# COMPLICATIONS OF ACUTE PANCREATITIS

*John A. Windsor • Benjamin P.T. Loveday • Sanjay Pandanaboyana*

## INTRODUCTION

A third of all patients with acute pancreatitis develop complications, and a quarter of those patients will not survive, but recovery is now expected for the remainder because of improvements in the diagnosis and management of acute pancreatitis.<sup>1</sup> The complications of acute pancreatitis can be local, regional, and/or systemic. The most important determinants of the severity of acute pancreatitis are infected local complications and persistent organ dysfunction,<sup>2</sup> which are the basis for classifying acute pancreatitis severity (Table 69-1).<sup>3,4</sup> This chapter focuses on the diagnosis and management of these important complications of acute pancreatitis.

**TABLE 69-1: CLASSIFICATION OF ACUTE PANCREATITIS SEVERITY BASED ON LOCAL AND SYSTEMIC COMPLICATIONS, ACCORDING TO THE DETERMINANTS-BASED CLASSIFICATION<sup>3</sup> AND THE REVISED ATLANTA**

## CLASSIFICATION<sup>6</sup>

### Determinants-Based Classification (2012)

	Mild AP	Moderate AP	Severe AP	Critical AP
Local complications	No <i>and</i>	Sterile <i>and / or</i>	Infected <i>or</i>	Infected <i>and</i>
Systemic complications	No	Transient OF	Persistent OF	Persistent OF

### Revised Atlanta Classification (2013)

	Mild AP	Moderately Severe AP	Severe AP
Local complications (or comorbidities <sup>a</sup> )	No <i>and</i>	Yes <i>and/or</i>	
Systemic complications	No	Transient OF	Persistent OF

<sup>a</sup>Exacerbation of existing comorbidities.  
Abbreviations: AP, acute pancreatitis; OF, organ failure.

## LOCAL COMPLICATIONS

The local complications of acute pancreatitis are related to fluid collections and tissue necrosis in and around the pancreas. These were defined by the Atlanta Symposium in 1992 by the terms pancreatic necrosis, pseudocyst, and abscess.<sup>5</sup> However, these terms have been confusing and new terminology has been introduced in an attempt to reflect current understanding of the pathophysiology and CT scan morphology of the disease.<sup>6</sup> Changes in the morphology of local collections can occur over time and these are now defined on the basis of their content, chronicity, and whether infection is present (Table 69-2).<sup>7</sup>

**TABLE 69-2: CLASSIFICATION OF LOCAL COMPLICATIONS OF ACUTE PANCREATITIS BASED ON CONTENT, CHRONICITY, AND INFECTION<sup>6,7</sup>**

Content	Acute (<4 weeks, no defined wall)		Chronic (>4 weeks, defined wall)	
	No Infection	Infection	No Infection	Infection
<b>Fluid</b>	Acute pancreatic fluid collection	Infected APFC	Pseudocyst	Infected pseudocyst
<b>Solid ± Fluid</b>	Acute necrotic collection	Infected ANC	Walled-off necrosis	Infected WON

The revised Atlanta Classification uses a 4-week cutoff, and fluid collections present for less time are called either an acute pancreatic fluid collection (APFC) or acute necrotic collection (ANC).<sup>6</sup> These acute collections can either spontaneously resolve or progress to become “walled-

off” or encapsulated, which is a reaction of the surrounding tissue to the enzyme-rich fluid. The resulting wall is usually well-defined on a CT scan after 4 weeks. A pancreatic pseudocyst is the term that has traditionally been applied to this encapsulated lesion, but it is now appreciated that the contents can be variable ranging from entirely fluid to containing solid necrotic tissue.<sup>6</sup> When a fluid collection has developed in association with pancreatic necrosis, the revised Atlanta Classification recommends the term “walled off necrosis” (WON). The term pseudocyst has now a more restricted definition and is only applied when the content is entirely fluid and has been present for 4 or more weeks.<sup>6,7</sup>

## **Acute Pancreatic Fluid Collections**

### **DESCRIPTION**

Acute fluid collections demonstrate no solid content or defined wall, and typically exist adjacent to the pancreas. These collections occur in 30% to 50% of cases and contain a mixture of inflammatory exudate and/or enzyme-rich pancreatic secretions from small side-branch ducts. The leaked pancreatic secretions can track widely through the retroperitoneum and mediastinum and may directly lead to pancreatic ascites and/or pleural effusions. The most common routes of extension are into the lesser sac, behind the pancreatic head, behind the left and right colon anterior to the psoas muscle, and into the small bowel mesentery, and may bulge through the transverse mesocolon.

### **DIAGNOSIS**

Acute fluid collections usually start to develop in the first 48 to 72 hours after the onset of symptoms. Contrast-enhanced CT (CECT), magnetic resonance imaging (MRI), transabdominal ultrasound (US), or endoscopic ultrasound (EUS) can be used to confirm the diagnosis. To distinguish an APFC from ANC, or more specifically determine whether there is necrosis within the collection, it is best to use MRI or US.<sup>6</sup> However, the presence of necrosis within a collection can often be inferred by the extent and pattern of hypoperfusion on CECT.

## MANAGEMENT

Acute fluid collections usually remain sterile and resolve spontaneously.<sup>8</sup> However, these are the precursors of pancreatic pseudocysts. Large collections of fluid around or within the pancreas are more likely to be due to disruption of the main pancreatic duct and are more likely to persist for a number of weeks or continue to increase in size.

Acute fluid collections are rarely symptomatic and do not require active treatment. Intervention by drainage (endoscopic, radiological, or surgical) risks introducing infection into a sterile collection. An asymptomatic fluid collection is managed by observation alone, and only when infection is present is drainage necessary. There is no role for diuretics or peritoneal lavage.<sup>9</sup> Rarely, leakage from a disrupted main pancreatic duct can be treated by endoscopic or surgical intervention. Endoscopic pancreatic duct stenting can be used across the sphincter of Oddi to decrease ductal pressure and facilitate drainage into the fluid collection through the disrupted duct to drain the collection directly or across the damaged duct to redirect drainage from the collection to the duodenum and to stent the duct to reduce the risk of stricture formation. Radiological percutaneous stenting in the presence of disrupted main pancreatic duct can result in an external pancreatic fistula. There is no role for the operative treatment of APFC.

The drainage of pleural effusions in patients with acute pancreatitis should be considered in the face of compromised respiratory function or inadequate oxygenation. Chronic pleural effusions may be due to an internal pancreatic fistula and are best treated with a chest tube, nasojejunal tube feeding, and a trial of somatostatin. Persistence or recurrence will require identification of a pancreatic leak by endoscopic pancreatography. Definitive treatment may require endoscopic or surgical internal drainage once a pseudocyst has developed, or rarely a distal resection of the pancreas if this will address the fistula.

## Acute Necrotic Collections

### DESCRIPTION

ANCs contain both solid material and fluid, but are not walled off by a fibrous capsule. A CECT will demonstrate hypoperfused pancreas associated

with a fluid collection. The necrosis is associated with disruption to branch ducts and sometimes the main pancreatic duct. Over time the necrotic tissue demarcates, sequesters, and liquefies, forming part of the APFC. With persistence and maturation, an encapsulating wall forms, and after 4 weeks this is termed WON. Postnecrotic collections are usually sterile but infection can occur. The term *pancreatic abscess* has been abandoned<sup>6</sup> because it does not distinguish between an infected acute fluid collection (AFC), infected pseudocyst, infected ANC, or infected WON.

## DIAGNOSIS

Acute postnecrotic fluid collections are diagnosed by CECT, MRI, US, or EUS and usually after the first week from disease onset. An infected APFC can be diagnosed by the presence of gas within the collection on CT (Fig. 69-1) within 4 weeks of disease onset. The definitive diagnosis of infected APFC requires image-guided fine-needle aspiration (FNA) for Gram stain and culture or culture of fluid obtained from percutaneous drainage. In practice a FNA is rarely required to confirm infection.<sup>6</sup> Endoscopic retrograde cholangiopancreatography (ERCP) can be used to determine whether there is any ductal communication associated with the collection, but this is rarely required and risks the introduction of infection.

A

B

**FIGURE 69-1** CT scan showing infected pancreatic necrosis with gas within the collection on cross-sectional (**A**) and coronal (**B**) views.

## Pseudocyst

A pseudocyst is a circumscribed collection that contains only fluid, has a well-defined wall, and has been present for 4 or more weeks after disease onset.<sup>6</sup> In the original Atlanta Classification,<sup>5</sup> a pseudocyst was defined as a collection of pancreatic juice enclosed by a wall of fibrous tissue, and there was no mention of the content. In practice, the lesion is either a fluid collection that does not contain necrosus, which when mature is best termed a pseudocyst, or a postnecrotic fluid collection that contains necrosus, which when mature is best termed WON. The result of this redefinition is that the term pseudocyst is applicable less frequently.

The precursor of a pseudocyst is the APFC, and it is differentiated from the latter by the presence of a well-defined wall (capsule) without an epithelial lining. This is in contrast to cystic neoplasms of the pancreas, which are characterized by an epithelial lining. This, however, is not an absolute distinction, as there may be discontinuous epithelium within cystic neoplasms (probably due to pressure atrophy) and partial epithelialization within chronic pseudocysts (facilitated by communication with the main pancreatic duct). In fewer than 20% of cases, more than one pseudocyst is present. Acute pseudocysts are located most often in close proximity to the pancreas, especially in the lesser sac ([Fig. 69-2](#)), but can be found in the pelvis, scrotum, mediastinum, or thorax.

**FIGURE 69-2** A CT scan of a pancreatic pseudocyst located in the lesser sac. P, pseudocyst; S, stomach.

## **PATHOGENESIS AND CLASSIFICATION**

The development of a pseudocyst requires pancreatic duct disruption. This occurs with acute pancreatitis in 10% to 15% of cases, but also in the case of pancreatic duct trauma (usually to the pancreatic neck), and in chronic pancreatitis where there may be multiple pseudocysts due to duct obstruction.<sup>10</sup> The leakage of enzyme-rich secretion incites a marked inflammatory reaction in the retroperitoneum, peritoneum, and serosa of adjacent viscera. As a result, the fluid is contained by a developing layer of granulation tissue and fibrosis that matures over time. If the communication between pancreatic duct and pseudocyst persists, the pseudocyst can continue to enlarge. The contents of the pseudocyst usually consist of a relatively clear, watery fluid. However, with hemorrhage it may contain clot and become xanthochromic. In the presence of infection, a pseudocyst will contain pus. If a fluid collection develops in the context of pancreatic necrosis, and it will contain solid tissue and should be termed WON.

Pseudocysts were classified by D'Egidio in 1991 ([Table 69-3](#)).<sup>11</sup> *Type I*

pseudocysts occur after an episode of acute pancreatitis and are associated with normal pancreatic duct anatomy, and rarely communicate with the main pancreatic duct. *Type II* pseudocysts occur after an episode of acute or chronic pancreatitis and have a diseased but not strictured pancreatic duct, and there is often a communication between the duct and the pseudocyst. *Type III* pseudocysts occur in chronic pancreatitis and are always associated with a duct stricture and a communication between the duct and the pseudocyst.

**TABLE 69-3: THE D’EGIDIO CLASSIFICATION OF PANCREATIC PSEUDOCYSTS AND THE PRIMARY TREATMENT OPTIONS<sup>11</sup>**

Type	Context	Pancreatic Duct	Duct–Pseudocyst Communication	Primary Treatment
I	Acute postnecrotic pancreatitis	Normal	No	Percutaneous drainage
II	Acute-on-chronic pancreatitis	Abnormal (no stricture)	50:50	Internal drainage or resection
III	Chronic pancreatitis	Abnormal (stricture)	Yes	Internal drainage with duct decompression

## COMPLICATIONS

Complications occur in about 10% of pseudocysts. The four most common complications of pseudocysts are infection, rupture, bleeding, or symptoms due to a mass effect.<sup>12</sup>

Pseudocysts are initially sterile, but infection can occur in up to 25% of cases.<sup>12,13</sup> The presence of sepsis due to an infected pseudocyst is an indication for drainage (see below).

The rupture of a pseudocyst can occur by erosion into adjacent organs, which may allow the pseudocyst to resolve or it may produce an internal cystoenteric fistula or fistula between the pancreas and other organs, including pleura, bronchus, and bladder. The term fistula is technically incorrect since the communication is not between two epithelial-lined structures. Rupture into the gastrointestinal tract may be associated with significant hemorrhage. Rupture into the peritoneum leads to pancreatic ascites and can be a dramatic presentation with acute abdominal pain and rigidity from chemical peritonitis.

Bleeding associated with a pancreatic pseudocyst can be life-threatening complication. There are several causes of bleeding. Bleeding may occur

secondary to erosion and rupture into the gastrointestinal tract and presents as hematemesis and/or melena. More ominous is bleeding from the direct erosion of a significant visceral vessel, including the splenic, gastroduodenal, and middle colic vessels. The action of pancreatic enzymes (especially elastase) on the vessel wall can lead to thinning of the vessel wall with aneurysm and pseudoaneurysm formation (Fig. 69-3). This situation carries a high mortality (~20%).<sup>14</sup> The risk of bleeding is increased in the presence of local infection. If time and patient stability permit, it may be possible to perform a CT scan with arterial phase contrast to demonstrate the pseudoaneurysm and sometimes active bleeding. However, emergency selective splanchnic angiography is frequently required to delineate the site of bleeding and to embolize the culprit vessel, which is the preferred treatment (Fig. 69-4). Bleeding into a mature pseudocyst may be arrested by tamponade, although with less mature pseudocysts there is the risk of pseudocyst rupture with hematoma. Emergency surgery is rarely required and is often very difficult where the objective is to oversew the bleeding vessel. The options then include packing if there are concerns regarding recurrent bleeding. Occasionally it is possible to resect the pseudocyst with the body/tail of the pancreas, which is effective in preventing recurrent hemorrhage.

**FIGURE 69-3** A contrast CT scan showing the pseudocysts, the medial one complicated by a pseudoaneurysm related to the splenic artery.

A

B

**FIGURE 69-4** Selective mesenteric angiogram showing a pseudoaneurysm related to the left gastric artery (**A**) and successful embolization (**B**).

A large pseudocyst may exert a mass effect and thereby produce early satiety (stomach), partial or complete intestinal obstruction (duodenum, gastric outlet, esophagogastric junction, and rarely small or large bowel), cholestasis (bile duct), and venous thrombosis (portal, superior mesenteric, and splenic veins) leading to portal or segmental hypertension and varices. Mass effect is more likely when a pseudocyst is greater than 6 cm in diameter.<sup>12</sup>

## DIAGNOSIS

With modern imaging there is a higher proportion of asymptomatic pseudocysts diagnosed. A pseudocyst may be suspected when a patient with acute pancreatitis fails to recover after the initial week of treatment or when, after initial improvement, symptoms return. In this setting there can be a moderate secondary rise in serum amylase/lipase. While a CECT is often performed, depending on the patient's habitus and how much intestinal gas is present, ultrasonography can often make the diagnosis, and has the advantage of confirming whether the content is fluid only or whether there is solid necrosum present. EUS can be useful in distinguishing a pseudocyst from a cystic neoplasm because it often delineates internal septation better than CT scan.<sup>15</sup> The advantage of CT scanning is that it is not operator dependent and is more useful in planning therapy. It will demonstrate the key features of a pseudocyst (ie, size, shape, wall thickness, and contents), the nature of the pancreas (ie, presence and extent of necrosis, diameter of pancreatic duct, and features of chronic pancreatitis, including atrophy and calcification), and, importantly, the relationship of these to the surrounding organs (Fig. 69-2), which is essential for planning internal surgical drainage. Triphasic helical CT scanning will delineate the regional arteries (to look for pseudoaneurysm formation) (Fig. 69-3) and veins (to look for thrombosis, cavernous transformation, and formation of varices).

ERCP is not routinely required as part of the diagnostic workup for pseudocysts. Over 90% of patients with a pseudocyst have some abnormality of the pancreatic duct, but not all require treatment. In symptomatic cases where treatment is likely, it is useful in planning further management and can

be both diagnostic and therapeutic. Because of the risks of exacerbating pancreatitis, perforation, bleeding, and introducing infection, it is best that ERCP is done within 48 hours of any planned drainage procedure. The unique diagnostic contribution of ERCP is to accurately delineate a communication between the main pancreatic duct and the pseudocyst, which occurs in up to a half of patients. A communication of this type is a relative contraindication to external drainage of a pseudocyst.<sup>16</sup> The classification of the main pancreatic duct by ERCP has been shown to assist in selecting the type of treatment, where the presence or absence of a stricture, communication, and obstruction is an important feature to note.<sup>17</sup> Magnetic resonance cholangiopancreatography (MRCP) may be used to assess pancreatic and biliary duct morphology instead of ERCP and in some centers has replaced ERCP in its diagnostic role. MRCP has the advantage of being noninvasive with similar diagnostic accuracy to ERCP, but lacks any potential therapeutic intervention.<sup>18</sup>

Diagnosing a complication in a known pseudocyst is usually straightforward. The rupture of a pseudocyst into the peritoneal cavity is associated with the onset of acute abdominal pain and signs of peritonitis. This is in contrast to the spontaneous decompression of a pseudocyst into an adjacent organ, which usually results in the relief of symptoms. Infection of a pseudocyst is accompanied by signs of sepsis. Infection can be confirmed with image-guided FNA for Gram stain and bacterial culture. Bleeding usually results in an increase in abdominal pain and possible syncope, tachycardia, and hypotension. A drop in hemoglobin concentration is expected.

Although cystic neoplasms are rare, they can be mistaken for pseudocysts. Absence of an antecedent history of acute pancreatitis, elevation of cyst fluid carcinoembryonic antigen (CEA) or carbohydrate antigen (CA 19-9), and/or the presence of internal septations should suggest this diagnosis. If EUS is available, it will enable the identification of septations (usually microcystic pattern for serous lesions or macrocystic pattern for mucinous lesions), mural nodules, echogenic debris, and calcification. It may also allow aspiration of fluid content for analysis. Pseudocysts usually contain fluid with elevated amylase (>5000 U/mL) and an absence of tumor markers, but this should not be relied upon for a definitive diagnosis.<sup>19</sup>

## INDICATIONS FOR INTERVENTION

The natural history of a pseudocyst is not easy to predict. Spontaneous resolution occurs frequently and usually within 6 weeks. Size alone is a poor predictor because resolution can occur even with very large pseudocysts. When larger than 6 cm in diameter and in the case of continued enlargement, a pseudocyst is more likely to persist and develop complications. Persistence is also more likely if there is a distal stricture of the main pancreatic duct and a proximal communication between the main pancreatic duct and the pseudocyst.

The two principal indications for treating pancreatic pseudocysts are to relieve symptoms and to treat complications. In the absence of symptoms or evidence of enlargement, conservative management is usually reasonable. A traditional approach that dictated treatment of all pseudocysts that have been present for more than 4 to 6 weeks is no longer justified.<sup>20</sup> The clinical decision about whether a pseudocyst in a particular patient requires active intervention can be difficult. The desire to allow time for spontaneous resolution to occur must be balanced against the risk of complications while waiting for cyst wall maturity. The traditional indication for treatment was the development of pseudocyst complications. Now the motivation is to prevent complications. An enlarging asymptomatic pseudocyst that has been present for 6 weeks is usually treated. A natural-history study from India indicates that asymptomatic pseudocysts less than 7.5 cm in diameter and without internal debris will resolve spontaneously on an average of 5 months.<sup>21</sup> The mean diameter of pseudocysts requiring treatment is about 9 cm.<sup>22,23</sup> While there has been a trend toward conservative management, there has been an increase in the number of ways to treat a pseudocyst, including open surgical, laparoscopic, endoscopic, and radiological techniques.

Two important rules in the treatment of pseudocysts are that a cystic neoplasm must not be treated as a pseudocyst and elective external drainage should not be done if there is downstream and unrelieved pancreatic ductal obstruction because of the high risk of an external pancreatic fistula. The approach to treatment (Table 69-4) depends on the features of the pseudocyst, the state of the main pancreatic duct (eg, stricture or communication), and the fitness and level of symptoms of the patient. Also important is the level of available expertise and experience with the various treatment modalities.

**TABLE 69-4: TREATMENT APPROACHES FOR PANCREATIC PSEUDOCYST**

<b>Approaches</b>	<b>Examples</b>
Endoscopic	Transgastric drainage ± self-expanding metal stent Transduodenal drainage ± self-expanding metal stent Transpapillary stent
Radiologic	Percutaneous drainage Percutaneous transgastric drainage
Surgical (open or laparoscopic)	Cystogastrostomy  Roux-en-Y cystojejunostomy Cystoduodenostomy Distal pancreatectomy ± splenectomy External tube drainage

The following general features of a pseudocyst are important in considering the most appropriate treatment:

- The thickness of the pseudocyst wall, which is usually a function of the duration of the pseudocyst. This is important because adherence of the wall is more likely with maturity and is relevant for wall-opposing metal stents and for safely securing sutures for surgical drainage procedures.
- The location of the pseudocyst. If adherent to the stomach or duodenum, the options are different than if the pseudocyst is deep within the retroperitoneum and covered by bowel loops.
- The contents of the pseudocyst. The presence of blood may indicate the need for prior embolization of a pseudoaneurysm. Pus will require drainage, either internally or externally. The presence of solid necrosium suggests the lesion is in fact WON and may require some form of necrosectomy.
- The number of pseudocysts. If multiple pseudocysts are present, then minimally invasive approaches are less feasible. Conservative management is less appropriate for multiple pseudocysts.

- The etiology of the pseudocyst. If there is evidence of acute-on-chronic pancreatitis, different treatment may be required than if it has arisen after the first episode of acute pancreatitis.
- The main pancreatic duct anatomy and degree of disruption. The pancreas and the pancreatic duct require separate consideration in planning the treatment of a pseudocyst. The pancreas may warrant treatment in its own right, especially if there is a ductal stricture, a dilated duct, regional disease, or a mass warranting resection.

## TREATMENT OPTIONS

Although there has been a trend toward more conservative management of pseudocysts, especially in the absence of symptoms or complications, there has been an increase in the number of treatment options available (Table 69-5).<sup>24</sup> The most effective and reliable means of treating a pseudocyst is probably still by internal drainage by an open surgical approach, but there is a lack of comparative studies between surgical, endoscopic, and radiological treatments. Despite this, less invasive options are now being used more frequently.

**TABLE 69-5: OPEN AND MINIMALLY INVASIVE APPROACHES TO THE TREATMENT OF PANCREATIC NECROSIS**

### Open surgery approaches

Pancreatic resection

Necrosectomy + wide tube drainage

Necrosectomy + relaparotomy (staged reexploration)

Necrosectomy + drainage + relaparotomy

Necrosectomy + laparostomy ± open packing

Necrosectomy + drainage + closed continuous lavage

### Minimally invasive approaches

Laparoscopic necrosectomy

Laparoscopic intracavity necrosectomy

Laparoscopic-assisted percutaneous drainage

Laparoscopic transgastric necrosectomy

Percutaneous necrosectomy and sinus tract endoscopy  
MRI–radiologically assisted necrosectomy  
Translumbar extraperitoneal retroperitoneoscopy  
Video-assisted retroperitoneal débridement

---

**Radiological Treatment.** The first description of direct percutaneous aspiration and external drainage using radiologic guidance was in the early 1980s. This technique has become widely practiced, with a reported morbidity of between 10% and 30%. It can be used with an immature pseudocyst wall, although the risk of complications is higher in this setting. Percutaneous drainage is best suited to D’Egidio type I pseudocysts in which there is no significant underlying duct abnormality or communication between the duct and pseudocyst. In simple, uncomplicated pseudocysts, percutaneous drainage is usually successful but is rarely necessary since this group is rarely symptomatic, has the lowest complication rate, and has the best chance of spontaneous resolution.

The introduction of a transgastric approach to percutaneous drainage has almost abolished the problem of external pancreatic fistulas (Fig. 69-5).<sup>24,25</sup> This produces a percutaneous cystogastrostomy but requires an initial period of external transgastric drainage and then subsequent internalization at about 2 weeks. Internalization can be facilitated with a concurrent endoscopic view, especially when using double pigtail catheters. Endoscopy is used to remove the catheters when the pseudocyst has resolved on imaging. A well-matched population-based study comparing percutaneous ( $n = 8121$ ) with open surgical drainage ( $n = 6409$ ) in 14,914 patients with pancreatic pseudocysts revealed a longer length of hospital stay and twice the mortality (5.9 vs 2.8%) for percutaneous drainage.<sup>26</sup> Currently there is a limited role for percutaneous catheter drainage of pseudocysts, but this is most likely to be used in unfit patients and those who are unstable with an infected pseudocyst.

B

**FIGURE 69-5** **A.** CT scan showing percutaneous transgastric drainage of pseudocyst. **B.** Plain radiograph showing double Malecot-type stent cystogastrostomy. (Used with permission from John Chen, MD.)

**Endoscopic Treatment.** There has been significant upsurge in the use of endoscopic treatment for pseudocysts over the last decade. Endoscopic transmural drainage is now widely used. It is wise to perform cross-sectional imaging first to ensure sound apposition of cyst and stomach. While a visible bulge from the pseudocyst may be apparent on endoscopy, EUS guidance during these procedures is now the standard of care. EUS allows greater accuracy and safety by confirming the anatomic route, assists in ruling out a cystic neoplasm, and can identify blood vessels, reducing the risk of bleeding. There are several options available once the cyst is punctured and a guidewire inserted into the cavity. If there is no solid material found in the pseudocyst, then a single pigtail catheter might be all that is required. Recurrence is a risk, especially if there is underlying communication with the main pancreatic duct. While multiple pigtail stents can be inserted following balloon dilation of the track, it is now preferable to insert a self-expanding metal stent designed for transgastric drainage.<sup>27</sup> A recent advance is the lumen-apposing design to reduce the risk of cyst content leaking into the lesser sac (Fig. 69-6).<sup>28</sup> These metal stents are removed endoscopically after pseudocyst resolution. Endoscopic transpapillary techniques include stenting the sphincter of Oddi to lower ductal pressures and to treat pancreatic ducts strictures. The stent can also be advanced via the pancreatic duct into the pseudocyst when there is a demonstrable communication.<sup>29</sup>

**FIGURE 69-6** Lumen apposing metal stent inserted for transgastric drainage of pseudocyst. (Reproduced with permission from Itoi T, Binmoeller KF, Shah J, et al: Clinical evaluation of a novel lumen-apposing metal stent for endosonography-guided pancreatic pseudocyst and gallbladder drainage (with videos), *Gastrointest Endosc.* 2012 Apr;75(4):870-876.)

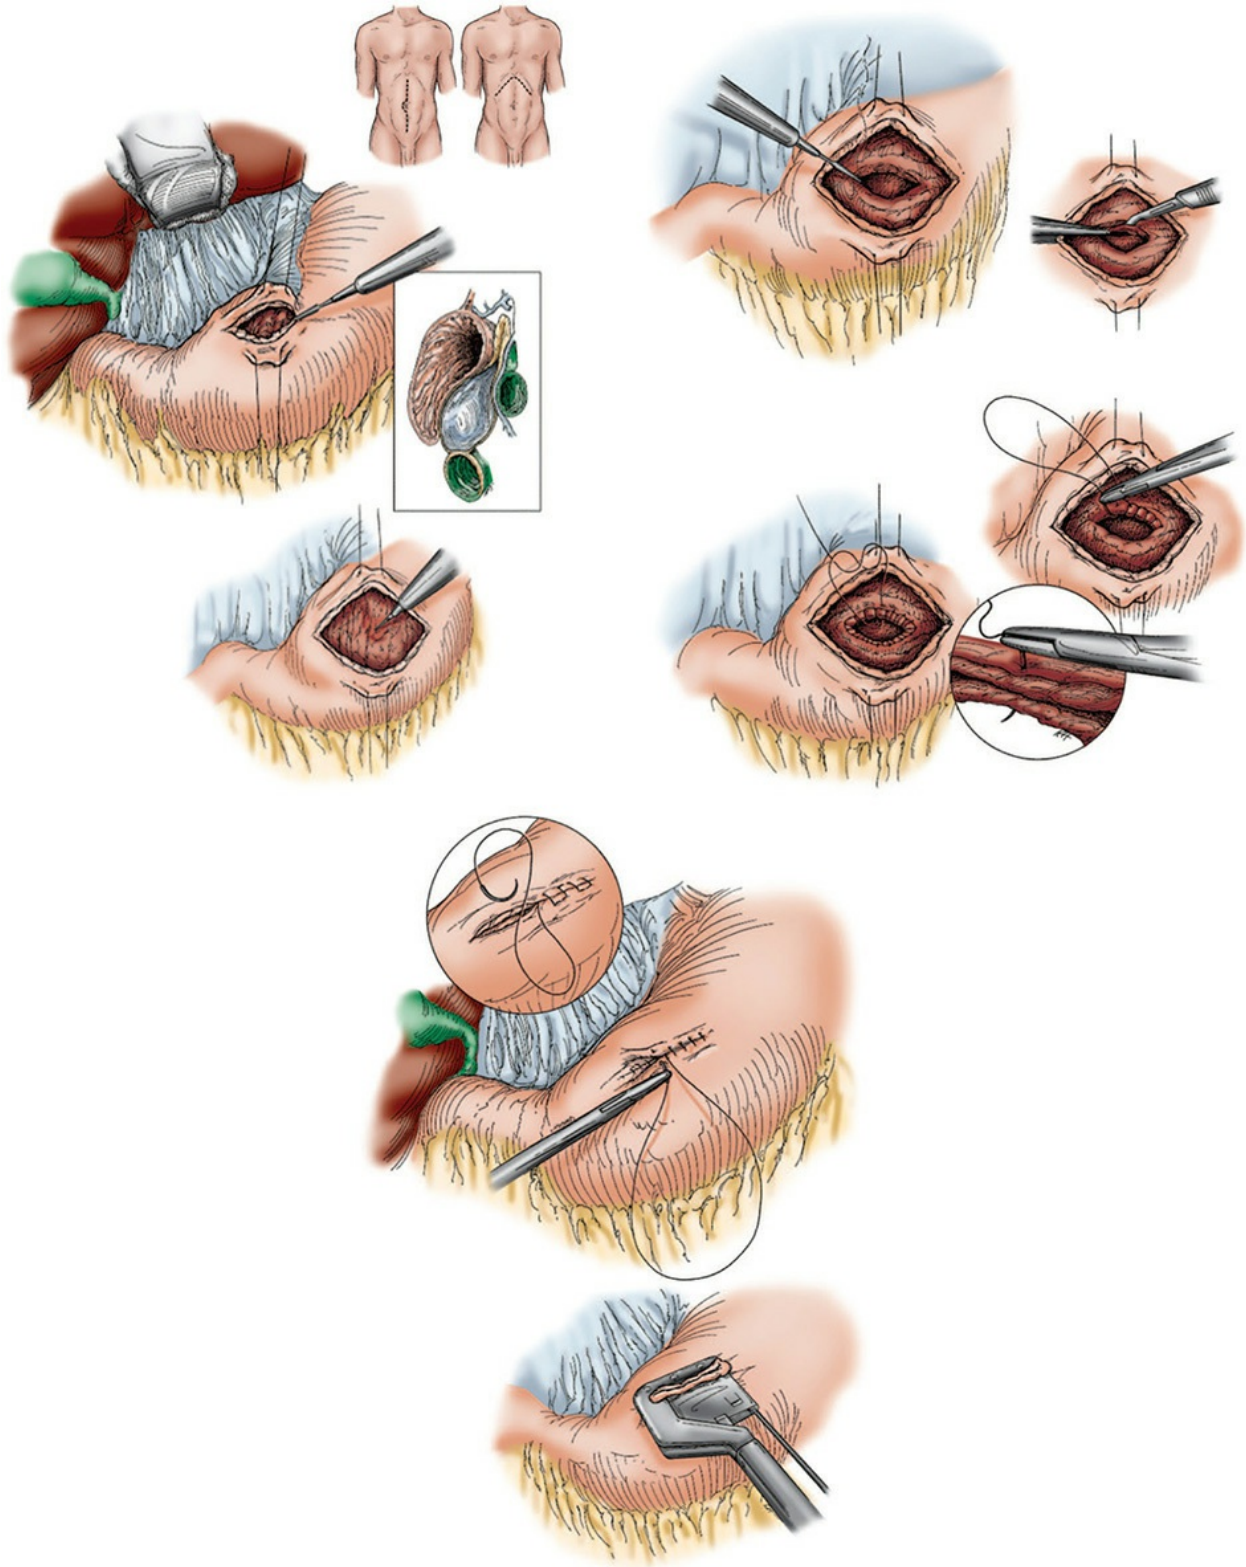

These endoscopic methods are still evolving but have a reported success rates over 90% with experienced practitioners, in well selected patients. Caution needs to be exercised because of the risks of perforation, peritonitis, bleeding, and infection. The risk of bleeding is significantly reduced when the initial puncture is guided by EUS.

**Open Surgical Treatment.** There is no single surgical procedure that is appropriate for all pseudocysts, and the rise of less invasive approaches has resulted in fewer operations being performed for more limited indications. Open surgery is now rarely required for a pseudocyst but may be used to

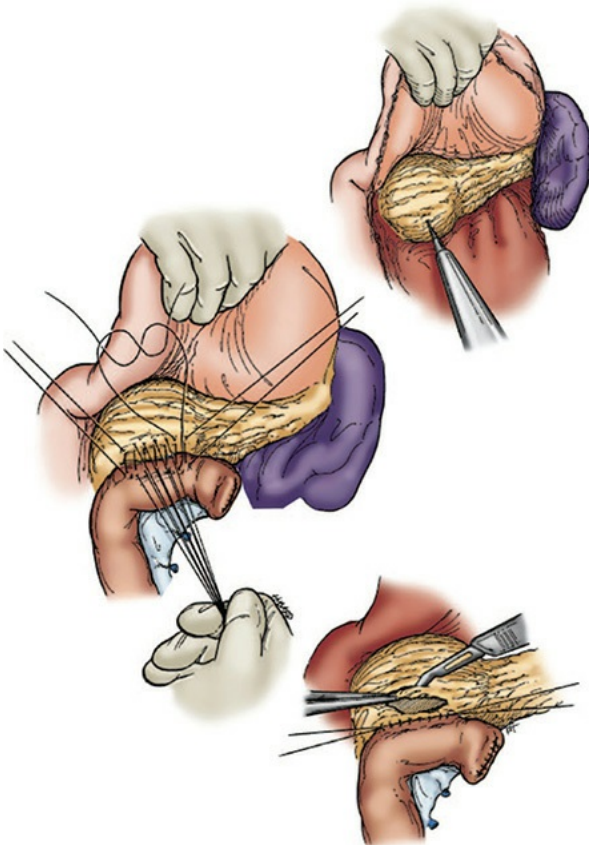

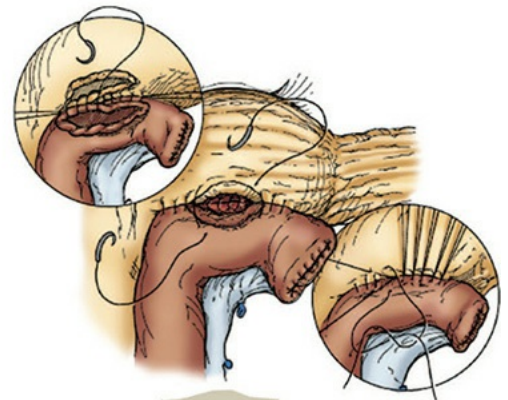

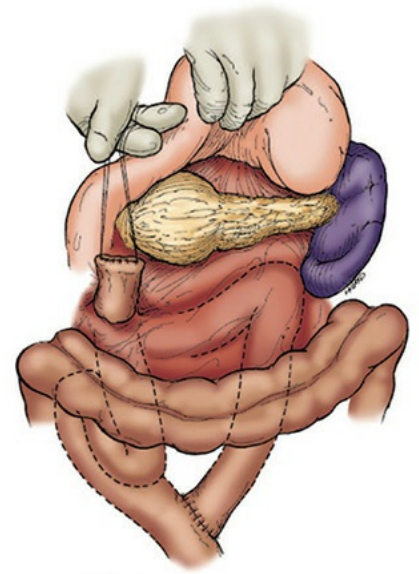

manage complications from other interventions. As with other treatments, an important factor dictating the choice is available expertise and equipment.<sup>24</sup>

In principle, drainage operations are preferred to resection because they preserve pancreatic function, are technically easier, and have a lower mortality rate. A D'Egidio type II pseudocyst with a mature wall is best treated by internal drainage, particularly when ductal disruption or stricture is present. Recurrence rates should be less than 5%, and mortality should be less than 2%. The pseudocyst can be drained into the stomach, the duodenum, or the jejunum. The choice of surgical procedure depends on the location of the pseudocyst and its relationship to these organs.

A cystogastrostomy is ideal when the pseudocyst is adherent to the posterior stomach and indenting it (Fig. 69-7). A longitudinal anterior gastrostomy is followed by the stepwise excision of a disk (~2 cm diameter) of stomach with subjacent pseudocyst wall. The tissue is sent for frozen section in all cases to exclude cystic neoplasia. Sutures are placed in stages to reduce the risk of edge bleeding as the disk is excised. Prior confirmation of the location of the pseudocyst may be required by needle aspiration, although it is usually obvious. The stoma should be large enough to allow transgastric débridement of any necrotic tissue if the collection proves to be WON rather than a pseudocyst. The disadvantage of the cystogastrostomy is that it is not a dependent stoma, and may act as a sump that allows accumulation of gastric debris. An alternative is a Roux-en-Y cystojejunostomy (Fig. 69-8) which is particularly suited to drainage of pseudocysts arising from the body and tail of the pancreas, when it is not adherent to the stomach and when it is bulging through the left transverse mesocolon.

**FIGURE 69-7** Internal drainage of a pseudocyst through the posterior wall of the stomach (cystogastrostomy).

**FIGURE 69-8** Internal drainage of a pseudocyst to the jejunum (Roux-en-Y cystojejunostomy).

Combining internal drainage of a pseudocyst with a lateral pancreateojejunostomy should be considered in patients with chronic pancreatitis and a dilated pancreatic duct because it will improve outcome without increasing the risk of the procedure. The blind end of the Roux limb should be placed toward the tail of the pancreas because this allows the head of the pancreas to be drained and the bile duct to be bypassed using the same limb, if required.

Distal pancreatic resection has a role, particularly when the head of the pancreas is relatively preserved. An endoscopic retrograde pancreatogram will help to define the extent of optimal resection. If there is no pancreatic duct obstruction there are very low recurrence and fistula rates.

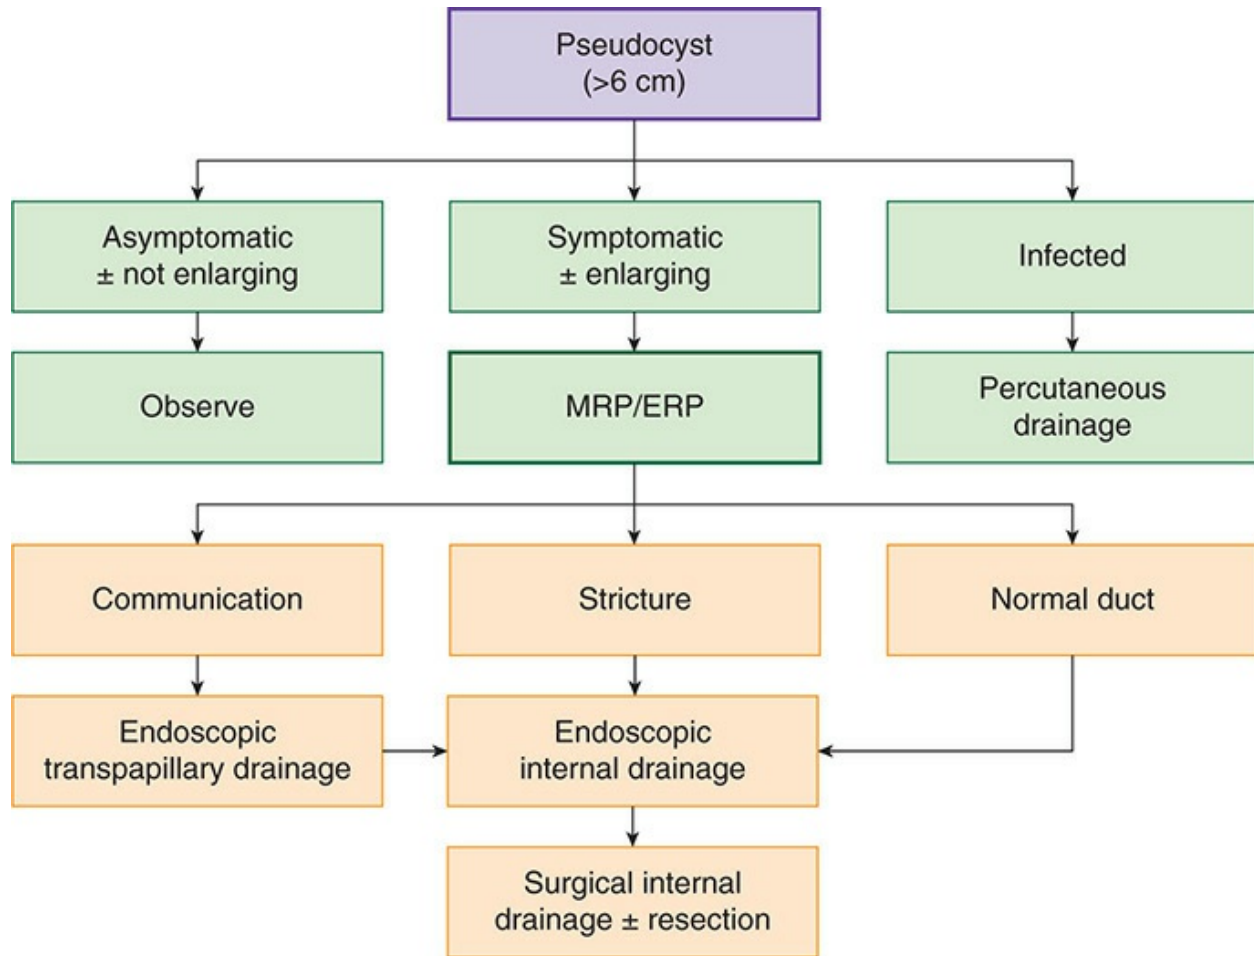

External surgical drainage of a pseudocyst has a very limited role in critically ill patients where radiological or endoscopic drainage is not technically feasible and the risk of a controlled external fistula is an acceptable outcome. Other rare indications for external drainage at the time of laparotomy include the control of an immature ruptured pseudocyst, and for some bleeding pseudocysts where there has been oversewing of the bleeding point. An external fistula may resolve more rapidly with placement of a transpapillary stent and with the adjunctive use of a long-acting somatostatin analogue.

**Minimally Invasive Surgery.** All open surgical techniques can now be performed using a laparoscopic approach. Intraluminal laparoscopic surgery, where the trocars are placed through the abdominal and stomach walls, has been successful. The cystogastrostomy can be performed with a stapler or by suture. A more recent modification of this approach is the mini-laparoscopic cystogastrostomy using a 2-mm intraluminal laparoscope. The view is augmented by the insertion of an oral flexible endoscope, which also can be used to explore the cyst cavity.

The balloon dilatation of a percutaneous catheter track using a similar approach to that used for percutaneous nephrolithotomy is feasible in many cases. It is worth considering this when the initial radiologic attempts have failed to bring resolution. The placement of a sheath then allows the insertion of an operating nephroscope to enable débridement of the pseudocyst and

removal of organized pancreatic necrosis and infected necrosus. This procedure can be repeated and allows the placement of a soft large-bore external drain.

**Summary of Treatment for Pseudocysts.** The treatment of choice for pancreatic pseudocysts depends on a number of factors, including size, number, and location of pseudocysts; whether the main pancreatic duct is obstructed or communicates with the pseudocyst; and whether there are complications of the pseudocyst. The clinical context is important (see [Table 69-2](#)). With the range of approaches to treatment and the variation in the availability of equipment and expertise, it is necessary to develop a rational treatment algorithm that is appropriate for the clinical setting and the patient (see [Fig. 69-9](#)). In practice, type I pseudocysts can usually be managed conservatively. Percutaneous drainage should be considered if the pseudocyst becomes symptomatic or infected. Type II pseudocysts are best managed by internal drainage, especially when there is communication between duct and pseudocyst. Endoscopic, laparoscopic, and radiologic approaches have an emerging role in expert hands. With type III pseudocysts, consideration needs to be given to decompression of the pancreatic duct and relieving the stricture at the same time as drainage of the pseudocyst.

## Pancreatic Necrosis

Necrosis may involve the pancreatic parenchyma and/or the peripancreatic tissue, and this differentiates necrotizing pancreatitis from edematous pancreatitis.<sup>6</sup> Initially poorly demarcated, the solid necrosis gradually liquefies and becomes surrounded by a capsule, such that after 4 weeks it is termed WON. This partially solid and partially fluid, encapsulated lesion has been described in the literature by a range of terms, including organized necrosis, necroma, and pancreatic sequestrum. The extent of tissue necrosis is not fixed and may progress, especially as the disease evolves over the first 1 to 2 weeks. The necrotizing process can extend widely to involve retroperitoneal fat, small and large bowel mesentery, and the retrocolic and

perinephric compartments. The presence of necrosis usually determines a more severe and protracted clinical course lasting weeks to months. From a clinical viewpoint, the development of necrosis is an important event in the course of acute pancreatitis because subsequent complications, both local and systemic,<sup>2</sup> are associated with this.

## **EPIDEMIOLOGY**

The incidence of acute pancreatitis exhibits marked regional differences, and has been reported to from 5 to 80/100,000.<sup>30,31</sup> The proportion of patients with acute pancreatitis who develop pancreatic necrosis is approximately 20%, and of these 25% to 70% will develop infected necrosis.<sup>32,33</sup> The risk of infection is higher when necrosis is more extensive (ie, ~30% of the gland).<sup>34</sup> In addition, the risk of infection increases with time, from 24% by the end of the first week of illness to 36% at the end of the second week, and to 71% by the end of the third week.<sup>35</sup> The overall mortality of edematous pancreatitis is 1% or less, that of sterile necrosis is 5%, and that of infected necrosis is 10% to 25% in the best published series.<sup>36</sup>

## **PATHOGENESIS**

Of the patients who develop pancreatic necrosis, 70% have evidence of it by 48 hours of the onset of abdominal pain, and all of them by 96 hours.<sup>35</sup> The premature activation of proteolytic enzymes within the acinar cells and interstitium of the lobule results in extensive necrosis of pancreatic tissue and the substantial accumulation and activation of leukocytes. There are a number of factors that contribute to the failure of the pancreatic microcirculation, which is evident histologically as stasis and/or thrombosis of intrapancreatic vessels. The failure of the pancreatic microcirculation leads to ischemia, which compounds the enzymatic and inflammatory injury and leads to the full syndrome of necrotizing pancreatitis. During this first week or so, in the so-called early or vasoactive phase, there is the release of proinflammatory mediators that contribute to the pathogenesis of pulmonary, cardiovascular, and renal insufficiency. This early systemic inflammatory response and multiorgan dysfunction are frequently present with evidence of pancreatic infection. In the septic or late phase, which occurs in most patients after 3 to 4 weeks, these systemic events usually occur as a consequence of infected

pancreatic necrosis.<sup>6</sup>

Mild edematous pancreatitis does not usually progress to necrotizing pancreatitis, implying that pathophysiological events soon after the onset of the disease are decisive in determining the course of the disease.<sup>37</sup> Necrotic lesions are most likely to permit entry of bacteria when they are demarcated by only a thin rim of granulation tissue (4-20 days). Over time, necrotic areas slowly resolve and are replaced by fibrotic scar tissue (necrosis-fibrosis sequence).<sup>37</sup>

## **MICROBIOLOGY OF INFECTED NECROSIS**

Pancreatic necrosis is most likely to become infected during the late phase of acute pancreatitis, with a median time from hospital admission to infection of 26 days.<sup>34</sup> There are five routes by which bacteria might infect pancreatic necrosis: (1) hematogenous, (2) transpapillary reflux of duodenal content into the pancreatic duct, (3) translocation of intestinal bacteria and toxins via the mesenteric lymphatics to the systemic circulation via the thoracic duct, and possibly directly to the pancreas via lymphatic connections between the intestine and pancreas, (4) reflux of bacteriobilia via a disrupted pancreatic duct into the necrotic parenchyma, and (5) transperitoneal spread.

Cultures of infected pancreatic necrosis are polymicrobial in approximately one-third of patients and monomicrobial in two-thirds of patients.<sup>38</sup> Gram-negative aerobic bacteria are the most common organisms identified (eg, *Escherichia coli*, *Pseudomonas*, *Proteus*, and *Klebsiella*), followed by gram-positive bacteria (eg, *Enterococcus*, *Staphylococcus aureus*). Anaerobic bacteria are identified in only around 5% of positive cultures, although this probably reflects inadequate culture techniques. Fungi may also be cultured, and are more common after use of prophylactic antibiotics.<sup>39</sup> The spectrum of bacteria cultured from infected necrosis demonstrates that enteric bacteria dominate, suggesting bacterial translocation is an important event in the pathogenesis of infected pancreatic.<sup>33</sup>

## **PREDICTION AND DIAGNOSIS**

The presentation of pancreatic necrosis is usually nonspecific, with abdominal pain, distension, guarding and associated low-grade fever, and

tachycardia. The severity of pain and the extent of hyperamylasemia do not correspond with the severity of acute pancreatitis or the extent of pancreatic necrosis. The classic skin signs of retroperitoneal necrosis, including discoloration of the navel (Cullen sign), the flanks (Grey-Turner sign), and the inguinal region (Fox sign), are rare and often not seen until the second or third week after disease onset. Patients presenting late with severe or critical disease will often have established multiorgan dysfunction. The diagnosis of pancreatic necrosis requires more than just clinical acumen.

Predicting the severity of acute pancreatitis and the presence of pancreatic necrosis remains an imprecise science.<sup>40</sup> Scoring systems, such as Ranson, Glasgow, APACHE II, or “bedside index for severity in acute pancreatitis” (BISAP), are often used for severity stratification, but are rarely better than 70% accurate.<sup>41,42</sup> Patients with predicted severe disease and high likelihood of pancreatic necrosis require radiological confirmation of the presence and extent of necrosis, which is conventionally categorized as less than 30%, 30% to 50%, and greater than 50% of the pancreas.<sup>43</sup> Dynamic contrast-enhanced CT (CECT) is the gold standard for diagnosing pancreatic necrosis and other local complications, but is not usually indicated within the first 48 to 72 hours after the onset of acute pancreatitis.<sup>1,6</sup> Pancreatic hypoperfusion is usually established by about 72 hours and imaging before then probably underestimates the extent of necrosis and the ultimate disease severity.<sup>44,45</sup>

Current guidelines recommend that CECT is indicated for patients with persisting organ failure, signs of sepsis, or clinical deterioration 6 to 10 days after admission.<sup>6</sup> Other imaging modalities have been developed to diagnose the extent of pancreatic necrosis, including MRI and echo-enhanced ultrasound (EEU), which are at least as accurate as CECT in diagnosing and determining the extent of pancreatic necrosis.<sup>46,47</sup> In practice, the indications to diagnose and determine the extent of pancreatic necrosis with CECT are when a patient fails to improve with initial resuscitation and/or when the CRP has crossed the predictive threshold (see later). CECT can be used to score the severity of acute pancreatitis by the CT severity index as proposed by Balthazar,<sup>48</sup> but is no better than other methods.<sup>41</sup> It is important to recognize the limitations of CECT, where a pseudocyst and WON can be difficult to distinguish. Imaging by MR or EUS can better delineate the solid components within a collection.

In the absence of a specific diagnostic marker of pancreatic necrosis, many

serum predictors have been proposed. An ideal predictor or prognostic indicator should be simple, cheap, reproducible, valid, available on admission, and specific for necrosis. While a full discussion of markers is beyond the scope of this chapter,<sup>42</sup> there are several that fulfill most of these criteria, compare favorably with CT scanning, and have an established role in routine clinical practice.

C-reactive protein (CRP) is the most widely used predictor of pancreatic necrosis and is also useful as a daily monitor of disease progress. The accuracy in predicting the presence of necrosis is about 85%, but it requires 3 to 4 days after the onset of the disease to reach this level. The threshold values depend on the assay and the study used. A commonly used threshold is greater than 120 mg/L.<sup>49</sup> Other prognostic markers, none of which has been shown to outperform CRP, include interleukin-6 (IL-6) (threshold >14 pg/mL) which peaks a day earlier than CRP; polymorphonuclear elastase (threshold >120 µg/L), which peaks early and reflects neutrophil activation and degranulation; and phospholipase A2 type II (threshold >15 U/L). Urinary trypsinogen-activating peptide has also been proposed as a predictor of necrosis, but is not the major advance that was first anticipated.<sup>50</sup> Procalcitonin has been proposed as a sensitive and specific marker for infected necrosis but it has not become part of routine management.<sup>6,33,34</sup>

The diagnosis of infected necrosis is very important because it is generally considered an indication for intervention. Rarely, the early invasion of gas-forming organisms, such as *Clostridium perfringens*, makes the diagnosis of infection on CT scanning straightforward.<sup>51</sup> It is more usual to suspect pancreatic infection with rapidly progressive disease or a secondary deterioration after 2 or 3 weeks of admission.<sup>34</sup> This is often heralded by a significant rise in CRP. A CECT scan will usually confirm the presence of a tense collection with rim enhancement arising from the region(s) of pancreatic necrosis. The presence of gas within the tissues confirms infection, with an “air bubble” appearance (Fig. 69-1), but this is present in the minority of cases.

Clinical practice guidelines are consistent in their recommendation to use FNA as the gold standard test to diagnose infected necrosis.<sup>1,52</sup> It is true that infected ANC and WON are most accurately diagnosed by image-guided (CT or ultrasound) FNA for Gram staining and/or bacterial culture. Suspicion of infection is raised with a significant and secondary clinical deterioration and

the associated rise in serum markers (eg, CRP, procalcitonin) which makes the diagnosis of infection highly probable.<sup>39</sup> Certainly there is usually enough suspicion to proceed with antibiotics, CECT, and percutaneous or endoscopic drainage, which allows bacterial cultures. There has been some concern that FNA is associated with a potential risk of secondary infection.<sup>53</sup> In summary, it is better to consider FNA of ANC or WON as an adjunctive measure and one that is only undertaken in a patient in whom there is already a strong clinical suspicion of infection and in whom confirmation of infection will directly result in intervention.<sup>54</sup>

## **INDICATIONS FOR INTERVENTION**

The decision to directly intervene to treat complicated acute pancreatitis is one of the most difficult decisions in clinical practice. Intervention is defined as invasive treatments (radiologic, endoscopic, surgical) beyond medical, nutritional, and intensive care management. The primary indication for intervention is the development of infected necrosis (in ANC or WON) in conjunction with clinical deterioration, but it is no longer considered an absolute indication for intervention in many centers. Other indications for further intervention are the failure of radiologic or endoscopic drainage, where there is evidence of persistent sepsis, and organ dysfunction. The indications for intervention in the absence of infection are very limited. A rare indication for intervention, irrespective of the infection status of the necrosis, is the development of massive hemorrhage or bowel perforation (eg, colon or duodenum). Intervention on patients with sterile necrosis is no longer advocated unless there is acute clinical deterioration despite maximal supportive care and there is a well-defined target lesion to drain or debride.<sup>55,56</sup> Intervention is also occasionally required in those patients with sterile necrosis who “fail to thrive” and are unable to be discharged. These patients often have abdominal symptoms and intolerance to oral feeding after a month or more. The vast majority of patients with sterile necrosis can and should be managed without surgery.<sup>56</sup>

## **TIMING OF INTERVENTION**

Historically, surgical intervention for pancreatic necrosis was performed during the first week after disease onset. Early surgery was advocated in

order to remove the dead tissue, the focus of infection, and terminate the inflammatory process. We now know that the inflammatory cascades are not easily switched off, and are exacerbated by the surgical procedure. Early surgery is more difficult and dangerous because the necrotic tissue is immature, poorly demarcated, and not easily separated from viable tissue, resulting in a significant risk of bleeding. In addition, early surgery may cause infection of sterile necrosis. With mortality rates of up to 65%, the trend toward early intervention has been curtailed,<sup>1,57</sup> and intervention has become progressively later. The current concept for timing of intervention is that it should be undertaken as late as possible after disease onset (preferably 3-4 weeks), when the necrotic process has stopped extending, when there is clear demarcation between viable and nonviable tissues, and when infected necrotic tissue has become organized and “walled off.”<sup>1,57</sup> Importantly, this delay allows time for stabilization of the patient through intensive care support, reduces the risk of new-onset organ dysfunction attributable to the intervention, and decreases the risk of bleeding and pancreatic insufficiency through the unnecessary removal of viable tissue.

This delay to debridement, by whatever means, is enabled by the adoption of the step-up approach (see later) that recommends radiological or endoscopic drainage first and then supportive measures. The concept of “drain first” should include efforts to optimize drainage by up-sizing, flushing, irrigation, replacement, and additional drains, as required.<sup>58</sup> Prior drainage often results in an improvement in the patient’s overall clinical status. The type and timing of further intervention is dictated by a number of factors, including the patient’s condition and comorbidities, local expertise, and the anatomical location and complexity of the lesion. This decision is best made in a high-volume center with experience and expertise to ensure the timing and type of intervention is optimal.<sup>1,59</sup>

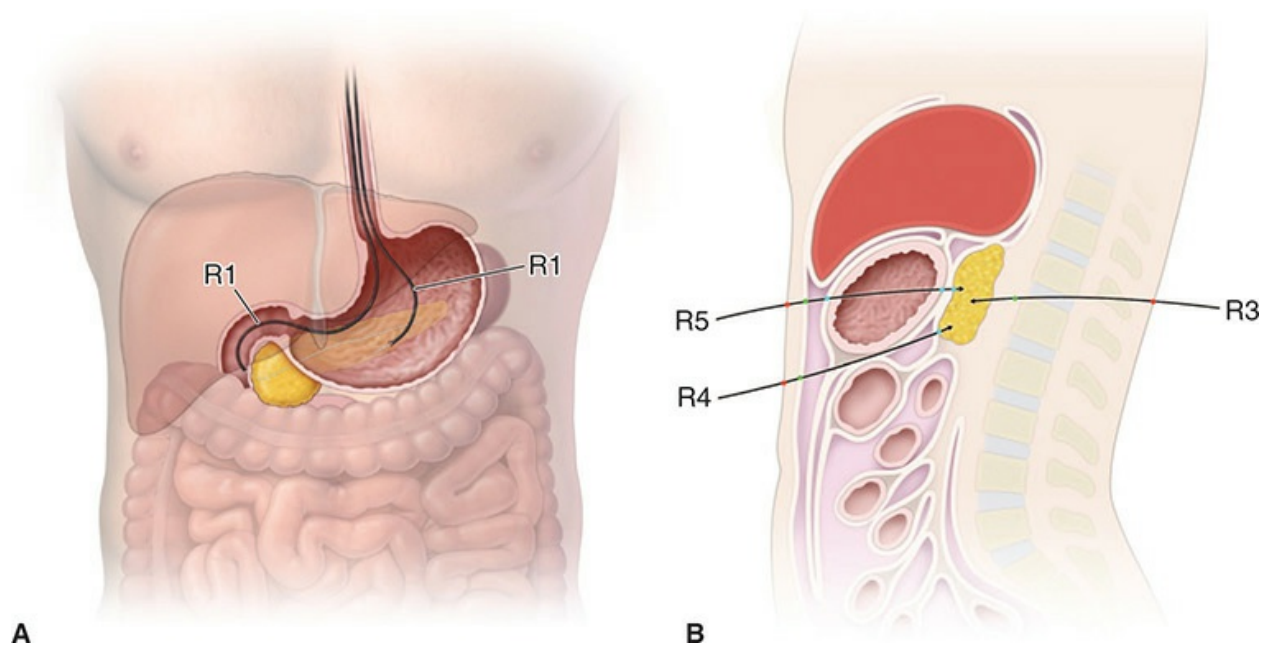

## **TYPES OF INTERVENTION**

There are many different interventions, and the challenge is to select the intervention appropriate for the particular local complication, taking into account the anatomical location, infection status and complexity of the target lesion(s), the physiological status, comorbidity of an individual patient, and the availability of expertise with the type of intervention. A review of current guidelines highlights the absence of level 1 evidence to guide decision

making regarding the types of intervention.<sup>60</sup> There have been two broad philosophies regarding the type of intervention used. Some experts state that open surgical drainage and necrosectomy remains the gold standard in the management of infected pancreatic necrosis, and reserve less invasive interventions for subsequent complications. These include percutaneous and endoscopic drainage of residual fluid complications. Such a *step-down approach* contrasts with the *step-up approach*, which advocates the use of less invasive interventions initially (eg, percutaneous or endoscopic drainage), and then stepping up to minimally invasive surgical interventions and only employing open surgical techniques later in the disease course in those who fail to respond. These two approaches have been subjected to a randomized controlled trial in the PANTER trial.<sup>61</sup> This demonstrated that the step-up approach reduced the rate of the composite endpoint of major complications and/or death. Mortality itself was not decreased, but new-onset multiple organ failure occurred less often in patients assigned to the step-up approach. Another important finding was that a third of patients who would have previously undergone an open necrosectomy were managed by drainage alone.

There is a need to standardize the description of invasive interventions to facilitate communication between clinicians, comparison of techniques, and controlled clinical trials. The VRP classification is based on the method used to Visualize the lesion, the anatomical Route taken to reach the lesion, and the Purpose of the intervention.<sup>62</sup>

- The various ways to *visualize* the target lesion include open procedures (where the operative site is exposed through the skin incision), endoscopic procedures (where the operative site is visualized with an endoscope (eg, gastroscope, laparoscope, or nephroscope), radiological procedures (where CT, ultrasound, or fluoroscopy are used to visualize the lesion during the procedure), and hybrid procedures that combine endoscopic and radiological techniques.
- The different *routes* taken by reach the target lesion include the external route into the body (skin or external orifice) and the internal route to reach the target lesion (through the gastrointestinal wall, peritoneum, or retroperitoneum) (Fig. 69-10).

**FIGURE 69-10** Possible routes to be taken during treatment of local complications of acute pancreatitis. R1, per-os transpapillary; R2, per-os transmural; R3, percutaneous retroperitoneal; R4, percutaneous transperitoneal; R5, percutaneous transmural.

- The overall *purpose* of treatment is to drain fluid and remove areas of necrotic and infected tissue. However, the way in which this is achieved varies considerably, with some procedures being considerably more aggressive than others. Therefore, the purpose of individual interventions may be to effect simple drainage alone, lavage of the necrotic cavity to assist drainage of necrotic debris, fragmentation of necrotic tissue to facilitate its drainage, débridement of necrotic tissue, and excision or resection of the pancreas. Drainage procedures involve allowing fluid and solid necrotic to drain externally out of the body or internally into the gastrointestinal tract. Lavage describes flushing away solid necrotic matter with fluid to facilitate external or internal drainage. Fragmentation is a method used to break down solid necrotic matter by instrumental or mechanical disruption to facilitate drainage. Débridement, which is often termed “necrosectomy,” involves removing solid necrotic matter (typically with blunt dissection), and may or may not include postoperative lavage. Débridement may involve removal of all or only some of the necrotic tissue, although normal tissue is not intentionally removed. Only during excision or resection of the pancreas is normal tissue intentionally

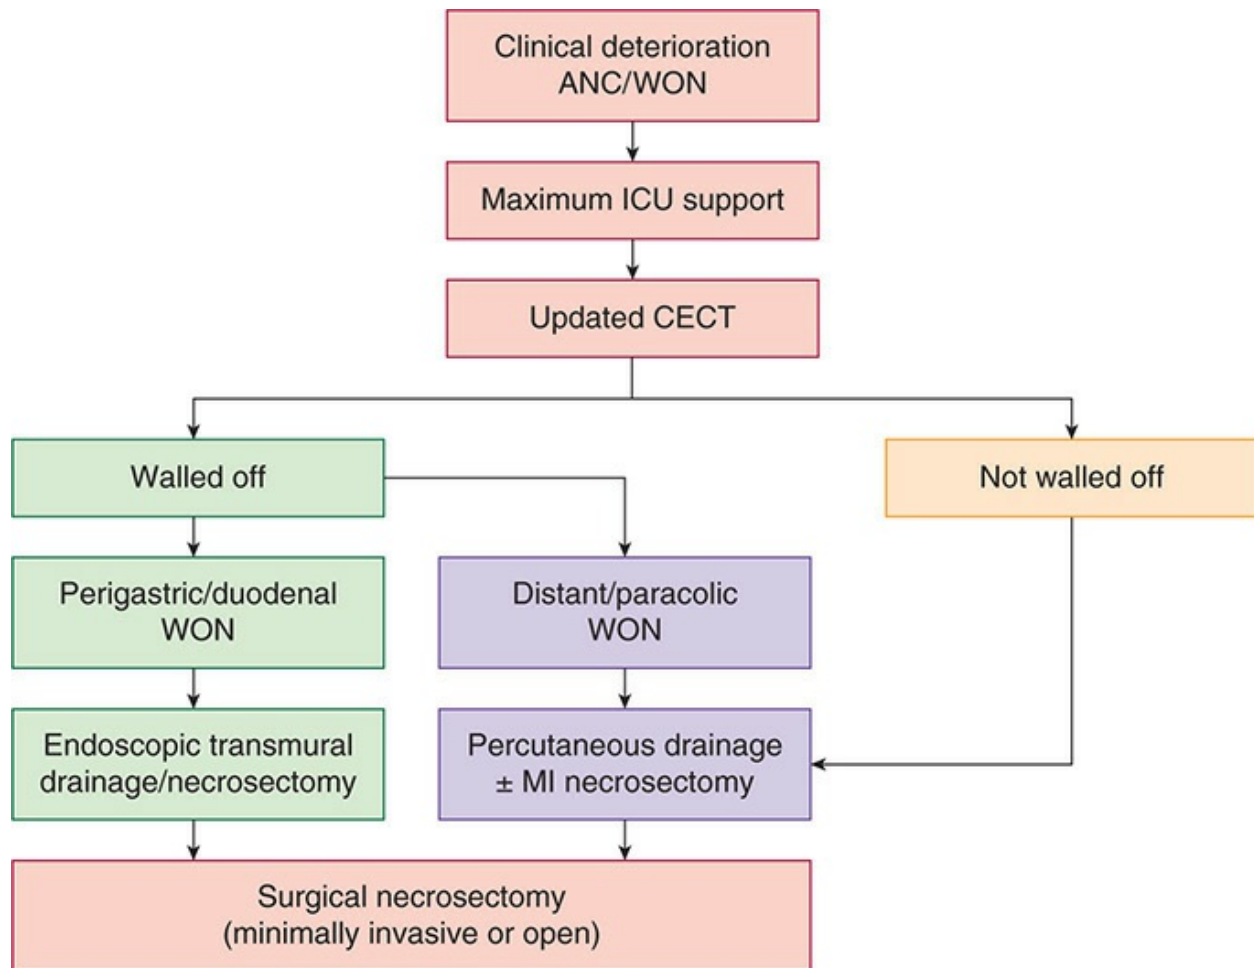

removed along with devitalized tissue. Such an approach is no longer recommended.

## **THE “STEP-UP APPROACH” TO INTERVENTION**

There have been significant changes in the approach to intervention in recent years.<sup>57</sup> The focus shifted from resection to debridement decades ago, and we are now in the process of shifting the emphasis from debridement to drainage. Complete debridement is no longer considered essential; rather, sufficient debridement of necrotic tissue should be achieved to optimize drainage.

Figure 69-11 is an algorithm for clinicians who are faced with the management of patients with infected necrosis (ANC or WON). In general, when patients deteriorate despite maximum intensive care, the intention is now to institute or optimize drainage (endoscopic or radiologic). If the patient does not show any improvement over 48 to 72 hours, then the intervention is intensified. This might entail insertion of further drains. Endoscopically, this would often mean the insertion of a self-expanding metal stent (see above) through which endoscopic debridement can be undertaken. Alternatively, a percutaneous track can be dilated or a small flank incision made to allow for minimally invasive surgical debridement using a nephroscope or laparoscope. When these approaches fail, and only then, open surgical debridement is considered.<sup>57</sup>

**FIGURE 69-11** Algorithm for the management of infected necrosis (ANC or WON).

The target lesion is best delineated by CECT or MRI scanning, noting the size, wall maturity, extent, complexity, and anatomical relationships. In addition, it is used to determine whether there is safe access to the lesion, and which route (Fig. 69-11) and which method (radiologic or endoscopic) is preferred for drainage.

## RADIOLOGIC INTERVENTION

The purpose of radiological techniques is to drain (with or without lavage) and to provide an aid to access for minimally invasive debridement (see below). Percutaneous catheter drainage can be used as a primary treatment for infected ANC/WON and more definitive treatment be delayed until the patient has clinically stabilized and wall-matured,<sup>63</sup> or as a secondary

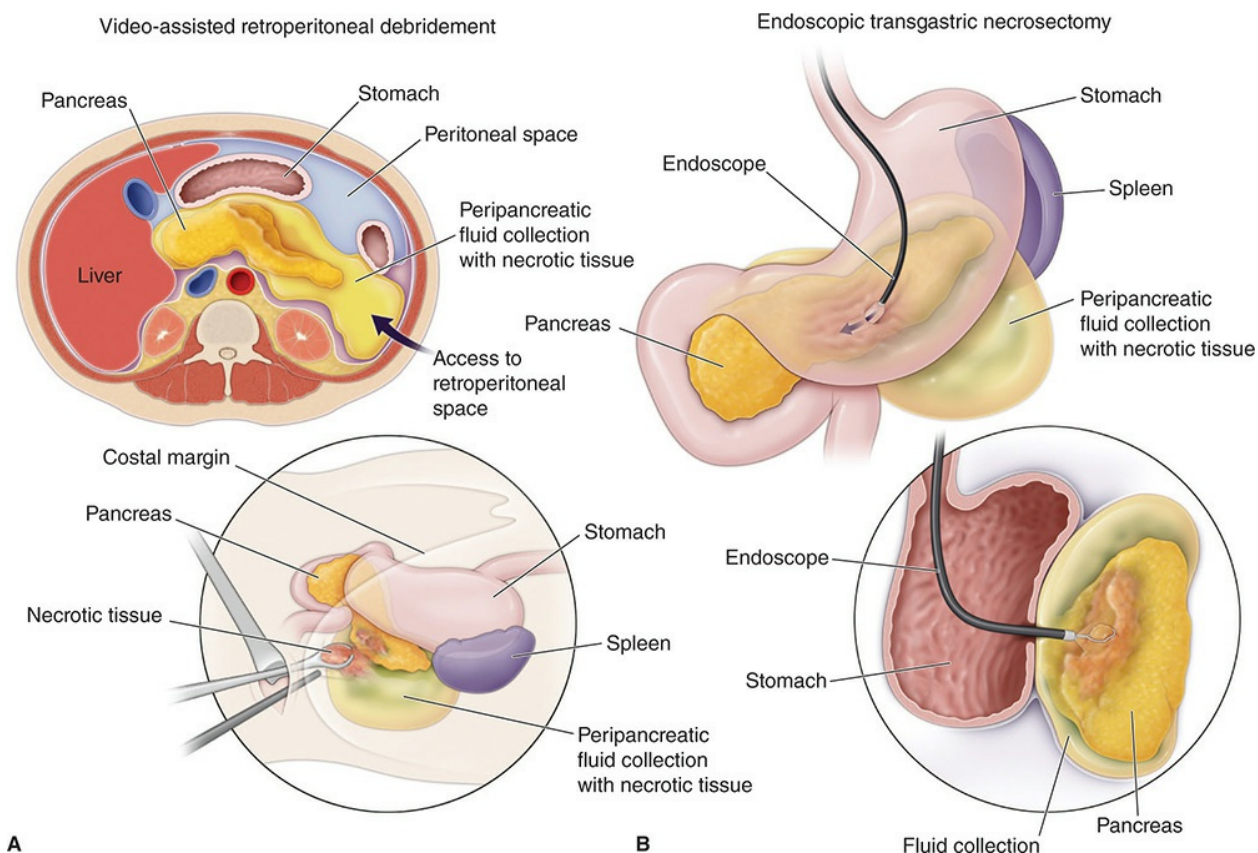

treatment for residual collections. Further, percutaneous drainage is the sole treatment in about half the patients.<sup>57,63</sup> Most collections are located in the lesser sac, anterior pararenal space, into the root of the small bowel mesentery and the paracolic gutters.<sup>64</sup> The usual internal routes to the target lesion are retroperitoneal or transperitoneal. Less commonly, transgastric, transduodenal, and transhepatic routes used.<sup>65</sup> While transgressing the stomach poses little infection risk, gastric peristalsis may dislodge the catheter over time. Transgressing the liver carries the risk of bleeding, but in practice is generally safe. Routes should avoid colon, small bowel, spleen, and kidney to minimize the risk of hemorrhage and bacterial contamination. A retroperitoneal approach that avoids the peritoneal cavity is the preferred route, as this prevents contamination of the peritoneal cavity and possible peritonitis.<sup>64</sup>

Typically percutaneous catheters have multiple side holes and a minimum diameter of 12 to 14 Fr (4.0-4.7 mm).<sup>65</sup> Sometimes multiple catheters are required, for large or complex lesions. Lavage can be employed to reduce the concentration of digestive enzymes and proinflammatory mediators in the lesion, help maintain patency, and to assist the removal of solid necrotic debris from the cavity.<sup>66</sup> There have been unsubstantiated concerns that lavage might spread infection, either from infected fluid spilling over into previously sterile cavities or from the increased intracavity pressure resulting in translocation of bacteria into portal circulation.

The efficacy of drainage procedures is limited by the contents of the target lesion. Success with predominantly solid lesions is rare. In patients with pancreatic necrosis treated with percutaneous catheter drainage, approximately half will be successful and not require surgical intervention.<sup>63,57</sup> Failure of catheter drainage includes persistent systemic or local manifestation of infected necrosis, physiological deterioration despite drain patency, persistent abdominal pain, and intolerance of oral intake after the systemic inflammatory response syndrome has resolved.<sup>67</sup> In some specialized centers, interventional radiologists have attempted debridement, through the use of snares, baskets, or by applying suction to a catheter during its removal.<sup>68-70</sup>

## **ENDOSCOPIC INTERVENTION**

Peroral flexible endoscopic techniques follow an internal route through either the gastric or duodenal wall or duodenal papilla, and some authors consider this to be a form of natural orifice transluminal endoscopic surgery (NOTES).<sup>71,57</sup> Initial descriptions of flexible endoscopic treatment of pancreatic necrosis used lavage and drainage without instrument-guided débridement.<sup>72</sup> A more aggressive approach was subsequently introduced, which demonstrated necrotic tissue could be debrided with baskets, snares, forceps, and suction.<sup>73,74</sup> ERCP may be used to diagnose any communication between the duct and cavity or duct stenosis or disruption, and transpapillary stenting can be employed to decompress the duct. Puncture of the posterior gastric wall into the target lesion is performed at the point of maximal bulging, although confirmation of the location with EUS helps achieve safe deployment to avoid injury to vessels.<sup>27</sup> The injection of contrast with fluoroscopy can be used to determine the extent of the cavity. The gastric insertion site is balloon-dilated. For lavage and drainage, a 7 Fr nasocystic (lavage) and a 10 Fr pigtail drain (drainage) are placed in the cavity. Necrosectomy may be performed with endoscopic instruments (eg, Dormia basket or polypectomy snare), and introduction of a forward-viewing endoscope into the necrotic cavity can be used for better visualization during the necrosectomy (Fig. 69-12). Multiple necrosectomy procedures are usually required to clear the cavity of necrotic tissue.

**FIGURE 69-12** Cross-sectional views depicting video-assisted debridement of infected “walled off necrosis”(A) and endoscopic transgastric drainage and necrosectomy (B).

The introduction of transgastric self-expanding metal stents (SEMS) has been a significant advance in the endoscopic treatment of infected ANC and WON. These stents are designed with a wide lumen (eg, 2.5 cm), wide flanges (to prevent migration) and even wall-apposing features (to reduce the risk of leakage) (Fig. 69-9).<sup>28</sup> This facilitates direct endoscopic debridement, but it has been noticed that this is less often required with the wide lumen stents, possibly because of the liquefying action of gastric juice on the necrotic tissue.

Flexible endoscopic debridement has also been used percutaneously (“sinus tract endoscopy”).<sup>75</sup> A similar technique has been described following open necrosectomy through a translumbar incision, where a flexible endoscope is inserted into the cavity for débridement.<sup>76</sup> Another endoscopic approach is to debride through a percutaneous endoscopic gastrostomy (PEG).<sup>77</sup> Usually multiple débridement procedures are required

because of the inefficiency of extraction. The wide range of endoscopic approaches to necrosectomy and the absence of formal comparison make a recommendation for the optimal approach difficult. The selection of an endoscopic technique will be influenced by training, experience, and availability of equipment.

## MINIMALLY INVASIVE SURGICAL INTERVENTION

Over the last decade, a wide range of endoscopic surgical approaches for pancreatic necrosectomy have been described, including infracolic laparoscopy, transgastric laparoscopy, hand-assisted laparoscopy, retroperitoneal laparoscopy, and retroperitoneal nephroscopy.<sup>78-82</sup> While some endoscopic procedures do not use radiologic imaging, many are hybrid procedures using fluoroscopy or EUS. This array of minimally invasive techniques can be classified by the type of scope used.<sup>83</sup>

**Laparoscopic Techniques.** In 1996, Gagner described the first true endoscopic treatment of necrotizing pancreatitis, where the pancreas was debrided using a laparoscopic approach.<sup>84</sup> Most laparoscopic techniques are minimally invasive versions of open surgical techniques, and use either an anterior or lateral approach (see below). In Gagner's original description of laparoscopic necrosectomy, two anterior routes (retrogastric retrocolic and transgastric) and one lateral route were described.<sup>84</sup> This technique has been modified. Of the lateral approaches, one of the most widely used laparoscopic techniques is videoscopic-assisted retroperitoneal débridement (VARD) (Fig. 69-12).<sup>82,61</sup> In this technique, prior percutaneous drainage is followed by a 4- to 6-cm incision in the left flank using the drain as a guide. A finger is used to probe and confirm entry into the necrotic cavity. Fluid and loose necrotic debris are removed by suction. Using right-angled retractors, the laparoscope is inserted along with the irrigating catheter (to aid visualization) and further debridement is achieved under direct vision with the gentle use of sponge forceps. The incision can be sealed with wet sponges and towel clips to allow better visualization by insufflation with CO<sub>2</sub>. The objective is not to achieve complete debridement but optimal drainage. Large bore drains (eg, 28-32 Fr Protex chest drains) are brought out through the flank incision. These drains are used for drainage and lavage. An ostomy bag can be positioned over the flank incision between lavage sessions.

The first randomized controlled trial comparing two different minimally invasive approaches to the treatment of infected pancreatic necrosis has now been published.<sup>85</sup> In this pilot study (“PENGUIN”), endoscopic transgastric necrosectomy was found to be superior to the VARD procedure. There was a reduction in the incidence of the predefined composite endpoint (new-onset multiple organ failure, intra-abdominal bleeding, enterocutaneous fistula, and/or pancreatic fistula) or death. There was a decrease in the incidence of new onset of multiple organ failure, supported by the finding that there was a significantly lower proinflammatory response after the procedure, and a reduction in the incidence of pancreatic fistulation.

**Nephroscopic Techniques.** The use of a nephroscope for necrosectomy was termed “percutaneous necrosectomy” by the unit that pioneered this approach.<sup>75</sup> The purpose is to debride necrotic tissue and establish continuous lavage. The rigid nephroscope has an irrigating channel that provides superior visualization to laparoscopic techniques. The limitation is the working channel, which limits the amount of debridement. The first step is to insert a drainage catheter under CT guidance into the pancreatic lesion. The preferred path for drainage is between the lower pole of the spleen and the splenic flexure, although in right-sided necrosis a path through the gastrocolic omentum (anterior to the duodenum) may be necessary. The patient is then transferred to the operating room and positioned in the appropriate lateral position. The drain tract is then dilated to allow insertion of a 34 Fr Amplatz sheath. The nephroscope is inserted through the sheath into the cavity, and lavage is used to clear away pus and debris. Following necrosectomy, a 32 Fr soft drainage tube is left in the cavity. An additional catheter may be used to allow continuous postoperative lavage. Repeat procedures are often required after 2 to 10 days.<sup>86</sup>

## **OPEN SURGICAL INTERVENTION**

The role of open surgical treatment of infected pancreatic necrosis is diminishing with the accumulating evidence for the less invasive approaches. It is now reserved for those who fail minimally invasive intervention and for when a laparotomy is required for additional reasons, such as abdominal compartment syndrome and intestinal infarction/perforation. Prior CECT scanning will allow determination of the extent of the target lesion and allow

formulation of the operative plan. The abdomen is best entered through a bilateral subcostal incision since this allows better access to the extremities of the gland and less contamination of the greater peritoneal sac if there are subsequent procedures. The pancreas is exposed by dividing the gastrocolic omentum (Fig. 69-11) or gastrohepatic omentum to access the pancreas through the lesser sac. The body and tail of the pancreas can be exposed by elevating the transverse colon and gaining access to the lesser sac via the transverse mesocolon (Fig. 69-12). Inflammatory adhesions may exist between the pancreas and stomach or transverse mesocolon, and great care is required during exposure. It is generally useful to take down both the hepatic and splenic flexures if possible, as this will facilitate exposure and reduce the risk of colonic fistula secondary to drain erosion. When the process involves the head of the pancreas, access might require medial mobilization of the duodenum.

The plan is to drain all fluid collections, debride all devitalized tissue, and avoid hemorrhage and enteric fistulation. Infected necrotic tissue and fluid are sent for bacterial culture to confirm the causative organisms and rationalize antibiotic therapy. Débridement of necrotic tissue is performed bluntly, usually with digital dissection, careful use of instruments, and lavage. Only loosely adherent necrotic tissue should be removed, and this is easier if there has been a significant delay between onset of disease and surgery. Use of a systematic approach, such as examining in turn the retroperitoneum behind the transverse, ascending, and descending colon, helps to ensure all areas of necrotic tissue are identified and removed. If multiple procedures are planned, the first necrosectomy provides the best exposure, and therefore the most complete débridement that is safe should be accomplished at this time. The thoroughness of the initial débridement is the most important factor in determining the need for subsequent reoperation.<sup>87</sup> The need for complete débridement has been questioned, and the risks of aggressive debridement have been balanced against the risks of persisting sepsis.

A key point is to avoid sharp dissection in order to prevent major hemorrhage. Adherent necrotic tissue should be left in situ, as this will subsequently demarcate and become loose. Strands of tissue forming bridges across the cavity may be vessels and should not be avulsed. This is important, because bleeding from inflamed vessels within the retroperitoneum is difficult to control and may require formal packing.

Following débridement, extensive irrigation is used to flush away necrotic debris, inflammatory exudates, and residual bacteria. Postoperative lavage may be employed, and this can be either intermittent or continuous (Fig. 69-11).<sup>88</sup> The fluids most commonly used for this purpose are normal saline or peritoneal dialysis fluid, although there is no evidence to support the best fluid or flow rate.

The choice of open surgical procedure is determined by the location, extent, and maturity of the necrotic material; status of the infection; the patient's condition; the degree of organ dysfunction; and the preference and experience of the surgeon.<sup>33</sup> A number of different approaches have been described (Table 69-4), some of which are only of historical interest. Interventions are complex, fraught with potentially life-threatening complications, and should only be performed by experienced surgeons in regional centers.

There are several approaches to open necrosectomy, and there is no high-level evidence to support one over the other. While the débridement technique for all the approaches is similar, they differ in terms of how they provide egress for infected fluid, debris, and tissue.

**Open necrosectomy with Closed Packing.** The goal of necrosectomy with closed packing is to perform a single operation, with thorough débridement and removal of necrotic and infected tissue, and to avoid or minimize the need for reoperation or subsequent drainage.<sup>56</sup> Some units use gauze-stuffed Penrose drains placed via separate stab incisions, but there are many variations in practice with regard to the type and number of drains. With the Penrose drain technique, the intention is to fill the cavity and provide compression rather than facilitate external drainage per se, and between two and twelve drains are usually placed. Additional silicon drains (eg, Jackson-Pratt) are placed in the pancreatic bed and lesser sac to drain fluid from the area. Primary closure of the abdomen is routine with this approach. The stuffed Penrose drains are removed once every other day, starting 5 to 7 days postoperatively. The silicone drains are removed last.

**Open Necrosectomy with Open Packing.** The difference between this approach and closed packing is that the abdomen is left open after débridement and packing of the abdomen.<sup>91</sup> An alternative form of open packing uses a 20-cm flank incision instead of an anterior laparotomy.<sup>89</sup>

Open packing techniques have been reported to have higher incidences of fistulae, bleeding, and incisional hernias, as well as a slightly higher mortality rate.<sup>90</sup> However, it should be noted there are no prospective trials comparing open packing with any other techniques.

**Open Necrosectomy with Continuous Closed Postoperative Lavage.** In this technique, débridement is followed by continuous peripancreatic lavage to remove infected necrotic debris, peripancreatic exudates, and extravasated pancreatic exocrine fluid.<sup>56,62</sup> Drainage catheters, usually two on each side, are placed with their tips at the head and tail of the pancreas behind the ascending and descending colon. Placement of sump drains (20-24 Fr) with two lumens allows inflow of lavage fluid and outflow of drainage fluid. Larger silicon drains (28-32 Fr) allow evacuation of larger necrotic debris. During closure, a closed peripancreatic compartment is attempted by resuturing the gastrocolic and duodenocolic ligaments. Postoperative continuous lavage is instituted at 1 to 10 L per day, and is usually continued until the effluent is clear and the patient shows improvement in clinical and laboratory parameters.<sup>56,91</sup> There is no evidence to support the best irrigation fluid, the optimal number or caliber of drains, or the duration of irrigation.

**Programmed Open Necrosectomy.** The principle of this approach is to be more conservative with débridement, particularly if the necrosis has not fully demarcated, with the intention of performing repeat procedures until débridement is no longer required.<sup>56</sup> Following necrosectomy, the pancreatic bed is packed and drains are placed on top of the packing. The abdominal wall is closed with a zipper or mesh sewn to the fascia. This allows easy repeated access to the abdomen and helps to prevent wound retraction. Reoperation is repeated every 48 hours until there is no further necrotic tissue to remove. In a proportion of patients, primary closure is not possible and healing by secondary intention is allowed to occur. This procedure may be modified with the addition of intra-abdominal vacuum sealing (negative pressure 50-75 mm Hg) in order to encourage granulation of the pancreatic bed.<sup>92</sup>

## REGIONAL COMPLICATIONS

## Vascular Complications

### VENOUS THROMBOSIS

Thrombosis of the splenic vein is a rare complication of acute pancreatitis and one that usually develops a few weeks after the onset. The etiology is multifactorial, but extrinsic compression of the vein by the swollen pancreas and/or fluid collection is important. Other factors include hypercoagulability and hemoconcentration. The consequences of splenic vein thrombosis are splenomegaly with discomfort and possible hypersplenism. Segmental venous hypertension may result in upper gastrointestinal bleeding from gastric varices. Because the risk of gastric variceal bleeding from pancreatitis-induced splenic vein thrombosis is low (5% for CT-identified varices and 18% for endoscopically identified varices) routine splenectomy is no longer recommended.<sup>93</sup> Portal vein thrombosis occurs insidiously, may be identified on CECT, and may be discovered after gastrointestinal hemorrhage has occurred. The consequences of acute superior mesenteric vein thrombosis are venous ischemia and infarction of the intestine. CECT scanning is helpful in the diagnosis of venous thrombosis and may show features of impaired mucosal enhancement, edematous swelling of the vessel wall, and most commonly, filling defects within the vein. The role of acute anticoagulation is controversial because of the risk of bleeding. If thrombosis occurs later in the disease course, anticoagulation can be prescribed with less trepidation. Thrombolytic therapy and surgical thrombectomy have no established role in the context of acute pancreatitis. Acute venous thrombosis is associated with a 25% recurrence rate without anticoagulant therapy and a 30% mortality. Anticoagulant therapy combined with surgery is associated with the lowest recurrence rate (3%-5%).

### BLEEDING

Bleeding associated with severe acute pancreatitis is usually, but not always, due to a pseudoaneurysm related to a pancreatic pseudocyst. The splenic artery is the most commonly affected artery (30%-50%) because of its proximity to the pancreas, followed by the gastroduodenal artery (10%-15%), the inferior and superior pancreaticoduodenal arteries (10%), and all others to a lesser extent.

**Pathogenesis.** The disruption of the pancreas by necrosis and the damage to pancreatic ducts leads to the accumulation of activated proteolytic enzymes (eg, elastase), weakens the vessel wall, and promotes aneurysmal dilatation. This process is accelerated in the presence of infection.

**Diagnosis.** Patients usually present with hypovolemic shock or with an unexplained drop in hemoglobin concentration. Bleeding may occur into a pseudocyst and tamponade, preventing any overt evidence of bleeding. Very rarely the diagnosis will be made in a patient with a known pseudocyst who develops an abdominal bruit.

Selective mesenteric angiography is the best way to make the diagnosis of pseudoaneurysm (Fig. 69-4), although it can often be detected on the arterial phase of CT scan, which is frequently used as a screening test in a stable patient. Angiography usually accurately identifies the location of the pseudoaneurysm and its relationship to named vessels.

**Treatment.** Pancreatic or peripancreatic bleeding is one of the most formidable and life-threatening complications of acute pancreatitis. The standard of care is angioembolization, with surgery only required in patients who have failed this approach or who are not stable enough to be managed in the interventional radiology suite. Success with embolization is operator-dependent, but approaches 90% in leading centers. Failure results from an inability to selectively cannulate the bleeding vessel, or poor placement of embolization material. Recurrent bleeding occurs in fewer than 40% of patients, and the overall mortality is under 20%.

If emergency laparotomy is required for bleeding, it may not be possible to arrange prior angioembolization. The lifesaving surgery may involve under-running the bleeding vessel (inside or outside the pseudocyst) and/or pancreatic resection. The mortality rate following surgical treatment of arterial hemorrhage during the acute phase of pancreatitis ranges from 28% to 56%, and is higher when bleeding is from the head of the pancreas. The mortality rate following surgical treatment of massive hemorrhage is usually over 50%.

## Intestinal Complications

### PARALYTIC ILEUS

The proximity of the inflamed pancreas to the root of the small bowel mesentery commonly results in regional self-limiting paralytic ileus affecting the duodenum, proximal jejunum, or transverse colon. Another factor that may contribute to the ileus is the relative splanchnic ischemia secondary to the reflex vasoconstriction in response to systemic hypotension, early in the disease course. An ileus gives rise to the classic “sentinel loop” and “colon cutoff” signs on plain abdominal radiographs.

## **INTESTINAL ISCHEMIA AND NECROSIS**

Subclinical mucosal ischemia is common in acute pancreatitis, particularly during the early phase, and occurs in response to hypovolemia and reflex splanchnic vasoconstriction. Intestinal ischemia might be compounded by abdominal compartment syndrome, nonselective inotropes, and the demands of early and continuous enteral feeding. These are risk factors for nonocclusive mesenteric ischemia. Full-thickness necrosis is rare and probably involves venous and/or arterial thrombosis at sites proximal to the inflammatory process. The middle mesocolic vessels and the transverse colon are most at risk.

## **INTESTINAL OBSTRUCTION**

Mechanical obstruction rarely complicates acute pancreatitis. The mechanism is usually inflammatory stenosis, which presents very late. It is unusual to require surgery.

## **CHOLESTASIS**

Biochemical and clinical jaundice occur in less than 20% of patients with acute pancreatitis. The early identification of concomitant cholangitis is important and will require early ERCP and duct decompression. Cholestasis may be due to common bile duct stones or extrahepatic bile duct compression by a peripancreatic fluid collection. Long-term total parenteral nutrition will contribute to cholestatic liver dysfunction.

## **SYSTEMIC COMPLICATIONS**

## Systemic Inflammatory Response Syndrome

The systemic inflammatory response syndrome (SIRS) is common with acute pancreatitis and encompasses the hallmarks of a proinflammatory state (ie, tachycardia, tachypnea or hyperpnea, hypotension, hypoperfusion, oliguria, leukocytosis or leukopenia, pyrexia or hypothermia, and the need for volume infusion) but without end-organ damage, identifiable bacteremia, or the need for pharmacologic support. SIRS is distinct from sepsis (where there is an identified pathogen) and septic shock (where there is associated hypotension). SIRS is best regarded as an exuberant host inflammatory response and the consequence of hypoperfusion.

There is no single trigger for SIRS. Instead, it represents a whole-organism response to a variety of quite different challenges. Theories on the drivers for SIRS include the immunologic dissonance theory (where there is imbalance between the pro- and anti-inflammatory responses)<sup>94</sup> and the gut motor theory (where decreased intestinal perfusion and subsequent damage to the mucosal and immunologic barriers may allow the translocation of endogenous bacteria or their products into the systemic circulation).<sup>95</sup> More recently, the intestinal mucosa has been considered another source of inflammatory mediators activated by hypoperfused mucosa.<sup>96</sup> Measurement of intramucosal pH (tonometry) can stratify mortality risk in acute pancreatitis.<sup>97</sup>

The mediation of SIRS is due to a number of well-described cytokines responsible for the proinflammatory state, a full description of which is beyond the scope of this chapter. In many patients with acute pancreatitis, SIRS progresses to multiple organ dysfunction syndrome (MODS) and possible end-organ damage. Occasionally, patients will be admitted with fulminant or early severe acute pancreatitis, often with respiratory and renal impairment from the outset, and these patients are responsible for early deaths. Organ failure on admission, which occurs in 30% to 40% of patients with necrotizing pancreatitis, is a very poor prognostic sign, doubling intensive care stay and increasing the mortality rate fourfold.<sup>35</sup> Early aggressive volume resuscitation has an important role in attenuating the systemic inflammatory response.<sup>96</sup>

## Multiple Organ Dysfunction Syndrome

The development of MODS is common in severe acute pancreatitis. The most commonly affected organ systems are cardiovascular, respiratory, and renal. It has been defined as the presence of altered organ function in a severely ill patient such that homeostasis cannot be maintained without intervention.<sup>98</sup> Many patients with early organ failure respond rapidly to supportive treatment and appear to have an otherwise uncomplicated outcome. These patients are said to have transient organ dysfunction, if it resolves within 48 hours.<sup>1</sup> Patients with persistence and progression of early organ failure have a mortality rate in excess of 50%. It has been shown that organ dysfunction in the first week of admission is a dynamic process and the response to the initial intensive care is an important determinant of outcome.<sup>99</sup>

Many potential early predictors of organ failure have been investigated. MODS can be predicted with reasonably high accuracy at the time of hospital admission using a combination of the anti-inflammatory cytokine IL-10 (an early marker of systemic inflammation) and serum calcium (an early marker of organ dysfunction).<sup>100</sup>

There are many different MODS scoring systems, but the one recommended for acute pancreatitis is the modified Marshall score.<sup>1</sup> The scoring systems do not tell the clinician when specific organ dysfunction is reversible or irreversible. Practically, a simple count of organs affected and the duration of the dysfunction will stratify mortality.

## **Respiratory Complications**

Respiratory impairment can result from several causes, including atelectasis, pleural effusion, pneumonia, mediastinal pseudocyst or abscess, and/or adult respiratory distress syndrome (ARDS). Tachypnea, mild respiratory alkalosis, and mild hypoxemia are common within 2 days of the onset of acute pancreatitis. These clinical features usually can be corrected with analgesia, supplemental oxygen, and chest physiotherapy. A pleural effusion may require a chest drain. Impending respiratory failure is suggested when the arterial PO<sub>2</sub> remains less than 60 mm Hg despite high-flow oxygen by mask. These patients should be considered for mechanical ventilation. Lung-protection ventilation strategies, with low tidal volumes for patients with ARDS, are recommended.<sup>101</sup> ARDS may occur within a few days of admission or after the development of infected necrosis and septicemia.

ARDS results from the release of activated pancreatic enzymes, vasoactive lysosomal enzymes, and especially phospholipase A2 (which destroys surfactant). Parenchymal injury appears to be due primarily to oxidative damage from the activated neutrophils in the lung.

**Renal Complications.** Renal impairment is usually due to both hypovolemia (prerenal failure) and direct nephrotoxicity from the inflammatory mediators of acute pancreatitis. Activation of the renin-angiotensin system may contribute to reduced renal perfusion. This manifests as oliguria (<30 mL/h) or anuria and as an increased serum concentration of creatinine and urea. The initial approach is adequate intravenous crystalloid administration to achieve a satisfactory urine output. Then diuretics (furosemide 20-200 mg/24 h) and dopamine infusion (4 µg/kg/min) should be considered. Further deterioration will necessitate continuous hemofiltration and/or hemodialysis.

**Cardiovascular Complications.** These include arrhythmias, pericardial effusion, impaired myocardial contractility, reduced peripheral vascular resistance, and increased permeability. Hypovolemia, from third-space fluid loss, is common during the first 12 hours and may be up to 30% of blood volume in severe acute pancreatitis. Circulatory failure (mean arterial pressure <70 mm Hg) requires prompt, aggressive fluid resuscitation and inotropic support. SIRS is characterized by decreased peripheral vascular resistance and is the reason for the preferred use of norepinephrine to increase vascular tone and blood pressure (dose 0.05-0.2 µg/kg/min). Epinephrine (dose 0.05-0.2 µg/kg/min) also may be used to support cardiac output. Unfortunately, these inotropes will compound splanchnic vasoconstriction because they are nonselective.

**Metabolic Complications.** Hypocalcemia is the most frequent metabolic disturbance, and it usually occurs during the first week. Low serum albumin will make the hypocalcemia appear worse, and therefore replacement should be based on ionized calcium. There are several factors likely to be responsible for low calcium. Primarily, calcium is sequestered in areas of fat necrosis by the process of saponification. In addition, there is probably a contribution from altered calcium-regulating hormones (eg, calcitonin, parathyroid hormone, and glucagon). Hypomagnesemia may inhibit parathyroid hormone and contribute to the hypocalcemia.

Hyperglycemia is a frequent finding and usually corrects without the need for treatment. There are three contributing factors to hyperglycemia, including a stress-induced increase in cortisol and catecholamines, hyperglucagonemia, and probably most important, an insulin deficiency that may reflect necrosis of the islet cells. Pre-diabetes and diabetes are common after acute pancreatitis, and occur in nearly 40% of patients after hospital discharge.<sup>102</sup> It does not appear to be related to the severity of acute pancreatitis. Prevalence of newly diagnosed diabetes is much higher after acute pancreatitis (23%) than the prevalence of diabetes in the general population (4%-9%).

Disseminated intravascular coagulopathy is not common, but there is a well-recognized tendency toward hypercoagulability in acute pancreatitis. Other rare complications include subcutaneous fat necrosis and polyarthritis, which are also seen in patients with acinar cell carcinoma of the pancreas and thought to be due to increased serum lipase. There have also been reports of osteolysis and rhabdomyolysis in severe acute pancreatitis.

Pancreatic encephalopathy is a rare complication of acute pancreatitis. Clinical features include focal neurologic signs and acute onset of dementia. This picture can fluctuate over time, and cyclic progression with remission and relapses has been described. Although the exact mechanisms are unclear, postmortem examination reveals amylase in the cerebrospinal fluid. MRI of the brain may be helpful, as patchy white matter signal abnormalities resembling the plaques seen in multiple sclerosis may reflect the lesions that are found in the cerebral white matter of postmortem-confirmed cases. Treatment is supportive. Any patient with suspicious or unusual neurologic symptoms and signs associated with possible malnutrition, hyperemesis, or malabsorption should be given intravenous thiamine to avoid the potential morbidity and mortality associated with undiagnosed Wernicke encephalopathy.

Protein-calorie malnutrition is a complication of acute pancreatitis, especially when it is severe and associated with infected necrosis. These patients have a significantly elevated resting energy expenditure, and it has been shown that total parenteral nutrition is unable to reverse this hypercatabolic insult on body protein.<sup>103</sup> This underlies the importance of sepsis control to achieve the full benefits of nutritional support, enteral or parenteral. A full discussion on nutritional support in patients with severe acute pancreatitis can be found in [Chapter 54](#).

## CONCLUSION

The many and varied complications of acute pancreatitis present a considerable clinical challenge and highlight the need for the treatment of patients with severe and critical acute pancreatitis to be in centers able to offer expertise in a wide range of disciplines including intensive care, surgery, endoscopy, radiology, infectious disease, and nutrition. The two primary goals of research in the field of acute pancreatitis should be aimed at preventing infected pancreatic necrosis and reducing the frequency and severity of multiple organ dysfunction. In the meantime, the clinician caring for patients with acute pancreatitis must remain vigilant to detect the development of local, regional, and systemic complications of this protean disease, and be well versed in the considerable recent progress in the treatment of local complications. This progress includes the more conservative approach to the simple pseudocyst, the step-up approach with the primary, and potentially sole, role of percutaneous drainage for infected local complications, and the evolution of minimally invasive techniques, which offer the opportunity for improved outcomes in patients with limited physiological reserve.

# PERSPECTIVE ON MANAGEMENT OF PATIENTS WITH ACUTE PANCREATITIS

*Stefan A.W. Bouwense • Hjalmar C. van Santvoort • Marc G.H. Besselink*

## INTRODUCTION

Acute pancreatitis is the most common gastrointestinal disease for which patients are acutely hospitalized, and its incidence continues to rise.<sup>1</sup> The majority of patients (approximately 80%) with acute pancreatitis have mild disease, and symptoms usually resolve within 1 week with basic supportive care.<sup>2,3</sup> The other 20% of patients develop a severe form of pancreatitis with organ failure and necrotizing pancreatitis. Necrotizing pancreatitis is now defined as either pancreatic parenchymal necrosis and peripancreatic fat necrosis or peripancreatic fat necrosis alone.<sup>2,4</sup> The clinical course of these patients is often characterized by a persisting systemic inflammatory response syndrome and/or (multiple) organ failure for the first 1 to 2 weeks. Despite

maximal supportive care in the intensive care unit, mortality is up to 30% in patients with early persisting organ failure.<sup>5,6</sup> Secondary infection of the necrosis develops in 30% of patients and carries a mortality risk of approximately 15%.<sup>7,8</sup>

## CLASSIFICATION OF ACUTE PANCREATITIS

A better understanding of local and systemic complications, together with better imaging and new interventions in acute pancreatitis, led to the Revised Atlanta Classification.<sup>2</sup> This revised classification aims to clarify terminology and stimulate the use of uniform definitions and standardized reporting in patients with acute pancreatitis. Based on the absence or presence of local or systemic complications, 3 categories were defined in acute pancreatitis: mild, moderate, and severe (Table 70-1). Acute pancreatitis itself is divided into interstitial edematous pancreatitis and necrotizing pancreatitis, where local complications are linked to 1 of the 2 subtypes. Local complications are peripancreatic fluid collections, pancreatic and peripancreatic necrosis (ie, sterile or infected), and walled-off necrosis (ie, sterile or infected) (Table 70-2).

**TABLE 70-1: CATEGORIES OF ACUTE PANCREATITIS AS DEFINED IN THE 2012 REVISED ATLANTA CLASSIFICATION**

Complications	2012 Revised Atlanta Classification		
	Mild	Moderate	Severe
<i>Local complications</i>	No	Yes	Yes
<i>Systemic complications:</i>			
Transient organ failure	No	Yes	Yes
Persistent organ failure	No	No	Yes
Exacerbation of preexisting comorbidity	No	Yes	Yes

**TABLE 70-2: COLLECTIONS AS DEFINED IN THE 2012 REVISED ATLANTA CLASSIFICATION**

<b>Definition</b>	<b>Description</b>
Acute fluid collection (<4 weeks after onset and edematous pancreatitis)	<ul style="list-style-type: none"><li>• Homogenous fluid density</li><li>• Confined by normal peripancreatic fascial planes</li><li>• No definable wall encapsulating the collection</li><li>• Adjacent to pancreas (not intrapancreatic)</li></ul>
Pseudocyst (rare, usually >4 weeks after onset and edematous pancreatitis)	<ul style="list-style-type: none"><li>• Well circumscribed, usually round/oval</li><li>• Homogenous fluid density</li><li>• Well-defined wall and completely encapsulated</li><li>• Adjacent to pancreas (not intrapancreatic)</li></ul>
Acute necrotic collection (<4 weeks after onset and necrotizing pancreatitis)	<ul style="list-style-type: none"><li>• Heterogeneous and nonliquid density</li><li>• No definable wall encapsulating the collection</li><li>• Location: intrapancreatic and/or extrapancreatic</li></ul>
Walled-off necrosis (usually >4 weeks after onset and necrotizing pancreatitis)	<ul style="list-style-type: none"><li>• Heterogeneous and nonliquid density</li><li>• Well-defined wall and completely encapsulated</li><li>• Location: intrapancreatic and/or extrapancreatic</li></ul>

The Revised Atlanta Classification is definitely a step forward in the classification of patients with acute pancreatitis. However, some practical issues with the classification need to be resolved. The cutoff value of 4 weeks is used for the definition of local complications. In the case of encapsulation of an acute necrotic collection, this is called walled-off necrosis after 4 weeks. The timing of encapsulation of collections, however, differs between patients and should probably be based on imaging instead of time from onset

of disease.<sup>9</sup> In acute pancreatitis, the most commonly used imaging modality is contrast-enhanced computed tomography (CECT). Determining the content of collections (ie, fluid and/or necrosis) can be difficult on CECT.<sup>9</sup> Magnetic resonance imaging (MRI) is superior in this respect but is impractical in critically ill patients. These limitations of computed tomography (CT) can make implementation of the new classification difficult in some cases.

## PREDICTING SEVERITY

To identify patients with a high risk for a severe course of their acute pancreatitis, prognostic scoring systems have been developed. There are several scoring systems, which are based on clinical and biochemical parameters (eg, the Ranson, Acute Physiology and Chronic Health Evaluation II [APACHE II], Imrie, or modified Glasgow scores). C-reactive protein and blood urea nitrogen are also often used in predicting severity during admission to the hospital. A systematic review on all these parameters showed that they have a high negative predictive value but low positive predictive value.<sup>10</sup> CECT can assess morphologic abnormalities and can be used in scoring systems (eg, the CT severity index). However, CECT can underestimate morphologic abnormalities in acute pancreatitis in the first days of admission and is inferior to clinical scoring systems.<sup>2,11</sup> A head-to-head comparison on the accuracy of scoring systems in predicting persisting organ failure showed that the modified Glasgow score served as best predictor.<sup>12</sup> Still, more accurate markers are needed to predict the severity of acute pancreatitis.

Persistent organ failure is the key determinant for mortality in acute pancreatitis. Together with the lack of a strong marker to predict severity, the International Association of Pancreatology (IAP)/American Pancreatic Association (APA) guidelines recommends that persistent systemic inflammatory response syndrome (>48 hours) be used as a marker to predict the severity of acute pancreatitis.<sup>3</sup> Persistent organ failure is also used in the Revised Atlanta Classification to define the severity of acute pancreatitis (Table 70-1).

## EARLY SUPPORTIVE MEASURES

## **Pain Management**

Abdominal pain is the most dominant feature of acute pancreatitis during admission. Specific pain management in acute pancreatitis is lacking; therefore, the World Health Organization analgesic ladder should be followed during admission.<sup>13</sup> Of course, proper pain management is crucial for all patients, but increasing evidence also suggests a beneficial impact of pain relief on both physiologic and immunologic response.<sup>14</sup>

## **Fluid Therapy**

Early in the onset of acute pancreatitis, there is often accumulation of fluid in the third space than can cause intravascular hypovolemia and might evoke or worsen organ failure. Extensive fluid resuscitation to correct or preferably prevent intravascular hypovolemia and maintain the microcirculation of the pancreas is therefore important in the supportive care during the first days of acute pancreatitis.<sup>15,16</sup> More recent evidence also showed that uncontrolled, aggressive fluid therapy may induce morbidity and even mortality.<sup>17,18</sup> For acute pancreatitis, there is a lack of quality evidence on which type of fluid therapy should be used.<sup>19</sup> Results from a trial in patients with severe sepsis showed that when patients were resuscitated with hydroxyethyl starch (HES) there was an increased risk for death compared to Ringer's lactate.<sup>20</sup> The recent update of the IAP/APA treatment guidelines for acute pancreatitis recommends closely monitoring urine production and vital parameters and using Ringer's lactate with an infusion rate of 5 to 10 mL/kg/h until resuscitation goals are reached.<sup>3,21</sup>

## **Prevention of Infection**

Prophylactic strategies should be focused on infections that occur early in acute pancreatitis and have a significant impact on mortality, especially bacteremia.<sup>22</sup>

It was hypothesized that administration of probiotics would be such a strategy. Before the PROPATRIA trial was performed, 2 smaller randomized, controlled, single-institution trials were conducted with probiotic prophylaxis in patients with severe acute pancreatitis. The first trial showed that

probiotics reduce pancreatic sepsis and the need for surgical intervention<sup>23</sup>; the second study suggested that early nasojejunal feeding with synbiotics may prevent organ dysfunction in the late phase of severe acute pancreatitis.<sup>24</sup> In the larger randomized controlled multicenter trial (PROPATRIA), probiotics were compared with placebo in patients with predicted severe pancreatitis. No effect was found on infectious complications, and increased rates of bowel ischemia (9% vs 0%) and mortality (16% vs. 6%) were present when compared to the placebo group.<sup>25</sup> Although the mechanism of this adverse effect remains unknown, use of probiotics in acute pancreatitis is not recommended.

Studies in intensive care units showed that selective decontamination of the intestinal tract reduces mortality in general.<sup>26</sup> Selective decontamination of the intestinal tract has also been performed in severe acute pancreatitis with beneficial results. However, no effect on mortality was found, and the design of the study was not optimal, with a lack of blinding and absence of a placebo.<sup>27</sup> Potential benefits of selective decontamination of the intestinal tract should be weighed against an increase in antibiotic resistance and fungal colonization.<sup>28</sup>

Several systematic reviews of randomized trials have shown that prophylactic administration of intravenous antibiotics does not prevent infected necrosis.<sup>29-31</sup> Therefore, antibiotics in acute pancreatitis are only indicated when infections are proven or there is a high suspicion of infected necrosis.<sup>3</sup>

## **Nutrition**

When oral nutrition is not tolerated, enteral or parenteral nutrition should be administered. In severe pancreatitis, enteral nutrition is considered a therapeutic measure. Enteral nutrition through a nasoenteric feeding tube is superior to parenteral nutrition in terms of reducing organ failure, infected necrosis, and even mortality.<sup>32</sup> These complications are thought to be caused by gut permeability, bacterial overgrowth, and bacterial translocation. Enteral nutrition is believed to stimulate intestinal motility and, with that, reduce bacterial overgrowth, which helps to conserve the gut mucosa.<sup>33,34</sup> In the PYTHON trial, patients with predicted severe pancreatitis were randomized between early nasoenteric tube feeding within 24 hours of presentation to the

emergency department or an oral diet initiated 72 hours after presentation, with tube feeding only provided if the oral diet was not tolerated. The primary endpoint was a composite of major infection (infected pancreatic necrosis, bacteremia, or pneumonia) or death during the 6 months of follow-up.<sup>35</sup> The main findings of the PYTHON trial were that routine early nasoenteral nutrition did not reduce the composite endpoint of infections or mortality. In the on-demand group, 69% of patients tolerated an oral diet and did not require tube feeding. Therefore, enteral nutrition is only recommended when an oral diet is not tolerated during the first 3 to 5 days of acute pancreatitis.

## **Endoscopic Retrograde Cholangiopancreatography**

In the case of biliary pancreatitis and cholangitis, an urgent endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy is indicated. There is no evidence that supports the use of ERCP in mild biliary pancreatitis in the absence of cholangitis or symptomatic common bile duct stones.<sup>3,36</sup> It is hypothesized that performing an ERCP with endoscopic sphincterotomy in patients with predicted severe pancreatitis and without cholangitis may decrease the severity of the disease course. However, meta-analyses of randomized trials show conflicting results.<sup>3,36,37</sup> The Dutch Pancreatitis Study Group is currently enrolling patients in a randomized multicenter trial to compare early ERCP with endoscopic sphincterotomy in patients with predicted severe pancreatitis without cholangitis (ISRCTN Registry No. ISRCTN97372133).

## **MANAGEMENT OF INFECTED NECROSIS**

When patients fail to show clinical improvement from their systemic inflammatory response syndrome and/or organ failure or when they deteriorate during the course of the disease, infected necrosis should be suspected.

A CECT in these patients may show acute necrotic collection(s) or walled-off necrosis.<sup>2,3</sup> Routine fine-needle aspiration (FNA) of peripancreatic collections to detect bacteria is not indicated because clinical signs and imaging signs are accurate predictors of infected necrosis in the majority of

patients.<sup>3</sup> Pathognomonic for infected necrosis are gas bubbles in collections, which are caused by gas-forming bacteria or fistulas between the collection and the intestinal tract.<sup>9</sup> FNA of the collection may be required when the diagnosis of infected necrosis is unclear. Still, one has to bear in mind that false-negative FNA results have been reported in 12% to 25% of patients and prospective studies with a proper design are lacking on this subject.<sup>38-40</sup>

If infected necrosis is suspected or proven, intravenous broad-spectrum antibiotics should be started, which subsequently can be narrowed down based on cultures of the infected collection.<sup>3</sup> Full recovery with antibiotics has been described in some case series, but in the vast majority of patients, antibiotics should be regarded as supportive care during the disease course, while drainage and/or necrosectomy of (suspected) infected necrotic collections are regarded as definitive treatment.<sup>7</sup>

Major surgery was traditionally performed early in the clinical course of necrotizing pancreatitis, but this practice has now been abandoned.<sup>41</sup> When feasible, interventions are now postponed until walled-off necrosis is present on CECT, a process that usually takes 3 to 4 weeks.<sup>9</sup> Delaying intervention until collections are completely encapsulated reduces morbidity and mortality when compared to early interventions in the first 2 weeks.<sup>7,42</sup>

Drainage of sterile collections carries a risk of introducing infection, thereby increasing the risk of morbidity and mortality. Therefore, in the acute phase, there is no indication for intervention in sterile collections.<sup>3,43</sup> Several weeks after onset of the disease, in rare cases of obstruction of the biliary or gastrointestinal tract, long-lasting pain, or collections resulting from a disrupted pancreatic duct, sterile collections may be drained.<sup>3</sup>

## INVASIVE TREATMENT

Complete necrosectomy by laparotomy has long been the standard intervention in patients with necrotizing pancreatitis who showed clinical deterioration. Mortality (11%-39%) and morbidity (up to 95%) for this procedure were initially high.<sup>44,45</sup> Due to better supportive care in the intensive care unit and optimal timing of surgery, recent studies have shown that the success rate of open necrosectomy has improved significantly (11%-19%).<sup>39,46</sup>

Due to the introduction of minimally invasive techniques to drain and debride pancreatic necrosis (ie, catheter drainage and video-assisted retroperitoneal debridement), the indications for laparotomy have sharply diminished.<sup>42,46,47</sup> Still, in the case of acute abdominal complications such as bowel ischemia, bowel perforation, and abdominal compartment syndrome, emergency laparotomy is required.<sup>7,48-50</sup> During these laparotomies, it is recommended not to explore the retroperitoneum when infected necrosis is not present. The international guideline for abdominal compartment syndrome suggested drainage of ascites as a reasonable initial approach.<sup>51</sup> However, this intervention should lead to rapid and sustained improvement of the patient's condition.

## **Minimally Invasive Interventions**

The first step of nearly all minimally invasive interventions is to drain the infected collections by a percutaneous catheter drain. If this drainage does not improve the clinical condition, drains may be revised, and if unsuccessful, necrosectomy of nonadherent necrotic tissue is performed. This approach causes less surgical injury and reduces the risk of iatrogenic damage and hemorrhage.

Several minimal invasive intervention strategies are available for drainage and/or debridement of infected necrotizing pancreatitis, such as percutaneous catheter drainage,<sup>52</sup> percutaneous necrosectomy,<sup>53</sup> video-assisted retroperitoneal debridement (VARD),<sup>54</sup> laparoscopic necrosectomy,<sup>55</sup> and endoscopic transluminal drainage and necrosectomy.<sup>56</sup>

## **Percutaneous Catheter Drainage and VARD**

To gain sepsis control in infected necrosis, a percutaneous catheter drain is used to drain “pus under pressure” in the necrotic collection and to serve as a bridge to definitive surgery. It is the least invasive procedure and is widely available. Success rates up to 50% (ie, no necrosectomy) have been described after percutaneous catheter drainage (Fig. 70-1).<sup>57,58</sup>

**FIGURE 70-1** Imaging of a patient with infected necrotizing pancreatitis. The patient recovered fully after a single large percutaneous drain was placed through the left retroperitoneum, without additional drainage procedures and without necrosectomy. *Arrows* point at the borders of the collection, with *big arrowheads* pointing at impacted gas bubbles and *small arrowheads* pointed at the gas-fluid level. (Reproduced with permission from van Brunschot S, Bakker OJ, Besselink MG, et al: Treatment of necrotizing pancreatitis, *Clin Gastroenterol Hepatol* 2012 Nov;10(11):1190-1201.)

Most of the peripancreatic collections can be reached percutaneously either via the retroperitoneal or transperitoneal route.<sup>46,59</sup> When possible, the retroperitoneal route is preferred because it is associated with fewer complications and can be used as guidance for minimally invasive retroperitoneal necrosectomy (Fig. 70-2).

**FIGURE 70-2** Percutaneous catheter drainage and video-assisted retroperitoneal debridement. **A.** Contrast-enhanced computed tomography (CT) image of a patient with necrotizing pancreatitis showing a transverse cross-sectional image. Catheter drainage through the left side of the retroperitoneum is the preferred route. **B.** Details on the drained area. **C.** Near the puncture site of the percutaneous drain, a small subcostal incision is made. The drain is used as a guide to the necrotic collection through the retroperitoneum. All visible necrosis is removed directly. **D.** Under vision of a 0-degree videoscope, further debridement is performed with laparoscopic instruments. (Reproduced with permission from van Brunschot S, Bakker OJ, Besselink MG, et al: Treatment of necrotizing pancreatitis, *Clin Gastroenterol Hepatol* 2012 Nov;10(11):1190-1201.)

In the PANTER trial, the minimal drain size was 12 Fr, and drains were irrigated 3 times daily with 250 mL of normal saline to keep the drains open.<sup>46</sup> Additional drains can be placed or drains can be upsized to help to deal with inadequately drained collections. A VARD should always be preceded by percutaneous catheter drainage because a necrosectomy can be prevented in 35% to 50% of patients.<sup>3,57</sup>

VARD is performed as follows. Under general anesthesia, in the right lateral position, a subcostal incision of a few centimeters is made near the exit of the drain. The drain is used, together with imaging, as a route through the retroperitoneum to the necrotic collection. Visible nonadherent necrosis is removed with grasping forceps from the collection. Under assistance of a 0-degree videoscope, loosely adherent necrosis is removed with long atraumatic graspers to reduce the risk of bleeding from viable underlying tissue. Finally, 2 large catheters are placed in the cavity for postoperative lavage (up to 10 L per 24 hours) exiting through stab incisions, and the fascia at the incision site is closed (Fig. 70-3).

A

B

**FIGURE 70-3** Endoscopic transluminal drainage and endoscopic transluminal necrosectomy. **A.** Through the stomach wall, the necrotic collection is punctured and a guidewire is placed in the collection, if needed, under guidance of endoscopic ultrasound. Over the guidewire, the tract is balloon dilated. Two pigtail drains and a nasocystic catheter are placed into the collection for continuous lavage. **B.** Further dilation of the cystogastrostomy is performed, and the collection is entered by an endoscope. A necrosectomy can be performed under direct vision. (Reproduced with permission from van Brunschot S, Bakker OJ, Besselink MG, et al: Treatment of necrotizing pancreatitis, *Clin Gastroenterol Hepatol* 2012 Nov;10(11):1190-1201.)

The PANTER trial was a Dutch randomized multicenter trial that included patients with (suspected) infected necrotizing pancreatitis who were randomized between primary open necrosectomy (by laparotomy) or a surgical step-up approach that consisted of percutaneous catheter drainage first followed, if no improvement was present after 72 hours, by VARD.<sup>46</sup> One-third of the patients in the trial were successfully treated with catheter drainage and reversal of sepsis after percutaneous catheter drainage occurred in the majority of patients. Also, due to the catheter drainage, a valuable time interval was created where the collections could become more encapsulated, facilitating the effectiveness of necrosectomy. The step-up approach showed a significantly lower rate of the combined endpoint of mortality and major complications compared to open necrosectomy (40% vs 69%). Some complications, such as pancreatic fistula formation (28% vs 38%), incisional hernia (7% vs 24%), and new-onset diabetes (16% vs 38%), were lower in the step-approach group when compared to the open necrosectomy group. Other complications, such as intra-abdominal bleeding (16% vs 22%) and enterocutaneous fistula or perforation of a visceral organ requiring intervention (14% vs 22%), did not differ significantly. Technical success in the step-up approach was high. Other retroperitoneal approaches are numerous (eg, single-port or multiport and flexible endoscopy access techniques).<sup>53,60-62</sup>

## Endoscopic Drainage and Necrosectomy

Endoscopic transluminal catheter drainage followed, if needed, by endoscopic transluminal necrosectomy can be an alternative to the surgical

step-up approach and is gaining popularity.<sup>56,63,64</sup>

When the infected collection lies close to the duodenum or stomach, endoscopic transluminal drainage can be considered. Under deep sedation or general anesthesia, the patient is placed in the left lateral position. The size, content, and relation to other structures of the collection are examined by endoscopic ultrasound.<sup>65</sup> Endoscopic drainage without ultrasound is possible, but the technical success is inferior to ultrasound-guided procedures.<sup>66,67</sup> A 19-gauge FNA needle is used to access the collection through the duodenum or stomach. Cultures are taken, and under fluoroscopic guidance, a guidewire is introduced and looped into the collection.<sup>68</sup> A larger fistula tract of up to 8 to 12 mm is created between the collection and the intestinal lumen by using electrocauterization and/or balloon dilatation. Two double pigtailed and a nasocystic catheter are placed into the cavity and are used to flush the contents of the collection into the stomach (1 L per 24 hours). Alternatively, metal stents are used progressively as they have the advantage of creating and maintaining a larger opening ( $\geq 1$  cm).<sup>69-71</sup> The use of stents seems promising due to the ease of the endoscopic procedure and drainage of the cavity, but bleeding is a reported risk and this technique needs to be validated in randomized trials. Multiple collections can be drained by multiple cystogastrotomies or, alternatively, by combined percutaneous and endoscopic drainage.<sup>72-74</sup>

If a patient does not improve within 72 hours after drainage, an endoscopic necrosectomy is performed. With a forward-viewing endoscope, the fistula tract is dilated up to 15 to 18 mm. The endoscope is advanced into the collection, and with endoscopic accessories (ie, snares, baskets, nets, and forceps), necrosectomy is performed through this tract, leaving the debris in the stomach. Finally, pigtailed and a nasocystic catheter are left in the cavity to leave the fistula tract open.<sup>68,75,76</sup> Until most necrotic material is removed, endoscopic necrosectomy is repeated every 48 hours.

The technical success of endoscopic drainage and necrosectomy is high and comparable with the surgical step-up approach, with clinical success rates up to 91%.<sup>65</sup> Major complications were bleeding, spontaneous perforation of a hollow organ, and pancreatic fistula. Air embolisms have been described and hence CO<sub>2</sub> insufflation is recommended although this is not 100% protective since endoscopes insufflate without pressure control.

## Which Technique Is Superior?

The method and route of drainage and/or necrosectomy depend largely on local experience available in the institution or region. Still, no definitive evidence exists as to what procedure should be the treatment of choice when necrosectomy is indicated. It is suggested that minimally invasive interventions are superior to open necrosectomy, although this has not yet been proven by well-designed trials. Head-to-head comparisons between all the different routes and techniques have not been performed. Even in the PANTER trial, VARD and open necrosectomy were not directly compared because VARD was always preceded by percutaneous drainage.<sup>46</sup>

Endoscopic transluminal necrosectomy was compared with VARD in a pilot study (the PENGUIN trial) in 22 patients with infected necrosis. The primary endpoint of the postoperative proinflammatory response and the combined endpoint of major complications and death were significantly reduced after endoscopic necrosectomy compared with VARD.<sup>77</sup> The superiority of the less invasive endoscopic step-up approach over the surgical step-up approach in terms of clinical and economic outcomes should be confirmed in a large, multicenter, randomized controlled trial. The TENSION trial (ISRCTN Registry No. ISRCTN09186711) compares the endoscopic step-up approach with the surgical step-up approach regarding major morbidity and mortality and completed inclusion in February 2015.<sup>78</sup>

# CHRONIC PANCREATITIS

*Marshall S. Baker • Jeffrey B. Matthews*

## INTRODUCTION

Chronic pancreatitis is an inflammatory and fibrosing disease of the exocrine pancreas characterized by irreversible morphological changes and permanent loss of function. The incidence of chronic pancreatitis has increased approximately fourfold over the past several decades. This apparent increase is due in part to a broadening of its definition and the inclusion of patients with earlier-stage disease. The natural history of chronic pancreatitis is unpredictable. Affected individuals typically suffer a pattern of persistent or recurrent attacks of pain and progressive pancreatic exocrine dysfunction. Additional symptoms may develop from extension peripancreatic inflammation and fibrosis to adjacent organs and vascular structures. In later stages, pancreatic endocrine insufficiency may develop. Decision making in the management of chronic pancreatitis must be individualized the specific anatomic and pathological circumstances, taking into account the extent of local expertise in various diagnostic and therapeutic modalities as well as the fact that there is a relative paucity of high-quality data on the clinical effectiveness of surgical and medical interventions. Optimal management is facilitated by a multidisciplinary approach that includes surgical, endoscopic,

and radiological expertise in addition to nutrition, endocrinology, pain management, and psychosocial support.

## DEFINITION AND RISK FACTORS

Pancreatitis is thought to have its origin as an autodigestive disease initiated by inappropriate activation of pancreatic zymogens. The terms *acute pancreatitis* and *chronic pancreatitis* are often used to draw the temporal distinction between an isolated episode and a more persistent illness associated with a gradual, progressive loss of pancreatic function. In fact, pancreatitis represents a far more heterogeneous clinical entity than can be captured by these two simple descriptors. A number of international conferences have been held in order to develop uniform terminology to characterize the spectrum of morphology seen in acute and chronic pancreatitis.

According to the Marseilles-Rome classification of 1988, the term *acute pancreatitis* is used to refer to single or repeated episodes of abdominal pain associated with a range of potentially reversible pancreatic lesions including pancreatic edema, necrosis, and hemorrhage, as well as peripancreatic fluid collections, necrosis, and pseudocysts. *Chronic pancreatitis* is used to refer to recurrent or persistent abdominal pain that is associated with irreversible and ongoing inflammatory destruction of exocrine parenchyma and eventually, islets. In practice, however, the distinction between acute and chronic pancreatitis is rarely made based on tissue sampling, and there is no consensus on the definition of irreversible morphological change.<sup>1</sup> It is also acknowledged that certain forms of chronic pancreatitis can occur in the absence of pain.

The Marseilles-Rome classification further divides chronic pancreatitis into several morphological subtypes that may coexist in the same patient. *Chronic obstructive pancreatitis* is characterized by exocrine atrophy and is associated with duct stenosis caused by tumors, pseudocyst, or scarring from prior acute pancreatitis. *Chronic calcifying pancreatitis* is characterized by intraductal calcifications and protein plugs, and is often associated with atrophy, stenotic ducts, and areas of acute inflammation or pseudocyst. *Chronic inflammatory pancreatitis* consists of dense infiltration of mononuclear inflammatory cells. *Retention cysts* and *pseudocysts*, seen in

both calcifying and obstructive forms, may also become infected. *Fibrosis* may develop in the absence of symptoms.

Chronic pancreatitis lacks a simple unifying theory of disease pathogenesis. The precise mechanism by which any specific agent or circumstance induces pancreatitis remains obscure. Acute pancreatitis clearly has the potential to evolve into chronic disease. However, repeated episodes of acute pancreatitis do not invariably lead to chronic pancreatitis, and chronic pancreatitis may present without prior acute attacks. Excessive alcohol ingestion has been associated with chronic pancreatitis since the term was introduced by Comfort in 1946.<sup>2</sup> Alcohol use continues to be the most commonly identified environmental risk factor clinically. The precise relationship between alcohol and chronic pancreatitis remains, however, poorly understood. Alcohol ingestion does not lead to pancreatitis in experimental animal models. Alcoholism is by no means uniform among human pancreatitis. Chronic pancreatitis in humans occurs in the absence of significant alcohol usage, and fewer than 5% of alcoholics actually develop pancreatic disease.<sup>3,4</sup> Acute and chronic forms of pancreatitis have been associated with exposure to toxic agents other than alcohol. As with alcohol, most individuals exposed to the other toxic substances associated with pancreatitis do not develop the chronic form of the disease.

Given the lack of an identified, uniform pathogenic trigger, the concept of risk modifiers rather than etiologies or causes of chronic pancreatitis may be more appropriate in classifying the disease, particularly when making decisions regarding patient management. Chronic pancreatitis is not simply a “drunkard’s disease,” but rather is more appropriately attributed to a variety of genetic, environmental, anatomic, immunologic, and other poorly understood susceptibility factors that interact to initiate and perpetuate the pathology. Whitcomb<sup>4</sup> has proposed the TIGAR-O system (Table 71-1) as a potential framework that allows various risk factors associated with the disease to be logically organized into categories: *Toxic or metabolic, Idiopathic, Genetic, Autoimmune, Recurrent acute, and Obstructive*. The TIGAR-O system reflects the fact that in chronic pancreatitis there is a diversity of etiologic risk factors that contributes to a spectrum of pathological and functional derangements, clinical features, and natural history.

**TABLE 71-1: TIGAR-O CATEGORIZATION OF RISK FACTORS FOR CHRONIC PANCREATITIS**

**Toxic/metabolic**

- Alcohol
- Tobacco
- Hypercalcemia (hypoparathyroidism)
- Dietary/nutritional (tropical)
- Hyperlipidemia
- Chronic renal failure (uremia)

**Idiopathic**

**Genetic**

- PRSS1, PRSS2*
- SPINK1
- CFTR
- Chymotrypsin C

**Autoimmune**

**Recurrent and severe acute pancreatitis**

**Obstructive/mechanical**

- Pancreas divisum
- Sphincter of Oddi dysfunction
- Annular pancreas
- Malignant obstruction of the pancreatic duct
- Primary pancreatic duct stones
- Choledochoceles

## **Toxic or Metabolic**

The majority of patients with chronic pancreatitis (55%-80%) will report significant alcohol intake over the years prior to diagnosis. A relationship between dose and duration of alcohol use has been repeatedly documented,

and there appears to be a threshold level for the risk of pancreatitis at approximately 50 g (four drinks) per day.<sup>5</sup> Several mechanisms have been proposed to account for pancreatic injury, including alterations in pancreaticobiliary secretory flow, ductal plugging, and direct toxic action on acinar cells. Chronic pancreatitis in the setting of alcohol use is associated with pancreatic calcification and ductal stone formation, but none of the proposed mechanisms is convincingly supported experimentally, and the hypotheses are not mutually exclusive. Several other toxic agents have been identified as risk factors for pancreatitis. Included among these is tobacco, which has been shown to confer increased risk of chronic pancreatitis independent of alcohol use.<sup>6</sup> Several medications have been implicated in acute pancreatitis but probably do not play a role in the chronic form of the disease. Similarly, hypercalcemia (eg, associated with hyperparathyroidism) and various forms of hyperlipidemia (eg, hypertriglyceridemia) are linked to acute but not chronic pancreatitis. So-called tropical chronic pancreatitis, described in children living in developing parts of the world, is thought to be either due to a dietary toxin or to an unidentified micronutrient deficiency.

## **Idiopathic**

About 20% of patients with chronic pancreatitis have no clinically obvious risk factor. It is suspected that a great many of these idiopathic cases will ultimately prove to harbor yet-unidentified genetic or molecular derangements that explain the process. In recent years, many patients previously considered to be idiopathic recurrent acute and chronic pancreatitis have been found to carry mutations, polymorphisms, or splice variants of the gene associated with cystic fibrosis (CF). Recent evidence also suggests that polymorphisms in genes associated with oxidative stress and xenobiotic metabolism may be more prevalent in patients with what is now characterized as idiopathic disease.<sup>7</sup> Thus, as new genetic associations that predispose to the development of chronic pancreatitis become recognized, the percentage of patients with truly idiopathic disease will decrease.

## **Genetic**

Hereditary pancreatitis was first characterized in 1952 as early onset of

chronic pancreatitis clustering in family members without other risk factors.<sup>8</sup> At least half of hereditary pancreatitis kindreds have been found to carry germline mutations in the cationic trypsinogen (*PRSS1*) gene.<sup>3,4,9</sup> The arginine-to-histidine (R122H) substitution is the most common defect. Hereditary pancreatitis has an autosomal dominant pattern of inheritance, with a high degree of penetrance. Cationic trypsinogen is produced in the pancreatic acinar cells and, upon cleavage by duodenal enteropeptidase, forms trypsin. Trypsin is a protease that acts to hydrolyze dietary proteins and plays the key role in both initial activation of other pancreatic zymogens (including trypsinogen itself) and in their subsequent proteolytic inactivation. Trypsin encoded by pancreatitis-associated *PRSS1* mutations is unusually stable and resists autolytic inactivation, predisposing to premature and extended activation of trypsin within the pancreatic parenchyma.<sup>10</sup> Mutations in other genes such as anionic trypsinogen (*PRSS2*) or the calcium-sensing receptor (*CASR*) have also been reported in some cases of hereditary pancreatitis, although in many other kindreds, the responsible gene has not yet been identified.<sup>11</sup> Other gene associations with hereditary or otherwise idiopathic chronic pancreatitis will undoubtedly emerge over the next several years. Recently, for example, inactivating mutations in the gene encoding for the trypsin-degrading enzyme chymotrypsin C have been identified in a German cohort.<sup>12</sup>

Another genetic disorder associated with pancreatic pathology is CF, a disease linked to mutations in the CF transmembrane conductance regulator (CFTR) gene.<sup>9,13–15</sup> CFTR is a chloride ion channel involved in water, chloride, and bicarbonate secretion by epithelial cells such as those lining the gastrointestinal tract and respiratory system. In the pancreas, CFTR is localized to centroacinar and proximal lobular duct cells.<sup>16</sup> Over 90% of CF patients are pancreatic insufficient, and while severe pancreatic fibrosis is common, acute pancreatitis is rare.<sup>17</sup> However, a subset of patients with otherwise idiopathic recurrent acute and chronic pancreatitis has been noted to have borderline abnormalities in functional tests for CF such as sweat chloride content. These patients harbor at least an eightfold increase in CF-associated CFTR mutations on a single allele. Various other CFTR mutations, polymorphisms, and splice variants not associated with classical pulmonary manifestations of CF are also frequently identified in patients with recurrent acute and chronic pancreatitis. The CFTR gene shows autosomal

recessive inheritance with incomplete penetrance, and thus a family history of CF or pancreatic disease is usually absent in CFTR-associated pancreatitis. The mechanism of CFTR-associated pancreatitis is thought to involve the viscous, low-volume, low-bicarbonate containing pancreatic fluid secretion leading to duct sludge, ductal obstruction, and enzyme hyperconcentration, enhancing the potential for intraglandular enzyme activation.

Mutations and polymorphisms in other genes may also modify susceptibility to chronic pancreatitis. Pancreatic serine protease inhibitor Kazal type 1 (SPINK1) is a natural protease inhibitor that localizes with trypsinogen within zymogen granules. SPINK1 binds to and inhibits activated trypsin, thus serving as a “buffer” of sorts against inappropriate early trypsinogen activation. Mutations of the SPINK1 gene (notably N34S) appear to increase the risk of recurrent acute and chronic pancreatitis, particularly in patients who harbor two mutated alleles.<sup>3,4,9</sup> A single mutated SPINK1 allele appears to increase the risk of alcohol-associated pancreatitis and tropical pancreatitis.

## Autoimmune

Autoimmune pancreatitis (AIP), also known as lymphoplasmocytic sclerosing pancreatitis, is characterized by diffuse glandular enlargement and infiltration with CD4- or CD8-positive lymphocytes and IgG4-positive plasma cells.<sup>3,4,18,19</sup> The exact immunologic etiology is unknown, although circulating antibodies with homology both to a peptide sequence associated with a protein from *Helicobacter pylori* (infection with which is associated with various autoimmune disorders including AIP) and to a protein highly expressed in pancreatic acinar cells have recently been found in over 90% of patients.<sup>20</sup> Inflammatory infiltrates are particularly concentrated in duct rather than acinar zones, however, and thus a duct-origin autoantigen has been postulated. Notably, diffused ductal narrowing rather than dilation is usually observed. Initially described predominately in young men, AIP has been increasingly recognized as a cause of biliary obstruction and pseudotumor in older individuals.<sup>21</sup> Most patients report little in the way of pain, and prior attacks of acute pancreatitis are unusual. It has been associated with serologic elevation of IgG4 levels in about two-thirds of patients and with other autoimmune conditions in approximately 20%, including Crohn’s disease,

ulcerative colitis, Sjögren syndrome, primary biliary cirrhosis, or primary sclerosing cholangitis.<sup>18,21</sup>

## Recurrent and Severe Acute Pancreatitis

Recurrent episodes, or even a single severe episode of acute pancreatitis, may lead to chronic pancreatitis, but the basis for progression is poorly understood. Patients with prior episodes of necrosis appear to be at particular risk for developing chronic disease. In many cases, progression may be due to postpancreatic ductal scarring, persistent activation of pancreatic stellate cells, and neuroplasticity leading to hyperalgesia.

## Obstructive

Post-traumatic duct strictures, or obstruction associated with tumors including cystic neoplasms, neuroendocrine lesions, and pancreatic adenocarcinoma have been associated with pancreatic pathology consistent with chronic pancreatitis, although these patients are often asymptomatic. Chronic pancreatitis has also been associated with anomalous anatomic variations in the pancreatic ductal system, most notably *pancreas divisum*, and it has been postulated that relative obstruction to pancreatic flow through the dorsal duct and minor papilla predisposes to recurrent acute and chronic pancreatitis. The evidence supporting the association to chronic pancreatitis in particular is largely circumstantial and may reflect referral bias,<sup>22</sup> but *pancreas divisum* may be a contributing factor in the presence of certain genetic risk factors (Fig. 71-1). Some cases of chronic pancreatitis are attributed to sphincter of Oddi dysfunction, although rigorous evidence to support this association is also lacking.

**FIGURE 71-1** Recurrent acute and chronic pancreatitis in a 41-year-old woman with pancreas divisum and a pancreatitis-associated mutation in the cystic fibrosis (CF) gene. Magnetic resonance cholangiopancreatography (MRCP) demonstrates noncommunicating dorsal (*arrow*) and ventral (*arrowhead*) pancreatic ducts.

## **PATHOPHYSIOLOGY AND MECHANISM OF PAIN**

Progress in elucidation of the pathogenesis of chronic pancreatitis has been hampered by the lack of a suitable experimental model that adequately recapitulates the features of the disease seen in humans.<sup>23</sup> However, existing evidence suggests a number of useful conceptual frameworks that may help guide efforts to treat patients with chronic pancreatitis. Traditional theories of

the pathogenesis of acute pancreatitis include the toxic-metabolic or oxidative stress hypotheses, in which normal acinar cell processing and release of zymogens are disrupted by a toxic or oxidative stressor, and the ductal obstruction hypothesis that proposes a mechanical role for ductal plugs and stones causing disruption of the integrity of the acinar cell (common in alcoholic and tropical disease). In certain situations, notably autoimmune disease, pancreatitis may begin not in the acinar cell but in the duct cell, triggered by the development of an as-yet-unidentified autoantigen on the duct epithelium. Recently, attention has focused on understanding the mechanism of pancreatic fibrosis, the central histological feature that characterizes the evolution from acute disease to chronic pancreatitis. One attractive hypothesis is that a sentinel acute pancreatitis event (SAPE) primes the pancreas for fibrogenesis.<sup>23</sup> According to the SAPE concept, local inflammatory cytokines released during acute pancreatitis activate circulating macrophages that infiltrate the gland as well as resident pancreatic stellate cells, myofibroblast-like cells that are normally quiescent. During the subsequent healing phase, anti-inflammatory mediators (particularly anti-inflammatory cytokines such as tumor growth factor beta [TGF- $\beta$ ]) drive stellate cells and tissue macrophages to synthesize and deposit fibrogenic matrix proteins. The pancreatic parenchyma may return to normal after a mild self-limited episode. However, the damage may not completely resolve after a severe attack, particularly if there has been significant tissue necrosis. Thus, following the SAPE, the local pancreatic environment may be permanently altered by the persistent presence of anti-inflammatory and profibrogenic cell populations that are perpetually activated by ongoing toxic-metabolic, oxidative, or mechanical stress. The pancreas then becomes subject to repeated cycles of inflammation and progressive fibrosis.

A comprehensive mechanistic explanation for pain, often the most debilitating symptom of chronic pancreatitis, also remains elusive.<sup>23</sup> One hypothesis is that pain results from capsular stretch associated with ductal or organ hypertension. This hypothesis is supported by the favorable results of surgical or endoscopic ductal drainage in patients with chronic pancreatitis associated with dilated pancreatic ducts, and the success of surgical resection in other selected patient populations. An alternative, possibly complementary, hypothesis is that the pain represents a neuropathy caused by repeated inflammatory insults and damage to retroperitoneal sensory nerves.<sup>23–25</sup> Recent evidence demonstrating neuroplasticity in nociceptive dorsal root

ganglia in chronic inflammatory states, with evidence of upregulation of nociceptors such as TRPV1 by proteolytic enzymes such as trypsin,<sup>26</sup> supports this theory.

## CLINICAL PRESENTATION

As in acute pancreatitis, pain in chronic pancreatitis typically localizes to the left upper quadrant or epigastric region, often radiating around or into the back. The pattern of pain is variable. Some patients experience recurrent attacks of moderate to severe pain interspersed with periods of relative or complete quiescence. In others, the pain may be persistent and lead to significant incapacitation and chronic disability. During acute exacerbations, the pain may be increased by food intake and is frequently associated with nausea and vomiting.

Weight loss and malnutrition are common, due to both decreased intake as well as exocrine insufficiency, with consequent malabsorption of protein and fat. Exocrine insufficiency is usually obvious in patients with classical steatorrhea (loose, bulky bowel movements that may be greasy, sticky, oily, or foul-smelling), but these symptoms are obscured by narcotic-associated constipation.

Endocrine insufficiency typically occurs late in the course of disease, often after exocrine insufficiency has appeared, and usually not before about 90% of the pancreatic parenchyma has been replaced by fibrosis. For reasons that are unclear, there is a relative sparing of islet cells until late in the course of the disease. Diabetes is more common in patients with alcohol-associated chronic calcifying pancreatitis, with 80% of these individuals demonstrating endocrine insufficiency within 10 years of the development of severe exocrine insufficiency.<sup>27</sup> Histologically, pancreatic islets are seen to persist within areas of extensive fibrotic replacement of exocrine tissue (Fig. 71-2). Because diabetes of chronic pancreatitis is associated with indiscriminate destruction of all cell types within the islets of Langerhans, counterregulatory glucose control may be considerably more labile than in either type I or type II diabetes. Less is known regarding the natural history of nonalcohol-associated chronic pancreatitis, but the risk of diabetes appears to be lower.<sup>27</sup> Both endocrine and exocrine insufficiency occur later and less frequently in patients with chronic pancreatitis associated with gene mutations than those

without gene mutations.<sup>28</sup>

**FIGURE 71-2** Histopathology of chronic pancreatitis showing islet entrapment within exocrine parenchymal fibrosis. (Used with permission from Dr. Jerrold Turner.)

On occasion, the initial manifestation of chronic pancreatitis will be related to extrapancreatic complications such as intestinal or biliary obstruction due to compression by a pseudocyst or progressive peripancreatic fibrosis and gastrointestinal hemorrhage due to blood lost into the pancreatic duct (*hemosuccus pancreaticus*) or due to rupture of pseudoaneurysm into a pseudocyst or to splenomesenteric vein thrombosis.

## DIAGNOSIS

The diagnosis is usually suspected based on an appropriate clinical history and is confirmed by imaging studies. Laboratory investigation is of limited value. Acute exacerbation of abdominal pain may be paralleled by a transient increase in serum amylase or lipase, but these may be normal with progressive destruction of acinar cell mass. Elevation of liver function tests, particularly serum bilirubin and alkaline phosphatase, may indicate the presence of bile duct obstruction.

The diagnosis of chronic pancreatitis is usually confirmed by imaging studies, most commonly computed tomography (CT). CT findings depend on

the morphologic type of chronic pancreatitis, the duration of disease, and the presence of complications. In the early phases of chronic pancreatitis, ductal or parenchymal changes may be rather subtle, but as the disease advances, progressive and irreversible changes in organ architecture are readily apparent. Chronic pancreatitis associated with toxic-metabolic or genetic risk factors, and idiopathic chronic pancreatitis may demonstrate calcifications either focally or scattered throughout the organ. There may be evidence of acute inflammatory changes or focal areas of enlargement associated with areas of dense calcifications, particularly in the pancreatic head (Fig. 71-3); this so-called “inflammatory head mass” appears to be more common in European than American cohorts.<sup>29</sup> There may be evidence of segmental or diffuse pancreatic ductal dilation related to stricture formation, and pseudocyst formation and evidence of extrapancreatic complications such as duodenal or biliary obstruction, or splenomesenteric vein thrombosis (Fig. 71-4). In AIP, calcifications are almost uniformly absent and the pancreas is usually diffusely enlarged, although a focal mass-forming variant is occasionally encountered.<sup>18</sup> In obstructive forms of chronic pancreatitis, the pancreatic duct is dilated upstream of the area of stenosis, and the acinar parenchyma appears atrophic.

**FIGURE 71-3** Axial cross-sectional abdominal CT demonstrating enlargement and dense calcifications (*arrow*) in the pancreatic head in alcohol-associated chronic pancreatitis.

**FIGURE 71-4** Axial cross-sectional abdominal CT demonstrating pseudocyst involving the splenic hilum with splenic vein compression (*arrow*) in alcohol-associated chronic pancreatitis.

Pancreatic ductography complements CT imaging. Endoscopic retrograde cholangiopancreatography (ERCP) has long served as a gold standard of sorts in mapping duct pathology and offers endotherapeutic options including sphincterotomy and stent placement (Fig. 71-5). Magnetic resonance cholangiopancreatography (MRCP) is less invasive and provides image quality that rivals ERCP; the addition of secretin stimulation further enhances duct visualization and allows some assessment of pancreatic exocrine function (Fig. 71-6).<sup>30</sup> Anatomic ductal anomalies such as pancreas divisum are readily defined by ERCP or MRCP, as are dominant focal duct strictures that might be amenable to endoscopic stenting or surgical drainage procedures. MR imaging integrates information regarding parenchymal and ductal involvement and may be particularly helpful when the disease is regionally heterogeneous and architecturally complex.

**FIGURE 71-5** ERCP image showing classic diagnostic features of chronic pancreatitis including marked main duct dilation, intraluminal filling defects (stones), clubbing of side-branches, and areas of duct stricture.

**FIGURE 71-6** Secretin-stimulated MRCP shows a diffusely dilated main pancreatic duct with obstruction to pancreatic flow associated with a dorsal duct stricture in the setting of pancreas divisum and chronic pancreatitis.

It is not difficult to establish the diagnosis of chronic pancreatitis in its advanced stages, when classical clinical symptoms are present or when imaging studies demonstrate obvious abnormalities such as strictures, ductal dilation, or pancreatic calcifications. Recognition of disease in its earlier stages presents more of a challenge. A 1983 conference held in Cambridge, England categorized chronic pancreatitis as equivocal, mild, moderate, or marked, and established criteria ([Table 71-2](#)) according to combinations of features seen in the main and side branch pancreatic ducts on CT and ductograms.<sup>1,31,32</sup> Although this consensus approach has proven useful over the years, there continues to be a subset of patients with symptoms suspicious for chronic pancreatitis but in whom imaging studies are negative. Some of

these patients may suffer from functional abdominal pain disorders rather than pancreatic disease.<sup>33</sup> Others may have early forms of chronic pancreatitis. Consensus workshops by the Japan Pancreas Society (1995 and 2001) continue to address the ongoing challenge of so-called “minimal change” disease in the context of evolving imaging and diagnostic modalities.

**TABLE 71-2: CAMBRIDGE CLASSIFICATION OF CHRONIC PANCREATITIS  
BASED ON ENDOSCOPIC RETROGRADE PANCREATOGRAPHY**

<b>Grade of Pancreatitis</b>	<b>Main Pancreatic Duct Appearance</b>	<b>Side Branch Pancreatic Duct Appearance</b>
Normal	Normal	Normal
Equivocal	Normal	<3 abnormal branches
Mild	Normal	>3 abnormal branches
Moderate	Abnormal	>3 abnormal branches
Marked	Abnormal plus any of the following: Cavity >10 mm Stricture Intraductal filling defects Pancreatic calcification Contiguous organ involvement on CT Severe duct dilation or irregularity	>3 abnormal branches

Endoscopic ultrasound (EUS) appears to be valuable in evaluation of the suspicious pancreatic mass and in characterizing cystic lesions of the pancreas.<sup>34</sup> EUS generally adds little to the evaluation of chronic pancreatitis in its advanced stages but has potential applicability in early-stage minimal-change disease where other imaging modalities fail to establish the diagnosis.<sup>3,35–37</sup> EUS appears to be more sensitive than ERCP or MRCP in detecting early parenchymal fibrosis and subtle ductal changes occurring in

early forms of chronic pancreatitis. Various systems using up to 11 different parenchymal and ductal endosonographic criteria (Table 71-3) to diagnose chronic pancreatitis have been proposed.<sup>38</sup> There is, however, no gold standard grading system or agreement on the threshold number of abnormalities that must be present for the diagnosis of chronic pancreatitis. Because of this, the value of EUS in making an early diagnosis of chronic pancreatitis remains uncertain. EUS may have more practical utility in cases of suspected AIP. Surgical interventions may be avoided in some of these patients who present with a mass-forming variant by EUS-directed core needle biopsy demonstrating the pathognomonic lymphoplasmacytic infiltrate<sup>39</sup> and thus ruling out malignancy.

**TABLE 71-3: ENDOSONOGRAPHIC CRITERIA FOR CHRONIC PANCREATITIS**

Parenchymal Criteria	Ductal Criteria
Hyperechoic foci	Main pancreatic duct dilation
Hyperechoic strands	Duct irregularity
Lobularity of the gland	Hyperechoic duct margins
Cysts	Dilated side branches
	Stones

Data from The International Working Group for Minimal Standard Terminology for Gastrointestinal Endosonography. Reproduction of minimum standard terminology in gastrointestinal endosonography, *Dig Endosc* 1998 Jan 22;10: 158–184.

Functional testing to demonstrate pancreatic exocrine insufficiency is occasionally helpful, although from a practical standpoint, the condition is usually clinically obvious. Symptoms of steatorrhea, postprandial gaseous distension, or progressive weight loss despite adequate caloric intake are all suggestive of exocrine insufficiency. Quantification of fecal fat content or measurement of fecal human elastase (FE-1) levels can confirm the diagnosis and can be used to monitor efficacy of enzyme supplementation and surgical intervention.<sup>40</sup> Unfortunately, these studies are most reliable in those patients in whom the diagnosis is clinically obvious. They are of questionable accuracy in the setting of patients with more subtle symptoms where objective documentation of exocrine insufficiency might be most needed.

Elevation in fasting serum glucose or glycosylated hemoglobin (H<sub>gA</sub><sub>1c</sub>) suggests pancreatic diabetes. Functional evaluation (eg, formal oral glucose or arginine-tolerance testing) for pancreatic endocrine insufficiency may be helpful in patients prior to pancreatic resection, particularly if autologous islet transplantation is under consideration.

In patients with suspected AIP, measurement of serum immunoglobulin G levels, particularly IgG4, is indicated. Other markers of autoimmune disease include rheumatoid factor, antinuclear antibody, C-reactive protein (CRP), or erythrocyte sedimentation rate, although these are less specific.<sup>19</sup>

The role of genetic testing in patients with idiopathic or suspected hereditary pancreatitis is controversial.<sup>41</sup> It may be most reasonable to screen for *PRSS1* mutations in patients with a strong family history of pancreatitis because of the autosomal dominant inheritance and the high risk of development of pancreatic cancer—a risk that is further dramatically elevated by tobacco use. However, hereditary pancreatitis patients without *PRSS1* mutations may have the same elevated risk of cancer, and there is no evidence that screening by serial imaging studies leads to earlier diagnosis or improved prognosis of pancreatic cancer. Identification of *CFTR* or *SPINK1* gene mutations may be useful in selected circumstances; for example, patients with idiopathic pancreatitis may feel reassured by having an “explanation” for their disease. In the absence of therapy directed at the specific functional defects associated with these mutations, however, the clinical value of gene testing is debatable. Genetic counseling is highly advisable in the context of whether to perform genetic testing and in interpretation of the results.

## MEDICAL MANAGEMENT

Cessation of potential inciting agents such as alcohol may reduce the intensity or frequency of exacerbations of chronic pancreatitis. Avoidance of high-fat foods and tobacco use may also be of value. Occasionally, patients are unable to tolerate oral food intake for extended periods of time, in which case nutritional support by an enteral route that minimizes pancreatic stimulation (eg, via nasojejunal or gastrojejunal tube) or by a parenteral approach may be required. Pancreatic enzyme replacement is used to treat steatorrhea and other symptoms of exocrine insufficiency. Enteric-coated

preparations are most useful in this setting.<sup>42</sup> Various formulations differ in lipase, protease, and amylase content, and enzyme replacement therapy should be titrated to effect.<sup>42,43</sup> Patients must be carefully instructed to time enzyme ingestion appropriately in relation to meals to optimize mixing.

In certain circumstances, medical therapy may alter the intensity or frequency of attacks. For example, some patients with early, small duct, or minimal change disease appear to benefit from high doses of noncoated enzyme preparations.<sup>42</sup> The presence of activated enzymes within the duodenum has been shown to decrease cholecystokinin-mediated stimulation of the pancreas. Noncoated enzyme preparations must be protected from destruction by gastric acid suppression therapy; trials that instead utilize enteric-coated delayed-release enzyme formulations showed no benefit.<sup>42,43</sup> Several randomized trials suggest that a five-component antioxidant regimen reduces the frequency and intensity of painful episodes.<sup>44</sup> Patients with AIP confirmed by elevated IgG4 levels or tissue biopsy may be treated with an 8-week tapering course of corticosteroids to positive effect, including resolution of jaundice related to mechanical biliary obstruction.<sup>21</sup>

The major reason patients with chronic pancreatitis seek medical attention is unrelenting or frequently relapsing pain. Pain, more than any other feature, accounts for intractability and overall loss of quality of life. While in some patients, the intensity of pain may burn out as the disease reaches its end stage, the natural history is highly variable and it may take years for relapsing episodes of pain to relent, if it occurs at all. Thus, a conservative, watch-and-wait approach is rarely acceptable. Pharmacotherapy for pain should begin with nonsteroidal anti-inflammatory medications, but if more powerful agents are needed, propoxyphene or tramadol may be used prior to escalating to more aggressive pharmacotherapy. Long-acting narcotics supplemented by short-acting narcotic formulations for breakthrough pain may be more effective than short-acting agents alone. Unfortunately, narcotic dependency is a common consequence of the use of these agents. Psychosocial supports such as counseling are essential to successful longitudinal management of chronic pain. Variable results have been reported with the use of long-acting somatostatin analogues. Occasionally, tricyclic antidepressants or gabapentin may be useful. Alternatives such as placement of infusion pumps for intrathecal delivery of narcotics have been anecdotally successful.<sup>45</sup>

Neurolysis may be considered in patients who have failed medical management and who do not appear to have favorable anatomic circumstances amenable to endoscopic or surgical intervention. The most common neurolytic procedure is celiac plexus block, which can be performed under radiological or endoscopic guidance. The initial approach involves injection of a combination of steroids and a local anesthetic into the celiac ganglion. If temporary relief is obtained, this is followed by permanent neurolysis with 100% alcohol injection. Results of celiac plexus block in chronic pancreatitis have been mixed, but transient improvement (typically no more than 6 months) may be of benefit in selected patients.<sup>36,46</sup> Splanchnicectomy, usually performed by a thoracoscopic approach, has also been used, but similar to other forms of neurolysis, permanent resolution of pain is unusual.<sup>47</sup>

Therapeutic endoscopic intervention may be considered in patients with obstructive and inflammatory disease. Lithotripsy of pancreatic duct stones and pancreatic duct stent placement has been reported in several small retrospective series. Technical success can be reliably achieved in appropriately selected patients (eg, manageable stone size and local density sufficiently close to the working end of the scope and without intervening duct stricture). However, the effectiveness of endotherapy over time is often less than 50% with respect to improvement in pain or reduction in frequency of attacks. Multiple procedures are often necessary, recurrence of strictures and stones is frequent, and the substantial fraction of patients who fail generally require surgical intervention (Fig. 71-7).<sup>48,49</sup> Long-term presence of stents within the pancreatic duct may worsen inflammatory ductal strictures, although most series find a few patients who achieve durable pain relief following removal of stents. Patients who are suitable for endotherapy are usually also candidates for surgical intervention, provided there are no medical contraindications to operation. The two randomized trials (Table 71-4) to date that directly compared surgical therapy to endoscopic stenting reported long-lasting superiority of the surgical approach with respect to pain relief, quality of life over time, and other endpoints.<sup>50,51</sup>

**FIGURE 71-7** Coronal CT image of a biliary endoprosthesis in a patient with chronic calcifying pancreatitis. Attempts at endoscopic pancreatic duct stone removal were unsuccessful, and the patient underwent pancreaticoduodenectomy.

## SURGICAL MANAGEMENT OF CHRONIC

## PANCREATITIS

Surgical therapy for chronic pancreatitis is usually reserved for patients with symptoms that are otherwise intractable to pharmacotherapy and other therapeutic approaches. In over 90% of patients, the main indication for operation is pain. Occasionally, an operation is performed to relieve biliary or gastrointestinal obstruction, to internally drain a symptomatic pseudocyst, or for vascular complications of chronic pancreatitis such as gastric variceal hemorrhage secondary to splenic vein thrombosis.

Operations on the pancreas when done in the context of chronic pancreatitis are typically technically demanding and carry significant risks of postoperative morbidity and mortality. Although in appropriately selected patients, the immediate results may be excellent, long-term success (durable pain relief) is achieved in at most 85% of patients at 5 years of follow-up. The optimal timing of a surgical intervention continues to be a subject of considerable debate. Most practitioners make an effort to hold off on intervention until all medical and endoscopic options have been exhausted, while others have begun to advocate for a more expeditious move to surgery in these patients under the notion that early definitive intervention may obviate risk of a permanent, refractory retroperitoneal neuropathy. There is little objective data available to guide decisions on timing of intervention in patients who have pain as their predominant symptom. One recent study presented from the Dutch Pancreatitis Study Group retrospectively evaluated 266 patients treated with surgical intervention for chronic pancreatitis and noted that surgery done within 3 years of symptoms was independently associated with more significant postoperative pain relief and less endocrine insufficiency.<sup>52</sup>

A number of pancreatic operations have been developed over several decades of international effort. These operations generally involve either ductal drainage, parenchymal resection, or some combination of resection and ductal drainage. The choice of operation depends on the anatomic morphology of the disease process. In many patients, the disease appears to be driven predominantly by pathology within the pancreatic head, sometimes considered the “pacemaker” of chronic pancreatitis, particularly in those with a sizable inflammatory mass in this region of the organ. Others present more diffuse disease involving extensive areas of stricture and dilation of the main pancreatic duct or its ductal tributaries. Occasionally, disease appears limited

to the body or tail. Alternatives for surgical intervention are best individualized and considered in the context of the most frequently encountered clinical and anatomic scenarios.

## Large-Duct Disease

Large-duct chronic pancreatitis is characterized by enlargement of the main pancreatic duct lumen to a diameter exceeding 7 to 8 mm. Ductal dilation is often diffuse along the length of the organ, but there may be one or more intervening areas of ductal stricture. In many patients, calcific deposits (stones) may be evident on imaging studies within the main or secondary ducts.

Puestow described a procedure to provide enteric drainage to a diffusely dilated main pancreatic duct, with the goal of achieving pain relief by duct decompression. In its initial description, the Puestow procedure consisted of a longitudinal unroofing of the dilated pancreatic duct in the body and neck of the gland, and also involved resection of the pancreatic tail.<sup>53</sup> A long-segment longitudinal pancreaticojejunostomy was then constructed to establish enteric drainage. A modification reported by Partington and Rochelle in 1960 eliminated the distal pancreatectomy. Lateral pancreaticojejunostomy is thus now referred to as either a (modified) Puestow or Partington-Rochelle procedure<sup>54</sup> and continues to be commonly used for disease characterized by a diffusely dilated main pancreatic duct with no mass and no significant biliary obstruction in the pancreatic head.

## LATERAL PANCREATICOJEJUNOSTOMY— TECHNIQUE

Midline or transverse upper abdominal incisions provide acceptable exposure for this procedure. The dissection is begun by incising the peritoneal lining adjacent to the lateral border of the second portion of the duodenum, extending laterally to release the hepatic flexure of the right colon. Using electrocautery, the retroperitoneal attachments lateral and posterior to the duodenum are divided to widely mobilize the duodenum and posterior aspect of the head of the pancreas (Kocher's maneuver). This dissection is carried inferiorly to free the third portion of the duodenum from the base of the transverse mesocolon, effectively exposing the head of the pancreas and

anterior surface of the duodenum from the pylorus to the level of the superior mesenteric vessels. Exposure of the anterior surface of the pancreatic body and tail requires access to the lesser sac, which is entered by dividing the gastrocolic omentum or by separating the avascular plane of attachment from the transverse colon and mesocolon. Next, the gastroduodenal artery (GDA) is identified at its supraduodenal origin from the common hepatic artery and traced across the head of the pancreas. The GDA is then suture ligated at both the superior and inferior border of the head of the pancreas in an effort to prevent intraoperative hemorrhage during incision of the pancreatic head and main pancreatic duct during the dissection as well as postoperative bleeding at the site of the pancreaticojejunostomy. The anterior surface of the pancreas is then carefully examined to confirm the presence of main duct dilation and the absence of suspicious mass lesions or unanticipated inflammatory changes in the head of the gland. The dilated pancreatic duct is usually visible by direct inspection or palpation of the anterior surface of the pancreas but can also be accessed by means of a fine needle and low-volume syringe. The duct can also be localized using intraoperative ultrasound, but this is usually not necessary. The pancreatic duct is then incised longitudinally along its full length using electrocautery. This ductotomy should extend across the neck into the head of the organ where the GDA traverses the pancreas, and should extend laterally as far as possible along the length of the tail so that the entire segment of dilated duct is unroofed. The pancreaticojejunal anastomosis is performed in Roux-en-Y fashion using a 40- to 50-cm defunctionalized jejunal limb. Using a linear gastrointestinal stapler, the proximal jejunum is divided at the apex of a mesojejunal vascular arcade of suitable mobility, typically at least 20 to 30 cm distal to the ligament of Treitz, although the precise distance is probably unimportant. The distal staple line is inverted using a series of 3-0 silk sutures placed in a Lembert fashion, which are tied (but not cut) and then held by a fine clamp that facilitates later positioning of the pancreatic anastomosis. Intestinal continuity is then reestablished by a handsewn or stapled enteroenterostomy such that the intestinal conduit is approximately 60 cm in length. The Roux limb is then advanced through the transverse mesocolon either to the right or left of the middle colic vessels. A longitudinal jejunostomy is made to correspond to the pancreatic ductotomy. The pancreaticojejunostomy is handsewn with a running absorbable suture (eg, 4-0 double-armed polyglyconate or polydioxanone suture), which, according to surgeon

preference, may be additionally reinforced by an outer layer of interrupted nonabsorbable suture (Fig. 71-8). After completion of the anastomosis, the distance between the pancreaticojejunostomy and the enteroenterostomy should measure at least 40 cm to prevent reflux of enteric contents up to the anastomosis.

pancreas & jejunum

**FIGURE 71-8** Cross-section of the anastomosis for a lateral pancreaticojejunostomy (applies to Puestow, Frey, or Izbicki procedures).

## LATERAL PANCREATICOJEJUNOSTOMY—OUTCOMES

Results of the Partington-Rochelle procedure in appropriately selected patients are generally favorable. In most series, 75% to 80% of patients with diffusely dilated main pancreatic ducts (>7 mm) and no dominant inflammatory mass have achieved durable pain relief over 5 to 10 years of follow-up.<sup>53,55-58</sup> Compared to other major pancreatic operations, perioperative morbidity is low, and because no pancreatic parenchyma is removed, endocrine and exocrine functions are generally preserved relative to

preoperative levels. Failure of lateral pancreaticojejunostomy is usually due to inappropriate patient selection (underappreciated extent of disease with the presence of significant fibrosis in the pancreatic head), or ongoing fibrosis with the progressive development of neuropathic pain.

## **Chronic Pancreatitis with a Dominant Pancreatic Head Mass**

Lateral pancreaticojejunostomy has limited applicability in patients without diffuse main duct dilation. Multiple groups have reported that an isolated drainage procedure in patients with complex inflammatory changes in the pancreatic head, body, or tail results in poor clinical outcome with quick recurrence of symptoms of pain and progression to exocrine insufficiency. For patients with an inflammatory mass, extensive calcifications, or duct stones in the pancreatic head, results appear to be better either with pure resectional or with hybrid resection and drainage procedures. The four procedures used with great frequency today are pancreaticoduodenectomy (Whipple procedure, with or without pyloric preservation) and three forms of duodenum-preserving pancreatic head resection (DPPHR): the Beger procedure, the Berne procedure, and the Frey procedure.

The outcomes associated with these procedures have been compared in several randomized trials enrolling small numbers of patients with head-predominant morphology. None of these studies has demonstrated any one of the techniques to be clearly superior to others (Table 71-5). There are no measurable differences in outcomes compared, the numbers in the trials are small, and the metrics used to evaluate the outcomes are variable and imperfect.<sup>59-62</sup> As a result, no consensus opinion among pancreatic experts about which procedure is the best in any given clinical situation has emerged. In recent years, European surgeons have tended to favor a duodenum-preserving approach and American surgeons have tended to favor pancreaticoduodenectomy. One recent survey of American surgeons who were members of the Pancreas Club found that of 59 surgeons surveyed, only 34 had ever performed DPPHR and that only 23 US surgeons continue to perform these procedures on a regular basis.<sup>63</sup>

Abbreviations: DPPHR, duodenal preserving pancreatic head resection; PPPD, pylorus-preserving pancreaticoduodenectomy; LR-LPJ, local resection pancreatic head with longitudinal pancreaticojejunostomy (Frey procedure).

In spite of the lack of data supporting the relative superiority of any given procedure, we do believe that each has specific applicability to certain subtypes of head-predominant morphology. A reasonable approach is to tailor the procedure to the anatomic morphology seen on the preoperative axial imaging and ductography. Patients with a dominant head mass and a dilated main pancreatic duct but no biliary dilation may be best served by a Frey procedure (limited duodenum-preserving resection of the pancreatic head with extended lateral pancreaticojejunostomy). Patients with a dominant head mass without main duct dilation and no biliary obstruction may be better suited for the Berne modification of the Beger procedure (limited duodenum-preserving resection of the pancreatic head without extension of the lateral pancreaticojejunostomy toward the tail). Patients with biliary obstruction or imaging characteristics more suspicious for the presence of malignancy should probably undergo pancreaticoduodenectomy rather than any form of DPPHR.

## PANCREATICODUODENECTOMY—TECHNIQUE

The early primary objective in the pancreaticoduodenectomy is making an efficient determination of whether or not the pathology allows safe resection. This typically involves a thorough manual examination of the abdomen to rule out metastatic cancer and then a rapid exposure of the pancreatic neck superiorly and inferiorly in an effort to assess the operator’s ability to free the

hepatic artery, superior mesenteric vein, and superior mesenteric artery from the pathology in the pancreatic head safely. Pancreaticoduodenectomy may be performed through a midline laparotomy or bilateral subcostal incision. Careful inspection and palpation of the peritoneal surfaces and liver is performed first, with frozen-section biopsy obtained of any suspicious lesions. Small areas of fat necrosis or fibrosis from prior attacks of pancreatitis are easily mistaken for metastatic deposits. The base of the transverse mesocolon should be inspected for evidence of foreshortening or inflammatory involvement that may herald a difficult or dangerous dissection in the vicinity of the superior mesenteric vessels, and to confirm the absence of otherwise unsuspected tumor extension. The hepatic flexure of the colon is mobilized by freeing the lateral retroperitoneal attachments using the electrocautery, an extended Kocher maneuver is performed, and the lesser sac is then entered by separation or division of the gastrocolic omentum, as described in the previous section. The mass in the head of the gland is palpated and determined to be safely free from the superior mesenteric vein (SMV) at the inferior border of the neck of the pancreas by preliminary dissection of the plane anterior to the SMV posterior to the neck of the pancreas. Attention is then turned to the supraduodenal region. A cholecystectomy is performed, and the portal dissection is initiated by isolating the common bile duct (CBD) at the level of the cystic duct stump. The bile duct is carefully freed from the anterolateral surface of the portal vein and secured temporarily with a vessel loop. The common hepatic artery is usually found anteromedially to the portal vein, and it should be carefully isolated with a vessel loop and preserved. The lateral, free edge of the gastrohepatic ligament at the foramen of Winslow should be carefully inspected and palpated for an accessory or replaced right hepatic artery, which, if present, should also be isolated and protected during the subsequent resection. The GDA is isolated at its origin from the common hepatic artery and secured temporarily with a vessel loop. The continued presence of pulsatile flow in the proper hepatic artery after temporary occlusion of the GDA should be assured, both to confirm the vascular anatomy and to ensure that there is no stenosis in the proximal common hepatic artery or celiac trunk due to atherosclerotic plaque. Preliminary dissection of the plane anterior to the portal vein is begun. These measures demonstrate that there is no evidence of unresectable cancer and that the pancreatic head can be removed without concern for undue injury to the blood supply of the small intestine

and liver.

At this point, technical resectability of the pancreatic head has been assured (Fig. 71-9). The GDA is divided between clamps and is doubly tied or suture ligated. The common hepatic duct is divided just proximal to the cystic duct entry, and bile flow is controlled with a small bulldog clamp. The right gastric artery is divided between suture ligatures. For a standard pancreaticoduodenectomy, the greater omentum is divided to a point on the greater curvature of the stomach in the vicinity of the junction of the right and left gastroepiploic arteries. The lesser omentum is divided at the level of the incisura of the lesser curvature of the stomach, and the descending branch of the left gastric artery is carefully secured. If a standard pancreaticoduodenectomy is to be performed, the stomach is then divided with two firings of a linear gastrointestinal stapler. The lesser curve staple line is inverted with silk Lembert sutures. For pyloric-preserving pancreaticoduodenectomy, the duodenum is divided using a stapler approximately 2 cm distal to the pyloric ring. The ligament of Treitz is taken down with electrocautery, being certain to avoid injury to the inferior mesenteric vein. The proximal jejunum is divided approximately 15 cm distal to the ligament of Treitz with a linear gastrointestinal stapler. The distal staple line is oversewn with interrupted Lembert sutures, initially left long to use for traction and positioning of the limb during the reconstruction. The short mesojejunal vessels of the proximal segment are carefully isolated and secured close to the mesenteric border of the jejunum using fine nonabsorbable ligatures, surgical clips, or an electrosurgical vessel-sealing device. This dissection is continued proximally to the duodenojejunal junction, and then the proximal jejunum is advanced into the supracolic compartment by passing it under the superior mesenteric vessels. At this point blunt dissection is used to complete development of a tunnel between the neck of the pancreas and the SMV or portal vein. The superior and inferior pancreatic vascular arcades are then ligated on either side of the planned transection site at the neck of the pancreas using nonabsorbable suture. The neck is then divided with electrocautery. Gentle retraction of the pancreatic head, distracting it from the right lateral wall of the SMV or portal vein, helps to expose small venous tributaries from the uncinate process, which should then be carefully controlled with fine ties or suture ligatures. The first jejunal venous tributary may be quite large and is easily injured during this dissection. The uncinate branches from the superior mesenteric

artery (SMA) are then divided sequentially between clamps with great care to preserve the integrity of the SMA. The specimen is then oriented and submitted for pathological examination.

**FIGURE 71-9** Retroperitoneal dissection for pancreaticoduodenectomy. Note the ligated gastroduodenal artery (GDA), portal vein, inferior vena cava (IVC), superior mesenteric artery and vein (SMA, SMV), and the main pancreatic duct at the edge the transected pancreas. (Reproduced with permission from Ahmad SA, Wray C, Rilo HL, et al: Chronic pancreatitis: recent advances and ongoing challenges, *Curr Probl Surg* 2006 Mar;43(3):127-238.)

The reconstruction begins with the pancreaticojejunostomy ([Fig. 71-10](#)). The jejunum is advanced through the transverse mesocolon either to the right or left of the middle colic vessels according to surgeon's preference. Several techniques of pancreaticojejunostomy have been described. One commonly used approach is a two-layer method that is begun by placing a posterior row of interrupted nonabsorbable sutures between the pancreatic capsule and the seromuscular layer at the antimesenteric aspect of the jejunum. A small enterotomy is then made with bovie cautery across from the site of the main pancreatic duct at the pancreatic neck. An inner layer of four to eight interrupted fine absorbable monofilament sutures is used to secure the pancreatic duct to the intestinal wall at the enterotomy in a duct-to-mucosa

fashion. An anterior row of interrupted nonabsorbable suture is then used to secure the anterior pancreatic capsule to the anterior serosa at the antimesenteric border of the jejunal limb. The duct-to-mucosa anastomosis may also be performed over a 5 Fr pediatric feeding tube, which can then be exteriorized through the jejunal limb using a Witzel-type closure. The choledochojejunostomy is then constructed at a site approximately 15 cm distal to the pancreaticojejunostomy. A small enterotomy is made at the antimesenteric border of the jejunal limb at this location. The choledochojejunostomy is also performed in a duct-to-mucosa fashion, either with a single layer of interrupted absorbable monofilament suture or, if the bile duct is dilated, using absorbable continuous suture. The pancreaticobiliary limb is then secured to the transverse mesocolon using interrupted sutures, and any potential gap through which herniation may occur is closed. The retroperitoneal space at the level of the ligament of Treitz is also closed. Gastric continuity is reestablished by means of an antecolic loop gastrojejunotomy performed at a site sufficiently distal to the transverse mesocolon closure to prevent angulation of the afferent limb. A Hofmeister-type configuration is typically used, wherein the lesser curvature half of the gastric transection line is oversewn and the anastomosis is performed to the greater curvature half. The jejunal limb is oriented with the afferent limb toward the lesser curvature, efferent limb to the greater curvature. A two-layered anastomosis is preferred, with an outer layer of nonabsorbable interrupted seromuscular Lembert sutures and an inner continuous absorbable Connell-style layer. The abdomen is then irrigated with saline or dilute antibiotic solution and the abdominal wall closed. No closed suction peritoneal drains are necessary.

**FIGURE 71-10** Pancreaticojejunostomy. At left, a duct-to-mucosa anastomosis is constructed using fine absorbable mattress sutures over a small (5 Fr) pediatric feeding tube. At right, the completed anastomosis, with transanastomotic stent exteriorized through the jejunum and abdominal wall to divert pancreatic secretions. ## **BEGER PROCEDURE—TECHNIQUE**

Duodenum-preserving pancreatic head resection was first described by Beger in 1972. The operation evolved from the premise that a pancreaticoduodenectomy was unnecessarily radical for benign pathology and that a more limited resection preserving the duodenum would avoid some of the adverse sequelae associated with pancreaticoduodenectomy such as delayed gastric emptying and insulin-dependent diabetes.<sup>64</sup> The procedure is performed through a midline laparotomy or bilateral subcostal incision. As at the start of the pancreaticoduodenectomy, the gastrocolic ligament is separated or divided, the transverse mesocolon is mobilized off the head of the pancreas and duodenum, and a wide Kocher maneuver is performed. A cholecystectomy is performed. The GDA is isolated and divided. A tunnel is then created between the pancreatic neck and superior mesenteric vein or portal vein. The pancreatic neck is divided at this location and the pancreatic head manually rotated out of the retroperitoneum so that the cut edge faces up into the midline wound. The cystic duct is cannulated with a Bakes dilator and the CBD manually palpated in the head of the pancreas. Electrocautery is

then used to core out the head of the gland with care taken to leave a rim of pancreas attached to the duodenum and to leave the bile duct intact within that rim (Fig. 71-11). The specimen is submitted to pathology for frozen-section examination to confirm the absence of malignancy.

Pancreaticocenteric drainage is then reestablished by means of a two-sided Roux-en-Y pancreaticojejunostomy (Fig. 71-12). A Roux limb of jejunum is fashioned and advanced into the supracolic compartment through the transverse mesocolon as described for the lateral pancreaticojejunostomy. A two-layered handsewn duct to mucosa pancreaticojejunostomy is constructed at the neck margin as done for a typical pancreaticoduodenectomy, with the exception that the anastomosis is sited closer to the mesenteric margin of the jejunum. The jejunal limb is then laid such that the antimesenteric border of the limb faces the midline wound. A second long pancreaticojejunostomy is constructed here by opening the border of the jejunal limb contralateral to the first pancreaticojejunostomy at the neck for a distance appropriate to include the entire length of the proximal pancreatic rim. This pancreatic margin is then secured to the long longitudinal enterotomy by means of a single layer of interrupted nonabsorbable suture. Intestinal continuity is then reestablished by means of a jejunojejunostomy performed as described earlier for the lateral pancreaticojejunostomy. The abdomen is irrigated and closed. No closed suction drains are necessary.

**FIGURE 71-11** The anatomy following transection of the neck of the pancreas and removal of the head during the Beger procedure.

**FIGURE 71-12** Final anatomy of the reconstruction following a Beger procedure.

## **BEGER PROCEDURE VERSUS PANCREATODUODENECTOMY—OUTCOMES**

Beger has recently reviewed his three-decade experience with DPPHR for chronic pancreatitis presenting with an inflammatory mass in the pancreatic head. His perioperative results demonstrate very reasonable rates of morbidity and mortality and an impressive improvement in pancreatic pain. His pancreatic fistula rate is reported as 3.3%, the rate of delayed emptying reported is 1.5%, and perioperative mortality rate is 0.7% in 603 consecutive patients. Late outcomes reported in this series demonstrated 91.3% of patients are free of pain at a median follow-up of 5.7 years.<sup>65</sup> There have been three randomized trials that have attempted to compare outcomes from DPPHR to those achieved with pylorus-preserving pancreatoduodenectomy (PPPD). The most widely cited is by Buchler and colleagues and has been

recently represented with long-term results. In this study 40 patients with chronic pancreatitis and a dominant focus in the pancreatic head were randomized to PPPD or DPPHR. The initial paper reported 6-month outcomes. This demonstrated a statistical advantage to DPPHR with regard to pain (75% of patients undergoing DPPHR were pain free at 6 months vs 40% of patients undergoing PPPD) and weight gain (average weight gain for those undergoing DPPHR was 4.1 kg whereas that for those undergoing PPPD was 1.9 kg).<sup>66</sup> Length of hospital stay, perioperative morbidity, and perioperative mortality rates were statistically identical. The authors of this study have recently presented their long-term results. At median follow-up of 7 years, the early advantages of the DPPHR were no longer evident with patients in each group having identical health-related quality of life scores, identical pain scores, and identical rates of exocrine and endocrine insufficiency. The other randomized comparison again studied only 40 patients for 12 months. This study demonstrated statistically identical rates of pain relief but a slight statistical advantage in terms of scores seen on a general assessment of health-related quality of life for patients undergoing DPPHR relative to those undergoing PPPD.<sup>59</sup> More recently, the group from Freiburg reported short- and long-term results from the third randomized trial comparing DPPHR including both Beger and Frey operations to PPPD. This study randomized 85 patients (43 to PPPD and 42 to DPPHR) and reported follow-up over 5 years. Postoperative quality of life was assessed by the EORTC QLQ-30 instrument. The authors noted a significant saving in operative time for DPPHR versus PPPD (360 minutes vs 435 minutes) but no differences in rates of postoperative morbidity, mortality, or long-term quality of life, pain control, and endocrine or exocrine function.<sup>67</sup>

## **FREY PROCEDURE—TECHNIQUE**

The disadvantage of the DPPHR as described by Beger is that it does not address disease (either diffuse parenchymal fibrosis with side branch disruption or stricturing with upstream dilation of the main pancreatic duct) that may coexist in the pancreatic body and tail. Late failures of the Beger procedure have been attributed to poor drainage of the pancreatic body and tail. In an effort to overcome this, and in large part to avoid the certain exocrine and endocrine insufficiency that comes with the near-total pancreatectomy pioneered by one of his early mentors, Frey and colleagues

developed a procedure that combines a duodenum-preserving pancreatic head resection with a hybrid resection or drainage procedure at the pancreatic body and tail (referred to as a local resection of the pancreatic head with longitudinal pancreaticojejunostomy [LR-LPJ]) (Fig. 71-13). In this procedure, no tunnel is created behind the pancreatic neck. Instead, the entire length of the pancreas is exposed anteriorly. The GDA is ligated. The gallbladder is removed. The cystic duct is cannulated using a Bakes dilator and the bile duct is identified in its course through the head of the pancreas by palpating the dilator. The pancreatic head is then excavated down to the level of the portal vein, with care taken to leave a rim of tissue surrounding the bile duct at the duodenal margin. From this cavity an extensive longitudinal unroofing of the pancreatic duct through the body and tail is made using electrocautery. If the duct is not dilated in the tail, then the body and tail may simply be excavated as done at the pancreatic head (Fig. 71-14). Pancreaticocenteric drainage is then accomplished by means of a lateral pancreaticojejunostomy covering the entire excavation cavity, typically constructed using a Roux-en-Y jejunal limb sewn to the pancreatic capsule in one or two layers.

**FIGURE 71-13** Cross-sectional drawing of the pancreas following coring of the pancreatic head during a Frey procedure.

**FIGURE 71-14** Pancreaticojejunostomy (Frey procedure).

## **FREY PROCEDURE VERSUS BEGER PROCEDURE— OUTCOMES**

In various reports including small randomized trials, the results of LR-LPJ appear similar to those reported for the Beger DPPHR, with postoperative mortality less than 1% and morbidity reported as 19% to 32%.<sup>61,68</sup> Excellent pain relief is obtained in about 75% of patients and the change in postoperative pain scores and rates of postoperative exocrine and endocrine insufficiency are identical over follow-up as long as 9 years. A small prospective randomized trial compared LR-LPJ to PPPD with an average length of follow-up of 2 years. None of the published evaluations of pancreatic surgery for pancreatitis grade perioperative morbidity, and it is difficult to truly gauge the relatively complicated profiles for the various procedures available to manage chronic pancreatitis; however, the hybrid procedures generally seem to be less morbid than pancreaticoduodenectomy. In the small prospective trial comparing Frey to PPPD, postoperative morbidity was significantly higher in the PPPD group compared to LR-LPJ (30% vs 17%). Although there was similar improvement in pain symptoms, the LR-LPJ group demonstrated a statistically better overall quality of life as measured by a general assessment of health-related quality of life.<sup>69</sup> Long-term results of the study were published in 2008 with a median follow-up of 7 years. At that length of follow-up, there were no statistical differences with regard to the improvement in pain, health-related quality of life, or the incidence of exocrine or endocrine insufficiency.<sup>70</sup> More recently the group has presented 15-year outcomes for 32 patients undergoing PD and 32 patients undergoing Frey procedure. At this time point, pain control was comparable between the cohorts but the group of patients managed with the Frey procedure demonstrated statistically better quality of life scores as measured by the EORTC QLQ C30 instrument. Patients undergoing Frey procedure demonstrated scores of 100 in physical status and working ability domains, whereas those undergoing PPPD demonstrated scores of 60 in the physical status domain and 50 in working ability domain.<sup>71</sup>

## **BERNE PROCEDURE—TECHNIQUE AND OUTCOMES**

There has been one further modification of the Beger DPPHR made in recent years. The Berne procedure adopts the technical safety advantage of the Frey LR-LPJ that comes by avoiding transection of the neck of the pancreas off the portal vein. In this modification, as in the Beger DPPHR, no lateral pancreaticojejunostomy is performed. The anterior surface of the mass in the head is palpated and then cored out by electrocautery. A Roux limb is then sewn to the residual pancreatic rim at this location. One randomized trial comparing the Berne modification to the standard Beger DPPHR showed rough equivalence of outcomes with these procedures.<sup>60</sup> One more recent publication has reported the results of retrospective evaluation of 160 patients managed by the Berne procedure with mean follow-up of 5.3 years (range 0.5 to 10 years). This represents one of the largest series reported on surgical management of chronic pancreatitis. The results demonstrate preserved endocrine function relative to preoperative functional tests, and significant and durable improvement in the amount of pain experienced and in quality of life relative to preoperative scores using the EORTC QLQ C30 instrument.<sup>72</sup>

## **Small Duct Disease or Diffuse Sclerosis**

In many instances, as the disease progresses there will be no dominant focus of ductal obstruction and no dominant mass. Instead, the morphology of the disease is characterized by diffuse calcification and/or diffuse fibrosis with atrophy of the pancreatic parenchyma. In these cases the pancreatic remnant may be quite small and will have a uniform firm consistency. Patients with this morphology of disease present a particular challenge, as there is no discrete target for either endoscopic or surgical intervention. Those manifesting intractable pain syndromes have had, until very recently, few and imperfect options for surgical management. These have included total or near-total pancreatectomy procedures that have traditionally been avoided due to the significant morbidity associated with profound postoperative exocrine and endocrine insufficiency.

Autologous islet transplantation may mitigate the diabetic consequences of total pancreatectomy. The first human autologous islet transplant was performed at the University of Minnesota in 1977. Since that time, several hundred procedures have been reported from Minnesota, Miami, Cincinnati, Leicester, and other emerging centers.<sup>73</sup> Taken together, the results from

these institutions suggest that in highly selected patients, complete pain relief (without the use of narcotics) and insulin independence can be achieved but that there is a significant rate of recidivism of pain after 1 year of follow-up. Although reports of assessment of quality of life after total pancreatectomy with autologous islet transplantation suggest that the procedure compares favorably to either total pancreatectomy without islet transplantation or to continue nonoperative management of pain, compelling evidence comparing this approach to alternative therapies in appropriately matched controls is lacking. Total pancreatectomy with autologous islet transplantation is costly and requires a high degree of technical expertise that is difficult to replicate. The indications for islet autotransplantation remain controversial and the overall safety and efficacy of the procedure have not been fully validated outside a handful of centers. Questions regarding the long-term viability of the islets and adverse impact on the surrounding liver parenchyma have been raised. Pathologic analysis of liver tissue that has been explanted following islet transplant has demonstrated that the transplanted islets typically migrate across the liver sinusoids and reside in the liver parenchyma. It has also been noted that the transplanted islets exhibit some degree of peri-islet fibrosis in the liver. There have been no reports of chronic hepatic fibrosis or cirrhosis in patients receiving autologous islets, but the concern exists. Complete long-term insulin independence is achieved only in a relatively small minority of patients after islet autotransplantation and that pain is persistent or recurrent in about half of patients even after total pancreatectomy.<sup>74</sup> Currently, the strongest arguments in favor of total pancreatectomy and islet autotransplantation can perhaps be made in the setting of a limited subset of patients with hereditary pancreatitis, who otherwise carry a significant long-term risk of developing pancreatic cancer. When a more traditional surgical operation (resection or drainage) is also possible in this setting, decision-making must be highly individualized (Fig. 71-15).

**FIGURE 71-15** Hereditary chronic pancreatitis associated with *PRSS1* gene mutation. A single calcification is evident in the pancreatic head, and the main pancreatic duct shows diffuse dilation. Lateral pancreaticoduodenectomy is an appropriate surgical option; total pancreatectomy with islet autotransplantation to eliminate cancer risk associated with hereditary pancreatitis is controversial.

### **TOTAL PANCREATECTOMY WITH AUTOLOGOUS ISLET TRANSPLANTATION—TECHNIQUE (TPAIT)**

Total pancreatectomy is performed as either an en bloc resection of the pancreatic head, body, and tail or, more commonly, in a staged fashion with a left pancreatectomy followed by a head resection (pancreaticoduodenectomy) allowing initial islet processing on the body and tail specimen. The isolation process relies on enzymatic and mechanical mechanisms to dissociate the islets from surrounding acinar tissue and fibrosis. Depending on the proximity of the islet isolation facilities and the efficiency of the process,

infusion of the islet preparation into the portal circulation may be performed during the same anesthetic or postoperatively (usually the same day) under radiological guidance.<sup>75</sup> Briefly, the resected pancreas is cooled to 4°C in an organ-preserving solution (eg, University of Wisconsin Solution). The pancreas is then transected at the neck of the gland and the pancreatic duct cannulated. The ductal system is then perfused with a cold solution of the purified digestive enzyme collagenase. The gland is sectioned and then physically shaken in a small digestion chamber at 37°C. The digestion of the gland is monitored continuously by means of a microscopic examination of samples of the digestate taken throughout the process. The digestion is continued until the acinar tissue is separated from the islets but stopped before the islets begin to fragment. The islets are then partially purified from the acinar debris by gradient density centrifugation on a cold dextrose gradient. The islets are washed and resuspended in an albumin-rich transplant medium or cultured. The islets are transplanted by direct injection into portal circulation, with access to the portal circulation being achieved under ultrasound-guided percutaneous placement of a transhepatic portovenous catheter in interventional radiology or by direct operative cannulation of the portal vein.

## **AUTOLOGUS ISLET TRANSPLANTATION—OUTCOMES**

Several recent publications have demonstrated the efficacy of autologous islet transplantation in both adult and pediatric populations. In general, short- and long-term outcomes in selected populations of adults have been favorable. One recent publication from the University of Cincinnati reported outcomes from 166 patients undergoing TPAIT and having 5 years of follow-up. At the 5-year mark, 74% of patients were narcotic-independent. All patients demonstrated stable glycemic control and 27% demonstrated long term insulin independence.<sup>76,77</sup> These results are consistent with previous publications on long-term results from TPAIT from the University of Minnesota.<sup>78</sup> Such successes of TPAIT in adult populations have been encouraging, and prompted groups doing the procedure to apply the technology to adolescents with severe early manifestation of hereditary forms of chronic pancreatitis. In general, TPAIT in these young people has been reported to be safe, with morbidity profiles and functional results similar to those found in adult populations undergoing TPAIT in the same centers.<sup>79,80</sup>

The technology has also been effectively employed as salvage therapy for patients with symptoms refractory to more well-established resection and drainage procedures. The group from Cincinnati has recently presented a series of 64 patients undergoing completion total pancreatectomy with islet auto transplantation (CPIAT) following an initial operative intervention (either pancreaticoduodenectomy, Frey, Puestow, or Berne procedure). Follow-up was only short-term, but islet yields were reasonable given the fact that there had been a prior partial pancreatectomy in most cases. Nearly half (44%) of patients achieved narcotic independence. Twenty percent of patients achieved insulin independence, and quality of life as assessed by the SF-36 metric was improved in all domains.<sup>81</sup>

## CONCLUSIONS

Chronic pancreatitis is a relapsing inflammatory process that results in a variable degree of parenchymal destruction and fibrotic change in the pancreas, with consequent clinical manifestations typically including characteristic abdominal pain, and exocrine and endocrine insufficiency. A single unifying model for the pathogenesis of chronic pancreatitis remains elusive, although recent basic and clinical research has identified a number of gene mutations, immunologic conditions, environmental toxins, and anatomic anomalies that alone and together confer risk of developing chronic pancreatitis. The morphology of pathological change seen in the gland at the time that patients present for treatment varies significantly from one patient to the next. A myriad of endointerventional and surgical procedures have been developed over time and are now applied in the treatment of the disease. Both the endoscopic and surgical procedures used are technically demanding and carry substantial risk of morbidity. While there is substantial retrospective case-series evidence demonstrating the utility of these approaches in well-selected patients, high-level evidence comparing the efficacy of the interventions in large series is lacking. For all of these reasons, chronic pancreatitis is often best managed in experienced centers in which multidisciplinary teams collaborate to individualize treatment in the context of established local expertise with various medical, endoscopic, and surgical therapies.

# CYSTIC NEOPLASMS OF THE PANCREAS

*Michael J. Pucci • Charles J. Yeo*

## INTRODUCTION

The collective phrase “cystic lesions of the pancreas,” typically described on cross-sectional imaging of the abdomen, refers to any cystic neoplasms of the pancreas and/or other cystic lesions, many of which cause “cyst-like” dilatations of the main or side branch pancreatic ducts. Specifically, the descriptor “cystic neoplasms of the pancreas” encompasses a wide variety of pathologic entities of the pancreas with variable malignant potential. The incidence of these cystic neoplasms seems to increase with age, with one autopsy study demonstrating that up to a quarter of elderly individuals harbor cystic lesions of the pancreas at their demise.<sup>1</sup> As the use of abdominal computed tomography (CT) and magnetic resonance imaging (MRI) is increasing, cystic lesions of the pancreas are being defined more frequently, with the majority asymptomatic at discovery.<sup>2,3</sup> Laffan and colleagues in 2008 estimated the incidence of asymptomatic discovered cysts on abdominal imaging for unrelated diagnoses at 2.6%.<sup>4</sup> Some of these lesions will be malignant or have malignant potential at diagnosis, while others are clearly

benign and may not warrant further surveillance. Resection of benign cystic pancreas lesions or those containing only high-grade dysplasia (pre-malignant) leads to nearly universal survival, while surgery for invasive carcinoma associated with cystic neoplasms generally has a more favorable prognosis than the results for resection of typical pancreatic ductal adenocarcinoma.<sup>5-7</sup> Thus, careful consideration must be given to the diagnosis and prognostic implications of these lesions. As more becomes known about these neoplasms, the treatment and observation algorithm will continue to evolve to minimize unnecessary interventions, while maximizing the impact of surgical treatment.

An ideal diagnostic approach would allow for the resection of only those lesions with concurrent or near-future risk of malignancy, while excluding from surgery those individuals with either nonenlarging benign lesions or a prohibitive operative risk, thus minimizing the potential occurrence of mortality and morbidity associated with the surgical treatment of these cystic lesions. Recent advancements in imaging by CT, MRI, and endoscopic ultrasonography (EUS), linked with refinements in the pathological, molecular, and genetic understanding of cystic neoplasms of the pancreas, have furthered this effort. History and clinical criteria, such as age, gender, presence of symptoms, location of the neoplasm within the pancreas, as well as morphology by cross-sectional imaging and cyst fluid analysis by EUS with fine-needle aspiration (EUS-FNA), all may play a role in the diagnosis of pancreatic cystic neoplasms and assessment of the need for resection. While the phrase “cystic neoplasm of the pancreas” encompasses a large variety of pathologic entities, this review will focus on the most commonly encountered that may require surgical intervention.

The most common non-neoplastic cysts of pancreas are typically considered to be pancreatic pseudocysts (or early post-pancreatitis acute fluid collections). Their diagnosis is aided (and typically confirmed) by a history of acute or chronic pancreatitis.<sup>8</sup> Congenital cysts are rare and include those associated with genetic diseases such as autosomal dominant polycystic disease,<sup>9</sup> cystic fibrosis,<sup>10</sup> and von Hippel–Lindau (VHL) disease.<sup>11,12</sup> Lymphoepithelial cysts are rare benign lesions of the pancreas lined with squamous epithelium.<sup>13</sup> Peripancreatic cystic lesions (such as esophageal or intestinal duplication cysts) may be mistaken for true pancreatic cystic lesions and need to be within the differential diagnosis in select situations.<sup>14</sup> Finally,

solid pseudopapillary neoplasms (which may have cystic components) are rare lesions occurring predominantly in young women, for which resection of the primary tumor results in an excellent opportunity for cure.

Three lesions make up approximately 90% of the cystic neoplasms seen in the pancreas: serous cystic neoplasms (SCNs), mucinous cystic neoplasms (MCNs), and intraductal papillary mucinous neoplasms (IPMNs). Overall, these three common pancreatic cystic neoplasms can be classified as either “mucinous” or “non-mucinous,” a distinction that has important clinical significance. SCNs (nonmucinous lesions) rarely demonstrate a progression to malignancy. Unequivocal proof of a SCN may permit nonoperative management of these lesions, provided symptoms do not mandate resection. Although the majority of non-mucin-producing lesions are benign in nature, cystic “degeneration” of other pancreatic tumors (ie, endocrine, solid pseudopapillary, or ductal adenocarcinoma) does occur and must be considered in the workup, as these may necessitate surgical resection. Mucin-producing lesions of the pancreas can be segregated into two types, which may differ significantly in natural history. Restriction of the definition of MCNs to include only those lesions with subendothelial ovarian-type stroma has permitted an improved distinction between MCNs and IPMNs.<sup>15</sup> Consensus guidelines developed (and recently revised) by the International Association of Pancreatology<sup>16,17</sup> (“Sendai” and “Fukuoka” guidelines) may assist in the management of cystic neoplasms of the pancreas. The premalignant nature of MCNs (and most IPMNs) prompts resection in patients who are acceptable operative risks, while observation of some branch duct IPMNs may be tenable, with an eventual risk of malignancy less than the operative mortality of pancreatic resection.<sup>18</sup>

## **PATHOLOGICAL CLASSIFICATION**

The accurate pathological description of pancreatic cystic neoplasms has evolved significantly in the past several decades, influenced largely by an improved understanding of the malignant potential of MCNs in comparison to the largely benign nature of SCNs, and the emergence of an understanding of the pathogenesis and behavior of IPMNs. Current classification of these tumors follows the World Health Organization (WHO) International Classification of Tumors as published in 2010 ([Table 72-1](#)).<sup>15,19</sup> While the

diagnostic criteria and organizational schema for these tumors are likely to be adapted further in future editions, the current classification system provides a means to stratify these tumors in terms of prognosis and management. In this review, particular attention will be paid to the three most common lesions: SCNs, MCNs, and IPMNs (Table 72-2). Although this chapter is organized by pathologic diagnosis, the actual workup and treatment of these cystic lesions of the pancreas may have significant overlap, as at times the diagnosis may be challenging to delineate until definitive surgical resection.

**TABLE 72-1: WORLD HEALTH ORGANIZATION INTERNATIONAL CLASSIFICATION OF TUMORS, 2010—CYSTIC NEOPLASMS OF THE PANCREAS**

Serous cystic neoplasms

Serous cystadenoma

    Serous microcystic adenoma

    Serous oligocystic adenoma

Serous cystadenocarcinoma

Mucinous cystic neoplasms

    Mucinous cystic neoplasm with low- or intermediate grade of dysplasia

    Mucinous cystic neoplasm with high-grade dysplasia

    Mucinous cystic neoplasm with an associated invasive carcinoma

Intraductal papillary mucinous neoplasm

    Intraductal papillary mucinous neoplasm with low- to intermediate-grade dysplasia

    Intraductal papillary mucinous neoplasm with high-grade dysplasia (noninvasive)

    Intraductal papillary mucinous neoplasm with an associated invasive carcinoma

**TABLE 72-2: COMMON CYSTIC NEOPLASMS OF THE PANCREAS**

Type of Neoplasm	Gender (Ratio F:M)	Age Range	Gross Feature	Microscopic Features	Imaging Features	Fluid Analysis	Malignant Potential	Suggested Treatment
Serous cystic neoplasm (SCN)	F >M (7:3)	60-80 years	Typically polycystic "microcystic" with central stellate scar, may be oligocystic	Clear cytoplasm, single-layer cuboidal epithelium, glycogen-rich cells	Microcystic, honeycomb pattern with central stellate scar	Low viscosity, clear glycogen rich cytoplasm Low CEA Low amylase	Almost uniformly benign	Stable size and asymptomatic: surveillance Symptomatic or enlarging: consider resection
Mucinous cystic neoplasm (MCN)	F >>M (>10:1)	Perimenopausal 40-50 years	Large, macrocystic, solitary, thick-walled	Subendothelial ovarian-type stroma, tall columnar mucin producing epithelium	Macrocystic lesion in the body or tail without communication to ductal system, peripheral calcifications	High viscosity, elevated CEA, low amylase	Potentially malignant (exhibit spectrum from adenoma to carcinoma)	Asymptomatic and size <3 cm: surveillance or resection (after patient education) Asymptomatic and size >3 cm: resect Symptomatic: resect
Intraductal papillary mucinous neoplasm (IPMN)	F = M (1:1)	60-70 years	Multilobar, involve main pancreatic duct and/or branch duct	Tall columnar mucin producing epithelium with variable degrees of dysplasia	Main duct IPMN: diffuse or segmental main pancreatic duct dilation Branch duct IPMN: pancreatic cyst with communication to ductal system Mixed type IPMN: combination of cyst with communication to ductal system and main duct dilation	High viscosity Elevated CEA Elevated amylase	Potentially malignant (exhibit spectrum from adenoma to carcinoma)	Main duct IPMN: resect with use of intraoperative pancreatoscopy and careful inspection of remnant pancreas for synchronous neoplastic lesions Branch duct IPMN: resect if symptomatic, tumor >3 cm, mural nodules, positive cytology, rapid growth, main duct dilation or young and healthy (age <55 years) Observe, if asymptomatic, tumor <3 cm, no mural nodules, negative cytology, stable size, normal main duct, and advanced age (>75 years)

## SEROUS CYSTIC NEOPLASMS

SCNs, previously referred to either as serous cystadenomas, glycogen-rich adenomas, or microcystic adenomas, are almost always benign. Careful delineation of the radiological and clinical features that distinguish these lesions may support and facilitate nonoperative management of these lesions when appropriate (Table 72-2).

### Pathological Features

The majority of SCNs are polycystic or so-called "microcystic adenomas," typically characterized by a well-circumscribed, soft mass which includes numerous small cysts filled with clear serous fluid arranged in a characteristic honeycomb-like pattern. Larger cysts may line the periphery of the lesion. The multiple small cystic loculations are well defined and are often accompanied by a central stellate scar with or without calcifications. These

features may be highly suggestive of an SCN when seen on CT or MRI (Figs 72-1 and 72-2). A small number of SCNs ( $\leq 10\%$ ) are oligocystic adenomas and present with one or more dominant cysts rather than multiple conjoined microcysts. Rarely, a single dominant cystic lesion may be identified. These unusual SCNs may be more difficult to distinguish radiographically from MCNs, IPMNs, pseudocysts, and other cystic lesions.

**FIGURE 72-1** This CT image depicts a cystic neoplasm in the head and neck of the pancreas (*small arrow*) detected incidentally in a 75-year-old man undergoing evaluation for nephrolithiasis. The patient underwent a pylorus-preserving pancreaticoduodenectomy without complications. Final pathology revealed a 6-cm serous cystic neoplasm without evidence of malignancy.

A

B

**FIGURE 72-2** **A.** Abdominal CT (axial image) of a 61-year-old woman who presented with pruritus and jaundice and was found to have a large cystic lesion in the head of the pancreas (*arrow*). **B.** On coronal CT image, this polycystic mass with central calcifications (*arrow*) abuts the proximal superior mesenteric vein (SM) and portal vein (PV), and was resected via a pylorus-preserving pancreaticoduodenectomy for complete resection. Final pathology revealed a benign serous cystic neoplasm.

Beyond these gross distinctions, both microcystic and oligocystic adenomas are composed of a single layer of simple cuboidal epithelium with rounded nuclei and clear cytoplasm which is glycogen rich and stains periodic acid-Schiff-positive (Fig. 72-3). The cystic fluid is serous (clear) and typically has no mucin content, with a low carcinoembryonic antigen (CEA) level ( $< 5$  ng/mL), factors that may provide diagnostic information upon cyst aspiration. Cytology diagnostic for SCN is present in less than 50% of cases; however, when positive the sensitivity is high.

**FIGURE 72-3** Photomicrograph of a typical SCN of the pancreas. Characteristic features include the single layer of cuboidal epithelial cells lining the microcysts within the lesion, uniform round nuclear architecture,

and clear cytoplasm. The cyst cavities contain serous fluid and little cellular debris.

The malignant potential of SCN is so low that most experienced centers recommend management of these lesions as benign entities. Certainly the argument can be made that a clearly documented classic-appearing SCN need not be resected unless symptomatic or enlarging. The incidence of serous cystadenocarcinoma is extremely low, and although the WHO has given serous cystadenocarcinoma a distinct definition, data on this extremely rare lesion are scarce. The WHO requires evidence of distant metastasis to verify the diagnosis. To date, there have been 42 cases of “invasive” or metastatic serous cystic neoplasms reported in the literature, with Reid et al. recently performing a critical analysis of these cases, finding that most would no longer be considered as serous “cystadenocarcinoma” based on the WHO 2010 classification.<sup>20</sup> Khashab and colleagues reviewed the Johns Hopkins Hospital experience with 257 resected serous cystic neoplasms. Of these 257 cases, fourteen patients had “aggressive” tumors (defined as local extension or invasion), with two of these cases having liver metastases (considered malignant).<sup>21</sup> The authors found that tumor size and location in the head of the pancreas are independent risk factors for aggressive behavior. Evidence of distant metastatic disease is considered necessary to confirm the rare diagnosis of serous cystadenocarcinoma according to the WHO, as both the primary and extrapancreatic disease may appear histologically indistinguishable from benign SCN.<sup>22,23</sup> Importantly, vascular and perineural invasion, or local invasion of the stomach and duodenum, are not sufficient criteria for the diagnosis of malignancy of SCN.<sup>24,25</sup> Hence, true histologic malignancy in the setting of serous cystic neoplasms is exceedingly rare.<sup>20</sup>

## **Clinical Presentation**

SCNs occur predominately in women in the sixth decade of life, while men tend to present at a later age. Bassi and colleagues described 100 patients with SCN, 87 of whom were female, with a mean age at presentation of 52 years.<sup>26</sup> The average age of the 13 male patients was 54 years. In another study from the Massachusetts General Hospital, 75% patients were women, and the female patients were significantly younger at presentation than were

the men (60 vs 67 years,  $p = .018$ ).<sup>27</sup> In the recent review of 257 cases from the Johns Hopkins Hospital, 179 patients were female, with a mean age of 61 years.<sup>21</sup>

The majority of patients with SCN are asymptomatic. When symptoms exist, abdominal pain is the most common presenting symptom,<sup>24,26,27</sup> weight loss is seen in 14 to 22% of patients,<sup>24,26</sup> and fewer patients (10%)<sup>26</sup> present with a mass or fullness. Symptoms typically associated with invasive disease, such as jaundice (6%) or pancreatitis, are uncommon (Fig. 72-2).<sup>24</sup> Nausea and vomiting related to compression of the upper gastrointestinal tract may occur in 7% to 10% of patients.<sup>26</sup> Traditionally, SCNs have been described as having a predilection for the pancreatic body and tail, although Le Borgne and coworkers described a relatively even distribution throughout the gland in 170 lesions (38% head, 41% body, 20% tail).<sup>28</sup> Khashab et al. reported 39% of SCN in the pancreatic head, 21% in the body, 31% in the tail, and 9% were considered “extensive.”<sup>21</sup> Large SCNs located in the head are surprisingly unlikely to cause biliary or duodenal obstruction, reflecting their slow pattern of growth, soft texture, and lack of invasive behavior. Rarely, extremely large tumors have been seen in elderly patients, with considerable symptoms of abdominal fullness and occasionally gastroduodenal obstruction or jaundice.

One clinical condition that has been clearly associated with SCNs of the pancreas is the VHL syndrome. Simple pancreatic cysts or SCNs occur in 17% to 56% of patients with this heritable multisystem neoplastic syndrome.<sup>29</sup> The VHL tumor suppressor gene is located on chromosome 3p25. Vortmeyer et al. demonstrated deletion of 3p25 in 7 of 10 sporadic SCN cases studied, suggesting a role for the VHL gene in SCN tumorigenesis, even in the absence of the VHL syndrome.<sup>30</sup> A recent review of 23 patients with VHL syndrome operated on for nonfunctioning pancreatic neuroendocrine tumors described that 13 (57%) of those patients had associated SCNs of the pancreas.<sup>31</sup>

## Diagnosis

SCNs often have a characteristic imaging phenotype (see Figs 72-1 and 72-2). Most are well-demarcated solitary multicystic masses composed of innumerable small cysts. Up to one-third have a central, calcified starburst

scar.<sup>28,32</sup> SCNs may also present as oligocystic or unilocular cystic lesions, making differentiation from other cystic lesions of the pancreas difficult. Lee and colleagues reported on the preoperative diagnostic accuracy of CT in pathologically confirmed SCN.<sup>33</sup> Radiological features led to a correct diagnosis in only 36% of unilocular SCNs, while honeycombed microcystic and multilocular macrocystic SCNs were appropriately defined in 81% and 88%, respectively ( $p = .005$ ). Overall in their series, CT diagnosis was accurate in 71% of SCNs. In 164 patients with surgically verified pancreatic cystic lesions, 28 of whom had a SCN, Shah et al. suggested that the CT features predictive of the diagnosis of SCN are microcystic appearance (22/28, 78%), surface lobulations (25/28, 89%), and central scar (9/28, 32%).<sup>34</sup> Stepwise logistic regression analysis showed that only a microcystic appearance was predictive for the CT diagnosis of SCN ( $p = .0001$ ). MRI correctly predicted the pathological diagnosis of SCN with greater frequency than did CT in the study by Bassi and coworkers.<sup>26</sup> CT allowed for the correct diagnosis in 54%, incorrect diagnosis in 34%, and was nondiagnostic in 12% of SCNs. The results with MRI were 74%, 26%, and 0%, respectively. A recent study by Chu and colleagues using pancreas protocol CT imaging in resected SCNs revealed that only 20% of cases had the “classic appearance” of multilocular masses with central stellate scars and calcifications. CT attenuation was helpful in distinguishing SCNs from MCNs, IPMNs, pseudocysts, and insulinomas, but not pancreatic ductal adenocarcinoma. The presence of external lobulations and the absence of “aggressive” features (such as pancreatic duct dilation, vascular invasion, lymphadenopathy, and liver metastasis) were helpful in distinguishing between SCN and classic pancreatic ductal adenocarcinoma.<sup>35</sup>

The limitations of the radiological diagnosis of SCN may call for additional analysis, which is frequently sought by EUS-FNA with cyst fluid cytology and biochemical analysis. The risk of complications with EUS-FNA is relatively low.<sup>36-38</sup> Cyst fluid aspirates from SCN are frequently sparsely cellular and may be contaminated with columnar enterocytes and mucin from the scope and needle traversing the gastric or intestinal mucosa, potentially clouding the diagnostic accuracy of cytology. Cytology alone was found to be diagnostic of SCN in only 7 of 21 cases studied by Huang and others from MD Anderson Cancer Center.<sup>39,40</sup> Detection of intracytoplasmic glycogen was noted to enhance the diagnostic confidence for the diagnosis of SCN.

Cyst fluid analysis is an additional adjunct (beyond cytology) to improve the diagnostic accuracy of EUS-FNA. Fluid from within an SCN is typically low in viscosity and amylase due to a consistent lack of connection to the pancreatic ductal system.<sup>41</sup> CEA levels less than 5 ng/mL have a sensitivity of 54% to 100%, and specificity of 77% to 86% in the differentiation of SCN from other pancreatic cystic lesions.<sup>42,43</sup> The finding of a cyst fluid carbohydrate antigen (CA) 19-9 level less than 37 U/L and a CEA less than 5 ng/mL virtually excludes an MCN or IPMN.

Allen et al. reported on the analysis of cyst fluid using a biomarker panel developed for pancreatic cancer.<sup>43</sup> Assessment of protein expression within the cyst fluid led to an error rate in classification of lesions of 27% when all three types of cystic neoplasms were evaluated (SCN, MCN, and IPMN). When limiting the analysis to separating SCN from IPMN, this method had an error rate of only 8%, compared with a 14% error rate with the use of CEA levels alone. The greatest utility of protein expression analysis might be in the differentiation of cystic lesions of the head of the pancreas, as the vast majority of MCNs occur in the body and tail of the pancreas. However, the cost of this method may not be justified by the relatively small improvement in diagnostic accuracy. In addition, Cao and colleagues recently studied a three-marker panel of glycoforms of MUC5AC and endorepellian and showed 89% sensitivity and 100% specificity in distinguishing between mucinous (MCN, IPMN) and nonmucinous (SCN, pseudocysts) cystic neoplasms of the pancreas.<sup>44</sup> Recently, Springer and colleagues examined a combination of molecular and clinical markers from a multi-institutional collaboration of resected cystic neoplasms of the pancreas and identified a combination of markers that approach 100% sensitivity and 98% specificity in diagnosing SCNs. The combination of the clinical characteristics of patients >25 years of age without abdominal pain or evidence of communication of the cyst with the pancreatic ductal system and the molecular presence of a *VHL* mutation and/or loss of heterozygosity of chromosome 3, as well as the absence of *KRAS*, *GNAS*, and *RNF43* mutations, allowed for excellent diagnostic power.<sup>45</sup>

## Treatment

Observation of patients with SCN may be appropriate in asymptomatic

patients. When a secure diagnosis of SCN is made, modern series demonstrate that a growing number of SCNs are being kept under surveillance by serial imaging (Table 72-2). Typically a pathological diagnosis is not required when classic imaging characteristics are observed. Bassi and colleagues followed 32 patients with the diagnosis of SCN for a median time of 69 months, without any observed development of malignancy or significant increase in diameter of the lesion.<sup>26</sup> Rapid rate of growth of a lesion may heighten suspicion for the development of malignancy or increase the likelihood of developing symptoms. In a report from the Massachusetts General Hospital, Tseng and coworkers found a more rapid rate of growth in SCNs greater than or equal to 4 cm in size at presentation, compared with smaller tumors (1.98 cm/yr vs 0.12 cm/yr,  $p = .0002$ ).<sup>27</sup> Tumors less than 4 cm were less likely to be symptomatic than were those greater than or equal to 4 cm (22 vs 72%,  $p < .001$ ). Resection was thus suggested by these authors, even for asymptomatic SCNs that were greater than or equal to 4 cm. A recent multinational review of over 2600 SCNs revealed that the average tumor size of patients who underwent surgical resection was 40 mm, with the most common indication being an “unclear diagnosis.” Only three serous cystadenocarcinomas were encountered in this entire cohort.<sup>46</sup>

When the diagnosis of SCN is uncertain, pancreatic resection is most often performed according to oncological principles, as if the lesion was malignant or had malignant potential (Fig. 72-2). Standard procedures include distal pancreatectomy for lesions of the body or tail, or pancreaticoduodenectomy for right-sided lesions. This practice avoids performance of an inadequate cancer operation in cases in which a malignancy is found on final pathological analysis. However, if the diagnosis of SCN is confirmed preoperatively, a less radical approach may be considered. Enucleation of SCNs has been shown to be technically feasible, although it can be challenging and is associated with a significant risk of pancreatic fistula.<sup>47-49</sup> A central pancreatectomy, with remnant pancreatic reconstruction being performed via pancreaticogastrostomy or Roux-en-Y pancreaticojejunostomy (PJ), may be considered in select patients with lesions of the pancreatic neck.<sup>50</sup> Distal pancreatectomy with splenic preservation may also be considered, particularly for small lesions in the tail, where the splenic hilum is more easily dissected. Lesions in the head of the pancreas that are not amenable to enucleation are best treated with pylorus-preserving pancreaticoduodenectomy. Many patients undergoing

pancreaticoduodenectomy will have an otherwise normal pancreas, hence meticulous attention must be paid to the technique of PJ, since such patients have a significantly higher risk for developing a pancreatic fistula related to a failure of healing at the PJ. There has been some enthusiasm for duodenum-preserving pancreatic head resection as well, although this procedure has not had widespread application.<sup>51</sup> The use of minimally invasive techniques is encouraged in institutions with experience and training in these complex procedures. Patients with pathologically proven, completely resected SCNs do not require serial imaging in follow-up. Recommendations for appropriate monitoring of unresected SCNs vary, but serial imaging with either CT or MRI every 6 months for 2 years and then annually or every other year thereafter seems reasonable.<sup>52</sup>

## MUCINOUS CYSTIC NEOPLASMS

Progress in the diagnosis and management of pancreatic cystic neoplasms has been aided in large part by the recognition of distinct pathological features that distinguish MCNs from other cystic lesions.<sup>53,54</sup> The distinction between MCN and SCN is critical, as the premalignant and malignant behavior of MCNs stand in stark contrast to the nearly universally benign nature of SCNs. Many of the same diagnostic challenges that exist for SCNs are true for MCNs, but the management decisions may be quite different, due to the differing clinical phenotype of these lesions.

While the true prevalence of MCNs is difficult to identify, more recent series suggest that approximately 15% to 30% of cystic neoplasms of the pancreas are MCNs.<sup>2,52,55,56</sup> However, our experience at the Thomas Jefferson University Hospital reflects a lower percentage. Clinical series published prior to the establishment of the diagnostic criteria for IPMN in 1996 likely overestimated the relative prevalence of MCNs in comparison to other cystic lesions, since they included what are now categorized as IPMNs as various “mucinous tumors.”

### Pathological Features

MCNs (Table 72-2) are typically spherical, thick-walled, septated or unilocular cysts with a tall columnar mucin-producing epithelium

accompanied by a subendothelial ovarian-type stroma that appears as a dense layer of spindle cells with sparse cytoplasm and uniform, elongated nuclei (Fig. 72-4). This stroma regularly expresses progesterone receptors, and less frequently estrogen receptors, and over 60% of these stroma stain for human chorionic gonadotropin.<sup>57</sup> Both the WHO and the Armed Forces Institute of Pathology (AFIP) have defined the presence of this ovarian-like stroma as a requirement for the diagnosis of an MCN.<sup>4,53,54</sup> The original and updated International Consensus Guidelines (“Sendai” and “Fukuoka”) for the management IPMN and MCN have also required the presence of ovarian-type stroma as a necessary criterion for the diagnosis of MCN, so as to prevent the misclassification of IPMN as MCN.<sup>16,17</sup> In addition, MCNs typically do not communicate with the pancreatic ductal system, and this serves as another distinction between IPMNs.<sup>58</sup> Given the similarity of the histology and immunohistochemistry between MCNs and ovarian mucinous cystadenomas, MCNs have been postulated to arise from ovarian rests (or ovarian-like stem cells) within the pancreas.<sup>59</sup>

**FIGURE 72-4** MCNs of the pancreas are distinguished by a uniform columnar epithelium (*top*) associated with a dense underlying ovarian-like stroma (*bottom*).

MCNs exhibit characteristics of an adenoma-carcinoma sequence.

Dependent on the degree of atypia, they are classified as mucinous cystadenomas, mucinous cystic tumors (borderline lesions), in situ lesions (high-grade dysplasia), or invasive cystadenocarcinomas (mucinous cystadenocarcinomas). Atypical changes within the lining epithelium may be patchy and sparse, with abrupt transitions to normal mucosa. Classification of MCN should be based upon the highest degree of atypia present, and the entire lesion should be examined pathologically.<sup>60,61</sup> Invasive carcinomas arising within MCNs are usually tubular or ductal type, although some may be undifferentiated carcinoma with osteoclast-like giant cells,<sup>62</sup> adenosquamous carcinoma,<sup>63</sup> choriocarcinoma, or even high-grade sarcomas.<sup>64</sup> Colloid carcinomas are extremely rare in MCN, but they occur commonly in IPMN.<sup>61</sup> The molecular pathway of the pathogenesis of MCNs is not clearly understood. *K-ras* and *p53* mutations have been implicated, as well as loss of *DPC4*.<sup>65,66</sup> Interestingly, a recent study using a mouse model showed that APC haploinsufficiency coupled with *p53* loss resulted in the development of MCN with invasive carcinoma with 100% penetrance.<sup>67</sup>

## Clinical Presentation

In light of the mandatory presence of the underlying ovarian-type stroma, not surprisingly MCNs are now diagnosed almost entirely in women.<sup>57,59,68-73</sup> This requirement, combined with the usual lack of communication with the pancreatic duct, defines a unique phenotype separate from IPMN. In a combined report from the University of Verona and the Massachusetts General Hospital, Crippa and colleagues reviewed their experience with 163 MCNs that met the WHO criteria for diagnosis.<sup>72</sup> Of the 163 patients, 95% (155 patients) were perimenopausal females. Only eight males were identified, and they were significantly older than the female patients (63 vs 44 years,  $p = .011$ ). The location of MCN within the gland was almost entirely confined to the body and tail of the pancreas (97%), and only five lesions were found in the pancreatic head. In reviewing the literature regarding MCN, these researchers noted the importance of segregating studies according to whether or not the presence of ovarian-type stroma was required for inclusion of pathological specimens within collected reports. Goh et al. reviewed those studies where the presence of ovarian-type stroma was a mandatory criterion for the diagnosis of MCN and found that 99.7% of

the patients were women, the mean age at presentation was 47 (range, 18-95) years, and 95% of MCNs occurred to the left of the pancreatic neck.<sup>74</sup> By comparison, when this criterion was previously not a prerequisite to diagnose MCN, patients were older, more often male, and the lesions were located in the head with a frequency exceeding 30%.

Abdominal pain or discomfort is the most common presenting symptom, occurring in over 70% of patients.<sup>69-71</sup> A history of acute pancreatitis may also be elicited in 9% to 13% of patients, although less commonly than in patients with IPMN.<sup>4,69,72</sup> Patients with an MCN with an associated invasive carcinoma present 11 years later than those with noninvasive neoplasms, likely representing the longer time required to progress to overt malignancy within these neoplasms.<sup>72</sup>

## Diagnosis

In a female patient with a macrocystic lesion in the body or tail of the pancreas, MCN should be strongly considered. In addition, MCNs have some characteristic features that may be evident during imaging or preoperative evaluation. Classically, MCNs contain large septated cysts with thick irregular walls that may be well visualized on CT, MRI, or ultrasound evaluation. Papillary projections from the epithelium often extend into the cystic cavities and may be visible, particularly on high-quality axial or endoscopic ultrasound imaging. In a minority of cases, the wall of the MCN may contain calcifications, a characteristic associated with a higher likelihood of malignancy.<sup>75</sup> MCNs may also present as large unilocular cysts that may appear similar on cross-sectional imaging to long-standing pseudocysts (Fig. 72-5). Two distinguishing characteristics in this scenario that suggest the diagnosis of MCN are the lack of surrounding inflammatory changes beyond the wall of the neoplasm in MCNs and the absence of pancreatitis.<sup>8</sup> Demonstration of ductal communication with the cyst by MRI or magnetic resonance cholangiopancreatography (MRCP) may distinguish pseudocysts or IPMNs from MCNs, although MCNs can in rare instances exhibit a connection with the pancreatic duct.<sup>74</sup>

**FIGURE 72-5** Abdominal CT performed on a 69-year-old healthy man who had a palpable abdominal mass detected on routine physical examination. The mass (*arrow*) was homogeneous in character and was initially presumed to be a pseudocyst. Pylorus-preserving pancreaticoduodenectomy was performed, revealing an 8.5-cm mucinous cystic neoplasm without malignancy.

Similar to SCN, determination of a treatment plan for MCN is predicated upon whether or not a given lesion is mucinous. Analysis of cyst fluid aspirated from MCNs typically show elevated levels of CEA and low amylase concentrations (as MCNs do not typically communicate with the pancreatic ductal system). The Cooperative Pancreatic Cyst Study demonstrated that a cyst fluid CEA value greater than 192 ng/mL achieved the greatest efficiency for differentiating mucinous from nonmucinous lesions.<sup>32</sup> The accuracy of cyst fluid CEA (88/111, 79%) was greater than the accuracy of EUS morphology or cytology ( $p < .05$ ). No combination of tests further improved diagnostic accuracy. A cyst fluid CEA level greater than 800 ng/mL has a specificity of 98% for predicting MCN, but a sensitivity of only 48%.<sup>76</sup> Khalid and his coinvestigators tested the utility of DNA analysis

of cyst fluid to diagnose mucinous and malignant cysts.<sup>77</sup> The presence of a *K-ras* mutation was highly specific for a mucinous cyst (96%) but had a low sensitivity of only 45%. A considerable selection bias was introduced by the study design, which may have overestimated the ability of DNA analysis to define a mucinous cyst.<sup>78</sup> Presence of a *K-ras* mutation in cyst fluid may provide additional information when CEA levels are not discriminative, particularly in lesions that appear to not have clear imaging patterns that allow separation of SCN versus MCN.

A recent multi-institutional review of resected pancreatic cystic neoplasms showed promising results using a combination of a panel of molecular markers known to be implicated in pancreatic cysts and clinical features to predict lesions requiring resection versus observation. In reviewing MCNs, the authors approached 90% sensitivity and 97% specificity with the combination of certain molecular markers (including the absence of *CTNNB11* and *GNAS* mutations, loss of heterozygosity on chromosome 3, and aneuploidy in chromosome 1q and 22q) and the following clinical markers: age <75 years old and the absence of all three of the following features: male sex, communication with the main pancreatic ductal system, and multiple cysts.<sup>45</sup> In addition, as stated in the SCN section, additional biomarkers are being investigated to distinguish between mucinous and nonmucinous cysts.<sup>44</sup>

## Treatment

In their pooled review of the literature, including 10 studies of MCN defined by ovarian-type stroma, Goh and coworkers noted that in the 40 invasive carcinomas found in 344 patients, only one of the malignant MCNs was less than 4.5 cm in size at the time of resection.<sup>74</sup> Crippa and colleagues noted that lesions containing either in situ or invasive carcinoma were larger (median size 80 vs 45 mm,  $p = .0001$ ), and intracystic nodules or papillae were more frequently present (64% vs 4%,  $p = .0001$ ), when compared with benign neoplasms.<sup>72</sup> All lesions demonstrating cancer on pathology were either greater than 4 cm in diameter or contained nodules by preoperative imaging. Careful observation of asymptomatic lesions less than 3 cm in size, without the presence of nodules, appears to be a reasonable approach for MCN (see [Table 72-2](#)). However, a post-hoc analysis by Sawhney and

associates has questioned whether size alone, based on the original Sendai Consensus criteria, is a sufficient predictor of malignancy in pancreatic cysts.<sup>16,79</sup> Their data indicated that the original consensus guidelines should be applied with caution, and that more accurate diagnoses might be generated by the combination of cyst size and main pancreatic duct dilation greater than 3 mm. Crippa et al. reported a 73% rate of adenoma in their series of resected MCNs; however, this leaves approximately 27% of cases with at least borderline MCN pathology.

Biopsy of MCN should not be utilized to determine the presence of carcinoma, because the presence of invasion within a lesion may be patchy or discontinuous and a negative biopsy result may be obtained erroneously based on sampling error. Due to the significant rate of malignancy and the risk of progression to malignancy associated with MCN, symptomatic neoplasms, lesions greater than 3 cm, or those containing nodules or papillae should undergo resection. In addition, young, fit patients with MCNs should be considered for resection, as the cumulative risk of malignant transformation exceeds life expectancy. As with SCN, enucleation has been documented to be an effective strategy for resection in selected MCN cases.<sup>47,48,80</sup> However, there is some risk of performing an inadequate oncologic resection for an MCN should it harbor an invasive component, while there is virtually no risk for SCN. Therefore, enucleation should only be applied to highly selected cases of small, peripherally located MCNs with confirmation of a noninvasive component by extensive frozen-section analysis. Likewise, segmental pancreatic resections for lesions in the pancreatic neck and body (central pancreatectomy) or tail (spleen-preserving distal pancreatectomy) should be performed cautiously in selected patients without any indication of invasive disease. Larger tumors in older patients (ie, patients fitting the characteristics of MCN with an associated invasive cancer) should be treated with formal pancreatic resection to include specimen-associated lymph node harvest. Lesions in the pancreatic head are best treated with pancreaticoduodenectomy, while left-sided lesions are treated via distal pancreatectomy with or without en bloc splenectomy. Extended lymphadenectomy, which has not been shown to definitively improve locoregional control or survival in patients with pancreatic ductal adenocarcinoma, has no role in the treatment of patients with cystic neoplasms.<sup>81,82</sup> Minimally invasive resection techniques should be considered when appropriate at institutions with considerable experience and

acceptable quality outcomes.

The 5-year disease-specific survival for benign or noninvasive MCN is 100%, but falls to 50% to 60% for patients with invasive mucinous cystadenocarcinoma<sup>72</sup> (Fig. 72-6). Failure to completely resect a noninvasive MCN may result in a later recurrence (persistence), and a missed opportunity for cure.

**FIGURE 72-6** Kaplan–Meier disease-specific actuarial survival curves for invasive MCN (*hatched line*) and noninvasive MCN (*black line*) among 163 patients resected at the University of Verona and the Massachusetts General Hospital from 1988 to 2005. Five-year survival for patients with invasive MCN is approximately 57%, while for those with noninvasive MCN it is 100%. (Reproduced with permission from Crippa S, Salvia R, Warshaw AL, et al: Mucinous cystic neoplasm of the pancreas is not an aggressive entity: lessons from 163 resected patients, *Ann Surg* 2008 Apr;247(4):571-579.)

Adjuvant chemotherapy or chemoradiation therapy for mucinous cystadenocarcinoma has been poorly investigated and has no proven benefit. A single case report describes the use of neoadjuvant chemoradiation and treatment monitoring by serum CEA level, but no prospective clinical trials have been performed.<sup>83</sup> Some high-volume centers would likely offer

adjuvant chemotherapy to patients with invasive cystadenocarcinoma, extrapolating from the experience with ductal adenocarcinoma.<sup>84</sup> There are no data to support the utility of adjuvant radiotherapy. Follow-up with serial MR imaging every 6 months for 2 years and annually thereafter appears reasonable for patients with resected MCN with an associated invasive cancer.<sup>47</sup> Patients with resected noninvasive MCNs should receive no postoperative adjuvant therapy and are not typically followed with serial imaging (as they are universally considered cured, with no additional risk for distant recurrence or the remnant gland developing pancreatic cancer).

## INTRADUCTAL PAPILLARY MUCINOUS NEOPLASMS

IPMNs are mucin-producing epithelial tumors arising from the pancreatic ductal system that cause dilation of this system (Table 72-2). The study of IPMN is one of the most rapidly evolving fields in pancreatology, as these are relatively “newly” described pancreatic lesions that in the past were variably referred to as mucinous ductal ectasia, intraductal papillomatosis, intraductal adenoma or adenomatosis, intraductal mucin-secreting tumor, and intraductal papillary mucinous tumor. The earliest report of this “new” lesion is attributed to Ohashi and Maruyama and was published in the Japanese literature in 1982.<sup>85</sup> This report described four malignant lesions associated with the main pancreatic duct and characterized the now well-described copious amounts of mucus that distend and emanate from the ductal system. The authors noted the comparatively better survival of these patients compared to those with classic invasive ductal adenocarcinoma of the pancreas. While many subsequent authors have helped to further characterize the subtleties of IPMN, these initial observations accurately depict typical cases.

In 1996, the WHO first formally recognized IPMN as a distinct entity; establishing criteria for the pathological diagnosis of these lesions.<sup>53</sup> Characteristic features include a tall, columnar epithelium with marked mucin production, and cystic transformation of either the main pancreatic duct or one of its side branches (Fig. 72-7). More recent versions of these diagnostic criteria have allowed the stratification of noninvasive IPMNs based on their degree of dysplastic change and identification of distinct morphologic

subtypes with varying prognostic implications.<sup>15</sup>

**FIGURE 72-7** MRCP reconstruction of abdominal MRI of a 73-year-old man who presented with abdominal pain and pancreatitis. The patient underwent a pylorus-preserving pancreaticoduodenectomy; final pathology revealed a main-duct IPMN with moderate-grade dysplasia located in the head of the pancreas. All resection margins were negative for neoplasia. Notable findings on this image characteristic of IPMN include the multiloculated cystic mass in the right side of the pancreas (*circle*) associated with moderate pancreatic ductal dilatation (*arrow*).

Improvements in the diagnosis, identification, and stratification of these intraductal lesions offer clinicians the opportunity to safely observe lesions with a very low risk to progress to carcinoma and the ability to intervene surgically when the risk of preinvasive neoplasia is high (or overt invasive

carcinoma exists). At both ends of the spectrum of IPMNs, the management is well substantiated. However, it is the indeterminate lesions where clinical subtleties mean the difference between unnecessary surgical intervention and the “missed” progression to invasive carcinoma. Multiple guideline statements of been developed to assist clinicians, although to this point, none are 100% specific and sensitive (Table 72-3).<sup>16,17,86</sup> These guidelines are named after the sites of the consensus meetings in Japan—Fukuoka and Sendai.

## Pathological Features

Histologically, IPMNs are characterized by intraductal proliferation of mucinous cells which form papillae. Secretion of mucin leads to dilatation of the pancreatic ducts (Fig. 72-8). Lesions may be localized, multicentric, or involve the entire ductal system. The proliferation of mucinous cells may involve the main pancreatic duct (“main duct type,” MD-IPMN), or be confined to the branch ducts (“branch duct type,” BD-IPMN), or show a pattern spanning both areas in a “mixed-type.” The mucosa of IPMNs display the typical range of dysplasia-to-invasive carcinoma sequence. The degree of dysplasia will be classified as either low-, moderate-, or high-grade based on the highest grade present within a resected specimen.

**FIGURE 72-8** Gross photograph of a distal pancreatectomy specimen from a patient with an IPMN with carcinoma in situ. Characteristic features include the mass in direct communication with a markedly dilated main pancreatic duct.

IPMNs demonstrate a progressive precursor model of carcinogenesis similar to that seen in colon cancer.<sup>87-89</sup> Tall mucin-producing columnar epithelial cells that remain well differentiated characterize IPMN adenoma (low-grade dysplasia). Little or no dysplasia is present in these lesions. IPMN

borderline lesions (moderate-grade dysplasia) are described as lesions with moderate epithelial dysplasia, characterized by moderate loss of polarity, changes in nuclear morphology, and pseudopapillary formation (Fig. 72-9). IPMNs with high-grade dysplasia have severe dysplastic changes. These lesions may be papillary or micropapillary. Severely dysplastic lesions may lose the ability to secrete mucin. IPMNs are pathologically similar to pancreatic intraepithelial neoplasia (PanIN) with the caveat that the former are macroscopic lesions while the latter are microscopic. IPMNs, like PanIN lesions, are intraductal lesions that may demonstrate a range of cellular atypia and malignant transformation. However, IPMNs may be distinguished based on their gross visibility and involvement of large ducts. PanINs should be considered a microscopic finding involving ducts less than 5 mm in diameter, while IPMNs are macroscopic findings.<sup>90</sup>

**FIGURE 72-9** Photomicrograph of an IPMN with borderline features. Characteristic features include the tall columnar cells lining the papillary projections of the tumor, moderate dysplastic changes of the epithelium, and varied nuclear morphology.

Further investigation has identified histologic subtypes of the papillae that seem to influence biologic behavior (and ultimately clinical prognosis).

Currently, four morphologic patterns of IPMN can be seen, and include gastric foveolar-type, intestinal-type, pancreatobiliary-type, and intraductal oncocytic papillary-type.<sup>87,91</sup> In the gastric foveolar-type, mostly seen in BD-IPMNs, the lesion resembles gastric epithelium and demonstrates papillae lined by tall columnar cells with basally oriented nuclei and abundant pale mucin. This pattern is also prevalent in the nonpapillary areas of MD-IPMN. The neoplastic cells in gastric foveolar-type do not express MUC1 and MUC2, but highly express gastric-type mucins including MUC5AC and MUC6, supporting their gastric differentiation. These lesions are generally low-grade (although occasional high-grade lesions can be encountered).<sup>91</sup> Most MD-IPMNs are of the intestinal type and closely resemble colonic villous adenomas, being composed of well-formed, long, finger-like projections lined by columnar mucin-producing neoplastic cells with enlarged nuclei. Typically, moderate-grade or high-grade dysplasia is present. The neoplastic cells of intestinal-type IPMNs do not express MUC1 but strongly express MUC5AC and MUC2. In addition, intestinal-type IPMNs are strongly immunoreactive with antibodies to CDX2.<sup>88,91</sup> Cancers arising in these IPMNs are typically colloid carcinomas and may have a more favorable prognosis (Fig. 72-10). Pancreatobiliary-type IPMN consists of cuboidal neoplastic cells that are atypical, tend to contain less mucin, and are more frequently high-grade. The immunohistochemical pattern of pancreatobiliary-type IPMNs is similar to that of PanINs, expressing MUC1 and MUC5AC.<sup>91</sup> Invasive cancers associated with the pancreatobiliary morphology are usually tubular, with a histologic structure similar to typical ductal adenocarcinoma. The more recently defined fourth histologic subtype of IPMN is intraductal oncocytic papillary neoplasms. These lesions are very rare, with a complex architecture with arborizing papillae, cribriform formations, and solid nests, all growing into the lumina of the dilated duct. They demonstrate a characteristic abundant eosinophilic cytoplasm due to accumulation of mitochondria, and express MUC1 and MUC6. Typically high-grade lesions, invasive carcinoma arising from these oncocytic lesions may retain the oncocytic cytology. Interestingly, they tend to lack the *KRAS* mutation seen in typical ductal adenocarcinoma<sup>58,91</sup> and seem to exhibit excellent long-term prognosis and survival.<sup>92</sup> While both the villous-intestinal and the pancreatobiliary types may be found alongside the gastric-foveolar type, it is uncommon to identify both the villous-intestinal and pancreatobiliary type of

papillae in the same IPMN.<sup>87</sup> Differentiation of histologic subtypes may help predict the prognosis of IPMNs. Invasive carcinomas developing in a background of intestinal subtypes typically are colloid carcinomas and have a generally more favorable 5-year survival (70%-83%) compared with tubular ductal carcinoma arising in the background of pancreatobiliary IPMN (24%-50% 5-year survival).<sup>58</sup> In addition, a recent review of the rare oncocytic-type had a 46% recurrence rate after 10 years; however, no patients died of the disease at median follow-up of 7 years.<sup>92</sup>

**FIGURE 72-10** Photomicrograph of a colloid carcinoma within an IPMN. Note the largely acellular nature of these cancers and their abundant mucus production.

IPMNs appear also to have distinct molecular events contributing to the clinical and pathological behavior that further distinguish them from lesions in the PanIN–ductal adenocarcinoma sequence. Iacobuzio-Donahue and associates described the intact (normal) expression of the tumor-suppressor gene *Dpc4* in the intraductal components of 79 IPMNs.<sup>93</sup> In contrast, *Dpc4* inactivation has been shown to be relatively specific for pancreatic adenocarcinoma, and its persistence in both noninvasive and invasive IPMNs

argues that these lesions may arise through a pathway that is distinct from the PanIN–ductal adenocarcinoma sequence. IPMNs also appear to have a significantly lower rate of *KRAS* and *p53* mutations, which are common in ductal adenocarcinoma.<sup>94</sup> Fritz and coworkers demonstrated that losses of chromosome 5q, 6q, and 11q were significantly higher in IPMNs with high-grade dysplasia or invasion compared with classic ductal adenocarcinoma.<sup>95</sup> These data and others suggest that IPMNs are unique pancreatic neoplasms, with a pathogenesis that is distinct from that of the PanIN–ductal adenocarcinoma sequence. In addition, while many of the common genetic mutations seen in standard ductal adenocarcinoma are present in IPMN, they tend to occur much less frequently. Also, other mutations have been discovered that occur in some IPMNs (such as *PIK3CA* and *GNAS*) and not in standard pancreatic ductal adenocarcinoma.<sup>96,97</sup> Recently, Tan and colleagues showed that mutations in *KRAS* and *GNAS* do occur early in IPMN carcinogenesis, with mutations in *GNAS* predominant in colloid carcinoma, and *KRAS* mutations predominant in tubular carcinoma. In addition, these mutations showed some ability to predict outcome in IPMN-associated invasive carcinoma, with *GNAS* mutated colloid carcinoma showing excellent survival at 4 years post-resection.<sup>98</sup>

## Clinical Presentation

The biologic behavior of IPMNs parallels their classification according to their distribution within the pancreatic ductal system. Main duct type and combined main duct and branch duct type lesions (mixed-type) are more likely to present with symptoms, while strictly BD-IPMNs are more frequently detected as asymptomatic cystic neoplasms on cross-sectional imaging.<sup>99</sup> Pancreatitis is seen more commonly in MD-IPMN, possibly related to mucin plugging the main duct and the ampulla. In a combined experience of the Massachusetts General Hospital and the University of Verona reported by Salvia and colleagues, acute pancreatitis occurred in 23% of 140 patients with main duct variant IPMN.<sup>100</sup> A recent review, again by the group at the Massachusetts General Hospital, identified that 21% of patients who underwent resection for IPMN presented with at least one episode of acute pancreatitis. In this setting, an episode of pancreatitis was associated with intestinal subtype, malignancy, and main duct

involvement.<sup>101</sup>

Both genders are affected by IPMNs, with a moderate male predominance in some series. Patients with IPMN tend to be older, with a mean age of 65 years, as compared with those having MCN, who are predominantly perimenopausal. Patients diagnosed with invasive MD-IPMNs are typically 5 or more years older than those patients with noninvasive MD-IPMNs. This interesting observation again supports the adenoma-carcinoma sequence theory and gives some insight into the amount of time required for progression along this sequence.<sup>100</sup> Malignant IPMNs are more likely to present with symptoms typically attributed to ductal adenocarcinoma, such as obstructive jaundice and weight loss.<sup>5,100</sup>

The development of symptoms more commonly attributed to ductal adenocarcinoma in patients with IPMN may herald the occurrence of carcinoma either synchronously or metachronously in the gland. Several studies have demonstrated the presence of an invasive ductal adenocarcinoma elsewhere in the pancreas, distinct from the location of the cystic neoplasm in up to 10% of IPMN patients.<sup>52,102,103</sup> Ingkakul and colleagues showed that in a multivariate analysis, worsening diabetes (odds ratio 15.73 [95% CI: 4.40-56.25];  $p < .001$ ), and an abnormal serum CA 19-9 (odds ratio 3.70 [95% CI: 1.19-11.48];  $p = .024$ ) are independent factors predictive of synchronous or metachronous separate ductal adenocarcinoma in patients with IPMN.<sup>103</sup> A recent review of 223 patients with IPMNs with main duct involvement showed that 43% of patients presented without symptoms, while the most common presenting symptoms were weight loss (32%), pancreatitis (26%), and obstructive jaundice (14%).<sup>104</sup> In addition, the incidence of extrapancreatic malignancies appears to be higher in patients with IPMN.<sup>105,106</sup> The development of colorectal adenomas and carcinomas, Barrett mucosa, and gastric carcinomas appear to be important accompanying entities seen in IPMN patients.

## Diagnosis

Distinguishing IPMNs from other cystic pancreatic neoplasia can at times be challenging. The International Association of Pancreatology consensus guidelines of 2012 (Fukuoka) summarize the evaluation and treatment for mucinous cystic lesions of the pancreas (IPMN and MCN) with the best

supporting evidence available at the time (Table 72-3).<sup>16,17</sup> Despite these guidelines (which are revised from the initial “Sendai” guidelines of 2006), clinicians will still have difficulty at times accurately selecting patients in which true preinvasive (or invasive) neoplasia is present (and thus require operative intervention). When evaluating IPMNs, it is important to classify the lesion as either having evidence of invasive cancer, high-risk stigmata, or strictly benign characteristics. Typically this is accomplished with a combination of imaging modalities. High-quality multidetector CT imaging (with thin sections through the pancreas) is primarily used in the evaluation of pancreatic and associated lesions. This modality provides excellent visualization and classification of pancreatic cystic neoplasia, as well as the surrounding pancreatic parenchyma (which may be a site of an adjacent malignancy). In addition, high-quality CT imaging can identify septations, mural nodules, and calcifications within the cystic lesions. While advancements in CT imaging abound, abdominal MRI imaging, particularly in combination with MRCP reconstruction, remains a reliable and equally efficacious tool in the identification of IPMNs. Importantly, MRI/MRCP can often accurately identify whether there is communication with the pancreatic ductal system and the cystic lesion. This may help distinguish between small branch duct IPMNs and other cystic lesions. IPMNs characteristically appear as cystic masses resulting from dilatation of the main pancreatic duct or side branch ducts. Polypoid projections (mural nodules) into the cystic spaces may be present. Approximately half of IPMNs occur in the pancreatic head, although they may be present anywhere within the pancreas and can diffusely involve the entire gland. Currently, MRCP is the modality of choice for defining mural nodules, demonstration of the communication of the cystic neoplasm with the pancreatic ductal system, and evaluating the extent of the pancreatic ductal dilatation.<sup>107</sup> Use of MRCP has largely supplanted endoscopic retrograde cholangiopancreatography (ERCP) in the diagnosis of IPMN, since MRCP is noninvasive, does not require sedation, and does not carry the risks of pancreatitis and perforation that accompany ERCP.

In order to appropriately classify IPMNs (observation vs resection), a thorough search for “high-risk” characteristics is necessary. The 2012 Fukuoka consensus guidelines list the following as high-risk stigmata (requiring operative intervention in appropriate patients): obstructive jaundice in the setting of a cystic mass in the head of pancreas, an enhancing solid component within a cyst, or main pancreatic duct dilation >10 mm. In

addition, “worrisome” characteristics (requiring additional workup with EUS) are defined as the following: a cyst  $\geq 3$  cm, thickened or enhancing cystic wall, main pancreatic duct size 5 to 9 mm, nonenhancing mural nodule, or abrupt change in caliber of pancreatic duct with distal pancreatic gland atrophy.<sup>17</sup> In combination with clinical history, this guideline frames an algorithm for clinicians to stratify patients.

The initial Sendai consensus guidelines published in 2006 included a cyst  $>3$  cm in size in the “high-risk” group. This was based on available data at the time that revealed imaging features suggestive of the presence of malignancy, including tumor size (cyst diameter  $\geq 30$ , 40, or 50 mm), MD-IPMN, main duct dilatation greater than or equal to 10 or 15 mm, patulous papilla, mural nodules ( $\geq 3$ , 5, or 10 mm in size), presence of biliary ductal dilatation greater than or equal to 15 mm, a solid mass, or occurrence of an area of abnormal attenuation in the surrounding pancreas.<sup>107-115</sup> Importantly, Salvia and colleagues, in Verona, Italy, followed 121 patients with multifocal branch duct IPMN (median diameter of the largest lesion being 1.7 cm) over a 40-month observation period.<sup>116</sup> All of the 121 patients remained alive, without surgery, and all remained asymptomatic. Thus, there is clearly a role for conservatism in the management of patients with BD-IPMNs and no additional worrisome features. Critical review of these initial Sendai guidelines confirmed the rising practice leading to resection of low-grade BD-IPMNs utilizing the  $>3$  cm size criteria. This ultimately prompted the “revised” Fukuoka consensus guidelines published in 2012 to change the  $>3$  cm size criteria to a “worrisome” feature instead of a “high-risk” feature (See [Table 72-3](#)), perhaps favoring a more conservative posture.

Recently, Ammori and colleagues reviewed their experience with resected IPMNs, specifically examining cases with either isolated uncinete process ductal dilatation or a combination of main pancreatic duct and uncinete process ductal dilatation. In 184 cases, 47 patients had dilatation of the uncinete process duct and 50 patients had an uncinete process cystic lesion. While uncinete process cystic lesions were not associated with high-grade dysplasia or invasive carcinoma (pathologic IPMN), dilatation of the uncinete process duct was associated with pathologic IPMN in 64% of cases. In cases of only uncinete process duct dilatation (without associated main pancreatic duct dilatation), 65% of patients harbored high-grade dysplasia or invasive carcinoma. This is in stark contrast to the 18% of patients who harbored pathologic IPMN in the setting of only branch-duct dilatation (without main

pancreatic or uncinate duct dilation). These data suggest that uncinate process duct dilation may be considered an additional risk factor for pathologic IPMN.<sup>117</sup>

EUS is an important adjunct in select patients requiring further investigation (worrisome features). Ohno et al. demonstrated that the finding of a papillary mural nodule or a nodule exhibiting an invasive component on EUS was predictive of malignancy with a sensitivity of 60%, specificity of 93%, and an accuracy of 76%.<sup>118</sup> EUS-FNA may also be useful in reinforcing a decision not to resect a BD-IPMN if it is otherwise without features predictive of malignancy. Marie and colleagues found that the combination of a CEA level less than 200 ng/mL and a CA 19.9 level greater than 40 U/mL retrieved from the cystic material of an IPMN together had a 96% negative predictive value for the diagnosis of malignancy.<sup>119</sup> In addition, endoscopic sampling of cyst fluid is an area of active investigation at many high volume centers. Unfortunately, results have been less than definitive. Cyst fluid CEA and amylase may add important objective data, however, is not universally consistent. Interestingly, cytologic or molecular analysis (such as cyst inflammatory markers) may allow for advancements in diagnosis, and continues to be an area of active investigation.<sup>120</sup>

The addition of positron emission tomography (PET) with CT (PET/CT) using 18F-fluoro-deoxyglucose has been investigated in an effort to improve identification of IPMN with high-grade dysplasia or invasive carcinoma. Recently, Roch et al. studied the use of PET/CT in combination with the 2012 International Consensus Guidelines and found an increase of the sensitivity and specificity of detecting IPMN with malignancy to 78% and 100%, respectively. In addition, the combination of PET/CT and guideline criteria increased the sensitivity and specificity in detecting IPMN with high-grade dysplasia to 100% and 71%, respectively.<sup>121</sup>

With the creation of the Sendai and Fukuoka guidelines, as well guidelines from the American Gastroenterological Association,<sup>16,17,86</sup> debate on the appropriate management of pancreatic cystic neoplasia continues. Fundamental differences in the viewpoint regarding the risks of pancreatic surgery and the risk of progression to malignancy allows for discord between clinicians managing patients affected with pancreatic cysts. In addition, the relatively new nature of this field of study lends for confusing, at times conflicting, and typically low-quality data, making definitive management

guidelines challenging. Thus, clinicians managing these patients must take into account the individual patient situation as well as all available information on the cyst (ie, imaging characteristics, etc), as well as access to high-volume quality pancreatic surgeons.<sup>122</sup> Critical appraisal of the updated Fukuoka guidelines both confirms and questions the accuracy of strict adherence in detecting malignant cysts. Kaimakliotis and colleagues compared the original Sendai criteria to the updated Fukuoka guidelines and showed no difference in either guideline in predicting patients with advanced neoplasia; however, two patients considered “low risk” using the Fukuoka guidelines had high-grade dysplasia.<sup>123</sup> Recent reviews, including a systemic review of 1382 patients, confirm that some malignant IPMNs would be missed with strict adherence to the Fukuoka guidelines.<sup>124,125</sup> These reviews underscore the imprecise nature of the best expert consensus guidelines and the need for patient-specific consideration on a case-by-case basis (with the inclusion of pancreatic surgeons).

## Treatment

The goals of treatment for IPMN include minimizing the exposure to unnecessary surgical risk while optimizing the removal of all premalignant neoplasia and frank carcinoma. In addition, the natural history of IPMN must be compared to the individual patient’s clinical status and situation. The Japan Pancreas Society performed a multi-institutional, retrospective study of 1379 cases of IPMN drawn from 98 of their member programs in 2004. The clinicopathologic features of benign IPMN (adenoma [low-grade dysplasia] and borderline lesions [moderate dysplasia];  $n = 564$ ) were strikingly different when compared with tumors containing frank adenocarcinoma ( $n = 445$ ).<sup>110</sup> Patients with adenocarcinoma were significantly older (67 vs 65 years,  $p = .0002$ ) and more frequently symptomatic (49 vs 35%,  $p < .0001$ ), as compared to the noncarcinoma group. Cancer occurred more commonly in either main duct-type or combined-type tumors, as compared to branch duct-type neoplasms (60%, 65%, and 30% respectively,  $p < .001$ ). The preoperative imaging of patients who were subsequently found to have adenocarcinoma on pathology demonstrated a higher incidence (63% vs 28%) and size of mural nodules (12 vs 5 mm) when compared with those who had benign lesions (both  $p < .0001$ ). Branch duct-type tumors with

cancer were larger (35 vs 28 mm,  $p < .0001$ ) than those without cancer.

Based on the data generated in the earlier report, the International Association of Pancreatology convened a consensus conference in Sendai, Japan, in 2004. The subsequent guidelines published in 2006 (and then revised in 2012) have become a new benchmark for the management of IPMN (Table 72-3).<sup>16,17</sup> The current “Fukuoka” guidelines recommend the resection of all IPMN of a main duct type and mixed variants, those showing main pancreatic duct dilatation greater than or equal to 10 mm, as well as those with the presence of enhancing mural nodules (solid components), or a positive cytology, provided the patients are reasonable candidates for surgery with an acceptable life expectancy. All symptomatic IPMNs (abdominal pain or obstructive jaundice) were deemed to warrant resection. These recommendations were predicated upon the risk of carcinoma in symptomatic or main duct type lesions. Additional “worrisome” stigmata were included in the guidelines, and patients with these stigmata should undergo additional work-up with endoscopic ultrasound evaluation. These stigmata include cyst size greater than 3 cm, prior pancreatitis, thickened or enhancing cyst wall, main pancreatic duct size of 5 to 9 mm, nonenhancing mural nodule, or an abrupt change in the caliber of the main pancreatic duct with distal gland atrophy. And while the original “Sendai” guidelines recommended that BD-IPMNs greater than 30 mm in diameter undergo resection, more recent data suggest that this may overtreat many patients with low-grade pathology. This has led to the revision of the guidelines to move BD-IPMN greater than 3 cm to the “worrisome” group requiring further investigation, instead of recommending surgical resection for these cysts without further worrisome features. Data suggest that BD-IPMNs less than 30 mm in diameter, without evidence of mural nodules or main duct dilatation, have low malignant potential and that such patients are candidates for careful observation. At follow-up examinations, appearance of symptoms, cyst enlargement to greater than 30 mm, detection of positive cytology on FNA, development or identification of mural nodules or main pancreatic duct dilatation ( $\geq 6$  mm) were deemed indications for resection.

Since the development and revision of the Sendai guidelines, much of the subsequent literature has sought to examine the accuracy of the recommendations, particularly with regard to the observation of asymptomatic BD-IPMN. Pelaez-Luna and colleagues identified 147 patients with BD-IPMN, of whom 66 underwent resection at diagnosis and 81 were

followed over time (of which 11 were resected during the follow-up period).<sup>126</sup> Of the patients undergoing resection who demonstrated Sendai consensus guideline indications for surgical therapy, 9/61 (15%) had carcinoma on pathology, whereas none of the 16 patients without consensus indications for resection had malignancy ( $p = .1$ ). A single guideline indication for resection taken as an indicator of carcinoma had a sensitivity, specificity, positive predictive value, and negative predictive value of 100%, 23%, 14%, and 100%, respectively.

Several studies have suggested that the development of mural nodules is predictive of the risk of developing malignancy, while a progressive dilatation of duct size remains controversial. Schmidt and colleagues identified 103 patients with BD-IPMN.<sup>127</sup> The mean size of the 20 malignant lesions was  $2.0 \pm 0.1$  cm, while the mean size of the nonmalignant neoplasms was  $2.2 \pm 0.1$  cm, suggesting that size alone is an insufficient indicator of malignancy. In multivariate analysis, only the presence of mural nodules and atypical cytopathology were predictive of the presence of carcinoma. Tanno et al. prospectively followed 82 patients with flat lesions within BD-IPMN diagnosed by CT or MR and EUS.<sup>128</sup> During a median follow-up of 59 months, 9/82 patients (11%) exhibited progressive dilatation of the cystic lesion. Six elected to continue regular screening, while three underwent resection; the IPMNs resected were staged as IPMN-adenoma in two and IPMN-borderline in one. Four patients (5%) developed mural nodules during a median follow-up of 105 months. All four of these individuals were resected, demonstrating IPMN-adenoma in three and carcinoma in situ in the fourth. Sixty-nine of the 82 patients (84%) showed no changes in their dilated branch duct lesions over a median follow-up of 57 months.

A study from Kyushu University in 2009 attempted to determine whether cyst size is predictive of the malignant potential in flat BD-IPMN.<sup>129</sup> One hundred seventy patients with BD-IPMNs without mural nodules were retrospectively identified from their previous 10-year experience. Seventy-three patients underwent resection of their IPMN: 26 patients had lesions less than 30 mm in size, while 47 patients had neoplasms greater than 30 mm in diameter. Importantly, all of the noninvasive ( $n = 5$ ) and invasive ( $n = 1$ ) malignancies were seen in the IPMN of greater than or equal to 30 mm. In a similar report, Salvia and coworkers followed 89 patients with flat BD-IPMNs less than or equal to 3.5 cm in size for a median time period of 32

months.<sup>130</sup> Five patients (5.6%) exhibited an increase in diameter of the cystic lesion, none of which demonstrated carcinoma in the resection specimen pathologically. Alternatively, a study by Fritz and colleagues identified malignancy (invasive carcinoma or high-grade dysplasia) in 25% of “Sendai Negative” branch-duct IPMNs that were resected at their institution.<sup>131</sup> Clearly, longer follow-up and further investigation will be needed to determine whether or not these guidelines accurately predict high-risk or malignant disease in small, flat, asymptomatic BD-IPMNs. As might be anticipated, increasing knowledge and follow-up have raised questions about the universal accuracy of the consensus guidelines.

The majority of studies, particularly those following IPMNs conservatively in a prospective fashion, would suggest that the development of invasive carcinoma in flat BD-IPMN less than 30 mm in size is unusual. The occurrence of high-risk stigmata (mural nodules, dilated main duct, or positive cytology) clearly has great predictive value for the ultimate finding of malignancy. EUS appears to be an important adjuvant to fully evaluate IPMN patients for the presence of mural nodules, as well as for aspiration of cytologic specimens. Some authorities insist that any lesion that is to be followed conservatively should be examined by EUS at regular intervals. We have tended to use MRI or MRCP for serial surveillance of small (<3 cm) BD-IPMNs, as this is a noninvasive procedure (as compared to EUS) which avoids radiation exposure (as compared to CT).

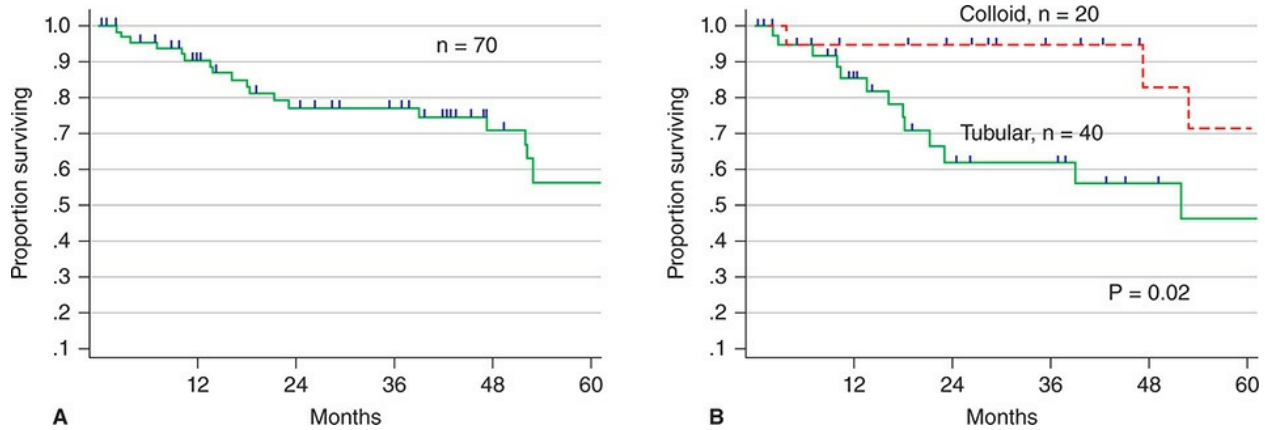

Given the excellent survival following resection of IPMNs free of an invasive component, every effort must be made to define lesions at risk for the development of carcinoma at the earliest point possible (Fig. 72-11). Schnelldorfer and coworkers have demonstrated that the survival after pancreatectomy of patients with IPMN with invasive adenocarcinoma is roughly equivalent to that of a matched cohort of patients following resection of ductal adenocarcinoma (median survival, 32 vs 21 months; 5-year survival rate, 31 vs 24%;  $p = .26$ ).<sup>132</sup> Other studies have revealed that survival of resected patients without lymph node involvement and invasive IPMN is quite good, while patients with lymph node involvement and invasive IPMN have equivalent outcomes to patients with lymph node–positive pancreatic ductal adenocarcinoma.<sup>5</sup> A recent study by Marchegiani et al. of 223 resected IPMNs involving the main duct revealed a 69% 5-year survival, which is significantly better than standard pancreatic ductal adenocarcinoma (Fig. 72-

11).<sup>104</sup> Winter and colleagues reviewed a multi-institutional experience of resected IPMNs with a small (<20 mm) invasive component and while 5-year survival was 59%, the recurrence rate was as high as 24%, with lymph node metastasis present in 19% of cases (Fig. 72-12).<sup>7</sup> Thus, although overall survival appears to be improved, there is a real risk of recurrence and aggressive disease despite only small foci of invasive carcinoma. Despite the poor survival in patients with invasive disease, surgery remains the best opportunity for cure. Swartz et al. have recently shown that adjuvant chemoradiotherapy confers a 57% decrease in the relative risk of mortality after pancreaticoduodenectomy for invasive IPMN after adjusting for major confounders.<sup>133</sup> This effect was most significant in patients with lymph node metastases or positive surgical margins.

**FIGURE 72-11** Kaplan–Meier overall survival curves comparing 106 patients with noninvasive IPMN to 67 patients with invasive IPMN following pancreatic resection at the Massachusetts General Hospital (1990-2013). Patients with noninvasive IPMN have a significantly greater survival than those with invasive carcinoma ( $p < .001$ ). (Reproduced with permission from

## Main Duct IPMN/Mixed-Type IPMN

Treatment of IPMN depends upon the predicted risk of malignancy or high-grade dysplasia. A distinction between main duct or mixed-type IPMN and branch duct IPMN is important, as generally the risk of high-grade dysplasia or invasive cancer is as high as 60% in main-duct or mixed-type. Thus, once the diagnosis of MD-IPMN is made, resection should be considered in the fit surgical candidate; however, controversy surrounds the extent and type of resection necessary. Generally, the goal of operative intervention is the removal of all high-risk disease and invasive cancer. This typically requires pancreaticoduodenectomy for disease within the head/uncinatus process of the pancreas and distal pancreatectomy with en bloc splenectomy for disease located in the body or tail of the pancreas. When operating for highly-suspected (or confirmed) invasive cancer, pancreatectomy should be completed to remove all invasive disease; however, we often avoid total

pancreatectomy to remove residual noninvasive IPMN at a surgical margin (as distant metastasis becomes a more likely outcome than synchronous invasive cancer within the remnant pancreas). Due to the endocrine liability and other associated morbidity after total pancreatectomy, we recommend using this operation sparingly.

In patients without overt evidence of malignancy and confined disease, segmental pancreatectomy depending on location should be performed. We typically utilize intraoperative frozen section analysis of the pancreatic margin in order to identify any lesion with high-grade dysplasia or occult invasive cancer. If any high-risk disease is identified at the margin, the resection should be extended. In the setting of main or mixed type IPMN with a diffusely dilated pancreatic duct, determining the extent of resection can be challenging. Diffuse pancreatic ductal dilation may be secondary to mucin obstruction of the duct (either proximally or distally to the lesion itself) or may be evidence of disease within the entire duct. When there is an associated intraductal mass, nodule, or obvious cystic lesion, segmental pancreatectomy may be performed. It is our practice at the Thomas Jefferson University Hospital to use intraoperative flexible pancreatoscopy in order to evaluate the residual remnant pancreatic duct for evidence of papillary projections, mural nodules, or other stigmata of IPMN.<sup>134</sup> If any of these findings are present, strong consideration (based on patient characteristics) is given to extend the resection to include the abnormality (Fig. 72-13). In patients with a diffusely dilated pancreatic duct without any associated signs of an intraductal mass/lesion, strong consideration must be given to total pancreatectomy. However, the risk of developing malignancy must be weighed with the morbidity and mortality associated with total pancreatectomy. We typically reserve this option for fit patients who have a long life expectancy (and thus a longer time for progression to invasive cancer in a nonresected state). When residual pancreatic parenchyma remains after resection, surveillance of the gland is required. Surveillance is typically performed by cross-sectional imaging at varying intervals based on degree of dysplasia seen in the resected gland and if any macroscopic abnormalities exist in the remnant gland. If invasive carcinoma is discovered in the resected specimen, surveillance should be performed as for routine pancreatic ductal adenocarcinoma (evaluating for metastatic, recurrent, or synchronous disease).

## Branch Duct IPMN

Based on resectional studies, the risk of malignancy in BD-IPMNs seems to be much less than mixed-type and MD-IPMNs. As such, resection for BD-IPMN should be considered more carefully to assess for evidence of invasive cancer or high-risk stigmata. According to the initial Sendai guidelines, BD-IPMNs greater than 3 cm, those with evidence of mural nodules, or those lesions that cause symptoms should be considered for resection. Since the initial guidelines (and revision), many institutional reviews of resected BD-IPMNs have been published to support and criticize the criteria. While some groups recommend more conservative management than the criteria, other groups have shown a real risk of invasive cancer or high-grade dysplasia in patients with BD-IPMNs for which the guidelines would recommend no surgical treatment.<sup>131</sup>

An additional consideration unique to the branch-duct type of IPMN (especially small-sized lesions) is distinguishing between IPMN and other small pancreatic cysts (either mucinous or nonmucinous). This distinction is sometimes impossible to identify preoperatively. This necessitates a selective approach to cystic neoplasms of the pancreas in general. Many groups will not perform resection in lesions smaller than 3 cm without worrisome features (solid components, mural nodules, increasing size). In addition, the age and surgical fitness of the patient will play a role in the decision-making in this circumstance. Also, the institutional surgical outcomes for pancreatic resections are important factors to consider and to balance with the risk of malignancy.

Resectional principles for BD-IPMN should be in line with MD-IPMN or mixed-type, with the goal of oncologic resection of all high-grade dysplasia or invasive carcinoma. Surveillance of the remnant pancreas should follow

accordingly, based on the degree of dysplasia (or presence of invasive carcinoma) in the resected specimen. Typically considered a “field defect,” the remaining pancreas is at risk for malignant transformation.

Use of the Fukuoka consensus guidelines means that the preponderance of resections for IPMN will be performed with at least a suspicion of the presence of carcinoma. Targeted pancreatectomies, either pancreaticoduodenectomy or distal pancreatectomy with en bloc splenectomy, have been advocated so as to adhere to oncologic principles of resection. Most centers have advocated the use of frozen-section examination of the pancreatic margin, with attempted clearance of microscopically malignant margins by re-resection and occasional conversion to total pancreatectomy when needed to achieve negative margins. Skip lesions clearly occur, such that a normal resection margin may not be indicative of a lack of neoplasia in the pancreatic remnant. A report by Nara et al. from Tokyo analyzed 130 consecutive patients undergoing resection for IPMN with frozen-section analysis of the pancreatic margin.<sup>135</sup> While the majority of initial frozen-section results showed no neoplasia at the margin, 29 patients had additional pancreas resected for “positive” frozen-section results (12 for low or moderate dysplasia, 10 for high-grade dysplasia, 1 for floating cancer cells, and 6 for invasive cancer). Most patients who recurred following reresection had their recurrence at a distance from the pancreatic margin (peritoneum, liver, and lymph nodes), raising doubt about the true value of reresection for margins determined to be positive at frozen section. The role of total pancreatectomy to achieve clearance of all dysplastic epithelium, even prophylactic total pancreatectomy, is controversial. Notably, of the 84 patients with noninvasive IPMN described by Sohn and colleagues, 7 patients developed recurrent disease in the pancreatic remnant.<sup>6</sup> Negative margins at resection do not eliminate the need for chronic surveillance of the pancreatic remnant, perhaps best done by annual MRI/MRCP.

## UNUSUAL PANCREATIC CYSTIC NEOPLASMS

### **Solid Pseudopapillary Neoplasm (Solid and Papillary Neoplasm)**

These rare tumors (approximately 1%-3% of all pancreatic tumors) first described by Frantz in 1959 and then further classified by Hamoudi are notable for several characteristic clinical and pathological features. The ratio of women to men is roughly 10:1, with lesions typically appearing in the second or third decade of life (mean age 22 years, range 2-85 years). Patients often present either with abdominal pain or a palpable abdominal mass. The lesions may be large, presenting in one review at a mean size of 6.1 cm (range 0.5-34.5 cm).<sup>136</sup> On CT, these tumors often appear well circumscribed, with hypodense areas representing hemorrhage or necrosis (Fig. 72-14). Lesions can be evenly distributed throughout the pancreas, although around 70% of tumors arise in the left of the gland.<sup>137-139</sup>  $\beta$ -catenin mutations are pathognomonic for these tumors, and in addition, most lesions express the beta subtype of estrogen receptors and stain for galectin-3.<sup>140</sup> Although the vast majority of these tumors are benign, some may be considered low-grade malignancies, with local invasion into contiguous structures and occasional distant metastases (roughly 10%-15% of cases). A recent multi-institutional review from Korea reported only 9 out of 317 (2.8%) patients had recurrence after surgical resection. Three clinically detectable parameters were found to be statistically significant to predict recurrence: tumor size >8 cm, microscopic malignant features (cellular pleomorphism, capsule invasion, peripancreatic fat invasion, perineural invasion, lymphovascular invasion, lymph node metastasis), and Stage 4 disease (hepatic or peritoneal metastasis).<sup>137</sup> An aggressive surgical approach is warranted for both the primary and metastatic disease, as 5-year survival in completely resected patients exceeds 95%.<sup>141</sup>

**FIGURE 72-14** Abdominal CT scan of a 29-year-old woman with a right-sided solid and papillary neoplasm. **A.** The tumor (T) resides within the duodenal C loop, and there is some deformation of the portal vein. **B.** On this more inferior image the tumor (T) is seen to further deform the superior mesenteric vein (SMV), but not touch the superior mesenteric artery. The tumor was resected via a pylorus-preserving pancreaticoduodenectomy, which was extended to include the proximal body of the pancreas. The tumor was dissected free from the SMV and portal vein, and no venous resection was needed.

## Cystic Pancreatic Endocrine Neoplasms

Endocrine tumors showing partial or complete cystic components are uncommon. The Cooperative Pancreatic Cyst Study demonstrated only 5 of these lesions out of 341 cystic neoplasms. Immunohistochemical staining of cytological specimens obtained by EUS-FNA demonstrating endocrine markers confirms the diagnosis.<sup>142,143</sup> In a retrospective review of 170 patients undergoing resection for a pancreatic endocrine tumor at the Massachusetts General Hospital over a 30-year period, 29 cystic endocrine tumors were identified.<sup>144</sup> Ten (34%) of the cystic lesions were purely cystic, while 19 (66%) were partially cystic. Cystic neuroendocrine neoplasms were larger (49 vs 23.5 mm,  $p < .05$ ), more likely to be symptomatic (73 vs 45%,  $p < .05$ ), and more likely to be nonfunctional (80 vs 50%,  $p < .05$ ) when compared with solid pancreatic neuroendocrine lesions. The propensity for metastases, invasion, and survival (87 vs 77% at 5 years,  $p = .38$ ) in patients

with cystic lesions was the same as in those with solid pancreatic endocrine neoplasms. More recently, Koh and colleagues performed a systematic review and meta-analysis of solid versus cystic pancreatic endocrine tumors. This review showed that cystic endocrine tumors were more likely to have benign characteristics, be nonfunctional, have a lower mitotic count and Ki67 index, and were less likely to have lymph node metastasis. Interestingly, the 5-year overall and disease-free survivals were similar to solid tumors.<sup>145</sup> Thus, these lesions have a favorable prognosis if completely resected and should be treated aggressively and with similar technique as for a solid endocrine tumor in appropriate surgical candidates, although consideration of nonoperative management is reasonable in high surgical risk patients.

## **Cystic Acinar Cell Neoplasms**

Acinar cell carcinoma of the pancreas is a rare neoplasm; however, several recent registry reviews and multi-institutional series have better defined this entity.<sup>146,147</sup> This lesion has a 2:1 male predominance and although many individuals will present with advanced disease, stage-specific survival is statistically better than that seen in ductal pancreatic adenocarcinoma.<sup>146</sup> Occasionally, acinar cell carcinoma may display an intraductal, papillary, or papilocystic growth pattern and may appear to mimic IPMN with a cystic component. A significant proportion of these tumors (up to 40%) may demonstrate a concomitant endocrine neoplasm.<sup>147</sup> Acinar cell neoplasms with intraductal growth patterns tend to present somewhat earlier than typical acinar cell carcinoma, secondary to the pancreatitis resulting from duct obstruction.<sup>147</sup> Characteristic immunohistochemical staining for trypsin and chymotrypsin as well as the presence of eosinophilic granular cytoplasm in acinar cell carcinoma are helpful in establishing the correct diagnosis.<sup>147</sup> In addition, acinar cell cystadenoma, a very rare benign lesion that lacks mitotic figures (differentiating them from acinar cell carcinoma), has been described, with approximately 20 cases in the literature.<sup>148</sup>

## **Cystic Degeneration of Pancreatic Ductal Adenocarcinoma**

While not truly a distinct lesion, it is important to note that pancreatic ductal adenocarcinoma may present with cystic features.<sup>149</sup> Thus all cystic lesions should at least be considered as potential pancreatic ductal adenocarcinomas until an alternative diagnosis is established. In a comparative review of symptomatic and incidental pancreatic cysts by Fernandez-del Castillo and colleagues, 9% of symptomatic lesions and 2% of incidental cysts proved to harbor pancreatic ductal adenocarcinoma.<sup>55</sup> Adenocarcinomas that obstruct the pancreatic duct may be associated with retention cysts in up to 8% of patients.<sup>150</sup>

# CANCERS OF THE PERIAMPULLARY REGION AND PANCREAS

*Csaba Gajdos • Martin McCarter • Barish Edil • Alessandro Paniccia • Richard D. Schulick*

## INTRODUCTION

Periampullary adenocarcinomas are a set of neoplasms that arise near the ampulla of Vater. Although they are all adenocarcinomas, they arise from the different mucosal tissues of the pancreatic duct, bile duct, ampulla, and duodenum. They are often discussed together because they often share a common clinical presentation, they can be hard to distinguish on cross-sectional imaging, and when respectable, they are treated with pancreaticoduodenectomy.

Pancreatic adenocarcinoma is by far the most common of the 4 periampullary tumors. In fact, in 2016, it became the third most common cause of cancer death in the United States, and it is predicted that in the near future, it will become the second most common cause of cancer death.<sup>1</sup> Pancreatic adenocarcinoma accounts for a vast majority of the periampullary

cancers, with the other 3 types being much less frequent. The 4 cancers have different resectability rates and long-term survival rates. Long-term survival is dependent on where cancer arose from, stage at diagnosis, degree of differentiation, and ability to completely resect cancer with negative margins.

In addition to these 4 types of adenocarcinomas, other less common tumors arise in the periampullary region including neuroendocrine tumors, acinar cell cancers, squamous cell carcinomas, gastrointestinal tumors, lymphoma, and metastases from other sites.

## PERIAMPULLARY CANCER TYPES

### Pancreatic Ductal Adenocarcinoma

Pancreatic ductal adenocarcinoma is the third leading cause of cancer death in the United States. In 2016, there will be an estimated 53,000 new cases diagnosed with 42,000 deaths from this disease.<sup>1,2</sup> The peak incidence of pancreatic cancer occurs in the seventh decade of life. African Americans have a higher risk of developing pancreatic ductal adenocarcinoma than do whites. There is a slightly higher incidence in men compared to women. The lifetime risk of developing pancreatic cancer is 1 in 65 and 1 in 67 in men and women, respectively, in the United States. Smoking is one of the strongest risk factors for the development of pancreatic cancer. Obesity has also been implicated, and other factors, such as diabetes and alcohol use, have also been implicated.

It is estimated that up to 10% of patients who develop pancreatic ductal adenocarcinoma have a familial predisposition. In the majority of these families, the genetic predisposition has not been identified. We do know, however, that mutations in the following genes can increase the risk of pancreatic cancer: *BRCA2* (familial breast and ovarian cancer), *PRSS1* (hereditary pancreatitis), *p16* (familial atypical multiple mole and melanoma), and *HNPCC* (hereditary nonpolyposis colorectal cancer).<sup>3</sup>

### Distal Bile Duct Cancer (Cholangiocarcinoma)

Distal cholangiocarcinoma is the second most common of the periampullary

adenocarcinomas. Bile duct cancers or distal cholangiocarcinomas are typically grouped into 3 forms based on anatomic origin. Peripheral or proximal bile duct adenocarcinomas arise in the intrahepatic biliary tree. Perihilar cholangiocarcinomas arise near the bifurcation of the right and left bile ducts. Distal cholangiocarcinomas arise in the most distal part of the bile duct from the junction of the cystic duct to the ampulla of Vater. The incidence of cholangiocarcinoma is much less than that of pancreatic adenocarcinoma.<sup>4</sup> Approximately 30% of bile duct adenocarcinomas are diagnosed as arising in the distal bile duct. It is a disease of the elderly, with a peak incidence in the seventh decade of life. Risk factors for the development of cholangiocarcinoma include sclerosing cholangitis, choledochal cysts, hepatolithiasis, and infestation with liver flukes.<sup>5</sup> The common etiologic factor with these conditions is continued long-term chronic inflammation.

## **Adenocarcinoma of the Ampulla of Vater**

Ampullary adenocarcinoma is the third most common of the periampullary malignancies.<sup>6</sup> These cancers are slightly more common in males and have a peak incidence in the seventh decade of life. These cancers tend to cause symptoms of obstructive jaundice relatively early in their course, so they tend to be discovered at a smaller size and earlier stage. Additionally, they tend to have less biologic aggressiveness than pancreatic and distal bile duct adenocarcinomas. Several groups have further subdivided adenocarcinomas into various histologic subtypes including pancreatic, biliary, intestinal, and gastric. Patients with the intestinal subtype have much better prognosis than patients with the other subtypes.

## **Duodenal Adenocarcinoma**

Duodenal adenocarcinomas are the least common of the 4 periampullary malignancies discussed in this chapter. They are equally prevalent in men and women and have a peak incidence in the seventh decade. These cancers can arise from benign polyps, as in the colon. Patient with duodenal adenocarcinoma, especially if they have multiple polyps, should be ruled out for familial adenomatous polyposis syndromes.

Patients with duodenal adenocarcinoma can present with gastric outlet

obstruction and/or with jaundice if it arises right next to the ampulla. Duodenal adenocarcinomas tend to be larger at diagnosis than pancreatic, biliary, and ampullary adenocarcinomas because of the lack of symptoms until significant intraluminal growth. Patients with duodenal adenocarcinoma have much better prognosis, stage for stage, than patients with pancreatic and biliary adenocarcinomas.

## DIAGNOSIS AND STAGING EVALUATIONS

### Clinical Presentation

The signs and symptoms associated with periampullary and pancreatic tumors tend to be nonspecific, which often contributes to a delay in diagnosis. Presenting symptoms are commonly jaundice and vague mid-epigastric abdominal pain. Unfortunately, by the time such symptoms are manifest, the tumor is often in its late stages, with an estimated 80% of patients presenting with metastatic or unresectable disease.<sup>7</sup> The combination of jaundice (painless or painful) with pruritus, acholic stools, and tea-colored urine in the absence of acute biliary disease is a constellation of symptoms that should prompt the suspicion of a periampullary tumor. Upon further questioning, a history of vague pain and unintended weight loss is often present. Often, a more severe and persistent mid-epigastric pain that radiates to the back indicates a more advanced tumor. Other relatively nonspecific symptoms such as malaise, fatigue, anorexia, indigestion, or early satiety are often noted upon evaluation. Signs of pancreatic insufficiency (malabsorption, frequent fatty or floating stool) would suggest obstruction of the main pancreatic duct, whereas nausea and vomiting would suggest gastric outlet or duodenal obstruction. A quite subtle sign, but one that is now known to be associated with the ultimate diagnosis of pancreatic malignancies, is the rather sudden development of adult-onset diabetes in previously healthy patients in their sixth decade of life.<sup>8</sup>

The location of the tumor will often influence the signs and symptoms of presentation. For example, tumors in the body and tail of the pancreas are more likely to present at a later stage, with larger tumors contributing to more abdominal pain and weight loss. However, tumors that occur within or adjacent to the distal bile duct tend to present at an earlier stage and manifest

as painless jaundice.

Physical exam findings include scleral icterus, jaundice, and skin excoriation from pruritus and scratching. The Courvoisier sign, noted by palpation of an enlarged gallbladder, may be present without peritoneal signs. More advanced disease may include the findings of cachexia, palpable left supraclavicular lymph nodes (Virchow node), palpable periumbilical nodes (Sister Mary Joseph node), and palpable pelvic metastatic disease on a rectal exam (Blumer shelf).

## Laboratory Evaluation

Patients who present with signs of biliary obstruction are initially evaluated with basic laboratory testing including a complete blood count, electrolytes, liver function tests, albumin, and prothrombin time. If separate testing suggests a periampullary or pancreatic mass, then additional laboratory values that may be useful include tumor markers such as carbohydrate antigen CA 19-9, carcinoembryonic antigen (CEA), or chromogranin A (if a neuroendocrine tumor is suspected).

Extrahepatic biliary obstruction generally results in hyperbilirubinemia with the direct (or conjugated) bilirubin being more elevated than the indirect (or unconjugated) bilirubin. In addition, the alkaline phosphatase is generally more significantly elevated with extrahepatic biliary obstruction than the transaminases (alanine aminotransferase or aspartate aminotransferase). The prothrombin time or international normalized ratio (INR) may be abnormal due to malabsorption of fat-soluble vitamins such as vitamin K.

Hypoalbuminemia from malabsorption and weight loss may be present. While the tumor marker CA 19-9 may be helpful, its sensitivity and specificity can be limited by certain conditions. First, the blood test for CA 19-9 is dependent on the Lewis blood group antigen phenotype and is not detectable in patients with Lewis AB<sup>-</sup> phenotype (approximately 5%-10% of the population). Second, biliary obstruction artificially elevates CA 19-9 levels, and therefore, it is not a reliable tumor marker in the presence of an ongoing obstruction. After relief of the biliary obstruction and subsequent normalization of the bilirubin, CA 19-9 may then become a more reliable tumor marker. Other conditions such as inflammation, cholangitis, and nonpancreatic tumors (gastrointestinal, ovarian) are also associated with increased CA 19-9 levels. Therefore, CA19-9 can support a diagnosis of

perampullary or pancreatic adenocarcinoma but it should not be used to infer the actual diagnosis. An elevated CA 19-9 may be useful for monitoring response to therapy or for monitoring disease progression.

## Imaging Evaluation

Accurate imaging of perampullary and pancreatic tumors is essential for optimal treatment planning. Well-done imaging provides information about the extent of disease and staging estimation and assists the surgeon in determining the potential for a complete resection. A dedicated, fine-cut, 3-phase pancreas protocol computed tomography (CT) scan provides valuable information regarding local (primarily vascular) and regional (primarily the liver as the most common site of metastasis) spread of disease (Fig. 73-1).<sup>9</sup> Alternatively, for patients with CT contrast allergy or renal insufficiency, a magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP) study can provide similar information (Fig. 73-2). In the absence of metastatic disease, attention is paid to the local vasculature that will affect operative planning. Namely, the relationship of the tumor to the inferior vena cava (IVC), portal vein (PV), superior mesenteric vein (SMV), superior mesenteric artery (SMA), celiac trunk, and hepatic artery is assessed. Signs of abutment or invasion of these vessels is not a direct contraindication for resection, but these tumors are considered borderline resectable and the neoadjuvant treatment planning and the operative technique will likely be altered (Fig. 73-3).<sup>10</sup> For locally advanced adenocarcinoma of the pancreas, we favor a neoadjuvant approach to test the biology of the tumor and attempt to downstage the tumor before considering a resection.<sup>11</sup>

**FIGURE 73-1** Axial and coronal computed tomography scans demonstrating a resectable tumor in the head of the pancreas (note plastic biliary stent) with clear tissue planes around the superior mesenteric artery and portal vein.

**FIGURE 73-2** Magnetic resonance cholangiopancreatography demonstrating an abrupt cutoff in the common bile duct from a tumor in the head of the pancreas. The pancreatic duct is also dilated, giving a strong suspicion of malignancy.

**FIGURE 73-3** Arterial phase cross-sectional computed tomography imaging demonstrating pancreatic adenocarcinoma tumor abutting the superior mesenteric artery and superior mesenteric vein.

Additional imaging with endoscopic ultrasound (EUS) and concomitant fine-needle aspiration (FNA) biopsy can both add valuable information regarding the relationship of the tumor to the mesenteric vessels and simultaneously confirm a tissue diagnosis. Biopsy confirmation is not always necessary for resectable lesions; however, the treatment approaches to neuroendocrine tumors, lymphomas, and other tumors that occur in the periampullary and pancreatic region vary significantly such that biopsy is often warranted.

The routine use of positron emission tomography (PET) combined with CT for periampullary and pancreatic tumors is common, but its ultimate utility is still being debated.<sup>12</sup> The lack of resolution and fine detail around the vasculature is such that the need for a pancreas protocol contrasted CT scan is not obviated. However, PET-CT may be useful in resolving suspicious potentially metastatic lesions noted on other imaging modalities (Fig. 73-4). Despite the use of improved imaging techniques (including PET-CT), small subcapsular liver nodules or occult peritoneal implants are still discovered in approximately 10% to 20% of patients who meet operative

criteria.<sup>13</sup>

**FIGURE 73-4** Positron emission tomography/computed tomography scan demonstrating a focus of discrete hypermetabolic activity in a small lesion of the liver adjacent to the gallbladder consistent with metastatic adenocarcinoma of the pancreas.

## **Biliary Decompression and Tissue Diagnosis**

Jaundice is often the first presenting sign for periampullary tumors prompting further diagnostic and therapeutic interventions. The advantage of endoscopic retrograde cholangiography (ERC) is that it directly evaluates the periampullary region. Periampullary adenomas, adenocarcinomas, or other lesions may be visualized for direct biopsy. ERC may also be useful for diagnosing and treating benign causes of jaundice such as choledocholithiasis or inflammatory conditions such as primary sclerosing cholangitis. At ERC, tumors involving the distal bile duct region often demonstrate an abrupt (as opposed to smoothly tapered) cutoff suggestive of malignancy (Fig. 73-5). The double duct sign (dilation of the extrahepatic common bile duct and the pancreas duct) is most often a sign of malignancy (Fig. 73-6).<sup>14</sup> ERC also

provides the opportunity for biopsy or brushing of the bile duct to obtain a tissue diagnosis. If a definitive diagnosis is not obtained at ERC and is desired for treatment planning, then other approaches such as EUS with FNA or direct cholangioscopic-guided biopsy may be necessary.

**FIGURE 73-5** Endoscopic retrograde cholangiography demonstrating a narrow tapering of the common bile duct secondary to a tumor in the distal bile duct.

**FIGURE 73-6** Computed tomography scan evidence of a double duct sign with dilated common and intrahepatic biliary system and the main pancreas duct.

The need for biliary stenting depends on staging, the patient's condition, and the timing of potential surgical resection. Patients with metastatic or locally advanced tumors will benefit from stenting, and the immediate relief from the obstruction allows for the patient's symptoms to improve while the remainder of the evaluation is conducted. Most patients are grateful for the symptom relief from pruritus, malabsorption, scleral icterus, and changes in stool color, although this can take several days to weeks depending on the degree of acquired liver dysfunction. For patients presenting with resectable disease, the value of routine preoperative stenting is an area of controversy. A recent prospective randomized trial in pancreatic cancer patients presenting with a total bilirubin level of 2.3 to 14.6 mg/dL found that routine preoperative stenting was associated with an increase in serious complications with no change in mortality or length of stay compared to patients who went straight to surgery within 7 days of diagnosis.<sup>15</sup> Select patients with resectable tumors may still benefit from biliary stenting if they

have evidence of cholangitis, intractable pruritus, or significant nutritional deficiencies or if surgery cannot be arranged in a timely (<7 days) fashion.

## **SURGICAL APPROACHES**

### **Laparoscopy**

The use of staging or diagnostic laparoscopy varies significantly from provider to provider and institution to institution. Proponents of the technique argue that it can potentially save some patients from the morbidity of a nontherapeutic exploratory laparotomy. Opponents of routine staging laparoscopy argue that improvements in cross-sectional imaging have significantly reduced the number of patients discovered to have occult metastasis and that the extra cost and inefficient use of operative room time do not justify the added expense. Most high-volume pancreatic and hepatobiliary centers employ a selective approach to staging laparoscopy.<sup>16</sup> The likelihood of finding metastatic disease is relatively greater in patients with larger tumors of the body and tail of the pancreas or patients with markedly elevated CA 19-9 (>200 U/mL).

### **Whipple Procedure**

A potentially curative pancreaticoduodenectomy is the preferred approach to resectable periampullary carcinomas. An upper midline or bilateral subcostal incision is used to gain access to the abdomen. The primary survey for an occult metastatic disease is conducted by exploring the entire abdomen with particular attention to the liver, omentum, peritoneal surfaces, and base of the transverse mesocolon. The secondary survey assesses the involvement of the tumor with the adjacent mesenteric vessels. The exact sequence of secondary assessment may vary depending on preoperative imaging and suspicion of potential vascular involvement; however, a consistent and systematic approach is favored to reduce variability and enhance reliability.<sup>17,18</sup>

The duodenum is mobilized and a Kocher maneuver is performed to assess the relationship of the tumor to the SMA and retroperitoneal structures such as the IVC, right renal vein, and aorta. Following this, the SMV is

located as it courses posterior to the neck of the pancreas. It may be helpful to lift up the transverse mesocolon and follow the middle colic vein until it enters the SMV. The tunnel under the neck of the pancreas is cleared by gentle blunt dissection of the SMV away from the posterior neck of the pancreas. The PV assessment on the superior aspect of the pancreas is generally accessed after first ensuring that the common hepatic artery is clear of tumor involvement. The common hepatic artery is identified coursing parallel and close to the superior border of the pancreatic head. Tracing the hepatic artery leads to the gastroduodenal artery tracking in a caudal direction. The gastroduodenal artery is dissected near its origin from the proper hepatic artery and test clamped to ensure adequate flow through the hepatic artery prior to dividing the gastroduodenal artery. Division of the gastroduodenal artery allows for better visualization of the PV and subsequent creation of a tunnel on the cephalad side of the pancreas neck to connect with the prior SMV dissection from below. At this point, the major vascular structures have been evaluated, and an assessment is made regarding the chances of achieving a margin-negative resection with or without the need for vascular reconstruction. If necessary, the procedure can be abandoned at this juncture since no enteric structures have been divided.

Once the decision has been made to proceed with pancreaticoduodenectomy, a cholecystectomy is performed and the common bile duct is encircled, dissected free, and divided around the level of the cystic duct insertion. The decision to perform a pylorus-preserving versus classic Whipple procedure is contingent on local tumor extent and surgeon preference. Each approach has its relative proponents and opponents.<sup>19</sup> If the tumor is well away from the pylorus, a pyloric-preserving approach may be taken by dividing the duodenum 1 to 2 cm beyond the pylorus with a stapling device. If tumor encroaches upon the pylorus, then a wider margin (classic Whipple) with the division of the stomach to include the antrum with the specimen is undertaken. The right gastroepiploic vessels are divided to allow retraction of the stomach out of the field. The previously dissected tunnel posterior to the neck of the pancreas is reaffirmed, and hemostatic stay sutures are placed along the superior and inferior edges of the pancreatic neck to control bleeding, provide retraction, and facilitate exposure of the SMV. While protecting the SMV, the pancreatic neck is divided sharply so that the main pancreatic duct can be easily identified. A frozen section of the pancreatic duct margin is sent early such that additional pancreatic margins

may be obtained before reconstruction. Cautery is applied to control the small vessels bleeding from the cut edge of the pancreas.

Moving approximately 15 to 20 cm distal to the ligament of Treitz, the jejunum is divided with a stapling device. The proximal jejunum and fourth portion of the duodenum are separated from the root of the mesentery using clips or a cautery device to control the many small vessels going to the jejunum. The intestine to be removed with the specimen is passed posterior to the root of the mesentery and into the right upper quadrant. The attachments from the head and uncinate process of the pancreas are carefully dissected away from the SMV and PV, clipping or ligating small venous branches. The duodenum and uncinate process are rotated out of the retroperitoneum to allow dissection along the lateral border of the SMA. Working in a combination of both anterior and posterior approaches, the final attachments of the pancreas to the SMA and SMV/PV are separated. A search for any additional regional lymph nodes is made to ensure an adequate lymph node dissection. Extensive periaortic and vena cava lymph node dissections are not necessary as they have not been shown to improve survival.<sup>20</sup> The specimen is oriented and marked to facilitate pathologic analysis. Careful examination of the retroperitoneal margin is of crucial importance.

Reconstruction is commenced by passing the divided jejunum either through the transverse mesocolon to the right of the middle colic vessels or posterior to the mesenteric vessels to lay in the right upper quadrant as an upside down "J." The body of the pancreas is freed from the splenic vein for approximately 2 cm to provide length for the jejunal anastomosis. An end pancreas to side of jejunum anastomosis is prepared for a mucosa-to-mucosa connection. Fine-caliber absorbable suture is used on the mucosa in an interrupted fashion. Although routine pancreatic duct stenting has not been shown to reduce pancreatic fistula rates,<sup>21</sup> in some patients with a soft pancreatic gland or a small pancreatic duct, a pediatric feeding tube may be sized to the pancreatic duct, trimmed to about 6 cm, and fixed in place across the anastomosis. An outer layer of a permanent suture is used on the serosa and pancreatic capsule to buttress the pancreas against the jejunum. The internal pancreatic stent will generally pass unnoticed in the stool several weeks later.

The hepaticojejunostomy is created about 5 to 10 cm away from the pancreaticojejunostomy. Because the common bile duct has often been obstructed, the bile duct is often dilated and fibrotic, thus facilitating the

anastomosis. This is generally performed in a side jejunum to end common bile duct manner, with a duct-to-mucosal anastomosis using a fine absorbable monofilament in either a running or interrupted fashion. If the bile duct was not obstructed, a small internal stent similar to that used for the pancreatic duct anastomosis may also be used. A few buttressing absorbable outer sutures are placed to hold the jejunum in place against the hilum of the liver.

Reconstruction of the stomach or duodenum to the jejunum is accomplished in an antecolic manner about 20 to 25 cm downstream to the biliary anastomosis. This may be done using stapling devices or with a 2-layer hand-sewn technique according to surgeon preference. Closed suction drains are placed around the pancreatic and biliary anastomoses in an effort to control potential biliary or pancreatic fistulae, which are responsible for much of the morbidity and mortality associated with this operation.<sup>22</sup> Figure 73-7 shows the steps of the Whipple operation with reconstruction.

**FIGURE 73-7** Organs removed during Whipple operation and reconstruction: **(A)** lines of transection on stomach/proximal duodenum, pancreas, and distal duodenum; **(B)** specimen removed during pancreaticoduodenectomy including, gallbladder, duodenum, distal bile duct, and head of pancreas; and **(C)** reconstruction with pancreaticojejunostomy, choledochojejunostomy, and gastrojejunostomy.

## Distal Pancreatectomy

For cancers of the pancreatic body and tail, a distal pancreatectomy and splenectomy compose the preferred operative approach. For benign conditions of the pancreas or very small neuroendocrine tumors, a spleen-preserving distal pancreatectomy may be considered. The reported advantage

of preserving the spleen is due to the potential risk of postsplenectomy sepsis. However, removing the spleen with the tail of the pancreas simplifies the procedure and reduces the risk of significant bleeding associated with the tedious dissection of the splenic artery and vein along the pancreas. Furthermore, the potential for postsplenectomy sepsis in adults is quite low, and this risk can be further mitigated through the administration of vaccination for pneumococcus, *Haemophilus meningitides*, and *Haemophilus influenzae*. For adenocarcinomas and larger neuroendocrine tumors in the pancreas, including the splenectomy enhances the removal of prognostically relevant regional peripancreatic lymph nodes.

Diagnostic and therapeutic laparoscopy can be very useful for tumors in the body and tail of the pancreas. Access to the abdomen can be made by inserting the laparoscope near the umbilicus for the initial exploration to rule out occult metastatic disease. A decision can then be made to proceed with a resection using laparoscopic techniques or converting to an open approach. Similar operative principles apply to either technique. Depending on the size and location of the tumor, either a midline incision or a left subcostal incision may be selected. The lesser sac is entered and the colon is dissected free from the attachments to the stomach and spleen. The short gastric vessels are divided, and the peritoneal attachments between the posterior stomach and anterior pancreas are opened to allow retraction of the stomach cephalad. The peritoneal attachments on the inferior border of the pancreas are divided, and an assessment of the tumor location and anticipated pancreatic transection are noted. Care is taken to identify and preserve the inferior mesenteric vein as it enters the splenic vein posteriorly near or at the SMV–splenic vein junction. The splenic artery is identified on the superior aspect of the pancreas and traced back to its origin near the celiac trunk. The splenic artery is encircled and a test clamp applied to ensure that there is still adequate flow to the liver through the hepatic artery. Tumors in the body and neck region of the pancreas often track along the splenic artery, so it is important to ensure that a clear margin can be established at the takeoff from the celiac trunk. The artery is intentionally secured and divided first to reduce blood loss. The dissection of the pancreas is conducted from lateral to medial (releasing the splenic attachments and lifting the spleen up with the tail of the pancreas) or from medial to lateral by dividing the pancreatic parenchyma first.

Management of the stump of the pancreas is controversial as a variety of techniques have been employed (eg, stapling device, electrocautery,

harmonic scalpel, direct oversewing of the pancreatic duct, or buttressed compression sutures) without any one technique demonstrating a reproducible reduction in pancreatic fistulae.<sup>23</sup> The splenic vein is divided close to the PV while preserving inferior mesenteric vein inflow. Pancreatic fistula is a common complication (20%-30%), and therefore, a surgical drain is left in place adjacent to the pancreatic stump to control any potential pancreatic leak.<sup>22</sup>

## **Palliative Operations**

When patients are discovered to have a metastatic or unresectable disease at the time of operative exploration, it is important to have a good understanding of their symptoms, desires, and estimated life expectancy to inform the decision regarding operative palliation. The additional operative morbidity and mortality must be balanced against estimated life expectancy and the more durable palliation achieved with operative hepaticojejunostomy or gastrojejunostomy. For patients with relatively lower tumor burden and distal bile duct obstruction, an end-to-side Roux-en-Y hepaticojejunostomy provides the most durable intervention for relief of biliary obstruction. The decision regarding the need for relief of potential gastric outlet obstruction can be more challenging because of the vague symptoms often associated with pancreatic head tumors that do not necessarily cause a mechanical obstruction. Furthermore, the published literature regarding gastric outlet obstruction in unresectable pancreatic cancer patients demonstrates a wide range (3%-20%) in the ultimate need for intervention.<sup>24</sup> An antecolic loop gastrojejunostomy is sufficient to allow patients the simple pleasure of being able to eat again. A final consideration for operative palliation is the use of a chemical splanchnicectomy at the time of open operation. The celiac trunk is palpated, and 20 mL of 50% ethanol is injected along either side of the aorta at the level of the celiac plexus with a spinal needle. A prospective randomized trial comparing saline to 50% ethanol injection demonstrated superior pain control at 2 to 6 months in the ethanol group.<sup>25</sup>

## **Minimally Invasive Pancreatic Surgery**

### **LAPAROSCOPIC PANCREAS SURGERY**

Laparoscopic surgery has become the standard of care for several abdominal operations. The inherent challenges of pancreas surgery, including the retroperitoneal location of the pancreas, proximity to the mesenteric and hepatic vasculature, and the technical challenge of reconstruction, have slowed the acceptance of laparoscopic pancreas surgery and specifically the pancreaticoduodenectomy. However, this is an emerging field that continues to gain acceptance and, in the appropriate clinical scenario, can potentially minimize operative morbidity and blood loss while improving the quality of life. Since the first reported cases of a laparoscopic distal pancreatectomy and a laparoscopic pancreaticoduodenectomy in the 1990s, the acceptance and adoption of these complex minimally invasive operations has increased.<sup>26</sup> There is also a continually growing body of literature that demonstrates that these minimally invasive procedures can offer benefits when compared to their open counterparts. While initial reports argued these operations should be reserved for benign surgical indications, there is now increasing evidence that minimally invasive resections for malignancies not only are feasible but may also reduce morbidity and improve subsequent delivery of adjuvant therapy.

The first laparoscopic pancreaticoduodenectomy was reported in 1994, and as a result of more reports in the literature showing that laparoscopic pancreaticoduodenectomy can be performed safely and with acceptable complication rates, the popularity has been increasing, particularly in the past decade. There have been several retrospective studies that have attempted to compare laparoscopic versus open pancreaticoduodenectomy. Asbun and Stauffer<sup>27</sup> compared a cohort of 53 laparoscopic pancreaticoduodenectomies versus 215 open procedures from 2005 to 2011.<sup>27</sup> In this cohort of patients, the laparoscopic group had significantly less blood loss (1032 vs 195 mL), fewer transfusions (4.7 vs 0.64 units), shorter intensive care unit stays (3 vs 1.1 days), and shorter overall hospital stays (12.4 vs 8 days). Complication rates were similar between the 2 groups. Oncologic outcomes demonstrated that the number of lymph nodes removed was greater for the laparoscopic group (16.84 vs 23.44 nodes) and margin status was equivalent. Operating time was significantly longer in the laparoscopic group (401 vs 541 minutes). Although the cohorts in this study were well matched, if major vascular resection was required, open surgery was performed, adding some selection bias.

Croome and Yamashita<sup>28</sup> went on to look specifically at patients

undergoing resection for pancreatic ductal adenocarcinoma and compared 108 laparoscopic pancreaticoduodenectomies to 214 open resections. Importantly, these 2 groups were equivalent with regard to tumor size, T stage, and tumor grade.<sup>28</sup> When comparing the 2 approaches, they found similar node resection rates, margin status, and postoperative complications. Notably, they showed that the laparoscopic cohort required fewer blood transfusions (19% vs 33%) and had a shorter time to initiation of adjuvant therapy (59 vs 48 days), and there was a significantly higher proportion of patients in the open cohort (12%) who had a delay of over 90 days or who did not receive adjuvant chemotherapy at all compared to the laparoscopic cohort (5%). There was no overall survival difference between the 2 groups after a median follow-up of 16 months, but there was a significant improvement in progression-free survival in the laparoscopic group. This study clearly illustrates that in an experienced center, laparoscopic pancreaticoduodenectomy can be safely performed for pancreatic ductal adenocarcinoma with comparable oncologic resections. Laparoscopic resection may also improve outcomes by reducing transfusion burden and increasing successful delivery of adjuvant therapy, which may have long-term implications.

## **ROBOTIC PANCREATIC SURGERY**

Robotic pancreatic surgery is another area of growing interest that has not been studied yet in as much depth as laparoscopic pancreatic surgery. The first robotic distal pancreatectomy was described in 2003.<sup>29</sup> Shortly thereafter, this was followed by the first description of a robot-assisted pancreaticoduodenectomy in which laparoscopy was used for pancreatic resection and the robot was used to perform intracorporeal biliojejunal and gastrojejunal anastomoses. Subsequent refinements of the robotic technique have resulted in total robotic pancreaticoduodenectomies.

The largest series studying robotic distal pancreatectomies and pancreaticoduodenectomies originate from the University of Pittsburgh. Shakir et al<sup>30</sup> reported a series of the first 100 robotic distal pancreatectomies performed from 2008 to 2013 at the University of Pittsburgh. In this study, they identified a learning curve of 40 cases, after which significant reductions were seen in the operative time (from 331 to 210 minutes) and readmission rates (from 28% to 20%). Boone et al<sup>31</sup> from this same group reported a

series of 200 consecutive robotic pancreaticoduodenectomies from 2008 to 2014. In this study, a significant learning curve was again reported, with improvements in blood loss and conversion to open surgery after 20 cases (600 vs 250 mL and 35% vs 3.3%, respectively), reduction in incidence of pancreatic fistula after 40 cases (27.5% vs 14.4%), and reduction in operative time after 80 cases (581 vs 417 minutes). In both of these series, the authors demonstrate that after optimization beyond the learning curve, robotic distal pancreatectomies and pancreaticoduodenectomies can be performed with longer operative times but with similar mortality and morbidity rates compared to historical open standards.

To more directly compare robotic versus open pancreaticoduodenectomy, a multicenter study was recently completed comparing perioperative data for patients who underwent robotic (211 patients) versus open (817 patients) pancreaticoduodenectomies.<sup>32</sup> The robotic procedures were performed at centers within the United States that perform a large number of these procedures annually, and only operations performed “after the learning curve” were analyzed. The robotic procedure was found to have longer operative times by 75 minutes, reduced blood loss, and an overall reduction in major complications. However, hospital lengths of stay and readmission rates were equivalent. Future analysis of robotic pancreatic resection that critically appraises the cost-benefit analysis of the robotic platform, quality of life, and long-term outcomes will be important in understanding the future role of robotics in pancreatic surgery.

## Technique

At our institution, we offer the laparoscopic approach for pancreas surgery for anyone who has a resectable lesion. Relative contraindications include body mass index  $>35 \text{ kg/m}^2$ , borderline lesions, and neoadjuvant treatment of cancer.

We start the operation with 5 ports to create a semicircle around the pancreas. After evaluating the abdomen for the absence of metastatic disease in the lesser sac, the hepatic and gastroduodenal arteries are identified. Dissection and ligation of the gastroduodenal artery are done, allowing for orientation and evaluation of the PV below. At this point, attention is redirected to the SMV, along the lower edge of the pancreas in relation to the

previously identified PV. This is followed by the creation of the tunnel underneath the neck of the pancreas. Once completed, the gallbladder is taken down from the gallbladder fossa and used for retraction to allow dissection and transection of the common bile duct. At this point, the ligament of Treitz is dissected and opened by extending our Kocher maneuver. The proximal jejunum is brought through and is then stapled and transected.

Attention is brought back to the right upper quadrant where the distal stomach is stapled and transected. The neck of the pancreas is also transected, paying attention to good hemostasis of the superior and inferior pancreaticoduodenal artery branches. The transected jejunum mesentery is taken down leading to the uncinate process. This leaves an excellent view of the SMA, allowing for transection of the uncinate process right along it.

Finally, the 3 anastomoses are completed, in a similar fashion to the open technique, using intracorporeal knots in either a running or interrupted fashion to the jejunum, which is already in proper position from the previous maneuvers and brought through the previous ligament under the mesenteric vessels. We have found that a pediatric feeding tube for both the pancreas and bile duct facilitates the anastomosis laparoscopically.

## **POSTOPERATIVE CARE AFTER PANCREAS SURGERY**

Pancreatic head resections are complicated procedures with high rates of postoperative morbidity. Rates of postsurgical complications have been decreasing over the past several years, resulting in significant improvement in perioperative mortality. This substantial change can be attributed to multiple factors; nevertheless, a standardized approach to operative technique, postoperative care, refined intraoperative resuscitation, and clear communication between various teams are all critical in our experience.

We consider optimizing intraoperative patient resuscitation a high priority; this consists of formulating a dedicated team of anesthesiologists with a consistent approach to intraoperative resuscitation. Operations performed with minimal blood loss should obviously be resuscitated differently than the rare cases of massive blood loss. Over- or underresuscitation will lead to an increased risk of postoperative complications.

A direct and detailed checkout process between the operating and critical

care teams is important to reduce the risk of any potential miscommunication. We developed a standardized postoperative order set to improve adherence to our postoperative pancreas resection protocol. We familiarized our surgical unit nurses with our postoperative recovery pathway and significantly improved communication between physicians and nurses. We set up regular meetings to continue to improve our intra- and postoperative care

Our current post-Whipple pathway ([Table 73-1](#)) includes close observation in a monitored unit for the first 24 hours. We usually transfer patients to a dedicated surgical nursing unit on postoperative day (POD) 2. Nasogastric tubes are generally discontinued on POD 1 depending on output. Ice chips and sips of water are permitted early on. Aggressive use of incentive spirometers, early ambulation, and tight blood sugar control are critical. The formal introduction of a clear liquid diet usually waits until POD 3 or 4. Regular diet is usually introduced in the next 48 hours. Nausea and vomiting may be rate-limiting steps to advancing diet.

**TABLE 73-1: POSTPANCREATICOUDENECTOMY PATHWAY**

POD	POD 0 (day of surgery; direct transfer from OR to SICU; extubate in OR)	POD 1 (SICU; transfer to surgical specialty in morning if no issues)	POD 2	POD3	POD 4	POD 5	POD 6 (discharge)
Labs	CBC, CMP, Mg, Phos, ABG, serum amylase	CBC, CMP, Mg, Phos, coagulation tests	CBC, CMP, Mg, Phos	No labs	CBC, CMP, Mg, Phos	Drain amylase after breakfast	CBC, CMP, Mg, Phos; drain amylase after breakfast if needed
Medications	SSI, PCEA/PCA, PPI, LR at 150 or as ordered, SQH every 8 h, octreotide, erythromycin	SSI, PCEA/PCA, PPI, LR at 84 or as ordered, SQH every 8 h, wean O <sub>2</sub> as per protocol, PO medication okay if no NGT, tamsulosin (Flomax) if needed	SSI, PCEA/PCA, PPI, D5 ½ NS + 20 KCl at 20, SQH every 8-12 h, docusate BID, insulin coverage	SSI, PCEA/PCA, PPI, D5 ½ NS + 20 KCl at 20, SQH every 8-12 h, docusate BID, insulin coverage	SSI, PO pain pills, discontinue PCEA/PCA after PO pain pill given, PPI, discontinue IVF, SQH every 8-12 h, docusate BID, pancrelipase (24,000 units TID with meals)	SSI, PO pain pills, PPI, docusate BID, SQH every 8-12 h, pancrelipase	SSI, PO pain pills, PPI, docusate BID, pancrelipase; <i>all patients discharged home on PPI</i>
Diet	NPO	Sips/chips <250 mL/4 h	Sips/chips <250 mL/4 h	Clear liquid diabetic diet	Post-Whipple diet	Post-Whipple diet	Post-Whipple diet
Activity	OOB/TC; IS 10 times per hour	OOB as tolerated; IS 10 times per hour; pulmonary toilet	OOB, laps × 3; IS 10 times per hour; pulmonary toilet	OOB, laps × 4; IS 10 times per hour; pulmonary toilet	OOB, laps × 5; IS 10 times per hour; pulmonary toilet	OOB, laps × 6; IS 10 times per hour; pulmonary toilet	OOB; home with IS
Devices/ tests	NGT to LIWS (flusing protocol), JP drains to bulb suction, SCDs, TEDs, Foley	Discontinue NGT unless laparoscopic Whipple (in which case keep in until POD 3); JP to bulb suction; maintain Foley and SCDs while in bed; TEDs	Discontinue Foley, JP to bulb suction, SCDs at night	Discontinue NGT if laparoscopic Whipple; JP to bulb suction	JP to bulb suction	Discontinue JP1 if appropriate; otherwise, send home with drain	Discontinue JP2 if appropriate; otherwise, send home with drain(s)
Physician notes	PT/OT consult; no CPAP postoperatively; GMT consult	Discontinue arterial line or central line, if applicable; transfer to floor order in by 8:00 AM with telemetry	Case management consult; diabetes educator consult	Nutrition consult	Change insulin to AC + HS, cover >120	Insulin AC + HS; tee up for discharge; all paperwork completed and scripts written	Discharge order; <i>vaccines if distal pancreatectomy/ splenectomy</i>
Nurse notes	Vitals every hour; POCG every 4 h; flush NGT every 6 h with 30 mL	Vitals every 4 h; POCG every 4 h; patient OOB; all labs checked; flush NGT every 6 h with 30 mL until discontinued; PT/OT consult	Void check 6 h after Foley discontinued; vitals every 4 h; POCG every 4 h; PT/OT consult; social work consult (if needed); labs checked	Vitals every 8 h; POCG every 4 h; encourage PO intake; nutrition C/S education	Vitals every 8 h; POCG AC + HS; encourage PO intake; labs checked; drain teaching initiated (if needed); nutrition and medication education	Drain amylase after breakfast; reinforce drain teaching and medication and nutrition education; reinforce glucose management; ensure patient has glucometer; prescriptions sent to pharmacy	See POD 5; discontinue IV catheter

Abbreviations: ABG, arterial blood gas; AC, before meals; BID, twice a day; CBC, complete blood count; CMP, comprehensive metabolic panel; CPAP, continuous positive airway pressure; D5, dextrose 5%; GMT, geriatric medicine team; HS, at bedtime; IS, incentive spirometry; IV, intravenous; IVE, intravenous fluid; JP, Jackson-Pratt; KCl, potassium chloride; LIWS, low intermittent wall suction; LR, lactated Ringer's; Mg, magnesium; NGT, nasogastric tube; NPO, nothing by mouth; NS, normal saline; OOB, out of bed; OOB/TC, out of bed to chair; OR, operating room; OT, occupational therapy; PCA, patient-controlled analgesia; PCEA, patient-controlled epidural analgesia; Phos, phosphate; PO, oral; POCG, point-of-care glucose; POD, postoperative day; PPI, proton pump inhibitor; PT, physical therapy; SCD, sequential compression device; SICU, surgical intensive care unit; SQH, subcutaneous heparin; SSI, sliding scale insulin; TED, thromboembolic deterrent hose; TID, 3 times a day.

While previous studies showed no difference between pylorus preservation and classic Whipple operations, we found that transection of the very distal stomach, just above the pylorus, with a wide antecolic gastrojejunostomy reconstruction, has reduced delayed gastric emptying substantially. Delayed gastric emptying is usually self-limited. Nasogastric tube reinsertion may become necessary in the setting of delayed gastric emptying; it is paramount that this is done by experienced personnel sometimes under fluoroscopic guidance to avoid any insertion-related complications. Parenteral nutrition is usually initiated after POD 7 to 10 if there is still no hope for adequate oral intake. Motility agents have been shown to improve gastric emptying after pancreaticoduodenectomy.

The Achilles heel of pancreatic resections is pancreatic duct leak (Figs 73-8 and 73-9). A meticulous surgical technique is key to reduce this potentially life-threatening complication. Reported leak rates are highly variable and dependent on definition. Volume-only-based definitions are difficult to interpret. The most commonly used definition compares serum amylase

levels with drain amylase levels. Surgically placed drains have been shown to decrease morbidity and mortality from pancreas juice leaks.<sup>33</sup> Systemic signs of infection (eg, fever, elevated white blood cell count) on POD 4 to 5 or later should prompt laboratory and radiographic workup. Postoperative abdominal or retroperitoneal fluid collections should raise suspicion for an anastomotic/pancreatic juice leak. These fluid collections should be drained and samples sent for amylase levels and cultures for targeted antibiotic therapy under appropriate circumstances. Pancreatic leaks in the setting of dilated ducts and firm pancreas in pancreatic cancer patients should be low. Patients with small pancreatic ducts and soft pancreas with other types of periampullary cancers (eg, bile duct, ampulla) are at higher risk for an anastomotic leak.

**FIGURE 73-8** Extravasation of contrast from main pancreatic duct.

**FIGURE 73-9** Computed tomography image of postoperative pancreas leak.

The need for postsurgical drain placement after pancreaticoduodenectomies has been questioned. Some retrospective studies failed to show a clear benefit to routine drainage. However, a recent prospective, randomized, multicenter study showed that elimination of intraoperative drainage following pancreaticoduodenectomies increases the frequency and severity of complications.<sup>22</sup> Drain placement significantly decreased gastroparesis, intraabdominal fluid collections, intraabdominal abscesses, severe diarrhea, need for postoperative drain placement, hospital stay, and mortality. The data safety monitoring board terminated the study early secondary to the significantly increased mortality in the no-drain group.

We favor intraoperative drain placement as well, because it decreases the

severity of postoperative complications in our experience. Surgically placed drains are routinely tested for amylase levels and compared with serum levels after advancement to regular diet.

A prospective study from Europe found that early drain removal in a selected group of patients could be beneficial, as it was associated with a lower pancreatic fistula rate and decreased abdominal/pulmonary complications, resulting in decreased hospital stay and cost.<sup>33</sup>

Management of high-output fistulas can be more challenging. Drains should be well secured to prevent accidental removal. Decreasing drain output can be managed with slow, gradual removal of external drains allowing enough time for the tissue around the drain to form a track. In the setting of persistently high drain output, nothing by mouth (NPO) status with total parenteral nutrition should be considered.

The role of octreotide remains controversial. Theoretically, somatostatin and its analogs are decreasing enteric secretions, but systematic reviews have failed to identify significant differences in postoperative mortality. Somatostatin can be helpful in the control of high-output fistulas.

Pasireotide was shown to decrease clinically significant pancreatic fistulas and abscesses in a recently published single-institution randomized clinical trial. Three hundred patients were randomized to receive 900 µg of subcutaneous pasireotide or placebo twice daily for 7 days. The rates of clinically significant postoperative fistulas, leaks, and abscesses were all significantly lower in the pasireotide group after pancreaticoduodenectomies or distal pancreatectomies.<sup>34</sup>

Postpancreatectomy hemorrhage is a rare but serious postoperative complication. It is frequently associated with a pancreatic anastomotic leak and can present with blood loss via abdominal drains, hematemesis/melena, unexplained hypotension, or as a laboratory finding. Sentinel bleed (small amount of blood in a drain hours before massive hemorrhage) could be a warning sign and has to be taken seriously. The final diagnosis is made via CT scan or angiography (Fig. 73-10). We consider angiography the gold standard (Fig. 73-11). The risk of the dreaded bleeding from the gastroduodenal artery can be minimized with a careful intraoperative management of the gastroduodenal artery stump via double tying or clipping the arterial stump with nonabsorbable suture.

**FIGURE 73-10** Postoperative computed tomography scan of intravenous contrast extravasation from gastroduodenal artery stump (marked by *arrow*).

**FIGURE 73-11 A and B.** Angiographic image of gastroduodenal artery stump leak before and after coil placement.

Postpancreatectomy chyle leak is infrequent and usually self-limiting. A low-fat diet should be considered in most cases; nevertheless, persistent leak or high-output fistulas should be treated with NPO status and total parenteral

nutrition. A recent consensus statement by the International Study Group on Pancreatic Surgery defined chyle leak as the occurrence of a milky colored fluid output from a drain on or after POD 3 with triglyceride content of greater than 100 mg/mL. Three different grades of severity were defined as follows: grade A, oral dietary restrictions; grade B, prolonged hospital stay, total parenteral nutrition, octreotide, or drain placement; and grade C, intensive care unit admission or mortality.<sup>35</sup>

## **SURGICAL OUTCOMES**

### **Postoperative Complications**

Perioperative morbidity and mortality for major pancreatic resections have declined significantly over the past 2 decades. An increasing number of publications have addressed the surgical volume-outcome relationship. There is mounting evidence that complex pancreaticobiliary resections should be performed in high-volume centers to decrease postoperative complications.<sup>36</sup> The exact definition of a high-volume surgeon or center is debated; however, 10 to 12 cases per year usually qualifies as high volume.

Although postsurgical mortality in high-volume centers is low (0%-3%), postoperative morbidity continues to remain high (30%-50%). The frequent serious postoperative complications are delayed gastric emptying (15%-20%), pancreatic anastomotic leak (10%-20%), wound infection (8%-10%), intra-abdominal (8%-10%) abscess, postoperative hemorrhage (1%-8%), and pancreas fistula (5%).<sup>18</sup>

The International Study Group of Pancreatic Surgery has greatly contributed to our understanding and better definition of postoperative complications. A series of publications by this group standardized definitions for postpancreatectomy hemorrhage, delayed gastric emptying, and pancreatic anastomotic leakage. Postpancreatectomy hemorrhage has been categorized by 3 important parameters: onset (before or after 24 hours from the time of surgery), location (intra- or extraluminal), and severity (low or high). Delayed gastric emptying has been defined as the inability to return to a standard diet by the end of the first postoperative week. Categories of A, B, and C have been established considering the inability to tolerate solid food by 7, 14, or 21 days or nasogastric tube requirement by 3, 7, or 14 days

postoperatively or reinsertion of a nasogastric tube between the days mentioned above. Postoperative pancreatic fistula has been defined as drain output of any measurable volume of fluid on or after POD 3 with amylase content greater than 3 times the serum amylase activity, with the following grades established: A (no clinical impact), B (deviation from normal postoperative course, percutaneous drain placement), or C (reoperation or death). Measurable drain output past 3 days with negative drain amylase signals no leak in the majority of patients in our experience.

## **SURVIVAL, ADJUVANT, AND NEOADJUVANT THERAPY**

### **Survival**

Surgically treated periampullary cancers continue to have high recurrence rate and poor overall survival. Only a small minority (15%) of all newly diagnosed patients undergo curative-intent surgical resections. Long-term survival in periampullary cancers is a rare event. A recent paper using a large population-based dataset identified lymph node ratio (number of nodes harboring disease/total number of nodes examined), adjuvant chemotherapy, and pathologic T stage as being the top 3 variables associated with long-term survival in pancreatic cancer patients.<sup>37</sup> Ten-year overall survival in over 11,000 surgically treated patients was 3.9% (Fig. 73-12). The authors developed an easy to use nomogram to help identify potential long-term survival from surgically treated pancreatic cancer (Fig. 73-13 and Table 73-2)

Patients at risk 11912 6778 3457 2172 1625 1311 1011 841 725 602 431 265 144 61 15

The presence or absence of nodal disease has been shown to impact survival in multiple previous studies. A recent meta-analysis examined overall survival rates in surgically treated periampullary cancers based on the location of the positive node. Intraoperatively diagnosed nodal disease in a hepatic artery node resulted in no 3-year survivors, compared with a 23% 3-year survival rate in patients with nodal disease and without hepatic artery nodal involvement. Para-aortic nodal involvement discovered intraoperatively resulted in even worse survival rates. These retrospective data suggest that in addition to lymph node ratio, the exact location of nodal involvement has additional significant implications on postsurgical survival in periampullary cancers.<sup>38</sup>

Autopsy series have suggested that there are 2 major groups of patients with advanced pancreas adenocarcinoma: those who die from bulky metastatic disease and those who die from complications of locoregional tumor recurrence. The first group of patients appears to be much more predominant in our experience. As a result, certain subgroups of patients may benefit from increased intensity therapy locally, whereas other groups may

benefit from increased systemic therapy.

The relative contribution of various treatment modalities to survival in periampullary cancers continues to be debated. Currently, accepted treatment modalities include surgery, chemotherapy, and radiation in various combinations. Preoperative or adjuvant chemotherapy likely meaningfully increases chances of survival, although the benefit is likely on the order of months rather than years.

Large population-based studies continue to show dismal results, with overall survival as low as 13 months, in the setting of curative intent resection for pancreatic adenocarcinoma followed by adjuvant chemotherapy. Even today, selected centers of excellence continue to report median survival times of 24 months or shorter for pancreatic cancer treated with curative intent surgery and adjuvant therapy.<sup>39</sup> This translates into a 5-year survival of about 20%.<sup>40</sup>

Five-year survival of patients with resected invasive ampullary adenocarcinoma is significantly better (40%-50%). Patients with resected distal bile duct cancer seem to be surviving longer than pancreatic cancer patients but shorter than patients with invasive ampullary cancers (25%-30%). Patients with duodenal cancer have 5-year survival rates comparable to patients with ampullary cancers (45%). Surgical margin status and the presence of lymph node metastasis continue to be strong predictors of long-term outcome for all periampullary cancers.<sup>40</sup>

## Adjuvant Therapy

The benefits of adjuvant chemotherapy and radiation in resected, early-stage periampullary cancers are poorly studied. Earlier published trials lumped various periampullary tumors together or enrolled metastatic and locally advanced patients, making interpretation of these studies difficult. Adjuvant therapy is typically administered 1 to 2 months after surgery. Postoperative complications can delay adjuvant treatment. The best adjuvant chemotherapy combination continues to be debated.

The first adjuvant therapy for pancreas adenocarcinoma dates back to 1985. This small phase III trial randomized patients to receive adjuvant fluorouracil (FU) and radiation versus observation in the postoperative setting. The adjuvant therapy group had a significant survival advantage (20

vs 11 months).<sup>41</sup>

A phase III European Organization for Research and Treatment of Cancer trial studied adjuvant radiotherapy and FU following curative-intent resection of cancers of the pancreas and periampullary region. Two hundred and eighteen patients were randomized to adjuvant therapy or observation, with over half of the patients having pancreatic cancer. When results were stratified by tumor location, the 2-year survival rate was 63% in the observation group and 67% in the treatment group. Progression-free survival was also similar between treatment groups.<sup>42</sup>

Although gemcitabine showed promise in early clinical trials, it had no survival benefit over FU plus folic acid, with both arms having a median overall survival of 23 months, in the European Study Group for Pancreatic Cancer (ESPAC)-3 trial for surgically resected pancreatic adenocarcinoma.<sup>43</sup> Gemcitabine has been combined with various other drugs in multiple other studies without a significant improvement in overall survival. A more recently published study from Europe compared single-agent gemcitabine (11% response rate) with a combination regimen (FU, leucovorin, irinotecan, and oxaliplatin [FOLFIRINOX]; 31% response rate) in the setting of stage IV pancreatic cancer. Similarly, in the metastatic setting, the combination of nab-paclitaxel plus gemcitabine increased median overall survival by nearly 2 months, compared to gemcitabine alone.<sup>44</sup> Although results from these trials enrolling patients with metastatic pancreatic cancer are not directly applicable to patients with resected pancreatic cancer, early clinical trials and retrospective studies using neoadjuvant FOLFIRINOX in locally advanced pancreatic cancer are encouraging.<sup>11</sup>

The recently presented ESPAC-4 trial showed potentially promising advances in the adjuvant treatment of surgically resected pancreatic cancers. Seven hundred and thirty-two patients were randomized to receive the standard of care (gemcitabine) or gemcitabine plus capecitabine for 24 weeks within 12 weeks of surgery. The median overall survival was 28 months for the combination regimen versus 25.5 months for gemcitabine alone; however, the estimated 5-year survival rates were 28.8% and 16.3%, respectively, for the 2 groups, with comparable rates of toxicities.<sup>45</sup>

The role of radiation in the treatment of periampullary cancers is even more debatable. Because most patients experience recurrence with distant disease, systemic chemotherapy is usually given before radiation. A

controversial, prospectively randomized trial studying the effects of radiation in pancreatic cancer from Europe (ESPAC-1) showed potentially detrimental effects of postoperative radiation.<sup>46</sup> Other retrospective reviews showed potential benefit, but the effects of radiation are difficult to separate from the potential benefits of chemotherapy. Study outcomes have also been scrutinized by the inclusion of patients with positive or unknown surgical resection margin status. Radiation may be best used in the setting of preoperative chemoradiation in pancreatic cancer for concerns of major vessel involvement or for close or involved resection margins in the postoperative setting for periampullary tumors, but the data, especially in ampullary and biliary cancers, are rather sparse.

The Advanced Biliary Cancer (ABC)-02 trial randomly assigned over 400 patients with locally advanced or metastatic cholangiocarcinoma, gallbladder cancer, or ampullary cancer to receive either cisplatin followed by gemcitabine or gemcitabine alone. Median overall survival was 11.7 months in the cisplatin-gemcitabine group compared with 8.1 months in the gemcitabine-only group. While combining cisplatin with gemcitabine appears to be beneficial in locally advanced or metastatic cholangiocarcinomas and ampullary cancers, the trial obviously provides no evidence for its use in resected, early-stage cancers.<sup>47</sup>

## Neoadjuvant Therapy

Several studies examined the risks and benefits of neoadjuvant chemotherapy or chemoradiation in the setting of resectable and locally advanced pancreatic cancer. Arguments used for administration of neoadjuvant therapy include the following: high risk of undiagnosed stage IV disease (15%-30%); conversion of locally unresectable disease to resectable disease (15%-40%); preoperative radiation given in well-vascularized tissue may be more effective; preoperative selection tool in patients with marginal candidacy for surgery from a general medical standpoint; increase in margin-negative resection rate; and most patients will receive some form of chemotherapy or radiation (up to 100%), as opposed to the large number of patients having to omit or delay adjuvant therapy secondary to postoperative complications (up to 40%).<sup>48</sup>

Neoadjuvant therapy remains highly controversial in localized disease,

even for pancreatic cancer, where it has been the most studied. Some investigators reported overall survival of approximately 3 years after administration of neoadjuvant chemoradiation to patients with resectable pancreatic cancer.<sup>48</sup> This survival time is almost a year longer compared with survival curves reported from other major institutions in the United States<sup>39</sup> in the setting of curative intent surgery followed by adjuvant therapy. However, these findings are not uniform, and recent meta-analysis of studies addressing potential benefits of neoadjuvant treatment for pancreatic cancer found little to no evidence of survival benefit for resectable or borderline resectable tumors treated in a neoadjuvant fashion. Given all the above, surgically resectable periampullary cancers undergo upfront surgery in our practice.

Neoadjuvant therapy for borderline resectable pancreatic cancer is more accepted. Several societies published papers on their definition of borderline resectable disease, but one could still argue for a more rigorous definition to facilitate comparison of clinical trials and for developing a more homogenous treatment approach. All definitions are based on the relationship of the primary tumor and surrounding important vasculature. The Americas Hepatopancreatobiliary Association/Society for Surgery of the Alimentary Tract/Society of Surgical Oncology/National Comprehensive Cancer Network definition of borderline resectable pancreatic tumors includes the following: (1) venous involvement of the SMV/PV demonstrating tumor abutment, encasement, short segment venous occlusion but with suitable vessel proximal and distal to the area of the vessel involvement, for safe resection and reconstruction; (2) gastroduodenal artery encasement up to the hepatic artery and short segment encasement/direct tumor abutment of the hepatic artery with no extension to the celiac trunk; and (3) less than 180-degree involvement of the SMA.<sup>49</sup> A more recent simplified definition by Cao et al<sup>50</sup> used a tumor vein circumferential interface grouping (TVI) system, as follows: no interface, <180 degrees of vessel circumference, or >180 degree of vessel circumference or occlusion.

The best neoadjuvant therapy protocols continue to be debated. Several centers, including ours, have used regimens used in clinical trials for stage IV disease with reasonable safety profiles (FOLFIRINOX, nab-paclitaxel, and gemcitabine). Gemcitabine-based chemoradiation protocols have also been studied in clinical trials.<sup>51</sup> Patients should undergo a thorough clinical and

radiographic reevaluation after neoadjuvant therapy to rule out newly developed stage IV disease. Surgery should be performed within 4 to 8 weeks after completion of neoadjuvant therapy. Delaying surgery beyond 3 months following the administration of neoadjuvant radiation could result in more challenging operations with potentially further increased risk of complications secondary to radiation-induced fibrosis in our experience.

We recommend starting neoadjuvant therapy with induction chemotherapy. This approach spares the potential toxicities of radiation in that relatively large subset of patients (up to 30%) who develop widespread stage IV disease while receiving induction chemotherapy. Standard-dose radiation therapy is 50.4 Gy in 1.8 Gy fractions. However, recent developments in radiation therapy, such as intensity-modulated radiation therapy and stereotactic body radiation therapy, have resulted in higher biological doses and fewer toxicities with potential improvement in outcomes.

## **Immunotherapy**

Immunotherapy is an emerging modality for many cancers such as melanoma and renal cell cancer. However, its role in pancreatic cancer has yet to be defined.<sup>52</sup> The purpose of immunotherapy is to activate both the cellular and humoral immune components of the immune system. It is an attractive modality because it has a distinct toxicity profile from chemotherapy and radiation therapy. It can reach all areas in the body and potentially allow for memory to prevent recurrence. Pancreatic cancer was originally thought to be poorly immunogenic. However, recent data suggest otherwise. For example, patients with higher levels of CD4+ and CD8+ tumor-infiltrating lymphocytes had longer overall survival after surgical resection.<sup>53</sup>

Since 1995, there have been 4 peptide vaccine trials, 2 recombinant vaccine trials, 1 dendritic cell vaccine, 4 whole cell vaccines, and 1 combination immunotherapy trial. Although encouraging, the results from single-agent immunotherapy in pancreatic cancer patients have been disappointing. Because pancreatic cancer is an immune-tolerant tumor, the treatment strategy requires all modalities: surgery, chemotherapy, radiation, and immunotherapy. The future of pancreatic cancer immunotherapy lies in identifying more tumor antigens, targeting multiple antigens, incorporating

checkpoint blockade inhibitors, and tumor microenvironment manipulation. The role will be better understood with continued clinical trials.<sup>8</sup>

## FUTURE DIRECTIONS

Progress in the neoadjuvant and adjuvant therapy of periampullary cancers has been modest at best. Slight improvements in survival have been observed with the use of various polychemotherapy combinations. To date, new targeted therapies have shown little to no significant impact on survival. Similarly, administration of targeted agents mostly in conjunction with gemcitabine blocking a single pathway in a molecularly unselected patient population has not led to consistent improvements. Strategies involving blockade at multiple levels may be more promising given the complexity of the pancreatic cancer genome. A better understanding of the molecular and genetic pathophysiology of periampullary adenocarcinomas will hopefully open up new treatment opportunities in the future.

# ENDOCRINE TUMORS OF THE PANCREAS

*Mary E. Dillhoff • E. Christopher Ellison*

## INTRODUCTION

Pancreatic neuroendocrine tumors (PNETs), traditionally termed *islet cell tumors*, are rare cancers occurring in approximately 1000 patients per year in the United States, representing 3% of all pancreatic tumors.<sup>1</sup> The incidence of neuroendocrine tumors has increased over the last three decades, likely from increased use of and improvement in imaging modalities.<sup>2-4</sup> The incidence overall of PNETs is increasing from .17 per 100,000 people in 1973 to .47 per 100,000 people in 2007.<sup>5</sup> The peak incidence for PNET is between the ages of 40 and 69 years. While survival is significantly longer than patients with pancreatic adenocarcinoma, once patients have metastatic disease cure is not likely. However, surgical treatment plays a very important role in palliation of symptoms from hormone-producing tumors. Overall survival rate of resected tumors is 55%, but is only 15% with metastatic disease. Surgical resection for localized disease is the only curative treatment. The majority of PNETs are nonfunctional; however, some may secrete active gastrointestinal hormones that produce clinical syndromes. Most tumors are

sporadic; however, some are associated with syndromes such as multiple endocrine neoplasia (MEN), von Hippel–Lindau syndrome, neurofibromatosis, tuberous sclerosis, and von Recklinghausen syndrome. Tumors associated with MEN syndromes are more likely to be aggressive and multifocal.

PNETs have a wide spectrum of biologic behavior. Some are low grade and indolent, while others behave aggressively and have a propensity to metastasize. Some functional tumors are more likely to be benign, such as insulinomas, while others such as glucagonomas are almost always malignant. Tumors may produce multiple hormones complicating the diagnosis. The functional tumors typically produce symptoms related to the dominant hormone that is produced. This chapter reviews the clinical syndromes, workup, and treatment for pancreatic endocrine tumors.

## ANATOMY AND PHYSIOLOGY

Endocrine tumors of the pancreas originate from islet cells, hence the traditional name of islet cell tumors. The islets arise from either neural crest cells or embryonic foregut endoderm. They appear histologically similar to carcinoid tumors of the gastrointestinal tract. The tumors are broadly classified into functional and nonfunctional tumors. Nonfunctional tumors compose 40% to 90% of all PNETs and are more common than functional tumors. Functional tumors cause symptoms that are indicative of the hormone the tumor produces. Most commonly these include gastrinomas, vasoactive intestinal polypeptide-secreting tumors (VIPomas), glucagonomas, somatostatinomas, and other rare functional tumors (Table 74-1; Fig. 74-1).

**TABLE 74-1: FUNCTIONAL TUMOR TYPES**

Cell Type	Hormone	Tumor Type	Presentation	Location	Malignant
Alpha	Insulin	Insulinoma	Whipple triad	Entire pancreas	10%
Beta	Glucagon	Glucagonoma	Necrolytic migratory erythema	Tail	>70%
Delta	Somatostatin	Somatostatinoma	Diabetes, diarrhea, cholelithiasis	Pancreas, duodenum, small bowel	70%
G	Gastrin	Gastrinoma	Ulcer disease	Passaro triangle	
D <sub>2</sub>	VIP	VIPoma/WDHA	Watery diarrhea, hypokalemia, achlorhydria	Tail	50%

**FIGURE 74-1** Incidence of pancreatic endocrine tumors.

The endocrine portion of the pancreas makes up about 1% to 2% of the gland by weight. Pancreatic islets are composed of four main cell types: alpha cells that secrete glucagon, beta cells that secrete insulin and amylin, delta cells that secrete somatostatin, D<sub>2</sub> cells that secrete vasoactive intestinal peptide (VIP), and F cells that secrete pancreatic polypeptide (PP). The distribution of the endocrine cell types varies within in the gland. Beta and delta cells are distributed evenly throughout the pancreas, whereas alpha cells are concentrated in the body and tail, and F cells are mostly in the uncinate process. This has clinical consequence when partial pancreatectomies are performed.

## HISTORY

Endocrine tumors of the pancreas were first described by the symptoms a functional tumor would cause. In 1908, the first description of a pancreatic adenoma was described by Nichols, and subsequently Mayo described a

pancreatic islet cell tumor and hyperinsulinemia. This was followed by the Whipple triad in 1935 by Whipple and Frantz.<sup>6</sup> Next, Becker described what would be a glucagonoma when describing a tumor causing dermatitis, anemia, and diabetes.<sup>7</sup> Zollinger and Ellison described an islet cell tumor of the pancreas causing peptic ulcer disease and acid hypersecretion in 1955, and later gastrin was found to be the hormone responsible for this syndrome, known as Zollinger–Ellison syndrome (ZES).<sup>8</sup> VIPomas were described in 1958 by Verner and Morrison, who presented two patients with watery diarrhea and hypokalemia with an associated islet cell tumor.<sup>9</sup> Most recently, secretin has been confirmed as a diarrheogenic hormone from a case first described in 1968 by Zollinger and Ellison.<sup>10</sup>

## GENETIC SYNDROMES

Multiple endocrine neoplasia type I (MEN-1) is an autosomal dominant inherited disease.<sup>11</sup> MEN-1 is characterized by primary hyperparathyroidism in approximately 90% to 100% of patients with the syndrome. Pancreatic neuroendocrine tumors are next most common, and can be functional or nonfunctional. These are usually nonfunctional. Gastrinomas are the most common functional PNET associated with MEN 1.<sup>12</sup> Pituitary adenomas occur less commonly (20%-65%) as do adrenal tumors (10%-73%) and thyroid adenomas (0%-10%).<sup>13,14</sup> MEN-1 gene is a tumor suppressor gene that codes for the protein MENIN and is located on chromosome 11q13, and is responsible for this syndrome.<sup>15</sup> Typically, patients with MEN develop tumors at an earlier age than patients without the inherited disorder—usually between 30 and 40 years old.

Suspicion of MEN-1 should be considered when a patient has a family history of endocrine tumors of the pancreas, family members with pituitary or thyroid disease, kidney stones, young age of diagnosis of functional endocrine tumor, endocrine tumor with associated hypercalcemia, or any patient with ZES. Twenty percent of patients with ZES have MEN-1.<sup>16</sup> Genetic screening should be offered to any patient with two or more MEN-1–related tumors, recurrent hyperparathyroidism at a young age, gastrinoma and hyperparathyroidism, or multiple pancreatic neuroendocrine tumors.<sup>17</sup>

Workup of patients with suspected MEN-1 syndrome should include biochemical screening for gastrin, insulin, pancreatic polypeptide, glucagon,

and chromogranin A. In addition, calcium level should be obtained. Hyperparathyroidism should be treated first, before treatment of the pancreatic endocrine tumor. ZES is more difficult to cure in patients with MEN-1, as these tumors are often multiple and can have diffuse hyperplasia of the islets and present with metastasis 50% of the time. Other genetic syndromes such as Von Hippel–Lindau and neurofibromatosis type 1 are also associated with pancreatic endocrine tumors.

## NONFUNCTIONAL TUMORS

The majority of pancreatic neuroendocrine tumors are nonfunctional (60%-90%), and many present with distant metastatic disease because they do not have symptoms until late in the course of the disease.<sup>18,19</sup> Tumors that produce PP, neurotensin, and calcitonin are categorized as nonfunctional, as they do not produce a definable hormonal syndrome. Nonfunctional tumors appear similar on cross-sectional imaging. These tumors are often larger and two-thirds are malignant, while up to 80% have metastasized at the time of diagnosis.

## FUNCTIONAL TUMORS

### Insulinoma

Insulinomas are the most common functional tumor and occur with an annual incidence of 1 per million patients per year, with the average age at diagnosis of 45 years old.<sup>20</sup> Only 10% of these tumors are malignant. The tumors are located in equal distribution throughout the pancreas. Most are solitary, however when associated with MEN 1 may be multiple. It should be noted that insulinomas rarely occur in MEN 1. These tumors, like most functional tumors, are diagnosed because of symptoms. The Whipple triad classic diagnostic test and includes symptoms of hypoglycemia, plasma glucose less than 50 mg/dL when symptomatic, and relief of symptoms when given glucose (Table 74-2). The neuroglycopenic symptoms are typically headache, lethargy, dizziness, blurred vision, anxiety, excessive sweating, tachycardia, and nervousness. Patients may eat to relieve these symptoms, and as a result

often present with weight gain.

**TABLE 74-2: WHIPPLE TRIAD**

- 1. Symptoms of hypoglycemia**
  - 2. Blood glucose <50 mg/dL**
  - 3. Relief of symptoms with glucose**
- 

Diagnosis can be confirmed with an elevated insulin-to-glucose ratio greater than 0.3 during fasting, and an associated elevated C-peptide. This ratio can sometimes be found in obese patients but these patients are not hypoglycemic. If the diagnosis cannot be established, a monitored 72-hour fast may be required. The fast should be monitored to prevent life-threatening complications of profound hypoglycemia and to ensure that the hypoglycemia is not factitious. Obtaining sulfonylurea levels and C-peptide may also be necessary if factitious hypoglycemia is suspected. Insulin levels greater than 10  $\mu\text{g}/\text{mL}$  and hypoglycemia are very suggestive of insulinomas, however not diagnostic, as these levels of insulin can be seen in other conditions. C-peptide levels greater than 1.2  $\mu\text{g}/\text{mL}$  with a glucose less than 40  $\text{mL}/\text{dL}$  also suggest an insulinomas.<sup>21</sup> The differential diagnosis includes factitious hypoglycemia, chronic adrenal insufficiency, hypopituitarism, nesidioblastosis, and noninsulinoma pancreatogenous hypoglycemia (NIPH). Nesidioblastosis is not associated with a tumor but patients with this do manifest symptoms of hypoglycemia.<sup>22</sup>

Resection is the mainstay of treatment for insulinomas (Fig. 74-2). Preoperative hypoglycemia should be managed with frequent small meals. Octreotide is not typically useful and should be used cautiously, as it can worsen hypoglycemia by suppressing the secretion of glucagon. Diazoxide can also be used to suppress the secretion of insulin. Enucleation is an option for resection of insulinomas given the majority are not malignant. Localization of insulinomas can sometimes be difficult due to the small size of these tumors, averaging 1.0 to 1.5 cm. CT or MRI is usually sufficient to locate the tumor, but endoscopic ultrasound is often a useful adjunct. Determining the relationship of the lesion to the pancreatic duct can help in planning the operative approach. Insulinomas that are in close proximity to

the duct may lead to a pancreatic leak if an enucleation is performed, and a more formal pancreatic resection may be indicated if this is a concern. Intraoperative ultrasound can be used if there has been difficulty in identifying the tumor during the surgery, and again may help in determining the location of the pancreatic duct. If the tumor is not located using these methods, blind resection is not indicated. With current imaging techniques and endoscopic ultrasound, angiography or selective portal venous sampling for insulin levels is used rarely. Injection of calcium into the celiac and superior mesenteric arteries can also further increase the sensitivity of this test.

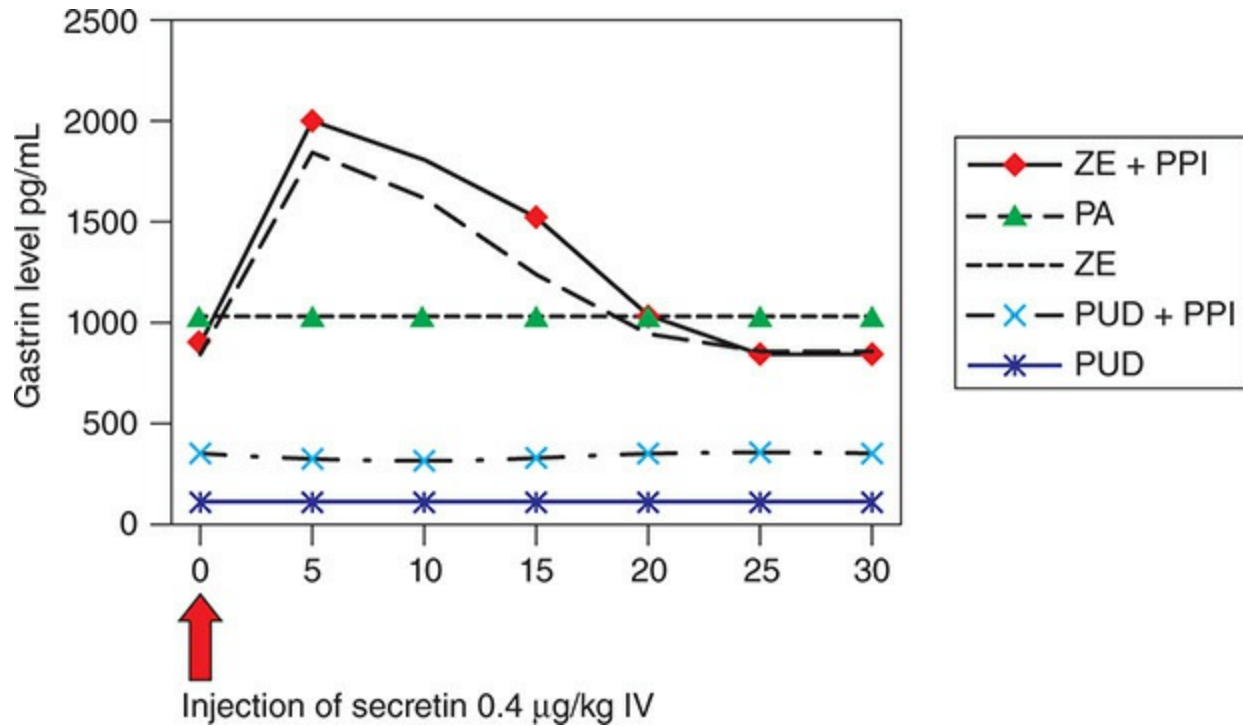

**FIGURE 74-2** Distal pancreatectomy and splenectomy for insulinoma.

## **Gastrinoma**

ZES was initially described in 1955 in two index cases of refractory ulcer disease and diarrhea.<sup>8</sup> The mean age at diagnosis is 50 years, with most cases diagnosed between the ages of 20 and 60 with a male predominance (60%). Those with MEN-associated gastrinomas typically present at a younger age. It is important to consider the diagnosis of MEN-1 in patients with ZES, as 20% of them will have MEN-associated disease.<sup>12</sup> Frequently, gastrinomas are not recognized at the initial clinical presentation and are therefore often

managed incorrectly. Symptoms that should raise suspicion of a gastrinoma include idiopathic peptic ulcer disease or longstanding diarrhea. The high acid load delivered to the duodenum inactivates pancreatic enzymes, causing malabsorption and diarrhea; thus the diarrhea is relieved by nasogastric suction. The liver is the most common site of metastases, with 70% to 80% of patients diagnosed with liver metastases at the time of diagnosis.

Confirmation of a gastrinoma can be made with a fasting serum gastrin level. A fasting serum gastrin greater than 1000 pg/mL is virtually diagnostic for ZES. This must be drawn while that patient is off proton pump inhibitors (PPIs) for 72 hours prior to the test. Gastrinomas do not secrete gastrin to normal stimuli such as amino acids and peptides or gastric distention. The normal inhibition of gastrin by low luminal pH does not occur, and secretin causes stimulation rather than inhibition of gastrin. Other medical conditions can also cause hypergastrinemia, thus serum gastrin by itself is not diagnostic of ZES. Pernicious anemia, atrophic gastritis, and the use of proton pump inhibitors all can cause elevation of serum gastrin and achlorhydria. Acid hypersecretion and hypergastrinemia may be found with many conditions such as *Helicobacter pylori* infection, gastric outlet obstruction associated with peptic ulcer, retained antrum, short gut syndrome, or renal failure. A secretin stimulation test can confirm ZES by measuring serum gastrin level after the intravenous injection of 0.4 µg/kg of secretin (Fig. 74-3). Patients can remain on PPIs during this test. Gastrin levels will increase by 200 pg/mL in patients with ZES. A rise in gastrin level by greater than 110 pg/mL over baseline is considered a positive test. Imaging with CT or MRI should be performed to locate the tumor.<sup>23</sup> EUS is very sensitive for detection as is somatostatin scintigraphy using [<sup>111</sup>In-DTPA-DPhe1] octreotide.<sup>24</sup> Ninety percent of gastrinomas are located in the gastrinoma triangle (Passaro triangle), which is bounded by cystic duct, the junction of the second and third portions of the duodenum, and the junction of the neck and body of the pancreas (Fig. 74-4).

**FIGURE 74-3** Secretin stimulation test. Response of serum gastrin to IV secretin in various conditions. Zollinger–Ellison syndrome will increase by at least 110 pg/mL. The paradoxical response is maintained in patients taking proton pump inhibitors. There is no increase in gastrin over baseline in patients with achlorhydria or with elevations of gastrin secondary to PPI treatment. ZE, Zollinger–Ellison; PA, pernicious anemia; PUD, peptic ulcer disease; PPI, proton pump inhibitor.

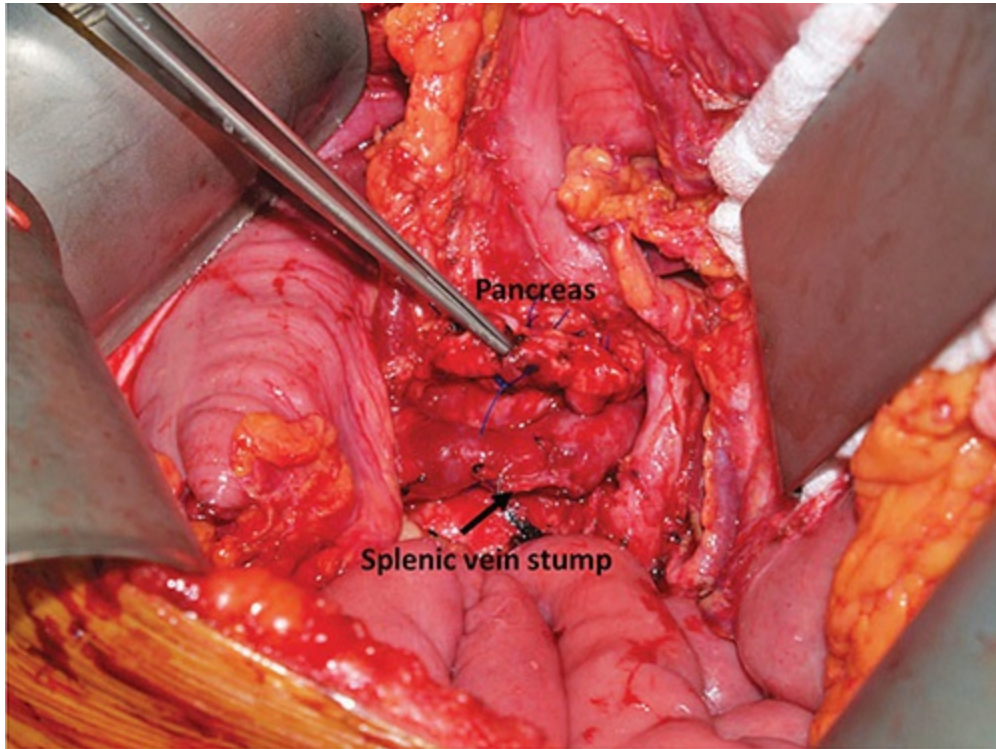

**FIGURE 74-4** The gastrinoma triangle—the anatomic triangle in which approximately 90% of gastrinomas are found. The gastrinoma triangle is defined by the cystic duct, the junction of the second and third portion of the duodenum, and the neck/body of the pancreas.

Treatment includes resection of the primary tumor (Figs 74-5 and 74-6). In patients may undergo exploration with intraoperative ultrasound to help locate the tumor if no imaging test has identified the lesion preoperatively. When unable to locate the gastrinoma preoperatively the surgeon should undergo a thorough intraoperative search to locate the gastrinoma including a wide Kocher maneuver, which allows for palpation of the head and uncinate of the pancreas, mobilization of the body and tail, intraoperative ultrasound and lastly duodenotomy and exploration of the duodenal mucosa. The duodenum is the most common location of gastrinomas typically in the first or second portion. The mucosa should be inspected carefully as the tumor can be <2 mm and can be multiple. After the duodenum the pancreas is the next

most common location. Intraoperative ultrasound may be useful to locate the tumor as they can be multiple. If a pancreatic tumor is identified duodenotomy should be undertaken given the possibility of a second tumor which be present in as many as 50% of cases.

**FIGURE 74-5** Intraoperative photograph after distal pancreatectomy and splenectomy showing the cut edge of the pancreas and the splenic vein stump.

**FIGURE 74-6** Gross specimen distal pancreatectomy and splenectomy for gastrinoma.

Patients with MEN-1 associated gastrinomas are rarely cured with surgery. Their hyperparathyroidism should be addressed with subtotal parathyroidectomy or total parathyroidectomy and autotransplant of parathyroid tissue. This helps reduce serum gastrin by removing the stimulation from the elevated calcium. Patients with MEN associated ZES with negative imaging should not undergo exploration as cure is rare because of development of metachronous primary tumors owing to the underlying syndrome. Although a low cure rate is to be expected, some studies have still shown prolonged survival.<sup>25,26</sup> Surgeons that advocate surgical intervention in MEN-related gastrinomas typically would consider the Thompson procedure.<sup>27,28</sup> This includes a distal pancreatectomy, enucleation of tumors in the head, a duodenotomy and exploration of the duodenum with resection of any duodenal tumors as well as a portal lymph node dissection.<sup>29</sup> For patients with tumors greater than 2 to 2.5 cm in size surgery is recommended. Ellison et al. reported on 106 gastrinomas 26 of which were MEN related. Those that underwent complete resection had a 10 year disease-specific survival of 100% compared to 40% for an incomplete resection. Despite these results serum gastrin levels remained elevated in 94% of these patients.<sup>30</sup>

## VIPoma

Vasoactive intestinal peptide secreting tumor (VIPoma) was classically described as the WDHA syndrome (watery diarrhea, hypokalemia, and achlorhydria). Patients can have over 10 liters/day of diarrhea even when fasting and this has been described as pancreatic cholera. These tumors are extremely rare with an incidence of 1 in 10,000,000 population.<sup>31</sup> Fasting VIP levels can reach nearly 1000 pg/mL in most cases but above 200pg/mL is suggestive of VIPoma. Localization with CT or MRI imaging or octreotide scan is the most common. Fifty percent of these tumors are metastatic at diagnosis and commonly are located in the tail of the pancreas. When treating a VIPoma correction of electrolyte abnormalities must be completed prior to surgical intervention. Octreotide can be useful for symptom control prior to surgery. Resection for palliation is sometimes undertaken to help control symptoms, but this likely does not impact long term survival.

## Glucagonoma

Glucagonomas are also very rare with an incidence of less than 1 per 10,000,000-20,000,000 population.<sup>32</sup> The tumors are 2 to 3 times more common in women than men. At presentation, they are usually larger than other PNETs with an average size of 5-10 cm at diagnosis. These tumors arise from alpha cells and are found more often in the body and tail which is where more alpha cells are located. A minority of these tumors are MEN-1 related (5%-17%). Similar to other MEN-related PNETs, these patients tend to present earlier and 60% of patients present with distant metastatic disease at diagnosis.

Two-thirds of patients with glucagonomas present with a characteristic rash called necrolytic migratory erythema and this can be the first symptom of the glucagonoma. The rash is severe, with raised, scaly, erythematous patches on the perineum, trunk and extremities. They also typically present with diabetes, anemia, stomatitis, weight loss, and diarrhea. Dermatologists are often the first to recognize this syndrome. The “four D’s” are often used to describe this constellation of symptoms associated with glucagonoma: diabetes, dermatitis, DVT, and depression.<sup>33</sup> The diagnosis of glucagonoma is confirmed by fasting serum glucagon levels greater than 1000 pg/mL. CT

or MRI is commonly used to locate the tumor.

## Somatostatinoma

Somatostatinomas are even rarer with less than 100 ever reported and were first described in 1977.<sup>34</sup> Patients with somatostatinomas typically present with diabetes, cholelithiasis, diarrhea, and steatorrhea. Somatostatin inhibits insulin, cholecystikinin (CCK) and pancreatic enzyme secretion thus causing the associated diabetes, cholelithiasis, and diarrhea.<sup>35</sup> Somatostatin level greater than 100 pg/mL are diagnostic. Seventy percent of these tumors are metastatic and large at diagnosis. They are most commonly found in the pancreas but can be found in the duodenum and small bowel. Localization is typically easily accomplished with cross-sectional imaging given their large size.

## Other Functional Tumors

Many other rare functional tumors have been described including adrenocorticotropin-producing tumors (ACTHoma), parathyroid hormone-related peptide (PTH-RP), secretinoma, Gastrin releasing factor, calcitonin, enteroglucagon, CCK, gastric inhibitory peptide, luteinizing hormone, neurotensin or ghrelin.

## IMAGING

Cross-sectional imaging with CT or MRI should be the first step in locating the PNET. Insulinomas and gastrinomas are more difficult to localize with standard imaging because of their small size. PNETs typically have a vascular blush giving them a characteristic enhancement that is helpful in identification and differentiation from other pancreatic tumors or cancer. (Fig. 74-7) Many PNETs express the somatostatin receptor and thus somatostatin-receptor scintigraphy (SRS) (octreotide scan) can be used to image these tumors. If a tumor is unable to be located with CT or MRI, SRS is 80% sensitive in locating the tumor. The sensitivity for insulinomas is less than 50% owing to the fact that the tumor cells frequently lack the somatostatin 2 receptor. SRS is a sensitive imaging technique; however, it is

only able to show the location of the tumor within several centimeters. Endoscopic ultrasound (EUS) is also an alternative imaging technique if CT or MRI hasn't revealed the location of the tumor. Biopsy is also able to be accomplished at the time of EUS. The sensitivity of EUS to localize small PNETs has been shown to be as high as 97% compared to CT (85%) or MRI (70%).<sup>36</sup> (Fig. 74-8) Angiography can be utilized to localize tumors that are small and unable to be localized by CT, MRI, SRS, or EUS. Angiography can localize up to 70% of small tumors (<5 mm) with a characteristic blush. Selective portal sampling for the hormone in question can also be done to help localize the tumor when other methods have failed. Provocative testing is also described but only used currently when the above tests have failed to localize the tumor and there remains a high level of clinical suspicion that the patient has a functional PNET. This is called arterial stimulation venous sampling (ASVS) and is performed by injecting calcium or secretin into the celiac and superior mesenteric arteries followed by sampling from the inferior vena cava for the appropriate hormone in question. (Fig. 74-9) If all imaging tests have been performed and negative exploration and intraoperative ultrasound may be warranted, however, blind resection is not warranted in the majority of cases.

**FIGURE 74-7** CT scan of nonfunctional pancreatic endocrine tumor in the body pancreas.

**FIGURE 74-8** Endoscopic ultrasound of gastrinoma in the tail of the pancreas.

**FIGURE 74-9** Selective secretin arterial stimulation.

68G Ga-Dotatate positron emission tomography (PET) CT seems to be an excellent imaging modality for PNETs and may be the imaging modality of choice. With availability of positron emitting tomography in recent years, PET tracers labeled somatostatin analogues have been developed rapidly.

PNETs demonstrate high uptake of  $^{68}\text{Ga}$  DOTATATE because neuroendocrine tumors express a significant number of somatostatin 2 receptors.

## **INTRAOPERATIVE IMAGING**

Few advances in imaging techniques over the past several decades have advanced the surgical management of PNETs. Given the difficulty in preoperative localization of these tumors novel intraoperative imaging techniques have been developed. Hall et al. have described using a combined intraoperative portable large field of view gamma camera and a handheld gamma detection probe for  $^{111}\text{In}$ -pentetate radioguided localization and confirmation of gastrinoma in 5 patients.<sup>37</sup> They were able to detect additional tumor foci in 3/5 patients with this imaging technique (Figs 74-10 and 74-11).

**FIGURE 74-10** Intraoperative imaging—preoperative injection of  $^{111}\text{In}$ -pentetreotide.

**FIGURE 74-11** Intraoperative octreotide scan.

## **SURGICAL CONSIDERATIONS**

### **Localized**

Surgical resection is the only curative treatment for pancreatic endocrine tumors. Small tumors can sometimes be enucleated in select cases. Insulinomas are sometimes amenable to this approach. Laparoscopic or robotic resections are becoming more common at experienced institutions. Generally pancreatic head tumors less than or equal to 2 cm may be

enucleated unless the pancreatic duct is involved. Intraoperative ultrasound may help in making this determination. Pancreatic head tumors greater than 2 cm usually require pancreaticoduodenectomy. Tumors in the tail usually require distal pancreatectomy with splenectomy. However with small insulinomas distal pancreatectomy with splenic preservation is an acceptable oncologic operation as the majority are benign. This is not the case with the other functional tumors that are considered malignant in the majority of cases. As noted, tumors less than 2 cm are usually resected, but in the patient with significant comorbidities and with patient preference close observation may be warranted as small tumors are less likely to metastasize. Close follow-up is required in these cases. The goal of surgical intervention is to obtain negative margins even if adjacent organs need to be resected. Liver metastasis should also be removed at the time of operation if feasible. Consideration of cholecystectomy if the surgeon anticipates the future use of octreotide.

## **Metastatic**

The quality and length of life is often dictated by the disease burden in the liver. Debulking of functional tumors can be effective palliation of symptoms, but patient selection must carefully weigh the risk and benefit and whether symptoms can be controlled with medical management and is employed less often given other ablative treatment options. For non-functional tumors complete resection of both the primary and liver metastases is the goal. Combination of liver resection and ablative therapies may be used to clear the liver of metastatic disease. As more effective systemic therapies are approved, resection may be more commonplace even in the setting of metastatic disease. Liver-directed therapy using transarterial chemoembolization or surgical resection has been shown beneficial in asymptomatic patients with >25% liver tumor burden. Transarterial chemoembolization (TACE) or bland transarterial embolization (TAE) and radionuclide-laden spheres (yttrium-90) are effective therapies, as the tumors derive most of their blood supply from the arterial circulation. These therapies are often able to stabilize tumor growth and palliate symptoms due to hormonal production.

Peptide receptor radiation therapy (PRRT) is not currently available in the United States, however, shows some promise in treating metastatic PNETs by

delivering a cytotoxic dose of radiation therapy directly to the tumor.

## SYSTEMIC TREATMENTS

### Somatostatin Analogs

Somatostatin analogs such as octreotide and lanreotide have been shown to prolong progression-free survival and are thought to stabilize tumor growth in addition to relieving symptoms associated with functional tumors.<sup>38,39</sup>

### Targeted Therapy

Targeted therapies have shown great promise in the treatment of PNETs. Both everolimus and sunitinib are FDA-approved treatments for advanced pancreatic endocrine tumors.<sup>40</sup> A randomized controlled trial of everolimus, an oral inhibitor of mammalian target of rapamycin (mTor) showed an increase in progression-free survival from 4.6 months to 11.0 months.<sup>41</sup> Sunitinib, a multitargeted tyrosine kinase inhibitor, has also been shown to increase progression-free survival to 11.4 months from 5.5 months for placebo, and to increase overall survival in patients with metastatic unresectable disease.<sup>42</sup> Although both have been shown to increase progression-free survival, response rates by RECIST criteria are low. There are no current data for the use of these agents in the adjuvant setting.

### Cytotoxic Chemotherapy

Cytotoxic chemotherapy currently used for PNETs includes streptozocin-, 5FU- or temozolamide-based regimens. Streptozocin was the first cytotoxic agent described with efficacy in pancreatic endocrine tumors.<sup>43</sup> In comparison with the targeted therapies, the objective response rates with cytotoxic agents have been greater. Capecitabine and temozolamide have been shown to have a high and durable response in PNETs in a small study.<sup>44</sup> Seventy percent of patients had a radiographic response, with median progression-free survival of 18 months. Given this radiographic response, this regimen has also been reported in the neoadjuvant setting.<sup>45</sup>

## CONCLUSIONS

Management of pancreatic endocrine tumors requires a multidisciplinary team and a thorough understanding of the biological behavior to determine optimal treatment and surgical therapy. Surgical resection continues to be the only curative therapy. Newer imaging techniques may help identify tumors intraoperatively, as small tumors remain difficult to image with standard CT or MRI. Debulking of metastatic disease continues to play an important role in control of symptoms due to hormone production. Liver-directed therapies such as TACE or Y-90 can also stabilize disease and provide symptom relief. Systemic therapies have shown promise by increasing progression-free survival but have not lengthened overall survival. Patients with MEN-associated PNETs often have multifocal and more aggressive disease, thus if surgical resection is entertained these factors must be considered.

# PERSPECTIVE ON PANCREATIC NEOPLASMS

*Douglas B. Evans*

## CANCERS OF THE PERIAMPULLARY REGION AND PANCREAS

Drs. Gajdos, McCarter, Edil, Paniccia, and Schulick provide an extremely comprehensive chapter on the evaluation and treatment of patients with cancer of the periampullary region and especially the pancreatic head ([Chapter 73](#)). Importantly, there has been a tremendous advance in both the understanding of the molecular biology of pancreatic cancer as well as our ability to accurately image the pancreas and periampullary region prior to surgery. Advances in computed tomography (CT) and magnetic resonance imaging (MRI) have allowed for accurate assessment of critically important tumor-vessel relationships. Such accurate assessment of the relevant anatomy is important for both pretreatment staging and for planning the operation, especially if vascular resection and reconstruction may be indicated. The ability to preoperatively classify patients as having resectable, borderline resectable, or locally advanced pancreatic cancer (LAPC) allows for optimal treatment sequencing (often including neoadjuvant therapy), the evaluation of

patients for investigator-initiated and cooperative group clinical trials, and the referral of patients to higher volume centers.<sup>1</sup> Indeed, to the extent that outcome is improved for patients with localized disease at high-volume centers (by high-volume surgeons), patients will need to be accurately staged (CT imaging) and, when necessary, have biliary stents placed safely in order to facilitate referral to a specialty center. The ability to perform endoscopic ultrasound (EUS)-guided fine-needle aspiration (FNA) biopsy will prevent diagnostic uncertainty and allow for medical oncology consultation and multidisciplinary care.

Fortunately, the past decade has witnessed the development of consensus for the CT staging of pancreatic cancer. In an attempt to clarify the anatomy of resectable, borderline resectable, and locally advanced disease, Varadhachary and colleagues from The University of Texas M.D. Anderson Cancer Center proposed an objectively defined, CT-based classification that distinguishes borderline resectable pancreatic cancer from both resectable pancreatic cancer and LAPC.<sup>2</sup> This definition was developed for the conduct of clinical trials of neoadjuvant treatment sequencing and was not intended to support a surgery-first strategy for patients who may require vascular resection and reconstruction. The Varadhachary definitions also assumed the technical capability to resect and reconstruct the superior mesenteric–portal vein (SMPV) confluence (when necessary) and that the major determinants of margin status (R status) were the tumor-artery (celiac, hepatic, and superior mesenteric artery) relationships. In contrast to the management of resectable and borderline resectable pancreatic cancer, surgery has typically not been applied to patients with locally advanced or metastatic disease. Patients with LAPC were considered to have inoperable tumors; surgery was felt not to be technically possible. With recent improvements in response rates for systemic therapy, an increasing number of patients with LAPC are found to have stable or responding disease after a prolonged course of systemic therapy (4-6 months or more) with or without having received radiation therapy. Such patients have only 1 site of measurable disease—the primary tumor—and therefore are often sent for surgical consultation to consider removal of the only remaining abnormality seen on cross-sectional imaging. The patient is often confused: Surgery was initially thought not to be possible, and now there is a difference of opinion? In an effort to add clarity to the goals of treatment for patients with LAPC, we recently described a system for categorizing locally advanced disease based on the

tumor-vessel anatomy<sup>3,4</sup>; in LAPC type A, surgery may be considered after systemic therapy and chemoradiation, and in LAPC type B, surgery will likely never be possible (Table 75-1).

**TABLE 75-1: CLASSIFICATION OF LOCALLY ADVANCED PANCREATIC ADENOCARCINOMAS INTO TYPES A AND B AND COMPARISON TO THE DEFINITIONS USED FOR RESECTABLE AND BORDERLINE RESECTABLE DISEASE**

Vascular Structures That Determine the Stage of Disease for Localized Pancreatic Cancer		Resectable	Borderline Resectable	Locally Advanced	
				Type A	Type B
Tumor-artery anatomy (relationship)	SMA (usually pertains to a tumor of the head or uncinate process)	No radiographic evidence of abutment or encasement	≤180 degrees (abutment)	>180 degrees (encasement) but ≤270 degrees	>270-degree encasement
	Celiac artery (usually pertains to a tumor of the pancreatic body)	No radiographic evidence of abutment or encasement	≤180 degrees (abutment)	>180 degrees (encasement) but does not extend to the aorta and amenable to celiac resection (with or without reconstruction)	>180 degrees and abutment/encasement of the aorta
	Hepatic artery (usually pertains to a tumor of the pancreatic neck/head)	No radiographic evidence of abutment or encasement	Short segment abutment/encasement without extension to celiac artery or HA bifurcation	>180-degree encasement with extension to celiac artery and amenable to vascular reconstruction	>180-degree encasement with extension beyond bifurcation of proper HA into right and left hepatic arteries
Tumor-vein anatomy (relationship)	SMV-PV	≤50% narrowing of SMV, PV, SMV-PV	>50% narrowing of SMV, PV, SMV-PV with a distal and proximal target for reconstruction	Occlusion <i>without</i> obvious option for reconstruction.	
Potential for successful resection after neoadjuvant therapy (%)		90	75	60	25

Abbreviations: HA, hepatic artery; PV, portal vein; SMA, superior mesenteric artery; SMV, superior mesenteric vein; SMV-PV, superior mesenteric–portal vein. Modified with permission from Evans DB, George B, Tsai S: Non-metastatic Pancreatic Cancer: Resectable, Borderline Resectable, and Locally Advanced-Definitions of Increasing Importance for the Optimal Delivery of Multimodality Therapy, *Ann Surg Oncol* 2015 Oct;22(11):3409-3413.

For surgeons who recommend a surgery-first strategy to patients with localized, potentially resectable pancreatic cancer, the CT definition of what should be considered “resectable,” and for which immediate surgery may be considered, is becoming more limited, which is a logical response to the clinical observation that almost all patients with apparent operable pancreatic cancer have radiographically occult micrometastatic disease. In general, there is an increasing trend for the management of localized pancreatic cancer with systemic therapy first.<sup>5-7</sup> Most clinical trials incorporate a period of induction

systemic therapy, especially in those with arterial abutment, to include 2 to 4 months of chemotherapy, which may be followed by chemoradiation. Emerging clinical trials, as well as off-protocol therapy, include (as a backbone of therapy) what has been proven successful in metastatic disease, such as gemcitabine plus nanoparticle albumin-bound (nab)-paclitaxel (Abraxane) and FOLFIRINOX (fluorouracil, leucovorin, irinotecan, and oxaliplatin).<sup>8</sup> Our management of localized, operable pancreatic cancer is evolving toward a total neoadjuvant approach (4-6 months) with surgery considered after all intended systemic therapy and chemoradiation. Restaging is performed after each 2 months of therapy; if there is significant treatment response (eg, clinical, radiographic, biochemical [cancer antigen 19-9]), then additional chemotherapy is prescribed with careful follow-up every 2 months. In the setting of stable or, hopefully, responding disease after 4 months of chemotherapy, a transition to chemoradiation is usually recommended. Importantly, our treatment algorithm incorporates a stepwise evolution of treatment that starts with accurate staging and proceeds to an extended course of chemotherapy, followed by chemoradiation and, finally, surgical resection. In the absence of disease response, the chemotherapy regimen can be changed (eg, FOLFIRINOX to gemcitabine plus nab-paclitaxel or vice versa). The length of induction systemic therapy, the timing and dose of radiation therapy, and the use of a variety of biomarkers to assess the presence or absence of response are areas of active investigation. Although chemotherapy and chemoradiation do not increase the risk for pancreatic leak or other known surgery-associated complications, it is likely that some patients of advanced age cannot tolerate multiple treatments in series and thus may not be suitable surgical candidates at the time of posttreatment/preoperative restaging; such patients likely receive a greater oncologic benefit from induction therapy than they would from a surgery-first/surgery-only approach.

Probably the most important technical aspect of pancreaticoduodenectomy is the dissection of the superior mesenteric artery (SMA). In general, exposure of the SMA is facilitated by complete mobilization of the SMPV confluence to the patient's left. This allows for careful separation of the uncinate process from the jejunal branch of the superior mesenteric vein and, ultimately, exposure of the SMA. Our current understanding of the pathophysiology of local recurrence after pancreaticoduodenectomy (with or without multimodality therapy) is microscopic infiltration of the autonomic

neural sheath that surrounds the SMA (and celiac/hepatic arteries). Adenocarcinoma of the pancreas has a predisposition to spread along neural tissue, and this is likely responsible for the high frequency of local recurrence. As our systemic therapies become more effective, local recurrence may become a more dominant pattern of failure.

## CYSTIC NEOPLASMS OF THE PANCREAS

The chapter by Drs. Pucci and Yeo ([Chapter 75](#)) is equally comprehensive in their superb discussion of cystic neoplasms of the pancreas. They focus predominantly on serous cystadenoma, mucinous cystic neoplasm (MCN), and intraductal papillary mucinous neoplasm (IPMN). With regard to serous cystadenoma, this histology demonstrates fascinating tumor biology. As mentioned by the authors, it is generally felt that serous cystadenomas do not have the biologic ability to metastasize to distant organs or regional lymph nodes. However, they can be locally invasive and erode into adjacent bowel (duodenum, transverse colon, stomach) and occasionally can obstruct the splenic vein (resulting in sinistral portal hypertension) or the superior mesenteric and/or portal veins (resulting in extrahepatic portal hypertension). Importantly, the diagnosis of (microcystic) serous cystadenoma can usually be made on high-quality CT imaging with or without the additional benefit of EUS due to its characteristic imaging appearance (unless the serous cystadenoma is macrocystic). When referring a patient for EUS to confirm a diagnosis of serous cystadenoma (the EUS appearance is often diagnostic), we would recommend an FNA biopsy if the EUS is not consistent with this diagnosis or there appears to be discrepancy between CT or MRI imaging and the EUS appearance. A biopsy is often needed only when the imaging findings are not all congruent and inconsistent with a diagnosis of serous cystadenoma. Serous cystadenomas are characterized by a cyst fluid carcinoembryonic antigen (CEA) level that is usually undetectable or very low (<5 ng/mL). At present, the diagnosis of a serous cystadenoma is usually not difficult; however, knowing when to intervene with surgery is often challenging. As patients age and operative risk (medical comorbidities) increase, the benefit of surgery in an otherwise asymptomatic patient may be low. For example, it is relatively easy to understand a recommendation for surgery in an otherwise completely healthy 60-year-old patient with a serous cystadenoma of 6 cm or greater.<sup>9</sup> However, the same pancreatic tumor in a

75-year-old patient with 1 or 2 coronary stents and a relatively sedentary lifestyle is not the correct approach. In our practice, we try to carefully weigh risk versus benefit in asymptomatic patients. In addition, for serous cystadenomas that are less than 4 to 5 cm in size, we usually require that they demonstrate growth, over a period of observation, prior to proceeding with surgery; there simply is no down side to this approach. Our underlying philosophy is to completely avoid surgery-related mortality and major morbidity in patients who are asymptomatic with a tumor histology (such as serous cystadenoma) that poses no risk for distant metastases.

As emphasized by Drs. Pucci and Yeo, ovarian stroma is required to secure a diagnosis of MCN and differentiate it from IPMN (in women). However, ovarian stroma is appreciated on histologic assessment of the resected specimen and therefore is a diagnosis made after operation. It is impossible to preoperatively differentiate an MCN from a unifocal branch duct IPMN in a woman. However, MCNs occur in the pancreatic body and tail and are exceedingly rare in the pancreatic head or uncinate process. We would consider an MCN in the pancreatic head or uncinate process to represent an IPMN. Although the relationship between size of the MCN and malignant potential is perhaps not as well studied as with IPMN, in the absence of a solid component or mural nodule (which represent clear indications for surgery), presumed MCNs less than 3 cm in diameter will rarely harbor invasive cancer. Management of such small presumed MCNs is often based on the size of the cyst and the age or medical comorbidities of the patient. For example, after an EUS-FNA biopsy consistent with a mucinous neoplasm in a woman with a single, 3-cm cystic neoplasm in the body or tail of the pancreas that is otherwise normal in appearance (main pancreatic duct not dilated), the decision to proceed with surgery versus observation is typically based on the age and medical comorbidities of the patient. What remains controversial is the surgical approach to MCNs of presumed low malignant potential. If we imagine for a moment that the woman with a 3-cm, FNA-proven MCN in the proximal pancreatic body (mucinous nature of the cyst fluid has been confirmed) is 50 years old, surgery would typically be recommended because of the patient's young age and the knowledge that such an MCN is premalignant. The contemporary question relates to the recommended form of operation—middle segment pancreatectomy, distal pancreatectomy (with or without splenic preservation), or enucleation. In patients without cancer, we do need to pay more attention to preservation of

islet cell mass in an effort to avoid the intermediate- and long-term complications of insulin-dependent diabetes (in addition to lifestyle changes and risk of hypoglycemia). Our choice for operation in this patient would be a middle segment pancreatectomy with pancreaticogastrostomy for the distal pancreas and coverage of the proximal pancreatic transection site with a falciform ligament pedicle flap. This would hopefully minimize the risk for anastomotic leak, preserve islet cell mass, and ensure that the lesion is completely excised with negative margins. We have not yet adopted enucleation as a routine part of our practice when dealing with mucinous (pre-malignant) neoplasms.

When dealing with patients who have presumed IPMN, especially those with branch duct disease, the International Consensus Guidelines (formerly Sendai criteria) have now been widely incorporated into clinical practice. As noted by the authors, use of these guidelines will result in a slightly more conservative approach to surgery than may otherwise be the case. By definition, low-risk patients would be treated with at least a period of observation until the size of the cyst or the CT characteristics prompt surgical intervention. Such a strategy is designed to avoid surgery and its associated risk for mortality and morbidity in patients with small cystic neoplasms who have no chance of harboring an invasive cancer. In our practice, enucleation would rarely be considered because we do not operate on cystic neoplasms that would be considered most appropriate for enucleation (those of very low risk). However, the increasing use of cross-sectional imaging has resulted in many more patients being diagnosed with cystic neoplasms of the pancreas. Is it reasonable to consider a lesser procedure (enucleation or endoscopic ablation) for smaller branch duct IPMNs that are diagnosed in younger patients? Is there a role for enucleation or ablative therapies in patients in whom the risk for invasive carcinoma is approaching zero? This is an area of active investigation and frequent discussion at national meetings.

Fortunately, when dealing with a patient who has IPMN and requires surgery, the need for total pancreatectomy is uncommon. If the right or left side of the pancreas requires resection, we commonly send the pancreatic transection margin for frozen section analysis. Work from our group and others has demonstrated that it is probably unnecessary to chase a margin with low-grade dysplasia (pancreatic intraepithelial neoplasia 1 [PanIN-1]) because this can result in the unnecessary resection of additional pancreas. Importantly, at many institutions, there is only modest expertise in the

interpretation of frozen section evaluation of pancreatic transection margins. Surgeons should be cautioned to avoid overaggressive resection of grossly normal pancreatic parenchyma based on frozen section evaluation of pancreatic transection margins, especially when dealing with IPMN. Another area of operative and technical challenge includes IPMNs (often combined main duct/branch duct) involving the neck of the pancreas, should one resect the right or the left side of the gland or perform a middle segment pancreatectomy? In this situation, we would typically divide the pancreas to the right of the neoplasm at the junction of the head and neck of the pancreas. We would then send this margin for frozen section evaluation prior to committing the patient to an extended distal pancreatectomy (in those cases where middle segment pancreatectomy is not preferred). When performing an extended distal pancreatectomy, one needs to be certain that the proximal pancreatic transection margin will be negative, especially if the patient could also be treated with an extended pancreaticoduodenectomy, and thereby preserve some islet cell mass. In general, the preservation of islet cell mass does facilitate improved blood sugar control even if not obviating the need for insulin. This is especially important in patients with limited resources and modest family support in whom a hypoglycemic episode could be life threatening. Finally, it is important to note that patients who undergo surgery for IPMN (in contrast to those who undergo pancreatectomy for MCN) do require long-term follow-up. We typically obtain a baseline MRI of the abdomen 2 to 4 months after surgery, and our next scan would typically occur 1 year later. If there is no evidence of an abnormality in the remaining pancreas, our MRI interval is in the range of 12 to 24 months depending on the histology of the previous resection and the age and general health of the patient.

## **ENDOCRINE TUMORS OF THE PANCREAS**

As described by Drs. Dillhoff and Ellison ([Chapter 74](#)), pancreatic neuroendocrine tumors (pNETs) are usually low- to intermediate-grade tumors arising from the pancreatic islets. They are also known as pancreatic endocrine tumors, islet cell carcinomas, and pancreatic carcinoid tumors. The current preferred nomenclature is pancreatic neuroendocrine tumors, or pNETs.<sup>10</sup> The biology of this class of tumors is both unique and fascinating. For example, why do sporadic, nonmetastatic insulinomas virtually never

develop distant recurrence and only very rarely recur locally (virtually all local recurrences are secondary to incomplete enucleation)? Metastatic insulinoma is rare, and when seen, it is always synchronous at the time of diagnosis; we have not seen a case of metachronous metastases. In contrast, patients with multiple endocrine neoplasia type 1 (MEN1) who have nonfunctioning pNETs have a risk of metastatic spread that appears to be related to the size of the primary tumor in the pancreas. Patients with primary tumors less than 2.5 cm in size rarely have associated liver metastases. When weighing the risk of long-term insulin-dependent diabetes with the risk for distant metastases, we often observe small (<1.5 cm) nonfunctioning pNETs in young MEN1 patients. Further, why does the biology of patients with Zollinger-Ellison syndrome differ based on whether the primary tumor is in the pancreas or the duodenum, and what determines where the tumor arises? Equally mystifying is why duodenal gastrinomas are so small, often less than 1 cm in diameter, and rarely associated with liver metastases. Gastrinomas, when located in the pancreas, are usually found within the pancreatic head or uncinate process (gastrinoma triangle), and those 3 cm in size and larger are frequently associated with liver metastases. Consistent with the biology of duodenal gastrinoma, patients with carcinoid tumors of the duodenum almost never have synchronous or metachronous liver metastases even though lymph node metastases are very common.<sup>11</sup> Indeed, the biologic explanation for the varied metastatic potential of functioning and nonfunctioning pNETs is an area of active investigation.

When evaluating a patient with hypergastrinemia, it is important to remember that the major cause of hypergastrinemia is parietal cell dysfunction resulting in achlorhydria and pernicious anemia. Such patients can be differentiated from those with Zollinger-Ellison syndrome by the absence of gastric acid production. In the outpatient center, placement of a nasogastric tube with aspiration of gastric juice for pH testing will easily make this diagnosis. We frequently see patients who have elevated serum gastrin levels either from concomitant administration of a proton pump inhibitor or because of parietal cell dysfunction. A pancreatic or duodenal gastrin-producing tumor is a much less frequent cause of hypergastrinemia. Importantly, consistent with the optimal operative management of virtually all pNETs, regional lymphadenectomy is an essential part of the operative procedure for patients with gastrinoma. Patients with functioning or nonfunctioning pNETs can have persistent or recurrent disease in regional

lymph nodes in the absence of liver, bone, or lung metastases. Careful attention to regional lymphadenectomy is an underemphasized and very important component of the surgical management of patients with pNETs.

Patients with insulinoma virtually always have an insulin level greater than 3  $\mu$ IU/mL (usually  $>6$   $\mu$ IU/mL) when the blood glucose is less than 40 to 45 mg/dL and an insulin-to-glucose ratio of  $\leq 0.3$ , reflecting the inappropriate secretion of insulin at the time of hypoglycemia. It is critically important to confirm the diagnosis of insulinoma by allowing the glucose to decline to less than 45 mg/dL (at which point, the patient is usually symptomatic) and observing the relief of symptoms with the administration of glucagon. Glucagon (1 mg intravenously) is associated with an elevation of serum glucose of approximately 20 mg/dL. The reversal of hypoglycemia with glucagon confirms that hypoglycemia is insulin mediated. In contrast to gastrinomas, which usually occur in the duodenum and pancreatic head/uncinate, insulinomas may develop anywhere throughout the pancreas and do not arise in the duodenum. In the absence of MEN1, the overwhelming majority of insulinomas are unifocal. As previously mentioned, if metastatic disease is not seen at the time of diagnosis, metachronous distant metastases from a presumed benign insulinoma do not occur. However, if the insulinoma is incompletely enucleated, a local recurrence can develop; such local recurrences may not occur for years after the primary operation. When we perform an enucleation of a benign insulinoma, we typically use bipolar forceps, and we are extremely careful to avoid violation of the tumor capsule. The advantage of bipolar cautery is that the operative field remains dry and one can appreciate the junction of the tumor capsule and the normal pancreatic parenchyma. Because the pancreas is highly vascular, it is critically important to keep the operative field as dry as possible. Proper technique for enucleation is much more important than whether the operation is done laparoscopically or open. In the event of a pancreatic fistula, the presence or absence of an abdominal incision becomes insignificant. When an enucleation is performed, the anatomy of the primary tumor in relation to the pancreatic duct should be appreciated on preoperative imaging, and if needed, this important anatomic relationship can be confirmed with intraoperative ultrasound. If one performs a very large enucleation or injures the pancreatic duct, a Roux-en-Y limb of jejunum can be used to create a pancreaticojejunostomy. For large defects in the pancreas, we have made liberal use of Roux-limbs for internal drainage.

With regard to MEN1, all at-risk patients should undergo genetic testing. In addition to MEN1, pNETs can occur in association with tuberous sclerosis, neurofibromatosis, and von Hippel-Lindau (vHL) syndrome. As previously mentioned, there is a defined association between tumor size and risk for liver metastases in MEN1 patients with nonfunctioning pNETs. Balancing the risk for insulin-dependent diabetes with the risk for metachronous liver metastases is indeed a difficult challenge. In our practice, the timing of pancreatic surgery in MEN1-associated nonfunctional pNETs is based on the age of the patient, the size of the pancreatic tumors, and sometimes the tumor biology seen within the family (frequency of metastases and death secondary to metastatic pNET); this latter characteristic may or may not be helpful because biologic heterogeneity within kindreds is well described. We strive to limit the operations performed in MEN1 patients to 2 over the course of their lifetime. In the first operation, we remove either the right or left side of the pancreas (sometimes a lesser procedure) depending on which side of the pancreas can be partially or fully cleared of obvious tumors with local enucleations if needed. The goal is to limit oncologic risk (metastatic disease) and preserve islet cell function (avoid insulin dependence) for as long as possible. If the first operation occurs at a young age, we expect metachronous recurrence in the remaining pancreas in the future, at which time a completion total pancreatectomy may be necessary. However, one would hope that the second operation to complete the total pancreatectomy would not occur until many years after the first operation, thereby avoiding insulin dependence until later in life, at which time the long-term complications of type 1 diabetes are less likely. Because the natural history of MEN1-associated pNETs becomes clear only after decades of follow-up, we still have much to learn in the management of these patients.

Importantly, the past decade has witnessed an explosion in the understanding of the biology of pNETs, imaging technology, and the development of targeted therapies. In 2016, the US Food and Drug Administration approved gallium-68–dotatate for clinical use and the gallium-68–dotatate positron emission tomography (PET)/CT scan has revolutionized the ability to image small pNETs. Most clinicians are now appreciating the understaging of disease that occurred in the era before dotatate imaging. How to use this information responsibly is the current challenge because, in some patients, small-volume disease may pose less risk to length and quality of life than do aggressive interventions. Tyrosine kinase

inhibitors, such as sunitinib, and the mammalian target of rapamycin (mTOR) inhibitor everolimus have shown activity in patients with metastatic pNETs and have stimulated renewed interest in translational research and novel therapies for this disease. Peptide receptor radionuclide therapy (PRRT) with lutetium-177–dotatate is also emerging as an effective therapy for properly selected patients with neuroendocrine tumors. Importantly, many patients who develop metachronous recurrence years after pancreatectomy for a nonfunctioning pNET will have somewhat indolent disease. The majority of these patients will be treated with somatostatin analogue therapy (lanreotide), and disease stabilization is frequently seen with this treatment. The optimal management of patients with low-volume metastatic pancreatic neuroendocrine carcinoma requires thoughtful multidisciplinary input from oncologists, interventional radiologists, and frequently surgeons. Liver resection, systemic therapy (to include lanreotide), PRRT, and local ablative therapies, both intra-arterial and percutaneous, can all add to improved length and quality of life for affected patients; however, their optimal sequencing is critically important.

Finally, in our practice, we rarely proceed with surgery in a patient with a nonfunctioning pNET if a gross, complete resection cannot be performed. However, in the setting of known metastatic disease or a large, borderline resectable primary tumor, we frequently use neoadjuvant therapy (cytotoxic and/or biologic). In the setting of synchronous liver metastases, a 1- or 2-stage surgical approach can be used with or without neoadjuvant therapy. In contrast to exocrine pancreatic cancer, we frequently resect neuroendocrine liver metastases. When dealing with a resectable primary tumor and resectable liver metastases, we usually remove the pancreatic tumor first; if the pancreatectomy goes well, then some or all of the liver disease can be addressed at the same operation. If the magnitude of surgery required for the pancreatic primary is too large, the liver surgery should be performed at a second stage. As one can imagine, there are various degrees of complexity with regard to combined pancreas-liver resections. For patients with more advanced liver metastases, in whom a future liver remnant can be cleared at the time of the initial pancreatectomy, one can even consider portal vein embolization and second-stage extended hepatectomy. This of course assumes excellent health of the patient, a reasonable age category, and the absence of medical comorbidities. Indeed, future options to combine novel systemic therapies with advanced surgical techniques hold great promise for

patients with pNETs, even those with disease that may have been considered nonoperable in the past.

# COMPLICATIONS OF PANCREATECTOMY

*Mu Xu • O. Joe Hines*

## INTRODUCTION

### **Pancreaticoduodenectomy**

Perhaps one of the most technically challenging abdominal surgeries, pancreatectomy has evolved from a bold innovative intervention to a well-refined lifesaving procedure over the past decades. Pancreatectomy is, however, associated with a long history of high mortality and morbidity. In 1899, William S. Halsted performed the first successful resection of ampullary carcinoma through a transduodenal approach at Johns Hopkins Hospital. In this surgery, he reimplanted the common bile duct and pancreatic duct onto the duodenum, but did not resect the head of pancreas. The first true pancreatectomy did not occur until 1912, when the German surgeon Walther Carl Eduard Kausch performed the first two-stage pancreaticoduodenectomy with an en bloc resection of the head of pancreas for ampullary carcinoma. Mortality was as high as 25%, and mostly resulted from postoperative hemorrhage, peritonitis, and pancreatic fistula.

The transduodenal approach to pancreatectomy continued to be the approach of choice until 1935. In that year, Allen O. Whipple from Columbia University published his first three cases of the two-stage pancreaticoduodenectomy for ampullary carcinoma (Whipple et al., 1935). Whipple described oversewing the pancreatic stump in order to avoid disruption of the pancreaticojejunostomy. Of the three patients in this report, one died during the immediate postoperative period, one died of anastomotic leak a few months later, and the other suffered from pancreatic fistula but survived. Whipple later modified the pancreaticoduodenectomy into a one-stage procedure. Alexander Brunschwig from the University of Chicago is credited, though, as the first to perform a one-stage procedure to resect a pancreatic head cancer. In 1941, Whipple reported his experience with 41 cases of pancreaticoduodenectomy, emphasizing the importance of one-stage procedure to avoid inflammatory adhesions from a two-stage resection along with an end-to-side choledochojejunostomy and jejunojejunostomy for prevention of reflux cholangitis (Whipple, 1941).

From the 1940s to the early 1970s, the mortality from pancreaticoduodenectomy remained at least 25% in most series. The one exception was a report by Dr. John M. Howard in 1968, in which 41 cases of pancreaticoduodenectomy were performed without any mortality at the Hahnemann Hospital (Howard, 1968). With the advent of preoperative risk stratification improved imaging, high-volume pancreatic surgery centers, and interventional radiology, the mortality has decreased significantly, to below <2%. In 1990, Dr. Michael Trede from Heidelberg published the experience of 118 consecutive pancreaticoduodenectomies without mortality (Trede et al., 1990). In 1997, Charles Yeo et al. published the experience at Johns Hopkins Hospital with 650 pancreaticoduodenectomies and an overall mortality of 1.4%. Despite these improvements in mortality and the expansion of the indications for a variety of pathologies, the morbidity remains high to this day, ranging from 25% to 45% at most centers. These complications include pancreatic fistula (PF), delayed gastric emptying (DGE), post-pancreatectomy hemorrhage (PPH), biliary leaks, and pancreatic insufficiency. General complications nonspecific to pancreatectomy such as wound infections, sepsis, cardiac and pulmonary events, and renal failure have significantly decreased.

## **Distal Pancreatectomy**

Distal pancreatectomy for resection of tumors in the body or tail of the pancreas developed at a slower pace than pancreaticoduodenectomy, largely due to its associated pathology. Carcinoma of the pancreas has been very difficult to diagnose historically—especially the lesions located in the body or tail of the pancreas, since these patients usually present later, manifesting metastatic disease. With improved imaging and the recognition of other entities like pancreatic neuroendocrine tumors, cystic neoplasms, and intraductal papillary mucinous neoplasm (IPMN), distal pancreatectomy has become a more frequent procedure.

The German surgeon Werner Körtz reported that Trendelenburg performed perhaps the first reported distal pancreatectomy for sarcoma in the tail of the pancreas in 1882. The patient died after a few months. Theodor Billroth performed the first successful distal pancreatectomy with resection of the most of the body and tail of the pancreas in 1884. Since then there were not many reported cases of this procedure until the 1910s. John M.T. Finney from Johns Hopkins Hospital reviewed 16 cases of pancreatectomy from the literature and also reported one case of his own. In the 16 reviewed cases, four cases appeared to be distal pancreatectomy for a variety of pathologies and included the 1882 Trendelenburg case (Finney, 1910). His own case was actually a central pancreatectomy for pancreatic cystadenoma. This case was complicated postoperatively by pancreatic fistula that eventually resolved, and the patient survived. In 1913, William J. Mayo from the Mayo Clinic reported one case of distal pancreatectomy with the resection of the body and tail of the pancreas for a benign pancreatic cyst (Mayo, 1913). Keith D. Lillemoe published in 1999 the experience of 235 cases of distal pancreatectomies at Johns Hopkins Hospital (Lillemoe et al., 1999). The mortality was less than 1% but the morbidity was 30%. The most common complications were new-onset diabetes, pancreatic fistula, intraabdominal abscess, small bowel obstruction, and postoperative hemorrhage. Other studies have reported pancreatic fistula as being the most common complication in as many as 25% of patients.

## **Total Pancreatectomy**

The most radical pancreatic resection is the total pancreatectomy, and this

was first performed in 1944 by James T. Priestly from Mayo Clinic to remove an insulinoma (Priestley et al., 1944). Alexander Brunschwig also reported the first case of total pancreatectomy for carcinoma in 1944 (Brunschwig, 1944). The concept of total pancreatectomy became popularized in the 1960s and 1970s in order to prevent the high recurrence of pancreatic cancer after partial resection, which was thought to be from a multicentric disease. In addition, surgeons believed that the rate of pancreatic fistula was unacceptably high, and removing the entire gland would obviate this concern. However, studies in the 1980s demonstrated that total pancreatectomy carried the same oncological outcome as partial resection (Karpoff et al., 2001; Schnelldorfer et al., 2008; Sperti et al., 1997; Westerdahl et al., 1993). One reason is that total pancreatectomy does not increase the rate of a negative resection margin compared to partial pancreatectomy. In addition, most pancreatic fistulae can be managed medically without significant long-term complications, negating one potential benefit of total pancreatectomy.

The mortality of total pancreatectomy has decreased significantly over the years. In reports published since 1980s, the mortality ranges from 0% to 17% (Balcom et al., 2001; Karpoff et al., 2001; Swope et al., 1994) in high-volume centers. Total pancreatectomy carries significant endocrine and exocrine sequela that require preoperative evaluation and patient education along with lifelong management of this inherent pancreatic insufficiency. The concerns and risks of diabetes can be potentially mitigated with concurrent islet cell autotransplantation for patients undergoing resection for benign conditions such as chronic pancreatitis. However, a long-term follow-up study from the University of Minnesota has shown that 46% of patients became insulin-dependent again after 5 years despite initial insulin independence immediately after surgery (Sutherland et al., 2012).

In this chapter, we discuss the major complications from pancreatectomy: PF, DGE, PPH, biliary leak, and pancreatic insufficiency. These complications can significantly delay patient recovery, the initiation of adjuvant chemoradiotherapy, and impact patients for years following resection. Progress in the understanding and management of these complications has been made. The International Study Group of Pancreatic Surgery (ISGPS) has significantly contributed to these areas and has formulated consensus definitions and grading of PF, DGE, and PPH.

# COMPLICATIONS FROM PANCREATECTOMY

## Pancreatic Fistula

Pancreatic fistula is one of the most common and feared complications from partial pancreatectomy and occurs generally in 10% to 25% of cases. The most common clinical presentation is the appearance of murky fluid in a drain left next to the pancreaticoenteric anastomosis or cut edge of the pancreas. Alternatively, the patient manifests an intraabdominal fluid collection of pancreatic juice or abscess following the operation. Historically there have been many different names for this complication, such as pancreatic leak and pancreatic anastomotic insufficiency. The ISGPS has determined these terms as interchangeable and prefers the use of the term “pancreatic fistula” (Shukla et al., 2010).

## ETIOLOGY

Pancreatic fistula often results from the disruption of the pancreaticoenteric anastomosis either from ischemia, erosion by pancreatic enzymes, or other technical issues. Pancreatic fistula can also develop from the cut edge of the pancreas if the pancreatic duct has not been sufficiently ligated with suture or controlled with staples.

## RISK FACTORS

The texture of the pancreas appears to be the most important risk factor of pancreatic fistula after pancreatectomy. A soft pancreas does not hold suture or staples well, and postoperatively the local inflammatory process can disrupt these. Soft glands are often found in patients with neuroendocrine tumors, ampullary tumors, and cystic lesions. In patients with chronic pancreatitis, the nature of this disease process leads to inflammation and fibrosis of the pancreas, making the gland firm, and the occurrence of pancreatic fistula is relatively low (Donahue and Reber, 2015). Pancreatic cancer is associated with a fibrotic pancreas and this is responsible for a lower PF rate in patients with this disease. Other risk factors include the size of the pancreatic duct diameter and intraoperative blood loss. The ISGPS has posted an on-line risk calculator to help inform the risk of developing a

fistula following resection (<https://www.pancreasclub.com/calculators/isgps-calculator/>).

## CLINICAL PRESENTATION

Most commonly, patients with a pancreatic fistula simply demonstrate a change in the character of the effluent found in a surgically placed drain. The fluid no longer appears serosanguinous and instead becomes cloudy or completely clear. Some patients will manifest systemic signs ranging from a prolonged ileus or an elevated white blood cell count with a fever to more ominous signs of a significant inflammatory response with tachycardia, renal dysfunction, and mental confusion. The surgeon should be suspicious of the occurrence of a PF, checking for these changes each postoperative day.

## DIAGNOSIS

The criteria to diagnose a pancreatic fistula have varied considerably in the literature. A widely used criteria is fluid output via an operatively placed drain (or a subsequently placed percutaneous drain) of any measurable volume on or after postoperative day 3 with an amylase content greater than three times the upper normal serum value. Abnormal-appearing drainage other than clear pancreatic juice can also be a sign of pancreatic fistula. In the literature, there are at least four widely used criteria, summarized in [Table 76-1](#) (Bassi et al., 2005).

**TABLE 76-1: DEFINITIONS OF PANCREATIC FISTULA**

1. Output >10 mL/d of amylase-rich fluid ( $>3\times$  serum amylase) postoperative (postop) day 5 or for >5 days
2. Output >10 mL/d of amylase-rich fluid after postop day 8 or for >8 days
3. Output between 25 mL/d and 100 mL/d of amylase-rich fluid after postop day 8 or for >8 days
4. Output >50 mL/d of amylase-rich fluid after postop day 11 or for >11 days

Four final definitions summarizing the current pancreatic fistula concept according to the literature. Reproduced with permission from Bassi C, Dervenis C, Butturini G, et al. Postoperative pancreatic fistula: an international study group (ISGPF) definition, *Surgery* 2005 Jul;138(1):8-13.

In 2005, the ISGPS released a report to categorize pancreatic fistula into three grades: grade A (mild), grade B (moderate), and grade C (severe). This system was modified recently and the details are outline in [Table 76-2](#).

**TABLE 76-2: GRADES OF PANCREATIC FISTULA FROM ISGPF**

**Main Parameters for POPF Grading**

Grade	Biochemical Leak	B	C
Clinical conditions	Well	Often well	Ill appearing
Specific treatment	No	Yes/no	Yes
US/CT (if obtained)	Negative	Negative/positive	Positive
Persistent drainage (after 3 weeks)	No	Yes	Yes
Reoperation	No	No	Yes
Death related to POPF	No	No	Possibly yes
Signs of infections	No	Yes	Yes
Sepsis	No	No	Yes
Organ failure	No	No	Yes/no

Reproduced with permission from Bassi C, Dervenis C, Butturini G, et al. Postoperative pancreatic fistula: an international study group (ISGPF) definition, *Surgery* 2005 Jul;138(1):8-13.

Imaging is not required to diagnose pancreatic fistula; however, it may be helpful to assess the size and location of the potential intraabdominal abscess, placement of the surgical drain, and the existence of complications that lead to gastric outlet obstruction from anatomical abnormalities.

**TREATMENT**

The treatment of pancreatic fistula is mostly conservative, and fortunately, most pancreatic fistulae (70%-82%) will resolve within weeks with conservative management. This is true for both pancreaticoduodenectomy and distal pancreatectomy.

With biochemical leak pancreatic fistula, which is the most common form of pancreatic fistula, the patients can still feed orally. Total parenteral nutrition (TPN) or somatostatin analog such as octreotide is not required and this class of fistula rarely delays hospital discharge. In contrast, grade B pancreatic fistula requires significant adjustment from the standard clinical pathway. The patient may require strict NPO and TPN. Octreotide may be indicated if the volume is significant. If the patient has fever or leukocytosis, antibiotics are also needed. Hospital discharged is likely to be delayed as these patients may need interventional drainage of fluid collections or angiographic embolization for hemorrhage, and readmission is more likely to occur. However, the patient can often be discharged home with surgical drain in place and followed up in an outpatient setting.

Grade C pancreatic fistula requires major changes of the standard clinical pathway. The patient often requires NPO, TPN, intravenous antibiotics, and somatostatin analog and care in an intensive care unit. CT scan may show peripancreatic fluid collection. Hospital stays are often lengthened. If the patient continues to deteriorate clinically, reoperation may be required to repair or revise the pancreaticoenteric anastomosis. In extreme conditions, completion pancreatectomy may be necessary.

## **PREVENTION**

Over the years, there have been many studies on potential methods to prevent pancreatic fistula. Fibrin glue and other hemostatic agents have been tested. One of the early trials by Kram et al. (1991) has shown promising results. In their report, no pancreatic fistula occurred in 15 patients. However, late reports consistently failed to show the advantage of fibrin glue (Lillemoe et al., 2004; Orci et al., 2014). For example, Lillemoe et al. (2004) reported that out of 125 patients, pancreatic fistula occurred in 26% of the fibrin-glue group, compared to 30% of the control group. A variation of this method, by internal occlusion of the pancreaticojejunostomy anastomosis, also failed to find a significant difference in the incidence of pancreatic fistula (Lorenz et al., 1988).

A double-blinded randomized clinical trial by Allen et al. (2014) from Memorial Sloan-Kettering Cancer Center has shown promising results with pasireotide for prevention of pancreatic fistula. Pasireotide is another somatostatin analog with higher half-life and better binding capacity than

octreotide. Pasireotide or placebo is administered subcutaneously twice daily for 7 days after pancreatectomy. The authors found significant decrease in pancreatic fistula in the pasireotide group compared to the placebo group (9% vs 21%).

## **Delayed Gastric Emptying**

DGE is characterized by oral intolerance, inability to remove the nasogastric tube, and/or the necessity of reinserting the nasogastric tube several days after the operation. It can significantly delay the patient recovery, nutritional improvement, and the initiation of adjuvant therapy. In most reports, the rate of DGE ranges from 19% to 57%. (Martignoni et al., 2000; Miedema et al., 1992; Richter et al., 2003; Wente et al., 2007a; Yamaguchi et al., 1999; Yeo et al., 1997).

### **ETIOLOGY/RISK FACTORS**

The mechanism of DGE is largely unknown. It has been postulated that the resection of duodenum can trigger DGE, and this is supported by the fact that there is less DGE with duodenum-preserving pancreatic head resection. In addition, distal pancreatectomy that does not involve duodenal resection rarely causes DGE. Decreased motilin level has also been suggested to trigger DGE, given that the prokinetic drug erythromycin, which is a motilin agonist, can reduce the incidence of DGE.

Pylorus-preserving pancreaticoduodenectomy is one of the most common variations of the classic pancreaticoduodenectomy, and some reports have claimed that it is associated with higher incidence of DGE, while others have shown the opposite. The etiology of this may be that pylorus-preserving pancreaticoduodenectomy can cause devascularization or denervation of the pylorus with subsequent pylorospasm.

### **CLINICAL PRESENTATION**

DGE is frequently manifested as failure to tolerate PO intake, failure to remove nasogastric tube, or emesis after removal of nasogastric tube.

### **DIAGNOSIS**

There have been many definitions of DGE historically. In order to reconcile the difference, the ISGPS has released a consensus definition of DGE in 2007 and also classified DGE into three grades, as shown in [Table 76-3](#).

**TABLE 76-3: THE ISGPS DEFINITION OF DELAYED GASTRIC EMPTYING**

Consensus definition of DGE after pancreatic surgery				
DGE Grade	NGT Required	Unable to Tolerate Solid Oral Intake by POD	Vomiting/Gastric Distension	Use of Prokinetics
A	4-7 days or reinsertion > POD 3	7	±	±
B	8-14 days or reinsertion > POD 7	14	+	+
C	>14 days or reinsertion > POD 14	21	+	+

Reproduced with permission from Wente MN, Bassi C, Dervenis C, et al. Delayed gastric emptying (DGE) after pancreatic surgery: a suggested definition by the International Study Group of Pancreatic Surgery (ISGPS), *Surgery* 2007 Nov;142(5):761-768.

In contrast to pancreatic fistula, for which imaging is often not required, diagnosis of DGE frequently requires imaging. The most commonly used study is fluoroscopic upper gastrointestinal series. CT scan can also be used to visualize distended stomach and also rule out stenosis in the gastric outlet, which may require reoperation or endoscopic management.

## TREATMENT

Grade A DGE is not commonly associated with vomiting. Prokinetic medications and TPN may not be required in the first 14 days after the operation. It only causes minor adjustment of the standard clinical pathway, and hospital discharge is often not delayed.

In contrast, grade B DGE involves significant adjustment of the standard clinical pathway. The patients often have vomiting if a nasogastric tube is not in place, necessitating replacement of this. TPN and prokinetic medications are frequently required. Hospital discharge is often delayed, as well patient recovery and likely the initiation of adjuvant therapy.

Grade C DGE necessitates major changes in clinical management and is often associated with other complications such as pancreatic fistula and intraabdominal abscess, which frequently requires radiological or even operative intervention. Prokinetic medications, nasogastric tube, and TPN are required. Hospital discharge and adjuvant therapy are frequently delayed. [Table 76-4](#) shows parameters of DGE.

**TABLE 76-4: PARAMETERS OF DGE**

DGE	Grade A	Grade B	Grade C
Clinical condition	Well	Often well/minor discomfort	Ill/bad/severe discomfort (increased overall risk owing to complications and procedures)
Comorbidities	No	Possibly yes (pancreatic leak or fistula, intraabdominal abscess)	Possibly yes (pancreatic leak or fistula, intraabdominal abscess)
Specific treatment	Possibly yes (prokinetic drugs)	Yes (prokinetic drugs, potential reinsertion of NGT)	Yes (prokinetic drugs, NGT)
Nutritional support (enteral or parenteral)	Possibly yes (slower return to solid food intake)	Yes (partial parenteral nutrition)	Yes (total parenteral or enteral nutrition via NGT, prolonged, ie, >3 weeks postoperatively)
Diagnostic evaluation	No	Possibly yes (endoscopy, upper GI contrast study, CT)	Yes (endoscopy, upper GI contrast study, CT)
Interventional treatment	No	No	Possibly yes (eg, abscess drainage, relaparotomy for complication, relaparotomy for DGE)
Prolongation of hospital stay	Possibly yes	Yes	Yes
Delay of potential adjuvant therapy	No	No	Yes

Reproduced with permission from Wente MN, Bassi C, Dervenis C, et al. Delayed gastric emptying (DGE) after pancreatic surgery: a suggested definition by the International Study Group of Pancreatic Surgery (ISGPS), *Surgery* 2007 Nov;142(5):761-768.

## Post-Pancreatectomy Hemorrhage

Perhaps the most severe complication of pancreatectomy, PPH only accounts for 1% to 8% of all complications after pancreatectomy. However, PPH results in an 11% to 38% overall mortality rate. In the early era of pancreatectomy, PPH was one of the major causes of postoperative death, partially due to the severity of bleeding, lack of intensive care units and interventional radiology, and the generally poor health status of the patients. Today PPH is rare in high-volume surgical centers. However, the importance of recognizing and treating PPH cannot be overemphasized.

### ETIOLOGY/RISK FACTORS

Based on timing, PPH can be categorized as either early or late, according to the ISGPS definition (Table 76-5). Early PPH occurs within 24 hours postoperatively and is often a result of surgical error or patient coagulopathy. Late PPH occurs after 24 hours postoperatively and is often a sign of erosion of major blood vessels by the pancreatic juice. It is therefore common to find other complications such as pancreatic fistula or intraabdominal abscess along with late PPH. Another scenario of late PPH is pseudoaneurysm resulting from vascular injury during the index operation. PPH can occur in major visceral arteries or veins, pancreatocenteric anastomosis, raw surface

of the pancreas after resection, and biliary stent placed intraoperatively. The common vascular source of PPH includes the stump of the gastroduodenal artery, splenic artery, branches of the superior mesenteric artery (eg, inferior pancreaticoduodenal artery), the splenic vein stump, or, rarely, an intrapancreatic artery (Wente et al., 2007b).

**TABLE 76-5: DIAGNOSTIC DEFINITION OF POST-PANCREATECTOMY  
HEMORRHAGE**

Proposed definition of postpancreatectomy hemorrhage (PPH)

Time of onset

Early hemorrhage ( $\leq 24$  h after the end of the index operation)

Late hemorrhage ( $> 24$  h after the end of the index operation)

Location

Intraluminal (intraenteric; eg, anastomotic suture line at stomach or duodenum, or pancreatic surface at anastomosis, stress ulcer, pseudoaneurysm)

Extraluminal (extraenteric, bleeding into the abdominal cavity; eg, from arterial or venous vessels, diffuse bleeding from resection area, anastomosis suture lines, pseudoaneurysm)

Severity of Hemorrhage

Mild

Small or medium volume blood loss (from drains, nasogastric tube, or on ultrasonography, decrease in hemoglobin concentration  $< 3$  g/dL)

Mild clinical impairment of the patient, no therapeutic consequence, or at most the need for noninvasive treatment with volume resuscitation or blood transfusions (2-3 units packed cells within 24 h of end of operation or 1-3 units if later than 24 h after operation)

No need for reoperation or interventional angiographic embolization; endoscopic treatment of anastomotic bleeding may occur provided the other conditions apply

Severe

Large volume blood loss (drop of hemoglobin level by  $\geq 3$  g/dL)

Clinically significant impairment (eg, tachycardia, hypotension, oliguria, hypovolemic shock), need for blood transfusion ( $> 3$  units packed cells)

Need for invasive treatment (interventional angiographic embolization, or relaparotomy)

---

Reproduced with permission from Wente MN, Veit JA, Bassi C, et al. Postpancreatectomy hemorrhage (PPH): an International Study Group of Pancreatic Surgery (ISGPS) definition, *Surgery* 2007 Jul;142(1):20-25.

## CLINICAL PRESENTATION

PPH can manifest itself in a variety of ways, such as bleeding from the nasogastric tube or surgical drains, hematemesis, melena, unexplained hypotension, tachycardia, etc. A small initial bleed from the nasogastric tube or surgical drain can be a sentinel bleeding, heralding a massive hemorrhage within a few hours. High clinical suspicion is therefore paramount in identifying and diagnosing PPH.

## DIAGNOSIS

There has been a significant variety in the definition of PPH in the literature. In 2007, ISGPS released a consensus definition of PPH based on three criteria: (1) timing of onset: *early* (within 24 hours of the index operation), or *late* (after 24 hours since the index operation); (2) location: intraluminal (eg, pancreatic surface, anastomoses, gastric/duodenal ulcer/erosion, or hemobilia), or *extraluminal* (eg, arterial or venous vessel, operating field, external suture or staple line, or pseudoaneurysm); (3) severity of bleeding: *mild* or *severe*. *Mild bleeding* is characterized as a small or medium volume blood loss (drop of hemoglobin concentration of less than 3 g/dL) with no or minimal clinical impairment, no need for invasive intervention (reoperation or interventional angiography), and successful conservative treatment (fluid resuscitation and blood transfusion of 2 to 3 units packed red blood cells if it is an early bleed, or three units while hospitalized and late bleed). *Severe bleeding* is a larger-volume blood loss (decrease in hemoglobin concentration of  $\geq 3$  g/dL) and potentially life-threatening complications with tachycardia, hypotension, and/or oliguria; treatment involves the need for blood transfusion ( $\geq 3$  units packed red blood cells) and/or invasive treatment (reoperation or interventional angiography).

Grade A PPH requires only a minor and temporary adjustment from the standard clinical pathway and has no major clinical impact. Hospital discharge is often not delayed. Grade B PPH, on the other hand, requires adjustment of a standard clinical pathway and often involves workup and intervention such as transfusion, radiological intervention such as embolization, reoperation, readmission, and/or intensive care unit transfer. Hospital discharge is often delayed. Grade C PPH is the most severe form and often requires immediate workup and interventions such as embolization

or reoperation. Intensive care unit admission is frequent, and hospital stay is almost always prolonged.

## **TREATMENT**

PPH is often a significant complication that requires prompt recognition and management. Once PPH is suspected, resuscitation is mandatory, while diagnostic testing may be carried out at the same time to identify the location and cause of the bleed. The diagnostic tests include, but are not limited to, complete blood count, coagulation panel, CT angiography, etc. Transfusion may be required for grade B PPH and is often necessary for grade C PPH. For pseudoaneurysm, radiological embolization is frequently used. If the PPH is caused by disruption of the anastomosis or erosion of the visceral vessels by the pancreatic juice, reoperation is frequently necessary.

## **Biliary Leak**

Biliary leak is a fairly uncommon complication following pancreaticoduodenectomy. This is perhaps due to the resection of the distal, also the narrowest, portion of the common bile duct, and the common use of larger-caliber anastomosis from hepatojejunostomy. Miedema et al. (1992) reported 24 patients with postoperative biliary-enteric anastomotic leak rate out of 279 patients (9%) who underwent pancreaticoduodenectomy at the Mayo Clinic from 1980 to 1989. Sohn et al. (2003) further reported that of 1061 patients who underwent pancreaticoduodenectomy at Johns Hopkins Hospital from 1995 to 2000, only 39 (3.7%) required postoperative drainage for biliary leaks from etiologies such as from biliary anastomotic disruption, undrained biliary segments, or T-tube/bile stent dislodgment. Of note, out of 1061 patients, 342 had preoperative biliary drainage, which may have decreased the incidence of postoperative biliary leak. In a report by Behrman et al. (2004) from the University of Tennessee, no biliary complication was reported out of 125 patients who underwent pancreaticoduodenectomy, distal pancreatectomy, or total pancreatectomy.

Nevertheless, biliary leak increases postoperative morbidity and mortality. In Miedema's report, mortality increased from 2% to 17% with biliary leak ( $p < 0.05$ ).

## **ETIOLOGY/RISK FACTORS**

No particular risk factors have been identified. In the report by Miedema et al. (1992), biliary leak is not associated with bile duct size, preoperative or postoperative bile duct drainage, or preoperative serum bilirubin level.

## **DIAGNOSIS**

Biliary leak usually does not require special diagnostic workup. It is often evidenced by bile in the fluid collected by the surgical drain left at the time of operation. If it presents as abdominal abscess, CT scan can often be sufficient.

## **TREATMENT**

Although postoperative biliary leak is associated with increased morbidity and mortality, it usually can be managed conservatively without percutaneous drainage or reoperation. For some patients with high-volume output, diversion with a transhepatic catheter may be helpful. Miedema et al. (1992) only reported 3 out of 24 patients who required reoperation. In Sohn et al.'s report, only 3.7% required percutaneous drainage.

## **Pancreatic Insufficiency**

Pancreatic exocrine insufficiency is fairly common with chronic pancreatitis or pancreatic cancer even prior to pancreatectomy. In a recent systematic review, Tseng et al. (2016) found that 20% to 63% of patients presented with preoperative pancreatic exocrine insufficiency. This rate increased to 67% to 80% 6 months after pancreatectomy. Another recent meta-analysis has found that exocrine insufficiency has occurred in 27% patients after pancreatectomy, with pancreaticoduodenectomy and female gender as independent risk factors (Kachare et al., 2014). The extent of pancreatic resection directly predicts the probability of developing pancreatic exocrine insufficiency imposing a significant negative impact on the quality of life (Okano et al., 2016). However, the mechanism of pancreatic exocrine insufficiency is multifactorial (Phillips, 2015). For example, the resection of stomach and duodenum can change the gut pH and interferes with the

pancreatic enzymatic activities (Tran et al., 2009). Pancreaticojejunostomy and hepatojejunostomy can cause asynchrony between pancreatic enzyme delivery and food absorption (Bruno et al., 1995; Sikkens et al., 2014).

Pancreatic exocrine insufficiency is often diagnosed with a combination of clinical presentation and pancreatic exocrine function tests with fecal fat content and fecal elastase determination. Patients may present with malnutrition. Steatorrhea is often a late symptom of pancreatic exocrine insufficiency and patients often avoid fatty food, further delaying the onset of steatorrhea.

Currently the mainstay therapy is pancreatic enzyme supplementation or replacement. Pancrelipase, often in the delayed-release form (Creon), is often used. A recent study by Whitcomb (2016) has shown that pancrelipase significantly increases fat and nitrogen absorption. Proton-pump inhibitors (PPIs) are also often used to suppress gastric pH, given the decrease pancreatic bicarbonate secretion. However, no significant difference in fat absorption has been found in the PPI group and the placebo group (Sander-Struckmeier et al., 2013).

## **New-Onset Diabetes**

Since pancreatectomy removes pancreatic endocrine components, it is not uncommon for patients to develop new-onset insulin-dependent diabetes. A study comparing quality of life after total pancreatectomy and partial pancreatic resection found that postoperative diabetes after both procedures had the largest negative impact on leisure and physical activities (Epelboym et al., 2014; Petrin et al., 1995).

If the pancreatectomy is for chronic pancreatitis, the pancreas is likely already compromised before the surgery. It is therefore not surprising that chronic pancreatitis patients have an even higher risk of insulin-dependent diabetes than other pancreatic surgical patients (Cannon et al., 2012; Maeda and Hanazaki, 2011). A large systematic review has shown that the risk of new-onset diabetes after distal pancreatectomy in patients with chronic pancreatitis is 39%, and the risk of development of diabetes after resection of pancreatic tumor is only 14% (De Bruijn and van Eijck, 2015). The amount of resection is also positively correlated with the risk of diabetes (Parikh and Lillemoe, 2015). On average, 77% of the patients with new-onset diabetes will require insulin (De Bruijn and van Eijck, 2015).

In patients with new-onset diabetes after pancreatectomy, glucose control is more difficult due to severe fluctuations in glucose levels associated with exogenous insulin and deficiency of pancreatic polypeptide (Cui and Andersen, 2011; Seymour et al., 1988). Mortality from hypoglycemia has been reported in patients with pancreaticoduodenectomy, and it was thought to result from a combination of exogenous insulin and lack of glucagon (Gall et al., 1981). Patients with distal pancreatectomy are at particularly high risk for hypoglycemia, because the glucagon-producing alpha cells are located mainly in the pancreatic body and tail (De Bruijn and van Eijck, 2015).

## SUMMARY

The development and optimization of different types of pancreatectomy have occurred because of a deepening understanding of the associated pathophysiology, advancement in surgical methods, diagnostic tools, and perioperative management, and also management of complications. The mortality associated with pancreatectomy has decreased significantly over the years, from a dismal 40% to less than 2% in high-volume centers. The emergence of high-volume centers have been one of the most important factors in the reduction of mortality. Although still a major undertaking, pancreatectomy nowadays is no longer associated with dreadful outcomes that some in the medical community and the general public still believe exist.

Postoperative morbidity, however, remains common, with a rate between 20% to 45% in most reports. Although most complications can be managed conservatively and will resolve within a few weeks, these complications delay patient recovery and the initiation of adjuvant therapy. Some complications such as hemorrhage can also be life-threatening. These complications underscore the importance of vigilant postoperative management, and also indicate the limitation of our understanding of the pathophysiology of the pancreas.

## **SPLEEN AND ADRENAL**

# THE SPLEEN

*Liane S. Feldman • Amani Munshi • Mohammed Al-Mahroos • Gerald M. Fried*

## BACKGROUND

The spleen was regarded by Galen as “an organ of mystery,” by Aristotle as unnecessary, and by Pliny as an organ that might hinder the speed of runners.<sup>1</sup> In many societies, the spleen was also thought to be affiliated with mood. The word *spleen* comes from a Greek word that has idiomatic equivalent of the heart in English, that is, to be good-spleened means to be good-hearted or compassionate. In contrast, the spleen has also been associated with melancholy, and in 19th-century England, women in bad humor were said to be afflicted by the spleen or the vapors of the spleen.

Until relatively recently, the spleen was considered expendable. The gradual realization of the valuable role of the spleen in host defense, beginning with reports of fulminant sepsis in children after splenectomy for hematologic disease, has increased interest in splenic conservation techniques.<sup>2,3</sup> The indications for splenectomy in both the emergency and elective settings continue to evolve. The introduction of laparoscopic approaches has decreased the morbidity of surgery, but a balance between the indications for splenectomy and the long-term consequences of splenectomy,

particularly sepsis, must always be considered.

In this chapter, we review the anatomy, physiology, and pathology of splenic diseases, before addressing operative techniques and strategies, focusing on the laparoscopic approach.

## RELEVANT ANATOMY

### Gross Anatomy

The spleen arises by mesenchymal differentiation along the left side of the dorsal mesogastrium in juxtaposition to the anlage of the left gonad in the 8-mm embryo. The organ ultimately migrates to the left upper quadrant.

In the healthy adult, the spleen weighs 150 g (range, 75-250 g), although there are variations based on sex, age, and racial background.<sup>4</sup> Although the ultrasonographic upper limit of normal for spleen size is 12 cm, it is larger in men and taller or heavier people, and sex- and size-corrected normal values are available.<sup>5</sup> The spleen is not normally palpable in adults. When the spleen tip can be felt below the left costal margin, splenomegaly should be assumed and further investigated.

The spleen resides in the posterior portion of the left upper quadrant lying deep to the 9th, 10th, and 11th ribs, with its long axis corresponding to that of the 10th rib. Its convex superior and lateral surfaces are immediately adjacent to the undersurface of the left leaf of the diaphragm. The configuration of the concave medial surface of the spleen is a consequence of impressions made by the stomach, pancreas, kidneys, and splenic flexure of the colon (Fig. 77-1).

**FIGURE 77-1** Gross anatomy of the spleen.

The position of the spleen is maintained by several suspensory ligaments, which need to be divided during a splenectomy to allow full mobilization of the organ. These are the gastrosplenic, splenophrenic, splenocolic, and splenorenal ligaments (Figs 77-2 and 77-3). The gastrosplenic ligament contains the short gastric vessels that course to the splenic hilum from the greater curvature, whereas the splenorenal ligament contains the pancreas and the splenic vessels. The remaining ligaments are generally avascular, except in patients with portal hypertension or myeloproliferative disorders. The tail of the pancreas is in direct contact with the spleen in 30% of cases and within 1 cm of the spleen in three-quarters of patients.<sup>6</sup>

**FIGURE 77-2** Anatomy of the spleen showing complicated peritoneal reflections in the region of the hilus.

**FIGURE 77-3** The multiple ligaments of the spleen.

Accessory spleens, which are distinct and separate masses of splenic tissue, have been reported in 14% to 30% of patients undergoing splenectomy, with a higher incidence in patients with hematologic disorders and a lower incidence at autopsy in people without hematologic or splenic disease (7%).<sup>7</sup> They are present in decreasing order of frequency in the hilum of the spleen, tail of the pancreas, greater omentum, gastrosplenic ligament, and splenocolic ligament (Fig. 77-4A). Accessory spleens may also occur in the pelvis, either in the presacral region or adjacent to the left ovary in the female, and in the scrotum in juxtaposition to the left testicle in the male (Fig. 77-4B). The accessory spleens can vary in size and may be small lesions that can be easily missed unless a careful examination is performed (Fig. 77-5).

The accuracy for intraoperative localization of accessory spleens seems higher than computed tomography (CT) scan, and so routine preoperative imaging for the purpose of diagnosis of accessory spleens prior to splenectomy is not routinely recommended.<sup>8</sup>

**FIGURE 77-4** **A.** The more common locations of accessory spleens. Accessory spleens are also found in the left ovary, in the left testicle along the course of the left ureter, and in the lesser sac and greater omentum. **B.** Locations of accessory spleens. Note position of presacral and paraureteric splenuli.

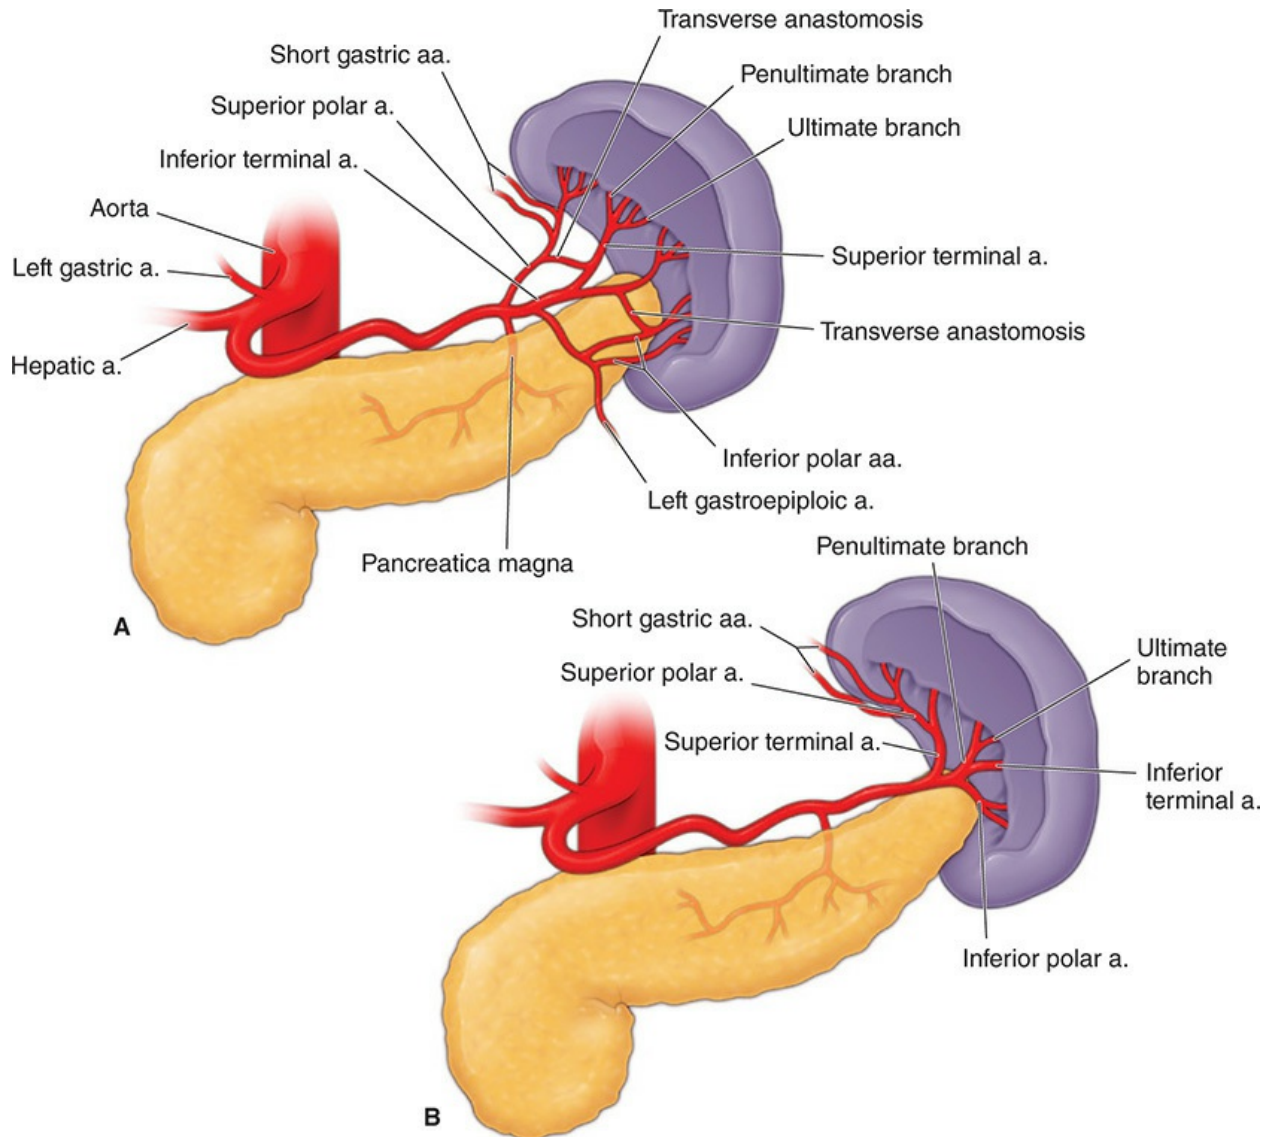

**FIGURE 77-5** Two small splenules in the greater omentum near the spleen.

*Splenoptosis* (wandering spleen) refers to a rare condition in which the spleen hangs by a long pedicle from the mesentery and may present itself as an asymptomatic mass or with symptoms of intermittent or acute abdominal pain due to torsion. Treatment involves splenectomy in cases of ischemia, but splenopexy should be considered in other cases.<sup>9</sup>

## **Splenic Blood Supply**

The spleen is supplied by the splenic artery, the short gastric vessels, and the left gastroepiploic artery. The splenic artery commonly arises from the celiac axis and is the longest of its 3 branches. Most of the splenic arterial supply is derived through this vessel. The 3 to 5 short gastric vessels lie in the gastrosplenic ligament, and there is often a connection between some of the short gastrics and the superior polar branch of the splenic artery. Similarly, there is often a connection between the left gastroepiploic and the inferior polar branch of the splenic artery. The splenic artery has a very tortuous course and has a highly variable pattern of distribution. In 1942, Michels divided the splenic arterial supply into 2 types: distributed and magistral.<sup>10</sup>

- *Distributed type*: The most common variation seen in 70% of cases. Here the main splenic artery is short, dividing into many long branches (6-12) that originate between 3 and 13 cm from the hilum and enter the spleen on the medial aspect, involving 75% of the medial surface (Fig. 77-6A).

**FIGURE 77-6** Different types of splenic artery distribution. The terminal vessels divide the spleen into independent lobes or segments **A**. Distributed type: short splenic artery that divides into long branches that enter the spleen medially, involving 75% of the medial surface. **B**. Magistral (bundled) type: the splenic artery is long with fewer hilar branches. (Reproduced with permission from Souba WW, Fink MP, Jurkovich GJ, et al: *ACS Surgery: Principles and Practice*, 6th ed. Hamilton, ONT, Canada: BC Decker; 2007.)

- *Magistral or bundled type*: The less common variation seen in 30% of cases. Here a long main trunk divides near the hilum into 3 to 4 large branches that enter the spleen medially but only involve 30% of the spleen's medial surface (Fig. 77-6B).

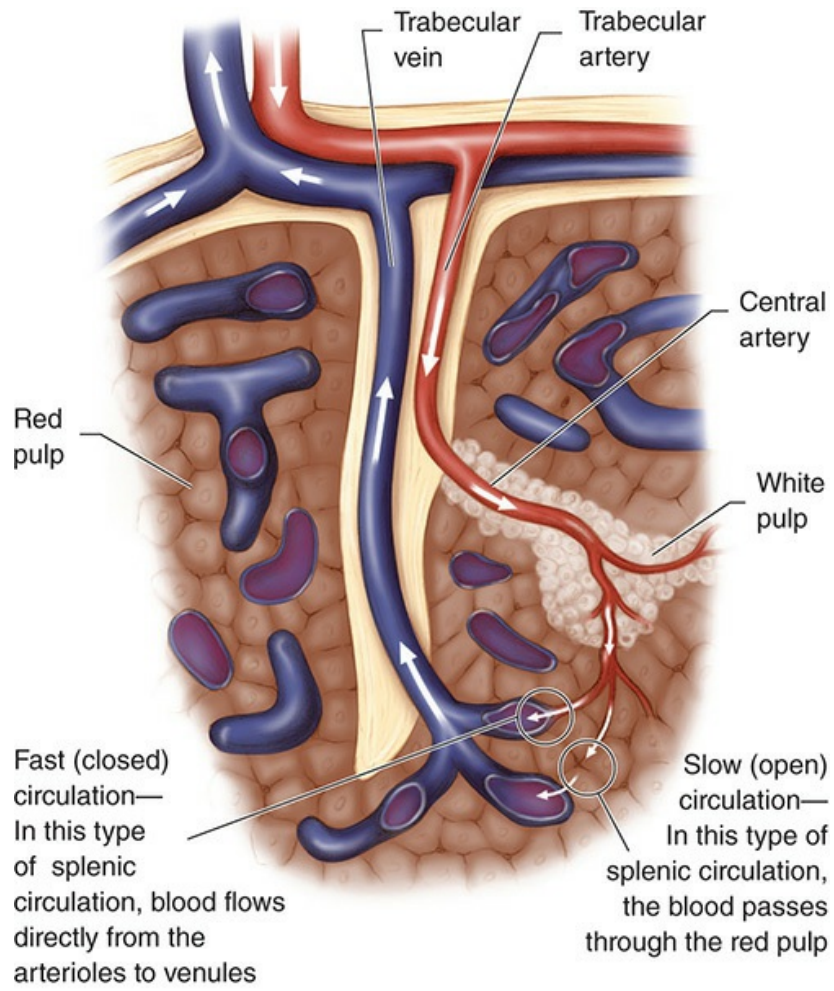

The common splenic artery divides into 2 lobar arteries (superior and inferior) in 86% of cases and 3 lobar arteries in 12% of cases (superior, inferior, and accessory). Each lobar artery divides into segmental arteries with a total of 3 to 5 segmental arteries in 94% of cases. These segmental arteries supply blood to a corresponding wedge-shaped splenic segment. There is a relatively avascular plane between the lobes and segments, so resection of the segmentally devascularized spleen can be performed without significant blood loss. Understanding these relationships is important in performing partial splenectomy.<sup>10</sup>

The splenic artery also has a pancreatic branch (pancreatica magna) that is worthy of note. Occlusion of this branch, most often seen after proximal splenic artery embolization, can lead to pancreatitis.

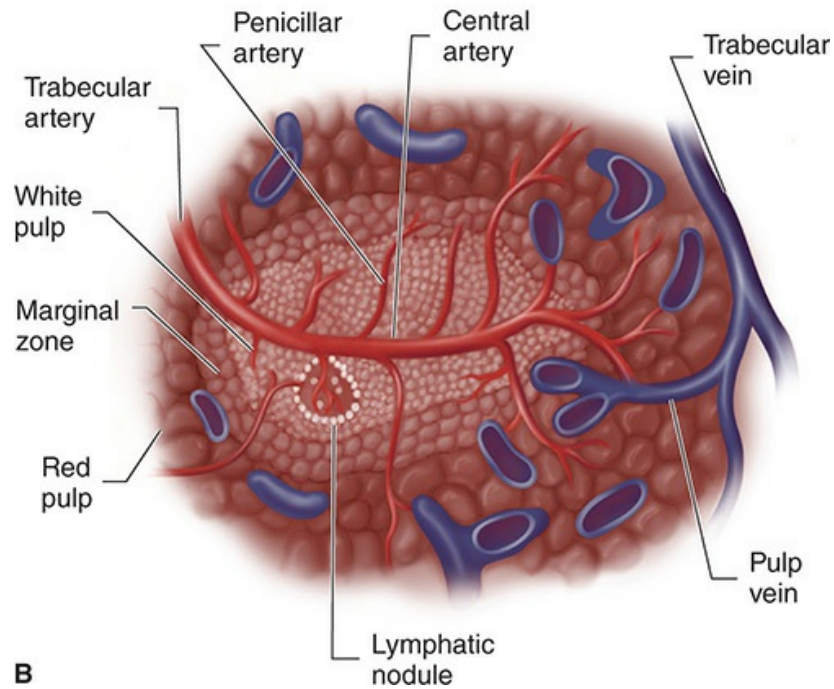

The major venous drainage flows through the splenic vein, which usually receives the inferior mesenteric vein centrally and then joins the superior mesenteric vein to form the portal vein. The veins generally lie behind the arteries except in the hilum where the anatomy is variable.

## Histology

The spleen is made up of a capsule that is normally 1 to 2 mm thick and trabeculae that surround and invaginate the pulp. Approximately 25% of the parenchyma (Fig. 77-7) is made up of “white pulp” that functions as an immunologic organ, with the remaining 75% made up of the “red pulp” that phagocytizes particulate matter from the blood. The 2 zones are separated by a narrow marginal zone.

**A**

**B**

**FIGURE 77-7** Diagram illustrating splenic compartments and the 2 different types of circulation.

The white pulp, which is central and surrounds a central artery, is made of lymphatic nodules with germinal centers and periarterial lymphatic sheaths that constitute a reticular network filled with lymphocytes and macrophages. Peripheral to the white pulp is the marginal zone that contains end arteries arising from the central artery and from peripheral penicilliary arteries. The marginal zone contains lymphocytes and macrophages and red blood cells (RBCs) that have exited from terminal arteries. The marginal zone also contains the marginal sinus, which filters material from the centrally located white pulp. Locally produced immunoglobulins enter the marginal zone, eventually coursing to the bloodstream.

## Physiology

The spleen receives 250 to 300 mL of blood per minute, which corresponds to 5% of the cardiac output. At any given time, however, it contains only 30 to 40 mL of blood. Although the spleen is not necessary for human life, it performs important functions that are generally attributed to its unique blood flow pattern. As the blood enters the spleen, it can take 2 paths of flow: a fast (closed) circulation that takes the blood directly from the arterioles to the venules or a slower (open) circulation that takes the blood through the pulp. The majority (90%) of flow is of the slow (open) type, which exposes the circulating cells and erythrocytes to splenic macrophages in the red pulp (see [Fig. 77-7](#)).

Functions of the spleen can be divided into the following:

*Erythrocyte quality control and removal of defective red cells:* This is achieved through pitting and culling. *Pitting* refers to the removal of rigid structures such as Heinz bodies (denatured intracellular hemoglobin), Howell-Jolly bodies, and hemosiderin granules from red cells. The process involves the removal of nondeformable intracellular substances from deformable cells. The rigid body is phagocytized, while the deformable cytoplasmic mass passes into the sinus and returns to the general circulation. The postsplenectomy blood smear is thus characterized by the presence of circulating erythrocytes with Howell-Jolly and Pappenheimer

bodies (siderotic granules).

*Culling* is the term applied to the spleen's ability to remove red cells that are aged or abnormal. During its 120-day life cycle, the red cell spends an estimated minimum of 2 days within the spleen. Normally, as the red cell ages after a life span of approximately 120 days, it loses osmotic balance and membrane integrity and therefore deformability. When these cells lose their deformability, they are phagocytized by native macrophages. The spleen does not represent the only site for red cell destruction, and there is no difference in red cell survival after splenectomy. About 20 mL of RBCs are removed daily from the blood.

*Pooling*: In health, the spleen does not serve as an important reservoir for blood cells but does so for platelets. Normally, about one-third of the platelet mass is pooled in the spleen, and this pool exchanges freely with the circulating platelets that have a life span of about 10 days. With splenomegaly, a large proportion of platelets are sequestered in the spleen (up to 80%), and this, coupled with accelerated platelet destruction in the spleen, accounts for thrombocytopenia. The role of the spleen in platelet storage also explains the elevation in platelet count that is seen after splenectomy.

The neutrophil has a half-life of about 6 hours; hence, 85% of neutrophils either migrate at random into tissues or are destroyed within 24 hours. Although the role of the spleen in the destruction of neutrophils under normal conditions is not well quantified, this role is amplified in some hypersplenic states, with resulting neutropenia. This augmented removal can occur because of splenic enlargement and accelerated sequestration of granulocytes or because of enhanced splenic removal of altered granulocytes, as seen in immune neutropenias.

*Hematopoiesis*: The spleen has an important hematopoietic function in fetal life that ceases by the seventh intrauterine month and does not occur in healthy adults with exception in certain pathologic conditions where bone marrow is unable to meet the needs (ie, extramedullary hematopoiesis).

*Filtration*: Macrophages residing in the splenic parenchyma capture cellular and noncellular material from blood, including encapsulated bacteria such as pneumococci, and destroy them. This function explains the increased risk of infections caused by encapsulated organisms that is

seen after splenectomy.

*Antibody synthesis in the white pulp:* In addition to the phagocytosis of antibody-coated cells, the immunologic functions of the spleen include antibody synthesis (especially immunoglobulin M [IgM]); generation of lymphocytes; and production of tuftsin, opsonins, properdin, and interferon. Foreign antigens that are filtered in the white pulp are presented to lymphoid cells. Here the immunoglobulin response is mounted, leading to release of antibodies.

## SPLENIC TRAUMA AND RUPTURE

### Etiology

Splenic rupture is defined as any disruption of the splenic parenchyma or capsule. It can be spontaneous, iatrogenic, or traumatic.

Spontaneous splenic rupture is a rare surgical emergency usually caused by splenic infiltration by hematologic, neoplastic, or infectious diseases. In a review of over 800 cases of spontaneous rupture, 6 major etiologic groups were defined: neoplastic (30.3%), infectious (27.3%), inflammatory (20.0%), drug and treatment related (9.2%), mechanical (6.8%), and normal spleen (6.4%). The majority of patients were treated with splenectomy with an overall mortality rate of 12%.<sup>11</sup>

Iatrogenic splenic injuries during abdominal procedures, especially colectomy, are well documented (Fig. 77-8). In a 16-year review of nearly 14,000 colectomies performed at the Mayo Clinic, splenic injury requiring a splenectomy or repair occurred in 0.4%. Although repair was attempted in 50% of cases, the majority of these patients ultimately required splenectomy. Those with an incidental splenectomy had high 30-day morbidity (34%) and mortality (15%).<sup>12</sup> A review of the national inpatient sample database focusing on colorectal surgery between 2006 and 2008 reported a higher incidence of splenic injury of 1%, with 85% of patients treated with splenectomy.<sup>13</sup> Patients who undergo an incidental splenectomy during colorectal surgery for cancer have a poorer prognosis compared to the nonsplenectomized group, suggesting a negative long-term impact of splenic injury in these patients.<sup>14</sup>

**FIGURE 77-8** A large splenic hematoma that developed after intraoperative injury to the spleen during gastric bypass surgery. The patient was hemodynamically stable, and the hematoma resolved without any further intervention.

Colonoscopy has also been associated with splenic injury. Although the rate is extremely low at 0.001%,<sup>15</sup> it is associated with significant morbidity, with more than 70% of patients requiring an operative intervention, and 5% mortality.<sup>16</sup>

The most common cause of splenic rupture is traumatic injury. Mechanism of injury can be blunt or penetrating. The trajectory of the penetrating wound may pass through the anterior abdominal wall, the posterior abdominal wall, the flank, or transthoracically, piercing the pleural space and diaphragm. It can be either isolated to the spleen or associated with injuries to surrounding structures including the stomach, left kidney, left

adrenal gland, colon, pancreas, and root of the mesentery.

## Diagnostic Studies

Signs associated with bleeding might be seen on investigation. A complete blood count might show a decrease in hemoglobin or hematocrit or an increase in white blood cell (WBC) count. A blood gas obtained in the trauma bay might show an increased lactate or abnormal base excess depending on how severe the bleeding is and how long the patient has been bleeding. Findings on routine abdominal films such as fractured ribs, elevated left hemidiaphragm, enlarged splenic shadow, medial gastric displacement, and widening of the space between the splenic flexure and the preperitoneal fat pad may be helpful. A focused assessment with sonography for trauma (FAST) examination may show evidence of intra-abdominal fluid accumulation. However, all these findings are not specific and can be found in trauma patients with no splenic injuries. Intravenous contrast-enhanced CT scan is the gold standard diagnostic study that will also provide detailed information regarding the American Association for the Surgery of Trauma (AAST) grading for severity of injury<sup>17</sup> (Table 77-1).

**TABLE 77-1: AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA  
SPLEEN INJURY SCALE**

Grade <sup>a</sup>	Injury Type	Description of Injury
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%-50% surface area Intraparenchymal, <5 cm in diameter
	Laceration	Capsular tear, 1-3 cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma ≥5 cm or expanding
	Laceration	>3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury with devascularizes spleen

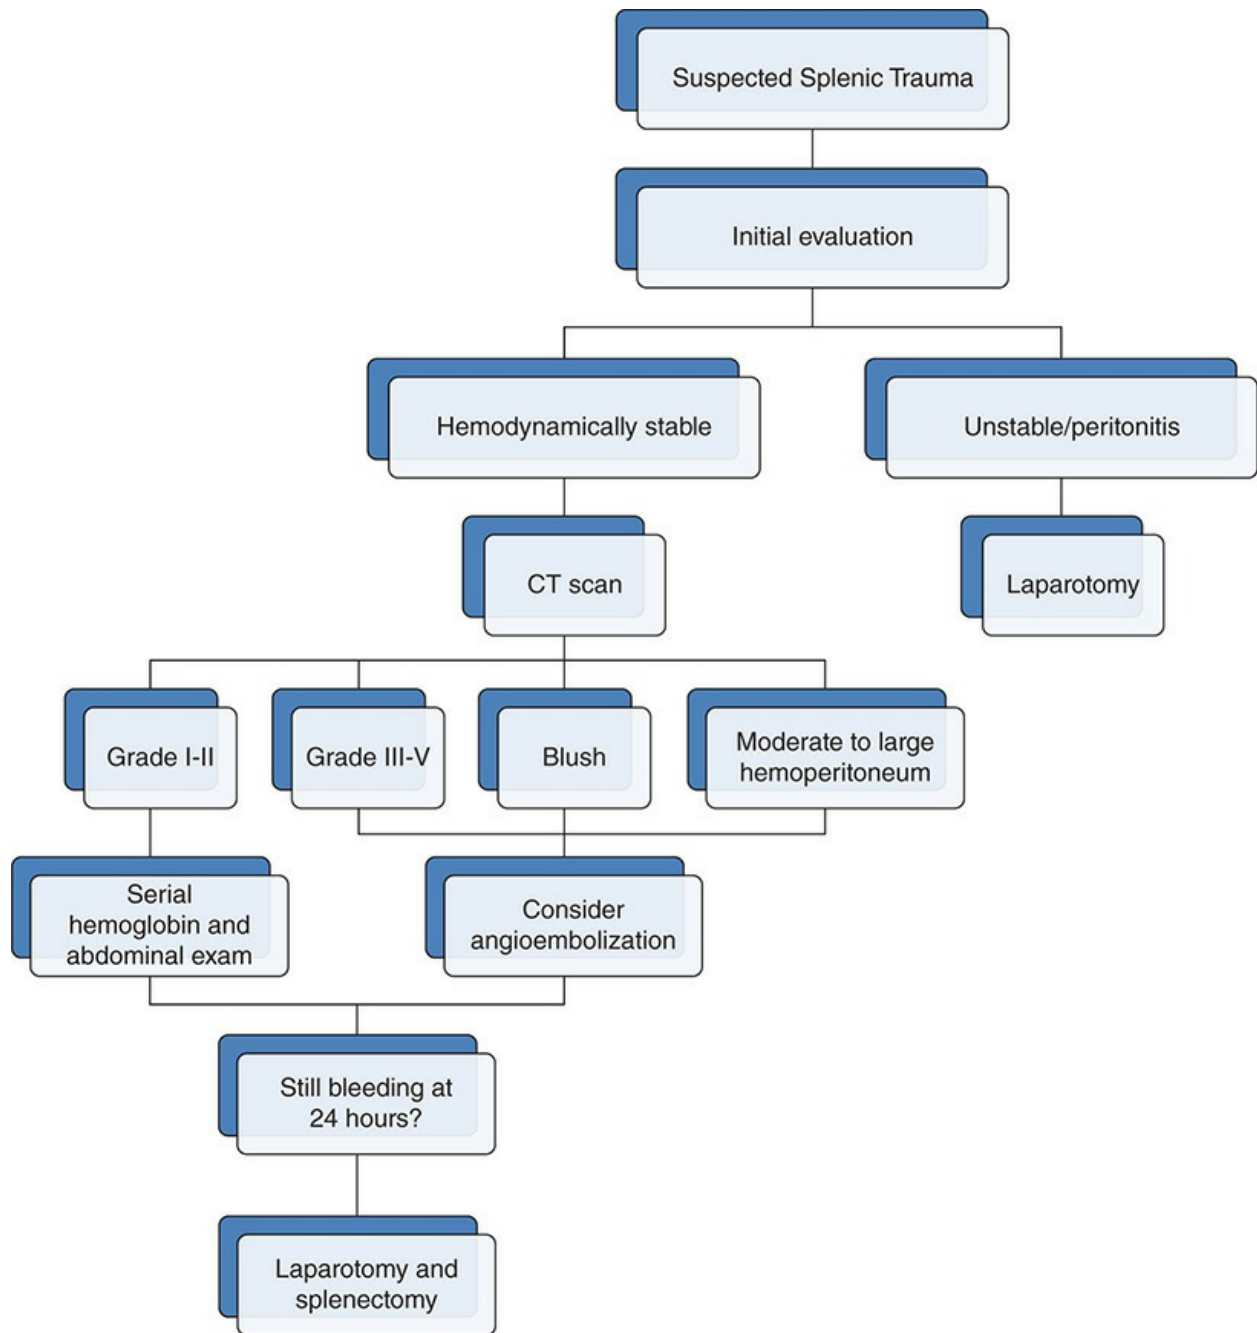

<sup>a</sup>Advance 1 grade for multiple injuries up to grade III.

## Management

The first total splenectomy for trauma was performed by Nicolaus Matthias in 1678 in Cape Town, South Africa, on a patient whose spleen protruded through a flank wound. However, partial splenectomy for trauma antedated this procedure, with the first successful partial splenectomy for trauma reported by Franciscus Rosetti in 1590. Increasing understanding of the functions of the spleen and increased risk of infection in splenectomized patients have rejuvenated interest in splenic salvage in trauma. The first successful partial splenectomy for trauma in modern times was reported by Campos Christo in 1962.<sup>1</sup>

The observation that splenic injury may heal itself has also supported nonoperative management (NOM) of splenic injuries. While this practice was largely accepted in the treatment of injured pediatric patients to salvage the spleen and its immunologic function, NOM is also the treatment of choice for hemodynamically stable adults with blunt splenic injuries, regardless of injury severity (Fig. 77-9). Penetrating injuries, hemodynamic instability, and associated peritonitis are all treated with laparotomy, as per the 2012 Eastern Association for the Surgery of Trauma (EAST) guidelines.<sup>18</sup>

**FIGURE 77-9** Suggested management algorithm for splenic trauma. CT, computed tomography.

NOM of blunt spleen injury requires a multidisciplinary strategy including careful clinical monitoring, repeated laboratory testing, and radiologic investigations. NOM should only be carried out in an institution that has a monitored intensive care unit, available surgical expertise, and easy access to the operating room. NOM procedures include supportive medical

management and angioembolization. The success rate depends on severity of injury and is reported greater than 95% for grade I injuries, greater than 90% for grade II injuries, and greater than 80% for grade III injuries. Splenic salvage is much less likely with grade IV and V injuries. In a multicenter review of 338 patients with grade IV or V blunt splenic injuries, 40% of patients were operated on immediately, while the remainder had an attempt at NOM. The success rate for NOM in these selected patients was 66% for grade IV and 40% for grade V injuries. Thus, overall, nearly two-thirds of patients with grade IV or V injuries required surgery, and there was higher mortality in patients who failed NOM compared to those in whom it was successful.<sup>19</sup> Prognostic factors that predict failure of NOM of blunt splenic trauma were evaluated in a systematic review.<sup>20</sup> The strongest predictors were age >40, Injury Severity Score >24, and grade III to V injury, with moderate evidence for presence of contrast extravasation or “blush” on CT scan.<sup>20</sup>

Splenic artery embolization (SAE) is an important adjunct for NOM, but its precise role remains controversial.<sup>18</sup> A meta-analysis to evaluate NOM of blunt splenic injury found that the overall failure rate was 8.4% (95% confidence interval [CI], 6.7%-10.2%) with failure rates increasing with more severe injuries, from about 5% in grade I to 83% in grade V.<sup>21</sup> The addition of SAE was associated with higher splenic salvage rates for more severe injuries compared to observational management alone (56% vs 83% for grade IV and 17% vs 75% for grade V).<sup>21</sup> Most studies have suggested that splenic function is preserved after SAE, but multiple different parameters were used. There are no reported cases of overwhelming postsplenectomy infections after SAE, and routine vaccination is not used.<sup>22</sup> Splenic embolization, however, has its own risks and may be complicated by splenic abscess, infarction, pain, fever, coil migration, pleural effusion, contrast nephropathy, and bleeding.<sup>23</sup> Currently, angiography is recommended for hemodynamically stable patients with grade III to V injuries, contrast blush, moderate hemoperitoneum, or clinical evidence of ongoing bleeding.<sup>18</sup>

NOM of splenic injuries should not exceed 24 hours. Failure of NOM is defined as persistent bleeding evident by laboratory testing, hemodynamic changes, or persistent requirement of blood transfusion after 24 hours. Failure of NOM is treated by laparotomy and splenectomy or splenorrhaphy.

After discharge, there is a lack of consensus on restriction of activities,

with most restricting activity for >2 months for high-grade injuries managed nonoperatively.<sup>24</sup> Patients should be aware of the risk of delayed splenic rupture, with the 180-day risk of readmission for splenectomy of 1.4% in one population-based study.<sup>25</sup>

## LOCAL SPLENIC DISORDERS

### Splenic Artery Aneurysm

Splenic artery aneurysm was first described by Baussier in 1770, and St. Leger Brockman described one of the first surgical cases in 1930. Although mycotic aneurysm can be seen in the splenic artery, the majority are idiopathic. The splenic artery is the most common visceral artery aneurysm and the third most common site of intra-abdominal aneurysms, after aneurysms of the abdominal aorta and iliac arteries. The incidence in autopsy series ranges between 0.02% and 0.16%, with a female predominance (4:1). They are commonly associated with pregnancy and portal hypertension. The incidence of splenic aneurysm is much higher in patients with cirrhosis and portal hypertension. Splenic artery aneurysms have been reported in 14% of patients awaiting liver transplant, which can lead to major hemorrhage after transplant.<sup>26</sup> Splenic artery aneurysms are also seen at a higher incidence in patients with arteritis, arterial fibrodysplasia, collagen vascular disease, and  $\alpha_1$ -antitrypsin deficiency.<sup>27</sup> Most are true aneurysms, but pseudoaneurysms may also develop as complications of pancreatitis and trauma.

In a contemporary review of 217 splenic aneurysms seen at the Mayo Clinic, the mean age at presentation was 62 years, with 79% of patients being female. Over 90% of the patients were asymptomatic, with a mean aneurysm size of 3.1 cm. Although more than 10% of men presented with a rupture, this rate was less than 3% in women, in large part due to larger aneurysm sizes in men. The mean size for nonruptured cases was 2.2 cm, and the smallest-diameter aneurysm to rupture was 2.2 cm.<sup>28</sup>

Splenic artery aneurysms are often incidental findings in asymptomatic patients. Most are under 2 cm in size, but on occasion, they can be much larger. They are generally saccular and solitary, and occur at a bifurcation in the splenic hilum.<sup>29</sup> Peripheral calcification and mural thrombus are

frequently noted (Fig. 77-10). Patients may present with symptoms of left upper quadrant or epigastric pain radiating to the shoulder. The overall risk of rupture is less than 2% but is higher for aneurysms larger than 2 cm, in liver transplant patients, and in pregnancy.<sup>29</sup> Such ruptures have been associated with maternal and fetal death rates of 22% and 15%, respectively.<sup>30</sup> Ruptures occur in the third trimester of pregnancy in 69% of cases.<sup>31</sup>

**FIGURE 77-10** A CT scan of a large splenic artery aneurysm with calcified wall. This calcified wall can also be seen on plain abdominal roentgenogram.

Rupture of the aneurysm is manifested by sudden abdominal pain. If the rupture is initially contained in the lesser sac, the patient may have upper abdominal pain but be hemodynamically stable. Once the rupture overflows into the peritoneal cavity, diffuse pain and hemorrhagic shock ensue. This sequence of events is termed the “double rupture phenomenon.” Mortality after emergency surgery is as high as 40%.<sup>32</sup>

Surgical resection in all symptomatic aneurysms is recommended; however, criteria for elective repair of asymptomatic aneurysms are not firm. In general, the presence of an aneurysm larger than 2 cm is an indication for surgery if the patient is a reasonable operative risk.<sup>29</sup> Asymptomatic patients with aneurysms between 1 and 2 cm should be closely monitored with serial

imaging done initially every 6 months.<sup>33</sup> Aneurysms of any size detected in pregnancy should be treated because many of the ruptured aneurysms during pregnancy are less than 2 cm in size.<sup>30</sup> This should be done before the third trimester, when the risk of rupture is at its peak. Liver transplant patients have a higher incidence of aneurysms and a higher risk of rupture, including in the posttransplant period, with a mortality over 50%. This has led to recommendations to treat splenic artery aneurysms over 1.5 cm in size with embolization prior to liver transplantation.<sup>34</sup>

The traditional approach to repair for lesions in the proximal or middle of the artery includes resection and primary end-to-end anastomosis, or proximal and distal ligation with resection of the involved segment.<sup>35</sup> Proximal ligation is reasonable because the spleen will not become ischemic following central ligation of the main splenic artery. Distal lesions located close to the hilum generally require splenectomy with resection of the involved splenic artery, now generally done laparoscopically (Fig. 77-11). The overall mortality rate ranges from 1% to 3%, with a perioperative complication rate of 9% to 25% due to splenic or pancreatic injury.<sup>33</sup>

**FIGURE 77-11** A 3-dimensional CT reconstruction of a partially thrombosed large splenic artery aneurysm with a smaller aneurysm more distal. Both aneurysms were treated by a laparoscopic splenectomy.

Percutaneous transcatheter embolization techniques have been increasingly used and are preferred over surgery for most splenic artery

aneurysms if the anatomy is suitable.<sup>36</sup> The endovascular therapeutic options include stenting, coil embolization, and the use of glue, *N*-butyl-2-cyanoacrylate; their uses vary based on aneurysm size and location, and there is not enough evidence to support the use of one over another. These techniques have been increasingly used since 2000, and a systematic review reports a technical success rate of over 95%.<sup>37</sup> Complications of endovascular repair include treatment failures, postprocedural pain, and abscess formation, as well as pancreatitis due to occlusion of the pancreatic magna vessel.<sup>38</sup> Major postoperative complications are higher in the open repair (1.1%) versus endovascular patients (0.8%). In the long term, however, there are more late complications in the endovascular group with a greater need for subsequent interventions compared to open repair (3.2% vs 0.5% per year).<sup>37</sup> Follow-up after endovascular repair is mandatory. Decision analysis modeling suggests that the endovascular approach is less costly and more effective than open surgery.<sup>39</sup> The endovascular approach has also been used in the emergency setting to treat ruptured aneurysms.

## Cysts

Splenic cysts are classified as primary or secondary (pseudocysts). Some splenic tumors may also have a cystic component (Fig. 77-12). Primary cysts have an epithelial lining and can be nonparasitic or parasitic (echinococcal).

A

B

**FIGURE 77-12** **A.** A large splenic cyst seen on CT. **B.** A large splenic cyst that, on careful review, had septations and calcifications. Patient underwent a splenectomy, and pathology confirmed an 8-cm lymphangioma.

## PARASITIC PRIMARY CYSTS

Worldwide, *Echinococcus* infection (hydatid disease) is the most common cause of a splenic cyst. The spleen is the third most common site of disease, after the liver and lung. *Echinococcus granulosus*, the most commonly implicated species, usually results in a unilocular cyst composed of an inner germinal layer (endocyst) and an outer laminated layer (ectocyst) surrounded by a fibrous capsule. Unlike the nonparasitic cysts, these are filled with fluid under positive pressure and also contain daughter cysts and infective scolices. Echinococcal cysts are usually asymptomatic unless they reach a size causing pressure symptoms or become secondarily infected or rupture. Overall, splenic involvement is rare, even in endemic areas, and comprises only 0.5% to 4% of all hydatid disease.<sup>40</sup> Once splenic disease is found, concomitant disease is usually found in other organs, with the liver and peritoneum the most common locations.

Splenic hydatid cysts grow slowly, approximately 0.3 to 2.0 cm per year,<sup>41</sup> and most patients remain asymptomatic for a long time. Symptoms occur due to the mass effect on nearby organs, usually with nonspecific and/or left upper quadrant abdominal pain. Diagnosis is made using imaging tests including ultrasound, CT, and magnetic resonance imaging (MRI) studies that demonstrate a septated cystic mass that contains daughter cysts. For diagnostic purposes, the older Casoni skin test has been replaced with serologic testing. Multiple serologic tests are available and include immunophoresis, enzyme-linked immunosorbent assay (ELISA), and latex and indirect hemagglutination. Sensitivity rates of 85% to 90% are seen with both ELISA and indirect hemagglutination testing; overall, ELISA testing is thought to be optimal. These are used for screening and diagnosis and can also be used on follow-up to detect any recurrences.<sup>40,41</sup>

Recommended management of splenic hydatid cysts is based on size and concomitant disease; options include medical management, percutaneous techniques (puncture, aspiration, injection, reaspiration [PAIR]), and surgical intervention. Medical management with anthelmintics (eg, albendazole, mebendazole, praziquantel) as a sole treatment modality is controversial

given low absorption of orally administered medication and subtherapeutic concentration in the cyst. Some still advocate for small cysts being treated with anthelmintic drugs alone.<sup>41</sup> The PAIR technique is used in conjunction with anthelmintic therapy in patients with prohibitive surgical risks or who refuse surgery and is safe for cysts under 5 cm in diameter. Larger and/or symptomatic cysts are treated surgically due to the risk of rupture. Traditionally, a complete splenectomy is advocated to reduce the risk of recurrence and is the treatment of choice. This is especially true for multiple or centrally located cysts or in patients with concomitant abdominal disease elsewhere. Care should be taken to avoid spilling the contents of the cyst. Intraoperatively, the lesions can be sterilized by instilling a 3% sodium chloride solution into the cysts. If intraperitoneal spillage occurs during the dissection, anaphylactic hypotension may occur and require epinephrine. With newer techniques emerging and concern for postsplenectomy septic complications, splenic-preserving procedures are being considered for small or peripherally located cysts. These include partial splenectomy, cyst enucleation, deroofting with omentoplasty, and internal drainage with cystojejunal anastomosis. Small case series show no recurrence after spleen-preserving procedures for small peripheral cysts in young patients.<sup>40</sup> Other studies comparing outcomes after total splenectomy and spleen-preserving surgery have found no difference in recurrence; however, these are all retrospective and heterogeneous studies, and definitive recommendations cannot be made. Larger studies are yet to be done, and the role of splenic-preserving procedures for hydatid cysts is not well established. The use of laparoscopy has also not been widely accepted in treating hydatid cysts because of a fear of spillage and anaphylaxis.<sup>42</sup>

## NONPARASITIC PRIMARY CYSTS

Nonparasitic primary cysts are increasingly discovered incidentally on imaging done for a variety of reasons. According to Morgenstern's classification, nonparasitic splenic cysts are classified based on pathogenesis as congenital, neoplastic, traumatic, or degenerative (Table 77-2).<sup>43</sup>

**TABLE 77-2: CLASSIFICATION OF NONPARASITIC SPLENIC CYSTS**

## Congenital

With mesothelial, transitional, or epidermoid epithelial cell lining

With characteristic gross appearance (interior trabeculation), despite lack of cellular lining

## Neoplastic

Neoplasms of endothelial origin

Lymphangioma

Hemangioma

Cystified primary or metastatic tumors

## Traumatic

Cysts in which there is clear evidence of normal splenic architecture, followed by cyst appearance after documented trauma; usually from nonresolving subcapsular hematoma

## Degenerative

Cystified splenic infarcts

---

Reproduced with permission from Morgenstern L. Nonparasitic splenic cysts: pathogenesis, classification, and treatment, *J Am Coll Surg.* 2002 Mar;194(3): 306-314.

Cysts with mesothelial, epidermoid, or transitional epithelial linings are probably congenital in origin, originating from an infolding of peritoneal mesothelioma during splenic development. The cellular lining can desquamate and be absent in places, but these cysts have a characteristic gross appearance, with a white, glistening interior containing coarse fibrous trabeculations.<sup>43</sup> The cyst fluid can be clear or cloudy and ranges in color from almost clear to yellow, green, or brown. The fluid may show elevated levels of carcinoembryonic antigen (CEA) and CA 19-9. A calcified portion of the cyst wall may also be observed in a small proportion of these cysts.

Congenital cysts of the spleen occur in children and in young adults in 75% of cases. About two-thirds of the patients are female. The clinical manifestations are dependent on the size and can include left upper abdominal discomfort, pain, or fullness. True dermoid cysts of the spleen are exceedingly rare; less than 10 cases have met the pathologic criteria of a squamous epithelium with dermal appendages such as hair follicles and sweat glands.

It can be difficult to differentiate these cysts from one another based on

imaging only, and usually the diagnosis is made when symptomatic cysts, usually greater than 5 cm, are excised and analyzed histologically.<sup>44</sup> Asymptomatic cysts, which are often smaller, are observed with no need for surgical resection. The recommendation for resection of splenic cysts over 5 cm originated in 1992 based on a report by Musy et al<sup>45</sup> and was reinforced in subsequent literature.<sup>43</sup> Some sources cite the 25% spontaneous rupture risk for cysts larger than 5 cm with an associated high mortality rate, but this was in the context of hemangiomas. More recent work by Kenney et al<sup>46</sup> reviewed 115 patients with splenic cysts, including 16 with cysts larger than 5 cm. There was only 1 patient with a large cyst who presented with rupture after a fall. The authors concluded that size should not be used to determine the need for intervention.<sup>46</sup> This applied to asymptomatic cysts with typical imaging findings, including smooth, regular wall contours and no solid component.

Aspiration of the cyst is not a definitive treatment because it is usually not successful. Only complete removal of the cyst avoids recurrence. Spleen-conserving approaches are feasible for most cysts, unless they are centrally located. One attractive approach with very low morbidity is near total resection of the cyst wall, leaving just the part of the wall of the cyst attached to the spleen in situ (“unroofing” or “decapsulation”). This is associated with low morbidity, but radiologic recurrence in children may be >65%<sup>47,48</sup>; however, these recurrences are usually smaller than the original cyst, and many are asymptomatic and can be managed conservatively.<sup>47</sup> In adults, reported long-term recurrence rates range from 20% to 60%.<sup>49-51</sup> Although partial splenectomy has higher potential morbidity related to bleeding or ischemia of the remnant, it is becoming a more common option given that it allows resection of the cyst itself but leaves splenic tissue behind, maintaining immunologic function. Leaving at minimum 25% of splenic tissue is thought to confer adequate immunologic function.<sup>52</sup> This can also be done safely via the laparoscopic approach, as discussed below.

## **Splenic Abscess**

Splenic abscesses tend to be rare, due to the spleen’s ability at fighting infections and bacteria. They are more frequently seen in areas with a high incidence of sickle cell anemia, with associated thrombosis of parenchymal

vessels and subsequent splenic infarction.

The major risk factors for such abscesses in the West are intravenous drug use, human immunodeficiency virus (HIV) infection, other hematogenous spread (endocarditis), splenic trauma, and contiguous spread. Endocarditis can be complicated with splenic abscesses in 5% of cases. These are often multiple abscesses similar to what is seen in other organs; the spleen is just a part of overwhelming sepsis.<sup>53</sup> Most infections are polymicrobial and include such organisms as *Staphylococcus*, *Salmonella*, *Escherichia coli*, *Proteus mirabilis*, *Streptococcus* group D, *Klebsiella pneumoniae*, *Peptostreptococcus*, *Bacteroides*, *Fusobacterium*, *Clostridium*, *Candida albicans*, and *Mycobacterium*.

The symptoms are usually nonspecific, such as malaise, weight loss, left upper quadrant pain, and fever. Most patients have a leukocytosis, and an ultrasound, CT, or MRI study establishes the diagnosis of a splenic abscess. Treatment consists of broad-spectrum antibiotics and percutaneous drainage, which, if it fails, will require laparoscopic or open splenectomy. Many patients have multiple other abscesses in other organs. Antibiotic treatment should continue until the drains or percutaneous catheters have been removed. If the spleen has multiple abscesses, splenectomy may be required.<sup>54</sup>

## Splenic Tumors

Splenic masses may be identified during workup of symptoms or incidentally during other imaging. Some of these masses have a large cystic component (see Fig. 77-12). Management of such lesions may result in difficult clinical decision making as imaging alone does not always result in a definitive diagnosis. Often, these lesions may need to be followed serially, or if concerning, splenectomy should be considered. The underlying pathology may depend on referral patterns. In a series of 44 such cases, half of whom were symptomatic and treated surgically, 75% of lesions were benign while the remainder were malignant.<sup>55</sup> In a similar study of 28 patients, the risk of a malignant diagnosis was significantly higher at 72%, although 25% of these patients had a previous history of lymphoproliferative disorder.<sup>56</sup> There are increasing data on the use of image-guided splenic fine-needle aspiration to differentiate such masses, with low complication rates.<sup>57</sup> Sensitivity and

specificity of such aspiration have been reported as 94% and 79%, respectively,<sup>58</sup> with low risk of complications, even for core-needle biopsy.<sup>59</sup>

## **BENIGN NEOPLASMS**

Splenic neoplasms generally arise from the lymphoid or vascular elements of the spleen. They include a broad range of lesions, from benign (hemangioma, hamartoma, lymphangioma, and sclerosing angiomatoid nodular transformation) to intermediate (littoral cell angioma, hemangioendothelioma, and hemangiocytoma) to malignant (angiosarcoma). The more commonly found benign lesions are discussed here.

Hemangiomas are the most common benign neoplasms of the spleen with an incidence ranging from 0.02% to 16% and can be single or multiple.<sup>60</sup> Most are now diagnosed incidentally during imaging for other pathology. Hemangiomas vary from well-circumscribed to irregular vascular proliferations. They consist of a benign overgrowth of nonencapsulated proliferation of new blood vessels of variable size, from capillary to cavernous formations. They are thought to be congenital in origin, and most are cavernous in nature. On CT scan, hemangiomas appear as homogeneous, hypodense, or multicystic lesions with variable calcification and peripheral enhancement. On MRI, they have high signal intensity on T2-weighted images with peripheral enhancement on delayed images.<sup>61</sup> The potential for malignant transformation to angiosarcoma is not known but appears to be low.

The majority of splenic hemangiomas do not require surgical intervention. Most are asymptomatic. Splenectomy is reserved for tumors that become symptomatic due to size or consumptive coagulopathy. Although there has traditionally been concern about risk of spontaneous rupture or rupture with blunt trauma, a contemporary series from the Mayo Clinic reported no spontaneous rupture among 32 patients with splenic hemangioma, 80% of whom were entirely asymptomatic.<sup>60</sup> Attempts at treatment using embolization of arterial branches or radiofrequency ablation have been reported, but more data are needed to understand their efficacy.

Sclerosing angiomatoid nodular transformation (SANT) is a benign vascular lesion first defined by Martel et al<sup>62</sup> in 2004. SANT consists of altered red pulp trapped by nonneoplastic stromal proliferation.<sup>63</sup> There is

often a central stellate scar. Patients are usually asymptomatic with a solitary splenic mass found incidentally on imaging. There is a 2:1 female predominance. Ultrasound shows a hypoechoic lesion. CT and MRI studies may show a central scar, enhancing capsule, and radiating bands corresponding to fibrosis.<sup>61,64</sup> The lesion may have <sup>18</sup>F-fluorodeoxyglucose (FDG) avidity on positron emission tomography (PET) scan.<sup>64</sup> The average size in a case series of resected patients was 5.8 cm (range, 3.2-10.2 cm).<sup>65</sup> Although SANT often displays characteristic radiologic findings, differentiation from other benign and malignant lesions may be challenging, and splenectomy may be required (Fig. 77-13).

**FIGURE 77-13** A 5.8 × 3.8 × 4.8 cm lesion located centrally in the spleen on magnetic resonance imaging. This was initially found incidentally on an ultrasound done for symptomatic gallstones. On positron emission tomography scan, the lesion was hypermetabolic with heterogeneous increased radiotracer accumulation, with a maximum standardized uptake value of 4.4. She underwent laparoscopic splenectomy and cholecystectomy. The pathology revealed sclerosing angiomatoid nodular transformation (SANT) in the spleen.

Littoral cell angiomoma (LCA) is a rare vascular tumor of the spleen. It is an

endothelial cell neoplasm arising from the cells lining the sinus channels of the splenic red pulp. These rare lesions express vascular and histiocyte-associated antigens. The autopsy incidence ranges from 0.03% to 14%. They are seen at any age range, with no sex-based predilection. Two forms of LCA are seen: diffuse multiple nodular LCA and the more rare solitary form. Imaging features on ultrasound vary widely from heterogeneous echotexture with no specific nodules to hyperechogenic-, hypoechoic-, or isoechogenic-appearing lesions. A comparison between sonographic and pathologic features has shown that lesions with minimal blood-filled spaces appear as hypoechoic spaces, whereas lesions with lots of blood-filled spaces appear as hyperechoic spaces. On an unenhanced CT imaging study, nodular LCA lesions are not visible unless they have a hemorrhagic component. On a contrast CT in the portal venous phase, LCAs appear as low-attenuation lesions; LCAs are iso-attenuating on delayed images.

Although classified as benign, recent literature classifies LCAs as having uncertain biologic behavior.<sup>66</sup> Malignant transformation to littoral cell angiosarcoma is very rare, but cases with dissemination to the liver and brain have been reported. An association with malignant lymphomas and other visceral organ cancers, including thyroid, colon, lung, pancreas, liver, brain, hematologic, ovarian, and testicular, has been reported.<sup>67</sup> This leads to reluctance in classifying it as a completely benign lesion. In addition, LCA is also associated with various congenital and immunologic conditions, including inflammatory bowel disease, Wiskott-Aldrich syndrome, Epstein syndrome, lymphocytic colitis, systemic lupus erythematosus, ankylosing spondylitis, psoriasis, Gaucher disease, myelodysplastic syndrome, chronic glomerulonephritis, and aplastic anemia.<sup>68</sup>

The majority of patients are asymptomatic. Symptomatic patients present with abdominal pain, left upper quadrant fullness with satiety, splenomegaly, anemia, thrombocytopenia, or constitutional symptoms such as weight loss, anorexia, or fever of unknown origin.<sup>69</sup> A preoperative diagnosis of LCA can be made with an image-guided fine-needle aspiration or needle biopsy. Some authors recommend close follow-up, but given its small malignant potential and possible concomitant malignancies, splenectomy may be recommended. The potential for familial predisposition has been raised, and screening for splenic lesions in family members is suggested.<sup>66</sup>

Lymphangiomas are congenital malformations thought to be due to

obstruction of the venolymphatic system (see [Fig. 77-12B](#)). Microscopically, these endothelium-lined spaces are filled with lymph and blood elements. The lesion may be focal or multiple, a small or large cystic mass, or may diffusely involve the spleen and account for splenomegaly. The diagnosis is made by ultrasound, CT scan, or MRI that reveals water-density cystic lesion(s) of the spleen. The lymphangioma may be isolated to the spleen or occur as a generalized lymphangiomatosis with multivisceral involvement and a poor prognosis. Symptoms, when present, are related to the size and mass effect of the lesion. Splenectomy is indicated for symptomatic lesions.

Inflammatory pseudotumor of the spleen is a reactive lesion characterized by a mixture of inflammatory cells and disorganized spindle cells.<sup>70</sup> It is infiltrative in nature and may mimic malignant lymphoproliferative disease. These are seen in middle-aged and older patients, with a higher incidence in women. This tumor is typically found incidentally and is generally asymptomatic but may present with systemic symptoms such as abdominal pain, splenomegaly, or symptoms suggestive of malignancy such as fever, malaise, and weight loss. Imaging studies are nonspecific. The differential diagnosis includes lymphatic neoplasms, inflammatory granulomatous processes, hamartomas, hemangiomas, hemangioendotheliomas, and angiosarcomas. Although inflammatory pseudotumors are benign, no method with adequate sensitivity or specificity is available to make a definitive diagnosis. The diagnosis can be made via percutaneous fine-needle aspiration cytology, but splenectomy may be required to rule out malignancy if a diagnosis cannot otherwise be made.

Other benign lesions of the spleen are uncommon. Splenic hamartomas are uncommon, with autopsy series noting an incidence of 0.024% to 0.13%. They are solid but may have a cystic or necrotic component.<sup>61</sup> Peliosis is not a true neoplastic lesion but a blood-filled cystic lesion without an endothelial lining that may be associated with focal, patchy, or diffuse involvement of the spleen. This lesion is likely reactive as it has been associated with steroids, oral contraceptives, immunosuppression medications, tuberculosis, renal disease, and malignancy. Other benign splenic tumors, such as angiomyolipoma, lipoma, hemangiopericytoma, and fibroma, are rare.

## **PRIMARY MALIGNANT TUMORS**

Primary, nonlymphoid, malignant tumors of the spleen are exceedingly rare.

These include angiosarcomas, malignant fibrous histiocytomas, and plasmacytomas. Angiosarcoma is the most common nonlymphoid primary malignant neoplasm of the spleen. The clinical presentation may include abdominal pain, left upper quadrant abdominal mass, and constitutional symptoms. Metastasis is frequent and often involves the liver. Spontaneous rupture has been reported and is associated with a dismal outcome. Normocytic anemia is present in the majority of cases. Splenomegaly with hypersplenism is also seen. CT imaging often identifies a splenic lesion with central necrosis. The primary treatment is splenectomy. Cisplatin-based chemotherapy has also been used. However, even without rupture, splenic angiosarcoma holds a poor prognosis. Recent studies have reported 1-, 3-, and 5-year survival rates of 60%, 40%, and 40%, respectively.<sup>71</sup>

## **METASTATIC TUMORS**

Splenic metastasis of nonhematologic malignancies is rarely seen clinically and usually represents widespread dissemination of disease. In a review of a German oncologic database, only 0.002% of patients with a malignancy developed reported splenic metastasis, with isolated splenic metastasis being extremely rare.<sup>72</sup> Despite the rarity of clinically evident splenic metastasis, postmortem evidence is reported to be higher, although the exact prevalence of this is debated, with older literature reporting rates as high as 34%, while contemporary reports put this rate at approximately 3%.<sup>73</sup> The most frequent sites of primary tumors with splenic metastasis are lung, colorectal, ovary, melanoma, and breast.<sup>74</sup>

The diagnosis of malignancy can be confirmed by PET scanning, although percutaneous biopsies for isolated lesions can also be performed (Fig. 77-14).<sup>75</sup> Splenectomy may be indicated to treat isolated metastatic disease, especially for patients with chemosensitive tumors or in whom cytoreductive surgery can improve outcomes.<sup>74</sup>

**FIGURE 77-14** The patient was found to have a splenic lesion on CT of the chest in the context of a right lung cancer. Percutaneous biopsy revealed adenocarcinoma consistent with lung primary. She underwent splenectomy for this isolated metastasis.

## HEMATOLOGIC DISORDERS

In 1887, Sir Thomas Spencer Wells, the renowned gynecologist, performed a therapeutic splenectomy for what proved to be hereditary spherocytosis. The first splenectomy for autoimmune hemolytic anemia (AIHA) was performed in 1911 by Micheli. Six years later, Schloffer, at the suggestion of a medical student, Kaznelson, performed a splenectomy for idiopathic thrombocytopenic purpura.<sup>1</sup> The indications for splenectomy in hematologic disease are continuously evolving, but there are many conditions for which splenectomy plays an important role. The most common hematologic indications for splenectomy are immune thrombocytopenia purpura, hereditary spherocytosis, and AIHA.

## ANEMIAS

Splenectomy is indicated for specific cases of anemia. The major categories

of anemia that benefit from splenectomy are those caused by the following:

- Membrane abnormalities: Hereditary spherocytosis and elliptocytosis
- Enzyme defects: Pyruvate kinase deficiency
- Hemoglobinopathy: Thalassemias and sickle cell
- AIHA

## Hereditary Spherocytosis

Hereditary spherocytosis (HS) is a hemolytic anemia that results from a genetic defect or deficiency in one of the components of the red cell cytoskeleton. It results in spherically shaped erythrocytes on blood smear, reticulocytosis, and splenomegaly. HS is transmitted as an autosomal dominant trait but occurs sporadically in rare instances. HS is the most common cause of familial chronic hemolytic anemia in North America and Northern Europe, with an incidence of 1 to 5 in 10,000 births, or even higher if mild cases of osmotic fragility are included.<sup>76</sup>

Abnormalities of the proteins in the red cell membrane (spectrin, ankyrin, band 3, and/or protein 4.2) cause increased osmotic fragility and changes in morphology, resulting in the spherical shape and decreased deformability. The red cell membrane change results in splenic trapping of the abnormal cells in the microcirculation, followed by their destruction by phagocytosis.<sup>77</sup> Thus, the spleen plays a critical role in the pathophysiology of HS, as it is the main site of hemolysis. Cells that escape the spleen on first passage are more susceptible to trapping and destruction during each successive passage.

The salient clinical features include anemia, jaundice, and splenomegaly, with spherocytes on blood smear, increased osmotic fragility, and positive family history.<sup>77</sup> The severity of disease varies widely and is classified as mild, moderate, and severe based on hemoglobin, bilirubin, and reticulocyte count (Table 77-3).<sup>78,79</sup> Approximately 30% of cases are mild, maintaining near-normal hemoglobin and bilirubin levels and compensatory reticulocytosis. Patients with severe spherocytosis are transfusion dependent with baseline hemoglobin level less than 6 g/dL.

## SPLENECTOMY

Classification	Trait	Mild	Moderate	Severe
Hemoglobin (g/L)	Normal	110-150	80-120	60-80
Reticulocyte count (%)	Normal (<3%)	3-6	>6	>10
Bilirubin (μmol/L)	<17	17-34	>34	>51
Splenectomy	Not required	Usually not necessary during childhood and adolescence	Necessary during school age before puberty	Necessary; delay until age 6 if possible

Reproduced with permission from Bolton-Maggs PH, Langer JC, Iolascon A, Tittensor P, King MJ; General Haematology Task Force of the British Committee for Standards in Haematology. Guidelines for the diagnosis and management of hereditary spherocytosis 2011 update, *Br J Haematol.* 2012 Jan;156(1):37-49.

The disease severity is related to the degree of red cell cytoskeleton protein deficiency, particularly spectrin shortage. The jaundice usually parallels the severity of anemia and generally is not intense. It is related to increased red cell destruction, resulting in abundant bile pigment that cannot be cleared by the liver. Most patients have mild to moderate spleen enlargement, but splenomegaly alone is not an indication for surgery. Increases in splenic size in patients with HS may be seen in the presence of acute infection. Periodic worsening of the associated anemia and jaundice may be seen, often following infection, emotional stress, fatigue, or prolonged exposure to cold. Gallstones are the most common complication of HS but are unusual in children younger than age 10 years. The gallstones are generally pigmented.

Splenectomy is effective in reducing the hemolysis associated with HS but at the price of a lifelong risk of severe sepsis from encapsulated organisms, and emerging evidence links splenectomy to late vascular complications such as pulmonary hypertension and atherosclerosis.<sup>79</sup> Splenectomy should not be recommended simply due to the diagnosis of HS but is based on the severity of anemia (see [Table 77-3](#)). Failures are uncommon and often reflect missed accessory spleens, which can be identified using radiocolloid liver-spleen scans.<sup>77</sup> The preferred approach is laparoscopic as it is associated with less postoperative morbidity and pain. Because of the increased risk of serious postsplenectomy sepsis among young children, with a subsequent mortality rate of 50% to 80%, splenectomy is reserved preferably for patients older than 6 years<sup>79</sup> and should not be done in children younger than age 3, even if chronic transfusions are needed.<sup>78</sup>

Concern over postsplenectomy sepsis risks, especially in young children, has led to investigation of the effectiveness of partial splenectomy to control hemolysis while leaving some functional spleen behind for immunologic

purposes.<sup>80,81</sup> Either the lower pole, based on the gastroepiploic, or the upper pole, based on the uppermost short gastrics, is preserved. This approach has somewhat less effective hemolytic control. A recent review of moderate-quality evidence reported that partial splenectomy resulted in increases of hemoglobin of 2.3 to 3.9 g/d, compared to 4 to 5 g/dL with total splenectomy, but both resulted in decreased reticulocyte counts, anemic crises, and transfusions. Most studies suggested that partial splenectomy maintained splenic immune function and phagocyte activity, but there was a lack of longer term studies comparing adverse events such as sepsis or vascular complications.<sup>82</sup> A multi-institutional review of 62 children of all ages undergoing a partial splenectomy showed a good response with no postsplenectomy sepsis with up to 18 years of follow-up and only 4.8% of patients requiring completion splenectomy. They noted that splenic remnant regeneration correlated with the degree of recurrence of anemia and clinical symptoms,<sup>83</sup> but this is not a consistent finding.<sup>84</sup> The Splenectomy in Hemolytic Anemia (SICHA) Consortium Registry compared outcomes after total and partial splenectomy. Excellent hematologic response through 1 year was seen after both procedures, with a more robust response (ie, greater increase in hemoglobin) after total splenectomy.<sup>85</sup> Guidelines conclude that partial splenectomy may be beneficial, but further follow-up studies are required.<sup>79</sup>

Concomitant cholecystectomy is performed if gallstones are present. Prophylactic cholecystectomy in the absence of stones is not required because patients no longer develop pigmented stones after splenectomy.<sup>79</sup> In a cohort of patients younger than 18 years, none developed cholelithiasis after splenectomy over a mean follow-up of 15 years.<sup>86</sup> The presence of Gilbert disease increases the risk of subsequent gallstones.<sup>87</sup> On the other hand, symptomatic gallstones have traditionally been an indication for concomitant splenectomy in children, due to the concern for the development of future biliary duct stones. This is now controversial in children with mild disease. In a series of 16 patients with mild HS having cholecystectomy without splenectomy, only 3 required subsequent splenectomy.<sup>88</sup>

## **Hereditary Elliptocytosis**

Hereditary elliptocytosis is a red cell hemolytic anemia affecting 3 to 5 of

every 10,000 people with a heterogeneous array of genotypes and phenotypes. It is more common in people of African and Mediterranean origin, presumably because it results in some resistance to malaria.<sup>77</sup> It is a group of erythrocyte disorders that have in common the presence of elongated, oval, or elliptically shaped RBCs on the peripheral blood film. Most are transmitted as an autosomal dominant trait. Most patients are asymptomatic or have a mild form of the disease with compensated hemolytic anemia, as the defects often do not significantly shorten the red cell life span despite striking abnormalities seen on blood film. The presence of hemolysis often is a familial characteristic, and it has been suggested that excessive hemolysis occurs only when the gene for elliptocytosis is present in the homozygous form or is modified in some other way. The signs and symptoms are related directly to the severity of hemolysis resulting from the extent of decreased membrane stability and subsequent loss of membrane surface area. Occasionally an acute hemolytic episode may be precipitated by infection. The clinical syndrome is indistinguishable from that described for HS. Gallstones and chronic leg ulcers have been reported in symptomatic patients. The spleen is usually palpably enlarged in symptomatic cases. Diagnosis is established by the smear.

Therapy is rarely required. Indication for splenectomy is the same as for HS and is almost always followed by lasting effects. Decreased hemolysis and corrected anemia result from longer circulatory life span of the red cells, although the morphologic abnormality of the RBC remains unchanged. Associated cholelithiasis should be managed as in HS.

## **Pyruvate Kinase Deficiency**

Pyruvate kinase deficiency is the most common RBC enzyme deficiency causing congenital nonspherocytotic hemolytic anemia. It is an autosomal recessive condition that has a much lower frequency than glucose-6-phosphatase deficiency (G6PD); however, it is a more common cause of anemia because G6PD patients rarely suffer hemolysis.

Clinical manifestation varies from transfusion-dependent anemia to compensated chronic hemolysis. Splenomegaly is common. There is no curative therapy. Splenectomy has a role in transfusion-dependent individuals and can reduce or even abolish the need for transfusion.<sup>89</sup> As with other

children being evaluated for splenectomy, the procedure should be delayed until after age 3 due to the immunosuppressive effect of the surgery.

## Thalassemia

Thalassemia (Mediterranean anemia) is a congenital disorder transmitted as a dominant trait in which the anemia is primarily the result of a defect in hemoglobin synthesis. Thalassemias are the most common monogenetic disease in man and have been referred to as *Cooley anemia*, *erythroblastic anemia*, and *target-cell anemia*. The disease is classified as alpha, beta, and gamma types, determined by the specific defect in the synthesis of the relevant globulin chain of the adult hemoglobin. As a consequence of the defect, there is imbalance in production of globulin chains with resultant formation of atypical hemoglobin proteins that can lead to intracellular precipitates (Heinz bodies) that contribute to premature red cell destruction. The hemoglobin-deficient red cells are small, thin, and misshapen, and have a characteristic resistance to osmotic lysis. Over 200 genetic mutations have been identified that lead to  $\beta$ -thalassemia.<sup>90</sup> The high prevalence and diversity of the thalassemias are related to heterozygote protection against malaria.<sup>91</sup>

In the United States, most patients suffer from  $\beta$ -thalassemia, and there is a quantitative reduction in the rate of  $\beta$ -chain synthesis, resulting in a decrease in hemoglobin A. The characteristic feature is the persistence of hemoglobin F and a reduction in hemoglobin A. Precipitation of the excess  $\alpha$  chains in erythroid precursors causes dyserythropoiesis and results in membrane defects and hemolysis in mature RBCs.<sup>92</sup> Gradations of the disease range from heterozygous thalassemia minor to severe homozygous thalassemia major. The latter is manifested by chronic anemia, jaundice, and splenomegaly.

Patients with homozygous thalassemia major usually present with clinical manifestations in the first year of life. In addition to the anemia and consequent pallor, failure to thrive, gastrointestinal symptoms, and feeding problems are also seen. With adequate transfusions, the children grow and develop normally, avoiding the typical features of Cooley anemia, including retarded body growth and enlargement of the head, leg ulcers, and infections.<sup>91</sup> Some patients present with repeated episodes of left upper

quadrant pain related to splenic infarction. Cardiac dilatation occurs, and in advanced stages, there is subcutaneous edema and effusion into serous cavities. Intercurrent infections occur frequently, often leading to death in more severe cases. These infections may be associated with aplastic crises. Gallstones have been reported in up to 24% of cases.

Therapy is directed only at symptomatic patients, those having thalassemia major or intermedia. In these patients, transfusions are usually required at regular intervals. Because most children with thalassemia major accommodate to low hemoglobin levels, transfusions are given when the hemoglobin level is less than 10 g/dL. By age 10, complications develop related to iron overload, including cardiomyopathy, liver fibrosis, and endocrine disturbances.<sup>92</sup> Iron overload is reduced using iron chelators. Stem cell transplantation from an human leukocyte antigen-identical donor is an exciting advance with a high rate of remission, especially in young, fit patients prior to the development of complications from iron overload or viral hepatitis.<sup>92</sup>

Although splenectomy does not influence the basic hematologic disorder, it may eliminate or reduce the hemolytic process responsible for accelerated destruction of normal donor red cells within the patient's circulation, and this reduces transfusion requirements. In general, the best results associated with splenectomy have been obtained in older children and in young adults with large spleens in whom excessive splenic sequestration of red cells has been demonstrated. Splenectomy should be avoided in children younger than age 5 years.<sup>91</sup> Occasionally, splenectomy may be indicated because of mass effect symptoms associated with marked splenomegaly or repeated episodes of abdominal pain due to splenic infarction.

## **Sickle Cell Disease**

Sickle cell anemia, first reported in 1910, is a hereditary disorder of hemoglobin characterized by the presence of crescent-shaped erythrocytes that, because of a lack of deformability, are trapped in the splenic cords. In this disorder, the normal hemoglobin A is replaced by hemoglobin S. Under conditions of reduced oxygen tension, hemoglobin S molecules undergo crystallization within the cell, which elongates and distorts the cell. The sickle cells increase the blood viscosity and circulatory stasis, thus

establishing a vicious cycle. Although the sickle cell trait occurs in approximately 9% of the black population, the majority of patients are asymptomatic. Sickle cell anemia is observed in 0.3% to 1.3% of blacks. Many body systems can be affected by sickle cell disease. Depending on the vessels affected by vascular occlusion, the patients may have bone or joint pain, osteomyelitis, priapism, neurologic manifestations, or skin ulcers. Abdominal pain and cramps due to visceral stasis are frequent.

The spleen is commonly affected in these patients. Sickling occurs so rapidly that blood flow through both the fast and slow compartments of the spleen is obstructed; as a consequence, a series of microinfarcts develop and eventually lead to "autosplenectomy." In most adult patients, only a fibrous area of the spleen remains, but autosplenectomy is preceded by splenomegaly in about 75% of patients. Calcification may occur with autoinfarction (Fig. 77-15). Such functional asplenia is defined and detected by the presence of Howell-Jolly bodies in the blood film and can be confirmed by absence of technetium-99m ( $^{99m}\text{Tc}$ ) splenic uptake. Patients are subsequently at risk of developing infection by encapsulated organisms such as *Streptococcus pneumoniae*, due to impaired filtration and antibody production of the spleen. Rarely thrombosis of the splenic vessels may result in the complication of splenic abscess manifested by splenomegaly, splenic pain, and spiking fever. Percutaneous drainage of such abscesses may be attempted, but it may require a splenectomy.

**FIGURE 77-15** Calcified spleen in a patient with sickle cell disease causing persistent pain. Splenectomy relieved the patient's pain.

For most patients with sickle cell anemia, only palliative therapy is available. Adequate hydration and partial exchange transfusion may help the crisis. Randomized multicenter studies have shown a role for hydroxyurea in treatment of adults with sickle cell disease. Such treatment leads to reduction in frequency of painful crisis, hospitalization, and transfusion.<sup>93</sup> The beneficial effects are in part due to an increase in hemoglobin F levels, although the mechanism underlying this process is not known. Hydroxyurea is therefore recommended in patients with 3 or more crises per year.<sup>94</sup> Other hemoglobin F–inducing agents and stem cell transplant are also currently under investigation.

There are 2 situations in sickle cell anemia where the spleen is a pathologic red cell reservoir, and splenectomy may have a role. The first is a form of chronic hypersplenism that usually occurs in childhood or adolescence and is manifested by reduced red cell survival, leukopenia, and thrombocytopenia. In these patients, for some unknown reason, there is a failure to undergo autosplenectomy. In this rare circumstance, splenectomy will correct the leukopenia and thrombocytopenia and will also increase the

rate of red cell survival and can lead to reduced transfusion requirement.<sup>94</sup> The second abnormality has been termed *acute splenic sequestration* and is marked by sudden splenic enlargement associated with worsening anemia and profound hypotension. It usually occurs in the first 5 years of life in a homozygous child; streptococcal pneumonia infection may act as a precipitating event in these patients. The acute splenic sequestration is usually effectively treated with packed red cell transfusion. If there is a propensity for recurrence, splenectomy may be indicated.

## Immune Hemolytic Anemia

The first description of this disease is credited to Chauffard and Troisier who, in 1908, demonstrated autohemolysins in the serum of several patients with acute hemolytic anemia. Three years later, Micheli performed the first planned, successful splenectomy, thus stimulating the application of splenectomy for hematologic disease.

Immune hemolytic anemia (IHA) is a disorder in which immunoglobulin G (IgG) and/or IgM antibodies bind to erythrocyte surface antigens and stimulate erythrocyte destruction. This occurs through the complement and reticuloendothelial systems. IHA is classified as autoimmune, alloimmune, or drug-induced. Alloimmune hemolytic anemia occurs only after exposure to allogeneic erythrocytes, such as through blood transfusion, pregnancy, or transplant. There is no antibody reactivity against autologous red cells. Acute hemolysis after transfusion is estimated to occur in 0.0003% to 0.0008% of patients, and a delayed response is seen in 0.05% to 0.07%.<sup>95</sup> Drug-induced IHA occurs as drug-induced antibodies recognize red cell antigens or erythrocyte-bound drug. More than 150 drugs have been associated, including methyl dopa, ibuprofen, penicillin, and second- and third-generation cephalosporin.<sup>96</sup> Drug-induced IHA should resolve with cessation of the medication in question but may require corticosteroids and have a protracted recovery.

Autoimmune hemolytic anemia (AIHA) is estimated to occur in 1 per 100,000 per year, with a prevalence of 17 per 100,000.<sup>97</sup> It is an antibody-mediated process that involves IgG or IgM antibodies. In cases of IgG-mediated disease, antibodies bind to the erythrocyte and are recognized by the Fc receptors of macrophages and other phagocytic cells of the

reticuloendothelial system. In contrast to IgG antibodies, IgM antibodies readily activate the classical complement pathway and may lead to intravascular hemolysis. Additionally, IgM-bound erythrocytes may undergo extravascular hemolysis, particularly in the liver.

Both warm and cold antibodies have been reported. Warm antibodies react best at 98.6°F (37°C), account for the approximately 70% of cases, and are mainly due to IgG.<sup>96</sup> Secondary causes of warm AIHA have been reported, most notably in the context of lymphoproliferative disorders such as chronic lymphocytic leukemia (CLL), lupus, infectious mononucleosis, HIV, and autoimmune hepatitis.<sup>96</sup> The presentation of warm AIHA is variable and includes vague constitutional symptoms consistent with anemia, such as weakness and dizziness. Additionally, fever, abdominal pain, cough, and bleeding may be seen. Symptoms vary with the severity of the hemolysis. Mild jaundice is often present. Splenomegaly is seen in approximately half of cases, and 25% may have associated cholelithiasis. While reticulocytopenia may occur early in the disease prior to adequate marrow response, reticulocytosis and elevated mean cell volume (MCV) are generally seen. Mild to moderate indirect hyperbilirubinemia and elevated lactate dehydrogenase (LDH) are often seen. Platelets are usually normal, but occasionally, AIHA and immune thrombocytopenic purpura occur together (Evan syndrome). More than 95% of patients with warm AIHA have a positive Coombs test (direct antiglobulin test), which indicates that antibodies or complement system are bound to the red cell surface antigens in vivo.

Therapy is guided by the severity of the hemolysis, with first-line treatment being corticosteroids. Prednisone therapy (1-1.5 mg/kg/d) is maintained for 3 weeks, with rapid response being the norm. If a satisfactory response is achieved, the steroid is gradually tapered over 6 months to avoid relapse. Approximately 80% of patients have a partial or complete response to steroids, but only 20% to 30% are cured.<sup>96</sup> In nonresponders or those requiring maintenance steroid dose greater than 10 to 15 mg of prednisone daily, second-line therapy should be considered. These options include splenectomy or rituximab, a monoclonal antibody against CD20 found on the surface of B cells. Splenectomy can lead to good short-term results, with early response in approximately 70% of patients and cure in 20% to 60%. Drawbacks are lack of a reliable way to predict outcome to splenectomy,<sup>98</sup> risk of long-term sepsis, and possible increased risk of thrombosis. Rituximab is increasingly used as second-line treatment, with response rates that appear

similar to splenectomy. There are no randomized trials comparing second-line therapies, so the choice of splenectomy or rituximab is based largely on patient and physician preferences and availability of newer medications.<sup>96</sup>

In contrast, cold agglutinin disease is due to IgM, resulting in intravascular hemolysis. Acute cold agglutinin disease is due to infections, whereas the chronic form occurs in lymphoproliferative or neoplastic diseases.<sup>96</sup> Primary cold agglutinin disease may only present with mild anemia and may respond favorably to cold exposure avoidance. Corticosteroids are less effective than in warm AIHA and require high doses. Rituximab is recommended as first-line therapy, with a 60% response rate. Plasmapheresis offers a temporary response in acute hemolytic crises. Splenectomy is ineffective in cold agglutinin syndrome.

Paroxysmal cold hemoglobinuria is an uncommon form of AIHA and is generally self-limited and treated with supportive care. Most cases occur in children, usually after a viral illness. Corticosteroids are often given to children with severe anemia but with unclear effectiveness.

## PURPURAS

### Immune Thrombocytopenia

Immune thrombocytopenia (ITP) is the most common hematologic indication for splenectomy. The terminology of primary ITP replaces the previous term *idiopathic thrombocytopenia purpura*.<sup>99</sup> ITP is an acquired disorder in which platelets are destroyed by circulating antiplatelet antibodies, often IgG antibodies targeted against glycoprotein IIb/IIIa proteins. Antibody-coated platelets bind to antigen-presenting cells via Fc receptors primarily in the spleen, leading to platelet destruction. An alternate mechanism for platelet destruction is via T-cell-mediated lysis. The spleen is the source of antiplatelet antibody production as well as the major site of platelet-antibody complex destruction by macrophage-induced phagocytosis. Antiplatelet glycoprotein antibodies also impair platelet production in the bone marrow by megakaryocytes, impairing the ability to compensate for the increased rate of platelet removal from the blood.<sup>100,101</sup>

The diagnostic criteria for primary ITP are a platelet count less than  $100 \times$

$10^9/L$  without an obvious initiating or underlying cause, whereas secondary ITP encompasses ITP associated with underlying diseases, infections, or medications.<sup>99</sup> The incidence is estimated to be between 1.6 and 4 per 100,000 per year.<sup>99</sup> Female patients outnumber males 3 to 1.

Many patients are diagnosed incidentally on routine evaluations.<sup>102</sup> Bleeding in ITP is usually not severe, even with very low platelet counts. Mucocutaneous bleeding involving the skin, oral cavity, and gastrointestinal tract is the most common clinical presentation.<sup>101</sup> Central nervous system (CNS) bleeding is estimated to occur in 1.4% (95% CI, 0.9%-2.1%) of adult patients with chronic ITP generally with platelet counts  $<10$  to  $20 \times 10^9/L$ . Older age is an identified risk factor for major bleeding.<sup>103</sup> Risk of hemorrhagic death is very low and estimated to be 0.02 to 0.04 cases per adult patient-year at risk.<sup>104</sup> The spleen is typically normal size. Generally, there is no significant anemia or leukopenia unless the ITP occurs in conjunction with AIHA (Evan syndrome).

ITP is often associated with other immune disorders, such as systemic lupus erythematosus. The workup should include examination of peripheral blood smear to exclude other causes of thrombocytopenia. Screening for HIV, hepatitis C virus (HCV), and *Helicobacter pylori* is recommended in adults.<sup>105</sup> If any of these infectious etiologies are identified, therapy should be aimed at treating the underlying process rather than platelet count per se. *H pylori* eradication is associated with response rates of approximately 50%.<sup>106</sup> A bone marrow examination is not necessary for diagnosis in patients with history, physical exam, complete blood count, and blood smear typical for ITP.<sup>106</sup>

ITP in children is typically self-limited and rarely requires surgical therapy. The disease in adults is usually more persistent with a low spontaneous remission rate (9%) and requires medical and possibly surgical treatment.<sup>107</sup> Treatment is generally not indicated in those with platelet counts  $>30 \times 10^9/L$  and no bleeding complications.<sup>99</sup> The goal of all medical therapies is to increase platelet count to a safe level and not to cure. Treatment in newly diagnosed ITP is aimed at rapid increase of platelets to treat or prevent bleeding. First-line treatment is usually a short course of corticosteroids (1 mg/kg/d for 2-3 weeks and rapidly tapered) and/or intravenous immunoglobulin infusion if a more rapid increase in platelets is needed.<sup>99,106</sup> Most patients respond within 1 week, but platelet counts

decrease again when the dose is tapered, with long-term remission in only 5% to 30% of patients.<sup>102</sup> A shorter course of high-dose dexamethasone may also be effective.<sup>106</sup> Intravenous immunoglobulin (IVIg) or anti-Rh(D) (in Rh-positive patients) can be used if corticosteroids are contraindicated.

In adults who do not respond to corticosteroids or with chronic ITP who require more than a minimal dose of corticosteroids to maintain safe platelet counts, second-line therapy is indicated. The objective of second-line therapy is to provide long-term and durable results. Splenectomy remains the most effective single therapy for ITP, with a complete or partial response rate of >80% and a cure rate of about 60% at 10 years.<sup>108,109</sup> In most patients, the platelet count rises to  $>100 \times 10^9/L$  within 7 days. Rarely, platelet normalization is more gradual over a period of months. Indications for splenectomy include patients who fail to respond to first-line therapies, who recur after steroid taper, who respond to medical therapy but cannot tolerate the side effects, or who develop intracranial bleeding or profound gastrointestinal bleeding and do not respond to intensive medical treatment.

The use of splenectomy as second-line treatment is declining, as new second-line therapies, such as rituximab and thrombopoietin receptor (TPO-R) agonists, emerge.<sup>110</sup> While initial response rates with rituximab are >50%, long-term response after 5 years is <20%.<sup>99</sup> In a recent randomized trial comparing rituximab to placebo in corticosteroid-unresponsive patients, there was no significant difference in the incidence of treatment failure at 18 months (58% in the rituximab group and 69% in the placebo group).<sup>111</sup> There are also safety concerns with rituximab including multifocal leukoencephalopathy and hypogammaglobulinemia, and it is predicted that the use of rituximab will decline with the availability of thrombopoietin agonists.<sup>112</sup> TPO-R agonists (eg, romiplostim and eltrombopag) are a new class of drugs that increase platelet production at the megakaryocyte level. They are well tolerated, and there is accumulating evidence regarding their efficacy. There are no direct comparisons between splenectomy, rituximab, and TPO-R as second-line therapies.<sup>99</sup> The American Society of Hematology 2011 guidelines recommend splenectomy as initial second-line therapy, with TPO-R or rituximab suggested for patients in whom splenectomy is contraindicated or who relapse after splenectomy.<sup>106</sup>

In patients who do not respond to splenectomy or who relapse, residual splenic tissue should be ruled out,<sup>102</sup> especially if the blood smear does not

show evidence of splenectomy (ie, no pitting or Howell-Jolly bodies in erythrocytes). Investigations include radionuclide scanning and MRI. These may be located in unusual or difficult-to-access locations including intrapancreatic locations, potentially requiring distal pancreatectomy. Removal of the residual tissue is recommended and can be done using laparoscopic techniques, which are facilitated using localization adjuncts.<sup>113</sup> Reported response rates vary widely, with a recent series reporting a 50% response rate in 10 adult patients at 1 month.<sup>114</sup>

Approximately 15% of patients fail to respond to splenectomy, and another 20% of responders relapse weeks to months later. Several factors that may predict response to splenectomy have been proposed including a response to IVIg and steroids<sup>112</sup>; preoperative platelet count, patient age, and duration of medical therapy are not predictive of response. Indium-labeled autologous platelet scanning may be the most sensitive predictor but is only available presently as a research tool. When the scan demonstrates splenic platelet destruction, the response rate to splenectomy is 90%.<sup>112</sup>

The laparoscopic approach to splenectomy is well suited for ITP because of the normal size of the spleen. While long-term outcomes are similar, a systematic review of 135 case series reported lower rates of complications (9.6% vs 12.9%) and mortality (0.2% vs 1%) after laparoscopic compared to open splenectomy.<sup>109</sup> Retrospective studies in patients with ITP have demonstrated reduced postoperative pain, less analgesic use, and shorter hospital stay in those undergoing laparoscopic splenectomy compared to open splenectomy.<sup>115</sup> Preoperative preparation with corticosteroids or IVIg is used to attempt to increase platelet counts because patients with platelet counts  $<20 \times 10^9/L$  may be at higher risk of complications.<sup>116</sup> However, in some patients, it may not be possible to increase platelet counts, and splenectomy can be done safely in ITP despite very low platelet counts.<sup>117</sup> Platelets should be available for patients with platelet counts  $<20 \times 10^9/L$  and transfused intraoperatively if there is bleeding after the splenic hilum is clamped.<sup>118</sup> Avoidance of splenic injury that may result in splenosis and assessment of the abdominal cavity for accessory spleens are critical to success of splenectomy for ITP.

## **Thrombotic Thrombocytopenic Purpura**

Thrombotic thrombocytopenic purpura (TTP) is a rare type of thrombotic microangiopathy, a family of disorders characterized by microangiopathic hemolytic anemia, thrombocytopenia, and microvascular thrombosis. Other forms of thrombotic microangiopathy include typical hemolytic uremic syndrome (HUS) caused by enteric infection-causing diarrhea, atypical HUS that occurs without a predisposing cause, and secondary thrombotic microangiopathy, an infrequent complication seen in different settings including disseminated cancer, systemic infection, drugs, transplantation, and other conditions.<sup>119</sup> The different kinds of thrombotic microangiopathies may be difficult to distinguish because they have overlapping clinical features, but their pathogenesis and prognosis differ.<sup>119</sup> In patients with TTP, neurologic symptoms predominate, whereas in those with HUS, renal complications are the dominant symptom. TTP is recognized as the pentad of microangiopathic hemolytic anemia, thrombocytopenia, fever, neurologic disturbance, and renal dysfunction. Most cases of TTP are caused by autoantibodies to ADAMS13, a metalloprotease required for cleavage of von Willebrand factor. TTP is a microvascular disorder affecting arterioles and capillaries with venule sparing. Platelet microthrombi cause partial vessel occlusion with overlying endothelial proliferation and subintimal hyalinization. Subsequent erythrocyte damage occurs during passage through the narrowed vascular channels with abnormal forms (especially schistocytes) seen on peripheral blood smear. Marked platelet trapping occurs, namely in the spleen, with resultant thrombocytopenia ( $<20 \times 10^9/L$ ). There may be a profound decrease in platelets within hours of onset. Petechial hemorrhage and, more rarely, epistaxis, retinal hemorrhage, gastrointestinal and genitourinary bleeding, and hemorrhagic stroke may be seen. However, it is more usual to see no bleeding even with severe thrombocytopenia partly because of the thrombotic nature of the disease. Other clinical manifestations include fever, general malaise and flu-like symptoms, headache, altered mental status, focal neurologic deficits, hematuria, and renal failure. The neurologic changes may be severe, such as coma, prompting emergent therapy.

Since the advent of plasma exchange therapy for TTP, which replaces stores of ADAMS13 and removes the antibody inhibitors,<sup>119</sup> mortality for the once uniformly fatal disease has decreased markedly to 10% to 20%.<sup>120</sup> Concomitant high-dose steroids are used.<sup>120</sup> Daily therapy is conducted until the hemolytic process is stabilized and the thrombocytopenic and neurologic

complications subside. Plasma exchange is then tapered. Rituximab is beneficial for those with refractory or relapsing disease.<sup>120</sup> Splenectomy is considered for refractory cases or those with recurrent disease after multiple plasma exchanges with a 70% remission rate.<sup>121</sup>

## HEMATOPOIETIC NEOPLASMS AND LYMPHOMAS

The classification of such malignancies, including lymphomas, leukemias, and myeloproliferative neoplasms, has evolved extensively over the past decade with the introduction of immunophenotyping and cytogenetics. Many tumor subtypes that were initially thought to be the same have been subdivided into groups with different management and prognosis. The 2008 World Health Organization (WHO) classification of hematopoietic and lymphoid malignancies has provided a framework for classification of these diseases, which encompasses over 65 different types of tumor. A detailed description of this classification is beyond the scope of this chapter. In general, however, these neoplasms fall into 3 categories<sup>122</sup>:

*Myeloid neoplasms:* Derived from bone marrow progenitors that form erythrocytes, granulocytes (neutrophils, basophils, eosinophils), and megakaryocytes.

*Lymphoid neoplasms:* Derived from cells that form T and B lymphocytes. When such neoplasms presented with predominantly bone marrow and blood involvement, they were referred to as *leukemia*, whereas those presenting with a mass were referred to as *lymphoma*. In the new classification, however, with new knowledge about tumorigenesis and the fact that lymphomas can present or evolve to a leukemia picture and that leukemia can present as a mass, more emphasis has been placed on cell of origin. This classification method based on cell type only, however, provides no information on clinical behavior of tumors. Some have therefore added a clinical classification to further group lymphomas as indolent (survival without treatment of years), aggressive (survival without treatment of months), highly aggressive (survival of untreated tumor of weeks), and Hodgkin lymphomas, which is generally regarded as a distinct entity with excellent prognosis.

*Histiocytic/dendritic neoplasms:* Derived from cells that develop into antigen-presenting cells such as dendritic cells and macrophages.

Indications for surgical intervention have evolved over the years as our knowledge and therapeutic options have expanded. Below is a brief overview, concentrating on situations where a splenectomy may be indicated.

## Myeloid Neoplasms

These tumors are generally subdivided into 3 categories: *acute myeloid leukemias*, for which there is little surgical role, and *myelodysplastic syndrome* and *myeloproliferative disorders*.

*Myelodysplastic syndrome* is a group of disorders that is associated with ineffective blood production and risk of transformation to acute leukemia. Again, there is little indication for splenectomy or surgery in this group of patients.

In *myeloproliferative disorders*, there is proliferation of 1 or more of the myeloid lineage cells, with increases in the numbers of 1 or more of the peripheral blood elements. There is usually an associated mutation that causes increase in tyrosine kinase– and growth factor–dependent proliferation of bone marrow elements. Examples of such mutations include the *BCR-ABL* fusion gene in chronic myeloid leukemia. Other diseases in this category include polycythemia vera, essential thrombocythemia, and primary myelofibrosis. The presenting symptoms include symptomatic splenomegaly and anemia.

Although splenectomy does not alter the course of these diseases, it may be indicated for transfusion-dependent anemia or thrombocytopenia or symptomatic splenomegaly. There may be massive splenic enlargement with myeloproliferative disorders causing pain, early satiety, and weight loss. Most patients will benefit from the procedure, with approximately half of transfusion-dependent patients becoming transfusion independent, resolution of constitutional and mechanical symptoms, and improved thrombocytopenia.<sup>123</sup> However, the morbidity associated with splenectomy for myeloid neoplasms makes it a high-risk procedure due to risks of bleeding, infection, portal vein thrombosis, and reoperation. Although effective for relief of symptomatic splenomegaly in most patients and to decrease transfusion requirements, a recent single-institution series of

splenectomy for myeloid neoplasms reported a 30-day mortality of 18% and a median survival of only 9 months that had not improved over time. Those with preoperative anemia and thrombocytopenia were at increased risk.<sup>124</sup>

## Lymphoid Neoplasms

Staging laparotomy in cases of Hodgkin lymphoma was once considered the key to determine the extent of abdominal involvement with stage I to II supradiaphragmatic disease and critical in determining the best therapy for patients. Those with disease limited to above the diaphragm were treated with radiation, while others received radiation and chemotherapy. Advances in imaging technology, including CT of the chest, abdomen, and pelvis, and 18-fluorodeoxyglucose PET, are now used for staging, and because chemotherapy is used in all stages, surgery is no longer performed to detect subclinical disease.<sup>125</sup>

Non-Hodgkin lymphoma is the most common malignant neoplasm involving the spleen and the most common indication for splenectomy in malignancy in more recent case series. The spleen is involved in approximately 30% to 40% of patients, usually as a result of spread from other sites.<sup>126</sup> Primary splenic lymphoma, confined to the spleen, is an uncommon presentation seen in fewer than 2% of patients with non-Hodgkin lymphoma.<sup>127</sup>

## Indications for Splenectomy in Lymphoproliferative Disorders

With new classifications of these disorders and variability in clinical presentation and treatment, the decision for splenectomy requires close collaboration with the hematologists and oncologists. In general, splenectomy is indicated for the following:

- Treatment of symptomatic splenomegaly: abdominal fullness, pain, early satiety, and constitutional symptoms
- Treatment of hypersplenism, defined as blood cytopenias in the setting of splenomegaly
- Treatment or tissue diagnosis when the spleen is the only or main site of

disease

Between 25% and 55% of patients with chronic lymphocytic leukemia (CLL) have palpable splenomegaly.<sup>128</sup> Splenectomy may improve cytopenias in advanced CLL, with a success rate of about 50%.<sup>129</sup> In patients with hemoglobin level of less than 10 g/dL or platelet count less  $<50 \times 10^9/L$ , splenectomy not only improves hematologic parameters but also may offer survival advantage compared to those who receive chemotherapy alone.<sup>130</sup> Splenectomy is also indicated to treat refractory or recurrent AIHA or thrombocytopenia that may occur in CLL.

Splenic marginal zone lymphoma is a rare type of non-Hodgkin lymphoma that presents with splenomegaly without peripheral lymphadenopathy, cytopenias, and a variable degree of bone marrow involvement. There may be splenic hilar nodes in 25% of cases. The disease is often associated with hepatitis C infection, which is thought to have a tumorigenic role in some cases. Splenectomy may be performed in patients with splenomegaly for diagnostic purposes but also has a therapeutic role in the disease and is the treatment of choice. Rituximab is used in those not suitable for surgery.<sup>131</sup>

Hairy cell leukemia (HCL) is an indolent B-cell lymphoproliferative disorder that was initially recognized by Ewald in 1923. It accounts for only 2% to 3% of adult leukemias. The typical presentation includes cytopenia, circulating hairy cells, and splenomegaly. Splenectomy was the first treatment for HCL, but highly effective chemotherapy with purine analogues now replaces splenectomy in most patients. Splenectomy is indicated for symptomatic splenomegaly, for refractory cytopenia, or as a temporizing measure in pregnancy.<sup>132</sup> Approximately 50% of patients will have normal hematologic parameters after splenectomy, and 90% will improve in at least 1 parameter.<sup>133</sup>

## OTHER DISEASES AND SPLENECTOMY

Splenectomy may significantly improve the neutropenia in patients with Felty syndrome characterized by splenomegaly, neutropenia, and arthralgia. Splenectomy is reserved for patients with severe granulocytopenia ( $<1 \times 10^9/L$ ) and recurrent infections despite antirheumatic drugs, increased

transfusion requirements, or marked thrombocytopenia. Although splenectomy does not reduce arthralgia, leg ulcers, when present, generally heal.

In patients with left-sided portal hypertension secondary to splenic vein thrombosis, splenectomy is effective to treat bleeding from gastric varices. The extensive hilar varices represent a contraindication to laparoscopic splenectomy. Indication for splenectomy is controversial in the setting of noncomplicated left-sided portal hypertension.

Splenectomy may also be indicated for symptomatic splenomegaly or severe secondary hypersplenism in patients with Gaucher disease or sarcoidosis, although splenectomy will not alter the course of the disease.

## SPLENECTOMY

The first recorded splenectomy was performed for splenomegaly on a 24-year-old Neapolitan woman in 1549 by Adrian Zacarelli. Over the next several centuries, however, only a few other splenectomies were attempted, most proving fatal. In a 1908 literature review of all published cases of splenectomy, totaling fewer than 50 splenectomies, surgery had a mortality rate close to 90%. Over the past 100 years, and in particular the first few decades of the 20th century, improvement in surgical techniques and a better understanding of the splenic anatomy have led to a significant reduction in surgical mortality and morbidity. By the 1970s, the mortality had been reduced to around 10%, and now most elective series report mortality rates of less than 1%.

Open splenectomy remains the standard therapy for splenic injury in trauma and emergencies, as it allows quick control of bleeding and easy assessment of other organs for injury. Although some trauma centers have reported successful management of splenic injuries laparoscopically,<sup>134</sup> the laparoscopic approach is typically reserved for elective procedures.

The laparoscopic approach is now the approach of choice for almost all diseases where splenectomy is required.<sup>118</sup> Benefits of the laparoscopic approach include less postoperative pain, decreased complications, shorter length of stay, faster return to full activity, and a better cosmetic result when compared with the open technique.<sup>118,135-137</sup> This also extends to many patients with splenomegaly ( $\geq 15$  cm length), who may benefit from a hand-

assisted laparoscopic approach with less pain and shorter hospital stay,<sup>138</sup> even for cases with massive splenomegaly ( $\geq 20$  cm). Although patients with malignancy and splenomegaly have a higher risk of complications compared to patients with smaller spleens, this is also the case for open splenectomy, and the laparoscopic approach is preferred when feasible.<sup>118</sup>

Although many single, higher-volume institutions report rapid uptake of laparoscopic splenectomy,<sup>139</sup> population data analysis suggest that the procedure is underused in the United States, with only 13% of nontrauma splenectomies performed laparoscopically and a conversion rate of 33%.<sup>140</sup> Therefore, there is significant room for improvement in the uptake of this approach, but this may be hampered by the fact that outside of large referral centers, the individual surgeon will have low case volumes and limited training opportunities.

Splenectomy is performed for diagnostic purposes or for clinical indications (eg, blood cell count, abdominal discomfort) rather than for a clinical diagnosis.<sup>141</sup> The clinical benefit of splenectomy should balance or outweigh the short-term and long-term risks of splenectomy.

## Preoperative Preparation and Vaccination

The spleen contributes to the immune system by cell filtration, antibody and opsonin production, and phagocytic clearance of bacteria. Asplenic or hyposplenic patients are particularly susceptible to encapsulated bacteria, such as pneumococcus and malaria. The liver may compensate for the loss of the immunologic function of the spleen, but this requires an intact complement system and higher antibody production.

The major concern after splenectomy is overwhelming postsplenectomy infections (OPSI), defined as rapidly evolving sepsis, meningitis, or pneumonia caused by *S pneumoniae*, *Haemophilus influenzae* type B, and *Neisseria meningitides*,<sup>142</sup> with a high mortality rate of 40% to 50%.<sup>143,144</sup> The exact prevalence is difficult to define due to variability in follow-up, indications for splenectomy, inclusion of adults and children, and use of vaccination. Young children, particularly those younger than 2 years, are at increased risk because of the immaturity of the immune system. A review of the literature from 1966 to 1996 found a crude rate of infection of 3% with an overall mortality of 1.5%. The lowest risks were after splenectomy for ITP

(infection, 2.1%; death, 1.2%) and trauma (infection, 2.3%; mortality, 1.1%).<sup>143</sup> The risk persists over the patient's lifetime, with cases reported even 20 to 30 years after splenectomy. Some of the risk is due to the underlying condition originally leading to splenectomy or to immunosuppressive therapies used to treat the condition. To account for this, an analysis of Danish splenectomized patients from 1996 to 2005 matched them to nonsplenectomized patients with the same disease. The overall incidence of infection was 7.7 per 100 person-years in splenectomized patients with the highest risk seen in the first 90 days after surgery. In this study, enteric rods were the most common cause of early and late bacteremia. The risk of infection requiring hospital care was 4.6 times higher in splenectomized patients compared to the general population. The highest risks were seen after splenectomy for underlying hematopoietic cancer, and patients with splenic trauma had the lowest risks. However, the risk was only modestly higher compared to nonsplenectomized patients with the same diagnosis; for ITP and trauma, the risk of late infections was not significantly higher than in nonsplenectomized controls.<sup>145</sup> Furthermore, although mortality risk was higher compared to the general population, most of this risk was accounted for by the underlying splenectomy indication. For ITP, after 1 year, splenectomized patients had a lower mortality risk than nonsplenectomized patients.<sup>146</sup>

Several strategies have been developed to reduce the risk of OPSI, and these include vaccination programs, prophylactic antibiotic use, patient education, empiric antibiotic use for febrile illness, and, importantly for the surgeon, splenic salvage whenever possible.<sup>147</sup>

## VACCINATION

Patients undergoing splenectomy or partial splenectomy should be vaccinated against encapsulated organisms with recombinant polyvalent *S pneumoniae*, *H influenzae* type B, and *N meningitides* vaccines. Although such vaccination routine is recommended by most, there is significant international variation between recommendations regarding exact vaccine type and boosters.<sup>148</sup> There are over 90 serotypes of *S pneumoniae*, and at least 30 can cause infections in humans.<sup>149</sup> The polyvalent pneumococcal vaccine (PPV-23) provides short-term immunity against 23 subtypes, and nonresponders at high risk for invasive disease can be identified by measuring antipneumococcal

antibodies.<sup>149</sup> A 13-valent pneumococcal conjugate vaccine (PCV-13) is more immunogenic but has more limited serotype coverage. This is a rapidly changing field with examples of recommendations for adults summarized in Table 77-4; updates are available from the appropriate national public health bodies (web pages listed in table).

\*If have not received PCV13 or PPV23 in the past.

These vaccines should be started at least 2 weeks before planned splenectomy and ideally when immunosuppressive agents are not used. Vaccine effectiveness may be reduced in patients who have received the anti-CD20 antibody rituximab in the previous 6 months.<sup>149</sup> Guidelines for postsplenectomy vaccinations for patients who have undergone an emergency procedure suggest that waiting until 2 weeks after splenectomy results in the highest antibody titers for the most common serotypes.<sup>150</sup> If there is concern that the person may not return for postsplenectomy vaccinations, vaccines should be given before discharge to improve vaccination rates, which have

been reported to be as low as 26%, even in more recent literature.<sup>151</sup> Patients should also receive the influenza vaccine annually due to the risk of secondary bacterial infections.

## **ANTIBIOTIC PROPHYLAXIS**

Recommendations for daily antibiotic prophylaxis are based on little evidence.<sup>142</sup> Lack of compliance and risk for selection of resistant pneumococcal strains are concerns with this approach. Guidelines recommend daily prophylactic antibiotics (benzylpenicillin) for children under 5, but there is a lack of consensus on when this should be discontinued. British guidelines recommend prophylaxis until the age of 16 and suggest that lifelong prophylaxis be offered for high-risk patients (inadequate serologic response to pneumococcal vaccination, history of invasive pneumococcal disease, splenectomy for underlying hematologic malignancy, ongoing immunosuppression, age >50 or <16 years).<sup>149</sup>

## **PATIENT EDUCATION AND RESCUE ANTIBIOTICS**

Many patients are not aware of their increased risk for sepsis, and informed patients seem to have lower risks of infections.<sup>152</sup> Patients should wear a medical alert bracelet. This is particularly important as vaccination does not imply immunity and the pneumococcal vaccine is only 70% protective even in the immunocompetent host.<sup>147</sup> OPSI is a medical emergency with septic shock that develops in only a few hours, and immediate treatment can reduce mortality. However, the initial prodrome of fever, myalgia, emesis, headache, and abdominal pain may go unrecognized without heightened awareness of the possibility of postsplenectomy sepsis. These early symptoms can quickly escalate into profound septic shock, accompanied by disseminated intravascular coagulation, and organ failure. Meningitis (particularly among children) and pneumonia are often seen. *S pneumoniae* is the most common cause, followed by *H influenzae* type B and *N meningitides*.<sup>142</sup> *E coli*, *Pseudomonas aeruginosa*, and other organisms can also be seen.<sup>142</sup> Asplenic or hyposplenic patients should be instructed to seek immediate medical attention at the first sign of illness, especially fever, and immediate treatment with empiric antibiotics is mandatory. Patients should have a supply of antibiotics on hand for emergency use. With the onset of fever, the patients

should take the first dose of antibiotics and then seek immediate medical evaluation. Amoxicillin-clavulanate and levofloxacin are appropriate choices for this purpose.

## **OTHER RISKS OF SPLENECTOMY**

In addition to OPSI, there are other short- and long-term risks of splenectomy that are taken into consideration when making clinical decisions and discussing risks and benefits with patients. These risks vary with the underlying condition but include early venous thromboembolic events, especially in the portal-splenic venous system (PSVT) (discussed below). There is concern that splenectomy may also increase the risk of late vascular events, including thromboembolism and pulmonary hypertension, especially when performed in patients with thalassemia and sickle cell disease. Splenectomy is now reserved for very rare indications in these diseases.<sup>144</sup>

## **SELECTION OF OPERATIVE APPROACH**

Laparoscopic splenectomy was first described by several groups in 1991 and 1992.<sup>153-157</sup> The original approach was anterior with the patient supine, as for open surgery. This was challenging, as the gastrosplenic and splenorenal ligaments lie on top of one another. The description of the lateral approach was an innovation enabling easier and safer access to the splenic hilum.<sup>158</sup> Advances in energy devices and staplers facilitated the diffusion of the approach, eliminating the need to dissect and control the short gastric and hilar vessels individually. Finally, the addition of the hand-assisted laparoscopic technique enabled many patients with splenomegaly, even massive splenomegaly, to benefit from a less invasive procedure. The benefits of laparoscopy are predicated on the fact that an intact specimen is usually not required for pathologic diagnosis so the spleen can be removed piecemeal through the small port incisions. Even when an intact specimen is needed, such as for a splenic mass, the incision will be smaller than a standard laparotomy and can be positioned lower in the abdomen.

Most patients undergoing elective splenectomy are candidates for a laparoscopic procedure. Decisions regarding the best operative approach are based on the spleen size, underlying disease, other comorbid conditions,

presence of perisplenic collaterals and inflammation, need for an intact specimen, and surgeon experience. Decisions about selection of operative approach begin with history and physical examination. The patient is examined in the supine position with arms at the sides, starting in the right lower quadrant and moving toward the left upper abdomen. Although normal splenic size varies depending on sex, age, and racial background, spleen size tends to decrease with age. While a palpable spleen up to 2 cm below the costal margin may be a normal variant in a young adult, it is likely abnormally enlarged in an older adult. A palpable spleen leads to imaging with ultrasound and/or CT scan to measure the maximal craniocaudal length of the spleen and look for other conditions that will increase technical complexity of splenectomy including perisplenic varices, splenic infarcts, and hilar lymphadenopathy.

Table 77-5 provides a general classification of spleen size that can be used for preoperative planning. Preoperative spleens that are >25 cm in length pose particular challenges laparoscopically.

**TABLE 77-5: DEGREES OF SPLENOMEGALY BASED ON CRANIOCAUDAL LENGTH ON COMPUTED TOMOGRAPHY OR POSTRESECTION WEIGHT**

	Splenic Length (cm)	Splenic Weight (g)
Normal spleen	Up to 13	<300
Mild splenomegaly	>13–15	300–500
Moderate splenomegaly	16–20	500–1000
Massive splenomegaly	>20	>1000

Some believe that preoperative splenic volume (rather than length alone) provides a more reliable assessment of the degree of splenic enlargement to predict difficulty of the laparoscopic approach. With improved CT technology, such volumetric assessment is increasingly easy to perform. However, until greater use and validation of these measurements are available, splenic length remains the most common measure of the degree of splenomegaly. Ultrasound splenic length measured with the patient in supine position has a good correlation with overall splenic volume on CT scan,

although measurements obtained with the patient in the right lateral decubitus position provide the strongest correlation with splenic volume.<sup>159</sup>

## **Patient Selection for Laparoscopic, Hand-Assisted Laparoscopic, or Open Approach**

Achieving the best outcomes depends on risk stratification, operative planning, and patient selection for laparoscopic, hand-assisted laparoscopic, or open surgery, based on spleen size, underlying disease, and surgeon experience. Perioperative risk increases as splenic size increases. Several studies document increased risks associated with conventional laparoscopy in the setting of splenomegaly (>1000 g). Challenges with large spleens include difficulties manipulating and moving the large organ, perisplenic adhesions and inflammation, large collateral vessels, reduced surgical space, and difficulties with extraction of the specimen. Laparoscopic splenectomy for splenomegaly has longer operative time, increased blood loss, higher risk of conversion to open splenectomy, increased postoperative length of stay, and higher postoperative morbidity when compared to splenectomy for smaller spleens.<sup>160,161</sup> This is related both to technical issues and risk of significant bleeding, but also to the older age and underlying malignant disease in many patients with splenomegaly.<sup>162</sup> However, significant morbidity is also seen after open splenectomy for splenomegaly,<sup>163</sup> and the more salient comparison is between laparoscopic and open surgery for splenomegaly. In experienced hands, a laparoscopic approach is preferred over open surgery, with lower blood loss, lower or similar morbidity, and lower hospital stay,<sup>135,162,164</sup> but it should be appreciated that splenomegaly cases are considerably more challenging than for normal-sized spleens. The introduction of the hand-assisted laparoscopic surgery (HALS) approach has improved safety for splenomegaly patients, with decreased conversions and fewer complications compared to standard laparoscopy<sup>165</sup> and to open surgery.<sup>138</sup> Conversion rates to open splenectomy start to increase with a spleen size of greater than 22 or 23 cm,<sup>166,167</sup> and patients converted for complications likely suffer poorer outcomes than patients who undergo a controlled open operation.<sup>168,169</sup>

The size cutoff above which conversion to open is inevitable based on lack of working space, inability to extract the spleen in a retrieval bag, or

conversion for complications is not clear. Some have proposed using clinical examination criteria, excluding those with spleens that extend below and to the right of the umbilicus.<sup>170</sup> Three-dimensional CT spleen volume >2700 mL was associated with an 87.5% conversion rate, with no conversions for spleens <1100 mL.<sup>169</sup> In earlier studies, conversion for spleens >25 cm was inevitable, but more recent series report excellent results from experienced groups with liberal use of HALS for massive splenomegaly, including removal of spleens up to 35 cm long.<sup>171-173</sup> The list of absolute contraindications to laparoscopic approach has diminished over time. Excellent outcomes even in the most challenging patients with splenomegaly in the context of cirrhosis have been reported in experienced hands.<sup>174</sup> Splenic length >20 cm is a reasonable measure of anticipated difficulty, and a hand-assisted approach or open surgery for these patients is appropriate, depending on available expertise (Fig. 77-16).

**FIGURE 77-16** This patient had slowly increasing splenomegaly for 13 years. She became symptomatic and was referred for splenectomy for diagnosis and treatment when the spleen measured 24 × 13 × 11 cm. Hand-assisted laparoscopic splenectomy was performed revealing splenic marginal zone B-cell lymphoma.

## Preoperative Splenic Artery Embolization

Although initial experience with total splenic artery embolization (SAE) was discouraging and associated with significant complications, partial SAE has been used to manage select cases of splenic trauma (see above). SAE has also been used by some as a preoperative intervention to reduce vascularity and size of massive spleens in preparation for a laparoscopic approach. Embolization is achieved using microcoils and/or Gelfoam.

It is generally agreed that SAE is not helpful in laparoscopic cases where the spleen measures less than 20 cm in length.<sup>175</sup> The benefit of SAE in preoperative management of larger spleens remains controversial. Although some studies have shown that preoperative SAE can lead to reduced intraoperative blood loss in cases of large spleens, they reported no significant differences in conversion rates, incidence of postoperative complications, or length of hospital stay.<sup>176</sup> The potential for a modest reduction in blood loss, however, needs to be balanced against the potential risks and additive nature of this procedure. Complications have been reported in up to 20% of cases and include catheter site hematoma and pseudoaneurysm, pancreatitis, splenic abscess or rupture, peritonitis, and postembolization syndrome (ie, pain, fever, ileus, and/or pleural effusion). Some of these risks can be reduced by performing surgery as soon as possible (ideally within a few hours) after embolization,<sup>177</sup> but this may not be feasible in all settings. There is also a theoretical concern about stapler integrity when firing across vessels occluded by coils.<sup>178</sup> In general, preoperative SAE is now infrequently used.

## Laparoscopic Splenectomy

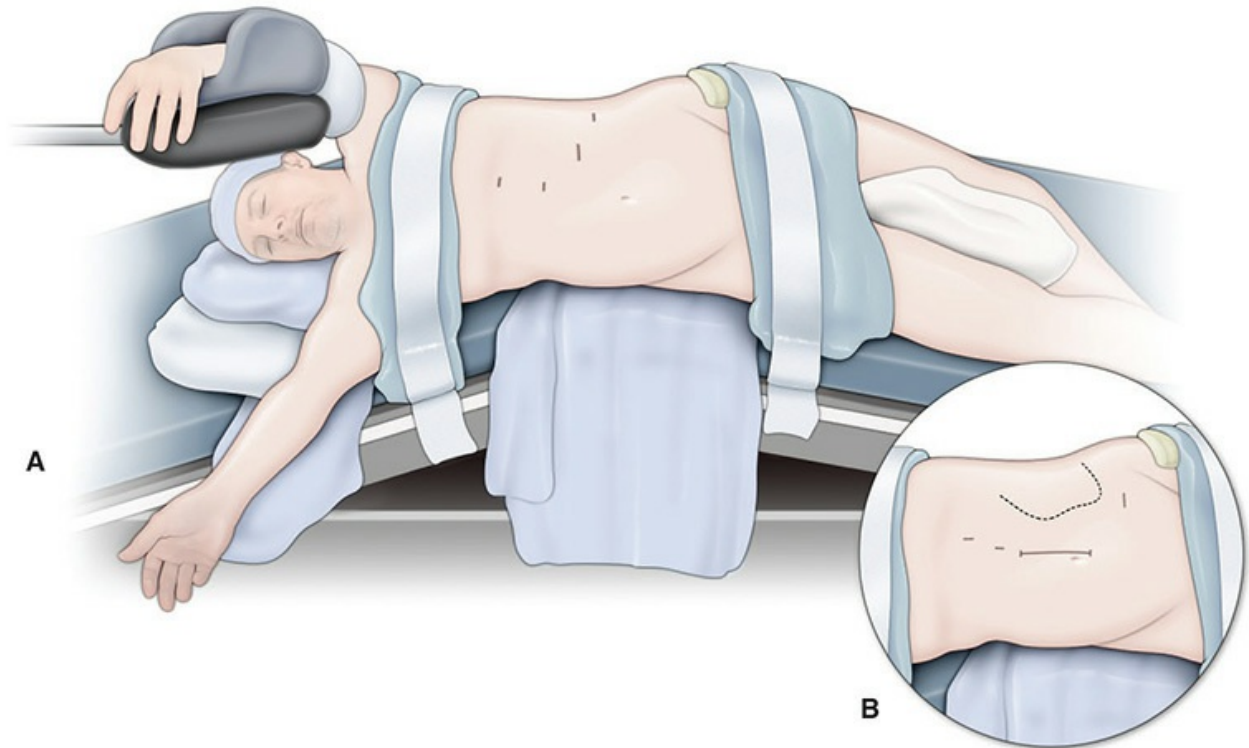

The first attempts at laparoscopic splenectomy were performed through an anterior approach. This was performed with the patient in the lithotomy

position using 5 laparoscopic ports. Most now favor the lateral approach.<sup>179</sup> The lateral approach, initially developed for adrenalectomy, uses the weight of the spleen and gravity to gain exposure during various steps of the procedure. In addition, it facilitates dissection of the superior short gastrics and superior pole when compared to the traditional anterior approach. A fully laparoscopic approach is chosen for spleens <15 to 20 cm in length when an intact specimen is not required, allowing for splenic morcellation and removal through a small port. Otherwise, a hand-assisted approach will be planned (see below).

## **Details of the Operative Procedure: Lateral Approach**

### **PATIENT POSITIONING AND ROOM SETUP**

Figure 77-17 illustrates the room setup and patient positioning for this procedure. Monitors are placed on either side of the patient toward the head. The surgeon and assistant will stand on the right of the table with the scrub nurse on the left side. With the patient supine, an orogastric tube is placed for gastric decompression, and compression stockings are used for prevention of thrombosis. A Foley catheter is placed if the case is expected to last over 3 hours. The patient is then positioned in right lateral decubitus at about 70 degrees. The umbilicus of the patient should be at the level of where the table will be flexed. A large gel roll is placed behind the patient, and an axillary roll is placed under the right arm. The right leg is bent and the left leg is straight, with a pillow between. The table is flexed to increase the distance between the costal margin and iliac crest. The patient is taped securely to the table at the shoulders and hips. The sterile field should extend from the nipples to the pubic bone in the cranial-caudal position and from the right anterior axillary line to the left scapular tip. A formal open laparotomy set should be readily available in case emergent conversion to an open procedure is necessary. A hand-assist device should also be available as this may prevent full conversion to open surgery in some cases.

**FIGURE 77-17** Patient and trocar positioning for laparoscopic splenectomy. Patient is in right lateral decubitus with table in flexion. **A.** Recommended trocar placement for normally sized spleen. One 12-mm port for introduction of the laparoscopic stapler. The remaining ports are 5 mm. **B.** Setup for hand-assisted laparoscopic splenectomy in the presence of splenomegaly. The usual hand-port placement is marked in cephalad to the umbilicus. (Reproduced with permission from Feldman LS. Laparoscopic splenectomy: standardized approach, *World J Surg.* 2011 Jul;35(7):1487-1495.)

## TROCAR PLACEMENT

A 4-trocar technique is used, including one 12-mm port and three 5-mm ports, with a 5-mm 30-degree laparoscope for visualization. We use an open technique to insert a 12-mm port about 5 cm below the costal margin along a line drawn from the umbilicus to the costal margin. If the spleen is palpable, this trocar is moved downward to avoid splenic injury. This port will be used for the surgeon's right hand, including stapler placement, and later for specimen retrieval. Long-acting local anesthetics are infiltrated prior to incisions. Pneumoperitoneum with carbon dioxide to a pressure of 12 mm Hg is usually adequate for exposure. The table is placed in reversed Trendelenburg position. Two 5-mm trocars are then placed under direct

vision, one to the left of the xiphoid and the next one lower down toward the midline. Lateral colonic attachments may need to be divided to place the fourth 5-mm trocar laterally below the costal margin. The camera port is placed in the most medial port to begin the dissection of the gastrosplenic ligament with the lateral port used for the assistant to provide gentle traction on the spleen (see [Fig. 77-17](#)).

## DISSECTION

The procedure begins by exploring the abdomen to identify any accessory spleens. They are present in up to 20% of patients and may be the source for inadequate response to splenectomy in the treatment of hematologic disease, such as ITP. The rate of retrieval of accessory spleens is similar after laparoscopic and open surgery.<sup>135</sup> The splenic hilum, gastrosplenic ligament, gastrocolic ligament, greater omentum, mesentery, and presacral space are potential sites for accessory spleens, with the splenic hilum being the most common (see [Fig. 77-4](#)). Each of these sites should be considered as the dissection continues.

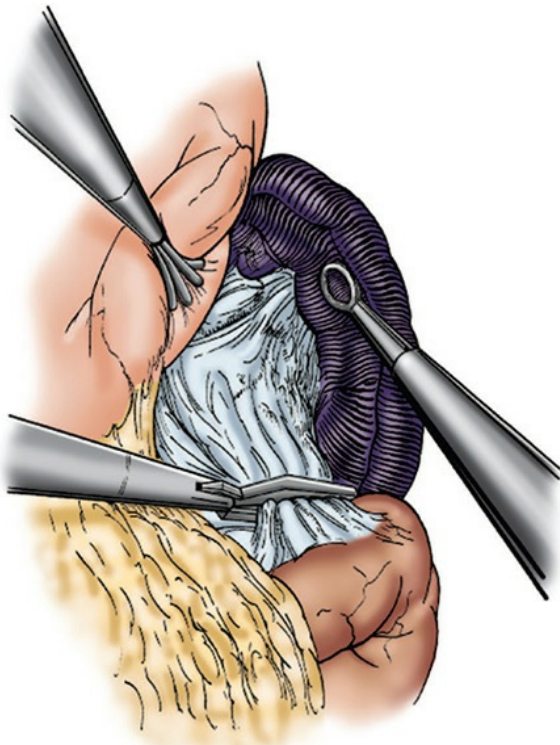

We use an ultrasonic energy device for the dissection. It is important for the surgeon and assistants to avoid injuring the spleen, which can result in splenosis or tumor rupture. Retracting instruments are always placed with the tip past the spleen to avoid inadvertent injury (“past pointing”). The dissection begins by mobilizing the splenic flexure of the colon to provide adequate exposure to the inferior pole of the spleen ([Fig. 77-18A](#)). We begin medially with control of the short gastric vessels. With the stomach gently retracted medially by the surgeon’s left hand, and the spleen gently retracted leftward through the assistant’s lateral port, the lesser sac is entered in an avascular area near the lower pole of the spleen. Subsequently, the short gastric vessels are identified and divided using the ultrasonic dissector moving cranially. It is important to avoid any injury to the stomach or the spleen, especially cranially as the short gastrics may be very short ([Fig. 77-19](#)). Opening up the first layer of peritoneum of the gastrosplenic ligament at the top of the spleen may help to increase the length between the stomach and spleen and facilitate vessel control. Ongoing medial rotation of the stomach will help expose these vessels and ensure complete ligation ([Fig. 77-18B](#)).

A

B

C

D

**E**

**FIGURE 77-18** Steps of laparoscopic splenectomy. **A.** Divide the short gastric vessels using ultrasonic dissecting shears. **B.** Medial rotation of the stomach can help visualize the superior-most vessels. Special care and attention should be given to these vessels, which are often very short in length. **C.** Dissection of the lower pole of the spleen away from the colon. **D.** The lateral attachments of the spleen are mobilized, freeing the spleen from its superior attachments and visualizing into the lesser sac from the lateral position. **E.** Divide the splenic hilum using an endoscopic stapler.

**FIGURE 77-19** Care must be taken to carefully dissect the uppermost short gastrics away from the stomach. These may be very short.

Once all the short gastrics are ligated, the lower pole of the spleen is elevated with a blunt dissector and any attachments are divided (Fig. 77-18C). Once the inferior pole of the spleen has been freed, attention is turned to the lateral splenic attachments (Fig. 77-18D). The scope is moved to the lateral port to improve exposure. The surgeon's nondominant hand provides gentle traction rightward on the spleen to expose the lateral attachments. These are divided moving caudal to cranial and staying 5 to 10 mm away from the spleen. At the upper pole, the spleen is retracted upward in order to place the posterior gastrosplenic peritoneal layer on stretch and reenter the lesser sac laterally. It is important to ensure complete mobilization superiorly in order to facilitate hilar control.

Once the spleen is fully mobilized, the position of the pancreas in relation to the hilum is assessed. The pancreas is usually within 1 cm of the hilum. If there does not appear to be sufficient space for a stapling device between the spleen and pancreas, additional fine division of tissue in this area can be achieved using hook dissection. The hilum is divided with an endoscopic stapling device (Fig. 77-18E). The hilum should be divided close to the spleen to avoid injury to the pancreatic tail. Depending on the spread between the hilar vessels, a 60 × 2.5-mm stapler or 45 × 2.5-mm stapler is chosen and

articulated to achieve precise application across the hilum. The splenic bed and short gastrics are inspected for hemostasis. Occasionally, oozing from the staple line may require application of a metal clip or suture.

## **REMOVAL OF THE SPECIMEN**

The 12-mm port is removed and the incision extended to enable a 15-mm endoscopic bag to be placed directly through the skin incision without a port. The spleen is placed in the endoscopic bag, and the bag is brought up through the skin. The spleen is then morcellized using a ring forceps and digital disruption and the pieces removed or suctioned until the entire bag can be removed from the abdominal cavity. Care should be taken during this part of the procedure to ensure that the ring forceps do not tear the retrieval bag causing splenosis or inadvertent grasping of intra-abdominal contents through the bottom of the bag. This can lead to unrecognized complications, such as small bowel or colonic injury. The 12-mm port is then replaced and pneumoperitoneum reinstilled in order to verify hemostasis and exclude any injury to the pancreas, diaphragm, or stomach. Adjuncts for controlling any oozing along the staple line may include application of fibrin sealant. In patients with ITP and low platelets who are oozing after hilar division, platelet transfusion is given.

The fascia of the extraction port is closed with slowly absorbable suture and the skin approximated with absorbable sutures. The orogastric tube is removed in the operating room and the urinary catheter is also removed, unless there was significant blood loss and need for ongoing close monitoring. We do not leave a closed suction drain unless there was concern of injury to the pancreatic tail. If a drain is placed, the drain fluid amylase and lipase are assessed after the patient starts on an oral diet, and if normal, the drain is removed. If the patient has evidence of a pancreatic leak, the patient is discharged with the drain left in place until output is less than 10 mL for 2 days.

## **Considerations for Splenomegaly**

Cases of massive splenomegaly ( $\geq 20$  cm length) are technically challenging, and the risk of complications and conversion is higher than for smaller

spleens, requiring some adjustments in strategy. The HALS technique is useful because it facilitates exposure and manipulation of the very large and heavy specimen in order to better access the splenic attachments, especially laterally and superiorly. Another advantage is that the placement of the large specimen in a bag for retrieval can be extremely difficult using small laparoscopic instruments. HALS increases safety significantly, with the ability for the hand to control the hilum in the case of bleeding, decreasing blood loss and avoiding conversion to open surgery<sup>180</sup> while maintaining the advantages of the laparoscopic approach.<sup>138,162</sup>

The planned 7- to 8-cm incision for the hand port is marked in the midline prior to positioning the patient and is for the surgeon's nondominant hand (Fig. 77-18B). Although variable positions for the port have been described, we place it in the supraumbilical midline, immediately cephalad to the umbilicus. A number of such ports are commercially available.

The patient is placed in right lateral decubitus but at less of an angle than for a smaller sized spleen to facilitate medial access to the lesser sac for early vascular control and conversion to open surgery if needed. The spleen edges are marked after positioning the patient, and initial port placement will be below the level of the palpable spleen to avoid injury. We prefer to begin the dissection laparoscopically because insertion of the hand will obscure the view somewhat. Attention should be paid to the presence of larger blood vessels, including to the lower pole and potentially vascularization of the usually avascular perisplenic attachments. The lesser sac is entered, and short gastrics are divided. With very large spleens, the splenic artery is identified proximal to the hilum, dissected, and controlled with a self-locking clip, suture, or TA stapler, without dividing the vessel (Fig. 77-20). The hand may be inserted at this point to facilitate identification and control of the splenic artery. Early ligation of the splenic artery decreases blood flow and splenic volume and provides some reassurance to the surgical team. If a clip is used, care is taken to ensure it is proximal to where the hilum will be stapled later to avoid misfiring.

**FIGURE 77-20** In cases with significant splenomegaly, the splenic artery is identified after opening the lesser sac and ligated prior to additional splenic mobilization.

In cases of massive splenomegaly, the lower pole attachments may contain sizable vessels that may require clips, ties, or stapling. Lateral splenic mobilization is greatly facilitated by the hand providing retraction rightward and downward as the upper pole is approached (Fig. 77-21). Similarly, stapler placement across the hilum in very large spleens is much easier and safer with HALS. Once the spleen is detached, placement of the spleen inside the specimen bags can be very challenging. For spleens greater than approximately 20 cm, we pull a large “bowel bag” over the spleen placed in the left upper quadrant with the patient in a head-down position.

**FIGURE 77-21** The hand can be useful in providing medial traction to expose the superior lateral attachments in cases of splenomegaly.

When there is significant perisplenic inflammation, there may be ongoing oozing from the wide dissection field. Applying hemostatic adjuncts like fibrin sealants using the spray applicator can be effective, as can sheets of absorbable oxidized cellulose.

## **Postoperative Management**

Traditionally surgeons have advocated postoperative decompression of the stomach with a nasogastric tube to prevent hemorrhage from the short gastrics. This is not necessary after uncomplicated splenectomy. Patients are given clear liquids on the night of surgery, advancing the diet the next morning. A single dose of preoperative antibiotics is used and is not repeated postoperatively. Perioperative thromboprophylaxis with subcutaneous heparin is used. The patients are provided patient-controlled analgesia for their first postoperative night and switched to oral analgesia in the morning. Unless the patient has an ongoing coagulation problem or low platelet counts, we use nonsteroidal anti-inflammatory drugs in management of their

postoperative pain. A complete blood count is checked the morning after surgery. Patients are typically discharged on postoperative day 1 or 2 after laparoscopic splenectomy and day 2 or 3 after HALS.

## Complications

Overall, the complication rate of elective laparoscopic splenectomy is 10% to 15%, with a mortality rate of less than 1%. Splenectomy for hematologic malignancy and splenomegaly has a higher complication rate, with reports of a 9% to 18% mortality rate for patients with myeloproliferative disorders.<sup>124,162,181</sup> In observational studies, the rate of complications was lower for patients having laparoscopic compared to open splenectomy,<sup>135,182</sup> including for splenomegaly.<sup>135</sup>

Patients must be closely monitored for early postoperative bleeding, particularly those with thrombocytopenia or myeloproliferative disorders. Patients with massive splenomegaly and underlying coagulopathy should be in a monitored setting in the immediate postoperative period. It is an error to ascribe bleeding to hematologic abnormalities, and although these should be corrected, it is generally safer to reexplore patients early and to evacuate a hematoma to reduce the incidence of subphrenic abscess.

Injury to the tail of the pancreas with a symptomatic complication can occur in up to 10% of cases.<sup>183</sup> Development of a pancreatic collection will require drainage that remains in place until the fistula closes. Pulmonary complications such as atelectasis, effusion, and pneumonia occur more frequently following open splenectomy. One intraoperative complication that may occur during laparoscopic splenectomy but is rarely seen with open splenectomy is diaphragmatic perforation, usually related to thermal injury during mobilization of the superior pole, emphasizing the importance of a good technique and visualization during the procedure.<sup>168</sup>

In unusual cases, the platelet count may rise to very high levels. In cases where the platelet count rises to  $>1000 \times 10^9/L$ , a drug that inhibits platelet aggregation, such as acetylsalicylic acid, can be used.

Thrombosis of the splenic vein, with extension into the portal vein and superior mesenteric vein, is a potentially lethal complication of splenectomy if it results in bowel ischemia or portal hypertension. A range of estimates for this complication (0% to 55%) has been reported due to variations in study

design, such as whether retrospective or prospective, indication for splenectomy, surgical approach, and method of diagnosis (with CT scan twice as sensitive as ultrasound). In a review of splenic-portal vein thrombosis (SPVT), the overall incidence of symptomatic thrombosis was 3.3% and similar between the open and laparoscopic approach.<sup>184</sup> However, when considering only prospective studies that screen for asymptomatic cases, the overall incidence increased to 12.3% and was significantly higher after laparoscopic compared to open surgery (23% vs 8%) (Fig. 77-22). Patients with myeloproliferative disorders, lymphoproliferative disorders, and hereditary hemolytic anemias (particularly HS and thalassemia) are at particularly high risk, whereas patients with ITP are at lower risk.<sup>184</sup> Interestingly, splenectomy for trauma is not associated with a significant risk for SPVT. Clinically, patients with splenomegaly are at higher risk than patients with smaller spleens. In one study, the incidence of SPVT on screening postoperative Doppler ultrasound was 78% for patients with spleen size >20 cm, 31% for spleens between 15 and 20 cm, and 13% for spleens ≤15 cm.<sup>185</sup> Although abnormalities in prothrombotic screening tests are very common, they do not predict SPVT.<sup>185</sup>

**FIGURE 77-22** Splenic-portal vein thrombosis (SPVT) after a laparoscopic splenectomy. The thrombosis may be small and involve intrahepatic branches of the portal vein only, as is the case here where the patient had thrombus in the anterior branch of the right portal vein. The patient was asymptomatic and was initially observed. Follow-up imaging after 3 weeks, however, showed persistent thrombosis, and she was therefore anticoagulated for 3 months.

The high incidence of asymptomatic SPVT has generated a debate about whether patients should have surveillance imaging (ultrasound or CT) after laparoscopic splenectomy, since untreated thrombosis could lead to significant morbidity and mortality. The median time from splenectomy to asymptomatic SPVT is 6 days, whereas the median interval to symptomatic SPVT is about 8 to 12 days.<sup>184</sup> Prompt treatment of asymptomatic PSVT leads to resolution in 90% of cases,<sup>184</sup> but it is also known that isolated thrombosis in the splenic vein may resolve without anticoagulation.<sup>186</sup> However, persistent thrombosis, portal hypertension, or cavernoma is present in 20% of patients after treatment of symptomatic SPVT.<sup>184</sup> Some advocate screening all patients with Doppler ultrasonography 1 to 3 weeks after laparoscopic splenectomy,<sup>187</sup> whereas others suggest screening only higher risk patients.<sup>118</sup> We perform routine postoperative surveillance ultrasound with color Doppler imaging on postoperative day 7 and anticoagulate patients for 3 to 6 months if SPVT is detected.<sup>187</sup> Since symptoms of SPVT can be subtle, abdominal imaging should be performed for any patient with any deviation from the expected postoperative course, including fever, abdominal pain, diarrhea, anorexia, or nausea.

Perioperative anticoagulation prophylaxis is recommended, and European Association for Endoscopic Surgery guidelines further recommend prophylactic anticoagulation for 4 weeks after surgery.<sup>118</sup> Although a single small randomized trial of extending postoperative prophylaxis failed to show a benefit,<sup>188</sup> this is strongly considered for patients at particularly high risk (eg, myelodysplastic disorders with splenomegaly) once hemostasis is assured.<sup>189</sup>

## OPEN SPLENECTOMY

The open approach is most commonly used in cases of trauma and splenic

injury, but it is also used in elective management of massive splenomegaly (Fig. 77-23).

A

B

**FIGURE 77-23** **A.** This spleen measured 27 cm and was successfully removed laparoscopically. **B.** This spleen measured over 30 cm and was removed through open surgery.

The patient is supine, with an optional small roll under the left flank. A variety of incisions including left subcostal or midline can be used depending on the nature of the disease and the personal preference of the surgeon. A midline incision is used for traumatic injury because of the speed of access as well as exposure of the spleen and other possibly injured viscera. A careful look for accessory spleens is made in hematologic disease around the splenic hilum, retroperitoneum around the pancreatic tail, and greater omentum.

Open splenectomy is performed by mobilizing the spleen medially and ultimately dissecting down to a pedicle of splenic artery and vein, which is then controlled and divided. The surgeon stands on the right side of the table. A self-retaining retractor is used to expose the left upper quadrant and retract the colon downward. The gastrosplenic omentum is opened in an avascular area, and the short gastric vessels are divided with clips, sutures, or an energy device, taking care to avoid injury to the stomach ([Fig. 77-24](#)). The most difficult area is high on the stomach where the vessels are shortest and the risk for bleeding and gastric injury are highest. If there is concern about the gastric wall, a seromuscular suture is placed on the stomach to invert the area of concern. In cases of massive splenomegaly, the splenic artery can be isolated and ligated after the short gastrics are divided. Alternatively, the splenic artery can be identified nearer to its origin, avoiding the splenic vein and tail of the pancreas, through the gastrohepatic ligament along the lesser curve of the stomach ([Fig. 77-25](#))

**FIGURE 77-24** Ligation of the short gastric vessels and the gastrosplenic omentum.

A

B

C

D

**FIGURE 77-25** In cases of massive splenomegaly, access is obtained to the lesser sac and the splenic vessels identified. The artery is often seen above the pancreas. The vessels are carefully dissected and ligated twice proximally and once distally before being divided. The splenic dissection and mobilization are then performed.

Splenic mobilization then proceeds around the inferior pole, and the splenocolic attachments are taken down, staying close to the spleen to avoid injury to the colon or going too deep and injuring the adrenal gland. The left gastroepiploic artery is usually encountered here and controlled. The surgeon's left hand then palpates along the surface of the spleen and progressively retracts the spleen medially, exposing the lateral attachments ([Fig. 77-26](#)). These can be divided with scissors or electrocautery staying close to the spleen. In the case of trauma, the hematoma has usually dissected these ligaments, and the spleen can quickly be delivered into the incision.

**FIGURE 77-26** Division of the ligamentous attachments of the spleen during open splenectomy.

The spleen can then be delivered into the wound after bluntly dissecting any retroperitoneal attachments. Laparotomy pads are placed posteriorly to elevate the spleen. Hilar dissection proceeds close to the spleen to separate the vessels from the pancreas. The splenic artery and vein are individually divided between clamps and doubly ligated proximally with suture ligature (Fig. 77-27). Alternatively, the vessels may be divided with a vascular linear stapler. This is a fast way to control the hilum in cases of bleeding.

**FIGURE 77-27** Division of the splenic hilum using the 3-clamp method of Federoff.

After the spleen is removed, hemostasis is checked in 3 areas: on the diaphragmatic surface, along the greater curve of the stomach, and in the hilum. In cases of splenomegaly or infarction when there is significant perisplenitis, there may be a large raw oozing surface along the diaphragm. Packs are placed in the left upper quadrant along the diaphragm, and the greater curve and hilum are examined. The packs are then removed, and if there is still oozing, fibrin glue spray along with oxidized cellulose usually is effective. Prophylactic drainage is not used unless the pancreas has been injured.

## **SPLEEN-PRESERVING APPROACHES**

The techniques to preserve splenic tissue and function are dictated by the extent of planned resection or, in case of trauma, splenic damage ([Fig. 77-28](#)). These approaches have garnered increased popularity because of the critical role of the spleen in fighting encapsulated organisms and the small, but real, risk of OPSI.

**FIGURE 77-28** Approaches to preserving a traumatized spleen. Depending on the degree of splenic injury, one of these techniques can be used.

## Splenorrhaphy

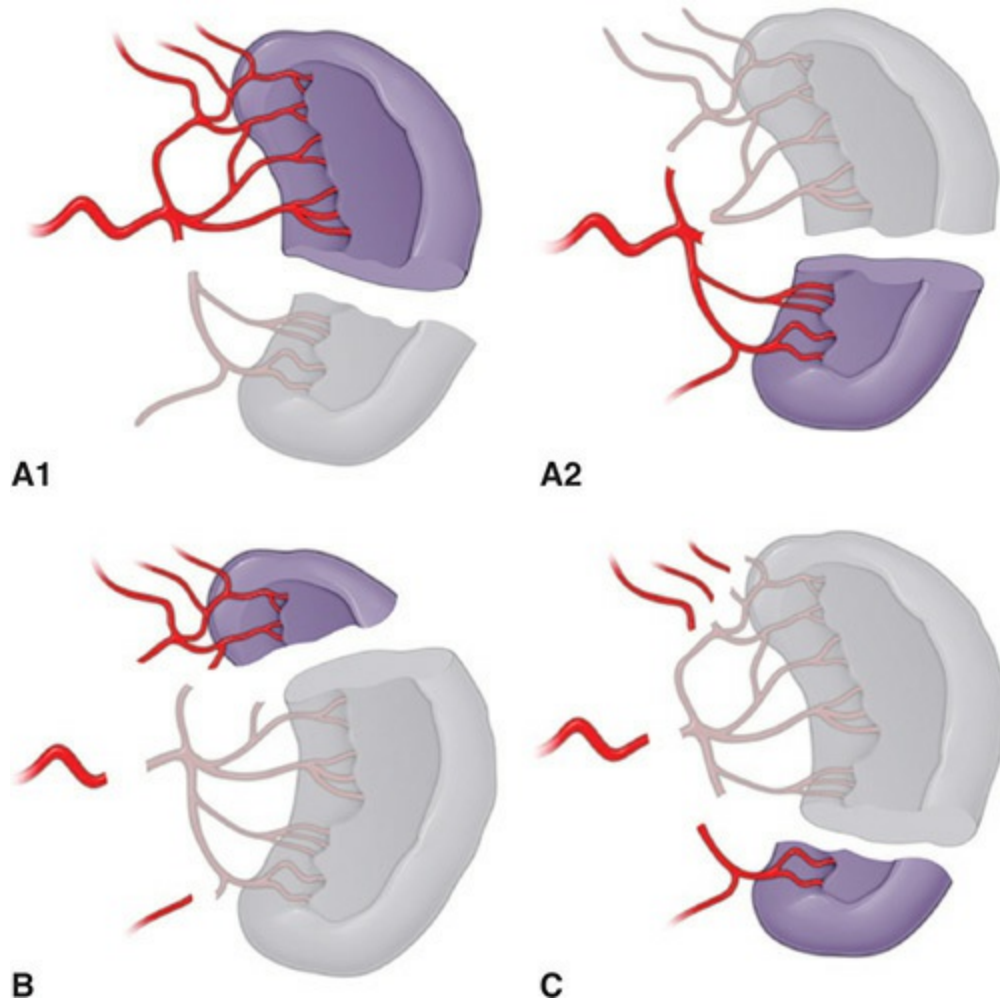

In hemodynamically stable patients with splenic trauma or iatrogenic injury, splenic repair may be attempted. In trauma, this situation is now relatively rare as many hemodynamically stable patients undergo splenic angioembolization. The spleen is mobilized to allow for thorough inspection of the organ. The ligamentous attachments must be divided as in splenectomy. Small lacerations can be managed by compression and the application of a hemostatic agent, such as oxidized cellulose, micronized collagen, thrombin, or fibrin glue. If the injury is localized to 1 pole of the spleen, the distal branches to that pole can be ligated near the hilum via the lesser sac, followed by reapplication of hemostatic agents and pressure. If this is not successful, a plicated repair using horizontal mattress sutures that

traverse the capsule and incorporate the injured parenchyma can be attempted. Finally, partial splenectomy can be considered, as described below. There is no tolerance for significant blood loss during attempted splenic salvage, and splenectomy should be performed if significant bleeding cannot be quickly controlled.

## Partial Splenectomy

Partial splenectomy is an attractive option to remove splenic lesions while preserving splenic function, which should decrease the long-term risk of sepsis and thrombosis. The indications include nonparasitic cysts, benign solid masses, Gaucher disease, and hematologic conditions such as HS or thalassemia.<sup>52</sup> Recommendations about the amount of remnant splenic tissue required for normal immunity vary from 10% to 25% of the normal spleen size.<sup>52</sup> Some authors suggest a splenopexy of the remnant to the retroperitoneum, abdominal wall, or gastric wall to prevent torsion. Because there is no specific information about whether patients having spleen-conserving therapy require vaccinations, the same preparation as for total splenectomy is recommended.<sup>142</sup>

Whether open or laparoscopic, the key to partial splenectomy is understanding the vascular anatomy. The spleen consists of 4 to 5 segments, each with its own terminal blood supply. The interlobar planes are relatively avascular, so resection of the segmentally devascularized spleen can be performed without significant blood loss. The inferior pole is supplied by the left gastroepiploic artery and the superior pole by the short gastrics; these vessels lie in the gastrosplenic ligament. In addition, there are 2 to 3 hilar branches lying with the tail of the pancreas in the splenorenal ligament (Fig. 77-6). Balaphas et al suggest the classification of partial splenectomy shown in Figure 77-29 and Table 77-6.

**FIGURE 77-29** Classification of types of partial splenectomy (see [Table 77-6](#)).

**TABLE 77-6: CLASSIFICATION OF TYPES OF PARTIAL SPLENECTOMY**

Technique	Segment of Spleen That Remains	Remaining Segment Supplied By:
A1	Upper half of spleen	Upper hilar vessels
A2	Lower half of spleen	Lower hilar vessels
B	Upper pole of spleen	Short gastrics (2-3)
C	Lower pole of spleen	Left gastroepiploic

Modified with permission from Balaphas A, Buchs NC, Meyer J, et al: Partial splenectomy in the era of minimally invasive surgery: the current laparoscopic and robotic experiences, *Surg Endosc.* 2015 Dec;29(12):3618-3627.

CT scan is used to plan the procedure, defining the vascular anatomy, the relationship to the lesions, and which splenic segments will be removed. Lesions in the poles of the spleen are most amenable, whereas centrally located lesions, unless an upper pole or lower pole segment can be preserved, will require total splenectomy. When partial splenectomy is performed for hereditary hemolytic anemias in children, the blood supply to the remnant spleen is maintained either through the upper short gastrics or inferior branches of the splenic artery and gastroepiploics to the lower pole, leaving about 15% to 25% of the splenic volume.<sup>190</sup>

## Laparoscopic Partial Splenectomy

This procedure was first reported by Poulin et al<sup>191,192</sup> in 1995, with a recent review identifying 187 cases.<sup>52</sup> The patient is positioned as per total splenectomy and 4 ports are used. The lesser sac is entered in an avascular area, preserving the uppermost short gastrics and the gastroepiploics at this point. The hilar vascular anatomy is examined. Laparoscopic ultrasound can be used to confirm the position of the pathology if it is not evident grossly. The spleen is partially mobilized laterally, except around the area of the spleen to be preserved. The branches to the segment to be removed are serially dissected at the level of the hilum anteriorly and controlled with clips, staplers, ligature, or a vessel-sealing energy device. As the arterial blood supply is divided, the splenic parenchyma will demarcate. The corresponding venous branches lie immediately posterior to the arteries, and care must be taken not to cause bleeding. It is confirmed that the partial resection will be

adequate to remove the pathology fully; if not, further branches are taken, or total splenectomy is performed. The venous branches to the devitalized segment are then divided either from the front or the back. To divide the capsule with minimal bleeding, it is first scored circumferentially with an electro-surgical device  $\geq 5$  mm on the devascularized side of the demarcation line. The devascularized parenchyma is then divided with an energy device with little bleeding. Fulguration is used to control surface oozing. Fibrin glue spray and oxidized cellulose are applied to the cut surface if necessary, and the specimen is removed in a bag.

Complications are relatively infrequent but include ischemia of the splenic remnant. Sonography and/or technetium-99m scanning are done to confirm perfusion.<sup>10</sup> Retained splenic phagocytic function is verified by absence of Howell-Jolly bodies on peripheral blood smear postoperatively.<sup>84</sup>

## Laparoscopic Unroofing of Nonparasitic Splenic Cyst

The positioning is the same as for laparoscopic splenectomy, and 3 or 4 trocars are used. The cyst is aspirated by introduction of the suction device through a thin area of the wall. The spleen is mobilized to gain access to the entire diameter of the cyst. In cases where there has been leakage or rupture, significant perisplenic adhesions are seen and care must be taken to avoid injury to the diaphragm when these are divided. The anterior cyst wall is opened at the level of the splenic parenchyma and circumferentially excised using an energy device, removing as much of the wall as possible. Significant calcifications in the wall of the cyst seen on preoperative imaging may preclude unroofing, and formal cystectomy or partial splenectomy may be required. The wall is removed in a retrieval bag. Hemostasis along the cut edge is obtained and omentum is sutured to the trabeculations seen on the back wall of the cyst through the empty cyst cavity.

# ADRENAL ANATOMY AND PHYSIOLOGY

*David Harris • Daniel Ruan*

## ANATOMY

The adrenal glands are paired retroperitoneal organs superomedial to the kidneys at the level of the 12th rib. They are surrounded by loosely attached fat posteriorly to diaphragmatic muscle. This fat can obscure the visualization and identification of adrenal tumors. Left-sided adrenal tumors lie adjacent to and can invade the spleen, pancreas tail, liver, kidney, or renal hilum. If not careful, it is possible to mistake the tail of the pancreas for the left adrenal gland given the similar texture and size. Right-sided adrenal tumors lie adjacent to and can invade the liver or inferior vena cava (IVC).

The arterial supply to the adrenals originates from the inferior phrenic arteries, aorta, and renal arteries. Despite being quite variable, the majority of the arterial supply approaches from the medial and inferior borders of the adrenals with few substantial arteries from the superior, posterior, or lateral sides. The adrenal arteries are generally small and amenable to electrocautery or vessel sealing devices.

Generally, the venous drainage from the right adrenal was thought to

consist of a single, large, short vein draining into the IVC. On the left, drainage was thought to proceed to the left renal vein or inferior phrenic vein via a longer, single vein. These anatomic descriptions were based largely on cadaveric studies on non-diseased adrenal glands. In the 1940s, Anson and Caudwell identified only a single venous variant in nearly 900 adrenals examined.<sup>1</sup> However, others have found significant heterogeneity in venous anatomy during operative intervention for adrenal pathology. Scholten et al. found 13% variance in venous anatomy in 546 consecutive adrenalectomies—no main adrenal vein, a single main vein with multiple small veins, double adrenal veins, and drainage sites including the IVC, hepatic vein, or inferior phrenic vein. The incidence of variant anatomy was more likely on the right side, with larger tumors, and with pheochromocytomas. Further, variant anatomy is associated with higher rates of transfusions due to operative complications.<sup>2</sup>

## PHYSIOLOGY

Each gland is divided into an outer cortex and an inner medulla, which are histologically and functionally distinct layers derived from separate embryologic origin. The cortex originates from mesodermal cells that form into cords of endocrine cells. In the adult, the cortex is composed of three zones. From outermost to innermost, they are: (1) *zona glomerulosa*, which regulates electrolyte homeostasis via production of aldosterone in response to the renin-angiotensin system, potassium concentration, and atrial natriuretic peptide, (2) *zona fasciculata*, which produces cortisol to promote gluconeogenesis and delivery of glucose to tissues, and (3) *zona reticularis*, which develops after roughly age 5 and produces the androgens dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) in response to adrenocorticotrophic hormone (ACTH) stimulation.<sup>3</sup>

The medulla is derived from neural crest cells, called chromaffin cells, which migrate and become imbedded into the inner portion of the gland. They develop into modified postganglionic sympathetic neurons that secrete up to 80% of the epinephrine and 20% of the norepinephrine in circulation in response to centrally mediated sympathetic cholinergic stimuli during stress. Cortisol produced in the cortex is shuttled past the medullary chromaffin cells, which increases production of phenylethanolamine-*N*-methyltransferase

(PNMT), which converts norepinephrine to epinephrine.<sup>3</sup>

## OPERATIVE ADRENAL DISEASE

The following sections detail specific conditions along with the evaluation and treatment approaches for adrenal disease. This is summarized in Table 81-1.

### Diseases of the Cortex

#### ADENOMA

**Cortisol Producing—Cushing Syndrome.** Adrenal adenomas that produce cortisol can be incidentally discovered during abdominal imaging or when the patient develops the signs and symptoms of Cushing syndrome. In the early 1930s, Harvey Cushing was among the first to describe the clinical entity of hypercortisolism, which is characterized by truncal obesity, round face, fragile skin, depression, and abdominal striae. These tumors autonomously secrete cortisol without the usual dependence on ACTH and can increase the risk of cardiovascular complications and mortality.

Preoperative testing includes overnight dexamethasone suppression test, 24-hour urine collection for free cortisol, and salivary cortisol measurement.<sup>4,5</sup>

To perform the overnight dexamethasone test, give 1 mg of dexamethasone at 11 pm and then check serum cortisol at 8 am, which should suppress under 5 µg/dL.<sup>6</sup> Some clinicians will increase the dose of dexamethasone to 2 or 3 mg, perform a 48-hour suppression test, or decrease the threshold of an abnormal am serum cortisol level to 1.8 µg/dL in order to reduce the false negative rate.<sup>7,8</sup> Table 78-2 shows common methods for testing.

TABLE 78-1: OPERATIVE ADRENAL DISEASE

	Phenotype	Pre-op Test	Treatment
<b>Disease of the cortex</b>			
Adenoma-Cortisol	Truncal obesity Round face Fragile skin Striae	CT/MRI Overnight dexamethasone suppression 24-hr urine collection	Lap adrenalectomy Possible bilateral adrenalectomy Post-op steroid taper
Adenoma-Aldosterone	Hypertension Hypokalemia	CT/MRI Plasma aldosterone:Renin ratio Salt loading Selective venous sampling	Lap adrenalectomy Partial adrenalectomy Hold antihypertensives immediately post-op
Adrenocortical Carcinoma	Maybe functional Compressive symptoms	CT/MRI PET-CT? <sup>123</sup> I imaging?	EDP-Mitotane Open adrenalectomy
<b>Disease of the medulla</b>			
Pheochromocytoma	Episodic headaches, palpitations, diaphoresis	CT/MRI 24-hr urine metanephrines Plasma metanephrines	Alpha-blockade + salt load Lap adrenalectomy
<b>Extra Adrenal</b>			
Metastasis	Compressive symptoms	CT/MRI	Lap adrenalectomy
Schwannoma	Non-functional	MRI	Surveillance
Paranglioma	Compressive symptoms	Core needle biopsy	Removal if symptoms
	Like Pheo Non-functional	CT/MRI 24-hr urine metanephrines	Alpha-blockade + salt load Lap adrenalectomy

**TABLE 78-2: TESTING FOR ADRENAL PATHOLOGY**

Test		Protocol	Pathologic results
<b>Cortisol-adenomas</b>			
Primary	Dexamethasone Suppression Test	Overnight low dose: 1 mg @11PM & check AM serum cortisol Overnight high dose: 3 mg @11PM and check AM serum cortisol. • Some clinicians use to reduce false negative rate 2 Day test: 0.5 mg q6hrs × 8 doses and measure serum cortisol 2 to 6 hours after the last dose	Cortisol >5 µg/dL
Confirmatory	Urine* Cortisol	24-hr urine collection	Urine free cortisol > 3× upper limit of normal
<b>Aldosteronomas</b>			
Primary	Aldosterone:Renin ratio	8 am plasma aldosterone and renin. For a quality test, the patient cannot be on spironolactone, eplerenone, or amiloride. It is okay to continue beta blockade.	Ratio >= 20 (lab dependent) [plasma aldosteron]>15 ng/dL
Confirmatory	Salt Loading	Assess plasma aldosterone concentration after administration of 2 L normal saline over 4 hr while in a recumbent position.	[Aldosterone] > 10 ng/dL
<b>Pheochromocytomas</b>			
Primary	Urine* Metanephrines	24-hr urine collection and test for fractionated metanephrines and catecholamines.	[Epinephrine] > 35 µg [Norepinephrine] > 170 µg [Normetanephrine] > 900 µg [Metanephrine] > 400 µg [Dopamine] > 700 µg
Primary	Serum Metanephrines	Only to be performed if the patient has high pretest probability due to high false positive rates	[Metanephrine] > 0.5 nmol/L [Normetanephrine] >0.9 nmol/L

\* For urinary test, creatinine should be checked to ensure adequate collection.

Adrenalectomy in this population has been associated with normalization of blood pressure, dyslipidemia, glucose metabolism, body mass index, and

improved quality of life.<sup>9</sup> Bilateral adrenalectomy is indicated for severe ACTH-independent and ACTH-dependent Cushing syndrome that cannot be medically controlled.<sup>10,11</sup>

Because adrenocortical carcinomas (ACCs) also frequently secrete cortisol, a careful preoperative evaluation should be performed to look for signs of malignancy, such as radiographic evidence of local invasion, regional lymphadenopathy, distant metastases, and rapid growth. Small tumor size and well-defined borders are features commonly found in benign, cortisol-producing adenomas. Furthermore, adenomas tend to be homogenous, lack necrosis, and have radiodensities lower than 10 Hounsfield units.<sup>4</sup> For newly discovered adrenal masses, the risk of ACC is significantly higher in tumors that are larger than 6 cm. When previous studies are available, comparison should be used to determine tumor growth, since ACCs tend to grow at a much higher rate than benign adenomas.

The obesity resulting from Cushing syndrome can present an additional technical challenge for laparoscopy. Furthermore, tissues tend to be weak such that port sites at the skin typically dilate during the procedure, resulting in gas leakage during the operation. Therefore, it is ideal to make the port site incisions as small as technically possible to avoid gas leakage during peritoneal insufflation.

Postoperatively, adrenal function may be suppressed in the contralateral gland, and patients should be given a prophylactic hydrocortisone taper to avoid potential postoperative adrenal insufficiency, which can be life threatening. The steroid taper can progress according to patient symptoms and can be monitored with serum cortisol and morning ACTH levels as well as an ACTH stimulation test. Clinicians should closely monitor for the signs of Addisonian crisis, which include hemodynamic instability, abdominal discomfort, fatigue, and electrolyte imbalance. Mineralocorticoid replacement with a fludrocortisone taper may also be required. Lastly, patients with mild or subclinical Cushing syndrome may not require a steroid taper. Some groups will check a serum cortisol level the morning after surgery; if levels exceed a threshold (eg, 8 µg/dL), patients can be followed closely for signs and symptoms of Addisonian crisis without a steroid taper.

**Aldosterone Producing—Conn Syndrome.** *Aldosteronomas* are cortical adrenal tumors that autonomously secrete aldosterone. Hyperaldosteronism was first described by Jerome Conn in 1955 and is characterized by

hypertension and hypokalemia.<sup>12</sup> These symptoms should be controlled preoperatively with an aldosterone antagonist and potassium supplements. Biochemical confirmation of autonomous hypersecretion of aldosterone should be confirmed prior to adrenalectomy. Primary preoperative testing includes measurement of the plasma aldosterone and renin concentration where an aldosterone to renin ratio greater than 20 ng/dL or an aldosterone level greater than 15 ng/dL is indicative of disease.<sup>4,13</sup> Confirmatory testing is best achieved by salt loading with normal saline solution and measurement of plasma aldosterone (Table 78-2).<sup>14</sup> Aldosterone antagonists should be held prior to testing for at least a few weeks. While there are several forms of primary hyperaldosteronism, surgery is indicated only in the setting of unilateral adrenal adenoma or hyperplasia. There is a general lack of randomized controlled trials comparing medical and surgical management of aldosteronomas in terms of managing hypertension and albuminuria. Surgery appears to be associated with need for fewer antihypertensives, less cost (due to decreased need for intense follow-up), and overall increased quality of life.<sup>15</sup>

Since benign, nonfunctional adrenal tumors are common relative to the incidence of Conn syndrome, selective venous sampling should be used to confirm laterality of disease in patients who are older than 40 years. Although many surgeons believe that computerized tomography (CT) or magnetic resonance imaging (MRI) is sufficient when unilateral disease is identified in younger patients, it is our practice to perform selective venous sampling for all patients who are considered candidates for adrenalectomy.<sup>16</sup> This is supported by a recent study that found that 50% of patients within a primary hyperaldosteronoma cohort would have been inappropriately managed based on preoperative CT findings alone.<sup>17</sup>

Postoperatively, normalization of aldosterone levels confirms surgical cure and is typically associated with correction of hypokalemia. Infrequently, hyperkalemia can result from chronic suppression of the contralateral adrenal gland. With complete resection of the aldosteronoma, nearly all patients have normal serum potassium levels and hypertension is improved in most. Approximately half of patients can stop all hypertensive medications after adrenalectomy, and the remainder require less medication. Thus, antihypertensive medications should be held for the first day after surgery to determine if the patient has persistent hypertension. When hypertension

persists after curative adrenalectomy, it is usually due to underlying essential hypertension.

## **ADRENOCORTICAL CARCINOMA**

ACC is a rare (1-2 cases per million individuals) and aggressive tumor derived from the adrenal cortex. Women are affected more frequently than men, and left-sided tumors are more common than right. The side predominance may be related to the proximity of right-sided tumors to the IVC, thus precluding surgery and national registration. Early age at diagnosis, a family history of cancer, and parallel primary tumors in a proband should raise suspicion of an inherited cancer syndrome such as Beckwith–Wiedemann, Li–Fraumeni, Carney, multiple endocrine neoplasia 1, or Lynch syndrome.<sup>18,19</sup>

At presentation, most tumors are large, and as many as 60% in adults autonomously hypersecrete cortisol or sex steroids. Preoperative findings consistent with ACC, and thus important for planning, are large size, irregular borders, and extension into surrounding structures. ACC tends to be vascular, greater than 10 Hounsfield units, and associated with necrosis on CT imaging.<sup>4</sup> Sturgeon et al. found that tumors greater than 4 cm in size and those that were greater than 8 cm had a 10% and 47% likelihood of malignancy, respectively.<sup>20</sup> Other methods such as PET-CT, mass spectrometry analysis of urinary steroid profiling, and <sup>123</sup>I imaging have shown utility in the diagnosis of ACC.<sup>18</sup>

The overall 5-year survival is roughly 30%. For tumors less than 5 cm and without lymph node involvement, median survival may be as high as 10 years.<sup>18</sup> Metastatic disease holds a grim prognosis and is predominately dealt with medically. We recommend surgical intervention if (1) complete resection of the primary tumor is feasible in the absence of metastases, (2) when resection or ablation of oligometastases is feasible, or (3) when the patient may benefit from the palliative debulking of a functional tumor.<sup>19</sup>

The cornerstone of systemic medical therapy is mitotane, which specifically targets the adrenal gland. However, mitotane is adrenolytic and it rarely results in a complete response. Other agents such as cisplatin and streptozosin are often used in concert.<sup>19,21</sup> Although there was no effect on overall survival, the FIRM-ACT trial showed that use of etoposide,

doxorubicin, and cisplatin in combination with mitotane, as opposed to streptozosin, was associated with increased progression-free survival and tumor response rate.<sup>21</sup>

Complete surgical resection is the only curative treatment for ACC. Classically, a formal lymph node dissection has not been carried out, but recent data suggest a prognostic benefit to lymph node dissection, a decreased risk of local recurrence, and a decrease in disease-related death when lymph node dissection is performed.<sup>18</sup>

Local invasion typically precludes complete extirpation. Thus, often a large incision is necessary for adequate exposure, complete resection of invaded structures, and vascular control. All structures with evidence of invasion require resection. In a study of 133 patients who underwent open anterior resection of their ACC, 55 had an extended operation consisting of removal of the kidney (27), kidney plus other (19), or other organ (9) at their index operation. Initial recurrence at 28 months occurred most often locally, followed by distant metastasis, nodal disease, and peritoneal carcinomatosis. Median disease-free survival was 13 months, and overall median life expectancy was 43 months.<sup>22</sup>

Patients with borderline resectable disease—as defined by imaging suggestive of resectable metastasis or local invasion requiring multiorgan or vascular resection—may benefit from neoadjuvant chemotherapy followed by complete surgical resection.<sup>23</sup> When counseling patients about their options, it is important to balance the morbidity that is often inherent in complete surgical resection and organ preservation that is potentially afforded by early use of chemotherapy.

Those with high risk of recurrence—as defined by large tumor size, positive margins, and tumor capsule rupture—are candidates for adjuvant chemotherapy and radiation. Postoperative follow-up includes regular imaging and biomarker analysis.

There have been multiple studies aimed at characterization of ACC tumor biology in hopes of defining molecular targets for therapy, disease prediction, and prognostication. Techniques such as next-generation sequencing and RNA interference are changing how we look at tumor biology and the information we can provide our patients. For example, while not yet clinically used, tumor microRNA analysis appears to provide important prognostic and diagnostic value in terms of disease progression, recurrence,

and survival.<sup>24</sup> As we become more sophisticated in our characterization, we stand to improve our clinical fidelity and decision making.

**Miscellaneous.** Simple cystic lesions are usually incidental, and surgery is not indicated unless there is a solid component to the cyst wall. Complex cysts with evidence of local invasion should undergo open resection. Large cysts that cause symptoms or that carry a high risk of spontaneous rupture can be excised by laparoscopic nodulectomy or subjected to fenestration of the cyst wall into the peritoneal cavity.

Myelolipomas are also typically discovered in an incidental manner. Their appearance can cause confusion with liposarcoma, a situation easily resolved with needle biopsy showing typical bone marrow elements. Patients with these benign adrenal lesions are often referred to surgery because of compressive symptoms

## **Diseases of the Medulla**

### **PHEOCHROMOCYTOMA**

*Pheochromocytomas* are rare neuroendocrine tumors that are derived from chromaffin cells and usually arise from the adrenal medulla. Although most pheochromocytomas are sporadic and unilateral, genetic syndromes such as multiple endocrine neoplasia 2a/2b and von Hippel–Lindau increase the risk of bilateral disease. They can produce catecholamines such as epinephrine, norepinephrine, and dopamine that can cause the classic clinical symptomatology of this disease: episodic headaches, palpitations, and diaphoresis. Rarely, pheochromocytomas are nonfunctional.

The Endocrine Society recently published practice guidelines for the evaluation and management of pheochromocytoma/paraganglioma.<sup>25</sup> The biochemical diagnosis can be made with either fractionated urine catecholamines (24-hour collection) or serum metanephrines (Table 78-2).<sup>26</sup> Due to the high level of false positive results, plasma metanephrine testing should be completed in patients with a high pretest probability.<sup>27</sup> Furthermore, at least a fourfold elevation of these biochemical tests should be expected from symptomatic pheochromocytoma. Surgeons should be aware that many medications could influence these biochemical tests, which include, but are not limited to, acetaminophen,  $\beta$ -blockers, vasodilators,  $\alpha$ -

blockers, stimulants, antipsychotics, antidepressants, and calcium channel blockers. Equivocal results should prompt repeat testing after holding these medications. Marginal elevations in biochemical tests are unlikely to be driven by pheochromocytoma. Clinical context is important for diagnosis, since pheochromocytoma can be excluded with confidence when testing results are normal in a hypertensive and symptomatic patient.<sup>25</sup> Borderline serum metanephrine elevations less than fourfold warrant repeat testing after 30 minutes of supine rest.

CT imaging is similar to that for ACC—tumors tend to be large, heterogeneous, solitary, hypervascular, and greater than 10 Hounsfield units.<sup>4</sup> Pheochromocytomas typically have a characteristic intensity on T2-weighted MRI. This is an ideal imaging modality for patients with surgical clips that cause artifacts on CT, in patients with an allergy to iodinated contrast agents, and in patients who cannot receive ionizing radiation. Meta-iodobenzylguanidine (MIBG) enables scintigraphic functional imaging of the whole body, which is useful when familial, extradrenal, or metastatic disease is suspected. Rarely, MIBG can be useful in the final diagnosis of equivocal cases. MIBG scanning is not as sensitive as FDG-PET CT for finding extra-adrenal tumors and metastatic disease. In patients with metastatic pheochromocytoma, I123-MIBG scanning can also be useful to determine whether future high-dose I131-MIBG can be a treatment option.<sup>28</sup>

Preoperative preparation with  $\alpha$ -blockade (eg, phenoxybenzamine, doxazosin) and salt loading should be undertaken. Ideally, this can be done in the outpatient setting. The  $\alpha$ -blocker is titrated up to the maximal tolerated dose, which is typically limited by orthostatic hypotension. Salt loading, either by ingestion of salty foods or by saline infusion, can help to reduce orthostasis and enable higher doses of  $\alpha$ -blocker. In addition,  $\beta$ -blockade can be added to the regimen if the patient has persistent tachyarrhythmias. Although the optimal preparation time before pheochromocytoma resection is controversial, we generally  $\alpha$ -block and salt-load patients for 1 to 2 weeks before elective adrenalectomy and operate only after orthostatic hypotension is achieved.

Delicate tissue handling and avoidance of tumor compression should be emphasized to minimize catecholamine release. Because tumor manipulation and adrenal vein clipping can result in significant hemodynamic changes, coordination and communication between the adrenal surgeon and anesthesiologist are critical to the success of this operation. It has been

generally proposed that in the resection of pheochromocytomas ligation of the adrenal vein should precede the rest of the dissection to limit hemodynamic instability. However, delayed ligation of the vein has been shown to result in a similar rate of intraoperative hypertension and concentration of plasma catecholamines when compared with early ligation.<sup>29,30</sup> Further, some authors caution that adrenal vein ligation increases intratumor venous pressure, which can increase bleeding.<sup>29</sup> In our practice we have found that grasping the tumor side of the divided adrenal vein to be quite helpful. Regardless of the decision on timing of ligation, communication between the surgical and anesthesia teams is imperative because hypotension often accompanies vein ligation.

## **Paraganglioma**

Paragangliomas are neuroendocrine tumors histologically similar to pheochromocytomas but that occur in extra-adrenal sites throughout the pelvis, abdomen, chest, neck, and head. Most of these tumors are sporadic, although some are associated with hereditary paraganglioma syndromes. They typically present as a painless mass or with the symptomatology of a pheochromocytoma resulting from catecholamine production. There are several case reports of successful laparoscopic resection of these tumors, but the decision to pursue laparoscopy again is determined by location and size of the paraganglioma.<sup>31-33</sup>

## **Peripheral Nerve Sheath tumors**

Schwannomas are rare and benign lesions that originate from the Schwann cells of peripheral nerve sheaths. They are occasionally encountered in the periadrenal or perirenal area and can mimic ACC or renal cell carcinoma in both preoperative imaging and in presentation due to compression of nearby structures.<sup>34-39</sup> Retroperitoneal schwannomas represent roughly 0.3% to 3% of all schwannomas and 4% of all retroperitoneal tumors.<sup>37,39,40</sup>

While many schwannomas are diagnosed only after resection in patients experiencing compressive symptoms or for concern of other primary malignancy, there are characteristic findings that may allow preoperative diagnosis. They tend to be well-circumscribed, do not invade surrounding

structures, they have central cystic degeneration with peripheral enhancement, are isointense on T1- and T2-weighted MRI, and are hyperintense compared to skeletal muscle. Core needle biopsy can reliably establish the diagnosis. On gross examination, they tend to be firm, fibrous, and white. They should be resected if they cause compressive symptoms. A small number of these tumors undergo malignant transformation and thus all preoperatively diagnosed schwannomas should have close surveillance.<sup>40</sup>

## **Metastasis**

Resection of adrenal metastases is controversial, and the role for surgical treatment is changing now that safe minimally invasive resection can be achieved with minimal morbidity. Although no prospective trials have proven that adrenal metastasectomy improves survival, many groups have reported safe laparoscopic resection of various secondary tumors, such as lung, renal cell, colorectal, gastric, ovarian, breast, and melanoma primaries.<sup>41-45</sup> Generally speaking, patient selection for metastasectomy should favor the following: (1) oligometastases, (2) metachronous lesions, (3) tumor response to systemic chemotherapy, and (4) good patient performance status.

## **CHOOSING THE OPTIMAL PROCEDURE**

### **Laparoscopic versus Open Adrenalectomy**

Since the first laparoscopic adrenalectomy in 1992,<sup>46</sup> multiple case series have compared endoscopic to open surgery. Most analyses show that laparoscopic adrenalectomy is associated with decreased length of hospital stay, decreased postoperative pain, and overall decreased morbidity.<sup>47-52</sup> In analyzing 669 adrenalectomies (358 laparoscopic and 311 open), Lee et al. showed that open surgery was associated with longer operative time (3.9 vs. 2.9 hours), higher transfusion rate, more reoperations (4.8 vs. 1.4%), longer length of stay (9.4 vs. 4.1 days), and higher 30-day morbidity rate (17 vs. 3.6%) even after adjusting for confounding factors.<sup>53</sup> Thus, for the treatment of small, benign disease, or functional tumors, laparoscopy is the method of choice. Many groups have reported that tumors greater than approximately 10

to 12 cm should be resected with open surgery.<sup>47,54-56</sup>

A randomized controlled trial of laparoscopic versus open adrenalectomy for pheochromocytoma found no significant differences in hemodynamic instability between the two groups, but operative time and blood loss were favored in the laparoscopic group.<sup>51</sup> Thus, endoscopic adrenalectomy is the favored procedure when there is no evidence of malignant disease.<sup>56</sup> However, conversion to an open procedure should be considered whenever there is difficulty achieving gross tumor clearance or capsular disruption seems imminent during endoscopic dissection.

An early observational study by Gonzalez et al. aimed at identifying the efficacy of laparoscopic surgery for the management of ACC showed that in laparoscopy the peritoneal recurrence was 83% ( $n = 6$ ) compared to 8% ( $n = 133$ ) in open transabdominal adrenalectomy. All tumors in this study were less than or equal to 8 cm and nonadherent to adjacent structures. Of note, all the laparoscopic procedures were performed at a separate institution prior to referral to the index center.<sup>22</sup> As a result of this study, open surgery became the standard when ACC is strongly considered (transverse diameter >4-6 cm and heterogeneity).<sup>22,57</sup> Recently, this paradigm has been challenged—especially at high-volume centers—with the success laparoscopic resection of malignant adrenal disease.<sup>18,58,59</sup> Donatini et al. showed that there was a decrease in postoperative morbidity but no difference in overall survival in patients who underwent laparoscopic section for stage I or II ACC with tumor size less than 10 cm as compared to open adrenalectomy.<sup>60</sup>

At our institution, we do not attempt minimally invasive adrenalectomy when local invasion is determined on preoperative imaging. Intraoperative difficulty with establishing tissue planes between the adrenal gland and neighboring structures, due to tumor extension, portends malignancy and should prompt immediate conversion to open adrenalectomy.

In contrast to patients who require attempted curative resection of primary ACC, it is reasonable to consider endoscopic palliative adrenalectomy of primary tumors and metastases. Strong et al. report equivalence between laparoscopy and open surgery in terms of local recurrence, disease-free interval, and overall survival.<sup>61</sup> Furthermore, there is a role for palliative laparoscopic resection for patients with symptomatic secondary tumors. Attempts at laparoscopic metastasectomy should be avoided in any patient with radiographic evidence of local invasion, as complete resection without

capsular disruption is unlikely.

## Retroperitoneoscopic

The posterior retroperitoneoscopic (RP) approach has quickly gained traction as an alternative, minimally invasive method to adrenal surgery that offers a more direct route to the retroperitoneal glands. This approach is usually performed in nonobese patients who have smaller lesions. Further, it is favored for bilateral lesions, as repositioning is not necessary.<sup>62</sup> The posterior approach is particularly useful for patients with adrenal disease who have undergone prior abdominal surgery, since these patients might have dense adhesions that make an intra-abdominal exposure formidable.

A few anthropometric parameters have been correlated with successful RP surgery: (1) less than 5 cm distance from Gerota's fascia to the skin, (2) the 12th rib at or rostral to the renal hilum.<sup>63</sup> Further, many surgeons will not perform RP surgery in obese patients given the difficulty with positioning and ventilation. However, this has been recently challenged.<sup>64,65</sup> Epelboym and colleagues showed a decreased length of stay in patients with BMI >30 who were offered a posterior laparoscopic as compared to a transperitoneal approach.<sup>64</sup>

Walz et al. retrospectively analyzed 560 consecutive RP adrenalectomies performed from 1994 to 2006 for tumors ranging from 0.5 to 10 cm. They showed that this approach was safe (1.3% major complication, 14.4% minor complication, and 0% mortality rate) when performed by an experienced surgeon.<sup>66</sup> Furthermore, when compared with transperitoneal laparoscopic adrenalectomy, the RP approach has been shown to take less time, result in less—albeit not likely clinically significant—blood loss, and is associated with fewer conversions to an open procedure.<sup>64</sup>

## Partial Adrenalectomy

Partial adrenal resection has the perceived benefit is sparing of the necessity of steroid replacement. Multiple small studies have found this approach a reasonable alternative procedure for benign, well circumscribed, and peripherally located tumors.<sup>47,67</sup> In a small, randomized clinical trial of RP total versus partial adrenalectomy for aldosterone-secreting adenomas, Fu et

al. showed essentially noninferiority of partial adrenalectomy in terms of postop complications and functional outcome. There was a statistically significant but clinically irrelevant increase in operative blood loss in the partial adrenalectomy group.<sup>68</sup>

While some studies have shown benefit, Quillo et al. showed that in nearly 21% of patients undergoing total unilateral adrenalectomy for hyperaldosteronism, there was additional hyperfunctional tissue. Further, they were unable to identify any preoperative predictors of having non-solitary versus solitary adenomas.<sup>69</sup> Thus, given the significant risk of missing an additional functional adenoma during partial adrenalectomy, most surgeons opt for a total adrenalectomy.

From a technical perspective, partial adrenalectomy is carried out in a similar way to total adrenalectomy as far as positioning and steps of dissection. While in general, preservation of the adrenal vein is recommended, division has been shown not to be detrimental to the function of the gland.<sup>47</sup>

## EXPOSURES AND OPERATIVE TECHNIQUE

### General Considerations

First, any bleeding substantially impairs visualization. Dissection should be gentle and every act of tissue division accompanied by a hemostatic maneuver. Second, obscuring blood is difficult to evacuate, and thus it tends to accumulate and obscure the bed of dissection. Third, removal of blood by suction tends to collapse the operative field and lead to tedious adjustment of retraction. For these reasons, we recommend small neurosurgical patties or rolled Kitner sponges to remove blood and to control minor bleeding. The use of instruments with hemostatic capability, such as ultrasonic shears or bipolar vessel sealing devices, can shorten operative times and make the use of clips or ligatures unnecessary. Fourth, patients with wide hips impair manipulation of instruments through the most lateral port. Port sites should be placed at least 7 cm apart to avoid limitations from instrument crowding. Finally, retraction of the adrenal can cause rupture and bleeding. When possible, retract the gland by touching the periadrenal fat rather than applying force to the capsule of the gland. The specimen side of the adrenal vein after ligation

can also be used as a handle for retraction. Otherwise, a rolled Kitner sponge held with a grasper can provide gentle and effective traction.

For retraction we recommend using a fan retractor. This is an adjustable broad-based, atraumatic instrument that provides excellent retraction on larger organs like the liver and smaller areas like the periadrenal fat. When combined with hook cautery or LigaSure<sup>TM</sup>, the surgeon has the ability to be expedient around the lateral liver edge and precise around the IVC.

## Positioning

As in all operations, patient positioning and exposure are critical to the success of adrenalectomy. The details of the positioning depend upon the approach selected.

Figure 78-1 depicts the positioning for the laparoscopic transperitoneal approach. Patients are placed in the lateral decubitus position, which favors retraction of the abdominal viscera by gravity and facilitates exposure of the adrenal gland. We use a pneumatic beanbag to help secure patients in the proper position. In obese patients, it may be useful to position the anterior border of the patient's body near the edge of the bed and allow the abdominal pannus to hang over the edge. Of note, the hips should be relatively open as compared to the shoulders.

**FIGURE 78-1** Optimal positioning of patient for a left laparoscopic adrenalectomy in the lateral decubitus position. The midabdomen is placed over the break in the table to optimize trunk extension and reduce interference with instrument movement by the iliac crest. The anterior abdominal wall should not be compressed.

To facilitate exposure, the surgical table should be flexed and a kidney bar elevated with the apex located slightly higher than the midpoint between the costal margin and the iliac crest. Care should be taken during flexion in the elderly and in patients with spine disease. The patient should be secured to the table with wide tape, an axillary roll placed, and all pressure points should

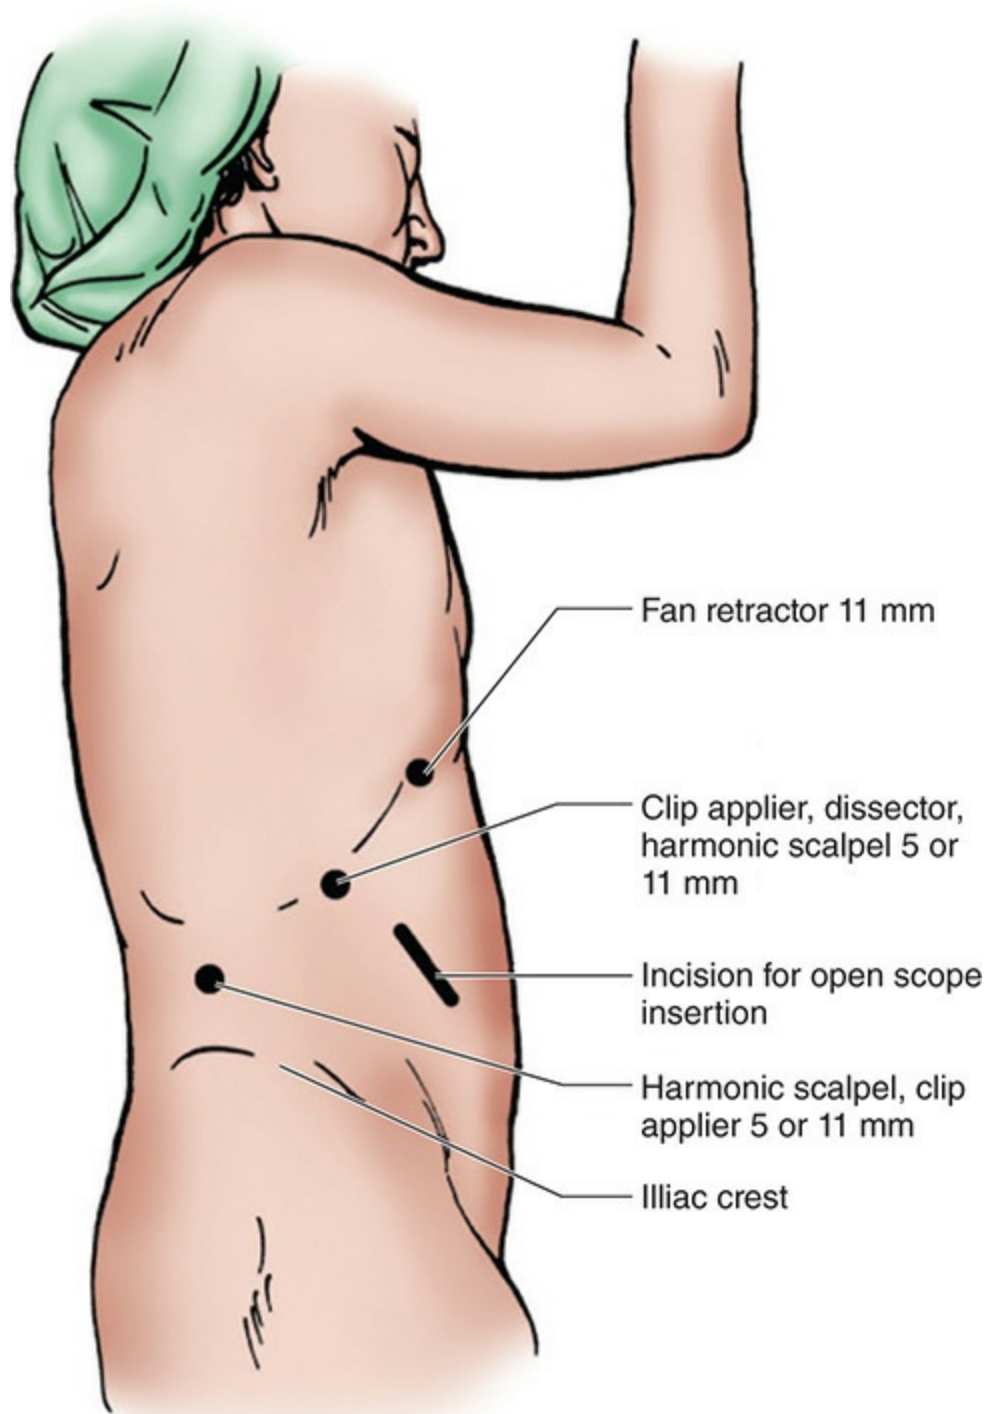

be adequately protected, including the peroneal nerves.

When preparing for RP adrenalectomy, the endotracheal tube and intravenous, arterial, and Foley catheters are placed with the patient in the supine position. The patient is then flipped into the prone position, with the hips and knees flexed. This positioning requires the use of bolsters across the chest and hips, as well as sufficient padding for the face, arms, and knees. The abdomen should hang down between the two transversely positioned bolsters.

## Laparoscopic Adrenalectomy

### RIGHT LAPAROSCOPIC ADRENALECTOMY

**Step 1: Port Positioning.** The patient is placed in the left lateral decubitus position, and the surgeon marks four port sites along the right costal margin from the xiphoid to the midaxillary line. Either a Veress needle entry or a muscle-splitting open entry can be used to gain access to the peritoneal cavity. After insufflation of the peritoneal cavity and placement of additional ports under direct vision, the fan retractor is placed in the most medial port and the camera is placed in the second most medial port ([Fig. 78-2](#)).

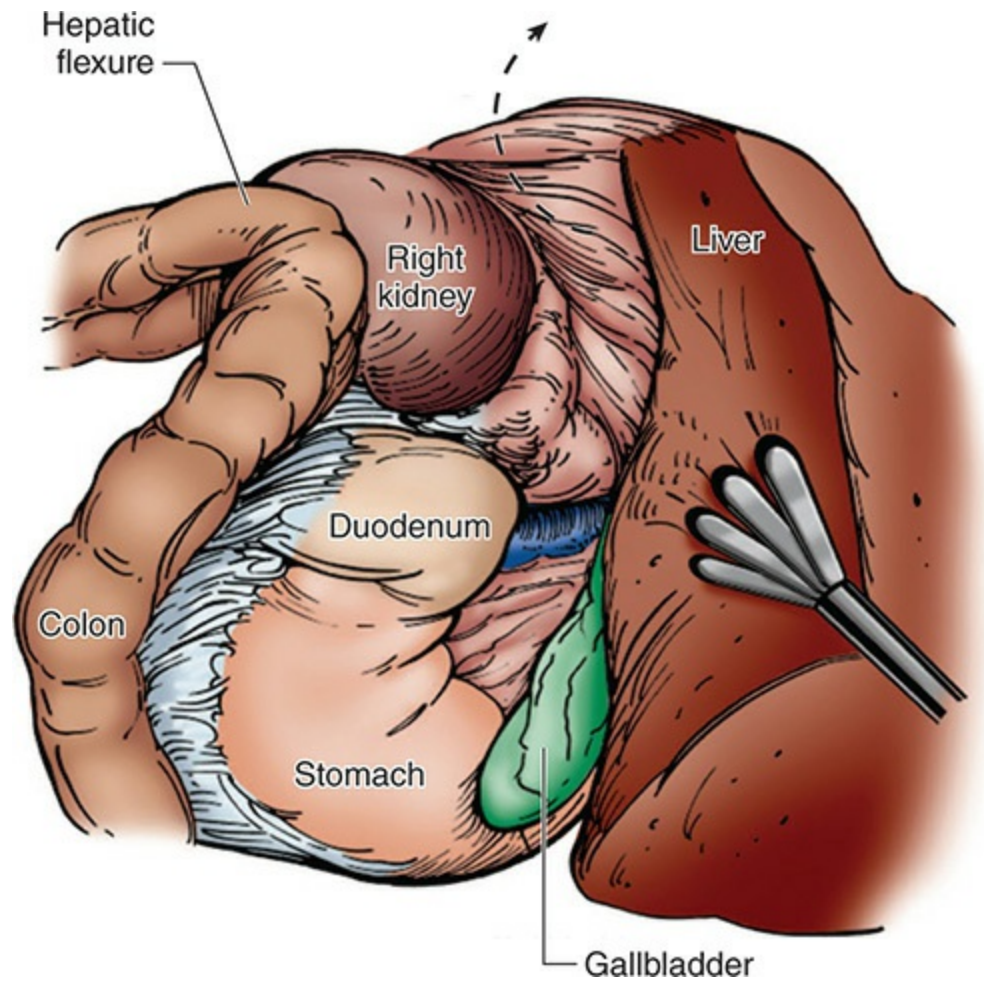

**FIGURE 78-2** Port placement for a right laparoscopic adrenalectomy. In this example, abdominal entry is gained under direct visualization through the most medial site.

**Step 2: Expose the Retroperitoneum.** The hepatic flexure of the colon is

freed from its attachments and allowed to retract inferomedially by gravity (Fig. 78-3). The fan retractor initially retracts the right lobe of the liver in the medial direction, and the right triangular ligament is taken down with a hook electrocautery (Fig. 78-4). This mobilization enables superior and anterior retraction of the right lobe of the liver, which uncovers the retroperitoneum near the adrenal gland (Fig. 78-5). In most cases, the kidney, periadrenal fat, and IVC are visible after this maneuver (Fig. 78-6).

**FIGURE 78-3** Initial view of right upper quadrant in a right laparoscopic adrenalectomy. The *arrow* indicates the direction of liver retraction from the epigastric port.

**FIGURE 78-4** View during right laparoscopic adrenalectomy with the liver retracted from the epigastric port. Some attachments of the right lobe of the liver to the diaphragm have been divided. The *dotted line* indicates the line of further peritoneal incision to mobilize the right lobe of the liver from the diaphragm.

**FIGURE 78-5** View during right laparoscopic adrenalectomy after initial dissection to mobilize the right adrenal. The *dotted line* shows the peritoneal incision under the retracted liver that exposes the adrenal.

**FIGURE 78-6** Dissection to expose the adrenal gland during right laparoscopic adrenalectomy.

**Step 3: Approach the Adrenal Gland.** We begin the dissection in the superolateral border of the periadrenal fat with a hook electrocautery. This exposes the diaphragm posteriorly, and the dissection is carried out in the medial direction along the superior border of the periadrenal fat. A few small arteries are typically located in this area, which can be controlled with electrocautery or a hemostatic device. Careful dissection with blunt graspers should be used while approaching the IVC, near the superomedial border of the periadrenal fat.

**Step 4: Divide the Adrenal Vein.** After establishing the superomedial corner of the periadrenal fat, the dissection is carried down in the caudal direction between the IVC and periadrenal fat. The tissue plane between the IVC and the adrenal vein is extremely thin, and thus blind use of hook cautery should be avoided. We prefer to use a combination of gentle, blunt dissection and the LigaSure device. The adrenal vein typically resides near the top third of this medial border and approaches the IVC at approximately a right angle. After

clip or stapler ligation of the adrenal vein, this medial plane of dissection opens significantly (Fig. 78-7). Notably, some surgeons routinely divide the adrenal vein with the LigaSure device without the use of a clips or staples.

**FIGURE 78-7** Dissection to expose the adrenal vein during right laparoscopic adrenalectomy. The length of the right adrenal vein is exaggerated in this schematic.

**Step 5: Dissect the Adrenal Gland from the Retroperitoneum.** At this point, the specimen side of the adrenal vein can be grasped for retraction. The inferomedial border of the dissection also requires careful blunt dissection, with special attention to avoid injuring the renal hilar vessels. The dissection is then carried laterally along the superior surface of the kidney. Special care must be taken to avoid accidental ligation of any arterial branches to the superior pole of the kidney. Once the plane of dissection is established between the inferior border of the periadrenal fat and the kidney, the only remaining attachments are posterior and lateral to the adrenal gland. A blunt grasper can be used to elevate the adrenal gland in the anterior direction, with special care taken to avoid disruption of the adrenal capsule. The remaining

posterior and lateral attachments can be divided with a LigaSure or Harmonic scalpel device. The dissection should clear all fibro-fatty and lymphatic tissue from the diaphragmatic surface.

**Step 6: Removal of the Adrenal Gland.** Once all attachments are divided, the gland is placed into an endoscopic bag for removal. If appropriate, the mouth of the bag can be exteriorized and the specimen can be morcellated and removed through a port incision. This maneuver should always be performed under laparoscopic vision, as opposed to blind morcellation. Alternatively, the specimen can be removed intact and en bloc, which typically requires dilation of the fascia and skin.

## **LEFT LAPAROSCOPIC ADRENALECTOMY**

**Step 1: Port Placement.** The patient is placed in the right lateral decubitus position and the surgeon marks three or four port sites along the costal margin from the xiphoid to the posterior axillary line. Sometimes the fourth port is not needed, as the spleen retracts medially with gravity ([Fig. 78-8](#)).

**FIGURE 78-8** Port placement for left laparoscopic adrenalectomy in the right lateral decubitus position. In this example, initial abdominal entry is gained through a medial incision. A fourth port is often not required on the left.

**Step 2: Expose the Retroperitoneum.** The splenic flexure of the colon is taken down (Fig. 78-9). The left liver and spleen are mobilized from the diaphragm using hook electrocautery. With medial mobilization of the spleen, the retroperitoneum is exposed. The left kidney, periadrenal fat, and tail of the pancreas are often visualized at this point.

**FIGURE 78-9** View during left laparoscopic adrenalectomy, showing division of the peritoneum over the kidney and progressive detachment of the spleen from the left diaphragm.

**Step 3: Approach the Adrenal Gland.** The dissection begins in the superolateral corner and proceeds in the medial direction between the spleen and the superior border of the adrenal gland. The splenic vessels are often in close proximity to this plane of dissection. Once the superomedial corner is reached, the tail of the pancreas and the inferior phrenic vein can often be seen. Note that the pancreas tail can appear similar to the adrenal gland ([Fig.](#)

78-10).

**FIGURE 78-10** View during left laparoscopic adrenalectomy. The spleen had been partially mobilized and is retracting to the right by gravity. The separation between the posterior pancreas and the anterior surface of the left adrenal had been developed. The left renal vein is exposed, as well as the takeoff of the left adrenal vein.

**Step 4: Divide the Adrenal Vein.** The dissection continues in the inferior direction along the medial border. The inferior phrenic vein can be used as an anatomic landmark and can be divided if necessary. The left adrenal vein is often located in the inferomedial portion of the dissection and often joins the inferior phrenic vein prior to joining with the renal vein (Fig. 78-11).

**FIGURE 78-11** View during left laparoscopic adrenalectomy. The spleen is fully mobilized. The adrenal vein has been divided between endoclips. The *dotted line* indicates the line of resection.

**Step 5: Dissect the Adrenal Gland from the Retroperitoneum.** After adrenal vein ligation, the dissection continues along the inferior border between the adrenal gland and the kidney. In a similar fashion to the right adrenalectomy, the remaining posterior and lateral attachments are divided flush to the surface of the kidney and diaphragm, and the adrenal tumor is removed in bloc with the surrounding periadrenal fat. Again, the specimen side of the divided adrenal vein can be grasped as a handle for retraction.

## RETROPERITONEOSCOPIC

**Step 1: Port Placement.** A small transverse incision is made just caudal to the tip of the 12th rib, and sharp dissection is used to dissect through the subcutaneous tissues and deep fascia. The length of this incision should be around 1.5 cm, which should be enough to accommodate the surgeon's index finger. Digital examination with the index finger can be used to confirm that the dissection is through the deep fascia, and it allows palpation of the smooth underside of the ribs. Some authors recommend placement of the trocars 1 to 2 cm caudal to the 12th rib to prevent neuralgia.<sup>63</sup> A second lateral 5-mm port is placed at near the midaxillary line at the same craniocaudal level under direct palpation, using the index finger as a guide through the first incision. Then a third 5-mm port is placed similarly under digital palpation, just lateral to the paraspinous muscles at the same craniocaudal level. This medial port should be approximately 3 or 4 cm caudal to the lowest rib. Then a 12-mm balloon port is placed in the middle incision to ensure an airtight seal. The space is insufflated to a pressure of 20 to 30 mm Hg. A 30-degree 10-mm scope is placed in the middle trocar with the angled view facing the ceiling.

**Step 2: Expose the Peritoneal Lining.** A blunt grasper is used through the lateral port to dissect through the Gerota fascia. Using blunt dissection, the tissues around the medial and lateral ports are cleared and space is created posterior to the kidney and adrenal gland. Usually, the paraspinous muscles can be seen medially. With some blunt dissection, the peritoneal lining can be visualized laterally. Inferiorly, at the floor of the dissection (anterior), careful blunt dissection can be used to visualize the kidney.

**Step 3: Approach the Adrenal Gland.** Dissection is carried along the superior border of the kidney from lateral to medial to separate the top of the kidney from periadrenal fat and to mobilize the kidney off the peritoneum such that it autoretracts inferiorly, which is necessary to expose the inferomedial portion of the adrenal gland. Usually during this portion of the dissection, the adrenal gland itself becomes evident through the periadrenal fat. On the right side, the IVC is found anterior and medial to the inferomedial border of the periadrenal fat.

**Step 4: Divide the Adrenal Vein.** The adrenal vein is usually anterior and thus can be difficult to visualize. In contrast to the laparoscopic approach, the

adrenal vein is seen relatively late in the dissection when performing an RP adrenalectomy. Division of the adrenal vein can be done with a LigaSure device with or without clips. The specimen side of the adrenal vein can be used to retract the adrenal gland in the cephalad and posterior directions.

**Step 5: Dissect the Adrenal Gland from the Retroperitoneum.** The remaining attachments between the periadrenal fat anteriorly and superiorly can be divided with a LigaSure device or electrocautery.

**Step 6: Removal of the Adrenal Gland.** Removal of the specimen can usually be achieved without morcellation or extension of the incision. Closure of the deep fascia in the middle incision usually requires only a single simple nonabsorbable suture. Hernia through these posterior incisions is uncommon.

As with laparoscopic adrenalectomy, the small adrenal arteries can be controlled with either hook electrocautery or a hemostatic device; clips are usually not required. Small holes in the peritoneum are of no significant consequence and do not require repair.

## Open Adrenalectomy

### ANTERIOR

The anterior approach allows access to both adrenal glands as well as extra-adrenal foci as in the case of pheochromocytoma. The patient is placed in the supine position on the operating table, and either a midline laparotomy or bilateral subcostal incision can be used. We find that the subcostal incision is adequate but the exposure is not as open as in the thoracoabdominal approach (below).

For right-side access, the hepatic flexure of the colon is taken down inferiorly, the liver is retracted superiorly, and a Kocher maneuver is performed to expose the retroperitoneal space. The Gerota fascia is identified and incised. Once the adrenal gland is exposed, the lateral and superior aspects of the gland are mobilized and the adrenal vein is ligated and divided. Given the proximity of the right adrenal gland to the IVC, the surgeon must use care when dissecting and ligating the right adrenal vein.

The left adrenal gland can be exposed from an anterior approach by a

medial visceral rotation of the stomach, spleen, splenic flexure of the colon, and pancreas toward the midline. The left adrenal vein can drain either into the left renal vein or the left inferior phrenic vein. The remainder of the dissection is similar to the right side.

## **Thoracoabdominal Approach**

For open adrenalectomy, we prefer the thoracoabdominal approach due to the superior exposure that it allows, the close proximity of the incision to the lesion, and the improved ability to remove large tumors. Much like in the laparoscopic approach, the patient is placed in the lateral decubitus position with the hips open and the shoulders closed. The shoulders should be roughly 90 degrees to the table.

The dissection is carried down between the eighth and ninth ribs, allowing the full exposure of the adrenal gland, renal fossa, and surrounding tissues. A vascular load GIA stapler is used to divide the diaphragm close to the lateral attachments, which facilitates closure at the end of the case. The remainder of the dissection is carried out as mentioned previously. A tube thoracostomy should be placed or the pneumothorax can be evacuated during closure.

## **RETROPERITONEAL**

In this operation, the patient is placed in the prone position on the operating table, and a curvilinear incision is made starting in the paramedian line and extending laterally. After the skin and subcutaneous tissues are incised, the latissimus dorsi muscle is divided with electrocautery near its origin and the serratus posterior is divided in a similar way. The 12th rib is removed to facilitate the exposure, and the 11th rib and the pleura are retracted superiorly, which exposes the underlying the Gerota fascia. The fascia is incised, and the adrenal gland and the kidney are exposed. The superior vessels are ligated and divided, and the superior aspect of the gland is dissected free. After the gland is mobilized, the adrenal vein is isolated, ligated, and divided. When the gland has been removed, closure is performed in layers.

## **COMPLICATIONS**

The intraoperative risks of adrenal surgery are due largely the close proximity to large vascular structures and other retroperitoneal organs. Consequently, minimally invasive adrenalectomy poses the same anatomic risks as open adrenalectomy: major vascular injury (IVC, splenic vessels, renal vessels) and injury to the spleen, liver, and colon. Although rare, transection of the porta hepatis, hepatic artery, ureter, and renal artery has been reported.<sup>70</sup>

Pneumoperitoneum poses several risks for this operation aside from traumatic injury relating to port placement. The dissection of the adrenal gland is in close proximity to the posterior aspect of the diaphragm, making ipsilateral pneumothorax a potential complication necessitating a tube thoracostomy in some. Further, pneumoperitoneum can impair venous return, which can be particularly dangerous in the setting of catecholamine surges during resection of pheochromocytoma. This risk can be minimized with pre- and intraoperative hydration. The spleen and liver are also at risk for injury during laparoscopic adrenalectomy; these organs can sustain trocar injuries, capsular tears from grasping or retraction, or vascular injury.

The most life-threatening complication of adrenalectomy is a vascular injury. On the right, the renal vein can have an oblique course and course through the inferior portion of the dissection, causing confusion with the adrenal vein. The right adrenal vein is often well visualized with laparoscopic technique but is also of variable location in a superior-inferior plane and anterior-posterior plane. A vein with a diameter significantly smaller than the length of a standard endoscopic clip should be viewed with skepticism if thought to be the adrenal vein. A vein with a diameter significantly larger than an endoclip or that does not clearly connect to the variegated dark yellow adrenal gland is a suspect for the renal vein and should not be divided without certain identification. On the left, there can be a segmental upper pole renal artery that lies just deep to the lower portion of the adrenal. The adrenal arteries are all quite narrow and can be ligated with the electrocautery or vessel-sealing device without the use of clips. Regarding RP adrenalectomy, higher insufflation pressures are tolerated well with less hemodynamic compromise, in comparison to the laparoscopic technique. Releasing insufflation and hyperventilating the patient can relieve intraoperative hypercarbia. Subcutaneous emphysema and subcostal nerve dysfunction can be observed after RP adrenalectomy, and both are transient in nature.

Hypoglycemia is a well-recognized complication in adrenalectomies performed for pheochromocytoma. In our experience, roughly 4% of patients

develop blood glucose levels less than 50 mg/dL, thought to be due to rebound hyperinsulinemia. This most often occurs in the first 24 hours and is associated with higher 24-hour urinary metanephrine levels, longer operative times, and larger neoplasms.<sup>71</sup>

In an effort to identify correctable causes of post-adrenalectomy complications, Hauch et al. performed a cross-sectional analysis of 7829 adrenalectomies included in the Nationwide Inpatient Sample from 2003 to 2009. They found that surgeons performing less than five adrenalectomies per year were more likely to have pulmonary, cardiovascular, bleeding, and technical complications than their counterparts performing greater than five adrenalectomies per year. Similarly, there were more complications seen in bilateral operations and those for malignancy.<sup>72</sup>
