrospectively reviewed 20 patients who underwent attempted laparoscopic cholecystectomy for acute cholecystitis and examined factors that were predictive of a successful procedure.<sup>42</sup> Seven of the 20 patients (35%) required conversion to open cholecystectomy. The interval from admission to cholecystectomy in the successful cases was 0.6 days versus 5 days in the cases requiring conversion to open cholecystectomy. Converted cases also had a significantly higher white blood cell (WBC) counts, alkaline phosphatase levels, and Acute Physiology and Chronic Health Evaluation II (APACHE II) scores compared to those undergoing successful laparoscopic cholecystectomy. Ultrasonographic findings such as gallbladder distention, wall thickness, and pericholecystic fluid did not correlate with the success of laparoscopic cholecystectomy.

More recent studies have confirmed that laparoscopic cholecystectomy is an equivalent or better option than open surgery for treating acute cholecystitis. In a study of 2 prospectively randomized groups, Johansson and associates reported that there were no differences in postoperative complications or pain when comparing laparoscopic to open cholecystectomy.<sup>43</sup> Using a cohort of almost 1 million patients from the National Hospital Discharge Surveys from 2000 to 2005, Csikesz and associates reported that patients undergoing laparoscopic cholecystectomy for acute cholecystitis have low conversion rates (9.5%) and also lower morbidity (16% vs 36%) and unadjusted mortality (0.4% vs 3%) compared to patients who undergo open cholecystectomy.<sup>45</sup>

It can be concluded that laparoscopic cholecystectomy should be performed immediately after the diagnosis of acute cholecystitis. Delaying surgery allows inflammation to become more intense and neovascularized, thus increasing the technical difficulty of laparoscopic cholecystectomy.

## **Intraoperative Gallbladder Perforation**

Perforation of the gallbladder with bile or stone leakage can be a nuisance but should not ordinarily require conversion to open cholecystectomy.

Perforation may occur secondary to traction applied by the grasping forceps

or because of electrosurgical thermal injury during removal of the gallbladder from its bed. In our experience, almost one-third of patients have had intraoperative spillage of bile or stones.<sup>3</sup> Patients with bile spillage have not experienced an increased incidence of infection, prolongation of hospitalization, or postoperative disability, or more adverse long-term complications<sup>46</sup> (mean follow-up of 41 months in 250 consecutive laparoscopic cholecystectomy patients). The only difference between patients with and without bile leakage was that the operating time of patients with a gallbladder perforation was approximately 10 minutes longer, presumably because of the time spent in cleaning up the operative field. When perforation does occur, the bile should be aspirated completely and irrigation used liberally. The hole in the gallbladder is best secured with a grasping instrument and can be sutured or tied with an endoloop. The stones should be retrieved and removed. Gallbladder spillage, when treated in this manner, results in no adverse short- or long-term complications. Escaped stones composed primarily of cholesterol pose little threat of infection. However, pigment stones frequently harbor viable bacteria and may potentially lead to subsequent infectious complications if allowed to remain in the peritoneal cavity.<sup>47,48</sup> The long-term complications of retained stones, either intra-abdominally with resultant abscess formation or intramurally with resultant port site abscess, have not been prospectively studied, but recent case reports and case series in the surgical literature document a clear potential for long-term infectious complications.<sup>49-51</sup> The relative infrequency of these complications probably does not justify conversion to open operation in the face of spilled stones, but vigilance in avoidance of perforation, a careful search for escaped stones, the aggressive use of irrigation, and liberal use of a plastic retrieval bag for large and friable gallbladders are recommended.

## COMPLICATIONS

### Laparoscopic Cholecystectomy

Most complications related to laparoscopic removal of the gallbladder are similar to those occurring during traditional open cholecystectomy. These complications include hemorrhage, bile duct injuries, bile leaks, retained stones, pancreatitis, wound infections, and incisional hernias. Other potential

complications are pneumoperitoneum related (gas embolism, vagal reaction, ventricular arrhythmias, or hypercarbia with acidosis) and trocar related (injuries to the abdominal wall, intra-abdominal organs, or major blood vessels). The protective shield on disposable trocars is not an insurance against perforation of intestine or major vessels, especially after previous abdominal operations. Regardless of the make of trocar, during its insertion, one should never aim toward the spine or the location of the great vessels, and a hand is used as a brake to prevent inadvertently introducing the trocar too far. Insertion of the initial trocar, especially when performed in a closed fashion, can cause iatrogenic injury to the bowel, bladder, aorta, iliac artery, or vena cava.<sup>52,53</sup> When a trocar injury to a major blood vessel is suspected, the patient must be opened immediately without removing the trocar until the involved blood vessel is isolated. In contrast, if the small-bore Veress needle enters a viscus or blood vessel, the operation can generally be completed and the patient monitored closely for signs of complications in the postoperative period.

The laparoscopic trocars may also lacerate blood vessels in the abdominal wall. Prior to removal, each trocar should be visualized from the peritoneal aspect using the laparoscope. If significant hemorrhage is seen, it can generally be controlled with cautery, intraoperative tamponade with a Foley catheter, or a through-and-through suture on each side of the trocar insertion site.

Most serious complications occur early in the surgeon's experience. For instance, in a multivariate regression analysis of 8839 laparoscopic cholecystectomies in which there were 15 bile duct injuries, the only significant factor associated with an adverse outcome was the surgeon's experience with the procedure.<sup>54</sup> The regression model predicted that a surgeon had a 1.7% chance of a bile duct injury occurring in the first case and a 0.17% chance of a bile duct injury in the 50th case.

Of all the potential complications, biliary injuries have received the most attention and are discussed at length elsewhere in this text. Most series quote a major bile duct injury rate of around 0.2% during open cholecystectomy, whereas the incidence of bile duct injuries during laparoscopic cholecystectomy is 0.40% or higher.<sup>34</sup> These injuries can cause major morbidity, prolonged hospitalization, high cost, and litigation.<sup>54,55</sup> In addition to the surgeon's experience and aberrant biliary anatomy, a number of reports

mention chronic inflammation with dense scarring, operative bleeding obscuring the field, or fat in the portal area contributing to the biliary injuries.<sup>35,56</sup> The classic biliary injury, however, occurs when the CBD or a right hepatic duct is mistaken for the cystic duct and is divided between clips. Many surgeons attribute this misidentification to the direction of traction of the gallbladder, which is pulling the CBD and the cystic duct into alignment, thus making them appear to be one. Other contributing factors to misidentification are a short cystic duct, a large stone in Hartmann's pouch (making retraction and display of the cystic duct difficult), and tethering of the infundibulum to the CBD by acute or chronic inflammation. Constant awareness of these potential misidentifications and technical causes of biliary injuries is the best method of prevention. If a partial bile duct injury occurs and is recognized intraoperatively, an immediate primary repair, possibly in conjunction with a T-tube, should be performed. A complete transection of the bile duct is a rare injury, and an end-to-end repair is a technically challenging procedure that may require assistance from an experienced hepatobiliary surgeon. When a bile duct injury is discovered in the postoperative period, a coordinated effort by radiologists, endoscopists, and surgeons is necessary to optimize management. There should be no hesitation in asking for the help of a surgeon experienced in biliary repair.

## **NEW AND INVESTIGATIONAL TECHNIQUES TO PERFORM CHOLECYSTECTOMY**

The advent of laparoscopic cholecystectomy provided a dramatic benefit to patients who previously underwent laparotomy for gallbladder disease. While laparoscopy has already set a high bar for cholecystectomy with regard to perioperative and intraoperative outcomes, there are areas of surgical research examining ways that could potentially make the procedure even less invasive.

### **Single-Incision Laparoscopic Surgery**

Single-incision laparoscopic surgery (SILS) is a recent development that involves introducing all operative instruments and devices through a single skin incision, usually at the umbilicus. The proposed benefit of single-incision laparoscopic cholecystectomy over traditional laparoscopic

cholecystectomy is by reducing the overall number of abdominal incisions from 3 or 4 to 1, thus resulting in less perioperative pain and fewer incisional complications. From a technical standpoint, single-port surgery leads to all of the instruments entering the operative field in line with the optics.

Triangulation and traction or countertraction are made more difficult, but new instruments are being developed to overcome these limitations.

Although data comparing single-incision to traditional 4-port cholecystectomy are limited, they are beginning to show significant drawbacks to the SILS approach, without the theoretical advantages of decreased pain and convalescence. A randomized trial by Jorgensen and colleagues compared the 2 techniques and found the single-incision approach to result in prolonged operative times without any difference in postoperative pain scores.<sup>57</sup> However, there was an advantage to the single-incision approach in terms of cosmesis ratings at 12 months after surgery. The most comprehensive trial comparing the 2 techniques thus far is a multicenter trial by Marks and colleagues that randomized 200 patients. It showed that perioperative outcomes and complication rates were similar but that single-incision cholecystectomy actually resulted in more postoperative pain and a higher incidence of incisional hernia formation at 1 year after surgery than a traditional 4-trocar approach (8.4% vs 1.2%).<sup>58,59</sup> Based on these data, most surgeons have abandoned single-incision laparoscopic cholecystectomy except in the rare instance that the cosmetic outcome of the incisions is of great importance to a particular patient.

## **Natural Orifice Transluminal Endoscopic Surgery**

Natural orifice transluminal endoscopic surgery (NOTES) is an investigational approach to intra-abdominal surgery that aims to reduce and eventually eliminate all abdominal incisions by accessing the peritoneum through natural orifice routes including transoral or transgastric, transvaginal, and transanal or transcolonic. By eliminating abdominal incisions, the hypothesis is that there will be less pain, fewer complications, and decreased morbidity associated with abdominal incisions. These benefits are proposed to include decreased incisional hernias, wound infections, and postoperative pain and improved cosmesis. Given the current state of technology and lack of appropriate instrumentation, few pure NOTES cholecystectomies have

been performed worldwide.<sup>60,61</sup> NOTES hybrid procedures, where a laparoscopic instrument is used in conjunction with the natural orifice devices, have been performed in greater numbers, although only in a relatively few specialized centers. These were initially performed via a transgastric approach using a flexible gastroscope inserted transorally. This approach proved to be incredibly technically challenging and time-consuming, while adding potential complications due to closure of the resulting gastrotomy and esophageal injury during transoral gallbladder extraction. For these reasons, this approach has since been abandoned.

Transvaginal hybrid NOTES cholecystectomy, using a standard rigid laparoscopic inserted through a culpotomy in the posterior fornix in conjunction with 1 or 2 additional transabdominal ports for dissection has proved to be a safe and viable procedure that is currently being performed in select centers, mostly in Germany and South America. So far, the limited outcomes data resulting from this technique have been encouraging. Several trials (both retrospective and randomized comparisons) have compared transvaginal hybrid NOTES cholecystectomy with a traditional laparoscopic approach and found NOTES to result in decreased postoperative pain with similar rates of perioperative complications.<sup>62,63</sup> While these initial results are promising, NOTES cholecystectomy remains an investigational procedure that should only be performed in the context of an Institutional Review Board–approved research protocol.

## CONCLUSION

Cholecystectomy remains one of the most common operations performed in the United States and worldwide. Laparoscopic cholecystectomy is currently the standard for treatment of gallstone and gallbladder disease. There are numerous advantages of laparoscopic cholecystectomy over open cholecystectomy, including decreased pain, length of stay, recovery time, and incisional complications, and improved cosmesis. However, occasionally anatomic or physiologic considerations will hinder or preclude the minimal access approach, and conversion to an open operation in such cases reflects sound clinical judgment and should not be considered a complication. The goal of any cholecystectomy, whether laparoscopic or open, is the safe removal of the gallbladder while avoiding injury to the CBD at all costs.

# CHOLEDOCHOLITHIASIS AND CHOLANGITIS

*Yu Liang • David W. McFadden • Brian D. Shames*

With advanced endoscopic and laparoscopic techniques readily accessible to the treating surgeon, determining the wisest path to the successful treatment of choledocholithiasis and cholangitis has become more challenging.

Nevertheless, a large number of options allow one to tailor specific therapy to each individual clinical situation in order to achieve the highest probability of safety and success. In this chapter, we offer the reader a review of the methods available for the diagnosis and treatment of common bile duct (CBD) stones and cholangitis so that treatment plans can be developed that are patient-specific and have the highest chance of success.

## CHOLEDOCHOLITHIASIS

### **Classification and Epidemiology**

A common entity in Western societies, gallstones are found in approximately 15% of Americans and result in 700,000 cholecystectomies a year. The annual cost of medical care for gallstones is almost \$6.5 billion compared

with colorectal cancer (\$9.5 billion), viral hepatitis (\$3.4 billion), and gastroesophageal reflux disease (GERD) (\$12.6 billion).<sup>1,2</sup> CBD (downstream of the confluence of the hepatic ducts) stones have been noted in 10% to 15% of patients with cholelithiasis, and this incidence increases with age to over 80% in those who are over 90 years old.<sup>3</sup> Choledocholithiasis in Western countries usually results from stones originating in the gallbladder and migrating through the cystic duct. These *secondary bile duct stones* are cholesterol stones in 75% and black pigment stones in 25% of patients. Cholesterol stones contain more than 70% cholesterol by weight, and variable amounts of bile salt and calcium. Over 90% of all cholesterol stones are radiolucent. Cholesterol stones are formed in the presence of cholesterol saturation, biliary stasis, and nucleating factors. Behavioral factors associated with cholesterol gallstones include nutrition, obesity, weight loss, and physical activity. Biologic factors linked to gallstones include increasing age, female sex and parity, serum lipid levels, and the Native American, Chilean, and Hispanic races.<sup>1</sup> The formation of black pigment stones is associated with hemolytic disorders, cirrhosis, ileal resection, prolonged fasting, and total parenteral nutrition.<sup>3</sup> These conditions lead to supersaturation of unconjugated bilirubin, which results in precipitation of bilirubinate with calcium and other anions in bile. The precipitated salt then becomes a nidus for black stone formation.

*Primary bile duct stones*, on the other hand, form within the bile ducts and usually are of the brown pigment variety. These tend to be less than 20% cholesterol and higher in bilirubin content as compared with secondary stones. Unlike secondary stones, primary stones are associated with biliary stasis and bacteria.<sup>4</sup> In fact, in the pathogenesis of brown pigment stones, bacterial enzymes unconjugate bilirubin glucuronide to form free bilirubin, which then precipitates with calcium to become the nidus for stone formation.<sup>5</sup> Moreover, bacteria have been found in brown pigment stones by electron microscopy but not in black pigment stones.

Primary bile duct stones are more common in Asian populations, and these often are associated with *primary intrahepatic stones* in this population.<sup>1</sup> These intrahepatic stones usually are calcium bilirubinate and mixed stones and contain more cholesterol and less bilirubin than the extrahepatic bile duct pigmented stones. The pathogenesis of these intrahepatic stones appears to involve bile infection, biliary stasis, low-protein, low-fat diets and

malnutrition, and parasitic infections. However, the role of *Ascaris lumbricoides* and *Clonorchis sinensis* in the formation of intrahepatic stones is controversial. While these parasites are found in many geographic areas, primary intrahepatic stones are found mainly in Southeast Asia. Therefore, in addition to parasitic infections, other factors must play a role in the formation of these stones.<sup>1</sup>

## Clinical Presentation and Natural History

Asymptomatic bile duct stones may be found incidentally during evaluation of patients with suspected gallstones. In fact, 5% of common duct stones found during surgery may be unsuspected by preoperative findings and discovered only during intraoperative evaluation of the biliary tree. In one autopsy study of 615 patients over age 60, 1% were found to have bile duct stones.<sup>3</sup> Patients with choledocholithiasis may present with biliary colic, bile duct obstruction, bilirubinuria (or tea-colored urine), pruritus, acholic stools, and jaundice. However, the biliary obstruction usually is incomplete. There may be nausea and vomiting with intermittent or constant epigastric or right upper quadrant pain.<sup>6</sup> The clinical course may be complicated by acute gallstone pancreatitis, cholangitis, or rarely, hepatic abscess. Infected patients may present with back pain, fever, hypotension, and mental status changes suggestive of cholangitis and ascending cholangitis. An asymptomatic state is also recognized.

CBD stones are covered by a bacterial biofilm of adherent quiescent bacteria residing in a hermetic environment. When stones cause obstruction of the ducts, cytokines released by epithelial cells activate these bacteria to the planktonic and virulent forms.<sup>1</sup> Therefore, bile duct obstruction secondary to stones often is accompanied by bacterial sepsis resulting from activation of the bacterial biofilm on these stones. Sepsis is much less likely to occur in the context of malignant obstruction without choledocholithiasis.

Although a majority of stones will pass spontaneously into the duodenum within hours, prolonged biliary obstruction can lead to biliary cirrhosis and portal hypertension. The average time for choledocholithiasis to lead to biliary cirrhosis is about 5 years, depending on the extent of obstruction.<sup>1</sup> Even with cirrhosis, however, the obstruction should be relieved because some reversal of portal hypertension and secondary biliary cirrhosis may be

possible.

Physical examination of patients with choledocholithiasis may be normal or may reveal jaundice, scleral icterus, and abdominal tenderness over the right upper quadrant without peritoneal signs. Early in the course, physical examination may not be very different from that of patients with cholecystitis. Severe tenderness may point to acute gallstone pancreatitis, whereas fever, hypotension, and confusion may suggest cholangitis.<sup>7</sup>

Blood tests may reveal elevation of serum alkaline phosphatase (ALP), gamma-glutamyl transpeptidase (GGT), and bilirubin. Mild elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) can be seen, whereas these are particularly abnormal in the situation of cholangitis. Although bilirubin and aminotransferase levels are high in 70% to 90% of patients at the onset of symptoms, almost all patients have elevation of ALP and GGT.<sup>7</sup> Elevated amylase and lipase may suggest pancreatitis. Leukocytosis may be seen with cholangitis, pancreatitis, or associated acute cholecystitis. It is worth noting that laboratory evaluation of patients with bile duct stones can be normal repeatedly, and this should not dissuade further evaluation of patients suspected to harbor duct stones.<sup>8</sup>

## Evaluation and Management

The evaluation and treatment of choledocholithiasis are best discussed by considering the three clinical circumstances in which patients who may have bile duct stones are seen: prior to cholecystectomy, during cholecystectomy, or some time after cholecystectomy.

### PREOPERATIVE

The diagnosis of choledocholithiasis cannot be made on the basis of history, physical examination, and laboratory investigations alone. Moreover, the distinction between the symptoms of bile duct stones and gallbladder stones is difficult. Increasing age, history of fever, cholangitis, and pancreatitis are risk factors for bile duct stones, whereas elevations of serum bilirubin, AST, or ALP are independent positive predictors.<sup>1,9</sup>

Biochemical tests can be used as an initial screen to identify patients with high probability of CBD stones. ALP has the highest sensitivity (79.5%) for

CBD stones. Total bilirubin (TB) has the highest specificity (87.5%) and accuracy (84.1%) for CBD stones. A normal gamma-glutamyl transferase is excellent for exclusion of CBD stones (odds ratio of 3.2; negative predictive value [NPV] of 97.9%). For a patient with normal GGT, the likelihood of CBD stone is only 2.1%. An elevated GGT, ALP, TB, ALT, and AST has a sensitivity of 87.5%, compare to sensitivity of 96% for endoscopic retrograde cholangiopancreatography (ERCP).<sup>10</sup>

*Transcutaneous ultrasound* has been the traditional method of evaluating patients with biliary disease. It is highly accurate in identifying acute calculous cholecystitis and the presence of gallstones greater than 2 mm. Sensitivities and specificities of 48% to 100% and 64% to 100%, respectively, have been reported.<sup>11</sup> However, the ability of transcutaneous ultrasound to establish the diagnosis of choledocholithiasis is only about 50%, varying from 30% to 90%.<sup>7,12</sup> The role of ultrasound as a screening test for bile duct stones was evaluated prospectively by Gross and colleagues.<sup>13</sup> Patients who were about to undergo ERCP were examined by right upper quadrant sonography to assess the size of the intra and extrahepatic ducts and for the presence or absence of bile duct stones. The findings were compared with ERCP, percutaneous transhepatic cholangiography, or surgical follow-up. Ultrasound was not found to be accurate in the diagnosis (sensitivity of 25%) or the exclusion (73% NPV) of choledocholithiasis.

Costi and colleagues studied the usefulness of the number and size of gallbladder stones for predicting asymptomatic choledocholithiasis.<sup>14</sup> Ultrasound data of 300 consecutive patients undergoing laparoscopic cholecystectomy were analyzed. Patients were divided into two groups: those with multiple small (<5 mm) gallbladder stones or variable ( $\leq$ 5 mm and >5 mm) stones and those with large (>5 mm) stones only. The classification of stone size was confirmed by surgery in 95% of patients. Moreover, the presence of multiple small and variable gallbladder stones represented a risk factor for synchronous asymptomatic bile duct stones (9.5%) as compared with large stones only (2.5%). In another study, ultrasonography was found to have a positive predictive value (PPV) of 69% and an NPV of 78% for choledocholithiasis in patients suspected to have bile duct stones.<sup>15</sup> This compared with serum transaminase tests having predictive values of 68% and 93%, respectively. In comparison to elevated serum transaminases and/or increased amylase levels, ultrasonographic evidence of CBD dilatation (>7

mm) has been described to be the best predictor of choledocholithiasis.<sup>16</sup> Nonetheless, it is worth noting that almost half the patients with CBD stones do not have dilated ducts by ultrasonography, hence a negative study has limited value.<sup>17</sup>

In order to predict the presence of bile duct stones more accurately, the combination of clinical, laboratory, and ultrasound risk factors has been used by several investigators.<sup>1,18,19</sup> For patients over 55 years old with a bilirubin greater than 30  $\mu\text{mol/L}$  (1.75 mg/dL) and a CBD more than 6 mm on ultrasound, the probability of a CBD stone is 72%.<sup>20</sup> By multivariate logistic regression analysis, the combination of dilated CBD with evidence of stones by ultrasonography, clinical evidence of cholangitis, elevated aspartate transaminase and bilirubin, the likelihood of having stones in the bile duct was 99%.<sup>19</sup> In the absence of all four of these findings, the probability of synchronous choledocholithiasis in patients with cholelithiasis was only 7%.<sup>19</sup> Unfortunately, many patients present with only some of these findings, and the prediction of bile duct stones based on these criteria becomes difficult. Moreover, ultrasound sensitivity is in part operator-dependent and altered by bowel gas, making the findings inconsistent.<sup>21</sup>

In 1968, ERCP was introduced as a diagnostic tool to aid in the management of biliary and pancreatic diseases.<sup>22</sup> Five years later, with the development of endoscopic sphincterotomy, ERCP was transformed into a therapeutic modality.<sup>23</sup> In 2009, 228,000 biliary endoscopies were performed in the United States, totaling \$900 million in healthcare costs.<sup>24</sup> Short of intraoperative examination, ERCP has long been considered the standard reference for the diagnosis of CBD stones.<sup>21</sup> The specificity and sensitivity of ERCP were reported in 1982 by Frey and colleagues.<sup>25</sup> ERCP was compared with findings on common duct exploration or cystic duct cholangiography in 72 patients and was found to have a sensitivity of 90%, specificity of 98%, and a 96% accuracy. Interestingly, the interval between performance of the procedure and operation was particularly important in patients with multiple small stones. Since small stones pass more readily from the gallbladder to the common duct and from the common duct to the duodenum, the longer the interval between ERCP and operation, the greater was the chance of discordant findings.

ERCP has the advantage of being both diagnostic and therapeutic for CBD stones (Figs 63-1 and 63-2). That is, after stones in the bile duct are

identified, endoscopic sphincterotomy and stone extraction can be performed at the same setting.<sup>21</sup> ERCP *stone extraction* is successful 80% to 90% of the time using the techniques of sphincterotomy and balloon catheter or Dormia basket stone retrieval.<sup>23,26</sup> The addition of mechanical, electrohydraulic, laser, or extracorporeal shockwave lithotripsy for large stones increases the success rate to over 95%.

**FIGURE 63-1** Endoscopic retrograde cholangiopancreatography (ERCP) with distal common bile duct (CBD) stone prior to cholecystectomy.

**FIGURE 63-2** Endoscopic retrograde cholangiopancreatography (ERCP) and common bile duct (CBD) stone extraction.

*Sphincterotomy* entails division of the papilla and sphincter muscles to widen the distal end of the CBD using a sphincterotome, a device consisting of a Teflon catheter with exposed cautery wire at the tip. The length of the intraduodenal part of the CBD limits the extent of the cut. *Balloon sphincteroplasty* is a sphincter-preserving alternative to sphincterotomy that uses a high-pressure hydrostatic balloon of either 6 or 8 mm diameter to dilate the papilla. One drawback of sphincteroplasty is the limited size of the papillary opening created as compared with sphincterotomy. Failure rates of 22% for stone extraction with balloon dilatation and the need for mechanical lithotripsy in 31% have been reported.<sup>26</sup> Furthermore, sphincteroplasty has been associated with a pancreatitis rate of 19 times greater than the rate associated with sphincterotomy.<sup>27</sup> A study evaluating the use of

sphincteroplasty, on the other hand, found that severe pancreatitis only occurred in 1 patient out of 63, whereas the successful stone extraction rate was 84%.<sup>28</sup>

Once the sphincter has been divided, most stones can be removed using a Dormia basket or a balloon catheter. The Dormia basket has better traction than the balloon and consequently is recommended for larger stones (>1 cm). The balloon catheter occludes the bile duct lumen after inflation and therefore is useful for removal of small stones and gravel. The catheter also can be inserted over a guidewire, making it useful for intrahepatic duct stones. Three situations that may lead to a difficult extraction are stone size greater than 1.5 cm, stone location proximal to a stricture, and multiple stones that are impacted. Alternative approaches to these situations include mechanical lithotripsy, electrohydraulic or laser lithotripsy, and extracorporeal shock wave lithotripsy. Mono-octanoin and methyl tertiary butyl ether (MTBE) have been used in the past to dissolve bile duct stones through nasobiliary drainage catheters or T-tubes. The practice largely has been abandoned because of high complication rates, poor results, and the technical difficulty of performing the dissolution.<sup>26</sup>

*Mechanical lithotripsy* is the most commonly used and simplest means of fragmenting large bile duct stones or when a significant discrepancy between the stone size and the diameter of the exit passage exists.<sup>29</sup> A large, strong basket is used to trap the stone. The stone then is crushed against a metal sheath by applying tension to the wires by the use of a crank handle. Reimann and colleagues first described the technique in 1982, and since then, many variations in design have become available.<sup>30,31</sup> When stones are extremely large, repeat application of the technique may be needed to further break the stone fragments and thus allow removal. Success rates between 80% and 90% have been reported for clearing the bile duct using the procedure.<sup>32-34</sup> One retrospective study of 162 patients undergoing mechanical lithotripsy found that the probability of bile duct clearance was over 90% for stones less than 1 cm diameter versus 68% for stones greater than 2.8 cm diameter.<sup>35</sup> Garg and colleagues presented data on 87 patients with stones greater than 1.5 cm that required mechanical lithotripsy.<sup>36</sup> They analyzed various predictive factors, including size and number of stones, stone impaction, serum bilirubin, presence of cholangitis, and bile duct diameter, in relation to the success or failure of lithotripsy. Impaction of the stones in the bile duct

was found to be the only significant factor that predicted failure of mechanical lithotripsy and subsequent bile duct clearance. The composition of the stone also has been found to affect the success of stone removal. Soft stones, such as those found in Oriental cholangitis, are large but amenable to crushing, sometimes even with the Dormia basket.<sup>29</sup> However, calcified stones are hard and resist mechanical crushing.

*Large-balloon dilatation* of the distal bile duct has been reported as a means of removing difficult bile duct stones after standard extraction has been unsuccessful.<sup>37</sup> In a retrospective analysis, 58 patients who failed standard sphincterotomy and standard basket or balloon extraction underwent dilation with a 10- to 20-mm-diameter balloon (esophageal type) followed by standard basket or balloon extraction. The patients were divided into two groups: 18 patients with a tapered distal bile duct (group 1) and 40 patients with square, barrel-shaped, and/or large (>15 mm) stones (group 2). Stone clearance was successful in 89% of group 1 patients and 95% of group 2 patients. In the two patients in each group in whom extraction was not possible after dilatation alone, mechanical lithotripsy allowed for stone removal. Complication rates were high: 33% for group 1 and 7.5% for group 2, including mild pancreatitis (two patients), mild cholangitis (two patients), and bleeding (five patients). No bleeding required surgery. Large-balloon dilatation offers an alternative in managing difficult bile duct stones, and further studies are needed to establish its role as compared with other lithotripsy options.

The management of complicated situations of choledocholithiasis may require several procedures or several sessions of the same procedure for successful clearance of the CBD. In such situations, partial stone impaction may lead to biliary stasis and cholangitis. Along with the administration of broad-spectrum antibiotics to cover gram-negative and gram-positive bacteria, it is important to decompress the biliary tree with either a nasobiliary catheter or a biliary stent as a temporizing measure pending more definitive treatment.<sup>26,29</sup> By doing this, serum bilirubin levels are allowed to decrease, and the rate of post-procedure cholangitis becomes similar to that after stone clearance. Interestingly, up to 30% of patients in whom a stent has been left in place for large stones have spontaneous disappearance of the stones, as noted on subsequent ERCP.<sup>29</sup> This may be secondary to the frictional movement of stone against the stent or as a result of improved bile flow with dissolution effects. Furthermore, by adding oral ursodeoxycholic

acid to stent placement, 9 of 10 patients have been reported to become stone-free by this combination as compared with 0 of 40 with stent placement only.<sup>38</sup> Long-term stent placement is an unconventional management option for patients with large, inextricable stones who are at high risk for surgical intervention, and should be used with caution. In a long-term follow-up study of 58 elderly patients, 40% of patients treated with permanent stents for endoscopically irretrievable stones developed 34 complications in 23 patients, with cholangitis being the most frequent.<sup>39</sup> At median follow-up of 36 months, 44 patients had died, 9 as a result of biliary-related causes. Hui and colleagues prospectively evaluated 36 high-risk patients with difficult CBD stones.<sup>40</sup> Of these, 19 underwent stent placement, and 17 underwent complete stone clearance with electrohydraulic lithotripsy. The actuarial incidence of recurrent acute cholangitis was 8% in the lithotripsy group versus 63% in the stent group. The actuarial mortality also was higher in the stent group compared with the lithotripsy group, 74% and 41%, respectively.

Although ERCP has developed over the years as a relatively safe endoscopic diagnostic and therapeutic tool, there are well-defined, potentially severe, and life-threatening complications associated with it. The reported rates of complications vary widely in different studies, and this may be related in part to study design, with retrospective studies being prone to under-reporting. Furthermore, the complication rates may diverge depending on the patient mix in the study and may be influenced in part by the definitions used for these complications.<sup>22</sup>

The mortality rate after diagnostic ERCP is about 0.2%, and this rate is more than doubled by therapeutic interventions, to 0.5%.<sup>21,22</sup> Remember, these are essentially the same rates as for laparoscopic cholecystectomy. Cardiopulmonary complications are the leading cause of death and include cardiac arrhythmia, hypoventilation, and aspiration. These may be the result of premorbid conditions or related to medications used during sedation and analgesia. Other significant complications include perforations (0.3%-0.6%), bleeding related primarily to sphincterotomy (0.8%-2%), cholecystitis (0.2%-0.5%), and cholangitis (1%). In a recent meta-analysis, prophylactic<sup>21</sup> antibiotics were not found to be beneficial in reducing infectious complications of ERCP. Moreover, another study failed to show a decrease in the rate of cholangitis in patients with distal bile duct stones or biliary strictures receiving antibiotic prophylaxis.<sup>22</sup>

Pancreatitis is the most common complication seen after ERCP. The consensus definition for ERCP-induced pancreatitis is new or worsened abdominal pain, serum amylase that is greater than three times the upper limits of normal at 24 hours post procedure, and a requirement of at least 2 days of hospitalization. Although the transient elevation of serum pancreatic enzyme levels is frequent, based on the consensus definition of ERCP pancreatitis, the expected rate of this complication is between 1% and 7%. Risk factors associated with ERCP-induced pancreatitis include a prior history of ERCP pancreatitis, nondilated biliary ducts, normal bilirubin, young age, female gender, and suspected sphincter of Oddi dysfunction. In fact, the risk of pancreatitis in women with normal bilirubin and suspected sphincter of Oddi dysfunction is 18%, compared with 1.1% for the low-risk patient.<sup>22,41</sup> Moreover, one of five episodes of pancreatitis in this setting will be severe, requiring more than a 10-day hospital stay and/or resulting in necrosis, pseudocyst, abscess formation needing surgery or percutaneous drainage, or death. Since the highest rate of complications appears to exist in the group of patients that is least likely to benefit from ERCP, the most effective method of reducing post-ERCP pancreatitis would appear to be to avoidance of unnecessary ERCP.

Pharmacologic methods of pancreatitis prophylaxis have been attempted to reduce this complication after ERCP.<sup>22</sup> Meta-analyses have suggested that somatostatin and gabexate are useful in reducing pancreatitis rates, but multicenter randomized, controlled trials have failed to confirm this. The use of nonionic contrast agents has not reduced the rate of pancreatitis. Glyceryl trinitrate (GTN) administered by both sublingual and transdermal routes has been shown to decrease post-ERCP pancreatitis in two placebo-controlled trials, supposedly by decreasing sphincter of Oddi pressure. Its hypotensive effects limit its use. The placement of pancreatic stents has been found to reduce the incidence of postbiliary sphincterotomy pancreatitis in patients suspected of sphincter of Oddi dysfunction.

Based on clinical, laboratory, and ultrasound criteria for CBD stones, up to 70% of patients may be found not to have duct stones at the time of preoperative ERCP.<sup>19,42,43</sup> Given this, a large number of patients may be subjected to an unnecessary ERCP and suffer its risks and costs. Several methods have become available to diagnose the presence of bile duct stones accurately prior to having patients undergo ERCP or operative interventions. The most important of these are magnetic resonance

cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), and computed tomography (CT).

Sensitivities of conventional CT for choledocholithiasis in the setting of suspected bile duct stones is 76% to 90%, whereas unenhanced helical CT has been shown to have a sensitivity of 88%, a specificity of 97%, and an accuracy of 94%.<sup>21</sup> When compared with ERCP as the reference standard, CT without biliary contrast material showed poor concordance with ERCP (sensitivity 65% and specificity 84%) but compared better when oral biliary contrast material was given (sensitivity and specificity greater than 90%).<sup>44</sup> CT with intravenous (IV) biliary contrast material in other studies has been found to have a sensitivity of 71% to 85% and a specificity of 88% to 95%.<sup>44</sup> Patel and colleagues reported a comparison between noncontrast-enhanced helical CT and the reference standard of EUS and found that CT had both a sensitivity and a specificity of 83% for the detection of CBD dilatation in the setting of choledocholithiasis. However, when CT was evaluated for identifying duct stones, it had a sensitivity of only 22% and a specificity of 83%.

Since its introduction over a decade ago, the use of MRCP for the diagnosis of CBD stones has increased eightfold, while the use of ERCP as a diagnostic tool has decreased substantially.<sup>24</sup> With sensitivities and specificities that approach those of ERCP, MRCP has emerged as a diagnostic alternative to ERCP for the detection and exclusion of choledocholithiasis.<sup>21</sup> Additionally, economical and clinical cost analysis showed diagnostic MRCP is favorable over diagnostic ERCP in selected patients.<sup>45</sup> Performed with T<sub>2</sub>-weighted sequences, the biliary tract is seen as a bright structure with high-signal intensity without the use of contrast material, instrumentation, or ionizing radiation. Common duct stones are seen as low-signal-intensity filling defects surrounded by high-intensity bile. Improvements over the past decade have resulted in the ability to image the entire biliary tract in a single breath-hold of 20 seconds with a resolution that allows visualization of fourth-order intrahepatic bile ducts and small stones. Stones as small as 2 mm can be detected even in the absence of biliary dilatation.<sup>21</sup> In one study of 97 patients, sensitivity of MRCP was 100% for stone diameters of 11 to 27 mm, 89% for stone diameters of 6 to 10 mm, and 71% for stone diameters of 3 to 5 mm.<sup>41</sup> In this study, MRCP had a 91% sensitivity compared with 100% for ERCP, whereas both tests had a

specificity of 100%. Studies with state-of-the-art techniques have found sensitivities of 90% to 100% with specificities of 92% to 100%.<sup>21</sup> In a prospective analysis by Ke and colleagues, 267 patients believed to have CBD stones were evaluated by MRCP and ERCP.<sup>46</sup> MRCP was found to have a sensitivity of 100%, a specificity of 96%, and an NPV of 100%. Kejriwal and colleagues retrospectively examined patients with cholelithiasis who underwent MRCP for suspected choledocholithiasis.<sup>47</sup> Patients were considered not to have clinically relevant common duct stones if they had a negative MRCP and did not present for readmission for choledocholithiasis after treatment of their cholelithiasis. MRCP was negative for bile duct stones in 74% of patients (60 of 81) and missed clinically relevant stones in two patients, resulting in a PPV of 95% and an NPV of 97%. With its ability to exclude bile duct stones, MRCP may allow the avoidance of unnecessary diagnostic ERCP. Demertines and colleagues found that even in patients with high and moderate risk of CBD stones based on laboratory findings, the performance of MRCP could have resulted in the avoidance of ERCP in 52% and 80% of patients, respectively.<sup>48</sup>

One of the limitations of MRCP is that its resolution remains less than that of ERCP, and therefore it cannot detect small stones and crystals consistently. Claustrophobia also may influence the use of MRCP, and patients may need sedation or even general anesthesia for its performance. Patient obesity may diminish the quality of images, whereas morbid obesity, pacemakers, and aneurysm clips preclude entry into the scanner.<sup>21</sup> Conversely, ERCP may be limited by an inability to access and cannulate the papilla and opacify the ductal system. Failed ERCP rates vary greatly among endoscopists, from 5% to 20%.<sup>21</sup> Moreover, alterations in the gastrointestinal tract anatomy, such as a Billroth II gastrojejunostomy, may preclude access to the ampulla. In summary, MRCP offers a method of evaluating the biliary system for bile duct stones with sensitivities and specificities that approach those of ERCP in a manner that is noninvasive and avoids the risks and limitations of ERCP. Patients with a positive MRCP then may be considered for more invasive therapeutic procedures.

Another sensitive method of evaluating the biliary system for CBD stones is EUS. EUS has been shown to have a diagnostic accuracy of 95% for bile duct stones.<sup>49</sup> With the high ultrasound frequencies used (7.5 and 12 MHz), EUS has a resolution of less than 1 mm, making it the best imaging technique

available for the extrahepatic biliary tract. Several studies have found EUS to be similar to ERCP in sensitivity and specificity for the evaluation of choledocholithiasis, with some showing ERCP to be better and others showing EUS to be better.<sup>44</sup> Compared with ERCP, EUS is semi-invasive, with almost no procedure-related complications and a negligible failure rate. In fact, several series comprising over 1000 patients have reported no complications.<sup>49</sup> In a prospective study by Buscarini and colleagues, 485 patients suspected to have choledocholithiasis based on clinical, laboratory, and ultrasound or CT findings underwent EUS.<sup>49</sup> Positive EUS findings were confirmed by surgery or ERCP with sphincterotomy; negative findings were confirmed by clinical follow-up of at least 6 months. EUS findings were verified in 463 patients as follows: 237 true positive, 216 true negative, 2 false positive, and 4 false negative, and in 4 patients EUS was incomplete (sensitivity 98%, specificity 99%, PPV 99%, NPV 98%, accuracy 97%). No complications were noted in the study. EUS offers higher resolution than MRCP and therefore is better able to detect small stones. It is able to identify bile duct stones as well as microlithiasis and is able to detect pathology that is not seen by ERCP. EUS prior to performing invasive diagnostic or therapeutic techniques would lower the rate of procedure-related complications in patients suspected of having bile duct stones. Cost analysis of EUS followed by ERCP versus ERCP alone is also in favor of EUS as a pre-therapeutic procedure.<sup>49</sup>

In patients for whom ERCP is not available, not possible secondary to anatomic considerations, or not successful, an alternative method of cholangiography and nonsurgical therapy is *percutaneous transhepatic cholangiography* (PTC) followed by transhepatic methods of stone removal. A needle is introduced into the intrahepatic bile ducts through the skin, and a cholangiogram is performed, followed by wire insertion and then a catheter over the wire for external biliary drainage and access to the biliary system. The method was introduced in Denmark in the 1970s and has been refined over the years with the addition of several therapeutic options.<sup>50</sup> This technique is particularly useful for evaluating intrahepatic stones or other proximal bile duct disease. After diagnosis of bile duct stones, several therapeutic options are available through the percutaneous route. In 1981, the removal of an 8-mm CBD stone by percutaneous transhepatic technique was reported by Fernstrom and colleagues.<sup>51</sup> In 1990, Stokes and colleagues,

from Boston, reported a series of 53 patients in whom surgery was contraindicated and ERCP unsuccessful.<sup>52</sup> By inserting a modified Dormia basket via a percutaneous transhepatic route, stones were advanced whole or after fragmentation into the duodenum. Mono-octanoin or MTBE were used in 30 patients to reduce stone size or remove debris. Morbidity and mortality were 12% and 4%, with a success rate of 93%. Transhepatic cholangioscopy and lithotripsy can be performed after PTC and dilatation of the intrahepatic channel with success rates of 90% to 100% and 5% to 8% complications.<sup>53</sup> In a series of 12 patients with bile duct stones, PTC in combination with laser or electrohydraulic lithotripsy to deliver stone fragments into the duodenum was found to be successful in all the patients.<sup>54</sup> In another series of 13 patients, laser lithotripsy was used with percutaneous cholangioscopy performed either transhepatically (12 patients) or through the T-tube track.<sup>55</sup> Stone fragmentation was successful in 92%, and stone clearance was possible in all patients. However, 11 patients required the addition of sphincterotomy (either by ERCP or by antegrade method with fluoroscopic monitoring) or stent insertion. Bleeding in two patients accounted for a 15% severe complication rate. Percutaneous transhepatic papillary balloon dilatation was reported by a Japanese group for the management of choledocholithiasis.<sup>56</sup> In the five patients in whom the method was used, bile duct stones were able to be pushed into the duodenum in all, with no complications or deaths. Ponchon and colleagues reported percutaneous choledochoscopy for stone extraction in 75 patients, with the transhepatic route used in 48 patients and T-tube tract used in 27 patients.<sup>57</sup> Complete clearance of bile duct stones was accomplished in 69 patients (92%).

**Role of Cholecystectomy Following CBD Stone Extraction.** After bile duct clearance is achieved by nonoperative methods, cholecystectomy generally is recommended in younger patients to decrease the risk of future cholecystitis and recurrent biliary colic. As many as 24% of patients have been found to require cholecystectomy at follow-up after endoscopic papillotomy at an average of 14 months.<sup>58</sup> Some authors have argued that sphincterotomy results in gallbladder stasis, bacterial overgrowth, and an increase in bile acids, and these may increase the risk of gallbladder cancer in 10 to 20 years.<sup>3</sup> On the other hand, Dhiman and colleagues studied the changes in gallbladder emptying and lithogenicity of bile following endoscopic

sphincterotomy in patients with choledocholithiasis and gallbladder in situ.<sup>59</sup> Sphincterotomy was found to decrease stasis of gallbladder bile, improve gallbladder emptying, and decrease the lithogenicity of bile as measured by prolongation of nucleation time. Meanwhile, there is much evidence to support leaving the gallbladder in situ after bile duct clearance in high-risk or elderly patients.<sup>60-69</sup> In a study of 191 patients (median age 76 years) in whom the gallbladder was left in situ post-ERCP, only 10 patients (5%) required subsequent uneventful cholecystectomy.<sup>63</sup> Twenty-six percent (49 patients) died during the review period from nonbiliary pathology. Kwon and colleagues followed 146 patients without elective cholecystectomy after endoscopic CBD stone removal for a period of 3 months or more to see if they could identify factors that predict subsequent gallbladder-related symptoms and need of cholecystectomy.<sup>65</sup> Fifty-nine patients had cholelithiasis, whereas 87 patients had no gallbladder stones. During a mean follow-up of 24 months, seven patients (5%) underwent cholecystectomy, on average 18 months after ERCP as a result of acute cholecystitis (four patients), biliary pain (two patients), and acute pancreatitis (one patient). Nine patients (6%) died of causes unrelated to biliary disease. Interestingly, Cox regression analysis revealed that the need for subsequent cholecystectomy did not correlate with age, sex, presence of gallbladder stones, number of gallbladder stones, or underlying disease. Kullman and colleagues found that at a median observation time of 42 months, cholecystectomy was needed in 11% (13 patients) of 118 patients with a gallbladder in situ after ERCP bile duct clearance.<sup>66</sup> Forty-nine patients (42%) died within 2 to 87 months after ERCP during the follow-up period. In another study of 33 elderly patients who were followed for an average of 42 months with gallbladder in situ after successful ERCP for choledocholithiasis, 3% (one patient) required cholecystectomy for acute cholecystitis, and 6% (two patients) had mild right upper quadrant pain, whereas 91% remained asymptomatic.<sup>67</sup> Over the course of the study, 30% of the patients died from nonbiliary causes.

The impact of gallbladder status on patient outcome after ESWL for complicated CBD stones was studied by a German group.<sup>64</sup> One-hundred twenty patients with an average age of 68 years (range 28-86 years) were followed for 3 to 9 years (mean 4 years). Thirty-seven had their gallbladder in situ, 27 had had a cholecystectomy after ESWL, and 56 had already

undergone cholecystectomy prior to diagnosis of choledocholithiasis. During the follow-up period, 30% (36 patients) experienced biliary symptoms. However, there was no significant difference in the incidence of these symptoms between the three groups. Repeat ERCP revealed 28 cases of recurrent bile duct stones. Although not reaching statistical significance ( $p = .077$ ), the recurrences occurred more often in the cholecystectomy groups. Given the multiple studies supporting leaving the gallbladder in situ after CBD clearance, it seems reasonable to perform cholecystectomies on high-risk or elderly patients as needed rather than prophylactically following nonoperative treatment of bile duct stones.

## INTRAOPERATIVE

When presenting to the operating room for cholecystectomy, patients may have CBD stones confirmed by preoperative studies (eg, ERCP, MRCP, or EUS), be suspected to have CBD stones by clinical presentation, laboratory values, or transabdominal ultrasound, or have no suspicion of bile duct stones. At the time of surgery, *intraoperative cholangiography* (IOC) is the diagnostic method used most often. Mirizzi first introduced IOC to open biliary surgery in the 1930s.<sup>70</sup> With the universal acceptance of laparoscopic cholecystectomy, laparoscopic IOC has developed into a very useful method to evaluate the biliary tree. IOC and ECRP have similar sensitivity and specificity in CBD stone detection.<sup>71</sup> The technique may be performed by injecting contrast material through a catheter introduced into the cystic duct via a variety of techniques.<sup>72</sup> Cannulation rates with successful cholangiography range from 75 to 100%, and the use of fluoroscopy has become standard.<sup>72,73</sup> The reported sensitivity, specificity, PPV, NPV, and accuracy for laparoscopic cholangiography are 80% to 90%, 76% to 97%, 67% to 90%, 90% to 98%, and 95%, respectively, and these are comparable with the values for open IOC.<sup>70</sup> The rate of false positive IOC in a recent large review was found to be 0.8% (34 of 4209 patients).<sup>74</sup>

Although approximately 10% to 15% of patients undergoing laparoscopic cholecystectomy harbor CBD stones, the need for routine IOC is a matter of much debate.<sup>74</sup> In a large Medline literature review, Metcalfe and colleagues found a 4% rate of CBD stones in eight laparoscopic cholecystectomy trials in which routine IOC was performed on 4209 patients without suspected bile

duct stones preoperatively.<sup>72</sup> This finding was felt to be consistent with previous reviews. On the other hand, in a total of 5179 patients without suspicion for bile duct stones who did not undergo IOC during laparoscopic cholecystectomy, 32 (0.6%) proceeded to develop symptoms from residual bile duct stones. Extrapolating this data, it would seem that of the 4% of patients with silent CBD stones at laparoscopic cholecystectomy, only 15% go on to develop symptoms from retained stones. In other words, 167 IOCs would have to be performed during laparoscopic cholecystectomy in order to detect one CBD stone that would go on to cause symptoms in patients without preoperative evidence of duct stones. This would result in eight unnecessary bile duct explorations or ERCPs.<sup>72</sup> It is possible that stones that are not manifested preoperatively are of the size that can pass spontaneously into the duodenum, never presenting with symptoms.

*Intraoperative ultrasound (IOUS)* is a noninvasive way to evaluate the biliary system at the time of surgery. First introduced in the mid-1980s in the time of open cholecystectomy, laparoscopic IOUS came into use in the mid-1990s.<sup>70</sup> Recent experience with laparoscopic IOUS has suggested that it is a very sensitive test for CBD stones and roughly equivalent to IOC in evaluating the biliary ductal system. Moreover, it lacks the potential of CBD injury that exists with placement of the cholangiography catheter during IOC and will not cause a false positive test owing to air introduced into the biliary tree.<sup>72</sup> The use of laparoscopic IOUS has been limited, however, secondary to equipment availability and cost, as well as the expertise and experience required for its use. There appears to be a considerable learning curve associated with the use of laparoscopic IOUS.<sup>75,76</sup>

Once the presence of CBD stones has been established at the time of surgery, there are several treatment options. Depending on local availability and expertise, these may include open or laparoscopic duct exploration and post-cholecystectomy nonoperative techniques such as ERCP or PTC. However, before embarking on a means of eradicating the biliary tree of stones, it is worth remembering that only 15% of patients with silent bile duct stones at the time of cholecystectomy present with symptoms of retained stones.<sup>72</sup> The natural history of choledocholithiasis was revisited in a prospective study by Collins and colleagues.<sup>77</sup> Operative cholangiography was attempted in 997 patients undergoing laparoscopic cholecystectomy and was successful in 962 patients. Patients with cholangiogram-positive stones

were restudied in 48 and 72 hours and 6 weeks after laparoscopic cholecystectomy through a cystic duct cholangiocatheter left in the cystic duct at the time of surgery. Of the 962 patients, 46 (4.6%) had at least one filling defect but 12 had normal cholangiograms 48 hours later, giving a 26% possible false positive cholangiogram rate. At 6 weeks, a further 12 patients had a normal cholangiogram, giving a 26% spontaneous passage rate of bile duct stones. This spontaneous passage was not predictable by either the number or size of stones or the diameter of the bile duct. Only 2.2% of the total population (22 patients, or 48% of the patients with stones) required postoperative endoscopic retrograde cholangiopancreatographic retrieval of persistent common duct calculi. **Thus a treatment decision based on the findings of IOC alone would have resulted in 52% of patients with positive findings undergoing unnecessary intervention.**

The first surgical exploration of the CBD was done in 1890 by Ludwig Courvoisier, a Swiss surgeon who made an incision in the CBD and removed a gallstone.<sup>73,78</sup> Prior to the development of laparoscopic cholecystectomy, patients found to have bile duct stones at surgery underwent *open CBD exploration* with greater than 90% successful duct clearance. ERCP was used for retained stones postoperatively or for patients who would not be able to tolerate extended general anesthesia. At the time of open cholecystectomy, the common duct is opened in the longitudinal direction so as to not compromise the blood supply to the duct. The bile duct is cleared of stones with the use of Fogarty balloons, saline irrigation, stone forceps, and scoops placed into the biliary tract through the opening. Choledochoscopy is particularly useful in evaluating the duct system during and after the clearance of residual stones and ruling out other ductal pathology. Moreover, a basket can be passed through the working channel of the scope and used under direct vision for stone removal. Although used commonly in the management of CBD stones in the era of open cholecystectomy, open bile duct exploration is used infrequently in the present age of minimally invasive surgery. In a series of 326 patients who underwent laparoscopic CBD exploration (LCBDE) for choledocholithiasis at the time of cholecystectomy, only five patients were converted to laparotomy and only two for open bile duct exploration and stone extraction.<sup>73</sup>

Over a hundred years after Langenbuch performed the first open cholecystectomy in 1882, laparoscopic cholecystectomy was introduced and soon became the standard treatment of symptomatic gallstones.<sup>73,78</sup> In the

early years after the development of laparoscopic cholecystectomy, LCBDE was used infrequently, and reliance on alternative methods of duct clearance was widespread.<sup>73</sup> With increasing experience in laparoscopic techniques and the demand for single-procedure minimally invasive duct clearance, the use of LCBDE gained greater acceptance among experienced biliary surgeons. Since the development of the technique, thousands of successful LCBDEs have been reported in the literature, and success rates of duct clearance are between 80% and 90%, comparable with the open method of bile duct exploration.<sup>70</sup> The morbidities range from 8% to 10% and are typical of laparoscopic procedures. Reported mortalities are from 0% to 2%.

The technique of LCBDE has been well described by Petelin.<sup>70,73</sup> Access to the biliary system, after obtaining a cholangiogram, can be either transcystic or transductal using a choledochotomy. Use of the transcystic approach varies from 5% to 98%, depending on the series. With this method, the gallbladder is retracted toward the right hemidiaphragm, and if needed, the cystic duct is dilated with either over-the-wire mechanical or pneumatic dilators. The transductal approach is favored for stones greater than 6 mm in diameter, intrahepatic stones, cystic duct diameter less than 4 mm, and cystic duct entrance either posterior or distal. When using the transductal method, a choledochotomy is made on the anterior surface of the CBD with a scissors or scalpel and is limited to 1 cm or the size of the largest stone.

Once the biliary tree has been accessed, choledocholithotomy is performed using several different techniques and is guided by either fluoroscopy or choledochoscopy. Although separate monitors may be used with a choledochoscope, the use of a video mixer to place the laparoscopic and choledochoscopic images on the same screen is helpful. Newer choledochoscopes with 3-mm diameters even can be passed through the cystic duct. CBD clearance is started with irrigation, which allows the flushing of small, less than 3-mm stones and sludge. The administration of 1 to 2 mg IV glucagon allows relaxation of the sphincter of Oddi and facilitates the irrigation process. Fogarty-type balloons (4F) then can be inserted into the bile duct for retrograde extraction of stones with withdrawal of the inflated balloon. Stones also may be captured with a Dormia-type basket inserted directly through the cystic duct or choledochotomy or through the working port of the choledochoscope. Intraoperative electrohydraulic or laser lithotripsy is useful for large stones or stones that are impacted and not responsive to other methods. Care is needed, however, to avoid injury to the

duct by inaccurate application of the lithotripsy device.

If a choledochotomy is used to perform the LCBDE, a T-tube may be left in place for later study of the biliary system, decompression if the biliary tree was not cleared, or access to the biliary system for recurrent stones. On the other hand, laparoscopic suturing with 4-0 or 5-0 Vicryl can be done instead to close the choledochotomy primarily. A recent study found that hospital stay was shorter in a group of patients who underwent primary closure versus placement of a T-tube (5 vs 9 days).<sup>79</sup> There does not appear to be an increase in the incidence of bile leak or peritonitis in patients undergoing primary closure.<sup>73</sup> This further abrogates the complications of T-tubes, including dislodgement, bacteremia, fracture of the tube, and the possibility of bile leak and peritonitis at the time of T-tube removal. An alternative to T-tube placement is a stent placed in an antegrade fashion into the duct similar to an ERCP-placed stent.<sup>80</sup> An alternative to a T-tube is a modified ureteral catheter placed through the cystic duct and brought out through the abdomen after closure of the choledochotomy.<sup>81</sup> In a study of 30 patients undergoing placement of this modified catheter, no complications related to the catheter were found, and removal was possible at a median of 5 days as compared with 29 days when a T-tube was used.

If LCBDE is unsuccessful, a transcystic catheter may be inserted through the abdominal wall to decompress the biliary system and allow for postoperative cholangiography. If the catheter is further advanced into the duodenum, it can aid in bile duct cannulation at the time of postoperative ERCP.<sup>70</sup> In addition to treating bile duct stones postoperatively following an incomplete laparoscopic duct clearance, the option of converting to an open duct exploration is also available to the operating surgeon.

There are several alternatives to laparoscopic or open duct exploration for bile duct stones encountered at the time of surgery. At the time of cholecystectomy, a *transcystic stent* may be placed over a wire antegrade through the sphincter of Oddi as initial treatment.<sup>82</sup> This allows for decompression of the biliary tree and can be followed postoperatively by ERCP and sphincterotomy with stent removal. Another option is the use of *intraoperative ERCP (IO-ERCP)*, allowing the same anesthetic to be used for both the cholecystectomy and the ERCP.<sup>83-85</sup> In a study by Enochsson and colleagues, 592 patients underwent IOC during laparoscopic cholecystectomy.<sup>85</sup> Thirty-four of these were subjected to IO-ERCP with a

100% CBD cannulation rate. The surgeon, while waiting for the endoscopist, introduced a thin guidewire into the IOC catheter and through the sphincter of Oddi into the duodenum. Bile duct clearance was possible in 94%, and a stent was left in place in the two patients with remaining stones. Operative time was prolonged by 1.5 hours as compared with laparoscopic cholecystectomy, but the length of hospitalization was not significantly longer for IO-ERCP patients. There were no cases of postoperative pancreatitis. In a report by Meyer and colleagues, 60 patients were treated with laparoscopic cholecystectomy and IO-ERCP for confirmed or suspected CBD stones.<sup>84</sup> The mean operative time for laparoscopic cholecystectomy was 60 minutes (range 40-90 minutes), and general anesthesia was prolonged only 40 minutes (range 30-60 minutes) for performing the IO-ERCP, including the time needed for setting up the endoscopic equipment. The papilla could not be catheterized in two patients. In one, postoperative ERCP was possible, and in the second patient, a small stone passed spontaneously. In one patient, secondary to multiple calculi in CBD, open surgery was performed immediately after IO-ERCP. Final duct clearance was achieved in 100% of patients. The argument for using IO-ERCP versus postoperative ERCP is that the former allows the identification of anatomic problems (such as duodenal diverticulum) that could make later ERCP unsuccessful. Thus the surgeon has the option to convert to open bile duct exploration at the same anesthetic.<sup>83</sup> If one chooses to use IO-ERCP, performing the cholecystectomy prior to the ERCP is important because this avoids endoscopy-induced small bowel distension from interfering with gallbladder visualization. Moreover, transcystic IOC at the time of cholecystectomy may avoid unnecessary ERCP if no stones are visualized by the cholangiogram.

## **POSTOPERATIVE**

Patients presenting with CBD stones after cholecystectomy generally are treated with ERCP<sup>73</sup> (Fig. 63-3). The noninvasive imaging techniques, such as ultrasound and MRI, are not different from those used preoperatively. If a T-tube (or other transabdominal drainage catheter) had been left in place at prior surgery, a cholangiogram can be obtained after surgery to establish the presence of bile duct stones. In situations in which ERCP is not possible or successful, other nonoperative methods can be used. For patients with T-tubes, percutaneous instrumentation under fluoroscopic guidance through the

T-tube tract can be used to remove bile duct stones. In one report, 23 of 25 patients underwent successful duct clearance through the T-tube tract for retained stones.<sup>86</sup> A choledochoscope also may be inserted through the T-tube tract to allow for either laser or electrohydraulic lithotripsy and stone extractions.<sup>57</sup> Other percutaneous transhepatic options described in the preoperative section of this chapter also may be used. Combinations and repeated techniques may be needed to achieve duct clearance. In the rare incidences where the biliary system cannot be cleared of stones nonoperatively, surgical duct exploration is considered, and the need for surgical drainage procedures must be addressed.

**FIGURE 63-3** Multiple retained stones after cholecystectomy, seen on endoscopic retrograde cholangiopancreatography (ERCP).

## SURGICAL BILIARY DRAINAGE PROCEDURES

Surgical biliary drainage procedures must be considered in situations of multiple stones, incomplete removal of all stones, impacted, irremovable distal bile duct stones, markedly dilated CBD, distal bile duct obstruction from tumor or stricture, and reoccurrence after previous bile duct exploration. The methods of surgical drainage include transduodenal sphincteroplasty, choledochoduodenostomy (CDD), and choledochojejunostomy (CDJ).

*Transduodenal sphincteroplasty* (TDS) is useful in the management of choledocholithiasis when there is stone impaction in the ampulla of Vater, papillary stenosis, and multiple stones, particularly in the presence of a nondilated bile duct.<sup>87-89</sup> The duodenum is Kocherized completely, and the ampulla is located by passing a biliary Fogarty catheter through the cystic duct into the duodenum. A longitudinal duodenotomy is made over the ampulla, and the entrance to the pancreatic duct is identified at the 4 o'clock position when possible. Intravenous secretin given at 0.2 g/kg over 1 minute sometimes is helpful in this identification. Absorbable sutures are placed on each side of the ampulla, and the sphincteroplasty is started at 11 o'clock and extended with sequential placement of sutures along the incision. After the opening is wide enough to fit a biliary dilator the size of the common duct, the last ampullary suture is placed at the apex to prevent a duodenal leak. The duodenotomy is then closed in the transverse direction to prevent duodenal stenosis, and a drain is left in place in the event that the duodenotomy leaks.

In a review by Suter and colleagues in 1994, of the 78 patients who underwent transduodenal sphincterotomy, 26 were operated on urgently.<sup>89</sup> Forty-seven (60%) were jaundiced, 15 (19%) had pancreatitis, and 12 (15%) had cholangitis before surgery. Three patients died, one from pulmonary embolism, one from pulmonary sepsis, and one from multiorgan failure syndrome complicating preoperative necrotizing pancreatitis. Of the 30 patients (38%) with complications, 20 were directly related to the surgery and included 4 cases of bleeding not requiring transfusion, 17 instances of hyperamylasemia with 1 case of clinical pancreatitis, and 1 case of duodenal fistula that healed after conservative therapy. No deaths were noted that were directly attributable to the TDS. In an older review by Meyhoff, a 10% postoperative mortality was noted after TDS, with four patients developing fatal pancreatitis.<sup>87</sup>

CDD was first performed by Riedel in 1888 in Europe.<sup>90</sup> Unfortunately,

the patient died of anastomotic disruption secondary to a missed stone in the distal CBD. The first successful operation was performed by Sprengel in 1891. CDD is indicated in patients with recurrent stones requiring repeated interventions, impacted or giant stones, biliary sludge, and ampullary stenosis. The funnel syndrome in which a distal bile duct stenosis exists in the presence of primary CBD stones is one of the most classic indications for CDD.<sup>90</sup> Most of the CBD stones in this situation are primary biliary stones forming as a result of biliary stasis. Any procedure done to remove only the stones has a temporary benefit if the stenosis is not addressed.

CDD can be performed either as an elective or an emergency operation, such as for cholangitis. The side-to-side anastomosis is the most commonly used technique, but an end-to-side is also an option. A CBD diameter of at least 1.2 cm is important in assessing the feasibility of CDD because this allows a wide enough stoma to ensure good biliary drainage and avert stenosis. The anastomosis is created in the most distal portion of the bile duct to decrease the chance of the well-described sump syndrome.<sup>90</sup> The duodenum is Kocherized widely to allow for a tension-free anastomosis and the CBD is dissected completely along its distal anterior surface. A longitudinal duodenotomy is made close to the bile duct along the long axis of the duodenum, perpendicular to the choledochotomy. For a side-to-side anastomosis a 2-cm CBD incision is made along the long axis of the bile duct as close to the duodenum as possible. After performing a CBD exploration and clearing the duct of stones, a side-to-side single-layered anastomosis is made with absorbable monofilament suture, and a drain is placed for the possibility of an anastomotic leakage.

The morbidity and mortality rates associated with CDD are 23% and 3%, respectively.<sup>90</sup> Mortality is most commonly from medical complications, such as pulmonary embolism, myocardial infarction (MI), or heart failure. Among the specific operative morbidities, cholangitis and sump syndrome are described most commonly.

The incidence of cholangitis ranges from 0% to 6% in the largest long-term follow-up series.<sup>90</sup> Initially thought to be caused by ascending reflux of duodenal contents into the biliary tree, cholangitis is now believed to be the result of stenosis of the anastomotic stoma. A wide anastomosis avoids stasis and stone retention by allowing free flow of duodenal and biliary contents. Sump syndrome is caused by food and debris accumulating between the

stoma and the papilla of Vater. This leads to contamination of the large and small bile ducts with resulting recurrent cholangitis and even secondary biliary cirrhosis.<sup>90</sup> Although the accumulation of debris in the blind segment of the bile duct may cause destruction of the stoma or cholangitis, some believe that the disease is caused by stenosis of the stoma. To avoid the problem, creating a stoma of at least 14 mm, along with placing the anastomosis near the duodenum, is important. Stomal patency is felt to be the most important factor for preventing both cholangitis and sump syndrome.<sup>90</sup> Other reported complications of CDD include wound infection, anastomotic leak, and intra-abdominal abscess. Long-term studies reveal that 70% to 80% of patients are asymptomatic 5 years after surgery.<sup>90</sup> In a review of 126 patients undergoing CDD after CBD exploration over a period of 19 years, Deutsch and colleagues reported a 4% mortality rate, with all deaths occurring in patients over 70 years old.<sup>91</sup> Morbidity included wound infections in 18 patients (14%) and bile leak through a drain for over 2 weeks in 4 patients (3%). Ninety-seven patients (94%) were symptom-free at a follow-up of 1 to 19 years.

Ramirez and colleagues reported their experience with CDD and transduodenal sphincterotomy for the treatment of choledocholithiasis over a period of 10 years.<sup>92</sup> Of the 591 patients who underwent choledochotomy for bile duct stones, 240 (40.6%) were treated with primary closure over a T-tube, 126 (21.3%) received primary closure over a T-tube along with a TDS, 216 (36.5%) had a supraduodenal CDD, and 9 (1.5%) had both a CDD and a TDS. CDD was performed when the bile duct was more than 12 mm in diameter, and TDS was used if a stone was impacted in the papilla and/or papillary stenosis was noted. Complications included six abdominal abscesses and three external biliary fistulas in the patients undergoing CDD, and four abscesses and two episodes of acute pancreatitis in the patients treated with TDS. There was no difference in mortality between the two groups, and after a mean follow-up of 5.6 years, 71.5% of the CDD group and 75.2% of the TDS group were asymptomatic. Symptoms noted in the remainder included dyspepsia, colicky pain, and episodes of cholangitis that resulted in reoperations for residual stones in nine patients, six from the CDD group and three from the TDS group. The same authors previously reported that of the patients who presented with symptoms after CDD and underwent endoscopy, no problems at the anastomosis were noted in patients who presented with dyspepsia, whereas 27% of those with biliary colic had an

anastomotic stenosis or sump syndrome, and all the patients with cholangitis had stenosis and residual stones.<sup>93</sup> On the other hand, in a comparison of 190 patients with CDD and 56 patients with TDS over a period of 10 years, Baker and colleagues found an overall mortality of approximately 5% in both groups.<sup>88</sup> The morbidity rates were 11.6% for CDD and 21.4% for TDS. With a mean follow-up of 4.5 years, six patients (3.3%) in the CDD group presented with sump syndrome, cholangitis, or both, and three patients (5.7%) in the TDS group had cholangitis. In another report by the same authors, an elevated serum ALP level was noted in 22% of CDD patients and 3% of the TDS patients, whereas radiological studies showed that the CDD stoma admitted air and barium more often than the TDS stoma.<sup>88</sup> Interestingly, neither the biochemical nor the radiological findings correlated with long-term symptomatic results after the two procedures.

An alternative to operative biliary drainage procedure to CDD is CDJ or hepaticojejunostomy, which can be performed with either a loop of jejunum or using a Roux-en-Y configuration. If a loop is used, a side-to-side (Braun) jejunojejunostomy is used to divert the flow of intestinal contents from the biliary tree. The authors prefer the Roux-en-Y reconstruction. The Roux-en-Y usually is brought retrocolic using a 40- to 60-cm afferent limb to protect against intestinal reflux and secondary cholangitis. In either case, an end-to-side CDJ is created using fine absorbable suture. The anastomosis can be decompressed using a T-tube if the remaining bile duct is long enough to allow one, or a transhepatic stent can be used if the remaining bile duct is short. As in the other methods of surgical drainage, a drain is left in place to guard against possible anastomotic leakage.

Gouma and colleagues reported their experience with 43 patients undergoing Roux-en-Y CDJ after complex clearance of the biliary tree for choledocholithiasis.<sup>94</sup> No mortalities were reported and only one major complication. Moreover, 98% of the patients had good long-term results with no signs or symptoms related to biliary obstruction or cholangitis. A comparison of CDD and CDJ for choledocholithiasis was evaluated by a French group.<sup>95</sup> One-hundred and thirty patients were included, of which 64 underwent CDD and 66 had a CDJ. No difference in morbidity or mortality was noted between the two groups. Of the 120 patients (58 CDD and 62 CDJ) available for a mean follow-up of 29 months, 107 were symptom free, 13 patients (6 CDD and 7 CDJ) experienced biliary symptoms suggestive of

cholangitis; 8 presented in the first postoperative year, and 5 presented in the second postoperative year. In the CDD group, the cholangitis was secondary to sump syndrome (three patients), anastomotic stricture (one patient), or unknown causes (two patients). Anastomotic strictures (three patients), residual intrahepatic stones (one patient), or unknown causes (three patients) were felt to be the cause of cholangitis in the CDJ group. The authors concluded that CDD is preferable given the similar outcomes because it is easier and faster to perform than CCJ and allows for easy endoscopic interventions if needed in the future. However, often the choice between the two operations is dictated by the anatomy and feasibility of creating a tension-free anastomosis.<sup>96</sup> One controversy in performing surgical biliary anastomoses is the use of biliary stents. Earlier studies have argued that stents allow for decompression of the bile duct and decreased risk of bile leak, postoperative radiographic evaluation of the biliary tree, and reduced fibrotic narrowing of the anastomosis during early healing.<sup>97</sup> Pitt and colleagues noted a higher success rate with the anastomosis stented for more than 1 month compared with those stented for less than 1 month or not stented at all.<sup>98</sup> Others also have noted good results with the use of stents.<sup>99,100</sup> However, Bismuth and colleagues showed that excellent results could be obtained in 86% of 123 patients undergoing stentless hepaticojejunostomy for benign biliary disorders.<sup>101</sup> Pellegrini and colleagues found that stenting for more than 1 month postoperatively resulted in outcomes no different from anastomoses done without stents.<sup>102</sup> The argument has been raised that stents cause an inflammatory reaction that may predispose to stenosis. DiFronzo and colleagues found that of the 97 patients having either a CDD (77%), CDJ (8%), hepaticoduodenostomy (1%), or hepaticojejunostomy (13%) without the use of stents, only one patient developed an anastomotic leak that resolved spontaneously within 1 week.<sup>97</sup> In the mean follow-up period of 13 months, no postoperative strictures were noted. Meanwhile, Tocchi and colleagues presented their data on performing hepaticojejunostomy (48 patients), CDJ (34 patients), and intrahepatic cholangiojejunostomy (8 patients) without stents in 84 patients over a period of 15 years for benign biliary strictures.<sup>96</sup> Excellent or good results were obtained in 83% of the patients. Anastomotic strictures occurred in 10 patients, 6 within 5 years and 4 at 62, 75, 85, and 96 months. By multivariate analysis, only postoperative complications and the degree of CBD dilatation proved to be significant

independent predictors of outcome. A bile duct dilatation of less than 15 mm was noted in 60% of patients with poor outcome. Although not reaching statistical significance, higher complications and restructures were noted in patients having a CDJ versus hepaticojejunostomy, and the authors changed their practice to performing only higher anastomosis during the study period for even low strictures. Peptic ulcers were noted in only 2.3% of the patients in the entire series, which is not higher than the normal population and does not appear to be related to diverting the flow of bile from the duodenum, as others have suggested.

Laparoscopic biliary drainage procedures have recently been reported for both benign and malignant biliary disease. A systemic review by Toumi et al. in 2011 reported on 89 patients from 19 separate reports in the literature. Many of these patients underwent laparoscopic biliary bypass combined with gastric bypass. The overall success rate was 98.9% with a morbidity rate of 12.3% and a mortality rate of 5.6%. Median follow-up was only 13 months. Longer-term data are needed as well as comparative studies with open surgical techniques.<sup>103</sup>

Despite the proliferation of robotic-assisted surgery, its application to biliary surgery has remained rather limited. The literature thus far includes only two separate case reports and one small case series.<sup>104</sup> One report describes robotic-assisted CBD exploration.<sup>105</sup> The other report describes a robotic CDJ with an intracorporeal Roux limb construction.<sup>106</sup>

Minimally invasive surgical drainage procedures are likely to become more widely used as experience increases and technology improves.

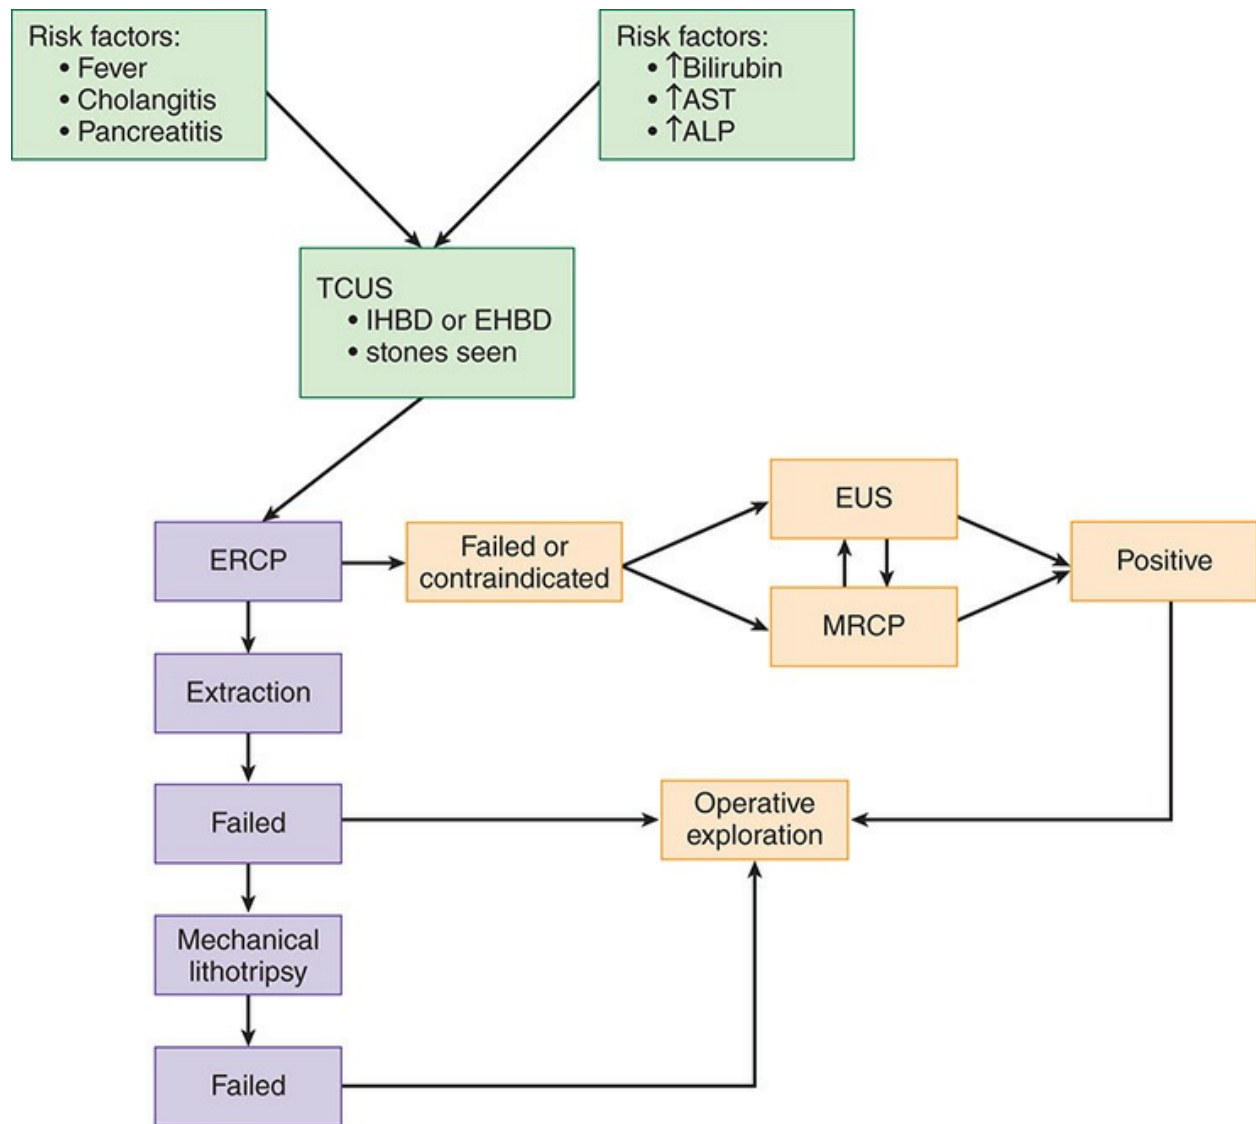

## **SUMMARY**

The evaluation and treatment of choledocholithiasis has evolved over the last 100 years. As newer and less invasive techniques emerge, the surgeons will find a variety of options and many paths that can lead to the successful treatment of a patient with CBD stones. Evaluation and diagnosis may involve an examination and simple laboratory tests or evaluation of the biliary tree with MRCP, ERCP, or an IOC. Treatment may be endoscopic, percutaneous, open, laparoscopic, or a combination of techniques. Given the multiple alternatives available, sometimes it is difficult to decide on the right one for a particular patient. Frequently, the best path is the one the surgeon is most adept at or the one that local expertise can accomplish most safely.

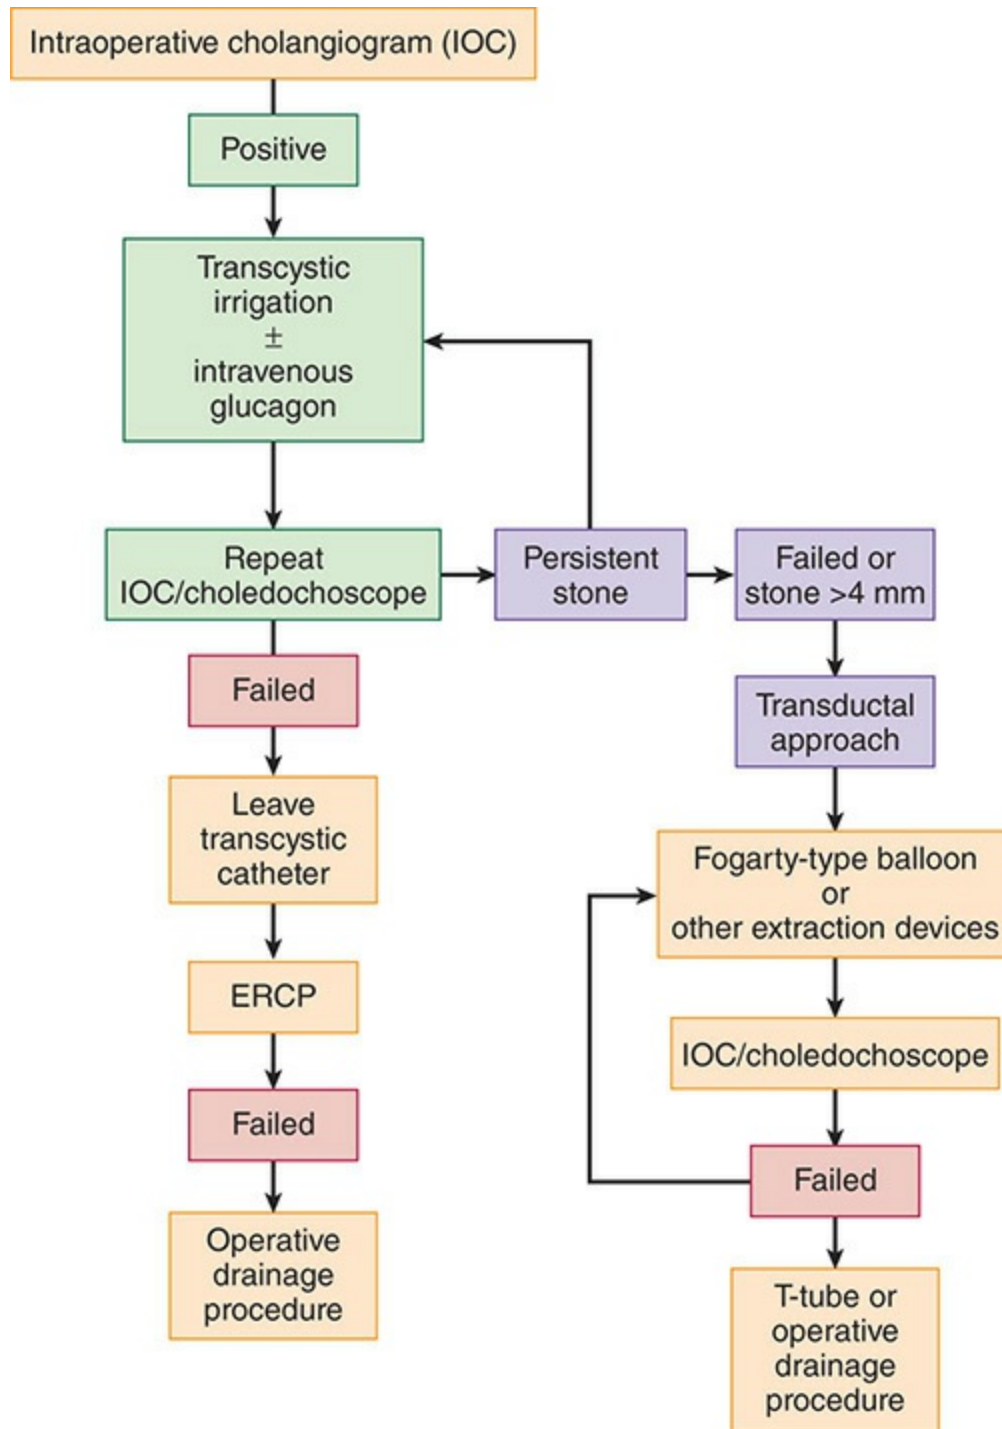

Sometimes, however, the safest approach is a transfer to a center where multiple treatment options are available so that the treatment can be tailored to fit each individual situation.

Figures 63-4 and 63-5 show the treatments followed at our institution for preoperative and intraoperative suspected choledocholithiasis (at cholecystectomy).

**FIGURE 63-4** Algorithm for treatment of preoperative suspected choledocholithiasis.

**FIGURE 63-5** Algorithm for treatment of intraoperative suspected choledocholithiasis (at cholecystectomy).

## CHOLANGITIS

Cholangitis is the most rapidly fatal complication of gallstones and occurs as a result of biliary tract bacterial infection in the setting of biliary tree obstruction. Mortality approaches 100% in patients who fail conservative therapy and do not undergo the needed drainage interventions.<sup>11</sup> Early diagnosis and treatment are imperative for a successful outcome.

## Pathophysiology

Although bile is normally sterile, when the biliary tree is obstructed or instrumented, such as by a stone, stricture, or endoprosthesis, bacteria are frequently cultured from the bile.<sup>107</sup> Along with the sphincter of Oddi and the bacteriostatic properties of bile, bile flow is an important component of maintaining sterility. Bile duct obstruction results in decreased antibacterial defenses, allowing bacteria to gain access to the biliary tree. Although the route of infection is unclear, ascent from the duodenum or hematogenous seeding are felt to be the possible sources.<sup>11</sup> Once colonization has occurred, stasis allows for exponential bacterial growth. As the biliary pressure rises with obstruction, bacteria and their endotoxins leak into the systemic circulation and cause the septicemia of cholangitis.<sup>107</sup>

Patients with partial obstruction have a higher chance of developing cholangitis than those with complete obstruction, and bile duct stones are associated more often with cholangitis than neoplasms causing obstruction. In the United States, secondary choledocholithiasis is the most common cause of cholangitis. Primary bile duct stones are common in areas where recurrent pyogenic cholangiohepatitis (previously known as oriental cholangiohepatitis) is endemic, including Hong Kong and Southeast Asia.<sup>11</sup> Other causes of cholangitis include obstructing periampullary tumors, tumors metastatic to the porta hepatis or peripancreatic lymph nodes, benign strictures, and primary sclerosing cholangitis. Biliary tract interventions may lead to post-procedural cholangitis, and rare cases of cholangitis may be caused by hemobilia, parasites, and congenital abnormalities of the biliary tree.

*Escherichia coli* (25%-50%), *Klebsiella* spp. (15%-20%), and *Enterobacteriaceae* (5%-10%) are the most common organisms cultured in cholangitis. Anaerobes may be present in 5% to 10% of patients.<sup>108</sup> *Pseudomonas* spp. and skin and oral flora are associated with biliary tract

interventions, whereas anaerobes are noted most commonly in the elderly after biliary surgery.<sup>11</sup>

## Clinical Presentation and Diagnosis

Charcot's triad of fever, right upper quadrant pain, and jaundice are present in 50% to 70% of patients with cholangitis at presentation, with fever, abdominal pain, and jaundice occurring in 90%, 70%, and 60% of patients, respectively. Hypotension (20%) and altered mental status (30%) are seen in septic patients and are known as *Reynolds's pentad* when presenting in the setting of Charcot's triad. Although peritonitis is uncommon, 65% of patients have right upper quadrant tenderness.<sup>11</sup> Laboratory and radiological studies are important for distinguishing cholangitis from other conditions such as acute cholecystitis, liver abscesses, and pancreatitis. Elevations of serum ALP, GGT, and bilirubin are typical. Mild increases in transaminases may be seen, whereas hyperamylasemia is found in up to 30% of patients. A discussion of imaging studies for the evaluation of choledocholithiasis has been presented in the section on CBD stones. In a patient presenting with signs of cholangitis, the most widely used imaging modalities are ultrasound and CT scan. Ultrasound is highly accurate in diagnosing acute cholecystitis and identifying gallstones. However, its ability to establish the diagnosis of choledocholithiasis is only 50%, varying from 30% to 90%.<sup>7,12</sup> Although the presence of bile duct stones can be inferred by associated bile duct dilatation, a normal ultrasound without duct dilatation does not exclude choledocholithiasis or cholangitis.<sup>11,17</sup> CT scan is better at determining the level of biliary tract obstruction and has a 94% accuracy in diagnosing choledocholithiasis in the setting of suspected bile duct calculi.<sup>21</sup> MRCP has sensitivities and specificities approaching ERCP in the diagnosis of bile duct stones and is useful in delineating biliary anatomy. However, its use in the setting of acute cholangitis is limited. ERCP is highly accurate in revealing the cause of biliary obstruction and at the same time allows for therapeutic intervention to occur at the same session.<sup>11</sup> Nonetheless, given the well-defined life-threatening complications associated with ERCP and the availability of other noninvasive imaging techniques, ERCP should not be used solely as a diagnostic tool in the setting of acute cholangitis.<sup>11</sup>

## TREATMENT

Patients with cholangitis can become extremely ill in a short period of time, and rapid initiation of treatment can be lifesaving. Supportive measures are begun without delay and include fluid resuscitation, correction of electrolyte deficits and coagulopathy, and administration of analgesics.<sup>109</sup> Empirical broad-spectrum antibiotics covering the common pathogens are started while blood cultures, and when available, bile cultures are sent. Aminoglycosides and ampicillin are associated with gram-negative resistance and nephrotoxicity and are no longer felt to be the ideal regimen. Newer effective therapies include combinations of extended-spectrum cephalosporins, extended-spectrum penicillins, metronidazole, and ampicillin; fluoroquinolones as single-agent or in combination with metronidazole; and ureidopenicillins alone or with metronidazole.<sup>11</sup> Anaerobic coverage is felt to be more important in the elderly and those with biliary manipulations. Antibiotics usually are given for 7 to 10 days, even if biliary decompression has been accomplished during the interim. A retrospective study by van Lent and colleagues evaluated whether continuation of antibiotics is needed after biliary drainage is achieved and signs of inflammation have subsided.<sup>107</sup> Eighty patients who were treated successfully for cholangitis with ERCP were included in the study and followed for 6 months. Forty-one patients received antibiotics for 3 days or less, 19 patients for 4 to 5 days, and 20 patients for more than 5 days. The three groups were well matched, and the rate of recurrent cholangitis (24%) was not different for the three groups. The authors felt that a 3-day duration of antibiotic therapy may be sufficient in treating cholangitis when adequate drainage has been achieved and fever is abating.

Drainage of the biliary tree is the mainstay of therapy for patients with acute cholangitis.<sup>107</sup> However, the timing and route of biliary decompression vary depending on the response of antibiotics, the cause of the obstruction, and the presence of morbidities.<sup>109</sup> Biliary sepsis will resolve in most patients with conservative therapy, allowing time for a detailed delineation of the biliary anatomy by noninvasive imaging (CT scan or MRI) to determine the cause and level of obstruction. However, urgent decompression is needed in the 10% to 15% of patients who fail to respond within 24 hours to supportive measures and antibiotic therapy.<sup>107</sup> When biliary decompression is not achieved, liver abscesses are inevitable.<sup>107</sup> Mortality approaches 100% in

patients who are not subjected to drainage interventions after failing conservative therapy.<sup>11</sup>

The methods of relieving biliary tract obstruction include endoscopic, percutaneous transhepatic, and surgical drainage techniques. In a landmark article in 1992, ERCP was demonstrated in a randomized trial to be effective in controlling sepsis, and had a significantly lower mortality than surgical decompression (10% mortality vs 32%).<sup>110</sup> More recent studies have confirmed this finding and further defined the benefits of ERCP over surgical decompression in the setting of cholangitis. In a study of 83 patients with acute cholangitis randomized to undergo either endoscopic or surgical decompression, the mortality was 10% in the endoscopic arm versus 30% in the surgical group.<sup>11</sup> Meanwhile, in an evaluation of 65 patients undergoing endoscopic drainage versus 40 patients receiving traditional surgery for acute cholangitis, 5 operated patients and no individuals subjected to endoscopy died.<sup>111</sup> In comparison with percutaneous drainage, ERCP also has been shown to have lower morbidity, shorter hospitalization, and higher definitive success rates.<sup>11</sup> Sugiyama and colleagues found that in elderly patients (age 80 or older) with acute cholangitis, endoscopic drainage had lower morbidity (16.7%) and mortality (5.6%) than surgical (87.5% and 25%, respectively) or percutaneous drainage (36.4 and 9.1%, respectively).<sup>112</sup> With a success rate of 90% to 98% and low morbidity and mortality, ERCP with bile duct clearance is superior to the other methods and is the modality of choice for decompressing the biliary tree during acute cholangitis, particularly if caused by choledocholithiasis.<sup>11,109</sup>

Various endoscopic treatment options are available from the placement of nasobiliary catheters or biliary stents to sphincterotomy and stone extraction. In patients who have responded to antibiotic therapy, sphincterotomy with bile duct clearance is preferred, whereas drainage catheters are used in those with ongoing sepsis and multiple large stones.<sup>109</sup> In critically ill patients or in those with coagulopathy, concerns about bleeding and increased procedure times are associated with endoscopic sphincterotomy.

In comparing nasobiliary catheters with biliary stents for the treatment of acute cholangitis, a randomized study found both to be equally effective, but stents were more comfortable and avoided the risk of accidental removal.<sup>11</sup>

Percutaneous transhepatic drainage is reserved for patients in whom the papilla is inaccessible or ERCP has failed and for those suspected of hilar

cholangiocarcinoma, hepatolithiasis, and intrasegmental cholangitis.<sup>11,109</sup> Although successful in 90% of patients with biliary obstruction, percutaneous drainage has higher rates of morbidity (30%-80%) and mortality (5%-15%) than endoscopic techniques. As with ERCP, coagulopathy must be corrected prior to the procedure.

Used for almost 100 years, open surgery for acute cholangitis is associated with mortality rates of up to 40%.<sup>11</sup> Surgery may be limited to choledochotomy, decompression, and T-tube insertion when performed for emergency situations. In patients who have undergone other methods of biliary drainage for the acute situations, surgery offers definitive treatment of the underlying disease and is associated with low mortality when performed electively after the initial treatment.

The need for cholecystectomy after CBD clearance in patients with cholelithiasis has been discussed in the section on choledocholithiasis. To prevent further biliary complications, some have advocated cholecystectomy for patients who are fit after the initial treatment of acute cholangitis. In nonrandomized and retrospective studies, the risk of developing subsequent biliary problems ranges from 4% to 12% in patients with CBD stones.<sup>11</sup> In a study by Boerma and colleagues, 47% of patients who were randomized to a wait-and-see approach after common duct clearance developed biliary symptoms compared with only 2% of patients who were allocated to cholecystectomy within 6 weeks of the endoscopic procedure.<sup>113</sup> Of the wait-and-see patients, 37% eventually needed cholecystectomy. Targarona and colleagues randomized 98 elderly (mean age 80) patients with biliary symptoms to either open cholecystectomy with operative cholangiography and (if necessary) bile duct exploration (48 patients) or to endoscopic sphincterotomy alone (50 patients).<sup>114</sup> There were no significant differences in immediate morbidity (23% and 16%) or mortality (4% and 6%) in the surgery versus endoscopic group. However, at a mean follow-up of 17 months, biliary symptoms recurred in three surgical patients, none of whom underwent repeat surgery, and in ten endoscopic patients, seven of whom had further biliary surgery. In conclusion, these studies suggest that patients with acute cholangitis should undergo elective cholecystectomy after bile duct clearance if they are able to tolerate an operation. Conversely, in Asian patients in whom bile duct stones may originate from intrahepatic stones, cholecystectomy may not prevent future biliary complications.<sup>11</sup>

## HEPATOLITHIASIS

Hepatolithiasis is a primary disease of the biliary ducts and is more refractory to surgical treatment than most other benign diseases of the biliary system.<sup>115,116</sup> The disease is defined as stones in ducts proximal to the confluence of the hepatic ducts regardless of the presence of stones within the gallbladder or CBD. The relative incidence in Western countries is approximately 1%, whereas in Taiwan, South Korea, and China it has been reported to be 20%, 18%, and 40%, respectively.<sup>117</sup> Originally felt to be common only in Southeast Asia and referred to as *oriental cholangiohepatitis* and *Hong Kong disease*, the widespread immigration of Asians to the United States has resulted in an increasing number of patients with hepatolithiasis presenting to American surgeons.<sup>115,118</sup> Moreover, the North American experience includes a significant number of Caucasians and Latin Americans. This increasing incidence may be attributed to different etiologies such as primary sclerosing cholangitis, choledochal cysts, and iatrogenic biliary strictures.

The pathogenesis of primary hepatic stones was discussed earlier in the section on choledocholithiasis and appears to involve bile infection, biliary stasis, low-protein, low-fat diets and malnutrition, and parasitic infections.<sup>1</sup> Brown pigment stones (calcium bilirubinate) are the most common stones and cholesterol stones are the second most common. Hepatolithiasis presents with recurrent pyogenic cholangitis and sepsis, complicated by parenchymal infection and liver abscesses, obstructive cholangiopathy, and subsequent parenchymal destruction and atrophy of involved lobe.<sup>116,118,119</sup> The natural course of the disease may lead to the development of biliary cirrhosis, portal hypertension, and liver failure and is complicated by cholangiocarcinoma in about 10% of patients.<sup>115,116,120</sup>

The diagnostic procedures used in establishing the diagnosis of hepatolithiasis include ultrasonography, CT scan, MRI, and direct (either endoscopic or percutaneous) cholangiography.<sup>21,116,121,122</sup> Characterizing features include varying combinations of ductal dilatation, intrahepatic and extrahepatic bile duct stones, segmental ductal strictures, and lobar or segmental atrophy. In acute exacerbation, parenchymal or ductal contrast enhancement, abscess formation, or biliary obstruction may be noted.<sup>116</sup>

The current management of hepatolithiasis is difficult and far from

satisfactory. The principles of treatment are centered on the decompression of abscesses, removal of stones, dealing with recurrences, and anticipating the development of malignancy. More than two-thirds of patients undergo multiple surgical procedures, and 10% ultimately require liver transplantation for liver failure.<sup>115</sup> Initial biliary decompression usually can be achieved by endoscopic or percutaneous transhepatic drainage.<sup>119</sup> The goal of definitive treatment is complete removal of all bile duct stones and elimination of bile stasis at the sites of intra- or extrahepatic strictures.

If the stones and strictures are located in a single segment or lobe of the liver, hepatic resection generally is recommended.<sup>115,119,123-126</sup> Interestingly, there appears to be a predisposition for the left lobe of the liver. Resection is particularly important for patients with parenchymal atrophy and stricture of the intrahepatic ducts who may have concomitant cholangiocarcinoma.<sup>115</sup> Even with resection, a significant number of patients will have recurrent disease. Kim and colleagues evaluated their experience with hepatectomy in 44 patients with hepatolithiasis by dividing them into two groups, those with intrahepatic biliary stricture and those without it.<sup>127</sup> At a median follow-up of 65 months, the incidence of residual or recurrent stones was 36% for those with stricture and 11% for those without. The incidence of late cholangitis was higher in the stricture group (54%) versus the no-stricture group (6%), as was the initial failure rate (50% vs 31%, respectively). Intrahepatic stricture recurred in 46% of the stricture group versus none in the no-stricture group, with stricture reoccurrence seen at the primary site in two-thirds. Therefore, the importance of including the strictured duct in the hepatic resection is emphasized by this study.

Nevertheless, the number of patients in whom resection is feasible is limited secondary to the diffuse and multifocal nature of the disease.<sup>123</sup> If stones are located predominantly in the extrahepatic ducts or at the primary convergence and there is minimal stenosis of the intrahepatic ducts, it may be possible to use endoscopic treatment. When stones or strictures are located at the secondary convergence or beyond, surgery and percutaneous transhepatic cholangioscopic lithotripsy have a complete stone clearance rate of 84% to 100% and 72% to 92%, respectively.<sup>115</sup> However, the stone recurrence rate is high, ranging from 33% to 40%. Hepaticojejunostomy has been used in the past to prevent biliary-enteric regurgitation and to decrease stagnation of debris and calculi in the intrahepatic ducts. The use of hepaticojejunostomy is

controversial and is refuted by some authors, who claim that increased biliary complications occur in patients with hepaticojejunostomies in the setting of hepatolithiasis.<sup>115</sup> However, adding a cutaneous stoma to the Roux limb of the hepaticojejunostomy creates an access point for entering the biliary system for treating future complications.<sup>128</sup> A more appealing alternative to a stoma is the creation of a Hutson loop. This entails tacking the jejunal loop of the biliary-enteric anastomosis to the abdominal wall and clearly marking it with staples or a metal ring such that it can be easily accessed by percutaneous means. We believe that this option should be considered in every patient who undergoes surgery.

With the advent of biliary endoscopy and radiological intervention, percutaneous choledochoscopic removal of intrahepatic stones has been well established.<sup>129</sup> Stones can be removed via cholangioscopic guidance with basket forceps or lithotripsy, and strictures can be dilated. In a study from Hong Kong, 79 patients with intrahepatic stones underwent percutaneous transhepatic choledochoscopy.<sup>129</sup> The success rate was 76.8%, with a complication rate of 21.5%. Cholangitis occurred within 3 to 5 years in one-third of the patients after the procedure. Another study found that recurrent calculi are more common in the setting of bile duct strictures, and addressing the strictures is mandatory part of treatment.<sup>130</sup> Meanwhile, one study of percutaneous transhepatic cholangioscopic lithotripsy reported a biliary clearance rate of 100%, with a mean of two sessions required and a complication rate of 6.7%.<sup>123</sup> During the follow-up period of 1 to 127 months (mean 75 months), one recurrence was noted and treated by repeat choledochoscopy. Some authors have used percutaneous intracorporeal electrohydraulic lithotripsy for hepatolithiasis. Using this technique, in a series of 53 patients, complete clearance of stones was achieved in 92%, and during a mean follow-up of 5 years, 9% had recurrent symptoms of biliary obstruction.<sup>131</sup> Han and colleagues described the use of laparoscopy in the treatment of intrahepatic stones.<sup>120</sup> A flexible choledochoscope, inserted through a choledochotomy, was used for stone removal in 12 patients, with a mean operating time of 288 minutes. Remnant stones were found in only one patient and removed by percutaneous choledochoscopy performed through the T-tube site. No cholangitis or recurrent stones were found at follow-up at 10 to 45 months.

The most recently documented North American experience describes

treating 42 patients between 1986 and 2005 at the University of Toronto.<sup>124</sup> They operated on 17 patients (46%) for indications of lobar atrophy or stones confined to a single lobe. Patients who underwent an operation were found to have less need for reintervention. The incidence of cholangiocarcinoma was 12%, including patients who were diagnosed at initial presentation.

Although the evolution of this disease is unclear, it will likely continue to challenge us. With lessons learned from more common biliary pathologies and the application of novel technologies, we would anticipate better outcomes for our future patients.

# CHOLEDOCHAL CYST AND BENIGN BILIARY STRICTURES

*Purvi Y. Parikh • Keith D. Lillemoe*

Benign conditions of the intrahepatic or extrahepatic bile ducts can range from focal or diffuse dilatations (choledochal cyst) to obstructive strictures of the biliary tree. Historically, choledochal cyst disease was considered a disease of childhood but is increasingly being recognized in adults. In the United States, benign biliary strictures most commonly occur as a result of injury after cholecystectomy but also occur in a number of diverse inflammatory conditions affecting the biliary tree. Both conditions represent significant clinical challenges where proper evaluation and management are paramount to prevent serious clinical sequelae.

## CHOLEDOCHAL CYST

Choledochal cysts are focal or diffuse dilatations of the biliary tree, and aside from biliary atresia, they are the most common congenital abnormality of the biliary tree. Choledochal cysts can occur as single or multiple cysts throughout the extrahepatic or intrahepatic bile ducts. The cysts can

predispose patients to recurrent cholangitis or pancreatitis, choledocholithiasis, secondary biliary cirrhosis, biliary stricture, and malignancy.

The incidence of choledochal cysts varies significantly throughout the world. Choledochal cysts appear to be most common in Asian countries with an estimated incidence of 1 in 13,500; the incidence has been reported to be as high as 1 in 1000 in studies from Japan. In Western countries, choledochal cysts occur much less frequently, with reported rates that vary from 1 in 150,000 to 1 in 2 million live births.<sup>1</sup> Biliary cysts are 4 times more common in women compared with men. Approximately 80% of choledochal cysts are diagnosed in children, and 20% of cases present in adults.<sup>2</sup> There are a few case reports of choledochal cysts occurring within families, but generally, they do not have a recognized hereditary pattern.

## Classification

The anatomy of choledochal cyst disease was first described by Vater in 1723, and in 1959, Alonso-Lej categorized 3 types of choledochal cysts.<sup>3</sup> The classification system was revised by Todani and colleagues in 1977 to the 5 cyst categories<sup>4</sup> that are in use today (Table 64-1). A similar classification has been proposed based on bile duct cholangiographic appearance.<sup>5,6</sup>

**TABLE 64-1: ALONSO-LEJ/TODANI MODIFICATION OF THE CLASSIFICATION OF CHOLEDOCHAL CYSTS**

Type I	Classic cyst type characterized by cystic dilatation of the common bile duct; most common, comprising 50%-80% of all biliary cysts; subdivided into IA (cystic), IB (fusiform), and IC (saccular)
Mixed type I and II	Fusiform dilation of the extrahepatic biliary tree in combination with a separate diverticulum, midportion of the common bile duct, with cystic duct entering in the right of the diverticulum, comprising 1%
Type II	Simple diverticulum of the extrahepatic biliary tree, comprising 2%-3% of all cysts; located proximal to the duodenum
Type III	Cystic dilatation of the intraduodenal portion of the extrahepatic common bile duct; also known as a choledochoceles; comprising approximately <10%
Type IV	Involve multiple cysts of the intrahepatic and extrahepatic biliary tree; subdivided into type IVA (both intrahepatic and extrahepatic cysts) and IVB (multiple extrahepatic cysts without intrahepatic involvement); type IVA is the second most common type of biliary cyst, comprising 30%-40%; type IVB comprises <5%
Type V	Isolated intrahepatic biliary cystic disease, also known as Caroli disease; associated with periportal fibrosis or cirrhosis; can be multilobar or confined to a single lobe, comprising <10%

---

Traditionally, the classic and most common choledochal cyst is type I disease: (A) cystic (Fig. 64-1A), (B) saccular, or (C) fusiform dilatation of the extrahepatic biliary tree. Type II cysts are simple diverticula of the common bile duct, which are usually extrahepatic, supraduodenal, and saccular (Fig. 64-1B). A rare combination of type I cystic dilatation and type II diverticulum was reported in a few cases representing a mixed type. A type III cyst, also known as *choledochocoele*, is a focal cystic dilatation of the most

distal segment of the bile duct (Fig. 64-1C). Manning and colleagues<sup>7</sup> described 2 anatomic variations of intraduodenal choledochoceles. The most frequent variety is with the common bile duct and main pancreatic duct entering into the choledochoceles separately. The second variety of intraduodenal choledochoceles is essentially a diverticulum off the common bile duct at the level of the ampulla of Vater, with the pancreatic duct entering the end of the common bile duct in the usual location. Multiple dilations of the intrahepatic and extrahepatic biliary tree are known as type IV cysts divided into type IVa and type IVb. Type IVa represents fusiform extrahepatic and intrahepatic cysts (Fig. 64-1D). Type IVb consists of multiple extrahepatic cysts (Fig. 64-1E). Type V cyst, Caroli disease, is confined to the entire liver or a solitary lobe, usually on the left (Fig. 64-1F).<sup>2,3</sup> This disease may be associated with periportal fibrosis and cirrhosis, leading to subsequent hepatosplenomegaly and portal hypertension.

**FIGURE 64-1** Illustrations of the Todani classification of choledochal cysts.

**A. Type IA. B. Type II. C. Type III. D. Type IVA. E. Type IVB. F. Type V.**

While Todani's 1977 schema is the most widely accepted classification, it is not without controversy. Some have argued that the term "choledochal cyst" should refer to only type I and IV cysts (which compose over 90% of biliary cysts).<sup>8</sup> This proposal is based on current understanding of pathogenesis, treatment, malignancy risk, and natural history, which vary substantially with type I and IV cysts versus type II, III, or V cysts. A review from Indiana University questioned whether choledochoceles were truly choledochal cysts. They reviewed 146 patients with choledochal cysts and identified 28 patients with choledochoceles. They concluded that classifications of choledochal cysts should not include choledochoceles because they differ from choledochal cysts with respect to age, sex, presentation, pancreatic ductal anatomy, and management.<sup>9</sup>

## **Pathogenesis**

The cause of choledochal cysts is unknown. While there have been reports of acquired cysts in the literature, most are congenital in nature. There may be multiple mechanisms involved in the creation of biliary cysts, and several theories have been proposed.

The high incidence of biliary cysts in Asia suggests a role for either genetic or environmental factors. The first theory pertains primarily to the pathogenesis of Caroli disease and is related to a defect in maturation with ductal plate malformation. This defect can be either sporadic or inherited, with both autosomal recessive and, rarely, autosomal dominant inheritance patterns seen in families. Ductal plates describe the development of intrahepatic liver progenitor cells that are in contact with the mesenchyme of the portal vein and are then remodeled into mature ducts. Defective bile duct plate remodeling during embryogenesis results in inflammation and ulceration of biliary epithelium into larger bile ducts. These ducts then become segmentally dilated in a focal, lobar, or multilobar distribution.<sup>10</sup>

The second theory for the etiology of choledochal cyst formation is that bile duct obstruction or distention in the prenatal or neonatal periods may contribute to biliary cyst formation. The obstruction may be secondary to a stricture, web, or sphincter of Oddi dysfunction. With distal biliary

obstruction, there is pancreatic juice reflux into the biliary tree resulting in chronic inflammation and increased bile duct pressure, leading to dilatation.<sup>11</sup> In animal models, bile duct ligation in neonates leads to cyst formation; in contrast, bile duct ligation in adult animals results in gallbladder distention.<sup>12</sup> In addition, there are case reports of a congenital web at the lower end of the common bile duct and antenatal choledochal cyst with distal common bile duct formation.<sup>13</sup>

The most common proposed theory for choledochal cyst formation is related to pancreaticobiliary maljunction.<sup>14</sup> Pancreaticobiliary maljunction is defined as an extramural junction of the pancreatic and biliary ducts in the duodenum beyond the intramural sphincter function and is characterized by a long common channel. On average, patients with this anomaly have a common channel that is 1.86 cm, compared with 0.46 cm in patients with a normal junction.<sup>15</sup> In the literature, pancreaticobiliary maljunction has been reported in 90% of patients with choledochal cyst disease (Fig. 64-2).<sup>16</sup> Pancreaticobiliary maljunction is also thought to be a significant risk factor for the development of cholangiocarcinoma in the biliary cyst,<sup>17</sup> as well as the development of gallbladder cancer. Several investigators have speculated on the embryologic etiology of pancreaticobiliary maljunction, hypothesizing that the development of pancreaticobiliary maljunction is a result of an arrest in the migration of the choledochopancreatic junction into the duodenal wall.<sup>18</sup>

**FIGURE 64-2** Pancreaticobiliary maljunction.

Because of the long common channel, patients with pancreaticobiliary maljunction may have increased reflux of pancreatic juice into the biliary tree, since the ductal junction lies outside the sphincter of Oddi and cannot prevent the mixing of bile and pancreatic juices.<sup>19</sup> The mixed juices then have the potential of stagnating in the ducts or gallbladder, resulting in a cycle of inflammation, activation of proteolytic enzymes, theoretical biliary epithelial damage, alterations in bile composition, and ductal distention. It is thought that a combination of these factors contributes to the development of malignancy within the choledochal cyst or gallbladder. Elevated sphincter of Oddi pressures have also been documented in patients with pancreaticobiliary maljunction, resulting in more reflux.<sup>20,21</sup>

On pathology, choledochal cysts have variable microscopic features, with appearance ranging from normal bile duct mucosa to carcinoma. In children, the classic histologic appearance is a thick and dense fibrotic cyst wall with evidence of acute or chronic inflammation. In adults, common findings are inflammation, erosions, sparseness of mucin glands, and metaplasia.<sup>1,22</sup> Type III cysts are most often lined by duodenal mucosa, although they sometimes are lined by bile duct epithelium.<sup>22</sup> When malignancy is present, it is most commonly found along the posterior cyst wall.

## Presentation

Choledochal cyst disease can present with a vast spectrum of symptoms. The classic triad of presentation of a choledochal cyst is a female child with jaundice, abdominal pain, and right upper quadrant abdominal mass. This triad is found in only a minority of children at the time of presentation. Infants commonly present with elevated conjugated bilirubin (80%), failure to thrive, or an abdominal mass (30%). An abdominal mass becomes less common with increasing age and is rarely appreciated in adults. In adults, abdominal pain and recurrent cholangitis are the most common presentations.<sup>23</sup> The abdominal pain usually mimics that of calculous cholecystitis, and many patients do have gallstones either in the cyst or in the gallbladder. Almost 38% of adult patients have had a cholecystectomy before the diagnosis of a choledochal cyst because of right upper quadrant pain, which was attributed to gallbladder disease.<sup>24</sup> Intermittent jaundice and recurrent cholangitis are also common, as is pancreatitis (30%), especially in patients with a type III cyst (choledochocele).<sup>1,9,25</sup> Rarely, choledochal cysts will present as intraperitoneal rupture or bleeding due to erosion into adjacent vessels.

## Diagnosis

The diagnosis of a choledochal cyst requires a high level of suspicion. Unless choledochal cyst is considered in the differential diagnosis in patients with ductal dilation, type I cysts may go undiagnosed. Patients with biliary obstruction, either acutely or chronically, may also have biliary dilatation that can mimic a type I cyst. In contrast to a type I cyst, an obstructing lesion will

often cause elevated alkaline phosphatase and bilirubin, as well as improvement in biliary dilation after appropriate treatment. The presence of pancreaticobiliary maljunction in uncertain cases can also be helpful in making the diagnosis of a type I cyst versus a biliary obstruction.

Ultrasonography is the most common first-line imaging tool and was used in 93% of the pediatric population and 72% of the adult patients in the Johns Hopkins series.<sup>24</sup> While ultrasound is the standard for antenatal and childhood diagnosis, computed tomography (CT) scan may be more appropriate in adult patients, in whom the differential diagnosis is broader. Important considerations on CT scan (Fig. 64-3) include assessing the hepatobiliary and pancreatic anatomy, with evaluation for possible biliary malignancy, metastatic disease, and vascular encasement.

A

B

**FIGURE 64-3** **A.** CT scan appearance of type IA choledochal cyst (*arrow* shows sludge within the cyst). **B.** CT scan appearance through the liver demonstrates multiple low-density structures (*arrows*) within the right and left lobe consistent with a type IVA choledochal cyst.

Ultimately, when choledochal cyst disease is suspected on imaging, visualization of the pancreatic, intrahepatic, and extrahepatic ductal anatomy is required. Magnetic resonance cholangiopancreatography (MRCP) has become the noninvasive procedure of choice for the diagnosis of choledochal cyst. As quality of MRCP has improved, many surgeons now consider MRCP the only imaging technique needed for diagnosis and operative planning. Park and colleagues<sup>26</sup> retrospectively reviewed 72 adult patients who underwent both MRCP and endoscopic retrograde cholangiopancreatography (ERCP) and found that when compared with ERCP, MRCP was accurate 100% of the time with type IVB and V cysts.

Cholangiography had previously been considered the gold standard for diagnosis of choledochal cysts but now only is necessary as primarily a therapeutic procedure to place stents to relieve jaundice or cholangitis or to obtain brushings for cytology. Cholangiography can demonstrate areas of cystic dilatation and the presence of stones and exclude complete obstruction of the bile duct (Fig. 64-4). It is also effective in demonstrating the presence of pancreaticobiliary maljunction. Percutaneous transhepatic cholangiography (PTC) or ERCP is typically performed on adults and larger children. In small children, ERCP is not the ideal tool because it involves the use of general anesthesia; can lead to pancreatitis; and may not define the very proximal biliary anatomy, which tends to be abnormal. Therefore, in children, intraoperative cholangiography may be used. In patients with type I or type IV cysts that extend to the hepatic bifurcation, PTC allows for the placement of 1 or 2 transhepatic biliary catheters, which may be helpful to facilitate complete resection and biliary reconstruction (Fig. 64-5). To decrease the high risk of pancreatitis in patients with pancreaticobiliary maljunction and a long channel, it is important to avoid placing the stent through the ampulla while performing PTC.

**FIGURE 64-4** Percutaneous cholangiogram via the right hepatic duct. A large type I choledochal cyst is seen. Note the anomalous choledochopancreatic duct junction.

**FIGURE 64-5** Type IVA choledochal cyst. Bilateral percutaneous biliary drainage catheters (*arrows*) were placed in this patient, who had extensive intrahepatic biliary duct dilatation (*arrowheads*) and a huge extrahepatic choledochal cyst (*curved arrow*). Note that the biliary catheters exit the cyst and enter the duodenum (*open arrows*).

## Management

Once the diagnosis of choledochal cyst is made and the patient's biliary anatomy is delineated through preoperative imaging, several important clinical considerations must be taken into account. If a patient presents with pancreatitis or cholangitis, these problems must be treated supportively prior to considering definitive operative management of the biliary cyst. Because of the extensive sludge or stones that may be present within choledochal

cysts and the high incidence of pancreaticobiliary maljunction, these patients are at especially high risk for pancreatitis. Furthermore, there is a risk of pancreatitis during ERCP with ampullary stent placement.

Another important clinical consideration in patients with choledochal cysts is the presence of malignancy. Adenocarcinoma comprises 73% to 84% of malignancy associated with choledochal cysts, and additional histologic subtypes include anaplastic carcinoma (10%), undifferentiated cancer (5%-7%), squamous cell carcinoma (5%), and other types such as bile duct sarcoma.<sup>27</sup> The incidence of cholangiocarcinoma with biliary cysts varies with patient age and cyst type. The lifetime risk of associated cholangiocarcinoma is 6% to 30% in several studies, and importantly, the rate of malignancy increases with age. Patients discovered in their 20s have only a 2.3% risk of concomitant malignancy, but this risk increases to 14.6% for patients with choledochal cysts discovered in their 30s and 40s.<sup>8,22,27-29</sup> In older untreated patients, the reported incidence of cholangiocarcinoma is as high as 75%.<sup>28</sup> In a review examining the occurrence of malignancy in 5780 patients with choledochal cyst, the overall incidence of biliary tract cancer was 7.5%. The incidence in children (age 0-18 years) was low (0.4%), with increased rates in those older than 18 years (11%). The incidence steadily increased with age up to 38% in patients older than 60 years. Among patients who develop malignancy, 70% arise as cholangiocarcinoma within the cyst wall and approximately 24% arise as gallbladder cancer.<sup>30</sup> Type I and IV cysts have a higher risk of cancer, whereas cancer is rare in type II and III cysts. In type III cysts, cancer risk may be limited to those choledochoceles lined by biliary and not duodenal epithelium. Caroli disease also carries a risk (approximately 7%) of cholangiocarcinoma. Most patients with Caroli disease, however, will present first with compromised liver function or cholangitis before developing malignancy.

The Johns Hopkins series included 92 choledochal cyst patients, with 8 of the patients being diagnosed with cancer at the time of surgery or in follow-up. Every cyst type, except types II and III, was involved with cancer. None of the patients who had a complete cyst excision developed cancer after a mean of 10 years of follow-up. However, this population was still at a greater risk of malignancy than the general population.<sup>28</sup> Malignancy may develop with incompletely resected cysts, at the anastomotic site, or in residual cyst left within the pancreas.<sup>28</sup>

Speculated etiologic factors in carcinogenesis associated with biliary cysts include bile stasis, reflux of pancreatic juice mixed with bile, superinfection, or inflammation.<sup>29,30</sup> Cholangiocarcinoma in choledochal cysts is strongly linked to patients with pancreaticobiliary maljunction.<sup>17</sup> There is strong pathologic evidence of a hyperplasia-dysplasia-carcinoma sequence of carcinogenesis in patients with pancreaticobiliary maljunction. While the exact pathways have yet to be elucidated, cells with hyperplasia in patients with pancreaticobiliary maljunction have elevated expression of cellular proliferation markers, including cyclooxygenase-2 and vascular epithelial growth factor.<sup>31</sup> On a molecular level, hyperplastic cells also have a high incidence of *K-ras* mutations (13%-63%),<sup>32,33</sup> whereas dysplastic cells frequently have microsatellite instability (60%)<sup>34</sup> and cancerous lesions often have overexpression of cyclin D1<sup>35</sup> and *p53* mutations.<sup>36</sup> Prophylactic cholecystectomy is also advised in all patients with either pancreaticobiliary maljunction or choledochal cyst.

In addition to the continued risk of cancer after excision, the most frequent long-term complication after biliary reconstruction is postoperative biliary stricture at the site of the anastomosis (approximately 25%).<sup>37</sup> Therefore, long-term follow-up should include surveying patients for the development of an anastomotic stricture. Significant elevations in serum alkaline phosphatase levels merit further investigation and treatment to prevent long-term complications from postoperative biliary strictures.

Unfortunately, current methods for screening for malignancy within a choledochal cyst have not proved effective, and therefore, expectant management cannot be advised for most patients. Intraductal ultrasound and cytologic brushings of the cyst wall show promise for potentially detecting malignancy. Patients with choledochal cysts who are poor candidates for or who refuse biliary reconstructive surgery may be candidates for lesser interventions to treat symptoms caused by gallstones or sludge, such as cholecystectomy or endoscopic treatment.

## **OPERATIVE MANAGEMENT**

Historically, choledochal cysts were managed with biliary-enteric drainage via cyst enterostomy. Recognition of an increased risk of bile duct and gallbladder cancer at an average of 10 years<sup>28</sup> after enteric drainage has

changed the recommended management to complete cyst excision. The current treatment of choice is surgical excision, because it is well documented to lead to a decrease in the rate of malignancy from 16% to less than 1%.<sup>25,29</sup> The main goal of management is therefore to prevent malignant degeneration of the cyst via surgical excision. In newly diagnosed adult patients with biliary cysts, the possibility of an existing cancer needs to be considered.

The operative management of choledochal cysts should first consist of careful exploration of the patient. Upon entry to the abdomen via a midline incision, the initial step should be searching for possible metastatic disease. Once metastatic disease has been excluded, management of the choledochal cyst consists of cholecystectomy and complete cyst excision. If possible, excision should include all remnants of the cyst. Because of the extensive fibrosis that may be present, complete excision of the cyst can be technically challenging. Following cholecystectomy and choledochal cyst excision, the bile duct is reconstructed. Standard methods to reconnect the bile duct include hepaticojejunostomy or hepaticoduodenostomy, although Roux-en-Y hepaticojejunostomy is by far the most commonly used technique.<sup>37</sup>

Enteric interposition grafts have been proposed as an option due to theoretical restoration of physiologic bile flow. Both jejunal interposition grafts and appendiceal interposition grafts between the duodenum and bile duct have been reported in the pediatric surgery literature. The value of these techniques, however, has been questioned because of graft dysfunction from stenosis and kinking.<sup>38</sup>

Successful resection and biliary reconstruction with type I and type II choledochal cysts have also been reported using laparoscopic techniques, particularly in children. A review of 35 adult patients with choledochal cysts that were resected laparoscopically was done, which showed a 0% mortality, 8.5% conversion rate, and 14.8% reoperation rate.<sup>39</sup> In another series by Senthilnathan et al,<sup>40</sup> 110 patients underwent laparoscopic resection and reconstruction of type I or type IVA choledochal cysts. The overall mortality was 1%, reoperative rate was 2%, and morbidity was 10%. Thus, this study demonstrated that laparoscopic surgery for choledochal cysts is feasible, safe, and even advantageous.<sup>40</sup> While the choice of performing these procedures via an open or laparoscopic approach should be a matter of preference and technical ability of the surgeon, it is important that the procedure not be compromised by the use of laparoscopy.

**Type I Cysts.** The surgical approach recommended for type I cysts is complete cyst excision with Roux-en-Y hepaticojejunostomy reconstruction. The technical aspects of this operation involve mobilization of the hepatic flexure and wide Kocher maneuver to expose the distal portion of the cyst that lies posterior to the duodenal wall (Fig. 64-6A). After the cyst has been exposed, the gallbladder, which usually arises from the mid-portion of the choledochal cyst, should be dissected away from the hepatic bed (Fig. 64-6B). The procedure then focuses on the distal portion of the choledochal cyst (Fig. 64-6C). Type IB (fusiform) cysts are particularly prone to extend distally within the common bile duct as it enters the dorsal aspect of the pancreas. The goal is then to excise the intrapancreatic portion of the cyst without injuring the pancreatic duct or the long common channel. Resection of the pancreatic head can usually be avoided unless there is documented malignancy. The distal portion of the cyst is encircled and transected as it enters into the pancreas and then reflected cephalad (Fig. 64-6D). This allows posterior dissection and identification of the portal vein and hepatic artery. The dissection may be facilitated by the presence of a preoperatively placed transhepatic stent. The dissection is continued until the most proximal portion of the duct at the hilum. The cyst is then resected at the hepatic duct confluence or more proximally if the cyst extends into the individual hepatic ducts (Fig. 64-6E). The excised cyst should be examined grossly for malignancy, and then the specimen should be sent for frozen section. If malignancy is present at the surgical margins, the resection may be extended either proximally or distally with the possibility of a pancreaticoduodenectomy to obtain negative margin and adequate lymph node dissection.

**FIGURE 64-6** Type I choledochal cyst resection and biliary reconstruction with Roux-en-Y hepaticojejunostomy. **A.** Exposure of cyst and gallbladder. **B.** Cholecystectomy and anterior dissection of the distal choledochal cyst. **C.** Distal extent of the cyst identified, encircled, and opened. **D.** Posterior dissection proceeds caudad to cephalad. **E.** Dissection proceeds until normal hepatic duct is identified. **F.** Cyst is transected and removed at normal duct. **G.** Excision is complete; reconstruction proceeds with a Roux-en-Y hepaticojejunostomy. If the bifurcation is involved, right and left hepaticojejunostomies can be performed. **H.** One-layer hepaticojejunostomy

at the hepatic bifurcation.

Reconstruction of the biliary tree is typically preformed with a Roux-en-Y hepaticojejunostomy at the bifurcation with a single anastomosis or multiple individual anastomoses with each of the hepatic ducts (Fig. 64-6F). A suitable segment of intestine is mobilized with a Roux-en-Y jejunal limb, approximately 60 cm in length, and the anastomosis is created with a standard retrocolic end-to-side Roux-en-Y hepaticojejunostomy, using a single layer of absorbable suture (Fig. 64-6G,H).

**Type II Cysts.** The recommended procedure for type II choledochal cysts is complete cyst excision. After the cyst has been exposed, the common bile duct wall defect should be closed transversely with or without a T-tube. A transverse closure helps minimize potential narrowing or stricturing of the common bile duct. These patients should also undergo a cholecystectomy at the time of cyst excision. Recently, resection of type II cysts has been completed successfully via a laparoscopic approach.

**Type III Cysts.** Because these cysts are unusual and have an overall lower rate of malignant transformation, reports of surgical excision of choledochoceles are uncommon. Primary management of choledochoceles is by ERCP with endoscopic unroofing of the choledochoceles and sphincterotomy of the common bile duct.<sup>9,41</sup> Surgical management is much less common in patients with choledochoceles compared to patients with other choledochal cysts. Although uncommon, surgical intervention for choledochoceles is needed for patients in whom sphincterotomy is very difficult or there is concern for malignancy.

The surgical approach for choledochoceles involves complete excision of the cyst and is approached via transverse duodenotomy in the second or third portion of the duodenum. Prior to duodenotomy, cholecystectomy is performed and then the ampulla can be localized by passing a biliary Fogarty catheter into the duodenum via the transected cystic duct. The anatomy can also be better defined via extensive Kocher maneuver and intraoperative ultrasound. The common bile duct and pancreatic duct must be identified to prevent injury to the pancreatic duct. After the duodenotomy, the pancreatic duct should be intubated with a small silastic tube so that the intraduodenal biliary cyst can be excised. The cyst is excised and a sphincterotomy can be

done by suturing the duodenal mucosa to the bile duct mucosa and pancreatic duct mucosa individually using interrupted absorbable sutures. A piece of 5- or 8-Fr plastic tubing can be placed into the pancreatic duct and secured with a single absorbable suture as a temporary stent to prevent acute pancreatitis. Finally, the duodenotomy is closed in a transverse fashion. It is highly unlikely that a Whipple procedure is required and should be considered only if malignancy is suspected.

**Type IV Cysts.** Type IVA and IVB cysts are managed similarly to type I cysts with regard to cholecystectomy, extrahepatic cyst excision, and biliary enteric anastomosis. However, the procedures are technically more challenging, and complete removal is not always possible for type IV cysts because of multiple extrahepatic cysts and intrahepatic cysts. Furthermore, these patients will most likely need reconstruction proximal to the bifurcation that involves anastomosing individual hepatic ducts. If 1 lobe of the liver is predominantly involving the intrahepatic cyst, then hepatic lobectomy should be recommended. In many situations, bilobar cyst disease remains, leaving this area at risk for malignancy. The long-term management in this situation is controversial. Intrahepatic disease in type IVA cysts and Caroli disease are prone to secondary biliary cirrhosis, hepatic atrophy, and portal hypertension. If the liver parenchyma is not cirrhotic and there is no evidence of intrahepatic duct malignancy, then the hepatic parenchyma should be preserved, even in the setting of stones or strictures. If cirrhosis is unilateral or segmental, resection of the involved parenchyma is necessary. Transhepatic biliary stents may be especially helpful for managing patients with type IV cysts, particularly those with type IVA cysts that extend into the intrahepatic ducts. The stents allow for proper decompression, alleviating chronic inflammation; may prevent or facilitate the management of long-term complications, such as biliary stasis, stones, cholangitis, and cirrhosis; and may be used for surveillance for malignant transformation.

Oncologic principles should be followed in cases in which malignancy is involved. If no metastatic disease is present and the vascular supply to the uninvolved hepatic parenchyma can be preserved, then resection of the involved bile ducts and adjacent parenchyma and lymph node dissection are indicated. In rare cases, extensive resections involving combined hepatic and pancreatic resection may be necessary. In cases in which metastatic disease is present, palliative stenting of the bile ducts is indicated.

**Type V Cysts.** Type V choledochal cyst (Caroli disease) is a difficult condition to manage, and the specific recommendations are not well defined. Current recommendations are to begin with conservative management treating infectious complications with drainage, stone extraction, antibiotics, and ursodiol. Although Caroli disease may be diffuse and bilobar, it is often confined to a single lobe and typically on the left side. Similar to type IVA cysts, Caroli disease, if unilateral or with segmental involvement with cirrhosis, can be managed by resection of the involved parenchyma, resulting in decreased incidence of recurrent cholangitis, pancreatitis, and cholestasis and decreased need for invasive procedures. Bilobar Caroli disease is a challenging problem. The use of ursodiol and antibiotics may improve bile flow and reduce the incidence of biliary stones, sludge, and cholangitis. In the absence of cirrhosis or malignancy, Roux-en-Y hepaticojejunostomy with bilateral transhepatic silastic stents may be indicated to improve biliary drainage. Following operative management, the stents are left in place for 6 to 12 months, depending on the extent of intrahepatic stones and strictures. Patients who continue to have recurrent cholangitis or recurrent stones often require indefinite transhepatic stenting. Patients with Caroli disease and progressive liver disease and cirrhosis should be considered for liver transplantation. The timing for when transplantation should be pursued is still under debate. Since patients with Caroli disease may also have polycystic kidney disease, combined liver-kidney transplants have had excellent outcomes. Mabrut and colleagues performed a multicenter study that included 155 patients with type V choledochal cysts from Western surgical centers. Patients underwent either hepatic resection (75%) or liver transplantation (19%) with excellent or good results achieved in 86% of patients. Five-year overall survival was 97% after liver resection and 89% after liver transplant.<sup>10</sup>

## **OPERATIVE RESULTS**

Early postoperative complications include pancreatitis, anastomotic leakage, cholangitis, and wound infection. Most series show morbidity rates of 9% to 41% and mortality rates of 0% to 3.3%.<sup>9,24,39</sup> The median length of stay ranges from 7 to 12 days after surgery; patients who undergo a laparoscopic approach have a slightly decreased hospital stay but longer operative time. Late postoperative complications include the formation of intrahepatic

strictures and stones, anastomotic stricture, malignancy, cirrhosis, and intrahepatic abscess formation.

However, long-term results following resection of a benign choledochal cyst with biliary reconstruction are generally excellent, especially with type I cysts. The rate of biliary stricture had been found to be very low. The management of more proximal cysts can be more challenging, particularly in the presence of extensive intrahepatic stone disease and liver damage. Type IVA cyst patients have the greatest risk for intrahepatic calculi and stricture formation secondary to the intrahepatic cystic disease. A series by Cho and associates<sup>42</sup> examined 204 patients with a mean follow-up of 14 years. Patients with type IVA disease with dilated intrahepatic ducts developed strictures at a rate of 24%, with virtually all presenting with cholangitis.<sup>42</sup> In contrast, management with large-bore silastic transhepatic stenting results in 90% success without recurrent cholangitis.<sup>43</sup> Patients remain at long-term risk for cholangitis, postoperative biliary strictures, intrahepatic stones, pancreatitis, or malignancy.

## Summary

Choledochal cyst disease is uncommon. The presentation of the disease is more common in children but has been increasing in the adult population, especially in Western countries. Currently, the diagnosis in adults is based on cross-sectional imaging and cholangiography, primarily CT and MRCP. The consequences of not treating choledochal cyst disease can lead to malignant degeneration. The majority of cases of biliary cysts can be treated effectively with cholecystectomy, cyst excision, and biliary-enteric reconstruction. Long-term follow-up is necessary for surveillance of cancer, cholangitis, intrahepatic stones, and postoperative biliary strictures.

## BENIGN BILIARY STRICTURES

Benign biliary strictures include several diverse clinical entities that share the common characteristic of biliary obstruction. Although advances in medical technology have greatly improved their management, bile duct strictures continue to pose a significant clinical challenge. Many of these strictures result from iatrogenic injuries, often in young patients who are otherwise in

good health and expected to live for years. Improper management may result in life-threatening complications including cholangitis, portal hypertension, biliary cirrhosis, and end-stage liver disease. Proper diagnosis and treatment are essential in preventing these complications.

Benign biliary strictures may affect the intrahepatic or extrahepatic bile ducts or both, and may be solitary or multiple. There are numerous etiologies of benign bile duct strictures ([Table 64-2](#)). The vast majority of strictures occur following injury to the bile duct during cholecystectomy; however, other procedures in the upper abdomen may injure the biliary tract, especially procedures involving the liver, pancreas, and stomach/duodenum. Inflammatory conditions such as pancreatitis, gallstone disease, and primary sclerosing cholangitis (PSC) are also important causes of benign bile duct strictures.

**TABLE 64-2: ETIOLOGY OF BENIGN BILIARY STRICTURES**

## **Congenital**

Biliary atresia

## **Postoperative Biliary Stricture**

The introduction and widespread use of laparoscopic cholecystectomy in the 1990s resulted in a significant increase in the frequency of biliary injuries and associated bile duct strictures. Postoperative bile duct injuries may present early in the postoperative period with biliary leak or months to years later with jaundice or cholangitis from biliary stricture. Proper management begins with delineation of biliary anatomy followed by repair. Nonoperative balloon dilatation via percutaneous transhepatic or endoscopic routes is appropriate in select patients with intact biliary-enteric continuity. Operative repair, however, remains the mainstay of treatment in patients with benign strictures.

## **INCIDENCE**

Most bile duct injuries and strictures occur in patients following abdominal surgery in the right upper quadrant. Cholecystectomy is performed on over 750,000 patients on an annual basis in the United States and accounts for over 90% of postoperative biliary strictures and injuries. Although the exact incidence of injuries is unknown because many cases go unreported, numerous studies have attempted to define the incidence and mechanisms of bile duct injuries associated with cholecystectomy. An incidence of 1 to 3 major bile duct injuries per 1000 cases was consistently reported during the era of open cholecystectomy. Roslyn and colleagues<sup>44</sup> demonstrated a 0.2% incidence of major bile duct injuries from a series of over 42,000 open cholecystectomies. A literature review by Strasberg and associates<sup>45</sup> of over 25,000 open cholecystectomies performed since 1980 revealed a 0.3% incidence of major bile duct injuries. In the 1990s, Strasberg and associates<sup>45</sup> reviewed nearly 125,000 laparoscopic cholecystectomies and reported an overall incidence of biliary injuries of 0.85% and an incidence of major injuries of 0.52%. Recently, multiple large studies from numerous centers have estimated the rate of major bile duct injury with laparoscopic cholecystectomy to be 0.08% to 0.6%.<sup>46-48</sup> A recent 5-year review of the New York State Planning and Research Cooperative System (SPARCS) showed that over 156,000 patients had undergone laparoscopic cholecystectomy and only 149 biliary injuries were identified, indicating a rate of 0.08%.<sup>46</sup> Therefore, it appears that the incidence of bile duct injury associated with laparoscopic cholecystectomy is now comparable to that with open cholecystectomy. This improvement likely reflects increased experience, improved instrumentation, and movement beyond the “learning

curve.” Finally, the effect of new techniques such as single-port laparoscopic cholecystectomy or the value of robotic technology in the safe performance of laparoscopic cholecystectomy is yet to be determined. However, some concern has been expressed related to the learning curve of such procedures when compared with the established laparoscopic procedure.

In the early 1990s, many authors ascribed the increased incidence of bile duct injuries with laparoscopic cholecystectomy as a “learning curve” associated with the new technique and projected that the rate of injury associated with laparoscopic cholecystectomy would decline with time. The rate of bile duct injuries appears now to have stabilized or perhaps decreased in the laparoscopic era; however, with newer graduates having less experience with open cholecystectomy, the rate of bile duct injury associated with a difficult cholecystectomy may be on the rise for the open procedure. Similarly, due to their lack of experience, conversion from laparoscopic cholecystectomy to open cholecystectomy may increase the rate of bile duct injuries.<sup>49</sup> An “extreme” vasculobiliary injury with injury to the hepatic artery and/or portal vein may occur in conversion from laparoscopic to open cholecystectomy in the presence of severe inflammation in and around the gallbladder when a fundus-down cholecystectomy is performed. Severe hemorrhage is common and is caused by dissection behind the cystic plate into the right portal pedicle involving vascular injury to a major hepatic artery and a portal vein. This “extreme” vasculobiliary injury can lead to infarction of the liver or diffuse bile duct infarction requiring possible hepatectomy or need for urgent liver transplantation or leading to death.<sup>50</sup>

## **PATHOGENESIS**

Several factors are associated with increased risk of bile duct injuries at the time of cholecystectomy. Some of these factors may be pathologic, anatomic variations, and/or technical problems that differ in the open or laparoscopic approach. Ultimately, the final common pathway of most injuries is either a technical error or misinterpretation of the anatomy. The chapter will focus primarily on laparoscopic cholecystectomies because 98% of cholecystectomies are initially started as a laparoscopic procedure. The “classic” biliary injury during laparoscopic cholecystectomy includes misidentification by the surgeon of the common bile duct as the cystic duct or misidentification of an aberrant right sectoral duct as the cystic duct (Fig. 64-

7).

**FIGURE 64-7** Classic laparoscopic bile duct injury. Confusion of the common bile duct with the cystic duct leads to clipping and division of the common bile duct. In many cases, the common hepatic duct will not be clipped but will instead be divided by scissors or cautery. (Reproduced with permission from Davidoff AM, Pappas TN, Murray EA, et al: Mechanisms of major biliary injury during laparoscopic cholecystectomy, *Ann Surg* 1992;Mar;215(3):196-202.)

**Pathologic Factors.** A number of patient-related factors have been associated with bile duct injury. Patients with acute cholecystitis may have severe inflammation in the porta hepatis and the Calot triangle, which can make an operation difficult. Patients also with complicated gallstone disease have a higher risk of injury than patients with chronic cholecystitis, symptomatic cholecystitis, or biliary colic. Tang and Cuschieri<sup>51</sup> reported that

complex cases, which included patients with acute cholecystitis, cholangitis, and gallstone pancreatitis, are associated with an increased incidence of bile duct injuries (1.2% vs 0.4%) versus other indications for laparoscopic cholecystectomy. These patients also have a higher rate of conversion to open cholecystectomy (30% vs 3%).

**Anatomic Variations.** Anatomic variations can also contribute to bile duct injury. A congenitally short cystic duct or a duct that appears shortened by an impacted stone may also lead to misidentification of the common bile duct, resulting in injury or transection. Other high-risk congenital anatomic anomalies include a long common wall between the cystic and common bile duct or the cystic duct inserting into the right hepatic duct. The cystic duct has a very variable pattern ranging from joining the common hepatic duct quite high, almost at the biliary confluence, to running parallel to the common hepatic duct before inserting into the common bile duct almost at the level of the pancreas. The risk of bile duct injury also appears to be increased in patients with obesity, chronic inflammation, excessive fat in the dissection area, inadequate exposure, poor or excessive clip placement, injudicious use of electrocautery, and bleeding into the operative field.

**Technical Factors.** Several technical factors associated with laparoscopic cholecystectomy make it prone to bile duct injury. First, standard laparoscopy gives a limited perspective from its end, viewing a 2-dimensional picture of the operative field. The classic laparoscopic injury occurs when the cystic duct and the common bile duct are aligned in the same plane, leading to clipping and dividing the common bile duct. Retraction of the gallbladder infundibulum excessively cephalad aligns the cystic and common bile duct, leading to misidentification and injury. As the operative dissection is carried cephalad, the common hepatic duct may also be transected, often without recognition, resulting in a postoperative bile leak. The right hepatic artery may also be injured, creating excessive bleeding. This classic injury is estimated to occur in over 75% of major bile duct injuries referred to major centers.<sup>52</sup> The classic laparoscopic injury is usually also associated with excision of a segment of bile duct, making the proximal extent of the injury high, usually at or near the hepatic duct bifurcation.

There is also a growing understanding of surgeon cognitive factors associated with bile duct injury during laparoscopic cholecystectomy. A

report examined 252 laparoscopic cholecystectomy bile duct injuries using the human error factor and cognitive science techniques and found that 97% of injuries were due to a visual perceptual illusion or inadequate visualization.<sup>53</sup> In a subsequent study from the same group, one of the main explanations for the surgeon's frequent inability to recognize a bile duct injury associated with laparoscopic cholecystectomy appears to be confirmation bias, which is the propensity to seek clues to confirm a belief and to discount clues that might discount that belief.<sup>54</sup> While cognitive factors are important for understanding the psychological issues associated with bile duct injuries, surgeons must continue to have appropriate corrective mechanisms in place to minimize the chance of these injuries, including knowledge of anatomy, typical mechanisms of injury, appropriate level of suspicion, and logic.<sup>55</sup>

The role of intraoperative cholangiography in preventing bile duct injury remains controversial, with mixed results from reported series. A large series in Australia demonstrated a protective effect,<sup>56</sup> whereas a review from the Veteran's Administration Hospitals demonstrated that bile duct injury occurred more commonly in patients undergoing cholangiography (0.7% vs 0.2%).<sup>45</sup> Clinical information from patients in the Texas Medicare claims data from 2000 through 2009 was examined, and the rate of injury was found to be higher when intraoperative cholangiography was not used.<sup>57</sup> In this study, surgeons who routinely performed intraoperative cholangiography had a lower rate of injuries than those who did not; however, when confounders were controlled with instrumental variable analysis, there was no statistically significant association between intraoperative cholangiography and common duct injury. This led to the conclusion that intraoperative cholangiography is not effective as a preventive strategy against common duct injury during cholecystectomy. Whether or not intraoperative cholangiography actually prevents bile duct injury, the procedure can often lead to early recognition of the injury and, therefore, potentially minimize the injury and its associated morbidity (Fig. 64-8).

**FIGURE 64-8** Intraoperative cholangiogram obtained during laparoscopic cholecystectomy. Cholangiogram demonstrates an injury to the common bile duct (which is clipped such that contrast does not fill the proximal biliary tree). Contrast fills the normal distal bile duct and duodenum.

The use of fluorescent cholangiography has recently been introduced to help determine biliary anatomy. Studies show that the frequency of detection of structures ranged from 72% to 100% for the cystic duct, 33% to 100% for the common hepatic duct, 50% to 100% for the common bile duct, and 25% to 100% for the common duct–common hepatic duct junction.<sup>58,59</sup> The best technical approach in preventing and limiting bile duct injuries, regardless of

the use of cholangiography, includes methodical dissection with careful exposure and identification of the structures of the triangle of Calot.<sup>44</sup>

The operative technique for laparoscopic cholecystectomy that defines the “critical view of safety” is a corrective mechanism that helps prevent misidentification and injury of the major bile ducts.<sup>60</sup> In this method, the triangle of Calot is cleared of fat and fibrous tissue. Only 2 structures are connected to the lower end of the gallbladder once this is done, the cystic duct and cystic artery, and the lowest part of the gallbladder attachment to the liver is exposed. Once the critical view is attained, the cystic duct and artery may be clipped and divided, as they have been conclusively identified. Failure to achieve the critical view is an indication for conversion or possible cholangiography. There are studies containing several thousand patients in which the critical view of safety was used for target identification without a biliary injury due to misidentification.<sup>61</sup> The critical view of safety is part of the Culture of Safety in Cholecystectomy (COSIC), and this problem has been addressed by the Society of American Gastrointestinal Endoscopic Surgeons (SAGES) in a novel effort called “Safe Cholecystectomy.”<sup>62</sup>

**Physiologic Factors.** Several physiologic processes have been implicated in the formation of bile duct strictures. Ischemia of the bile duct from excessive periductal dissection may have an important role in the formation of postoperative anastomotic strictures. Studies show that the blood supply to the ducts can be thought of having 3 elements: afferent arteries, marginal arteries, and the epicholedochal plexus. The afferent arteries are branches of the hepatic arteries or less commonly of the superior mesenteric artery or other upper abdominal arteries. The marginal arteries lie on and run parallel to the long axis of the bile ducts. Anatomically, these are the major arteries of the common bile duct located at the 3 and 9 o’clock positions that can be injured or divided by unnecessary dissection during cholecystectomy, or more commonly, the bile duct can be excessively “skeletonized” while performing a bile duct anastomosis.

Fibrosis and scarring can be intense following a bile duct injury. In canine models, bile duct ligation results in an elevation of bile duct pressure that is immediate and sustained and is accompanied by an increased bile duct diameter and formation of high local concentrations of bile salts at the canalicular membrane.<sup>63</sup> A month following bile duct ligation, the bile duct wall is thickened, will have reduced mucosal folds, and will have loss of

surface microvilli with epithelial degeneration. On pathologic staining 2 weeks after ligation, there is evidence of increased synthesis of collagen and proline hydroxylase activation. An animal model of bile duct injury demonstrated healing in traumatized bile duct tissue to occur in a mode of overhealing, implicating myofibroblasts as the main cause of contracture of scar and stricture of the bile duct.<sup>64</sup> Inflammation in the surrounding tissues compounds the problem by encouraging fibrosis, especially when associated with bile leakage.

Injuries and strictures of bile ducts occur less commonly in association with other operative procedures. After cholecystectomy, common bile duct exploration is the next most frequently associated procedure with stricture, typically occurring at the site of choledochotomy or an impacted stone. Procedures requiring biliary-enteric anastomoses may be complicated by postoperative stricture. Typically, these procedures involve choledochoenteric or hepaticoenteric anastomosis in such cases as reconstruction after pancreaticoduodenectomy, bile duct resection for mid-bile duct tumors, and excision of choledochal cysts. Gastrectomy and hepatic resection are the most common nonbiliary operations associated with postoperative strictures. Injuries associated with gastrectomy typically occur during pyloric and proximal duodenal dissection associated with closure of the duodenal stump or with creating a Billroth I gastroduodenostomy. Injuries during hepatic resection often take place during dissection of the hepatic hilum. Bile duct injury and stricture are also associated with hepatic transplantation, pancreatic procedures, and penetrating or blunt trauma. Finally, the recurrence of stricture after an initial attempt at repair is not uncommon and may occur over a decade following initial repair (Fig. 64-9).<sup>65</sup>

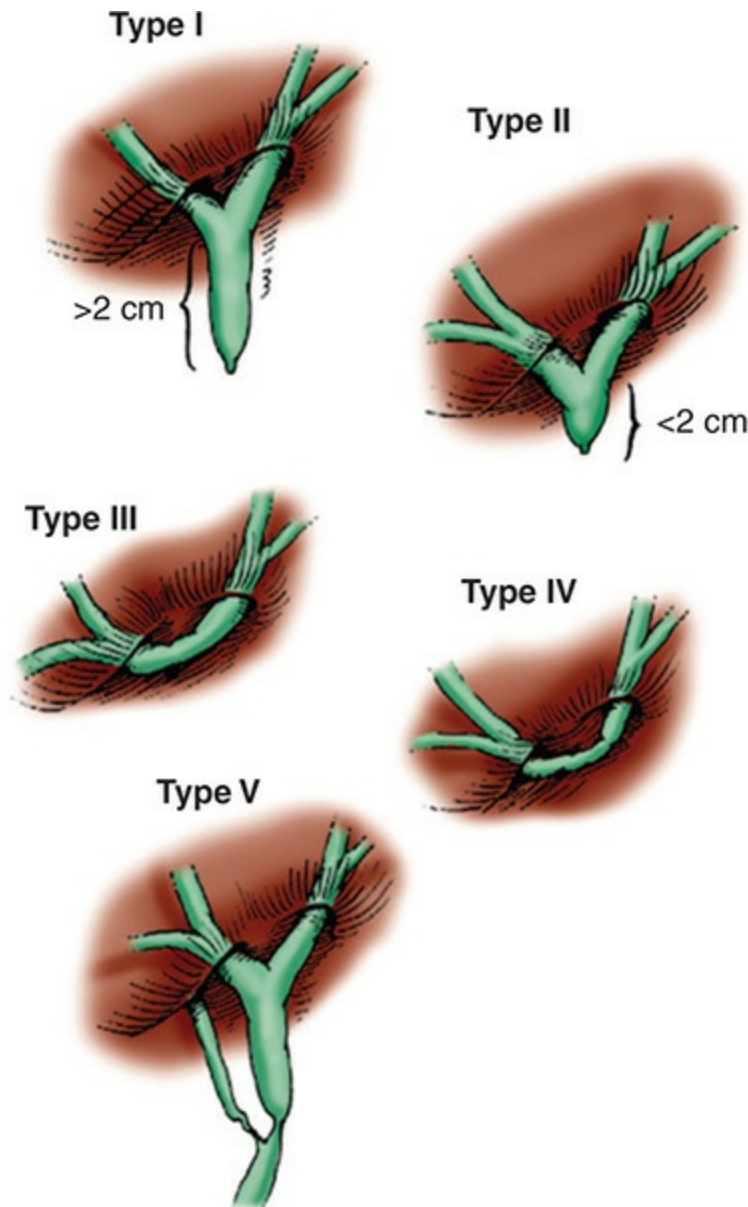

**FIGURE 64-9** The cumulative percentage of recurrent strictures is shown with respect to the time interval from the initial repair to the next repair. (Adapted with permission from Pitt HA, Miyamoto T, Parapatis SK, et al: Factors influencing outcome in patients with postoperative biliary strictures, *Am J Surg* 1982;July;144(1):14–21.)

## CLASSIFICATION

Strictures and injuries to the bile duct vary widely in their complexity and nature. The ease of management, operative risk, and outcome of biliary injuries vary considerably depending on the location and the type of injury. Injuries associated with laparoscopic cholecystectomy are often complex, located at or near the level of the hepatic duct bifurcation, and potentially include 1 or more hepatic duct branches. Minor injuries to the bile duct include lacerations of the bile duct, clip placement on an intact bile duct, injury via electrocautery, or avulsion of the cystic duct.

A number of classification systems of major bile duct strictures have been presented, with the traditional classification being that described by Bismuth (Fig. 64-10), which classifies major injuries based on the level of obstruction of the biliary tree with respect to the hepatic duct confluence or the involvement of an aberrant right sectoral hepatic duct with or without a concomitant hepatic duct stricture.<sup>66</sup> A drawback of the Bismuth classification system is that patients with limited strictures, isolated right

hepatic duct strictures, or cystic duct leaks cannot be classified. The Strasberg classification system has been developed to classify all types of injury and is used extensively in describing bile duct injuries associated with laparoscopic cholecystectomy (Table 64-3).<sup>60</sup>

**FIGURE 64-10** Bismuth classification system. Classification of bile duct strictures based on the level of the stricture in relation to the confluence of the hepatic ducts. Types III, IV, and V are usually considered complex injuries. (Reproduced with permission from Blumgart LH: *The Biliary Tract. Clinical Surgery International Series*, Vol. 5. Edinburgh, Scotland: Churchill Livingstone; 1983.)

**TABLE 64-3: STRASBERG CLASSIFICATION OF BILIARY INJURY AND STRICTURE**

Class A	Injury to small ducts in continuity with the biliary system, with cystic duct leak
Class B	Injury to sectoral duct with consequent obstruction
Class C	Injury to sectoral duct with consequent bile leak
Class D	Lateral injury to extrahepatic ducts
Class E <sub>1</sub>	Stricture >2 cm distal to bifurcation
Class E <sub>2</sub>	Stricture <2 cm distal to bifurcation
Class E <sub>3</sub>	Stricture at bifurcation
Class E <sub>4</sub>	Stricture involving right and left bile ducts; ducts are not in continuity
Class E <sub>5</sub>	Complete occlusion of all bile ducts

---

## PRESENTATION

Most patients with bile duct injuries unfortunately are not recognized at the time of laparoscopic cholecystectomy. After open cholecystectomy, only 10% of injuries are suspected after the first week, but nearly 70% are diagnosed within the first 6 months after operation.<sup>53</sup> However, injuries after laparoscopic cholecystectomy are recognized earlier more likely because of heightened awareness and suspicion.

Large series reviews have demonstrated that less than one-third of major bile duct injuries are detected at the time of injury during laparoscopic cholecystectomy.<sup>67,68</sup> Possible indications that a bile duct injury occurred intraoperatively include a persistent and unexpected bile leak, atypical anatomy, or a second bile duct discovered during dissection. Injuries may also be discovered if the removed gallbladder specimen and cystic duct are carefully examined to ensure normal duct anatomy. Intraoperative cholangiography will also diagnose bile duct injuries at the time of cholecystectomy and may minimize injury, allowing early repair (see Fig. 64-8).

The clinical presentation of patients with a bile duct injury in the early postoperative period depends on the type of injury. In most cases, the injury is associated with uncontrolled bile leakage into the peritoneal cavity, while

in others, the duct is completely ligated by clip placement, leading to obstructive jaundice usually without cholangitis. Patients with significant bile leaks generally present within the first week after operation with abdominal pain, distention, nausea, vomiting coupled with fever, or other signs of sepsis. Prompt investigation is required if patients have bilious drainage from incision sites or from intraoperatively placed drains. Bile leaks result in biliary ascites with associated chemical peritonitis if allowed to drain freely into the abdominal cavity, or alternatively, bile can become loculated, resulting in biloma (Fig. 64-11) or, if infected, a subhepatic or subdiaphragmatic abscess.<sup>69</sup> In the latter scenario, presentation is more subtle with low-grade fever and localized abdominal pain. Since significant abdominal complaints are uncommon after uncomplicated laparoscopic cholecystectomy, all patients with such symptoms should be appropriately evaluated without delay for possible bile leak to prevent progression to frank sepsis. Failure to recognize a major bile leak or to institute appropriate treatment can result in life-threatening sepsis and the development of multisystem organ failure. In the landmark series of 200 major bile duct injuries treated at the Johns Hopkins Hospital, 3 patients were transferred to a tertiary care center and died of complications of sepsis secondary to delayed or inadequate treatment.<sup>70</sup>

**FIGURE 64-11** CT scan demonstrating biloma associated with biliary leak after bile duct injury. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL: Postoperative bile duct strictures, *Surg Clin North Am* 1990;Dec;70(6):1355-1380.)

Bile duct strictures may also present months to years after the original operation. Patients with a slowly evolving stricture may have nonspecific abdominal complaints, jaundice, pruritus, cholangitis, or derangements in liver function tests. In addition, patients with an isolated right sectoral hepatic duct injury may present with a history of unexplained fevers, pain, or generalized malaise. Episodes of cholangitis are typically mild and respond effectively to antibiotics. Less often, patients can present with painless jaundice, which can be confused with a malignant stricture.

The findings on physical examination are usually not specific. Abdominal distention and pain may be seen in patients with bile peritonitis or focal tenderness if the patient presents with a collection or abscess. If the patient has jaundice, there may be multiple excoriations from pruritus. Hepatomegaly may be present in patients with chronic biliary obstruction or possible splenomegaly if there is any portal hypertension from portal venous injury or severe underlying hepatocellular damage.

## **DIAGNOSIS**

Patients presenting with a biliary leak from injury usually present without evidence of biliary obstruction, and bilirubin levels are normal or slightly elevated due to absorption of bile from the peritoneal cavity. Patients with postoperative bile leak or cholangitis will also have an elevated white blood cell count, pyrexia, or occasionally frank sepsis. Patients with postoperative bile duct strictures typically reveal a stereotypical biochemical profile of cholestasis. In particular, liver function tests typically consist of an elevated alkaline phosphatase and normal or slightly elevated liver transaminases (alanine and aspartate aminotransferases). Serum bilirubin levels are usually elevated in the range of 2 to 6 mg/dL. In rare cases, patients with long-term obstruction will present late in the course of disease with cirrhosis, diminished serum albumin, and abnormal coagulation studies from altered hepatic synthetic function.

Definitive diagnosis for bile duct strictures and injuries requires radiographic imaging. Ultrasound and abdominal CT scan are both helpful in

patients who present in the early postoperative period for the detection of bilomas and biliary ascites, as well as bile duct dilatation from obstruction. Ultrasound has little value in assessing the extent of a stricture and is unhelpful if the biliary tree is decompressed. Abdominal CT scan is usually the best first-line study often showing a dilated biliary tree or intra-abdominal collections or ascites, which can direct further investigations. The CT should be performed with arterial-phase contrast to evaluate for concomitant vascular injury. Nuclear medicine imaging with technetium-hepatobiliary iminodiacetic acid (HIDA) scanning can demonstrate bile leakage noninvasively but typically does not have the sensitivity to define the specific anatomic site of injury. MRCP has been demonstrated to be an effective noninvasive method for demonstrating biliary leakage or obstruction, as well as precisely defining biliary anatomy and the nature of the injury, such that in selected cases, this technique may be all that is needed to define anatomy prior to definitive repair ([Fig. 64-12](#)). Lastly, sinography, typically performed by injecting water-soluble contrast via operatively placed drains, can define the biliary anatomy and the source of bile leakage.

**FIGURE 64-12** Diagnostic MRCP demonstrating biliary anatomy associated with a cystic duct leak after laparoscopic cholecystectomy. There is an intact biliary system with extravasation of contrast in the subhepatic space.

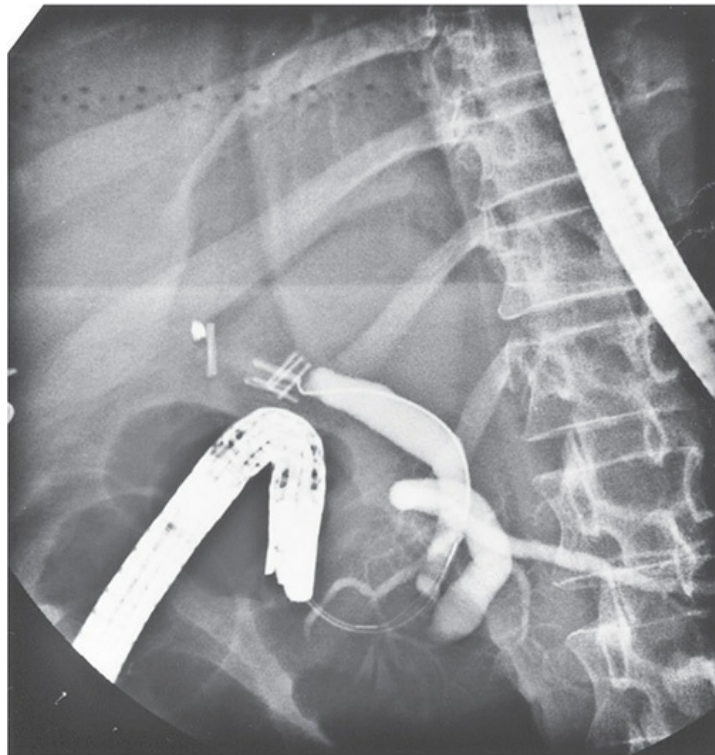

Cholangiography currently remains the gold standard for evaluating the biliary tree. Endoscopic retrograde cholangiography (ERC) is performed via a distal approach to the biliary tree and is useful only in patients if the native bile duct is intact, such as with partial injuries or after end-to-end repair. ERC is the procedure of choice for patients suspected of cystic duct leaks ([Fig. 64-13A](#)) or leaks from peripheral hepatic radicals (ducts of Lushka). In these cases, the biliary leak may be effectively controlled with the use of an

endoprosthesis. Most cases of major bile duct injury, however, are associated with complete duct transection, and the cholangiogram via the retrograde endoscopic route will demonstrate a normal distal bile duct terminating in misapplied clip (Fig. 64-13B). Therefore, ERC will not define the site of bile leakage nor the proximal anatomy necessary for reconstruction. In such cases, PTC is usually necessary to define the proximal biliary anatomy and the site of injury (Fig. 64-14). In addition to delineating the anatomy, a percutaneous biliary drainage catheter should be placed at the time of PTC to decompress the biliary tree, treat cholangitis, and control the biliary leak. Percutaneous biliary drainage catheters will also be useful at the time of operative repair as a guide for dissection and identification of the transected bile duct, which is often retracted high into the liver hilum. Finally, in cases in which biliary-enteric continuity exists, percutaneous catheters allow access for balloon dilatation.

**FIGURE 64-13** **A.** Endoscopic retrograde cholangiopancreatogram demonstrating cystic duct leak. **B.** Endoscopic retrograde cholangiopancreatogram with multiple clips across the common bile duct without visualization of the proximal biliary tree in a patient with total transection of the common bile duct during laparoscopic cholecystectomy.

**FIGURE 64-14** Percutaneous transhepatic cholangiogram in a patient with complete transection of the common hepatic bile duct. Note the surgical clips near the cutoff point.

Significant arterial injury associated with major bile duct injury has been increasingly reported in recent years. The “classic” biliary injury during laparoscopic cholecystectomy in which the common bile duct is mistaken for the cystic duct often includes injury to the right hepatic artery as it enters either above or below the hepatic duct. While this injury may cause bleeding at the time of operation, the arterial injury often is unnoticed, usually resulting in arterial occlusion or less commonly a hepatic artery pseudoaneurysm. In a large study by Stewart et al<sup>71</sup> on combined right hepatic artery and bile duct injury, there were 7 pseudoaneurysms compared to 77 right hepatic artery occlusions. The incidence of disruption of the right branch of the hepatic artery during major bile duct injury ranges between 12% and 39%.<sup>72</sup> However, the presence of an arterial injury does not appear to affect either early or late outcomes.<sup>71,73</sup> Due to the recognized association of vascular injuries during laparoscopic bile duct injuries, especially if there is a history of excessive bleeding at the time of cholecystectomy, a CT scan with arterial and venous phase contrast or arteriography should be obtained. Some authors believe that if arterial injury has occurred, biliary reconstruction should be delayed to decrease the risk of late stricture recurrence.<sup>60</sup> In patients presenting in a delayed manner after cholecystectomy, the combination of biliary and vascular injuries often leads to segmental or lobar atrophy, which may suggest a role for hepatic resection rather than reconstruction.

## **PREOPERATIVE MANAGEMENT**

The timing of presentation is often a primary determinant of the preoperative management of a patient with a postoperative bile duct stricture or injury. In the early postoperative period, patients with a bile leak associated with a bile duct injury are often either septic due to intra-abdominal infections or otherwise manifesting a systematic inflammatory response from chemical peritonitis associated with the bile leak. Treatment and control of sepsis may require broad-spectrum parenteral antibiotics, percutaneous biliary drainage, and percutaneous or, rarely, operative drainage of bilomas. Once sepsis is controlled, there is no hurry in proceeding with surgical reconstruction of the bile duct injury. Most biliary fistulae can be controlled with the combination of proximal biliary decompression and external drainage. After early control and clinical improvement, the patient may be discharged home for several

weeks to permit return of overall health and for the resolution of inflammation in the periportal region. Finally, as experience has been gained, selected patients, such as those with the bile duct clipped yet without a bile leak, may be managed without preoperative biliary catheters, if favorable anatomy is delineated by MRCP.

It should be stressed that despite the belief of many surgeons that a suspected bile leak warrants urgent reoperation, exploration with an attempt at repair should be avoided early after presentation with a bile leak. In this situation, exploration often reveals marked inflammation associated with bile spillage and small, decompressed bile ducts retracted high into the porta hepatis, making recognition of the injury and repair virtually impossible. Instead of proceeding to urgent exploration, a more prudent approach is to define biliary anatomy via preoperative cholangiography and to control the bile leak with percutaneous stents. Early operative intervention to deal with bile collections or ascites is not usually required because the intraperitoneal bile either can be drained percutaneously or is simply absorbed by the peritoneal cavity. Delayed reconstruction, with facilitation by percutaneous biliary catheters, allows for the most favorable operative results, especially when concurrent hepatic artery injury is suspected.

Patients who present with a biliary stricture remote from the initial operation usually experience symptoms of cholangitis that necessitate urgent cholangiography and biliary decompression. The choice of technique depends on the nature of any prior repair. If the native bile duct is intact, endoscopic drainage with stent placement can sometimes be achieved. If a prior hepaticojejunostomy has been performed, transhepatic biliary drainage will be necessary for diagnosis. Both parenteral antibiotics and biliary drainage are central to controlling sepsis. Patients who present with jaundice without cholangitis should undergo either ERC or PTC to define the anatomy. As with patients presenting early in the postoperative period, ERC may not completely define the proximal biliary anatomy, making PTC the more favorable procedure. Preoperative biliary decompression in patients presenting with jaundice without cholangitis has not been demonstrated to improve outcome.

## **OPERATIVE MANAGEMENT**

Operative repair for postoperative bile duct strictures is aimed at

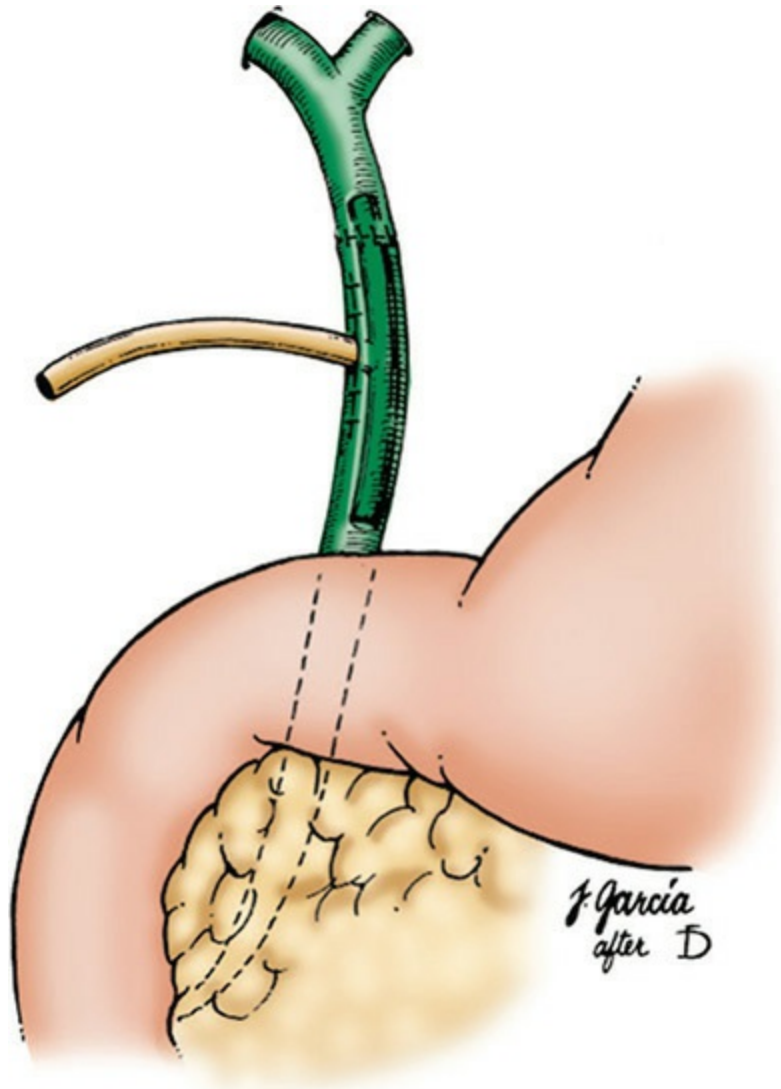

reestablishing a reliable, long-term conduit for bile flow from the biliary tree to the gastrointestinal tract. Complications of an unsuccessful operative procedure include bile leak resulting in fluid collection or abscess, recurrent stricture with stones or sludge and potentially cholangitis, and biliary cirrhosis. To this end, the ideal technical procedure results in a tension-free, mucosa-to-mucosa repair to a segment of uninjured bile duct. Ideally, surgeons should also seek to maintain ductal length by not sacrificing tissue. Options for operative repair may include end-to-end repair, Roux-en-Y hepaticojejunostomy, or choledochoduodenostomy. The optimal operative procedure is contingent upon the timing of presentation, overall clinical status of the patient, level of injury, and type of injury.

**Injury Recognized at Initial Operation.** If injury to the bile duct is recognized at the time of initial cholecystectomy, the surgeon should consider his or her ability to technically perform immediate reconstruction and should consider seeking the counsel and assistance of a more experienced surgeon. Studies show that immediate open repair by an experienced surgeon is associated with reduced morbidity, shorter duration of illness, and lower cost.<sup>70</sup> Each failed attempt at repair is associated with loss of bile duct length and exacerbation of a difficult situation. If the surgeon is unable to repair the injury and competent help is unavailable, no further attempt at dissection or removal of the gallbladder should be performed. Drains should be placed to control any bile leak and the patient referred immediately to a tertiary specialty center. If possible, the surgeon at the specialty center should be called from the operating room to guide decision making.

When the surgeon suspects an injury or variant anatomy, biliary anatomy must be clearly defined using intraoperative cholangiography and/or careful dissection, being cautious to avoid additional injury or devascularizing the bile duct. Conversion from laparoscopic to open cholecystectomy is often necessary to properly identify anatomy and the injury. Segmental or accessory duct injuries where the diameter of the bile duct is less than 3 mm and where the bile duct does not communicate with the major duct system or drain a large segment of hepatic parenchyma on cholangiography may be ligated. If bile ducts are 4 mm or larger in diameter or the cholangiogram shows sectoral or lobar drainage, then the ducts must be operatively repaired, as they likely drain multiple hepatic segments or an entire liver lobe.

Immediate intraoperative repair is indicated in most cases for a major

injury of the common hepatic or common bile duct. The nature of that repair is determined by the length of separation between opposed residual, viable ends of the injured duct. Partial common duct transections, involving less than 180-degree circumference of the biliary tree, may be closed primarily over a T-tube using interrupted absorbable sutures (Fig. 64-15). Transection of the common duct involving more than 180-degree circumference or complete transactions with an injury less than 1 cm in length can usually be repaired with an end-to-end anastomosis with a T-tube that exits either above or below the anastomosis via a separate choledochotomy. Primary reconstruction of the bile duct, however, should be used selectively and be avoided when the injury is near the bifurcation or when duct approximation cannot be accomplished without tension. A generous Kocher maneuver should be done to mobilize the duodenum out of the retroperitoneum and should be used to alleviate tension at the repair. In at least one series, a 100% stricture rate following primary end-to-end repair has been reported.<sup>74</sup> Other series have shown better results and suggest the advantage that if a stricture occurs, endoscopic access for balloon dilation remains an option.<sup>75</sup>

**FIGURE 64-15** Primary end-to-end repair of the biliary tree over a T-tube. In general, this technique is used for partial transections of the bile duct, when there has been no associated loss of duct length. Note that the T-tube does not exit at the site of injury.

Transections of the bile duct high in the biliary tree or with significant loss of bile duct length cannot be repaired with a primary biliary anastomosis that remains tension-free. These injuries require reconstruction using a biliary-enteric anastomosis typically using Roux-en-Y hepaticojejunostomy to ensure a tension-free repair. In this situation, the distal bile duct should be oversewn, the injured tissue in the proximal end debrided, and then a biliary-enteric end-to-side anastomosis to the Roux-en-Y jejunal limb performed. Transhepatic silastic biliary stents should be placed to control potential

anastomotic leaks and for postoperative cholangiography. A peri-anastomotic drain should also be placed in all cases so that any potential postoperative leak is well controlled.

**Injury Recognized in the Immediate Postoperative Period.** Biliary injuries that are not appreciated in the intraoperative period may present in the first few days. The presentation may include bile drainage from the wound, bile peritonitis, or progressive jaundice. The initial management of a patient who presents in the delayed fashion following laparoscopic cholecystectomy depends on the nature of the injury and the mode and timing of presentation. Any elective repair should generally occur only after preoperative clinical optimization of the patient and after exact anatomy of the biliary system has been identified. Those presenting with biliary leak should have the bile leak and sepsis controlled prior to having definitive repair. In this situation, the result of reconstruction is almost always better if the definitive repair is made well after the leak and the consequent intra-abdominal inflammation and sepsis are controlled with percutaneous biliary drainage. Biliary spillage and marked inflammation can obscure fields and can make identification of ducts difficult, making urgent early laparotomy prior to biliary decompression problematic. Finally, the patient should be clinically stabilized prior to elective repair to correct fluid and electrolyte balances, anemia, and malnutrition. The repair is ideally performed 6 to 8 weeks after adequate control of the leak has been attained.

In patients who present with biliary stricture weeks to months after cholecystectomy, identification of the biliary system is also essential. In patients with a stricture and symptoms of cholangitis, the patient should be treated with broad-spectrum antibiotics until sepsis is controlled, followed by biliary decompression with transhepatic percutaneous catheter placement.

**Definitive Management of Bile Duct Stricture.** The goal of operative management of a bile duct stricture is the establishment of bile flow into the proximal gastrointestinal tract in a manner that prevents sludge, stone formation, cholangitis, restructure, and cirrhosis. The type of repair should be determined by several factors: previous history of attempted repair, location of stricture or injury, surgeon experience, and surgeon preference. Intraoperatively, biliary anatomy must be carefully defined followed by exposure of healthy proximal bile ducts. Care must be taken to avoid

excessive dissection and devascularization of tissue. A biliary-enteric anastomosis is performed using a mucosa-to mucosa technique in a tension-free manner.

The preferred technique, with few exceptions, is a hepatico- or choledochojejunostomy to a Roux-en-Y limb of jejunum. End-to-end anastomosis after excision of the stricture or area of injury is not prudent due to the loss of bile duct length and associated fibrosis. Significant loss of bile duct length is also a strict contraindication to performing choledochoduodenostomy, which is unlikely to be performed in a tension-free fashion and is also associated with duodenal fistula if leak occurs.

The exact details of the reconstruction depend on the particular anatomic features of the stricture. For strictures where there is more than 2 cm of healthy common hepatic duct present (Bismuth I), a simple end-to-side biliary-enteric anastomosis will suffice. For strictures in which there is less than 2 cm of healthy common hepatic duct (Bismuth II) or the stricture involves the bifurcation of the hepatic duct but the left and right still communicate (Bismuth III), it may be necessary to lower the hilar plate and extend the choledochotomy along a short length of the left hepatic duct to allow a common biliary-enteric anastomosis. Strictures that completely separate the right and left biliary system (Bismuth IV and V) require separate right and left biliary-enteric anastomosis. When duct length cannot be found outside of the hepatic parenchyma, an intraoperative ultrasound is essential to locate the segment II and segment III ducts. Often, a wedge of liver may need to be resected until an adequate duct can be found to do a biliary-enteric anastomosis.

The use of percutaneous biliary stents with elective reconstruction of the biliary tree remains a topic of debate for hepatobiliary surgeons. Preoperatively placed stents act as intraoperative aids for defining anatomy, especially if the stricture is located proximally. Stents left in place after reconstruction also allow postoperative cholangiography and control early anastomotic leaks in the immediate postoperative period. Many surgeons also advocate extended postoperative transanastomotic stenting, with the purpose of minimizing fibrosis and risk of late anastomotic stricture. In this setting, follow-up cholangiography will reveal early evidence of anastomotic stricture and provide access for balloon dilatation if necessary.

Biliary reconstruction with the technique of hepaticojejunostomy with a Roux-en-Y limb with transhepatic biliary stents is depicted in [Figure 64-16](#).

Dissection of the porta hepatis is performed to clear any adhesions between the duodenum or colonic hepatic flexure to the gallbladder fossa, subhepatic space, or Glisson capsule. Preoperatively placed percutaneous stents are essential in assisting in dissection and bile duct identification in patients with a high bile duct transection. In patients with an intact but strictured bile duct, the duct is divided at the most distal portion of the stricture, and a segment of the strictured duct should be resected and sent to pathology for frozen section. The distal end of the stricture is then oversewn. The proximal extent of the duct should be debrided for a length not to exceed 5 mm to obtain healthy bile duct circumferentially for use in the anastomosis. Careful limited dissection is important to avoid vascular compromise to the bile duct. Preoperatively placed percutaneous transhepatic catheters, which now protrude from the proximal end, are usually exchanged for soft silastic stents. Silastic stents range from 12 to 22 Fr in size, with multiple side holes that are generally interspersed along 40% of the length of the catheter. A radiologic guidewire is placed through the percutaneous transhepatic catheter; using the Seldinger technique, a series of progressively larger coudé catheters are passed over the guidewire in order to dilate the system for silastic stent placement. The silastic stent is arranged with the side holes extending beyond the anastomosis distally and within the liver parenchyma proximally. The end of the silastic stent without holes is brought through the hepatic parenchyma and out through the upper anterior abdominal wall. A Roux-en-Y jejunal limb is then created by mobilizing a suitable segment of intestine of approximately 60 cm in length. The anastomosis is then constructed with a standard end-to-side Roux-en-Y hepatico- or choledochojejunostomy, typically using a single layer of 4-0 or 5-0 absorbable sutures.

**FIGURE 64-16** Roux-en-Y hepaticojejunostomy reconstruction of biliary tree. **A.** Repair of common hepatic duct stricture with transhepatic ring catheter exiting at the bifurcation. The stricture has been resected, and the distal biliary tree is oversewn. The hepaticojejunal anastomosis can then be performed over the ring catheter, or the ring catheter can be exchanged for a silastic transhepatic stent. **B.** The silastic transhepatic stent shown exiting the biliary tree, with the Roux-en-Y jejunal limb prepared for the hepaticojejunostomy. **C.** Completed repair showing the silastic biliary stent traversing the liver and the hepaticojejunostomy. The Roux-en-Y jejunal limb has been brought to the hepatic hilum in retrocolic position. (Reproduced with permission from Cameron JL: *Atlas of Surgery*, Vol. I. Hamilton, Ontario, Canada: BC Decker; 1990.)

In the postoperative period, silastic stents are left to external gravity drainage. A cholangiogram is then performed on postoperative day 4 or 5 (Fig. 64-17). If the biliary tree is adequately decompressed and no leakage is seen, the stents can be internalized, and the perianastomotic drain is removed.

**FIGURE 64-17** Postoperative cholangiography after hepaticojejunostomy via percutaneous silastic biliary stents; the image shows no evidence of anastomotic leak.

The length of postoperative transanastomotic stenting is dependent on the individual patient, the clinical setting, and surgeon preference. Long-term stenting involves fluoroscopic exchange of stents at regular 2- to 3-month intervals. Timing of stent removal can be aided by biliary manometric flow studies that give objective data about the adequacy of the anastomosis, or by passing a clinical trial with the stent placed above the anastomosis.<sup>76</sup>

An alternative described approach of doing a hepaticojejunostomy

involves an anterior longitudinal opening created in the bile duct and a long side-to-side anastomosis performed. Often this is done to the extrahepatic portion of the left hepatic duct after it is lowered by dividing the hepatic plate (Hepp-Couinard approach). This approach is particularly suitable for injuries at or just below the bifurcation. Right ducts do not lend themselves to this approach as well, since they have a short extrahepatic length. Sometimes the end of the right duct is used. However, dissection of the left duct provides a guide to the coronal plane in which the intrahepatic right hepatic ducts will be found and may further be exposed by removing liver tissue. During these procedures, exposure can be improved by dividing the bridge of tissue between segments III and IV and opening the gallbladder fossa. Finally, if still more exposure is needed, then resecting part of segment IVb and V will open the upper porta hepatis. The technique can avoid the need for postoperative stenting. Results of the Hepp-Couinard technique show that, at a mean follow-up of 4.9 years, anastomotic function was achieved in 96% of patients with stricture in only 5 patients; however, no reoperations were required for the recurrent stricture.<sup>77</sup>

**Nonoperative Therapy.** Nonoperative interventional radiology and endoscopic techniques have also been developed for the management of select patients with bile duct strictures and injuries. The most common nonoperative technique in these patients is interventional radiologic percutaneous stenting and balloon dilatation, which may be possible in patients with intact biliary-enteric continuity. With the administration of conscious sedation, the proximal biliary tree is accessed so that the stricture can be traversed using a guidewire under fluoroscopic guidance (Fig. 64-18). Angioplasty-type balloon catheters are used to perform dilatation of the stricture to a goal diameter based on the stricture location and the normal bile duct diameter. Following dilatation, a transhepatic biliary stent is left in place across the stricture. The stent allows for future cholangiography, repeat dilatation, and maintenance of the lumen while the bile duct heals. Complications of balloon dilatation occur in up to 16% of patients and include cholangitis, hemobilia, and bile leaks. Percutaneous management may still require repeated dilatations.

**FIGURE 64-18** Percutaneous balloon dilatation of postoperative bile duct stricture using an angioplasty-type balloon catheter. Cholangiogram showing mid-bile duct stricture.

Results for the treatment of bile duct strictures using percutaneous balloon dilatation have improved. In a retrospective review,<sup>78</sup> 109 patients with benign bilioenteric strictures were treated with percutaneous transhepatic balloon dilatation. The biliary drains were removed when no residual balloon waists were observed on at least 2 consecutive sessions, 6 weeks apart. Only 15% had recurrent biliary obstruction over a median follow-up of 59 months. Another study showed that percutaneous biliary dilatation was successful in

73% of patients after the first treatment.<sup>79</sup> These results would appear comparable to other series in the current laparoscopic cholecystectomy era.<sup>80,81</sup> However, the follow-up in most studies was less than 3 years, which is insufficient to make a definitive comment regarding long-term efficacy.

A series of 51 patients undergoing percutaneous balloon dilatation therapy for bile duct strictures following laparoscopic cholecystectomy was reported by Misra and associates.<sup>82</sup> At a median follow-up of 76 months, overall success with balloon dilatation, defined as stent-free without the need for further intervention, was 58%. With additional stenting and balloon dilatation for 2 patients and surgical reconstruction for the remaining patients, all but 1 patient (98%) had a successful long-term outcome. These results suggest that in highly selected patients, percutaneous balloon dilatation can provide long-term successful results.

Endoscopic balloon dilatation has a more limited application, since it is technically possible only in patients with primary bile duct stricture repair or with choledochoduodenal anastomosis. Endoscopic retrograde cholangiography is performed, followed by endoscopic sphincterotomy. Sequential balloon dilatation is performed after the stricture is traversed by a guidewire, often with 1 or more endoprotheses left in place after dilatation. Complications associated with stent placement include cholangitis, pancreatitis, stent occlusion, migration, dislodgment, and ductal perforation and have a reported incidence between 9% and 60%.<sup>83,84</sup>

Repeat cholangiography, often with repeat dilatations, may be performed at regular intervals of every 3 to 6 months. While most endoscopists advocate regular follow-up and reevaluation of the stricture, the risks of stent occlusion and replacement need to be weighed against the risks and costs of the repeat procedures, and there is still some debate about timing of stent change to avoid occlusion. Bergman and associates<sup>84</sup> demonstrated a 70% reobstruction rate with resultant jaundice or cholangitis when stents were not exchanged at 3-month intervals. In contrast, Cote and colleagues<sup>85</sup> describe and advocate leaving the stents in place until patients are symptomatic.

In addition, the rate of stent occlusion appears to vary with the type of stent used. Metallic stents provide a longer period of patency than plastic stents for patients with malignant obstruction, and the indications for their use in patients with benign strictures have increased. Some metallic stents cannot be routinely exchanged or removed, and several studies have

demonstrated high reocclusion rates at long-term follow-up.<sup>82-87</sup> Newer self-expandable covered metallic stents provide a suitable alternative as they can be changed or removed after completion of treatment.<sup>86</sup>

While there have been no determinative studies for the length of time that stents should remain in place, most studies having excellent results have used larger bore stents (10 Fr or greater) left in place for 6 to 12 months.<sup>82-85</sup> Long-term studies reporting the endoscopic treatment of benign bile duct injuries are few. One of the few studies that directly compared endoscopic therapy to surgical reconstruction was done by Pitt and colleagues from Indiana University.<sup>68</sup> In 289 patients with bile duct injury, 70 (24%) were managed by interventional radiologists, 115 (40%) by endoscopists, and 104 (36%) by surgeons. Endoscopic therapy and interventional therapy consisted of dilatation and placement of an endoprosthesis. In addition, patients treated by endoscopy had a median of 3 stent exchanges. Surgical repair consisted of primarily biliary-enteric anastomosis or end-to-end repair. Surgery was associated with successful outcome in 88% of patients compared with 76% of patient treated endoscopically and 50% of patient treated by interventional radiology with a mean follow-up of 48 months. Outcomes were best for patients who had stents for greater than 6 months. Recurrent strictures after stent removal in several other series have been reported to occur at a rate varying from 0% to 20% at median follow-up of 29 to 108 months.<sup>83,85,86</sup>

## **OPERATIVE RESULTS**

Biliary injury and stricture repair is associated with significant morbidity and mortality. With improved medical technology and experience, the incidence of operative mortality has decreased markedly. A series of 200 consecutive patients repaired at the Johns Hopkins Hospital reported a perioperative mortality of only 1.7%.<sup>70</sup> Advanced age, comorbid disease, and a history of major biliary tract infection are factors associated with operative mortality. Underlying liver disease is the most important correlated factor for operative mortality and morbidity, with advanced biliary cirrhosis and portal hypertension having mortality rates approaching 30%. Fortunately, in the modern era, such advanced disease is uncommon.

However, the effect of bile duct injuries on long-term life expectancy is a point of concern. An analysis of Medicare claims patients examined mortality associated with major bile duct injuries over an 8-year period in 791 elderly

patients and demonstrated a perioperative mortality of 2.7% associated with repair.<sup>88</sup> In addition, the study demonstrated that the adjusted hazard ratio for death during the follow-up period was significantly higher for patients with a bile duct injury than in patients without a bile duct injury. The hazard increased with advancing age and comorbidities and decreased with experience of the repairing surgeon. The adjusted hazard for death during follow-up was 11% greater if the repairing surgeon was the same as the injuring surgeon. This study gives supportive evidence for improved survival in patients with major bile duct injuries treated by experienced hepatobiliary surgeons at tertiary referral centers.

A recent 5-year review of the New York SPARCS administrative database detected 125 common duct injuries out of 156,958 laparoscopic cholecystectomies with no mortalities within 30 days of the operation.<sup>89</sup> However, the all-cause mortality was 20.8%, with a mean time to death of  $1.64 \pm 1.08$  years. Significant factors predictive of all-cause mortality included age >61 years, Medicare insurance, male sex, white race, diabetes, hypertension, and pulmonary complications following surgery. Timing and type of operative intervention did not influence mortality.

In most series, postoperative morbidity rates are in the range of 20% to 40%. Morbidity nonspecific to biliary surgery includes hemorrhage, infection, and risks associated with general anesthesia. Complications specific to biliary repairs include anastomotic leak, cholangitis, and hepatic insufficiency associated with preexisting liver disease. Anastomotic leaks can typically be managed via nonoperative means, especially when transanastomotic stenting has been used. Percutaneous transhepatic stenting may also have specific morbidity, including bile leaks from hepatotomy sites, hemobilia, and cholangitis from stent occlusion.

The series reporting the outcomes in 200 patients undergoing surgical reconstruction demonstrated a 43% overall postoperative complication rate.<sup>70</sup> The most common complications were wound infection (8%), cholangitis (6%), minor stent-related complications (6%), and intra-abdominal abscess/biloma (3%). Postoperative cholangiography revealed an anastomotic leak in 4.6% of patients and extravasation at the liver dome–stent exit site in 10.3% of patients. These complications were all managed conservatively with either new biliary stent placement or biliary stent exchanges, which were required in 2.3% of patients. Postoperative percutaneous abscess/biloma drainage was required in 9 patients (5.1%). No patients required reoperation

in the postoperative period. Despite the relatively high morbidity rate, median length of stay was similar to that in other reports ( $8 \pm 4.6$  days).

There are mixed results with respect to perioperative complications when vascular injury has occurred in association with a bile duct injury.<sup>73,90,91</sup> A report from Schmidt and associates<sup>90</sup> reported that a repair in the presence of uncontrolled infection, a concurrent hepatic artery injury, and injury level (at or above the bifurcation) were independent predictors of the development of major biliary complications. Another recent study showed that adequate sepsis control and delayed repair of biliary injuries should be considered for patients presenting between 8 days and 6 weeks after injury to prevent complications, especially if previous bile duct repair was attempted.<sup>92</sup>

The ultimate goal of the repair of a bile duct stricture is a successful repair with no further symptoms, including jaundice, cholangitis, and preserved liver function. Excellent long-term results following operative repair of postoperative bile duct injuries after open cholecystectomy have been reported, with approximately 80% to 90% having a successful outcome (Table 64-4).<sup>68,92-99</sup> Early reports and observations from the laparoscopic era were less favorable than those previously reported with open cholecystectomy repairs. Stewart and Way<sup>74</sup> reviewed 85 patients who had undergone 112 biliary repairs and defined 4 factors that influenced success or failure of operative repairs after laparoscopic cholecystectomy bile duct injury: (1) performance of preoperative cholangiography, (2) choice of surgical repair, (3) details of surgical repair, and (4) experience of the repairing surgeon. Procedures without preoperative cholangiography were unsuccessful 96% of the time, and those with incomplete cholangiography data had a success rate of only 31%. With complete cholangiography data, the success rate was 84%. All patients with complete transection of the bile duct who underwent primary end-to-end repair over a T-tube had a failed result. In contrast, 63% of Roux-en-Y hepaticojejunostomy repairs were successful. Initial repair by the original laparoscopic surgeon was successful in only 17% of cases. Repeat attempts at repair by the same surgeon were never successful. Finally, patients whose first repair was by a tertiary care biliary surgeon achieved a 94% success rate.

**TABLE 64-4: RESULTS OF SURGICAL REPAIR OF POSTOPERATIVE BILE DUCT STRICTURES**

A series providing long-term results after repair of bile duct injuries and strictures in the 1990s was reported by Lillemoe and associates.<sup>97</sup> A total of 156 consecutive patients underwent surgical reconstruction with a mean follow-up period of 57.5 months (range, 11-119 months; median, 54.7 months). The original operation consisted of laparoscopic cholecystectomy in 118 patients (76%), open cholecystectomy in 27 patients (17%), open cholecystectomy with bile duct exploration in 4 patients (3%), or other abdominal surgery or trauma in 7 patients (4%). Sixty patients (41%) had a previous attempt at repair prior to referral, with 8 patients (5.5%) having more than 1 attempt at repair prior to referral. Of the 156 operatively repaired patients, 142 patients had completed treatment at the time of final evaluation, with an overall success rate of 91%. Even though they were more likely to have had repair prior to referral and higher and more complex injuries, patients with repair of a stricture or injury associated with laparoscopic cholecystectomy had a better success rate than repair after other operations (94% vs 80%;  $P < .05$ ). There were 13 failures following surgical reconstruction. Ten patients had successful results following either surgical revision (1 patient) or percutaneous balloon dilatation (9 patients), resulting in an overall success rate of 98% including secondary intervention. Only 3 patients continued to require long-term biliary stents to prevent biliary obstruction symptoms and/or cholangitis. Comparable results have been reported from other high-volume hepatobiliary centers with similar volume of patients in the series.<sup>100,101</sup> Outcomes after surgical repair for laparoscopic

cholecystectomy injury from other series are outlined in Table 64-5.<sup>92,97,99-103</sup>

## EFFECT OF SURGICAL REPAIR ON QUALITY OF LIFE

Despite the overall high level of success in the surgical management of laparoscopic cholecystectomy bile duct injuries, there is an impression that patients may have an impaired quality of life even after a successful repair of their bile duct injury. Quality of life after laparoscopic cholecystectomy bile duct injury has been addressed in several recent reports, with differing results.<sup>104-108</sup> Two studies using the Short Form Health Survey quality-of-life instrument (SF-36) in patients with laparoscopic cholecystectomy injury found both the physical and mental quality of life aspects to be reduced compared to controls at approximately 5 years of follow-up.<sup>104,105</sup> A study using the SF-36 found that patients with laparoscopic bile duct injury and subsequent biliary reconstruction had quality of life similar to matched controls and national norms in all 8 quality-of-life areas.<sup>106</sup> Melton and associates<sup>105</sup> assessed quality of life in 54 patients who underwent successful surgical repair of laparoscopic cholecystectomy bile duct injuries and compared these results to quality-of-life measures in patients after

uncomplicated laparoscopic cholecystectomy and in healthy controls using a standard quality-of-life instrument, which was used to assess the physical, psychological, and social domains of health-related quality of life. Patients after surgical repair had overall quality-of-life scores comparable to those of controls. Only in the psychological dimension were patients post–bile duct injury repair found to have significantly worse scores compared to controls. Patients who reported pursuing a lawsuit following their injury (31%) had significantly worse quality-of-life scores in all domains when compared to those who did not entertain legal action ( $P < .01$ ). A recent study using the SF-36 found that quality of life improves significantly after the first year of surgical repair, reaching a plateau at 5 years. There was no difference in life summary scores from 5 years to 10 years after repair.<sup>108</sup>

## Summary

Postoperative bile duct strictures and major injuries remain a considerable surgical challenge. With proper diagnostic workup, clinical optimization, and definitive treatment, the vast majority of patients can achieve satisfactory outcomes. With success rates of over 90% at long-term follow-up, the gold standard for managing patients with major bile duct injuries and strictures in the current era remains surgical reconstruction. In select patients with biliary-enteric continuity, percutaneous or endoscopic management with balloon dilatation may be an appropriate alternative, with success rates of approximately 50% at long-term follow-up.

## INFLAMMATORY CAUSES OF BILIARY STRICTURE

Biliary strictures may occur in association with a wide range of processes causing fibrosis of the bile ducts. While inflammatory causes of bile duct strictures account only for a minority of biliary strictures in the United States, biliary strictures from these causes are important diagnostic and therapeutic challenges. Strictures from chronic pancreatitis, biliary calculous disease, sphincter of Oddi stenosis, and peptic ulcer disease can usually be managed with choledochoduodenostomy or Roux-en-Y hepaticojejunostomy without long-term stenting. The management of other infrequent causes of benign

biliary strictures depends on the etiology, natural history, and severity of disease.

## Chronic Pancreatitis

Chronic pancreatitis is an infrequent cause of bile duct stenosis and stricture, accounting for less than 10% of benign biliary strictures. While acute pancreatitis is frequently associated with transient partial obstruction of the distal common bile duct from inflammation and edema, chronic pancreatitis can result in distal bile duct obstruction from inflammation and parenchymal fibrosis of the pancreatic gland. Strictures from chronic pancreatitis typically involve the entire intrapancreatic segment of the common bile duct, resulting in proximal dilatation of the biliary tree.

Chronic pancreatitis resulting in bile duct stricture is most commonly caused by alcoholism. Strictures more commonly present in patients that have advanced disease with pancreatic calcification, diabetes, or malabsorption at the time of presentation. The exact incidence of common bile duct strictures in patients with chronic pancreatitis increased because cholangiography is more routinely performed. With a review of several studies, common bile duct strictures associated with chronic pancreatitis occur in approximately 8% of patients, with estimated ranges varying from 3% to 46% of patients.<sup>109-111</sup>

Common bile duct strictures due to chronic pancreatitis may have a wide range of clinical presentations. On one end of the spectrum, patients can be asymptomatic with only abnormal liver function tests. Serum alkaline phosphatase, the most sensitive liver function test, is elevated in over 80% of cases. Patients can also present with abdominal pain with or without jaundice. Importantly, abdominal pain from biliary strictures can be difficult to distinguish from pain caused by chronic pancreatitis. Patients with pain from biliary strictures that are not properly diagnosed and treated may undergo inappropriate and unsuccessful operative procedures to address pain presumed to be from chronic pancreatitis. Finally, patients who develop jaundice in the setting of chronic pancreatitis may present a diagnostic dilemma, as an underlying peri-ampullary malignancy must also be considered.<sup>112</sup>

Evaluation of bile duct strictures from chronic pancreatitis is most

effectively accomplished with cholangiography. MRCP is the preferred route for noninvasive assessment, with both ERCP and PTC effective at delineating anatomy and allowing decompression of the biliary tree in the setting of cholangitis or severe jaundice. ERCP is the preferred diagnostic procedure because it has the advantage of demonstrating pancreatic ductal anatomy, including possible abnormalities, which are especially useful in surgical management. The most common cholangiographic image in chronic pancreatitis-associated bile duct strictures is a long (usually 2-4 cm), smooth, gradual tapering of the distal common bile duct (Fig. 64-19).

**FIGURE 64-19** Stricture from chronic pancreatitis involving the entire

intrapancreatic segment of the common bile duct, resulting in proximal dilatation of the biliary tree. (Reproduced with permission from Mulholland MW, Lillemoe KD, Doherty GM, et al: *Greenfield's Surgery: Scientific Principles and Practice*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

There has been a gradual evolution in the endoscopic management of distal biliary strictures secondary to chronic pancreatitis. Most early series used single (usually 10 Fr) plastic stents for varying time periods. Long-term stricture resolution occurred in only approximately 25% of patients, and stent-related complications were high if stent exchanges were not performed routinely every 3 to 4 months. Recent studies show that either multiple plastic stents or self-expanding covered metallic stents produce resolution in 90% of patients at 12 months of follow-up.<sup>85,113,114</sup>

The most common accepted indications for operative management in common bile duct strictures from chronic pancreatitis are cholangitis, jaundice, or significant pain. It remains unclear, however, if biliary decompression in asymptomatic patients with elevated serum alkaline phosphatase is indicated. Many surgeons do advocate biliary bypass in this situation, as early biliary cirrhosis changes may be observed in liver biopsy specimens in patients with long-standing, significant biliary obstruction from chronic pancreatitis.<sup>115</sup>

Biliary bypass with choledochoduodenostomy or Roux-en-Y choledochojejunostomy represents the optimal form of management for bile duct strictures associated with chronic pancreatitis. Potential advantages of choledochoduodenostomy over Roux-en-Y choledochojejunostomy include maintenance of bile flow into the duodenum that may be more physiologic, increased technical ease, and no loss of small bowel length for formation of a Roux-en-Y limb. Operative management with pancreaticoduodenectomy is appropriate in patients in whom periampullary malignancy cannot be ruled out by imaging studies or clinical course or in those patients with significant pain attributed to proximal pancreatic duct disease. Both long-term and short-term outcomes of surgically managed distal bile duct strictures from pancreatitis are usually excellent.<sup>116,117</sup>

The management of common bile duct strictures from chronic pancreatitis with either transduodenal sphincterotomy or endoscopic sphincterotomy is not recommended due to the stricture's long length. While long-term follow-up is lacking, several series have reported success in 60% of patients with

follow-up at approximately 2 years after endoscopic balloon dilatation of distal bile strictures from chronic pancreatitis.<sup>118</sup> It would appear that in most cases when a benign process can be expected to require years of follow-up that surgery would be the best form of management.

## Gallstone Disease

Long-standing cholelithiasis with recurrent bouts of cholecystitis results in a progressively fibrosed, shrunken gallbladder. Eventually, the gallbladder lumen can lie alongside the common hepatic duct, resulting in inflammation and resultant bile duct stricture. Often referred to as Mirizzi syndrome, this process is typically subdivided into 2 categories. Type I Mirizzi syndrome occurs when the process results in either mechanical compression of the duct or an inflammatory stricture of the common hepatic duct. In contrast, type II consists of erosion of the stone in the duct, resulting in cholecystocholedochal fistula.

Mirizzi syndrome usually presents as jaundice or recurrent cholangitis. In some long-standing cases, these findings exist in the face of chronic gallbladder symptoms. In cases of Mirizzi syndrome associated with acute cholecystitis, care must be taken at the time of cholecystectomy to avoid bile duct injury during initial dissection. The presence of Mirizzi syndrome obliterates the triangle of Calot and makes laparoscopic cholecystectomy particularly difficult and will often require conversion to an open procedure. If Mirizzi syndrome is considered, intraoperative cholangiography should be performed.

If urgent cholecystectomy is not indicated, ERC or PTC can help to delineate the anatomy. Importantly, Mirizzi syndrome can be difficult to distinguish from strictures that result from gallbladder cancer or cholangiocarcinoma.<sup>119</sup> ERC can also be helpful for obtaining brush biopsies in these patients.

Formal management of strictures from biliary stones varies according to the extent of disease. Patients in whom the bile duct is inflamed and no fistula is present (type I) can often be managed with cholecystectomy. The common hepatic duct almost always returns to normal after the offending stone has been removed by cholecystectomy and the inflammatory process has resolved. Care must be taken, however, during the dissection to avoid

creating a defect in the common hepatic duct. Rarely, after the acute episode has resolved, a well-established stricture presents months to years after the acute episode. In such cases, management by Roux-en-Y hepaticojejunostomy is appropriate. If a cholecystocholedochal fistula (type II) is present, partial cholecystectomy is recommended, and the cuff of remaining gallbladder is used to repair the bile duct over a T-tube.

In addition to Mirizzi syndrome, calculous disease also rarely results in strictures due to choledocholithiasis. The pathogenesis of strictures from choledocholithiasis is thought to be from epithelial erosion of the distal bile duct from calculous disease, resulting in inflammation with subsequent fibrosis and stricture.

Nearly all stones remain entrapped in the intrapancreatic portion of the common bile duct because of the anatomic tapering of the common bile duct. These trapped stones are often difficult to remove via endoscopic means or via a supraduodenal approach during common bile duct exploration. In fact, common bile duct exploration to retrieve stones with forceps, scoops, and catheters can often result in additional trauma to the friable distal duct from excessive intraoperative manipulation. After stone removal, the distal bile duct should be gently sized with a soft rubber catheter to check for the presence of a stricture. Strictures often may not be recognized until the postoperative period when T-tube cholangiography is performed. When strictures are found postoperatively, stricture repair should be performed after inflammation has resolved, typically after 4 to 6 weeks. Stricture repair of the distal bile duct is indicated for persistent strictures using either Roux-en-Y choledochojejunostomy or choledochooduodenostomy biliary-enteric anastomosis. A choledochooduodenal anastomosis is preferable in patients with a large, dilated (>2 cm in diameter) proximal duct because of its technical ease and excellent results.

## **Recurrent Pyogenic Cholangitis and Other Parasitic Disease**

Recurrent pyogenic cholangitis, also known as Oriental cholangiohepatitis, is endemic in Southeast Asia. Recurrent pyogenic cholangitis occurs infrequently in Western countries, but with immigration from Asia, it is now increasingly encountered. Most cases are due to parasitic infection (*Ascaris*

*lumbricoides* or *Clonorchis sinensis*) of the biliary tree. The infection results in biliary stasis, bacterial overgrowth and inflammation, biliary sludge, and brown (calcium bilirubinate) stone formation. Patients will typically have multiple intrahepatic and extrahepatic stones and strictures, as well as recurrent cholangitis. Although strictures can occur throughout the biliary tree, they are most common in the main hepatic ducts, with disease in the left hepatic duct typically more frequent and more severe than the right. Classically, patients are young, thin, and of Asian descent and present with recurrent bouts of cholangitis. Cholangitis can range in severity from subclinical chronic illness to life-threatening acute suppurative cholangitis.

Diagnostic imaging modalities for Oriental cholangiohepatitis include ultrasonography, CT scan, MRCP, ERC, and PTC. Although ultrasound is poor at showing biliary strictures reliably, it is effective at demonstrating biliary obstruction, biliary tract stones, pneumobilia from gas-forming organism infection, and liver abscesses. Intrahepatic stones on ultrasound have a characteristic posterior acoustic shadowing. CT scan is useful for delineating hepatic anatomy and parenchymal involvement in more advanced disease, which is helpful for guiding potential liver resection. MRCP should be the first step to noninvasively define the biliary anatomy for the presence of strictures and stones. In addition, ERCP and PTC provide therapeutic biliary decompression in the setting of acute cholangitis (Fig. 64-20).

**FIGURE 64-20** Cholangiogram in a patient with cholangiohepatitis with diffuse bile duct dilatation. The biliary tree is filled with sludge (SI) and stones. (Reproduced with permission from Mulholland MW, Lillemoe KD, Doherty GM, et al: *Greenfield's Surgery: Scientific Principles and Practice*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Long-term management of recurrent pyogenic cholangitis is aimed at treating biliary strictures using improved biliary drainage via biliary reconstruction. Following temporary decompression of the biliary tree with ERCP or PTC for acute cholangitis, patients are allowed a period of several weeks for clinical optimization prior to further management. Attempts at percutaneous or endoscopic manipulations of the biliary tree for stone extraction and biliary stricture dilatation may be entertained. These interventions, however, have only temporary short-term benefit, and operative management will eventually need to be considered.

Standard operative management consists of Roux-en-Y hepaticojejunostomy, usually with a transhepatic stent. An attempt at

complete clearance of stones from the intrahepatic ducts should be made, including the use of choledochoscopy. The stent is useful for follow-up cholangiography and further stone clearance after the initial procedure. Another option for follow-up management is for the blind end of the Roux-en-Y limb to be sutured to the peritoneal surface of the abdominal wall, along with a radiopaque marker. This creates an enteric portal for future access to the biliary tree and anastomosis. In cases in which disease is confined to one portion of the liver with extensive fibrosis or hepatic abscess, hepatic resection may be considered.

Other causes of biliary strictures from parasites include various forms of echinococcal disease. Biliary strictures from echinococcal infection are primarily related to the compression of bile ducts by a thick-walled cyst. Because of its low rate of morbidity, long-term endoscopic stent therapy has become the initial therapy of choice in patients with biliary stricture from hydatid disease.<sup>120,121</sup> Operative therapy should be considered only in cases of failed previous repairs or failed endoscopic therapy. Surgical treatment of echinococcal liver and biliary disease is associated with a high rate of postoperative bile duct stricture, necessitating long-term clinical surveillance.

## **Sphincter of Oddi Stenosis**

Also referred to as papillitis, stenosis of the sphincter of Oddi is a benign intrinsic obstruction of the common bile duct outlet. Papillitis is typically associated with inflammation, fibrosis, or muscular hypertrophy of the sphincter of Oddi. Patients with sphincter of Oddi stenosis are prone to (1) common bile duct obstruction from fibrosis and stenosis of the papilla, (2) recurrent pancreatitis, and (3) recurrent right upper quadrant abdominal pain in the absence of jaundice or pancreatitis. Initial presentation is most often jaundice or cholangitis. Patients can also sometimes present with an impacted stone at the ampulla.

The etiology of papillitis is unknown. Many cases are thought to be caused by trauma from the passage of multiple small stones or sludge from the common bile duct through the ampulla, resulting in inflammation, fibrosis, and stricture formation. There are other patients, however, who have papillary stenosis without gallstones. The cause in these cases is less clear; potential triggers include primary sphincter motility disorders and congenital anomalies.

Management consists of proper diagnostic imaging and therapeutic sphincterotomy. Cholangiography with MRCP, PTC, or ERCP is the mainstay of diagnostic imaging. Therapeutic sphincterotomy can be performed either endoscopically or operatively in conjunction with cholecystectomy. The procedure of choice in patients with previous cholecystectomy is endoscopic sphincterotomy.<sup>122</sup>

## PRIMARY SCLEROSING CHOLANGITIS

PSC is an idiopathic condition characterized by a progressive, chronic cholestatic process resulting in diffuse inflammation, sclerosis, and obliteration of the intrahepatic and extrahepatic biliary duct systems and subsequently leading to liver cirrhosis. The diagnosis of PSC is confirmed by cholangiography, with findings of multiple areas of stricture and dilatation.

PSC has a variable course but can progress to biliary obstruction with secondary liver cirrhosis, portal hypertension with bleeding varices, or hepatic failure. Finally, PSC is a strong risk factor for the development of cholangiocarcinoma. Surgical management for symptomatic disease in patients with primarily extrahepatic and/or hilar disease and with no evidence of cirrhosis includes resection of the hepatic bifurcation with long-term transhepatic stenting. Finally, liver transplantation is the treatment of choice in patients with primarily intrahepatic strictures or advanced cirrhosis.

### Pathogenesis

The etiology of PSC remains unknown, and a variety of causal theories have been proposed. Inflammatory bowel disease, particularly ulcerative colitis, is present in 30% to 90% of patients with PSC in several large population-based studies.<sup>123,124</sup> This tight association with inflammatory bowel disease suggests an autoimmune process. However, other mechanisms likely have a role in pathogenesis since only a minority with ulcerative colitis have PSC.<sup>123</sup> Although both ulcerative colitis and PSC may occur in the same individual, the 2 disorders may occur at different times. PSC, for example, may occur years after colectomy for ulcerative colitis. In addition to commonly occurring in patients with ulcerative colitis, PSC can occur with multifocal fibrosclerosis syndromes, including retroperitoneal, mediastinal, and/or

periureteral fibrosis, Riedel thyroiditis, or pseudotumor of the orbit.

Due to the association between PSC and inflammatory bowel disease, several investigators have speculated that increased bacterial spread into the portal circulation from inflamed large or small intestine may lead to chronic or recurrent cholangitis. In support of this, an animal model of small intestinal bacterial overgrowth has biliary findings similar to PSC.<sup>125</sup> Although some studies have documented increased portal bacteremia in patients with PSC, other studies have not confirmed this finding.<sup>126,127</sup>

Correlating evidence for an immunologic cause of PSC includes its association with hypergammaglobulinemia (30%) and an increase in IgM (50%). Patients with PSC can also have autoantibodies, with titers in the range associated with autoimmune hepatitis. In particular, anti-smooth muscle antibodies and antinuclear antibodies are present in approximately 75% of patients.<sup>128</sup> Other autoantibodies commonly associated with the disease include cytoplasmic and nuclear antigens to neutrophils (perinuclear antineutrophil cytoplasmic antibodies [p-ANCA]). The autoantibody p-ANCA is often found in patients with PSC and no ulcerative colitis but is uncommon in patients with ulcerative colitis alone.<sup>128</sup>

Several genetic factors appear to give individuals a predisposition to PSC, including increased prevalence of HLA-B8, -DR3, and -Drw52a. The HLA-B8 and HLA-DR3 haplotypes are associated with other autoimmune diseases, including celiac disease, myasthenia gravis, and diabetes mellitus. A specific mutation of *MICA* (a major histocompatibility complex class I-related molecule) is also strongly associated with PSC (58% vs 22% in controls).<sup>129,130</sup>

In contrast to PSC, secondary sclerosing cholangitis has similar clinical characteristics but has identifiable causes. The inciting factors for secondary sclerosing cholangitis include infectious cholangiopathy associated with acquired immunodeficiency syndrome, congenital biliary abnormalities, ischemic cholangiopathy secondary to intrahepatic arterial infusion of fluorouracil, hepatic allograft rejection, graft-versus-host disease in bone marrow transplantation, collagen vascular diseases, histiocytosis X, sarcoidosis, and mast cell cholangiopathy. Patients with diffuse stricturing from fluorouracil are managed by simple discontinuation of infusion and, in some cases, percutaneous transhepatic drainage. Surgery should be reserved for patients with persistent evidence of biliary obstruction. The pathogenesis

of acquired immunodeficiency syndrome cholangiopathy is believed to be viral and related to cytomegalovirus infection. No experience in the surgical management of this condition has been reported.

## Presentation

PSC is predominantly a disease of young men. Approximately 70% of patients are male, and the average age at the time of diagnosis is 40 years. The typical presentation includes either an asymptomatic individual with abnormal liver function tests or an individual with intermittent jaundice. Other common symptoms may include right upper quadrant pain, weight loss, fever, pruritus, and fatigue. Despite its name, a minority have acute cholangitis, blood cultures are rarely positive, and approximately 10% are very symptomatic at the time of diagnosis; however, asymptomatic patients can have deceptively advanced disease.

## Diagnosis

Lab tests with PSC typically reveal a cholestatic picture. Patients will have an elevated alkaline phosphatase, and during exacerbations, they may have elevated bilirubin. Early in the disease course, patients will have a normal albumin. The diagnosis is usually made through cholangiography, usually MRCP or ERCP. The typical study reveals multifocal strictures and dilatations, referred to as “beading,” of the intrahepatic and extrahepatic ducts (Fig. 64-21). The therapeutic modality of choice for cases requiring intervention is via the endoscopic route. PTC may be difficult since cannulation of nondilated and fibrotic ducts associated with PSC can be technically challenging via this approach. At the time of diagnostic cholangiography, brushings for cytology should be obtained to help distinguish between benign and malignant strictures.

**FIGURE 64-21** Cholangiographic appearance in primary sclerosing cholangitis. Multiple irregular strictures and dilatation (beading) of intrahepatic ducts. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

## Management

Management of PSC has several important treatment goals, including halting or reversing the disease process, managing disease progression, and symptom control. Unfortunately, there are no effective medical treatments that slow the progression of PSC. Patients should be monitored closely with cholangiography, liver biopsy, and cytologic brushings to detect disease progression and development of malignancy or biliary cirrhosis.

Most medical therapies are aimed at symptomatic relief or antibiotic

treatment in the setting of cholangitis. Immunosuppression with glucocorticoids, methotrexate, azathioprine, 6-mercaptopurine, tacrolimus, or cyclosporine has not demonstrated efficacy for disease progression or survival. The use of ursodeoxycholic acid (UDCA) has demonstrated improvement of liver function tests and symptoms. A prospective, randomized, placebo-controlled trial of UDCA, however, did not demonstrate long-term clinical benefit with this agent.<sup>131</sup> High-dose UDCA in several small pilot studies has demonstrated decreased disease progression and improved survival<sup>131-133</sup>; larger-scale prospective trials with high-dose UDCA are still ongoing.

A dominant extrahepatic biliary stricture (a high-grade, localized area of narrowing) occurs in approximately 20% of patients with PSC. These patients can be managed potentially with endoscopic therapy using dilatation with or without stenting. Cytologic brushings at the time of endoscopy should also be obtained to investigate for cholangiocarcinoma. Several retrospective reports have demonstrated benefit in relieving symptoms and improving liver function tests from endoscopic therapy and possible delay in disease progression.<sup>134</sup> However, the durability of endoscopic therapy appears to be poor, with most patients requiring repeat dilatations at regular intervals. Whether patients should undergo stenting at the time of dilatation is not clear, with short-term results of stenting similar to those of dilatation treatment alone<sup>134,135</sup> and with no long-term outcomes at present comparing the 2 techniques.

Operative biliary reconstruction with transhepatic stenting for primarily extrahepatic and/or hilar disease in noncirrhotic patients has been demonstrated to have excellent long-term outcomes.<sup>134,135</sup> Ahrendt and associates<sup>136</sup> reported 146 patients with PSC managed with either biliary reconstruction or nonoperative biliary dilatation. Survival was significantly longer in noncirrhotic patients with PSC managed surgically compared to patients managed nonoperatively, and time before requiring liver transplantation was significantly longer in the surgically managed patients (Fig. 64-22).

**FIGURE 64-22** Actuarial survival rates among 31 noncirrhotic patients with primary sclerosing cholangitis who underwent resection of the hepatic bifurcation and long-term transhepatic stenting. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL: Primary sclerosing cholangitis, *Surg Clin North Am* 1990;Dec;70(6):1381-1402.)

The natural history of *PSC* is typically progressive. Regardless of therapy, median survival is typically 12 years after diagnosis.<sup>137</sup> Survival is significantly worse in patients symptomatic at the time of diagnosis.<sup>137</sup> The incidence of cholangiocarcinoma of *PSC* patients at 5 years is 10% to 15%, and at 10 years, it increases to 30%.

Hepatic transplantation provides excellent results in patients with *PSC* and end-stage liver disease, with 5-year actuarial survival and graft functioning of 85% and 72%, respectively.<sup>138</sup> Liver transplantation should be considered in patients with sclerosing cholangitis before the disease is too advanced. Primary indicators for referral for liver transplantation include persistently elevated bilirubin or decreased quality of life from disabling fatigue, severe pruritus, muscle wasting, or bacterial cholangitis. Biliary tract surgery prior to transplantation does not affect either short-term outcomes or survival following transplant.

Patients with preoperatively recognized cholangiocarcinoma have a poor prognosis. These patients are not appropriate candidates for transplantation.

On the other hand, the presence of a small (<1 cm) cholangiocarcinoma discovered incidentally on pathology at transplantation does not appear to portend a poor prognosis.

Patients transplanted for PSC are also at increased risk of postoperative biliary stricture compared to patients transplanted for other primary disease processes. Recurrent PSC occurs in approximately 20% of patients 5 years after transplantation, but with typically a less aggressive course.<sup>139</sup>

## SUMMARY

PSC currently has no proven effective medical treatment. Resection of the hepatic duct bifurcation in conjunction with long-term transhepatic stenting in noncirrhotic patients with primarily extrahepatic and/or hilar disease can delay or even prevent the need for hepatic transplantation. This operation does not influence the outcomes associated with hepatic transplantation. Transplantation is recommended in patients with primarily intrahepatic strictures or advanced cirrhosis.

# CANCER OF THE GALLBLADDER AND BILE DUCTS

*Jason S. Gold • Michael J. Zinner • Edward E. Whang*

## INTRODUCTION

This chapter focuses on gallbladder cancer and cholangiocarcinoma, including intrahepatic, perihilar, and extrahepatic variants. Because the epidemiology, clinical presentation and surgical approach for these tumors are distinct, they are discussed separately.

## GALLBLADDER CANCER

### **Epidemiology**

With an incidence of approximately 3000 cases annually in the United States (incidence 1.14 per 1000,000 people), gallbladder cancer it accounts for only 0.5% of all gastrointestinal tract malignancies in this country.<sup>1-3</sup> Incidence

increases with age and is two to three times higher in women than in men. Worldwide, the highest incidence rates (up to 8.0 per 100,000 in men and 22 per 100,000 in women) occur among populations in the Indian subcontinent, in the Western part of South America (eg, Colombia and Ecuador), and to a lesser extent in East Asia and Eastern Europe. In the United States, the incidence is higher in American Indians and in Hispanics.<sup>2,4</sup> The best characterized risk factor for the development of gallbladder cancer is chronic inflammation associated with gallstones (Table 65-1). Although only a small fraction of patients with cholelithiasis will develop gallbladder cancer, gallstones are present in 70% to 90% of patients diagnosed with gallbladder cancer.<sup>4-6</sup> Further, the geographic pattern of gallbladder cancer incidence correlates with that of cholelithiasis.

**TABLE 65-1: RISK FACTORS FOR DEVELOPING GALLBLADDER CANCER**

Cholelithiasis

Porcelain gallbladder

Adenomatous polyps of the gallbladder

Chronic *Salmonella typhi* infection

Carcinogens (eg, radon)

Abnormal pancreaticobiliary duct junction (APBDJ)

---

Other factors implicated to increase the risk of developing gallbladder cancer include porcelain gallbladder, adenomatous polyps of the gallbladder (in contrast, cholesterol and inflammatory polyps and adenomyomatosis are not believed to be the risk factors), chronic infection with *Salmonella typhi*, carcinogen exposure (eg, increased risk has been reported for miners exposed to radon), obesity, and abnormal pancreaticobiliary duct junction (APBDJ). In this latter condition, a long common channel, formed by an abnormally proximal junction between the pancreatic and common bile ducts (CBDs), and elevated sphincter of Oddi pressures create a predisposition to reflux pancreatic exocrine secretions into the bile ducts. APBDJ is most prevalent in Asian countries and appears to increase the risk of development of biliary cancers, especially gallbladder cancer.<sup>7</sup> Gallbladder cancers arising in patients with APBDJ tends to occur at a younger age, to have a lesser degree

of female predominance, and to be less often associated with cholelithiasis than those arising in patients without APBDJ.

## Pathogenesis and Pathology

Chronic inflammation of the gallbladder mucosa related to gallstones is hypothesized to be the major factor leading to malignant transformation in most cases of gallbladder cancer. The progression from dysplasia to carcinoma in situ (CIS), then to invasive cancer has been described for gallbladder cancer, although a less common pathway involves progression of adenomas to gallbladder cancer.<sup>8</sup> Reports outlining the molecular changes associated with this progression are emerging: frequently altered genes include *p53*, *K-ras*, *P16INK4A*, and *ERBB2/HER2*.<sup>9,10</sup>

Gallbladder cancers arising from adenomas may be associated with a distinct pathogenetic mechanism, especially when compared to those arising in patients with APBDJ. Adenomas have a high prevalence  $\beta$ -*catenin* mutations, whereas dysplastic lesions and cancers associated with APBDJ have a high prevalence of *K-ras* mutations and a low prevalence of  $\beta$ -*catenin* mutations. *p53* and *P16INK4A* mutations are not seen in adenomas or dysplastic lesions, and thus appear to be later events in gallbladder carcinogenesis.<sup>10</sup>

Eighty percent of primary gallbladder cancers are adenocarcinomas. Other histological types include small cell cancer, squamous cell carcinoma, lymphoma, and sarcoma. Gallbladder cancers are also classified according to morphology as infiltrative, nodular, papillary, or a combination of these types. Papillary cancers tend to grow within the gallbladder lumen and are less likely to invade the liver or to metastasize to lymph nodes; they are associated with the best prognosis. Infiltrative or nodular cancers have a more diffuse pattern of growth that is difficult to recognize on imaging studies. These lesions are more likely to have invaded the liver and to have metastasized to lymph nodes by the time of diagnosis.

## Clinical Presentation and Diagnosis

In the absence of advanced disease, patients with gallbladder cancer are asymptomatic or have symptoms such as abdominal pain, anorexia, nausea,

and vomiting that may be indistinguishable from those of cholelithiasis or cholecystitis. Due to these nonspecific symptoms, a diagnosis of gallbladder cancer is not made preoperatively in over half the cases and is often an unexpected finding on pathologic review of gallbladders removed for presumed benign (gallstone) disease. With advanced disease, patients can present with weight loss, obstructive jaundice (due to tumor invasion into the biliary tree or to liver metastases), and duodenal obstruction. Signs associated with advanced disease include palpable abdominal masses, hepatomegaly, and ascites.

Laboratory tests may suggest obstructive jaundice if this condition is present; otherwise, they are not helpful in the diagnosis of gallbladder cancer. Tumor markers such as carcinoembryonic antigen (CEA) or CA 19-9 may be elevated; however, they lack sufficient sensitivity or specificity to be useful in clinical decision-making for individual patients.

Patients with suspected gallstone- or gallbladder-related conditions typically undergo transabdominal ultrasonography (US). Findings suggestive of gallbladder cancer on ultrasonography include mural thickening or calcification, a gallbladder mass greater than 1 cm in diameter, and loss of the normal gallbladder wall–liver interface ([Fig. 65-1](#)). Relative to transabdominal ultrasonography, endoscopic ultrasonography (EUS) offers greater accuracy in assessing depth of gallbladder wall penetration by masses and regional lymph node enlargement and also may provide better characterization of gallbladder masses. As EUS is invasive and does not necessarily provide more clinically relevant information than other noninvasive imaging modalities, it is not widely utilized. EUS-guided biopsy, however, is an effective technique in cases in which a tissue diagnosis is required.

**FIGURE 65-1** Ultrasound of gallbladder cancer. The images demonstrate asymmetric wall thickening of the body and neck of the gallbladder. (Used with permission from Dr. Steven E. Seltzer, Department of Radiology, Brigham & Women's Hospital;

Cross-sectional imaging (ie, either computed tomography [CT] scanning or magnetic resonance imaging [MRI]) should be performed on patients suspected of having gallbladder cancer. CT is typically more widely available and less expensive than MRI. Findings of gallbladder cancer include a mass protruding into the gallbladder lumen or completely replacing the gallbladder and focal or diffuse thickening of the gallbladder wall (Fig. 65-2). CT scanning also offers information on the presence or absence of distant metastases, regional lymph node involvement, and local invasion into the liver and porta hepatis.

**FIGURE 65-2** CT scan of gallbladder cancer. The image shows a  $3.5 \times 4$  cm lesion arising from the gallbladder fundus and extending into segment 5 of the liver.

MRI, particularly with magnetic resonance cholangiopancreatography (MRCP), can offer additional information on invasion into the liver. It is not known, however, whether routine MRI adds to the results obtained from CT

scan, and thus it should be used selectively, for instance when CT findings are equivocal or precise delineation of biliary anatomy is warranted. Endoscopic or percutaneous cholangiography is not indicated for diagnostic purposes, and is reserved for therapeutic purposes. Similarly, diagnostic angiography has been replaced by CT and MRI angiography, which provide detailed imaging of vessels in the porta hepatitis.

While fluorodeoxyglucose (FDG) positron-emission tomography (PET) has not been universally accepted as a part of the routine staging evaluation for gallbladder cancer,<sup>11</sup> retrospective studies show that gallbladder cancer tends to be FDG-avid, and that when utilized PET is more sensitive than CT for the detection of distant metastases, and therefore alters management in a significant fraction of cases when used.<sup>12–14</sup> PET is less useful in differentiating benign versus malignant disease, and therefore is limited in its ability to differentiate between residual disease and post-surgical changes after cholecystectomy. While some favor the routine use of PET, others favor using PET selectively to further evaluate indeterminate findings on CT or MRI.

## Staging

Several staging systems for gallbladder cancer have been described. The Nevin staging system and the Japanese Biliary Surgical Society system are mainly of historical interest. The American Joint Committee on Cancer (AJCC) staging system,<sup>15</sup> now in its eighth edition (Table 65-2), which is based on the tumor depth, regional nodal involvement, and the presence of distant metastasis (tumor-node metastasis [TNM]) is currently the most widely used staging system. The current AJCC staging system numbered stages are useful in determining prognosis as well as for guiding appropriate treatment according to current paradigms.

TABLE 65-2: TNM STAGING OF GALLBLADDER CANCER

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T2a	N0	M0
Stage IIB	T2b	N0	M0
Stage IIIA	T3	N0	M0
Stage IIIB	T1-3	N1	M0
Stage IVA	T4	N0-1	M0
Stage IVB	Any T	N2	M0
Stage IVB	Any T	Any N	M1

Tis, carcinoma in situ; T1, cancer invades lamina propria and/or muscularis; T1a, cancer invades lamina propria; T1b, cancer invades muscularis; T2, cancer invades perimuscular connective tissue but not beyond serosa or into liver; T2a, cancer invades perimuscular connective tissue on peritoneal side without involvement of serosa; T2b, cancer invades perimuscular connective tissue on hepatic side without involvement of serosa; T3, cancer perforates serosa and/or directly invades the liver and/or one other adjacent organ or structure; T4, cancer invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures; N0, no regional lymph node metastasis; N1, metastasis to one to three regional lymph nodes (nodes along common bile duct, hepatic artery, portal vein, and cystic duct); N2, metastasis to four or more regional lymph nodes; M0, no distant metastasis; M1, distant metastasis.

## Surgical Therapy

Surgical resection is the only known curative form of therapy for gallbladder cancer. For patients in whom surgical exploration is contraindicated because of medical comorbidities or due to metastatic or unresectable disease, a percutaneous or endoscopic needle biopsy can be obtained to confirm the diagnosis. For patients in whom surgery is planned, a preoperative biopsy is contraindicated, as gallbladder cancer has a propensity for dissemination along needle tracts.

Recommendations for surgical treatment according to disease stage are given below. Specific technical issues are discussed subsequently.

## INCIDENTAL FINDINGS ASSOCIATED WITH RISK OF MALIGNANCY

Adenomas and gallbladder calcification have been associated with the risk of developing cancer or even harboring occult malignancy, and thus the management of these findings warrants specific discussion. While gallbladder polyps are noted in approximately 5% of patients undergoing gallbladder ultrasonography, not all polyps are adenomas. In fact, most are cholesterol polyps. Inflammatory polyps, hyperplastic polyps, and adenomyomatosis among other lesions can also appear as polypoid lesions in the gallbladder. Adenomyomatosis, which is an extension of Rokitansky-Aschoff sinuses through the muscular wall, can often be differentiated from adenomas by imaging, while distinction between adenomas and other polypoid lesions is more difficult. US can distinguish adenomyomatosis from other polypoid lesions in many cases, but occasionally axial imaging (CT or MRI) is needed. MRI is reported to be the most accurate imaging modality for making a diagnosis of adenomyomatosis.<sup>16</sup> Of the polypoid lesions in the gallbladder, only adenomas harbor any malignant potential. In recent series of resected gallbladder polyps, less than 20% were found to be adenomatous, and the rate of malignancy was around 5% or less.<sup>17,18</sup> Patients evaluated for gallbladder polyps should be assessed for symptoms attributable to the biliary system. While symptoms are rarely related to polyps, if another cause cannot be found, resection is warranted. The most consistent predictors of malignancy in polyps are older patient age and larger polyp size. Of these, size is particularly important as it is quite rare for malignancy to be identified in polyps <1 cm.<sup>18,19</sup> Thus, size  $\geq 1$  cm is the most widely accepted indication for surgery. As the coexistence of gallstones also predicts malignancy in some studies,<sup>19</sup> some authors advocate surgery in this setting. The finding of gallbladder polyps in patients with primary sclerosing cholangitis (PSC) warrants special consideration, as polyps in this setting are more likely to be neoplastic or even malignant. Several widely accepted consensus guideline advocate surgery for all polyps in patients with PSC,<sup>20–22</sup> while some authors recommend mandate surgery only for patients with polyps  $\geq 8$  mm in size.<sup>23</sup>

Patients with polypoid lesions of the gallbladder who do not undergo surgery should be followed with serial US unless a diagnosis other than adenoma is confirmed. Polyps that increase in size have a high chance of being neoplastic and should be resected.<sup>24</sup> There are little data to guide the frequency and duration of surveillance. It is reasonable to obtain an US at 6 months, 1 year, and then yearly. As polyps <5 mm are most frequently non-

neoplastic, it is likely not necessary to follow these lesions beyond 1 year if they are stable in size.

The operative approach for the patient with a polypoid lesion of the gallbladder should be carefully considered. Until recently, an open approach was favored whenever the possibility of malignancy was considered. As the probability of malignancy is quite low in cholecystectomies performed for presumed gallbladder polyps, laparoscopic cholecystectomy is an appropriate treatment for early-stage (T1a) cancer (see below) and as the outcome for cancers confined to the gallbladder is not dramatically worse when laparoscopic cholecystectomy is performed as the initial treatment, it is reasonable to start with a laparoscopic approach in selected cases. The patient needs to be aware that if malignancy is found, open exploration and extended resection may be indicated (see below). This can be performed in the same setting based on frozen section results. The laparoscopic approach should be reserved for cases where the preoperative imaging does not indicate features suggestive of malignancy. Similarly, if on preoperative imaging the mass is adjacent to the liver hilus, stronger consideration should be given to initial en bloc resection of the gallbladder with the cystic plate of the liver (see below). Lastly, there should be a low threshold for conversion to an open approach (eg, for findings concerning for more advanced tumors or with concern for violation of the gallbladder with bile spillage).

Calcification of the gallbladder is an uncommon condition related to chronic cholecystitis. The term “porcelain gallbladder” typically refers to the end-stage of the process with diffuse calcification of the gallbladder wall, often detected on plain abdominal x-rays, resulting in a brittle gallbladder with a bluish discoloration. Older series reported extremely high rates of malignancy associated with gallbladder calcification, and thus cholecystectomy was advocated. Modern series, however, report a much lower incidence of gallbladder carcinoma,<sup>25</sup> and thus routine cholecystectomy has fallen out of favor. The pattern of calcification may be important in determining the risk of malignancy, as patients with selective mucosal calcification or incomplete calcification of the gallbladder wall appear to be at higher risk than those with complete gallbladder wall calcification.<sup>26,27</sup> Thus, it is reasonable to reserve routine cholecystectomy for symptomatic patients and those with incomplete calcification. As cholecystectomy is a low-risk procedure and even minimal risk of harboring an aggressive malignancy may be unacceptable, surgery can also be

considered in low surgical risk patients with asymptomatic complete gallbladder calcification.

## **STAGES 0 AND I (TIS-T1, N0, M0)**

For Tis (carcinoma in situ) and T1a (cancer that invades the lamina propria but does not extend into the muscularis) lesions, the available retrospective data suggest that simple cholecystectomy is sufficient therapy in most cases, with a cure rate approaching 100%. These lesions are most frequently detected on pathological examination of gallbladders removed for presumed benign disease. Patients diagnosed with gallbladder cancer in this manner should undergo formal imaging-based staging, and the cholecystectomy specimen should be carefully examined to ensure that all margins are negative for cancer. Patients with imaging studies that reveal no evidence of residual or metastatic gallbladder cancer and are found to have a cystic duct margin that is positive for cancer should undergo reexploration with resection to a negative margin, which may involve common duct excision and hepaticojejunostomy. In contrast, patients with negative margins and negative imaging studies who undergo no additional treatment for their gallbladder cancer have excellent outcomes that are unlikely to be improved by radical surgery.<sup>28</sup>

The management of T1b (cancer that invades the muscularis but does not extend into the perimuscular connective tissues) lesions has been controversial. In published series, the 5-year survival rate for patients with T1b gallbladder cancer having undergone radical resection averages 87.5%, whereas it averages only 61.3% in patients having undergone simple cholecystectomy alone.<sup>29</sup> Further, a recently published decision analysis suggests that radical surgery (described later for stage II cancers) is associated with improved survival compared to that associated with simple cholecystectomy alone in most patients with T1b gallbladder cancer.<sup>29</sup> Therefore, we treat patients with T1b gallbladder cancer in the same way we treat patients with T2 gallbladder cancer.

## **STAGE II (T2, N0, M0)**

Patients found to have a T2 (cancer invasion into the perimuscular connective tissues of the gallbladder) lesion in their cholecystectomy specimen following

surgery for presumed benign disease should undergo staging (as described earlier), and in the absence of contraindications, radical resection. Simple cholecystectomy is performed using a subserosal dissection plane, as the serosa of the gallbladder is continuous with Glisson's capsule of the liver and thus there is no serosa between the gallbladder and the gallbladder fossa of the liver. Hence simple cholecystectomy may leave positive margins in the gallbladder fossa. Indeed, reexploration reveals residual tumor in 40% to 76% of these cases.<sup>30-33</sup> In addition, the probability of regional lymph node metastasis in patients with T2 gallbladder cancer has been reported to range from 28% to 63%.<sup>30-33</sup> These findings provide rationale for performing reexploration with liver resection and portal lymphadenectomy. There is convincing, albeit retrospective, evidence that such radical surgery is associated with improved survival for patients with T2 gallbladder cancer.<sup>30-37</sup>

### **STAGE III (T3, N0-1, M0 OR T1-3, N1, M0)**

A role for aggressive surgical resection for some stage III gallbladder cancers has been receiving increasing recognition. This stage includes T3 lesions (locally advanced cancers that perforate the gallbladder serosa or directly invade the liver and/or one adjacent organ) and T1 to T3 lesions associated with regional lymph node metastasis. Some have advocated neoadjuvant chemotherapy or neoadjuvant chemoradiation for this group of patients in order to evaluate the biology of disease and better select patient for surgery.

Surgery for patients with T3 lesions requires careful planning and must be tailored to individual patients. For some patients with liver invasion, hepatic resections encompassing segments 4b and 5 may be sufficient. However, because the gallbladder fossa bridges both right and left hemilivers, and due to the proximity of the cystic plate to the inflow of the right liver, extended right hepatectomy is often required. Adjacent involved structures, such as the hepatic flexure of the colon, should be resected en bloc. Long-term survival rates ranging from 15% to 63% have been reported from some centers to be associated with these extended procedures for T3 lesions.<sup>30-37</sup>

While the outcome for patients with lymph node metastases in the porta hepatis (N1) is considerably worse than for patients without uninvolved nodes (N0), the surgical approach is generally the same. The only possible exception would be the exceedingly unusual circumstance where a patient

with a T1a tumor is diagnosed with N1 disease in the absence of distant metastases. In such a scenario regional lymphadenectomy would be required.

## **STAGE IV (T4 OR N2 OR M1)**

Stage IVA (invasion of the main portal vein, hepatic artery, multiple extrahepatic organs) and stage IVB (N2 and/or distant metastasis) disease is generally considered unresectable. Reports of radical procedures involving resection of the main portal vein and/or common hepatic artery exist, but these procedures are associated with increased morbidity and mortality rates without any proven survival benefit. The outcome of patients with multiple regional lymph nodal metastases (N2 disease) is similar to patients with M1 disease, and these patients are not thought to benefit from resection.

There is no evidence that debulking cholecystectomy provides any therapeutic or palliative benefit.

## **Surgical Technique**

The surgical approach depends both on the stage of disease (as outlined above) as well as the clinical presentation. There are three common scenarios in which gallbladder cancer is discovered: (1) it can be found on pathologic review of a cholecystectomy performed for presumed benign disease; (2) it can be suspected or diagnosed preoperatively, either resulting from a workup for symptoms attributable to the tumor or found incidentally; or (3) it can be discovered intraoperatively, often on exploration for presumed cholecystitis. Specific considerations for each clinical scenario will be discussed separately.

## **GALLBLADDER CANCER DIAGNOSED AFTER CHOLECYSTECTOMY**

When gallbladder cancer is diagnosed after a previous cholecystectomy, the pathology report, the operative report, and any imaging obtained prior to the cholecystectomy should be thoroughly reviewed. In addition to depth of penetration and margin status, particularly that of the cystic duct, the pathology report can provide information on tumor location. Similarly, pre-cholecystectomy imaging can provide information on tumor location as well as possible liver or nodal involvement. Knowing the tumor location (ie, neck,

body, or fundus; abutting liver, or on the side of gallbladder away from liver) may help in operative planning and in the interpretation of the operative findings on reexploration. After completing the staging evaluation as above, patients with T1b-T3 tumors are prepared for reoperation. Given the propensity of gallbladder cancer to seed wound sites, reexcision of all surgical wounds, including laparoscopic port sites, has been recommended. However, port site metastasis is usually associated with other peritoneal metastases and excision of port sites has not been proven beneficial.<sup>38</sup>

The operative report from the prior cholecystectomy and/or discussion with the surgeon can elicit findings suggestive of disseminated disease within the abdomen. In the absence of such findings, a diagnostic laparoscopy is unlikely to be beneficial in this setting.

We generally use an extended right subcostal incision that starts in the upper midline below the xiphoid and curves to a form a line subcostally on the right side that can extend as far as a point midway between the inferior costal margin and anterior superior iliac spine if necessary. We first conduct a thorough examination for metastases. Often, hilar and celiac lymph nodes can be palpated before opening the entirety of the incision. The liver and peritoneal surfaces are also inspected.

The scope of the operation then performed is similar to that described by Glenn and Hays in the 1950s, which entailed resection of the gallbladder fossa of the liver as well as a regional lymphadenectomy of the hepatoduodenal ligament (Fig. 65-3).<sup>39</sup> We typically will perform the lymphadenectomy first. The hilar lymph node dissection proceeds similarly to that described below for perihilar cholangiocarcinoma, with the notable exception being that the bile duct is not routinely resected and is instead skeletonized along with the portal vein and hepatic artery. Some authors have advocated division of the bile duct, particularly as this facilitates the nodal dissection. While it is true that this makes the lymphadenectomy easier, it is associated with greater morbidity without improving nodal yield or survival.<sup>35,37,40,41</sup> As with perihilar carcinoma, on performing the Kocher maneuver and initiating the hilar dissection, retropancreatic, celiac, periaortic, and pericaval lymph nodes can be inspected and palpated. Hard or enlarged nodes are sampled and subjected to frozen-section analysis. If these lymph nodes are positive for metastases, M1 disease is present and radical resection is aborted.

**FIGURE 65-3** Radical resection of gallbladder cancer. This illustration depicts the operative field after radical cholecystectomy has been performed. The hatched line denotes the regions included in the lymphadenectomy.

In the reoperative setting it is not uncommon for fibrosis to be encountered in the porta hepatis. It may be difficult to differentiate fibrosis from tumor. Information gleaned from review of the pathology report and the pre-cholecystectomy imaging (eg, tumor location and cystic duct margin status) may aid in this assessment. If invasion of the common duct is suspected, the extrahepatic biliary system can be resected from the superior border of the duodenum to just below the bifurcation. Common duct resection may also facilitate resection of bulky nodal disease in the hepatoduodenal ligament. The CBD is clamped and transected at the superior border of the duodenum. Similarly, the common hepatic duct is transected near its bifurcation. We take care to minimize spillage of bile that may contain cancer cells. The distal bile duct is oversewn with a slowly absorbable monofilament suture such as polydioxanone (PDS). The proximal bile duct is reconstructed with a Roux-en-Y hepaticojejunostomy as described below. If invasion of the right inflow (right portal vein or right hepatic artery) is found, an extended right

hepatectomy is performed. We consider invasion of the main portal vein or proper/common hepatic artery to be unresectable and do not perform major vascular resection and reconstruction for advanced gallbladder cancer at our institution.

We then proceed to the liver resection. The gallbladder fossa of liver needs to be resected with at least a 2-cm margin. Although a nonanatomic liver resection can be performed, we favor a segmental resection of liver segments 4b and 5, which may be associated with less intraoperative bleeding.<sup>42</sup> The basic conduct of a liver resection is discussed elsewhere; however, some points bear mentioning. Intraoperative US is usually performed and may help in providing information on the intrahepatic vascular anatomy as well as occult metastatic disease. The segmental portal pedicles are usually controlled within the liver parenchyma. As the middle hepatic vein is located directly anterior to the gallbladder fossa, separating segments 4b and 5, care must be taken to avoid bleeding from the vein and its branches. The base of the gallbladder fossa is in close proximity to the porta hepatis, and precaution should be given at the end of the liver resection when these structures are approached. In particular, injury to the right anterior portal pedicle and the portal pedicle of segment 8 within the liver should be avoided. The routine use of more extended liver resections has not been proven to be of benefit.<sup>40</sup>

## **GALLBLADDER CANCER SUSPECTED OR DIAGNOSED PREOPERATIVELY**

For patients suspected of having resectable gallbladder cancer, the approach is similar. In this setting, we begin surgical exploration with laparoscopy, as even with a complete radiologic staging workup disseminated disease is occasionally found, and in these cases laparotomy can be spared.<sup>43</sup> The degree of suspicion for gallbladder cancer beyond T1a must be determined preoperatively. The approach for polypoid lesions, which generally do not harbor malignancy, is described above. For masses with features concerning for malignancy, we do not perform laparoscopic cholecystectomy because of the risk for gallbladder perforation and tumor spillage. In these cases extended cholecystectomy is usually performed as the initial procedure. In some cases, frozen-section analysis may be used either prior to performing the extended cholecystectomy or after an extended cholecystectomy but prior

to the lymphadenectomy. Although determining depth of cancer invasion can be difficult on frozen sections, these grossly apparent cancers are likely to be at least T1b. For masses with invasion beyond the gallbladder, intraoperative diagnosis is not needed. It should be noted, however, that rarely benign conditions, in particular xanthogranulomatous cholecystitis, can mimic this condition. In the case of suspected resectable gallbladder cancer with invasion beyond the gallbladder (T3 tumors), extended liver resections and/or en bloc resection of adjacent organs may be required. Gallbladder cancers presenting with obstructive jaundice due to involvement of the bile duct are typically very advanced tumors. A resection with curative intent can rarely be performed and even when performed, long-term survival is rare.<sup>44</sup>

## **GALLBLADDER CANCER DIAGNOSED INTRAOPERATIVELY**

In cases where gallbladder cancer is diagnosed intraoperatively but was not suspected preoperatively, a thorough inspection of the liver and peritoneum for metastatic disease should be performed. If cancer is discovered during an open procedure, the porta hepatis and celiac origin should be palpated for nodal involvement. If extensive dissection has not begun, it is appropriate to close the patient and complete the radiologic staging exam. Similarly, if the gallbladder has been completely resected and frozen section reveals cancer, it is likely wise to terminate the operation so as to complete staging and consent the patient prior to performing radical resection. In some cases, gallbladder cancer may be discovered late in the procedure when difficulty is encountered in attempting to remove the gallbladder from the gallbladder fossa of the liver. In this circumstance, if expertise is available, it may be appropriate to perform an extended cholecystectomy and proceed to lymphadenectomy if frozen section confirms gallbladder cancer.

## **Adjuvant Therapies**

Adjuvant chemoradiotherapy is commonly administered after resection of gallbladder cancers. External beam or intraoperative radiation therapy alone or in combination with 5-fluorouracil (5-FU) has been associated with diminished rates of local recurrence. Recently results, of the phase III multicenter **BILCAP trial** from the United Kingdom, were reported in

abstract form. This trial randomized 447 patients with gallbladder (18%) and biliary cancer (19% intrahepatic, 28% perihilar, 35% distal) to capecitabine or observation following complete surgical resection. Although in the intention to treat analysis, the benefit in median overall survival for capecitabine did not reach significance (51 months versus 36 months,  $p = 0.097$ ), the result was significant in the per protocol analysis (53 months versus 36 months,  $p = 0.028$ ).<sup>45</sup> Subgroup analysis from an older phase III trial randomizing 508 patients with pancreaticobiliary cancer (28% gallbladder cancer and 27% cholangiocarcinoma) to adjuvant treatment with fluorouracil and mitomycin C or observation showed improved survival with adjuvant treatment for patients with gallbladder cancer but not cholangiocarcinoma.<sup>46</sup>

## Treatment of Unresectable or Metastatic Disease

Of the several approaches that have been applied in patients with advanced gallbladder cancer, the only regimen supported by level one evidence is the combination of gemcitabine plus cisplatin. Data from a multicenter randomized controlled trial (**Advanced Biliary Cancer (ABC)-02 trial**) published in 2010 of patients with locally advanced or metastatic biliary tract cancer (of whom ~36% had gallbladder cancer) demonstrated that the combination of gemcitabine plus cisplatin is associated with improved overall and progression-free survival compared to gemcitabine alone.<sup>47</sup> As such, this gemcitabine-cisplatin combination represents the current standard treatment option for patients with advanced biliary tract cancers, including gallbladder cancer.<sup>11</sup> It should also be noted that based on the impressive results found for colorectal cancer with defective mismatch repair, patients with other solid tumors harboring defective mismatch repair were examined for response to the anti-PD-1 antibody pembrolizumab. In a series of 86 patients, including 4 with cholangiocarcinoma, responses were seen regardless of the cancers' tissue of origin.<sup>48</sup> Pembrolizumab is now approved for the treatment of patients with all metastatic and unresectable solid tumors having defective mismatch repair who have progressed through prior therapy and for whom there are no satisfactory treatment alternatives. Palliation of biliary obstruction, which can be required for advanced gallbladder cancer (Figs 65-4 and 65-5), is discussed below.

**FIGURE 65-4** CT scan of advanced gallbladder cancer. The image demonstrates an advanced gallbladder cancer with extensive liver invasion. A stent has been placed for palliation of obstructive jaundice.

**FIGURE 65-5** Palliation of gallbladder cancer. This radiograph depicts a Wallstent that has been placed for palliation of obstructive jaundice in a patient with advanced gallbladder cancer.

## Outcomes

Data derived from the National Cancer Database support the nihilistic view traditionally associated with gallbladder cancer.<sup>49</sup> In these population-based data, 5-year survival rates for patients with T1N0, T2N0, and T3N0 (or node-positive) disease are 39%, 15%, and 5%, respectively.

However, contemporary surgical series suggest that substantially improved outcomes can be achieved by the application of surgical resection of gallbladder cancers.<sup>31–37</sup> In these reports, 5-year survival rates following

resection of T1 lesions range from 85% to 100%. With radical resection of T2, T3, and T4 lesions, reported 5-year postoperative survival rates range from 41% to 90%, 15% to 63%, and 2% to 25%, respectively. Radical resection of node-positive disease has been reported to be associated with 5-year survival in as high as 60% of patients, although some reported series contained no patients who survived 2 or more years among those with lymph node metastasis.<sup>30–37</sup>

Reported morbidity and mortality rates associated with resection of gallbladder cancers range from 5% to 54% and from 0% to 21%, respectively. In general, the highest morbidity and mortality rates are associated with series describing more extensive resections.

The best reported outcomes among patients with unresectable biliary tract cancers are those from the **ABC-02 trial**. The median overall survival among patients treated with the combination of gemcitabine and cisplatin was 11.7 months, whereas it was 8.1 months in those treated with gemcitabine alone.<sup>47</sup>

## CHOLANGIOCARCINOMA

### Epidemiology

In this discussion, the term *cholangiocarcinoma* is used to denote cancers with cholangiocyte (ie, biliary) differentiation arising in the liver or biliary tree, exclusive of the ampulla of Vater and gallbladder. Cholangiocarcinomas are classified into three groups according to their anatomical location: (1) intrahepatic (iCCA, 10% of cases), (2) perihilar (pCCA, 50% of cases), and (3) distal (dCCA, 40% of cases). pCCA is defined as lesions proximal to the cystic duct up to and including lesions involving the second-degree bile ducts. Bile duct tumors involving the hepatic duct bifurcation have historically been known as *Klatskin tumors*. This classification is helpful in terms of the differing clinical presentation and management for these three tumors, and there is now increasing consensus that these are three distinct entities in terms of epidemiology and pathobiology.

Approximately 6000 new cases of cholangiocarcinoma are diagnosed annually in the United States.<sup>1</sup> Most patients are diagnosed in the fifth through the seventh decades of life. Unlike gallbladder cancer, for which

there is a clear female predominance, the incidence of bile duct cancer is slightly higher in males than in females.

Although most patients diagnosed with cholangiocarcinoma have no identifiable predisposing factors, several conditions clearly increase the risk of developing this cancer (Table 65-3). In Western countries, PSC is the most important risk factor; indeed, approximately 30% of cases of cholangiocarcinoma in the West are diagnosed in patients with PSC. Among patients with PSC, the estimated lifetime incidence of cholangiocarcinoma ranges from 5% to 10%, with approximately 50% of these cases being diagnosed within 24 months of the diagnosis of PSC. In addition, cholangiocarcinoma tends to be diagnosed at an earlier age (mean age in fourth decade of life) in patients with PSC than in the general population (mean age in seventh decade).<sup>23,50</sup>

**TABLE 65-3: RISK FACTORS FOR BILE DUCT CANCER**

Primary sclerosing cholangitis  
Liver flukes infestation (*Opisthorchis viverrini* and *Clonorchis sinensis*)  
Choledochal cysts  
Caroli disease  
Hepatolithiasis  
Chemicals (eg, Thorotrast and dioxin)  
Hepatitis C  
Lynch syndrome II  
Bile duct adenoma and multiple biliary papillomatosis

---

In Asian countries, infestation with the liver flukes *Opisthorchis viverrini* or *Clonorchis sinensis* and hepatolithiasis are important risk factors for cholangiocarcinoma. Cirrhosis and hepatitis B or C viral infection have recently been recognized as important etiologic factors, especially for intrahepatic cases. Other risk factors include choledochal cysts, Caroli disease, and exposure to the radiological contrast agent Thorotrast. The management of choledochal cysts in terms of prevention of cholangiocarcinoma is discussed elsewhere in this book. Increased risk has been reported for workers in the auto, rubber, chemical, and wood-finishing

industries. Two genetic conditions (Lynch syndrome II and multiple biliary papillomatosis) have been identified as increasing the risk of developing bile duct cancer. Obesity and metabolic syndrome are reported as risk factors, particularly for intrahepatic cholangiocarcinoma.

## Pathogenesis and Pathology

While there are several similarities in the pathogenesis and pathology of iCCA, pCCA, and dCCA, there are also notable differences. Recent genetic analyses have illustrated some of these distinctions. iCCA appears most dissimilar as compared to pCCA and dCCA. Genetic analyses comparing iCCAs to the other two types show that *ERBB2/HER2* is less frequently altered in iCCAs, whereas genes of the FGF pathway are more frequently altered. *SMAD4* may also be less frequently altered in iCCA. Alterations in *K-ras*, *p53* and *P16INK4A* are prevalent in all cholangiocarcinomas.<sup>9,10,51</sup> Alterations in chromatin remodeling genes such as *ARID1A* is common in iCCA and likely the other two types as well.<sup>9,51,52</sup> Perhaps the most notable genetic difference between iCCAs and the other types involves mutations in *isocitrate dehydrogenase 1* and *2 (IDH1/2)*, which occur in approximately 20% of iCCAs and are generally not found in other types of cholangiocarcinomas.<sup>9,51–53</sup> The pattern of mutations in cholangiocarcinomas associated with liver flukes also appears different from sporadic tumors.<sup>54</sup>

Even the cell of origin may differ between iCCAs and the other types of cholangiocarcinoma. While it was previously suspected that all cholangiocarcinomas result from the transformation of cells of bile duct epithelium (cholangiocytes), it has recently been shown that this may not always be the case for iCCA. Liver cells (hepatocytes, hepatoblasts, and hepatic progenitor cells) can give rise to iCCA.<sup>55–57</sup> A common cell of origin for iCCA and hepatocellular carcinoma (HCC) may explain the fact that many of the same etiologic factors are shared between these tumors and may also justify the fact that these tumors are often treated similarly. Further supporting the contention that iCCAs can originate from liver progenitor cells, it was recently shown that mutant *IDH1/2* blocks liver progenitor cells from undergoing hepatocyte differentiation and promotes biliary differentiation and transformation to iCCA.<sup>58</sup>

Greater than 90% of cholangiocarcinomas are adenocarcinomas. Other

cancer types include squamous cell carcinoma, small cell carcinoma, and sarcomas.

## **Clinical Presentation and Diagnosis**

iCCAs can present with nonspecific symptoms, such as abdominal pain, anorexia, weight loss, and malaise. Another mode of presentation for these cancers is the detection of an asymptomatic intrahepatic mass on imaging studies. The most common presentation of pCCA and dCCA (~90%) is painless jaundice. Other manifestations of biliary obstruction, such as acholic stools, dark urine, and pruritis, are also prevalent. It should be noted that in cases of pCCA without the obstruction of biliary flow from all segments of the liver, jaundice may not be present. Even a small, well-vascularized portion of the liver can maintain a normal bilirubin, especially with the resultant atrophy of the obstructed portions of the liver and consequent hypertrophy of the drained portions. Jaundice can also be intermittent in the case of papillary tumors intermittently obstructing the bile duct through a ball valve mechanism. Abdominal pain, fatigue, malaise, and weight loss can occur with advanced disease. Signs of advanced cholangiocarcinomas include right upper quadrant abdominal tenderness, hepatomegaly (more likely with iCCA), and a palpable gallbladder (pCCA and dCCA). Cholangitis is unusual in the absence of prior biliary tract instrumentation.

The differential diagnosis for iCCA (liver mass) is usually HCC and metastatic tumors. The differential diagnosis for pCCA and dCCA includes benign biliary strictures due to conditions such as PSC, choledocholithiasis, Mirizzi syndrome, and postoperative strictures. For strictures of the mid-bile duct, gallbladder cancer must be considered, as cholangiocarcinomas arising at the level of the cystic duct insertion are uncommon. For dCCA, often the distinction between this tumor and other periampullary (ampullary, pancreatic, and duodenal) neoplasms may be unclear preoperatively.

In patients with iCCA or pCCA incompletely obstructing bile flow, laboratory studies may reveal an increased alkaline phosphatase level in the setting of normal bilirubin levels. In patients with pCCA and dCCA, laboratory tests are usually consistent with the presence of obstructive jaundice. Tumor markers (eg, CEA, CA 19-9, and CEA in combination with CA 19-9) may have utility in surveillance of patients with PSC and may be helpful in following the course of disease; however, their sensitivities and

specificities are too low for them to be applicable to screening or diagnosis in the general population. Elevated serum immunoglobulin G4 (IgG4) has been advocated to assess for lymphoplasmacytic sclerosing cholangitis, also known as IgG4-related cholangiopathy, an important mimic of malignant bile duct stricture; however, IgG4 can also be elevated, sometimes quite markedly, in cholangiocarcinoma.<sup>59</sup>

Transabdominal US is a useful first study for evaluating obstructive jaundice. It can reveal dilation of the biliary tree. As the source of obstruction should be distal to biliary dilation, the location of the dilation (ie, confined to a portion of the liver, intrahepatic but not extrahepatic, or intrahepatic and extrahepatic) may help focus investigation on the location of the obstruction. Biliary dilation in the absence of a benign etiology such as choledocholithiasis suggests a possible biliary or, in the case of a distal obstruction, periampullary malignancy. Transabdominal US can also detect a liver mass incidentally or when used for screening in patient at risk for primary liver cancer (eg, cirrhotics and patients with chronic hepatitis B or C). US findings suspicious for cholangiocarcinoma typically require contrast-enhanced cross-sectional imaging (CT or MRI) for better characterization and surgical planning.

For iCCA, CT and MRI can both identify a mass and assess for vascular invasion. They may also identify other liver lesions, portal lymphadenopathy, and evidence of distant metastasis. iCCAs typically appear as a hypodense hepatic mass on unenhanced images with the development of peripheral rim enhancement in the arterial phase and progressive hyperattenuation on venous and delayed phases (Fig 65-6). MRI typically also shows the mass to be T2 hyperintense. MRI is not routinely preferred over CT but may provide improved detection and characterization of liver masses in patients with underlying cirrhosis.

**FIGURE 65-6** CT scan of intrahepatic cholangiocarcinoma. The image shows a hyperattenuating lesion in Segment 4 of the liver.

For pCCA and dCCA, CT and MRI can identify the level of biliary obstruction, vascular involvement, and hepatic atrophy. In pCCA, there are typically dilated intrahepatic bile ducts, which can be unilateral or bilateral depending on the site of obstruction with a normal or collapsed gallbladder (unless the obstruction occludes the cystic duct) and a normal-caliber distal CBD. In dCCA, the entire intra- and extrahepatic biliary tree and the gallbladder are dilated. The presence or absence of a mass in the head of the pancreas may help in the differentiation from pancreas cancer. In addition to offering information on the site of the primary lesion, CT and MRI offer valuable information necessary for staging and planning of therapies, including the presence or absence of local vascular invasion, regional lymphadenopathy, distant metastasis, and liver atrophy. Longstanding unilateral bile duct obstruction typically results in atrophy of the affected hemiliver together with hypertrophy of the unaffected hemiliver (atrophy-hypertrophy complex). Absence of the atrophy-hypertrophy complex can suggest vascular encasement by tumor. MRI is not routinely indicated over CT but may provide greater sensitivity in detection of masses associated with pCCA and dCCA and provides more precise delineation of the biliary anatomy.

More invasive studies are sometimes required in the preoperative evaluation of patients with cholangiocarcinoma. For iCCA, since a metastatic tumor to the liver often can have the same appearance and cannot even be excluded by a biopsy showing adenocarcinoma, upper endoscopy and colonoscopy can be considered to diagnose an occult primary gastrointestinal tumor. The cross-sectional imaging should also be examined closely for other tumors, such as pancreas cancer. For dCCA, upper endoscopy can help exclude another source of biliary obstruction such as duodenal or ampullary tumors.

Direct cholangiography is not routinely indicated preoperatively; however, many patients will have had endoscopic retrograde cholangiopancreatography (ERCP) and/or percutaneous transhepatic cholangiography (PTC) prior to referral. It should be noted that in many centers, particularly in Japan, detailed cholangiography is viewed as an essential part of preoperative planning for pCCA (Fig. 65-8, left). This practice is not widely shared in the United States. Direct cholangiography is utilized when biliary drainage or a histologic diagnosis is desired. As some reports suggest that MRCP when applied to patients with cholangiocarcinoma offers information equivalent to that offered by CT scanning and direct cholangiography combined (Fig. 65-8, right), MRCP has been supplanting traditional cholangiography in the evaluation of patients with suspected cholangiocarcinoma in many centers. Unlike direct cholangiography, MRCP is noninvasive and does not require instrumentation or the injection of contrast material in the biliary ductal system. This may be particularly important in pCCA when resection cannot be accomplished (see discussion of palliation for malignant biliary obstruction below).

**FIGURE 65-8** Percutaneous transhepatic cholangiography (PTC) and magnetic resonance cholangiography (MRCP) of hilar cholangiocarcinoma. The images depict a stricture at the confluence of the hepatic ducts in a

patient with a Klatskin tumor. In the left image, the biliary system is accessed through the right liver with lack of opacification of the common hepatic duct or the left biliary system. A stent had been placed by ERCP, but it failed to cross the stricture. In the right images, the MRCP shows the same stricture as seen by dilation of both the right and left intrahepatic biliary ducts with a non-dilated extrahepatic biliary system along with lack of visualization of the biliary confluence.

Similar to gallbladder cancer, PET scanning for the staging of cholangiocarcinoma is not universally accepted;<sup>11,60</sup> however, some studies show that it can identify occult metastases to regional lymph nodes and distant sites. PET is most useful in the evaluation of indeterminate findings on cross-sectional imaging.

If surgical exploration is planned, a preoperative attempt at histologic diagnosis is not indicated. This is particularly true with pCCA and dCCA, where obtaining a tissue diagnosis is notoriously difficult. Brushings obtained by ERCP or PTC are only 15% to 68% sensitive.<sup>61</sup> A mass is not often detected on cross-sectional imaging precluding percutaneous fine needle aspiration (FNA). EUS-FNA may have improved sensitivity (approaching 80%) compared to brushings, and is feasible in proximal as well as distal tumors.<sup>62</sup> It should also be noted that for patients with pCCA in whom transplantation is considered, due to the possibility of seeding and the need for immunosuppression, a transperitoneal biopsy attempt is considered an exclusion criterion. It bears mentioning that while resection of presumed malignant hilar or distal bile duct obstruction without a preoperative diagnosis of cancer will occasionally yield a benign diagnosis, the rate of such occurrences is low (~10%).<sup>63,64</sup>

A particularly challenging situation can arise in patients with PSC, 20% to 50% of whom will develop a benign dominant biliary stricture. These dominant strictures can be morphologically indistinguishable from cholangiocarcinomas on cholangiography. Cytological examination of brushings obtained during ERCP is the most common modality used for the diagnosis of cholangiocarcinoma in this setting; however, as in patients without PSC, the sensitivity of this modality (40%-80%) is poor.<sup>65</sup> EUS-FNA, which is the most accurate modality for making a diagnosis of cholangiocarcinoma, should be applied in patients with equivocal or negative brush cytological findings if clinical suspicion of cholangiocarcinoma in a

dominant stricture is high.<sup>62</sup>

## Morphological Classification, Anatomic Classification, and Staging

iCCAs are typically classified as mass-forming, periductal infiltrating, and intraductal based on their morphological pattern of growth. The mass-forming type accounts for almost 90% of cases.<sup>66</sup> pCCAs and dCCAs are morphologically classified as sclerosing, nodular, or papillary (analogous to the classification scheme for gallbladder adenocarcinomas). Sclerosing (scirrous) tumors, which comprise over 80% of cholangiocarcinomas, are associated with an intense desmoplastic reaction, tend to be highly invasive, and are associated with low resectability rates. Nodular tumors have the appearance of constricting annular lesions and are also associated with low resectability rates. Often tumors have both nodular and sclerosing features, and thus the term nodular-sclerosing is often used. Papillary tumors are rare (~10% of cases) and present as bulky masses that project into the bile duct lumen. It should be noted that although these tumors tend to spread within the bile duct lumen suggesting diffuse involvement, they often arise from a single well-defined stalk, facilitating resection. Because these lesions tend to cause symptomatic obstructive jaundice relatively early in their progression and because they are typically contained completely within the bile duct, they are associated with higher resectability rates than sclerosing or nodular tumors. Papillary tumors are associated with a more favorable prognosis,<sup>67</sup> and the same may be true of the intraductal type for iCCAs.<sup>68</sup>

The AJCC staging system now contains separate staging systems for iCCA (Table 65-4), pCCA (Table 65-5), and dCCA (Table 65-6).<sup>15</sup> For iCCA, AJCC staging is based on the major prognostic factors: number of tumors, tumor size, vascular invasion, lymph node metastasis, and distant metastasis. For pCCA, the T stage for the AJCC system incorporates both depth of invasion and extent of tumor involvement as a surrogate for resectability (see discussion of Memorial Sloan-Kettering Cancer Center [MSKCC] anatomical classification below). Similarly for dCCA, the T stage incorporates depth of invasion (now measured in mm in the AJCC eighth edition), with T4 tumors representing tumors that are unresectable due to major vascular invasion. AJCC staging for pCCA and dCCA also accounts

for metastasis to regional lymph node and distant sites.

**TABLE 65-4: TNM STAGING OF INTRAHEPATIC BILE DUCT CANCER**

Stage 0	Tis	N0	M0

As surgical planning and assessment of resectability are important in the preoperative evaluation of pCCA, additional anatomical classification systems are widely used. The modified Bismuth-Corlette classification scheme stratifies tumors based on the extent of bile duct involvement (Fig. 65-7, top).<sup>69</sup> This system may be useful for surgical planning but does not assess resectability. The MSKCC classification scheme, which takes into account extent of bile duct involvement as well as vascular invasion and hepatic atrophy, may help determine both the resectability for the tumor and the necessary surgical procedure (Fig. 65-7, bottom). Both the Bismuth-Corlette and the MSKCC systems, unlike the AJCC T stage for pCCA, are based on information that can be determined preoperatively from imaging studies and thus are of particular use to surgeons.

**FIGURE 65-7** Bismuth-Corlette classification scheme and the MSKCC staging system for perihilar cholangiocarcinoma. In the Bismuth-Corlette system (top), Type I tumors are located distal to the biliary confluence, Type

II tumors involve the junction of the right and left hepatic ducts, Type III tumors involve the secondary biliary confluence on either the right or the left, and Type IV tumors involve the secondary biliary confluence on both sides. In the MSKCC system (bottom), T1 tumors involve the biliary confluence with or without unilateral extension to second order biliary radicles, T2 tumors also have ipsilateral portal vein involvement and/or ipsilateral hepatic atrophy (not shown), and T3 tumors have bilateral extension to second-order biliary radicles or unilateral extension to a second-order biliary radicle with contralateral portal vein involvement and/or contralateral hepatic atrophy (not shown).

## Surgical Therapy

As is the case for gallbladder cancer, complete surgical extirpation is the only potentially curative therapy for patients with cholangiocarcinoma. Therefore, all fit patients suspected of having resectable cholangiocarcinoma should be offered surgery. Specific issues regarding preoperative treatment and choice of treatment modality are discussed below. Technical issues are then reviewed separately.

### ROLE OF PREOPERATIVE BILIARY DRAINAGE

The utility of preoperative biliary stenting in patients with biliary obstruction from cholangiocarcinoma is controversial. Available retrospective data and one recently reported multicenter randomized controlled trial (**DRainage vs Operation [DROP] trial**)<sup>70</sup> suggest that among patients undergoing pancreaticoduodenectomy for periampullary cancers, routine preoperative biliary stenting is associated with increased perioperative morbidity rates, especially with respect to infectious complications. Therefore, we do not recommend routine preoperative stenting for patients with distal bile duct cancers. Instead, selective application of stenting in patients with obstructive jaundice who experience significant delay until surgery is performed (eg, those undergoing neoadjuvant therapy) is appropriate. Furthermore, as patients with bilirubin >14.6 mg/dL were excluded from the DROP trial, and as profoundly elevated bilirubin can result in end organ dysfunction, the safest approach for these patients is not clear. This experience should not be extrapolated to patients with pCCAs, for whom the relationship between

preoperative stenting and operative outcomes is less clear. Some authors believe stents placed preoperatively make intraoperative assessment of tumor extent more difficult. However, as liver resection is indicated for most patients with pCCA (see below), there is concern about postoperative hepatic insufficiency due to the potentially impaired ability of the remnant liver to regenerate if biliary flow from that segment was obstructed preoperatively. Retrospective data indicate that preoperative biliary drainage may be of benefit prior to extended resections in patients expected to have a small future liver remnant (FLR),<sup>71</sup> but that routine drainage may not be required.<sup>72</sup>

When preoperative drainage is planned for patients with pCCA, a few points bear considering. First, as a potential benefit of drainage is the relief of obstruction in the portion of liver that will need to regenerate after resection, drainage of the FLR as opposed to the liver to be resected is preferred. The selection of what portion of the liver should be resected follows below. Second, it should be kept in mind that the patient may be found to be unresectable on exploration, so drainage should be planned according to the general principles for palliating hilar biliary obstruction discussed below. Notably, drains should be carefully placed without injecting contrast or instrumenting segments of the liver that are not drained, as cholangitis can subsequently develop in those segments. As discussed below, there is controversy over whether this can be effectively accomplished with ERCP as opposed to PTC; however, PTC has other disadvantages (eg, need for external drain, potential injury to liver). The ideal technique for preoperative biliary drainage is currently the subject of a randomized trial (**DRAINAGE trial**).<sup>73</sup> Lastly, when drainage is accomplished via PTC, as biliary obstruction or diversion can be associated with malnutrition and impaired intestinal barrier function, attention should be given internal drainage or replacing bile into the intestine.

## **ASSESSMENT OF RESECTABILITY FOR pCCA**

Resectability for pCCA depends on the ability to maintain a sufficient FLR after surgery. The general principles of liver resection are discussed elsewhere in this textbook, but are worth briefly reviewing here as it pertains to pCCA. After liver resection, the FLR needs to be of sufficient volume to be perfused by the portal vein and hepatic artery, to have outflow through a hepatic vein, and to have biliary drainage. As pCCAs are, by definition,

tumors in the hilus of the liver, while hepatic venous outflow is seldom a concern, maintaining an adequately sized remnant with portal venous and hepatic venous inflow as well as biliary drainage always needs to be considered. Thus, prohibitions to hepatic resection without vascular reconstruction include (1) bilateral invasion of portal vein and/or hepatic artery branches, (2) invasion of the main portal vein and/or hepatic artery, or (3) unilateral involvement of the hepatic vein and/or hepatic artery to the only side of the liver that could otherwise be preserved (ie, opposite side with non-reconstructable bile duct involvement or significant atrophy). Similarly, the side of the liver to be preserved (ie, with no significant atrophy, direct tumor involvement, or inflow issues) needs to be able to have the bile duct resected with a negative margin and reconstructed, thus (4) bilateral hepatic duct involvement to secondary radicles bilaterally and (5) unilateral duct involvement to the secondary radicles with contralateral vessel involvement and/or liver atrophy is considered unresectable. The MSKCC anatomical classification, which is mostly incorporated into the AJCC T stage for pCCA, well illustrates these principles of resectability. It should be noted that as with other major liver resections, in cases where an anticipated resection is expected to leave a small FLR, preoperative portal vein embolization (PVE) of the side of the liver to be resected to induce contralateral hypertrophy can be considered.

## **NEOADJUVANT CHEMORADIO THERAPY AND TRANSPLANTATION VERSUS RESECTION FOR pCCA**

While surgical resection has long been considered the standard of care for fit patients with technically resectable disease, recently neoadjuvant chemoradiotherapy followed by orthotopic liver transplantation (OLT) has become a preferred approach for selected patients in some centers. Initial reports of OLT without neoadjuvant treatment (mainly for technically unresectable patients or patients with underlying liver disease) revealed 5-year survival rates averaging approximately 20% with some reports of long-term survivors, although many of these patients had small tumors discovered incidentally. The University of Nebraska and the Mayo Clinic established an intensive protocol of neoadjuvant treatment followed by OLT for carefully selected and staged patients, and by 2005 were reporting provocative initial results.<sup>74</sup> The protocol consists of external beam radiation followed by

brachytherapy (transcatheter radiation) through catheters placed by ERCP or PTC along with radiosensitizing 5-fluorouracil, followed by chemotherapy (oral capecitabine) continued until the day of transplantation. After the initial radiochemotherapy, patients undergo a staging operation to assess the tumor extent and the presence of metastatic disease. At staging, lymph nodes are biopsied. Patients with nodal or distant metastases are excluded from OLT. By 2009, the United Network for Organ Sharing (UNOS) accepted pCCA as an indication for organ allocation. Subsequent studies have shown encouraging outcomes when this approach has been applied at other centers.<sup>75</sup> There are important difficulties, however, in comparing these results to those obtained with resection. The patients who are offered neoadjuvant chemoradiotherapy followed by OLT are highly selected due to the intensity of this regimen and the stringent criteria applied to potential OLT candidates. Also, as evidence suggests that much of the benefit of this approach may be due to the neoadjuvant treatment rather than OLT,<sup>76</sup> it remains to be seen whether similar results can be obtained with neoadjuvant therapy and surgical resection. Further clinical research in this area is needed. Currently, neoadjuvant radiochemotherapy should be strongly considered for patients with locally advanced pCCA not technically amenable to resection (eg, tumors involving second-order biliary radicles bilaterally) and in patients with underlying liver disease, such as PSC, where the results of resection have been less favorable.<sup>11,77</sup>

## **Surgical Technique**

Resectable iCCAs are treated using standard liver resections, and dCCAs are treated by pancreaticoduodenectomy. These procedures are discussed elsewhere in this textbook. A few points specific to these tumors, however, bear mentioning. First, as staging laparoscopy can identify peritoneal and liver metastases in a significant proportion of patients, its use should be considered for iCCA.<sup>78,79</sup> In contrast, the yield of diagnostic laparoscopy for dCCA in patients staged with contemporary imaging is low.<sup>80</sup> For iCCA, multifocal tumors generally represent metastatic disease, so this is usually a contraindication to resection. Acceptable results for resection of limited multifocal disease in selected patients have been reported. For iCCA, intraabdominal lymph nodes are the most common site of metastatic spread

and are present in up to 75% of patients. Lymph node involvement outside of hilar, periduodenal, and peripancreatic lymph nodes for right liver tumors and outside of inferior phrenic, hilar and gastrohepatic lymph nodes for left sided tumors is considered metastatic and is generally considered a contraindication to surgery. Even lymph node metastasis to the regional lymph nodes portends a poor prognosis, so all grossly enlarged lymph nodes should be sampled and resection considered only in selected cases. As occult regional lymph node metastases are common and represent an important prognostic factor, regional lymph node dissection (as below except with preservation of the bile duct) should be considered;<sup>11,77</sup> however, it is unknown whether this provides any therapeutic benefit.

The remainder of the discussion focuses on our surgical approach to metastatic or resectable pCCA. Reports suggest that 25% to 30% of patients undergoing laparoscopic exploration for cholangiocarcinoma are found to have unresectable disease during laparoscopy, and thus we generally start the operation with a staging laparoscopy.<sup>43</sup> If laparoscopic examination fails to reveal metastasis, we proceed with laparotomy through an extended right subcostal incision that starts in the upper midline below the xiphoid and curves to form a line subcostally on the right side that can extend as far as a point midway between the inferior costal margin and anterior superior iliac spine if necessary. A small portion of the incision can first be opened to assess for celiac lymphadenopathy. The presence of metastasis in non-regional lymph nodes (periaortic, pericaval, superior mesenteric artery, and/or celiac artery) is a contraindication to radical resection, and thus during the early part of the exploration, special attention is given to assessment of these nodes. Enlarged lymph nodes are biopsied and subject to frozen section analysis.

The surgeon must be prepared to perform a liver resection, which is necessary in the vast majority of cases. Liver resection is usually required to obtain a margin-negative resection. Even without vascular involvement, hilar tumors spread longitudinally in or along the bile duct wall, and thus the ability to achieve a bile duct margin-negative resection is often compromised by dividing both the right and left bile ducts outside the liver. In the case of equal involvement of the right and left bile ducts extending proximally from the bifurcation, the extrahepatic portion of the left bile duct is typically longer, as this duct traverses the underside of segment 4 before entering the liver in the umbilical fissure. In this case, a right hepatectomy can usually

increase the distance from tumor to the bile duct margin, which would thus be just outside the left liver to be preserved. Furthermore, hepatectomy increases the chance for a circumferential margin-negative resection, as preservation of the entire liver requires dissecting the tumor off the hilar plate bilaterally and off the caudate posteriorly. It should be noted that again in the case of a tumor with equal distance from the liver along the right and left bile ducts, a right-sided resection may be preferred because the right hepatic artery crosses the bile duct (usually posteriorly) in close proximity to the bifurcation, and thus removing this structure en bloc with the specimen can also increase the chance for a negative circumferential margin. It may be possible to achieve margin-negative resections without hepatectomy for the unusual pCCAs that are completely distal to the bifurcation (Bismuth-Corlette type I), but it should be considered that overall, the best outcomes for resection of pCCA have been reported when liver resection is performed, and that the benefit of liver resection seems to be apparent even in the proportion of patients achieving a microscopically margin-negative resection.<sup>67,81,82</sup>

We next divide the ligamentum teres and take down the falciform ligament from the anterior surface of the liver. The liver is then inspected and palpated to assess for metastases. An US of the liver is performed both to assess for metastases and to confirm the intrahepatic vascular anatomy. We then open the lesser sac and perform a wide Kocher maneuver. The retropancreatic lymph nodes are thus assessed and the porta hepatitis exposed.

The sequence of following steps may vary based on the clinical scenario. Usually at this point, the bile duct is divided just proximal to the duodenum and reflected upward. The distal bile duct is then oversewn with a slowly absorbable monofilament suture such as PDS. In situations where it is suspected the tumor is likely to be unresectable, the surgeon may attempt to lower the hilar plate (see below) and perform some of the dissection of the bile duct from the vessels to make an assessment of resectability prior to dividing the bile duct. With the bile duct transected distally, the fatty tissue containing the lymph nodes is also divided at the level of the duodenum and reflected toward the liver along with the bile duct. The common bile duct and nodal tissue are dissected off the portal vein and hepatic artery extending superiorly (Fig. 65-9). The gallbladder and cystic duct are then taken down from the liver and the cystic artery is divided. The entire extrahepatic biliary

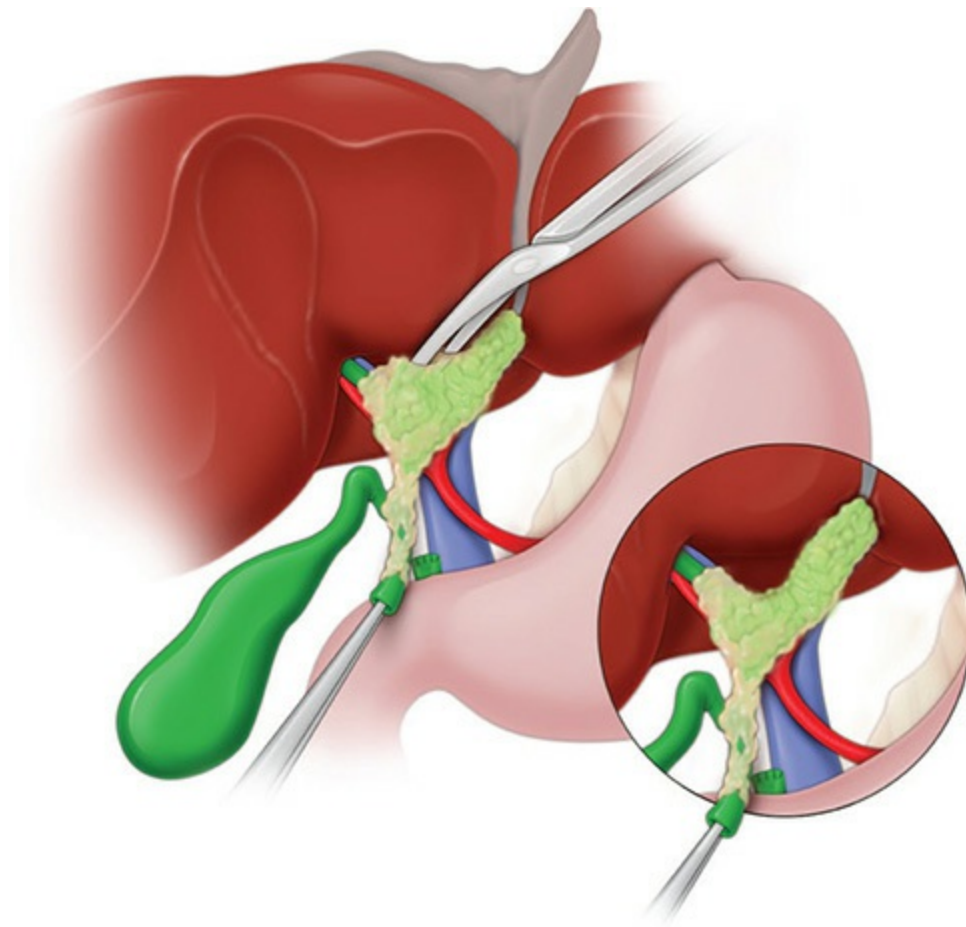

apparatus (common/hepatic bile duct, cystic duct and gallbladder) are then retracted toward the liver and dissection continued superiorly toward the liver, skeletonizing the vessels that will remain.

**FIGURE 65-9** Resection of hilar cholangiocarcinoma. This illustration shows the extrahepatic biliary tree along with the portal lymph nodes being dissected off of the portal vein and hepatic arteries. The dissection proceeds in a cephalad direction following transection of the distal bile duct.

At this point, the hilar plate is lowered by incising the liver capsule at the base of segment 4 and extending this incision between the gallbladder fossa and the umbilical fissure (Fig. 65-10). Dissection is continued between the biliary bifurcation and the liver separating the extrahepatic portions of the right and left ducts extending proximally from the bifurcation. The tumor can then be palpated in an attempt to assess its proximal and distal extent. During this portion of the dissection, a decision about which portion of the liver is to be resected must be made. The principles of such a determination are the same as in the preoperative assessment outlined above. It must be assured

that an adequate length of uninvolved extrahepatic bile duct exists on the side of the liver to remain in order to transect the bile duct with a sufficient margin from the tumor and preserving enough bile duct for reconstruction. Further dissection may be required at this point posterior to the biliary system to assure that the portal vein and hepatic artery to the FLR are free of the tumor.

**FIGURE 65-10** Lowering of hilar plate. The biliary confluence and portal lymphatic tissue are separated from their attachments to the liver capsule at the base of segment 4.

The bile duct on the side of the FLR as well as the portal vein and hepatic artery to the contralateral liver must then be divided (Fig. 65-11). The order in which this is accomplished may vary depending on the circumstance. Often by dividing the bile duct and reflecting the tumor along with the biliary system and nodal tissue toward the side of the liver to be resected, better exposure is obtained for division of the vessels, particularly the portal vein.

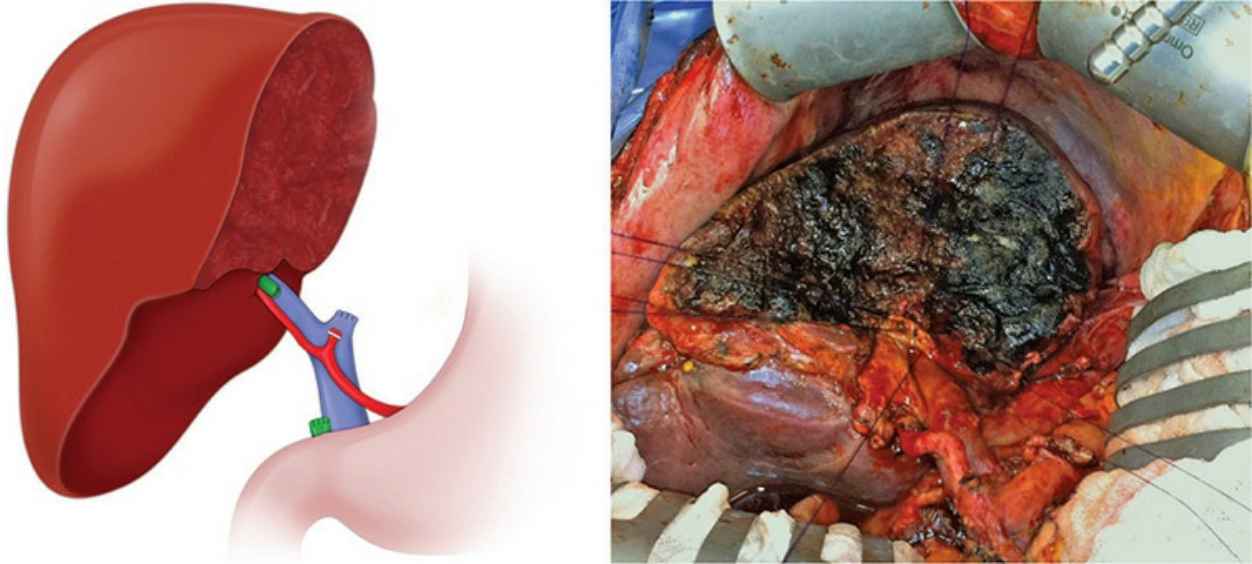

In some situations, the liver can be divided before dividing the bile duct, as splitting the liver facilitates circumferential exposure to the bile duct. Frozen sections of the bile duct are not routinely taken, as they can be falsely negative, and resection of a few extra millimeters of bile duct in the setting of an initial positive margin, even if a negative margin is ultimately achieved, appears to provide little if any benefit.<sup>83</sup> Instead, every attempt is made to resect the bile duct as proximal as possible on the side of the liver to remain. Frozen sections of the margins should be checked in the setting of attempting resection of a pCCA without liver resection, as converting to a liver resection could provide ample additional margin from the tumor in the setting of a positive frozen section on one side.

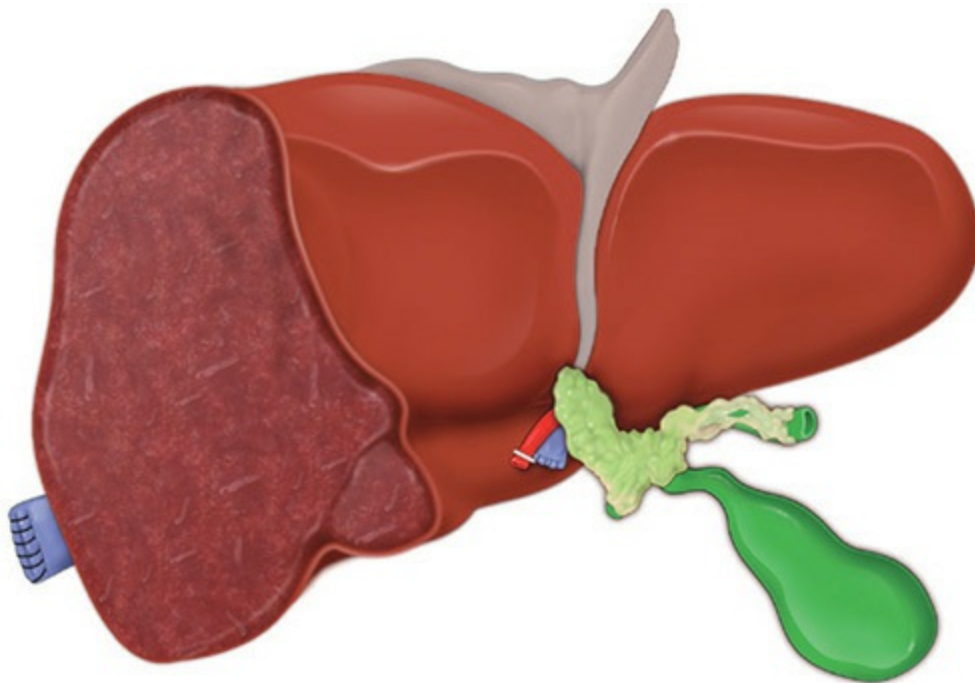

**FIGURE 65-11** Division of the hepatic duct, portal vein, and hepatic artery. The bile duct on the side of the liver to be preserved (right hepatic duct in illustration) as well as the portal vein and hepatic artery on the side of the liver to be preserved (left portal vein and left hepatic artery in illustration) are divided.

Some authors believe that the caudate should be resected in all cases of pCCA, while others believe it can be retained selectively. The argument for routine caudate resection is that in order to preserve the caudate, the tissue between the caudate and the biliary bifurcation/portal hepatitis, including the caudate bile duct, must be divided, thus potentially leaving tumor along with the caudate. If the tumor extends proximally from the bifurcation into the left bile duct, the caudate should be routinely resected, as the caudate bile duct, which usually drains into the left bile duct, may also be involved. The caudate can be resected by first mobilizing the caudate posteriorly off the inferior vena cava (IVC), which entails division of all the caudate veins draining into the IVC, and dividing the attachments of the caudate to the main portal vein and hepatic artery as well as their branches to the FLR. (The main caudate inflow typically comes from the left side.) For a left hepatectomy with caudate resection, the caudate process (the portion of the caudate where it attaches to the right posterior sector of the liver) must be divided, along with the typical division between the right and left hemilivers, during parenchymal transection.

In order to prepare for liver resection, with the vessels and bile duct divided and the biliary/nodal tissue reflected toward the specimen side, a line of parenchymal dissection is then mapped out. The plane can begin in the principle plane of the liver between the right and left hemilivers; however, in the area of the porta hepatis it will stay close to where the bile duct, portal vein, and hepatic artery enter the FLR to achieve the maximal margin (Figs 65-12 and 65-14). The parenchymal dissection (and control of the hepatic vein[s]) do not substantially differ from that described elsewhere in this textbook.

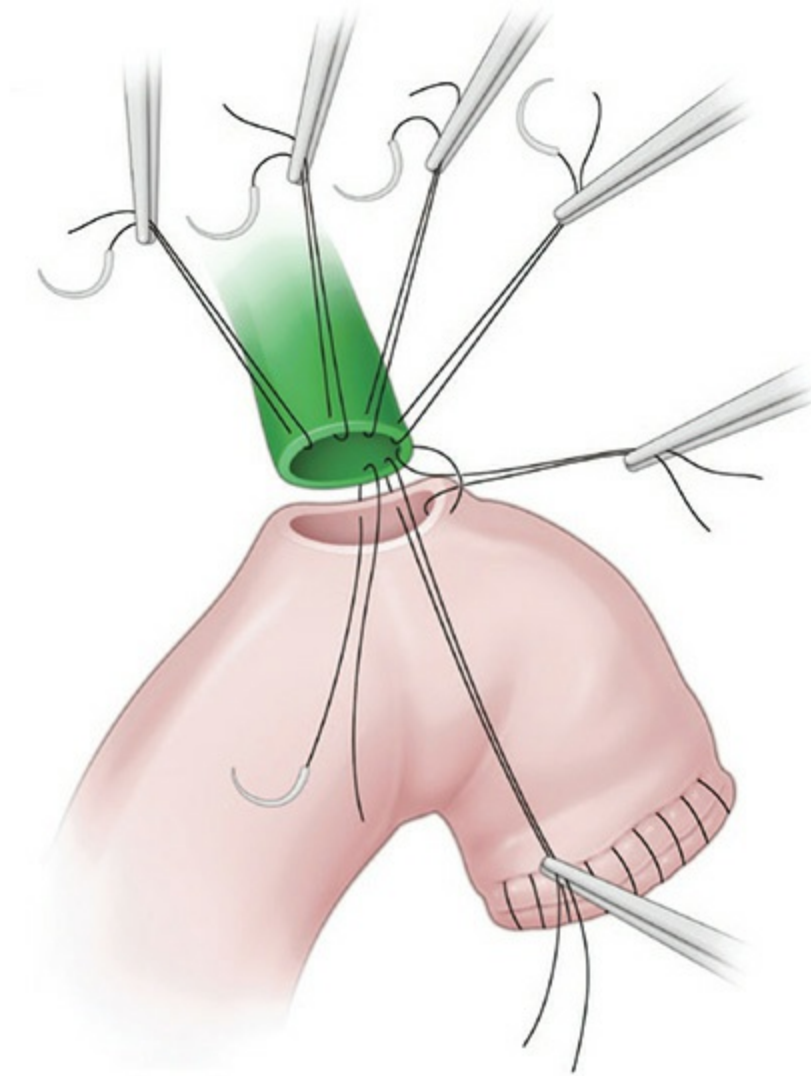

**FIGURE 65-12** Liver after resection of Klatskin tumor with left hepatectomy and caudate resection. The left panel shows an illustration depicting the appearance of the liver and portal structures after resection. The right panel shows an intraoperative photograph of the same. The sutures are placed through the right anterior and right posterior hepatic ducts on the surface of the remnant liver. The arrows mark where the left portal vein and left hepatic arteries were divided.

**FIGURE 65-13** Resection of hilar cholangiocarcinoma. This illustration depicts the resection specimen following removal of the extrahepatic bile

duct en bloc with the left lobe of the liver.

**FIGURE 65-14** Creation of the hepaticojejunostomy. The biliary–enteric anastomoses is performed using the method of Blumgart and Kelley with the anterior row of sutures used to splay open the bile duct while the posterior row of sutures is placed through the bile duct and jejunotomy.

While vascular reconstructions are sometimes used in the setting of vascular involvement during the resection of pCCA in appropriately selected patients, the description of these techniques are beyond the scope of this discussion. In rare cases, cholangiocarcinoma can involve the distal bile extending into the pancreas in addition to involving the biliary bifurcation. Combined liver resections with pancreaticoduodenectomies have been described, but these are morbid procedures.

Biliary reconstruction is accomplished between the remaining bile duct or ducts and a Roux-en-Y loop of jejunum using the technique of Blumgart and Kelley (Fig 65-13).<sup>84</sup> We divide the jejunum just distal to the ligament of Treitz and take the distal divided end retrocolically toward the liver. A single-layer anastomosis is created using 4-0 slowly absorbable monofilament suture such as PDS. The anterior row of sutures is taken full thickness through the bile duct and hung over the retractor to splay open the bile duct. An appropriately sized jejunotomy is created and sutures are taken through the full thickness of both the bile duct and jejunum walls. The anterior row of sutures is then taken through the full thickness of the jejunum before tying and dividing all the sutures (Fig. 65-15). In the case where there is more than one duct to anastomosis (eg, right anterior and posterior sectoral ducts are separated), it is usually easier to approximate the multiple ducts together with sutures through the lateral walls and treat as one as opposed to creating separate anastomoses to the jejunal loop. Intestinal continuity is restored by creating a jejunojejunostomy between the proximal end of the divided jejunum and the Roux loop of jejunum 60 cm distal to the hepaticojejunostomy. We place a Jackson-Pratt drain posterior to the hepaticojejunostomy and attach the end to a bile bag.

**FIGURE 65-15** Completed reconstruction. This illustration depicts the appearance of the remnant liver with the biliary enteric anastomosis at the completion of the operation.

## Adjuvant Therapies

Adjuvant chemotherapy, radiotherapy, or chemoradiotherapy is commonly offered, based on available data. However, unequivocal efficacy data derived

from prospective randomized clinical trials are lacking (see discussion in the section on adjuvant therapies for gallbladder cancer). Similarly, neoadjuvant therapy, associated with anecdotal reports of tumor response sufficient to permit margin-negative resection in patients with advanced cholangiocarcinoma, needs to be studied further.

## **Treatment of Unresectable or Metastatic Disease**

Recently published results of the **ABC-02 trial** (discussed earlier in the section on treatment of unresectable or metastatic gallbladder cancer) indicate that the combination of gemcitabine plus cisplatin should be offered to patients with advanced bile duct cancer.<sup>47</sup> While this trial also included gallbladder and ampullary cancers, nearly 60% of patients who were enrolled in this multicenter phase III trial had locally advanced or metastatic bile duct cancer. Administration of the gemcitabine-cisplatin combination was associated with prolongation of overall and progression-free survival compared to administration of gemcitabine alone. It should be noted that while the magnitude of benefit for this treatment did not appear to differ based on whether patients had iCCA, pCCA, dCCA, gallbladder cancer, or ampullary cancer in the subgroup analysis, in the group of patients with pCCA (and ampullary cancer) the benefit was not statistically significant. Checkpoint inhibitor therapy, specifically pembrolizumab, may be of benefit for metastatic or unresectable cholangiocarcinoma with defective mismatch repair (discussed earlier in the section on treatment of unresectable or metastatic gallbladder cancer).

While chemotherapy is the only treatment for metastatic and unresectable cholangiocarcinoma validated by level one evidence, liver-directed therapies are increasingly being used for liver-only iCCA. This approach is extrapolated from HCC and derives from the possible common origin of iCCA and HCC as well as increasing data reporting favorable results when applied to iCCA. Reports of transcatheter arterial chemoembolization, (TACE) transcatheter arterial radioembolization (TARE), and radiofrequency ablation (RFA) show that these treatments are safe and possibly efficacious. As in HCC, underlying liver disease may be the only limitation to surgical resection, making alternative locoregional therapies attractive.

## Outcomes

Fewer than 50% of patients diagnosed with perihilar cholangiocarcinoma are able to undergo curative resection. Reported 5-year postoperative survival rates for patients with these cancers are highly variable in modern series; they range from approximately 10% to 50%.<sup>77,85</sup> In general, the highest survival rates are associated with series containing a high proportion of cases in which R0 resection was achieved. Series containing the highest R0 resection rates (>75% of cases in some published experiences) tend to be reported by institutions where liver resection is applied liberally to patients with cholangiocarcinoma.<sup>77,85</sup> A caveat to remember is that these same series also tend to be associated with the highest perioperative mortality rates (up to 14% in some cases).

For patients with intrahepatic cholangiocarcinoma, reported 3-year survival rates following curative resection with negative margins range from 22% to 66%. For patients with distal cholangiocarcinoma, 5-year survival rates following pancreaticoduodenectomy range from 15% to 25% in most reported series. Among patients with node-negative disease, 5-year postoperative survival rates as high as 54% have been reported.

The best reported outcomes among patients with unresectable biliary tract cancers are those from the **ABC-02 trial**. The median overall survival among patients treated with the combination of gemcitabine and cisplatin was 11.7 months, whereas it was 8.1 months in those treated with gemcitabine alone.<sup>47</sup>

## PALLIATION OF MALIGNANT BILE DUCT OBSTRUCTION

Patients with gallbladder cancer and cholangiocarcinoma are often faced with bile duct obstruction. Surgical resection in these cases relieves the bile duct obstruction. The role of preoperative stenting of the bile duct obstruction for resectable tumors is discussed above. The management of malignant bile duct obstruction in cases of metastatic, unresectable, or recurrent gallbladder cancer and cholangiocarcinoma deserves special mention. While relief of obstruction for patients with distal bile duct obstruction is relatively straightforward, palliation of perihilar obstructions is much more difficult. As cholangitis seldom occurs in the setting of malignant biliary obstruction prior

to instrumentation of the biliary system, intervention is rarely urgent or emergent. Instead, the role of biliary decompression and the most effective way to achieve it, if indicated, should be deliberately considered, ideally in a multidisciplinary setting.

The goal of biliary decompression must be carefully considered. Jaundice or dilated ducts on imaging themselves do not necessarily warrant intervention. Symptomatic relief or intractable pruritis or cholangitis do benefit from drainage. Administration of effective chemotherapy for patients with gallbladder cancer or cholangiocarcinoma is often contingent on biliary drainage for effective metabolism or excretion, so it is rational to relieve biliary obstruction in patients who elect to receive systemic treatment. It should be noted, however, that other than for relief of pruritis, biliary decompression was not shown to improve quality of life in a prospective trial.<sup>86</sup>

Several interventions have been attempted for the relief of biliary obstruction. Of these, surgical bypasses and endoscopic or percutaneous stents or drains are the most common. While surgical bypasses have been shown to be more durable and associated with less need for reintervention as compared to endoscopic or percutaneous stents for both distal and perihilar obstructions, in practice, endoscopic or percutaneous biliary stenting are most often used preferentially due to the lower initial morbidity. Surgical biliary bypass is usually reserved for patients who are found to have unresectable disease at the time of surgical exploration or those in whom nonsurgical stenting cannot be accomplished.

The endoscopic approach to distal bile duct obstructions is generally preferred over the percutaneous approach. Endoscopic stenting is associated with low procedure-related morbidity and mortality and does not require an external drain. In contrast, the percutaneous transhepatic approach often requires at least temporary placement of an external drain. The choice of an endoscopic or percutaneous approach for drainage of perihilar bile duct obstructions is more contentious. Several principles of effective biliary drainage in this setting need to be kept in mind. First, it is often the case that drainage of a particular area of liver needs to be targeted. More than 30% of the functional hepatic parenchyma needs to be drained for relief of jaundice similar to the fact that approximately this volume of liver needs to be preserved after liver resection for effective liver function. As a biliary tumor progresses proximally in or along the bile ducts, it can segregate the biliary

systems draining various regions of the liver. For instance, if tumor segregates the right anterior sector of the liver from the right posterior sector and both from the left hemiliver, it may be most effective to target drainage of the left hemiliver for the best long-term palliation. Similarly, drainage of liver that is compromised by obstruction of portal inflow or atrophy is unlikely to contribute to relief of jaundice. Next, violation of any area of the liver that is not effectively drained or later becomes undrained due to progression of the tumor can be associated with the development of cholangitis. It is very common for patients with perihilar malignant bile duct obstructions to have bouts of cholangitis during the course of their disease once the biliary system is instrumented. A transhepatic percutaneous approach is often favored for perihilar malignant bile duct obstruction as it may allow more precise targeting of the specific area of liver to be drained without contaminating other areas of liver through contrast injection or inadvertent passage of wires that may occur when accessing the biliary system through the ampulla (Fig. 65-8). Some authors, however, have demonstrated that in certain experienced centers, the principles of safe and effective drainage of malignant perihilar bile duct obstructions can be followed and adequate results obtained with an endoscopic approach.

Metal stents tend to provide more durable palliation than plastic (polyethylene) stents (median stent patency of 8-12 vs 4.8 months) and are generally preferable in patients with malignant biliary obstruction. Plastic stents should be changed every 3 to 6 months to prevent episodes of cholangitis related to stent occlusion; these stents may be appropriate for patients with estimated survival durations of less than 3 months (eg, patients with diffuse metastases). Some authors have found that better outcomes are achieved when both hemilivers are drained; however, a prospective, randomized controlled trial of patients with pCCA found that unilateral biliary drainage provided adequate palliation of obstructive jaundice, and patients randomized to receive bilateral biliary stents had higher complication rates (cholangitis) but no detectable benefits.<sup>87</sup> The approach therefore needs to be individualized.

For patients with pCCA who are found to have carcinomatosis at the time of exploratory laparoscopy, laparoscopic cholecystectomy traditionally has been recommended, to prevent subsequent development of acute cholecystitis related to biliary stent-induced cystic duct obstruction. The value of prophylactic cholecystectomy in this setting is unproven and should not be

routinely performed. Stenting should be performed using percutaneous or endoscopic techniques postoperatively.

For patients who are found to have unresectable disease at the time of open exploration, available evidence suggests that surgical biliary bypass offers more durable palliation than percutaneous or endoscopic stenting. Patients with unresectable dCCA should undergo hepaticojejunostomy. The palliative options for patients with unresectable perihilar cholangiocarcinoma include Roux-en-Y hepaticojejunostomy to the left and/or right hepatic ducts in the hilus of the liver if feasible, or Roux-en-Y hepaticojejunostomy to segmental/sectoral ducts away from the tumor. The segment 3 hepatic duct can be approached by following the falciform ligament into the recess of the left hemiliver in the umbilical fissure. Localization of segmental or sectoral ducts on the right side of the liver (ie, right anterior sector duct, segment 5 duct, or segment 6 duct) is very difficult as no external anatomic landmarks exist, and considerable parenchymal dissection is often necessary. Intraoperative ultrasonography (IOUS) may facilitate localization. As with endoscopic and percutaneous drainage procedures, unilateral bypasses should be avoided in the presence of ipsilateral liver atrophy or portal vein obstruction.

External beam radiation and transcatheter brachytherapy may contribute to pain relief and biliary decompression; however, the data on the effects of radiation on survival duration are conflicting.

Finally, photodynamic therapy (PDT), in which endoscopic application of light activates a photosensitizer, leading to local cell death, has been associated with promising results. One prospective randomized trial, in which 19 patients with advanced cholangiocarcinoma were randomized to stenting alone or stenting followed by PDT, was terminated prematurely because patients randomized to the PDT arm were found to have a significantly longer survival (493 vs 98 days, median survival) in addition to improved biliary drainage and quality of life.<sup>88</sup> PDT-associated prolongation of survival was also observed in another prospective randomized trial.<sup>89</sup> These trials were small, and application of PDT is limited by its availability. Additional study of this modality is warranted.

# LAPAROSCOPIC BILIARY PROCEDURES

*Alexander Perez • Theodore N. Pappas*

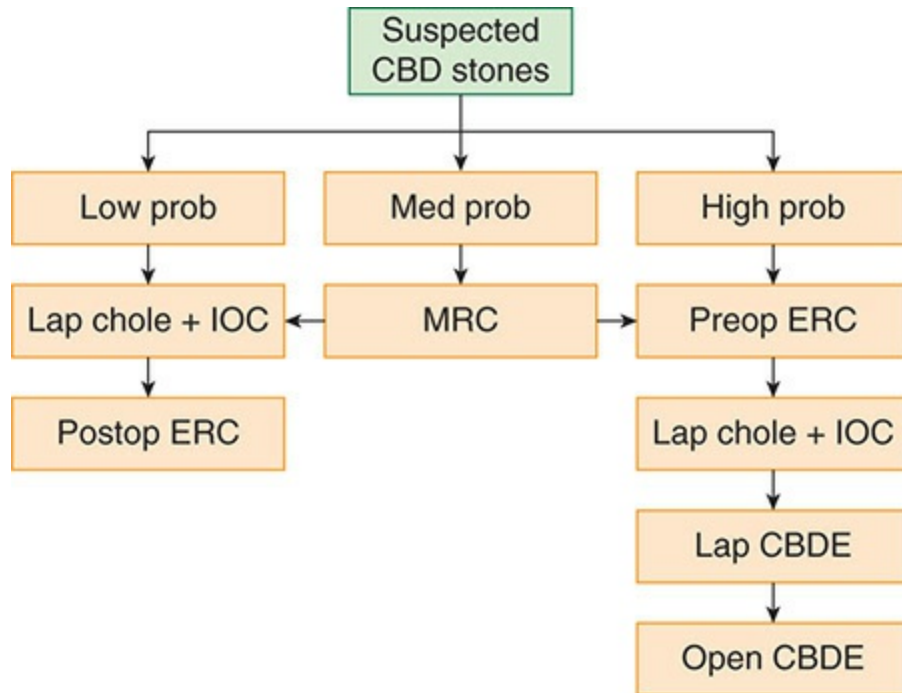

## INTRODUCTION

Minimally invasive surgery has revolutionized the way we perform surgery due to the benefits of enhanced recovery, specifically less postoperative pain and fewer wound-related complications. These surgical techniques have become widespread and the gold standard for the management of certain entities as a result of outcomes data, improved equipment (including smaller, user-friendly articulating instruments and robotic-assisted surgery), patient expectations, and the easily accessible worldwide media.

The advanced minimally invasive surgical techniques in this chapter address the role of intraoperative imaging and the management of bile tract stones, tumors, and cysts. These approaches are ideally offered in an environment where a multidisciplinary approach is provided. As the demand for less invasive and more subspecialized expertise increases, knowledge of how this field is evolving will be important in offering our patients the best clinical care with the least associated procedural risk.

## INTRAOPERATIVE IMAGING

Clarifying biliary anatomy to facilitate safe surgical dissection or identifying biliary ductal injuries is essential. A meticulous dissection of the gallbladder with the “critical view of safety” approach has been used for this purpose.<sup>1</sup> When this technique or other surgical approaches do not provide this information or when they cannot be performed safely, the use of intraoperative imaging such as intraoperative cholangiogram (IOC) is required. Additional indications for the use of IOC include the presence of jaundice, elevated liver function or pancreatic enzymes levels, biliary ductal dilation, or stones on imaging. A meta-analysis revealed that the incidence of unsuspected retained stones after a cholecystectomy was 4%, with only 15% of these going on to cause clinical problems.<sup>2</sup> The probability of this pathology can be classified as low (<5%), medium (5%-50%), and high (>50%) according to bilirubin level (<1.8, 1.8-4, and >4 mg/dL), dilation of common bile duct (CBD; >6 mm), and clinical signs of cholangitis.<sup>3</sup> Because small stones may pass spontaneously, a preoperative endoscopic retrograde cholangiography (ERC) is not necessary or efficient in most cases, and laparoscopic cholecystectomy with IOC will suffice to document a clear CBD during cholecystectomy; if needed, a postoperative ERC can be used for those with clinically significant residual stones.<sup>4-6</sup> Using fluoroscopic IOC, stones can be identified with greater than 95% sensitivity and specificity, with a 5% false-positive rate and 1% false-negative rate, although these rates are highly variable depending on the study.<sup>7</sup> Magnetic resonance cholangiography (MRC) has a high sensitivity (90%) and specificity (95%) for choledocholithiasis with a low-risk profile compared to ERC and thus occupies a place in the management algorithm when there is medium probability.<sup>8</sup> If stones are encountered during MRC, then proceeding with preoperative ERC is recommended. If stones are not diagnosed on MRC, proceeding with a laparoscopic cholecystectomy with IOC is recommended. A proposed algorithm to address clinically suspected CBD stone is presented (Fig. 66-1).

**FIGURE 66-1** Preoperative management algorithm for suspected clinically relevant common bile duct stones. CBD, common bile duct; CBDE, common bile duct exploration; ERC, endoscopic retrograde cholangiography; IOC, intraoperative cholangiography; Lap, laparoscopic; Lap Chole, laparoscopic cholecystectomy; Med, medium; MRC, magnetic resonance cholangiography; Postop, postoperative; Preop, preoperative; Prop, probability.

While the information obtained from IOC is valuable, its routine versus selective use continues to be debated due to the associated increased cost from additional instrumentation and increased operating room (OR) time on the one hand and decreased readmission rates from postcholecystectomy syndrome on the other.<sup>9,10</sup>

Other forms of intraoperative imaging including ultrasonography and infrared-activated fluorescence, although used less often, are finding their way into the OR as a result of their unique advantages. Ultrasonography is highly sensitive (83%-100%) and specific (98%-100%) in identifying CBD stones and ductal dilatation and is more cost effective compared to IOC (ultrasonography machines cost \$40,000-\$75,000, whereas C-arms and associated supplies cost \$500,000). Factors that have limited its widespread adoption include the lack of therapeutic capabilities and operator dependency.<sup>11</sup> An approach such as indocyanine green (ICG) fluorescence

would be advantageous in avoiding radiation exposure and penetrating the biliary ductal system as needed for direct injection of a contrast dye during standard IOC. Its reported ease of use and relatively low cost are another benefit. ICG is hydrophilic and binds to albumin in plasma as well as to  $\alpha_1$ -lipoprotein. It is exclusively eliminated in the liver and has no metabolism. ICG is injected intravenously approximately 60 minutes prior to making a surgical incision, and when illuminated by infrared light, the dye manifests fluorescence. Limiting factors of this approach include allergies to ICG dye, inability of the infrared light to penetrate thick and or deep tissue such as what would be encountered in morbid obesity or severe inflammation, and the need for specialized imaging system equipment.<sup>12-14</sup>

For a successful IOC, the patient should be positioned on the appropriate OR table in a way that the C-arm can have adequate access to the patient's right upper abdomen during the laparoscopic cholecystectomy. The most common approach for an IOC is using contrast dye injected directly into the infundibulum of the gallbladder or cystic duct. Advantages of accessing the gallbladder infundibulum directly include avoiding a ductotomy on what may turn out to be the CBD instead of the cystic duct. Another advantage is its ease of cannulation compared to the relatively smaller cystic duct. Disadvantages include the possibility that the dye may not leave the gallbladder due to an occluded infundibular-cystic duct junction from an impacted stone or inflammation, tortuosity of the cystic duct, and presence of the spiral valves of Heister. In either approach, proximal occlusion with either a grasper or clip will avoid inadvertent backflow of the dye and help orient the imaging. Traction on the gallbladder will provide additional exposure and duct alignment for better imaging interpretation. The cholangiogram catheter system should be flushed thoroughly with saline prior to its use to avoid misinterpretation of the air bubbles injected into the biliary ductal system from the tubing. The imaging should include the cystic duct, left and right hepatic ducts, common hepatic duct, and CBD, and the contrast should be seen filling the duodenum. To assist with improved visualization of the proximal biliary ductal system, enhanced filling by the contrast occurs with placing the patient in Trendelenburg position and administering 1 to 2 mg of intravenous morphine to induce sphincter of Oddi contraction. Visualization of the duodenum filling with contrast can be enhanced by administering 1 mg of intravenous glucagon to allow for sphincter of Oddi relaxation. Even with ideal imaging, it is important to always use caution

because misinterpretation is possible in cases where biliary ductal injuries occur.<sup>15</sup>

## LAPAROSCOPIC COMMON BILE DUCT EXPLORATION

Intraoperative common duct exploration has not gained wide acceptance in the surgical community, as shown in a US survey-based study and a Swedish nationwide retrospective study.<sup>16,17</sup> Although preoperative ERC is the predominant method of bile duct clearance in the setting of laparoscopic cholecystectomy, laparoscopic CBD exploration (LCBDE) has been shown to be a safe and effective single-stage option for the management of CBD stones due to the feasibility of successful completion laparoscopically (96%), few major complications (5%), and excellent long-term results.<sup>18,19</sup> When compared to preoperative ERC and subsequent laparoscopic cholecystectomy, both approaches were equivalently effective in detecting and removing CBD stones and were equivalent in overall cost and patient acceptance.<sup>20,21</sup> LCBDE does require advanced surgical expertise, longer OR time, and specialized equipment; however, LCBDE has been shown to reduce the length of hospital stay, reduce recurrent CBD stones, and eliminate the potential risks of ERC-associated pancreatitis and papillary stenosis with a single procedure.<sup>22-26</sup> When possible, a transcystic route is preferred to the transcholedocotomy approach due to the lower incidence of bile leaks and decreased overall morbidity.<sup>27</sup> A transcystic approach may not be feasible with anomalous anatomy, proximal stones, strictures, and large (>6 mm) or numerous (>5) stones.<sup>28</sup> Although large (>7 mm) and impacted stones have been associated with failure of stone clearance by LCBDE and may necessitate conversion to an open CBD exploration or reliance on postoperative endoscopic retrograde cholangiopancreatography (ERCP), others have performed successful LCBDE stone extraction after failed preoperative ERC. Other factors such as adhesions and altered anatomy seem to determine LCBDE success or conversion to an open procedure.<sup>29,30</sup> Intraoperative common duct exploration has been shown to be less effective than postoperative ERCP in terms of ductal clearance in cases of emergency surgery.<sup>31</sup>

After accessing the cystic duct, a flexible-tip guidewire is advanced into the CBD. To allow access of the choledoscope, a balloon catheter is used to dilate the cystic duct to 3 to 5 mm. Stone extraction proceeds in either a retrograde fashion through the cystic duct with a wire basket or in antegrade fashion by dilating the ampulla and pushing the stone through with a balloon catheter. Remaining debris should be flushed, and a completion cholangiogram should confirm clearance and identify any procedural-related ductal injuries. Traditionally a T-tube was left in place for drainage after CBD exploration, but recent studies have shown that primary duct closure following LCBDE is safe, can be employed routinely as an alternative to T-tube insertion, and has a short hospital stay and low morbidity rate.<sup>32,33</sup>

If stones cannot be cleared during LCBDE, a temporary stent may assist in decompression in the interim while awaiting postoperative ERC. Laparoscopic transampullary stenting has been shown to be a safe and feasible technique.<sup>34</sup>

## LAPAROSCOPY-ASSISTED ENDOSCOPIC RETROGRADE CHOLANGIOGRAPHY

Roux-en-Y gastric bypass surgery has become a standard approach in the management of morbid obesity. This results in more challenging access to the duodenum for diagnostic and therapeutic reasons. Advanced endoscopic instrumentation such as overtubes provides additional support to guide the endoscope to otherwise inaccessible locations, but when these fail, there still remains the need for surgical access to this excluded region.<sup>35</sup>

Technical challenges with laparoscopy-assisted endoscopic retrograde cholangiography (LAERC) may arise related to patient positioning since ERCs are typically performed with the patient in a prone position and loss of working space can occur due to bowel dilatation from endoscopic insufflation.

Another variation of LAERC includes the laparoscopic rendezvous technique of laparoscopic cholecystectomy and IOC with placement of a guidewire, which would then be used for simultaneous ERC. This approach has been shown to be feasible for the management of CBD stones during a single staged procedure. The laparoscopic positioning of the guidewire may allow reduced complications secondary to papilla cannulation.<sup>36</sup>

## LAPAROSCOPIC BILIARY BYPASS

A choledochoduodenostomy or choledochojejunostomy can be used in cases where biliary flow cannot be reestablished via the native ductal system due to impacted CBD stones. As a general approach, if the duodenum can be mobilized in a tension-free manner to a portion of nonobstructed distal CBD, a choledochoduodenostomy is favored because it requires 1 less anastomosis and still allows for postoperative endoscopic access.

A similar approach to the open technique is used during the laparoscopic choledochoduodenostomy (LCD), with exposure being provided by a liver retractor, meticulous hemostasis, and constant suctioning of bile and enteric content. A longitudinal incision is made in the center of the anterior surface of the distal CBD as close as possible to where it meets the duodenum. A longitudinal incision is made in the duodenum allowing for the anastomosis to be tented open as the corner stitches of each of these structures are placed. The length of the CBD incision is influenced by the diameter of the CBD. A small, nondilated duct may require a longer incision to avoid the need for postoperative reintervention due to anastomotic narrowing. The duodenal incision should begin as a small incision that is gradually enlarged depending on the dynamic assessment of tension and patency of the anastomosis. In general, an interrupted stitch using a small (4-0) absorbable suture is recommended to avoid narrowing and delayed stone formation. Although commercially available devices (eg, Endo Stitch, Autonomy, Laparo-Angle Articulating Instruments) and robotic technology may aid with sewing at awkward angles, most cases are amenable to free-hand sewing with laparoscopic needle drivers.

A laparoscopic hepaticojejunostomy (LHJ) may be used to reconstruct the extrahepatic biliary tract after laparoscopic choledochal cyst resection or as part of a more extensive procedure such as during a laparoscopic pancreaticoduodenectomy. For pathology of the pancreatic head and uncinate process, this procedure gives equal if not superior results compared to its open counterpart related to enhanced recovery as seen with most minimally invasive surgical procedures.<sup>37-39</sup>

Factors associated with the technical complexity of the LHJ are duct size and level of the anastomosis. A distally located, dilated common hepatic duct is more easily reconstructed than 2 separate, smaller, nondilated, proximally located left and right hepatic ducts. A segment of small bowel that is able to

reach the duct in a tension-free manner is brought through a defect in the transverse mesocolon to the right of the patient's midline taking care to avoid injury to the vasculature and underlying duodenum. We recommend fashioning the end-to-side hepaticojejunostomy before the side-to-side jejunojejunostomy to avoid excessive anastomotic tension (Figs 66-2 and 66-3).

**FIGURE 66-2** Choledochal cyst.

**FIGURE 66-3** Laparoscopic hepaticojejunostomy.

Occasionally, laparoscopic biliary bypasses are required for palliative reasons such as unresectable pancreatic cancer that is causing biliary obstruction unamenable to endoscopic stenting. Pancreatic cancer is the fourth leading cause of cancer-related death in Western society.<sup>40</sup> Eighty percent of these patients are not candidates for curative resection at the time of diagnosis, and 30% of them will present with nonmetastatic locally advanced disease.<sup>41</sup> Most pancreatic tumors are located in the head and cause obstructive jaundice, and approximately 20% of these patients will also develop duodenal obstruction.<sup>42</sup>

Palliation via a laparoscopic cholecystojejunostomy avoids the duodenum that may be involved in a locally obstructive process, such as the LCD, and requires less operative time compared the LHJ thanks to the relative ease of the stapled anastomosis of the gallbladder to the Roux limb of jejunum. This technique should not be used when flow of bile through the cystic duct cannot be confirmed.<sup>43</sup>

Endoscopic or percutaneous palliation is advantageous due to rapid

recovery, low morbidity rates, and shorter hospital stays, whereas disadvantages include stent obstruction, duodenal obstruction, higher number of reinterventions, and shorter hospital-free survival rate.<sup>44</sup> Open surgical palliation is advantageous due to longer lasting palliation and disadvantageous due to higher morbidity.<sup>45</sup> Laparoscopic palliation combines the advantages of nonsurgical methods with the advantages of open surgery with an acceptable morbidity rate and low mortality rate. Although technically demanding, these procedures have been performed laparoscopically with a high initial success rate (99%), low reintervention rate (1%), and relatively low morbidity rate (12%).<sup>46</sup> Endoscopically placed metallic stents are currently the best palliation method for patients with systemic disease; if stents fail, the laparoscopic approach is a viable treatment.<sup>47</sup>

## CONCLUSION

There is a constant evolution of both expectations of patients and trainees and technological advances with regard to minimally invasive surgery. Thanks to their feasibility, safety, efficacy, reliability, and teachability, these techniques will continue to replace their open counterparts as the standard approach to the management of biliary surgical pathology.

# PERSPECTIVE ON BILIARY CHAPTERS

*Steven M. Strasberg*

This is a perspective on biliary diseases to complement the excellent chapters on biliary tract disease in this text. It focuses on areas in my experience that I believe deserve emphasis.

## TOKYO GUIDELINES FOR ACUTE CHOLECYSTITIS AND ACUTE CHOLANGITIS

The Tokyo Guidelines (TG) provide evidence based criteria for the diagnosis and severity grading of acute cholecystitis and acute cholangitis. First published in 2007, there have been two revisions, the latest just published in 2018 (TG18). The guidelines are available in an app for smartphones, and the app is very useful in the ER and on the ward. Furthermore, standardization of criteria for diagnosis and severity grading provide a stable platform for performance of comparative outcome studies.<sup>1,2</sup> **Tables 67-1 through 67-4 are Tokyo guidelines 2018 diagnostic criteria and severity grading for acute cholangitis and acute cholecystitis respectively.**

**TABLE 67-1: TOKYO GUIDELINES 2018 DIAGNOSTIC CRITERIA FOR ACUTE CHOLECYSTITIS**

**A. Local signs of inflammation.**

(1) Murphy's sign, (2) RUQ mass/pain/tenderness

**B. Systemic signs of inflammation, etc.**

(1) fever, (2) elevated CRP, (3) elevated WBC count

**C. Imaging findings**

Imaging findings characteristic of acute cholecystitis

**Suspected diagnosis:** One item in A + one item in B

**Definite diagnosis:** One item in A + one item in B + C

Reproduced with permission from Yokoe M, Takada T, Strasberg SM, et al: New diagnostic criteria and severity assessment of acute cholecystitis in revised Tokyo Guidelines, *J Hepatobiliary Pancreat Sci.* 2012 Sep;19(5):578-585.

**TABLE 67-2: TOKYO GUIDELINES 2018 SEVERITY GRADING FOR ACUTE CHOLECYSTITIS**

**Grade III (Severe) acute cholecystitis**

“Grade III” acute cholecystitis is associated with dysfunction of any one of the following organs/systems

1. Cardiovascular dysfunction (hypotension requiring treatment with dopamine  $\geq 5\mu\text{g/kg}$  per min, or any dose of Norepinephrine)
2. Neurological dysfunction: decreased level of consciousness
3. Respiratory dysfunction PaO<sub>2</sub>/FiO<sub>2</sub> ratio < 300
4. Renal dysfunction Oliguria, creatinine > 2.0 mg/dl
5. Hepatic dysfunction PT-INR > 1.5
6. Hematological dysfunction Platelet count < 100,000/mm<sup>3</sup>

**Grade II (moderate) acute cholecystitis**

“Grade II” acute cholecystitis is associated with any one of the following conditions.

1. Elevated WBC count (> 18,000/mm<sup>3</sup>)
2. Palpable tender mass in the right upper abdominal quadrant

3. Duration of complaints > 72 hr
4. Marked local inflammation (gangrenous cholecystitis, pericholecystic abscess, hepatic abscess, biliary peritonitis, emphysematous cholecystitis)

### **Grade I (mild) acute cholecystitis**

“Grade I” acute cholecystitis that does not meet the criteria of “Grade III” or “Grade II” acute cholecystitis. It can also be defined as acute cholecystitis in a healthy patient with no organ dysfunction and mild inflammatory changes in the gallbladder, making cholecystectomy a safe and low-risk operative procedure.

---

Modified with permission from Yokoe M, Takada T, Strasberg SM, et al: New diagnostic criteria and severity assessment of acute cholecystitis in revised Tokyo Guidelines, *J Hepatobiliary Pancreat Sci.* 2012 Sep;19(5):578-585.

**TABLE 67-3: TG18/TG13 DIAGNOSTIC CRITERIA FOR ACUTE CHOLANGITIS**

## A. Systemic Inflammation

- A-1. Fever and/or shaking chills
- A-2. Laboratory data: Evidence of inflammatory response

## B. Cholestasis

- B-1. Jaundice
- B-2. Laboratory data: Abnormal liver function tests

## C. Imaging

- C-1. Biliary dilatation
- C-2. Evidence of the etiology on imaging (stricture, stone, stent, etc.)

**Suspected diagnosis:** One item in A + one item in either B or C

**Definite diagnosis:** One item in A, one item in B, and one item in C

### Note:

- A-2: Abnormal white blood cell counts, increase of serum C-reactive protein levels, and other changes indicating inflammation
- B-2: Increased serum ALP, r-GTP (GGT), AST, and ALT levels  
Other factors helpful in diagnosis of acute cholangitis include abdominal pain (RUQ or upper abdominal) and a history of biliary disease such as gallstones, previous biliary procedures, and placement of a biliary stent.  
In acute hepatitis, marked systematic inflammatory response is observed infrequently. Virological and serological tests are required when differential diagnosis is difficult.

### Thresholds:

A-1	Fever	BT	> 38°C
A-2	Evidence of inflammatory response	WBC ( $\times 1000/\mu\text{L}$ )	< 4, or > 10
		CRP (mg/dL)	$\geq 1$
B-1	Jaundice	T-Bil	$\geq 2$ (mg/dL)
B-2	Abnormal liver function tests	ALP (IU)	> 1.5 $\times$ STD
		$\gamma$ GTP (IU)	> 1.5 $\times$ STD
		AST (IU)	> 1.5 $\times$ STD
		ALT (IU)	> 1.5 $\times$ STD

---

Abbreviations: ALP, alkaline phosphatase; r-GTP (GGT), r-glutamyltransferase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; RUQ, right upper quadrant; STD, upper limit of normal value

**TABLE 67-4: TG18/TG13 SEVERITY ASSESSMENT CRITERIA FOR ACUTE CHOLANGITIS**

### **Grade III (Severe) Acute Cholangitis**

Grade III acute cholangitis is defined as acute cholangitis that is associated with the onset of dysfunction at least in any one of the following organs/systems

- |                               |   |
|-------------------------------|---|
| 1. Cardiovascular dysfunction | Hypotension requiring dopamine $\geq 5 \mu\text{g}/\text{k}/\text{min}$ or any dose of norepinephrine |
| 2. Neurological dysfunction   | Disturbance of consciousness  |
| 3. Respiratory dysfunction    | PaO <sub>2</sub> /FiO <sub>2</sub> ratio <300   |
| 4. Renal dysfunction          | Oliguria, serum creatinine >2.0 mg/dL   |
| 5. Hepatic dysfunction        | PT-INR >1.5   |
| 6. Hematological dysfunction  | Platelet count <100,000/mm <sup>3</sup>   |

### **Grade II (Moderate) acute cholangitis**

Grade II acute cholangitis is associated with any two of the following conditions:

1. Abnormal WBC count (>12,000/ $\mu\text{L}$ , <4000/ $\mu\text{L}$ )
2. High fever ( $\geq 39^\circ\text{C}$ )
3. Age ( $\geq 75$  years old)
4. Hyperbilirubinemia (total bilirubin  $\geq 5 \text{ mg}/\text{dL}$ )
5. Hypoalbuminemia (<STD  $\times 0.7$ )

### **Grade I (Mild) acute cholangitis**

Grade I acute cholangitis does not meet the criteria of “Grade III (severe)” or “Grade II (moderate)” acute cholangitis at initial diagnosis.

---

Early diagnosis, early biliary drainage and/or treatment for etiology, and antimicrobial administration are fundamental treatment for acute cholangitis classified not only “Grade III (severe)” and “Grade II (moderate)” but also “Grade I (mild)”. Therefore it is recommended that patients with acute cholangitis who do not respond to the initial medical treatment (general supportive care and antimicrobial therapy) undergo early biliary drainage or treatment for etiology.

Abbreviation: STD, lower limit of normal value.

Modified with permission from Yokoe M, Takada T, Strasberg SM, et al: New diagnostic criteria and severity assessment of acute cholecystitis in revised Tokyo Guidelines, *J Hepatobiliary Pancreat Sci.* 2012 Sep;19(5):578-585.

## BILIARY DYSKINESIA

While up to 20% of adult cholecystectomies performed in the United States are for biliary dyskinesia, cholecystectomy is rarely performed for this indication in other countries. Also, one-half of patients with suspected biliary dyskinesia have improvement in symptoms over time without cholecystectomy.<sup>3</sup> Exercise, proton pump inhibitors, and anticholinergics may affect outcome of quantitative cholescintigraphy, the test used to make the diagnosis. Our group has found that this test is poorly reproducible, with about 50% of patients having a normal ejection fraction of over 35% on retesting.<sup>4</sup> The comments in regard to the Rome diagnostic criteria for functional biliary pain by Teitelbaum and Soper in their chapter ([Chapter 62: Cholelithiasis and Cholecystitis](#)) deserve emphasis. Patients whose symptoms strictly fulfil the Rome criteria and whose symptoms seriously affect quality of life should be considered for cholecystectomy. Large clinical studies are needed to define the role of quantitative scintigraphy and the long-term results of cholecystectomy in relation to the presence of Rome criteria.

## Culture of Safety in Cholecystectomy

### CRITICAL VIEW OF SAFETY

Much has been written about the Critical View of Safety (CVS). CVS should be seen as a part of a **culture of safety in cholecystectomy (COSIC)**. It is a pillar of safety, but only one of the three pillars. One line of evidence supporting the utility of CVS is that studies that have looked at the mechanism of major biliary injury have found that CVS was not employed in patients sustaining injury.<sup>5,6</sup> Also, there are now multiple reports involving thousands of patients in which CVS was employed and in which there were few or no misidentification injuries, ie an injury rate well below what would be expected. In these studies some patients did not have a total cholecystectomy because of operative difficulty. Biliary injuries occur more commonly when operations are made more difficult due to the presence of severe acute and/or chronic inflammation. Under these conditions secure ductal identification by the CVS may be quite challenging or not obtainable because CVS requires clearing of the inflamed hepatocystic triangle in order to demonstrate the cystic duct, cystic artery, and the cystic plate. CVS is a

rigorous method but this is a strength of the CVS method of identification. The infundibular technique, in which the funnel-shaped infundibular-cystic duct junction is the rationale for identification, is much easier to achieve than CVS. However, biliary inflammatory fusion and contraction can make the common bile duct resemble the cystic duct when this technique is used, and this increases the chance of biliary injury. The CVS method protects because when the CVS is not achievable after a reasonable trial of dissection, surgeons are more likely to realize that conditions are too risky to proceed in the usual manner. When conditions make it too difficult and risky to get to CVS there must be a safe and effective method of dealing with difficult gallbladders. Safe means without bile duct injury, and effective means without need for a second operation. Otherwise surgeons might feel pressured to push on with a risky dissection in the hepatocystic triangle in order to avoid a second procedure or perform a cholecystostomy, which will usually necessitate a second operation. That procedure is a subtotal cholecystectomy, first described in 1898. It has been shown to be an effective bailout procedure when total cholecystectomy is dangerous.<sup>7</sup>

## **SUBTOTAL FENESTRATING CHOLECYSTECTOMY AND SUBTOTAL RECONSTITUTING CHOLECYSTECTOMY**

There has been terminological confusion in this area because the terms *partial cholecystectomy* and *subtotal cholecystectomy* have been used interchangeably. Also “partial” and “subtotal” are imprecise because they fail to encompass an essential element in these operations, which is whether a functional remnant gallbladder results as a consequence of performing these procedures. A new terminology has been introduced recently. In *subtotal fenestrating cholecystectomy*, the peritonealized gallbladder wall is removed, but the part of the wall on the cystic plate is left behind or only partially removed. The cystic duct is left open or sutured from the inside so that no closed gallbladder remnant remains. Biliary fistula is common after this procedure, but usually brief in duration. In subtotal reconstituting cholecystectomy, a small closed gallbladder remnant remains behind. Stones may reform in this gallbladder remnant and become the source of symptoms later, which could require a second operation, so the author favors the subtotal fenestrating operation. This operation can usually be done laparoscopically.

If CVS is one pillar of safety and subtotal cholecystectomy a second, then the third pillar is knowing when to stop trying to do a total cholecystectomy and proceed to a subtotal cholecystectomy. This has not been precisely defined, but the topic is one of intense interest. One problem in recommending a standard pathway is that the decision for abandoning the attempt to do total cholecystectomy will be affected by the experience and training of the surgeon. Fortunately, the ease and benefits of subtotal fenestrating cholecystectomy are making this choice easier.

## CHOLEDOCHAL CYSTS

This subject is covered completely by Parikh and Lillimoe in their chapter. This is an uncommon problem in which there is still are serious gaps in our knowledge. While choledochal cysts are associated with the development of cancer, the true incidence of cancer in this disease is unknown. Part of the reason is that there have not been good population-based studies that have searched for persons with asymptomatic cysts to determine natural history. As a result, the prevalence of asymptomatic cysts in the population is unknown. With the common use of CT scans to diagnose abdominal complaints, more choledochal cysts are being discovered incidentally. Currently, patients who are diagnosed by chance are advised to have resection. This strategy, although the current standard of care, can be questioned since it implies that a screening program should be in place. Furthermore, the threshold diameter of the bile duct that should be diagnosed as a choledochal cyst has not been defined. The upper limit of bile duct diameter is about 12 mm. Occasionally an asymptomatic fusiform bile duct of diameter 15 mm or slightly larger is found incidentally. Whether these should be classified as true choledochal cysts and whether they are associated with a higher incidence of cancer is uncertain. In these borderline cases, the presence of a high pancreatobiliary junction and a long common channel may be the deciding factor in determining that these should be classified as choledochal cysts.

Strictures at the hepaticojejunostomy may occur after resection of a choledochal cyst. This is usually due to cutting too high on the cyst proximally and then having to do anastomosis to several small ducts. The problem is that it is not apparent where to cut the cyst from the outside. We advocate cutting the cyst in half at its equator so that one can look into the

cyst and cut it off leaving a cuff of tissue around the normal ducts entering the cyst. This method has been published and illustrated.<sup>8</sup>

# MANAGEMENT OF ACUTE PANCREATITIS

*Thomas E. Clancy*

## INTRODUCTION

Acute pancreatitis can range from a mild, self-limiting process that responds to supportive care to severe disease with multiple organ failure and high mortality. Its incidence is increasing,<sup>1</sup> and pancreatitis is one of the most common causes of hospital admission for gastrointestinal illness.<sup>2</sup> Although most patients experience minor episodes characterized by mild parenchymal edema without organ dysfunction, response to conservative management, and complete recovery,<sup>3</sup> approximately 20% to 25% of patients develop clinically severe acute pancreatitis. More severe episodes may progress to pancreatic necrosis, systemic inflammatory response syndrome (SIRS), multiorgan failure, clinical deterioration, and even death.<sup>4</sup> Historically, mortality has been up to 15% in the setting of necrotizing pancreatitis and as high as 30% with infected pancreatic necrosis.<sup>5</sup> Recent years have seen advances in the classification and management of acute pancreatitis including evidence-based guidelines and a notable shift toward nonoperative management of even the most severe cases of infected pancreatic necrosis.

Given the wide spectrum of severity, patients with pancreatitis must receive highly individualized care. Mild acute pancreatitis can generally be managed with resuscitation and supportive care including a search for etiologic factors such as gallstones. Patients with severe pancreatitis and pancreatic necrosis may require maximal support in intensive care and occasionally surgical or endoscopic debridement of the pancreas. The indications for intervention in patients with severe pancreatitis have evolved significantly in the past 2 decades. Whereas early surgical debridement was used for most patients with pancreatic necrosis in the past, a far more conservative approach was adopted with recognition that surgical debridement was not necessary in the setting of most cases of pancreatic necrosis without infection.<sup>6</sup> Revision of the 1992 Atlanta Classification of acute pancreatitis<sup>7</sup> to provide a newer classification to more precisely describe the clinical behavior and imaging characteristics of acute pancreatitis<sup>8</sup> has allowed more uniform categorization of the disease in recent years. At the same time, the development of minimally invasive and nonsurgical approaches to necrotizing pancreatitis has led to increased consensus that most patients, including even those with the greatest disease severity, may avoid surgical debridement.<sup>9</sup> This chapter reviews contemporary management strategies in acute pancreatitis, including assessment of severity, nutritional support, the role of antibiotics, and indications for intervention.

## ETIOLOGY

Acute pancreatitis has been attributed to a range of etiologic factors ([Table 68-1](#)). Intra-acinar activation of trypsinogen, with subsequent activation of other pancreatic enzymes, is thought to play a central role in pathogenesis of the disease. A local inflammatory response is associated with liberation of oxygen-derived free radicals and cytokines including interleukin (IL)-1, IL-6, IL-8, tumor necrosis factor alpha (TNF- $\alpha$ ), and platelet-activating factor. These mediators play an essential role in transformation of the local inflammatory response to a systemic illness.

Most cases (70%-80%) of pancreatitis are associated with gallstones or sustained alcohol abuse; the relative frequency of these 2 factors depends on the prevalence of alcohol use in the population studied. Choledocholithiasis is the most common of known mechanical factors.<sup>10</sup> The majority of patients with non-alcohol-related pancreatitis will have gallstones, and many will develop recurrent acute pancreatitis if stones persist. Another known mechanical cause of pancreatitis is instrumentation of the pancreatic or biliary duct; at least 1% of patients undergoing endoscopic retrograde

cholangiopancreatography (ERCP) develop clinically detectable pancreatitis. Several metabolic processes are associated with pancreatitis, particularly alcohol abuse. Signs and symptoms of pancreatitis can be seen in patients with prolonged alcohol use, usually after 10 years or more of heavy ingestion. Binge drinking has not been related to pancreatitis,<sup>11</sup> but its development is thought to be related to consumption of over 4 to 5 drinks per day for more than 5 years.<sup>12</sup> The precise mechanism of this association is not well established.<sup>13</sup> Several drugs have been related to the development of pancreatitis, particularly corticosteroids, thiazide diuretics, estrogens, azathioprine, and furosemide. In approximately 10% of cases, no underlying cause can be identified. Some have suggested that occult biliary microlithiasis may be the etiology in most cases of idiopathic acute pancreatitis.<sup>14</sup> Smoking was thought to be a cofactor in alcohol-related pancreatitis, although it is now recognized as an independent risk factor in the disease with risk correlating to the extent of tobacco use.<sup>15</sup>

## DIAGNOSIS, ASSESSMENT, AND IMAGING

### Diagnosis

Early diagnosis and determination of disease severity are essential to guide appropriate therapy. Clinical diagnosis has changed very little in recent years. Clinical signs and symptoms such as upper abdominal pain, back pain, vomiting, fever, tachycardia, and leukocytosis are nonspecific. Although the classically described signs of umbilical and flank bruising may be seen with severe retroperitoneal hemorrhage (Cullen and Grey-Turner signs), these are rare in all but the most severe cases, are nonspecific, and may be seen with any cause of retroperitoneal bleeding. Therefore, diagnosis depends on clinical suspicion and demonstration of elevated plasma levels of pancreatic enzymes. In the setting of characteristic abdominal symptoms and/or characteristic imaging, serum amylase levels of amylase or lipase 3 times the upper limit of normal secure the diagnosis.<sup>1</sup> Levels of both amylase and lipase peak within the first 24 hours of symptoms, and amylase has a slightly shorter plasma half-life. Serum lipase, therefore, has a slightly higher sensitivity for detection, as elevations occur earlier and last longer than serum

amylase.<sup>16</sup> Furthermore, hyperamylasemia is not entirely specific for pancreatitis and is seen occasionally with other causes of abdominal pain such as tumors of the ovaries or even kidney failure.<sup>17</sup> Simultaneous determination of serum lipase and amylase only marginally improves the diagnosis of acute pancreatitis. Of note, plasma levels of pancreatic enzymes are useful for diagnosis but not for prognosis or assessment of disease severity, and absolute levels have no correlation with severity.

Assessment of disease severity is important for the initiation of goal-directed therapy. However, reproducible measures of disease severity are lacking.<sup>18</sup> Early evaluation is complicated by a nonspecific clinical presentation, and severe disease may present with a fulminant sepsis-like syndrome or in a relatively innocuous manner. Initial signs and symptoms with severe disease are only different in degree from edematous pancreatitis, and both severe and mild forms share the same etiologies.<sup>19</sup> Attempts to identify differences in the pathogenesis of mild and severe disease have not revealed differences, and available clinical models do not accurately predict which patients will progress to severe disease.<sup>20</sup>

## Assessment of Severity

Clinical scoring systems such as the Ranson<sup>21</sup> or Glasgow<sup>22</sup> scores incorporate multiple clinical variables to predict outcomes, comparing variables at admission and over the subsequent 48 hours. In Ranson's original report, the presence of 5 or 6 positive signs was associated with a 40% mortality and prolonged intensive care unit course in 50% of patients, whereas the presence of 7 or 8 signs was associated with a nearly 100% mortality. However, these systems require 48 hours from admission for full assessment, and current data suggest they are poor predictors of disease severity.<sup>23</sup> The Acute Physiology and Chronic Health Evaluation II (APACHE II) system is another physiologic scoring system that estimates disease severity based on quantifying multiple variables. Higher APACHE II scores at admission are associated with higher mortality, and data may be calculated within the first 24 hours. Despite this advantage, APACHE II scores in the first 24 hours have been found to have a limited positive predictive value of only 43% for severe acute pancreatitis. Updates that include clinical assessment of obesity (APACHE-O) or additional clinical

variables (APACHE III) have been proposed, but all updates have proven to be nonspecific with high false-positive rates, are somewhat unwieldy to use, and are not commonly incorporated into practice.

Numerous individual markers have been investigated as indicators of severity. Brown et al<sup>24</sup> and others have shown that hemoconcentration predicts parenchymal necrosis and organ failure. Persistence of hemoconcentration and azotemia despite fluid resuscitation is predictive of severe pancreatitis.<sup>25</sup> Increases in C-reactive protein levels with disease severity at 48 hours after admission may help identify severe disease with superior sensitivity and specificity relative to other markers,<sup>26</sup> although the delayed peak at 36 to 72 hours after admission leads to decreased efficacy for assessment on admission.

## IMAGING

Cross-sectional imaging, particularly contrast-enhanced computed tomography (CT), plays an essential role in evaluation of the progression to severe acute pancreatitis with associated complications. CT findings of simple edematous pancreatitis include enlargement of the pancreas with loss of peripancreatic fat planes, areas of decreased density, and occasional simple fluid collections (Fig. 68-1). The Balthazar scoring system and other similar grading systems incorporate imaging findings such as pancreatic inflammation and peripancreatic collections in an attempt to correlate radiographic appearance with morbidity and mortality.<sup>27,28</sup> CT is particularly useful in its ability to demonstrate pancreatic necrosis. From a baseline of 30 to 50 Hounsfield units (HU), viable pancreas will typically enhance by more than 50 HU with the administration of intravenous (IV) contrast. Nonviable pancreas, however, will not enhance with IV contrast (Fig. 68-2). Various criteria used to diagnose necrosis include nonenhancement of more than 30% of the pancreatic parenchyma or an area greater than 3 cm of the pancreas that does not enhance.<sup>7</sup> Magnetic resonance imaging (MRI) is sometimes used as an alternative in patients with moderate renal impairment or an allergy to IV contrast. MRI may have comparable sensitivity and specificity to CT for diagnosis of severe acute pancreatitis,<sup>29</sup> although MRI is less practical for the critically ill patient.

**FIGURE 68-1** Contrast-enhanced abdominal computed tomography scan in a 47-year-old man with acute pancreatitis. Relevant findings include significant fat stranding of the peripancreatic tissue, with a fluid collection at the tail of the pancreas measuring approximately  $4 \times 4$  cm. Pancreatic parenchyma enhances with intravenous contrast, with no evidence of pancreatic necrosis. (Reproduced with permission from Clancy TE, Benoit EP, Ashley SW: Current management of acute pancreatitis, *J Gastrointest Surg.* 2005 Mar;9(3):440-452.)

**FIGURE 68-2** Contrast-enhanced abdominal computed tomography scan in the same 47-year-old man with a second episode of acute pancreatitis. Scan shows stranding of peripancreatic fat, consistent with acute pancreatitis. Most notable is the near-complete absence of pancreatic enhancement, which is diagnostic of pancreatic necrosis. (Reproduced with permission from Clancy TE, Benoit EP, Ashley SW: Current management of acute pancreatitis, *J Gastrointest Surg.* 2005 Mar;9(3):440-452.)

The timing of and indications for CT in acute pancreatitis require clinical judgment rather than strict criteria. CT scans performed early in the course of the disease will often fail to identify developing local complications, as necrosis may only become evident 2 to 3 days after the onset of symptoms, significantly limiting its utility at admission.<sup>30</sup> The sensitivity for identifying pancreatic necrosis using contrast-enhanced CT approaches 100% after 4 days from diagnosis.<sup>18</sup> It is therefore advisable to obtain an abdominal CT with IV contrast in patients with clinical and radiographic features of acute pancreatitis who do not improve after several days of conservative management. Repeat CT may be obtained with signs of clinical deterioration.

CT scan is also essential to facilitate image-guided tissue aspiration in the diagnosis of infected pancreatic necrosis. The development of infected pancreatic necrosis, as discussed below, is an indication for radiographic,

endoscopic, or surgical intervention. However, clinical criteria do not easily differentiate severe pancreatitis from infected necrosis. Leukocytosis, fever, and organ failure may be seen with or without infection. Emphysematous pancreatitis, the demonstration of gas within the pancreatic parenchyma, is diagnostic of infection but is uncommonly seen (Fig. 68-3). Image-guided aspiration of the necrotic pancreas can be used to diagnose infected pancreatic necrosis with a high degree of accuracy (Fig. 68-4). CT-guided aspiration is reserved for patients with documented pancreatic necrosis who are not improving clinically or who experience clinical decline.

**FIGURE 68-3** Computed tomography scan demonstrating emphysematous pancreatitis, which is pathognomonic for infected pancreatic necrosis. Operative debridement is indicated without additional confirmation of pancreatic infection.

**FIGURE 68-4** Computed tomography (CT)-guided percutaneous fine-needle aspiration (FNA) of the pancreatic tail. The aspiration area had previously been identified as necrotic in the contrast-enhanced CT shown in [Figure 68-2](#). Gram stain and cultures were negative for organisms, consistent with sterile pancreatic necrosis. (Reproduced with permission from Clancy TE, Benoit EP, Ashley SW: Current management of acute pancreatitis, *J Gastrointest Surg.* 2005 Mar;9(3):440-452.)

The sensitivity and specificity for detection of infection with CT-guided aspiration are reported to be 96% and 99%, respectively, with a positive predictive value of 99.5% and a negative predictive value of 95%.<sup>31</sup> Areas of nonenhancing pancreas are aspirated, with samples sent for aerobic, anaerobic, and fungal culture. In most patients, diagnosis of infection may be made with a positive Gram stain of the aspirate rather than waiting for confirmatory culture.

Infection may occur at any point in the clinical course with pancreatic necrosis, with the incidence of infection increasing up to 3 weeks after presentation. In one study, infection was documented in 49% of patients in the first 14 days, but less than 15% had infection diagnosed after 35 days.<sup>31</sup> Infection may occur later in the course of the disease, even after a prior negative aspiration. Repeat CT-guided aspiration is therefore often necessary in the setting of clinical decline. In one series of patients with aspiration

demonstrating infection, the first aspirate was positive in 17 of 30 patients (57%), although 7 patients (23%) required 2 or more procedures and 6 patients (20%) required 3 or more aspirations to demonstrate infection.<sup>32</sup> Fine-needle aspiration should not be performed in the absence of suspected infection due to the small risk of introducing infection into a previously sterile collection.<sup>33</sup>

## CLASSIFICATION OF SEVERITY

Classification of disease severity is important for the timely administration of appropriate care as well as for the assessment of treatment modalities and standardization of reporting. The Atlanta Classification emerged from an interdisciplinary symposium in 1992.<sup>34</sup> This original Atlanta Classification defined acute pancreatitis, organ failure, and local complications of the disease in an attempt to introduce uniformity in assessment of severity and complications. This allowed some descriptive consistency, helping to standardize clinical care and aiding clinical research. Recognition of the deficiencies of this system, particularly the failure to incorporate organ failure, led to the development of the Revised Atlanta Classification (RAC) using a Web-based iterative consultative process.<sup>8</sup> The RAC defines categories of severity in terms of the following categories: (1) mild acute pancreatitis, with the absence of organ failure and systemic or local complications; (2) moderate acute pancreatitis, with transient organ failure and/or local complications requiring prolonged hospital stay or intervention; and (3) severe acute pancreatitis, with persistent organ failure. Another severity classification, the Determinant-Based Classification (DBC) arose from a meta-analysis of the literature.<sup>35</sup> The DBC incorporates pancreatic necrosis in the following categories: (1) mild acute pancreatitis, with no pancreatic or peripancreatic necrosis and no organ failure; (2) moderate acute pancreatitis, with sterile pancreatic or peripancreatic necrosis and/or transient organ failure; (3) severe acute pancreatitis, with infected pancreatic or peripancreatic necrosis or persistent organ failure; and (4) critical acute pancreatitis, with infected pancreatic or peripancreatic necrosis and persistent organ failure. In addition to assessment of severity, the RAC defines specific morphologic features of acute pancreatitis and its complications ([Table 68-2](#)).

**TABLE 68-2: REVISED DEFINITIONS OF MORPHOLOGIC FEATURES OF ACUTE PANCREATITIS PER REVISED ATLANTA CLASSIFICATION (RAC)**

1. Interstitial edematous pancreatitis  
Acute inflammation of the pancreatic parenchyma and peripancreatic tissues without tissue necrosis
2. Necrotizing pancreatitis  
Inflammation associated with pancreatic parenchymal necrosis and/or peripancreatic necrosis
3. Acute peripancreatic fluid collection (APFC)  
Peripancreatic fluid associated with interstitial edematous pancreatitis with no associated peripancreatic necrosis; applies to areas of peripancreatic fluid seen in the first 3 weeks after onset of interstitial edematous pancreatitis and without the features of a pseudocyst
- 4 Pancreatic pseudocyst  
An encapsulated collection of fluid with a well-defined inflammatory wall, usually outside the pancreas with minimal or no necrosis; usually occurs more than 4 weeks after onset of interstitial edematous pancreatitis
5. Acute necrotic collection (ANC)  
A collection containing variable amounts of fluid and necrosis associated with necrotizing pancreatitis; necrosis can involve pancreatic parenchyma and/or the peripancreatic tissues
6. Walled-off necrosis (WON)  
A mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall; usually occurs >4 weeks after onset of necrotizing pancreatitis

## **PRINCIPLES OF INITIAL MANAGEMENT**

### **Resuscitation and Monitoring**

Although patients with acute pancreatitis require management strategies

tailored to disease severity, the initial management of patients is increasingly standardized. A cornerstone of this initial management is aggressive fluid resuscitation to replace considerable extravascular or “third space” fluid losses. Volume depletion accounts for the hemoconcentration and azotemia associated with severe pancreatitis.<sup>36</sup> Animal data suggest that early aggressive fluid resuscitation prevents pancreatic necrosis,<sup>37</sup> and retrospective clinical data suggest that such aggressive fluid resuscitation in the first day after admission reduces complications.<sup>38,39</sup> While aggressive fluid administration does not necessarily prevent the progression to necrosis, patients with inadequate resuscitation have an increased risk of developing pancreatic necrosis.<sup>40</sup> Fluid resuscitation is particularly important in the initial 24 hours, at rates often exceeding 200 mL/h.<sup>25</sup> One randomized controlled trial suggested that the use of lactated Ringer’s solution versus normal saline reduced markers of SIRS.<sup>41</sup> Close monitoring of respiratory, cardiovascular, and renal function is essential to detect and treat hypovolemia. All patients require close assessment of fluid balance, including a Foley catheter. Patients with severe disease should be admitted to an intensive care unit for continuous monitoring.

## **Nutritional Support**

Historically, enteral feeding was limited in the setting of acute pancreatitis for the purpose of providing “pancreatic rest.” Enteral feeding was believed to exacerbate the existing inflammatory process through stimulation of exocrine pancreatic function and release of proteolytic enzymes. Nasogastric tubes were often used for the purpose of avoiding pancreatic stimulation and in the setting of paralytic ileus. No data support the use of nasogastric decompression in the absence of ileus, however. Although brief periods without full oral intake are common on initial presentation, limitation of nutritional intake may have serious consequences in the setting of critical illness with enhanced catabolism and negative nitrogen balance.<sup>42</sup> In this setting, total parenteral nutrition (TPN) has often been used for nutritional support in an effort to prevent further complications.<sup>43</sup>

Ample evidence now suggests that strict limitations on enteral nutrition are unnecessary and that, in fact, enteral nutrition may be feasible and safe even in severe pancreatitis.<sup>44</sup> Enteral nutrition helps support intestinal

mucosal integrity and avoids alterations to the intestinal barrier function and altered intestinal permeability seen with TPN.<sup>45</sup> Various studies comparing TPN to enteral feeding have demonstrated that enteral feeding is associated with fewer complications<sup>46,47</sup> and improvement in inflammatory markers and severity scores.<sup>48,49</sup> Meta-analyses of the literature have confirmed the preferential use of enteral nutrition to reduce complications, infection, and length of hospital admission.<sup>50,51</sup>

In patients with mild disease, data support the initiation of oral feeding even before resolution of pain or normalization of pancreatic enzyme levels,<sup>52</sup> and a low-fat diet has been demonstrated as safe soon after admission.<sup>53</sup> The need for assisted enteral feeding due to severe symptoms or an inability to tolerate oral feeding may be recognized in the first few hospital days. Early administration of nasoenteric feeding has not been shown to be superior to waiting 2 to 3 days to see if oral feeding is tolerated.<sup>54</sup> While most studies investigating the use of enteral feeding have used nasojejunal feeding, randomized trials<sup>55,56</sup> and a meta-analysis<sup>57</sup> have shown that nasogastric or postpyloric feeding is equivalent. Meta-analyses have shown no evidence to support the use of elemental or immune-enhanced feeding formulas versus standard formulas.<sup>58</sup>

## **The Role of ERCP and Cholecystectomy**

Cholelithiasis is recognized as a major cause of acute pancreatitis and the primary cause of acute pancreatitis in most populations. ERCP has therefore been used as a diagnostic and potentially therapeutic modality in acute pancreatitis. Patients are selected for ERCP predominantly based on whether evidence exists for obstructive cholelithiasis. The need for ERCP in the setting of biliary obstruction and cholangitis is paramount, although the need for ERCP without such evidence is less evident. Two randomized controlled trials demonstrated a significant reduction in morbidity without reduction in mortality with the routine use of ERCP in acute pancreatitis.<sup>59,60</sup> However, both studies were criticized for including patients with known obstruction and cholangitis, possibly accounting for the observed benefit. A more recent multicenter study that excluded patients with biliary obstruction showed increased complications and mortality in the group randomized to undergo ERCP.<sup>61</sup> ERCP is not indicated in the absence

of jaundice, with evidence of choledocholithiasis with a dilated bile duct on imaging, in cases of mild acute gallstone pancreatitis, or as a diagnostic test before cholecystectomy.<sup>62</sup>

Patients with gallstone pancreatitis have a high rate of recurrent disease. Several studies have documented a readmission rate of up to 18% for gallstone disease in patients admitted for acute gallstone pancreatitis and discharged without cholecystectomy.<sup>63</sup> A randomized controlled trial demonstrated that patients undergoing laparoscopic cholecystectomy within 48 hours of admission for gallstone pancreatitis had a shorter hospital stay compared to waiting for resolution of pain.<sup>64</sup> Early cholecystectomy is demonstrated as safe, without increases in complications or mortality, although patients with severe acute pancreatitis with signs of critical illness or pancreatic necrosis should wait several weeks prior to surgical intervention.

High rates of recurrence in patients with gallstone pancreatitis discharged without cholecystectomy have led to the use of ERCP and sphincterotomy for risk reduction. One prospective study showed a decrease in risk of recurrent gallstone disease from 37% to 0% with ERCP and sphincterotomy.<sup>65</sup> A systematic review showed reduction in all biliary events from 24% to 10% when patients not undergoing cholecystectomy underwent ERCP and sphincterotomy prior to hospital discharge.<sup>63</sup> Although cholecystectomy is indicated at the index admission for gallstone pancreatitis, patients who are unable to undergo surgery due to comorbid illness should be considered for ERCP and sphincterotomy.

## **Antibiotic Therapy**

The development of infected pancreatic necrosis significantly increases risk of mortality. Of patients with severe pancreatitis who succumb to the disease, most do so as a result of infectious complications, and prophylactic antibiotic therapy has been proposed in the past as a potential means of limiting infection. Infection increases over time for at least the first 3 weeks in the course of pancreatitis; in one study, 24% of patients undergoing surgery for pancreatitis had infected necrosis at 1 week, whereas 71% of patients had infection at 3 weeks.<sup>66</sup> Aerobic and anaerobic gastrointestinal flora are the primary organisms involved, and infection may be monomicrobial or

polymicrobial. The association of infection with mortality has been the rationale behind the use of prophylactic antibiotics targeted against enteric organisms for patients with pancreatic necrosis. However, this practice is demonstrated to lead to the development of antibiotic-resistant bacterial and fungal infections.

Few topics in pancreatitis have been as controversial in past years as the use of prophylactic antibiotics in severe pancreatitis. Several randomized controlled trials examined the role of prophylactic antibiotics, with conflicting recommendations. Early trials, however, were criticized for methodology including high use of antibiotics in control arms, poor accrual, small numbers, and poorly defined inclusion criteria. Two more recent randomized studies were considered more definitive. Rokke et al<sup>67</sup> showed no reduction in mortality or need for interventions with early use of imipenem, and Dellinger et al<sup>68</sup> showed no impact on pancreatic or peripancreatic infection, intervention rate, or mortality with the use of meropenem. Meta-analyses have confirmed no reduction in mortality, intervention rate, or incidence of pancreatic infection with prophylactic antibiotics.<sup>69-71</sup>

Despite the acceptance that antibiotics should not be used for prophylaxis, many patients still receive antibiotics in the absence of documented pancreatic infection.<sup>72</sup> This often represents suspected sepsis from another source, treatment initiated at another institution prior to transfer to a tertiary care center, or other clinical suspicion for infection. In all settings, antibiotics should be discontinued in the absence of documented infection.

## **INTERVENTION FOR PERIPANCREATIC FLUID COLLECTIONS AND PANCREATIC NECROSIS**

While interstitial acute pancreatitis is usually self-limited and managed with supportive care, approximately 20% of patients will proceed to necrotizing pancreatitis. This is notable for necrosis of the pancreatic parenchyma or peripancreatic tissue, manifestations of SIRS, risks of infection, and multiorgan failure.<sup>73</sup> Mortality can reach 15% with pancreatic necrosis and exceed 30% with infected pancreatic necrosis.<sup>5</sup> Local complications

identified on CT scan include peripancreatic fluid collections, acute necrotic collections (ANCs), pseudocysts, and walled-off necrosis. A number of surgical and other interventional approaches have been employed in an attempt to limit the morbidity and mortality of this process. Recent years have witnessed a significant change in the indications for intervention for necrotizing pancreatitis, timing of intervention, and methods of surgical, radiologic, and endoscopic interventions. The role of conservative management and minimally invasive approaches is now better defined, and more patients are able to avoid traditional surgical debridement with the use of percutaneous catheter drainage and endoscopic techniques. No universally accepted algorithms exist, although evidence-based consensus continues to develop.<sup>9</sup> Data support the preferred management of patients with complications of acute pancreatitis at high-volume centers capable of offering the full multidisciplinary complement of care.<sup>74,75</sup>

Only a few decades ago, the presence of pancreatic necrosis was considered an indication for surgical debridement. It was later recognized that nonoperative management could be pursued for sterile pancreatic necrosis, with surgical debridement limited to infected necrosis.<sup>6,32,66</sup> In this paradigm, the presence of infection was initially considered an absolute indication for surgical debridement, as infected pancreatic necrosis had been associated with a mortality of virtually 100% without debridement.<sup>76</sup> The need for surgery in all such patients was subsequently challenged by recognition that some patients with documented infected pancreatic necrosis were successfully managed with antibiotics and maximal supportive care.<sup>77</sup> Surgical therapy, when required, could often be delayed to a later stage of disease when the systemic inflammatory response had been stabilized and the pancreatic necrosus had become more well-defined and demarcated from surrounding tissue. Others have described series in which over half of the patients with infected necrosis are treated with nonoperative therapy,<sup>78</sup> and urgent surgical debridement for all patients with infected pancreatic necrosis is no longer considered mandatory. While the presence or absence of infection affects prognosis and management, clinical symptoms, rather than suspicion of infection, largely dictate management. The primary modality of intervention until recently was traditional “open” surgical debridement. This has evolved to incorporate endoscopic and radiologic techniques as well as multidisciplinary management.

## **Pancreatic Necrosis With Infection**

Many, if not most, patients with infected pancreatic necrosis will require some form of intervention. Although some asymptomatic patients with infected necrosis are successfully treated with antibiotics alone, these patients are susceptible to clinical decline and will require surgical, endoscopic, or radiographic intervention with the onset of clinical signs or symptoms that do not respond to medical management. Delayed surgical debridement was known to be far preferable to early surgery in the era of surgical management, with higher morbidity and mortality seen with early surgery.<sup>79-81</sup> Early surgical debridement is considered an independent predictor of poor outcome in necrotizing pancreatitis.<sup>82</sup> Expedited intervention may be required in patients with systemic sepsis or hemodynamic instability; otherwise, antibiotic therapy and conservative management allow further organization of the inflammatory process with delayed intervention if symptoms persist.<sup>9</sup>

Delayed intervention of infected pancreatic necrosis has been greatly facilitated by the use of percutaneous catheter drains. Freeny et al<sup>83</sup> in 1998 showed that some patients with infected necrosis might have surgical management delayed or completely avoided with the use of large-bore percutaneous catheters placed with radiographic guidance. A multicenter trial has validated this strategy<sup>84</sup>; comparing patients randomized to standard pancreatic debridement versus a “step-up” approach, complications were lower with the step-up approach, and approximately one-third of patients were managed with catheter drainage alone.

The recognition that patients with infected necrosis do not necessarily need urgent intervention has also changed the practice of pancreatic aspiration to diagnose infection. Patients with suspected infection are increasingly managed with antibiotics and supportive care to allow less invasive and delayed management of a walled-off collection.<sup>85</sup> As a result, diagnostic fine-needle aspiration is required less frequently in the management of suspected infection.

## **Symptomatic Pancreatic Necrosis**

The role of intervention in sterile pancreatic necrosis is less clear than in cases with infection. Although most patients without infection respond to

supportive care, others may experience clinical decline including organ failure. In past years, surgical debridement was pursued by some in the setting of disease progression or failure to improve, regardless of infection.<sup>86,87</sup> However, no universally accepted guidelines defined the criteria for intervention in this population. Some authors suggested debridement for necrosis of more than 50% of the pancreatic parenchyma,<sup>86</sup> rapid clinical deterioration with organ failure,<sup>88</sup> or the presence or persistence of organ failure.<sup>89,90</sup> Still, evidence did not support the use of any specific criteria as an absolute indication for intervention.

The process of walled-off pancreatic necrosis (WON) was previously described as “organized pancreatic necrosis.”<sup>19</sup> In this situation, an intrapancreatic or extrapancreatic heterogeneous semisolid collection that develops in the setting of acute necrotizing pancreatitis develops an encapsulated wall.<sup>8</sup> Some patients may experience a prolonged clinical course with persistent pain, malaise, and inability to eat, characterized as “persistent unwellness,”<sup>91</sup> and intervention was deemed necessary in some based on symptoms.

WON in the absence of symptoms does not require intervention, regardless of the size of the collection. Symptomatic WON, however, can be characterized by pain, intestinal or biliary obstruction, and later infection. In one series, approximately 10% of patients with sterile pancreatic necrosis underwent surgery for persistent pain and organized necrosis at a mean of 29 days after initial presentation.<sup>32</sup>

## **SURGICAL AND INTERVENTIONAL PROCEDURES**

The use of various radiologic, surgical, and endoscopic interventions varies among providers and institutions, partially due to varying institutional capabilities and evolving techniques. Delayed intervention is preferable in all patients, although interventional radiologic techniques may be performed earlier in the setting of suspected infection.<sup>80</sup> Even in the setting of infection, there is a growing trend to treat with supportive care and antibiotics unless signs of sepsis ensue, until the pancreatic collection becomes walled off.<sup>85</sup>

## Surgical Debridement

For years, laparotomy and traditional “open” surgical debridement were the only available interventions. Surgery has involved removing necrotic pancreatic and peripancreatic tissue, preserving viable pancreas, and allowing drainage for an expected pancreatic fistula. Methods include debridement with closure over drains, debridement with open packing of the pancreatic bed, or debridement with closure over irrigation drains.<sup>92-95</sup> Although open surgical necrosectomy allows an opportunity to remove all necrotic tissue, it is not typically required and is used when less invasive measures have failed.

When open surgical debridement is indicated, exploration may be initiated with a bilateral subcostal or midline incision (Fig. 68-5). The pancreatic bed may be approached via the gastrocolic ligament or through the transverse mesocolon. An approach through the mesocolon may avoid the dense inflammatory process obscuring planes between the stomach and transverse colon (Fig. 68-6).<sup>93</sup> Others have argued against this approach in order to avoid exposing the inframesocolic space to infection.<sup>94</sup> Pancreatic debridement is accomplished bluntly, using finger dissection to remove necrotic tissue that easily separates from surrounding structures. Overzealous removal of tissue can result in hemorrhage. All fluid and tissue is sent for aerobic and anaerobic culture. Exposure and removal of all tissue may require access to both paracolic gutters, the pararenal spaces, retroperitoneum into the pelvis, or the gastrohepatic omentum. Surgical debridement can be followed with closed-suction drainage (Fig. 68-7),<sup>95</sup> continuous closed lavage,<sup>96</sup> or marsupialization of the pancreatic bed with open drainage and repeat packing in patients with severe necrosis.<sup>97</sup> Comparison between these techniques is difficult given the heterogeneous nature of patients included and lack of standardization of operative indications.

**FIGURE 68-5** Operative approaches to open pancreatic debridement. Either a midline or bilateral subcostal approach is acceptable.

**FIGURE 68-6** Transmesocolic approach to the lesser sac. The necrotic pancreas is approached through the transverse mesocolon, to the left of the middle colic artery.

**FIGURE 68-7** Irrigation and drainage of pancreatic bed. Drainage tubes are

used for technique of closed drainage or postoperative saline lavage; for open packing technique, the pancreatic bed is packed with sterile bandages.

Several indications for open surgical debridement remain. Occasionally patients will have collections that are not accessible via image-guided techniques due to overlying abdominal structures. Collections may be multifocal or persist after minimally invasive necrosectomy. Persistent symptoms attributed to these collections may warrant access via laparotomy. In all cases, surgical therapy is delayed as long as possible, which may facilitate atraumatic debridement.<sup>98</sup>

## **Minimally Invasive Debridement**

The morbidity and mortality for open pancreatic debridement are considerable in most series, particularly in the setting of organ failure.<sup>99</sup> Minimally invasive surgical debridement techniques have been described as potential alternatives in order to decrease this risk of death and complications.<sup>100</sup> Laparoscopic approaches to pancreatic debridement are well described and may be more successful in removing all necrotic material compared to other minimally invasive methods.<sup>101</sup> Advantages of this approach include minimizing wound complications, although it carries some risk of further peritoneal infection with pneumoperitoneum. It is recognized that these are technically challenging laparoscopic procedures, perhaps limiting their overall utility.<sup>102</sup>

The technique of video-assisted retroperitoneal debridement (VARD) uses a retroperitoneal approach via dorsal lumbotomy and an endoscope advanced in the tract of a radiographically placed drain.<sup>103</sup> The tract is serially dilated to allow access of an endoscope or laparoscope to visualize the necrotic cavity. Extraction of the pancreatic necrosus in these cases is limited by the diameter of the access. Several interventions may be required for complete drainage, although subsequent laparotomy is required in few patients. Success with VARD has been described, with decreased morbidity and mortality compared to open debridement<sup>104</sup>; patients with necrosis extending medially or inferior to the mesentery may not be optimal candidates.

## **Direct Endoscopic Necrosectomy**

Endoscopic debridement is increasingly recognized as an alternative to open surgical debridement, although its availability is limited to specialized centers. Retroperitoneal endoscopy via transgastric fenestration allows direct visual access to retroperitoneal collections.<sup>105</sup> An approach to the necrotic collection may be obtained from the stomach or duodenum. Collections may be identified with endoscopic ultrasound if necessary and are punctured with serial dilations to allow stent placement. Necrotic tissue is evacuated using an endoscopic snare. One contemporary series from 6 US centers showed resolution of WON in 91% of patients with endoscopic necrosectomy, with only 4% requiring surgical debridement.<sup>106</sup> Other reviews have suggested 76% definitive resolution with endoscopic techniques, with a median of 4 sessions.<sup>107</sup> Endoscopic necrosectomy has been compared to surgical necrosectomy in a small randomized trial; endoscopic necrosectomy resulted in lower postprocedural inflammation, low organ failure, and lower pancreatic fistula, as well as lower morbidity and mortality.<sup>108</sup>

Not all patients with pancreatic necrosis are candidates for endoscopic debridement. For endoscopic access, collections are ideally not only walled off but also adjacent to the gastric or duodenal lumen. Some collections are not accessible endoscopically due to lack of abutment of the stomach or duodenum. Early collections are also not ideally suited for endoscopic access due to risk of intraabdominal spread, and multifocal collections are also less suitable for endoscopic debridement.

## **Percutaneous Catheter Drainage**

Freeny first described the use of image-guided percutaneous catheter drainage (PCD) to temporize patients with pancreatic necrosis and sepsis.<sup>83</sup> Surprisingly, half of the patients included were treated with PCD as the only intervention. Percutaneous drainage has evolved to a first-line treatment for many patients. One significant advantage of PCD is the opportunity to address symptomatic or infected necrosis before WON has developed. PCD may be useful in patients deemed unfit for surgical intervention or to address residual collections after surgical debridement. Catheters are placed under CT or ultrasound guidance, with a transperitoneal or retroperitoneal approach. Multiple catheter may be required, and repeat procedures to place new or larger catheters up to 30 Fr may be needed.<sup>109</sup>

Solid pancreatic debris has traditionally been thought to be too thick for evacuation with drains alone; nevertheless, studies have shown that catheters are often effective without necrosectomy. A systematic review of 11 studies from 2011 showed successful management with catheters alone in over 50% of patients.<sup>110</sup> Other studies demonstrate an approximately 50% success rate in treating necrotizing pancreatitis with PCD, whether sterile or infected.<sup>111</sup>

The use of PCD as the first modality in a “step-up” approach to manage peripancreatic collections is increasingly being instituted. This technique uses percutaneous or endoscopic access to manage initial symptoms or infection, with use of VARD for persistent sepsis. In the PANTER trial, catheter drainage reduced morbidity with equal mortality compared to surgical necrosectomy.<sup>84</sup> This same group in 2011 described a cohort of 639 patients with pancreatic or peripancreatic necrosis; 62% of patients were treated conservatively and 38% were treated with an intervention, either PCD, endoscopic debridement, or surgical debridement. Mortality was only 7% in the group managed conservatively versus 27% in the interventional cohort; in the group requiring intervention, 35% of patients required only catheter drainage.<sup>82</sup>

## SUMMARY

Acute pancreatitis, although often self-limited and managed conservatively, may progress to severe disease with sepsis, multiorgan failure, and death. Initial management is largely oriented toward relief of symptoms and preventing progression to more severe disease. Fluid resuscitation, close monitoring, and a search for inciting factors are standard. Improved recognition of severe disease and further improvements in the characterization of complications allow tailored management of complicated disease. Nonoperative management for most patients, including patients with severe disease, has become routine, and an increasing array of options including percutaneous catheter drainage and endoscopic drainage has been successfully employed to avoid the morbidity of surgery. Open surgical debridement, once considered the gold standard of management for infected pancreatic necrosis, has a more limited role, although it remains an important tool in patients who have failed other means of intervention. Future advances in minimally invasive options will likely continue to reduce the morbidity

and mortality of severe acute pancreatitis
