Radiofrequency application involves a catheter that is passed orally into the distal esophagus. The balloon is expanded and electrodes pierce into the esophageal submucosa. Radiofrequency energy is delivered. The subsequent tissue reaction results in contraction of the distal esophagus, “augmenting” the LES (Fig. 23-21). This approach has resulted in improvements in symptoms and objective measures of GERD, but the mechanism by which it works is poorly understood. While results across trials have been conflicting, a meta-analysis of trials comparing radiofrequency ablation (Stretta<sup>R</sup> system, Mederi Therapeutics, Inc., Norwalk, CT) with sham therapy and PPI for patients with GERD was found not to produce significant changes in physiologic and other parameters, including time spent at a pH less than 4, lower esophageal sphincter pressure, ability to stop PPIs, or health-related QoL.<sup>100</sup>

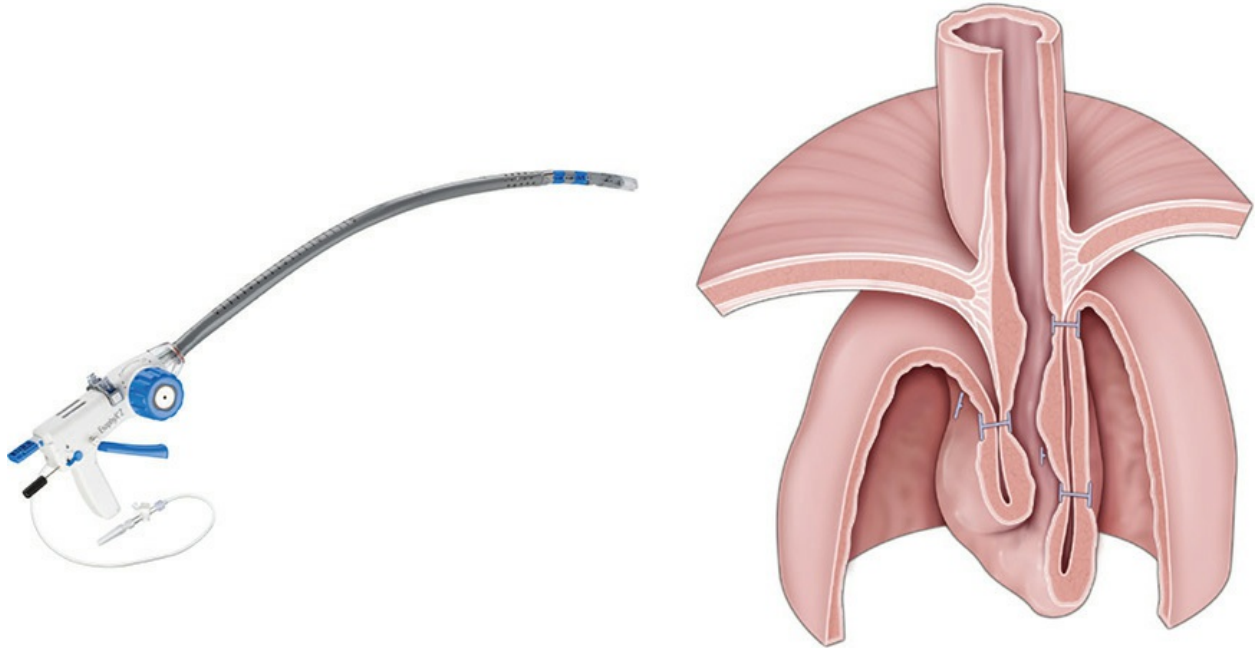

**FIGURE 23-21** Endolumenal radiofrequency energy application for gastroesophageal reflux disease. (Reproduced with permission from © 2018 Restech | Mederi-RF, LLC, Houston, TX.)

Few studies have investigated the long-term safety of this procedure, but those that have report a low mortality rate (<0.1%) and low overall morbidity (0.2%-8.6%), with superficial mucosal injury (2.5%-8.3%), transient post-procedure chest pain (1.7%-58%), and transient dysphagia (0.8%-8.3%) being most common. Esophageal stricture, while seemingly possible, has not been reported in large follow-up studies.<sup>101-103</sup> Although the device is still commercially available, its routine use remains controversial.

## **TRANSORAL INCISIONLESS FUNDOPLICATION**

Transoral incisionless fundoplication (TIF) was first described in 2008,<sup>103a</sup> and the EsophyX<sup>®</sup> device (EndoGastricSolutions, Inc., Redmond, WA) was FDA-cleared in 2007 (CE marked 2006). The TIF technique creates a “neo-gastroesophageal valve” (Fig. 23-22). The procedure was designed to create serosa-to-serosa plications, including the muscle layers, to construct valves 270-300 degrees in circumference and 3 cm long by deploying multiple nonabsorbable polypropylene fasteners through the esophageal and gastric layers in a circumferential pattern around the GEJ.<sup>104-106</sup> A randomized trial of TIF versus omeprazole reported TIF was an effective treatment for patients with GERD symptoms, particularly in those with persistent regurgitation despite PPI therapy,<sup>106a</sup> based on evaluation 6 months after the procedure.<sup>107</sup>

## Principles of Postoperative Care and Adverse Outcomes

Although there is some variation in practice with respect to postoperative care of patients having undergone antireflux surgery, certain principles need to be followed. Increased intra-abdominal pressure associated with nausea and vomiting should be aggressively avoided in the early postoperative period to prevent mechanical disruption of the fundoplication. Some surgeons routinely place a nasogastric tube at the end of the operation and use antiemetics liberally. Although some will perform an esophagogram with water-soluble contrast postoperatively to assess for fundoplication position and to rule out occult perforation, this is not mandatory. If an initial trial of liquid intake is undertaken without dysphagia, patients may be started on a soft diet as early as postoperative day 1. Typical postoperative hospital stay is 1 to 4 days, but patients are generally maintained on a soft diet for 2 to 6 weeks before being transitioned to a regular diet as tolerated. Some degree of postoperative dysphagia is common in the early period due to edema within the wrap, and patients should be reassured that in most cases dysphagia will resolve within 3 months. In up to 10% of cases, however, dysphagia persists

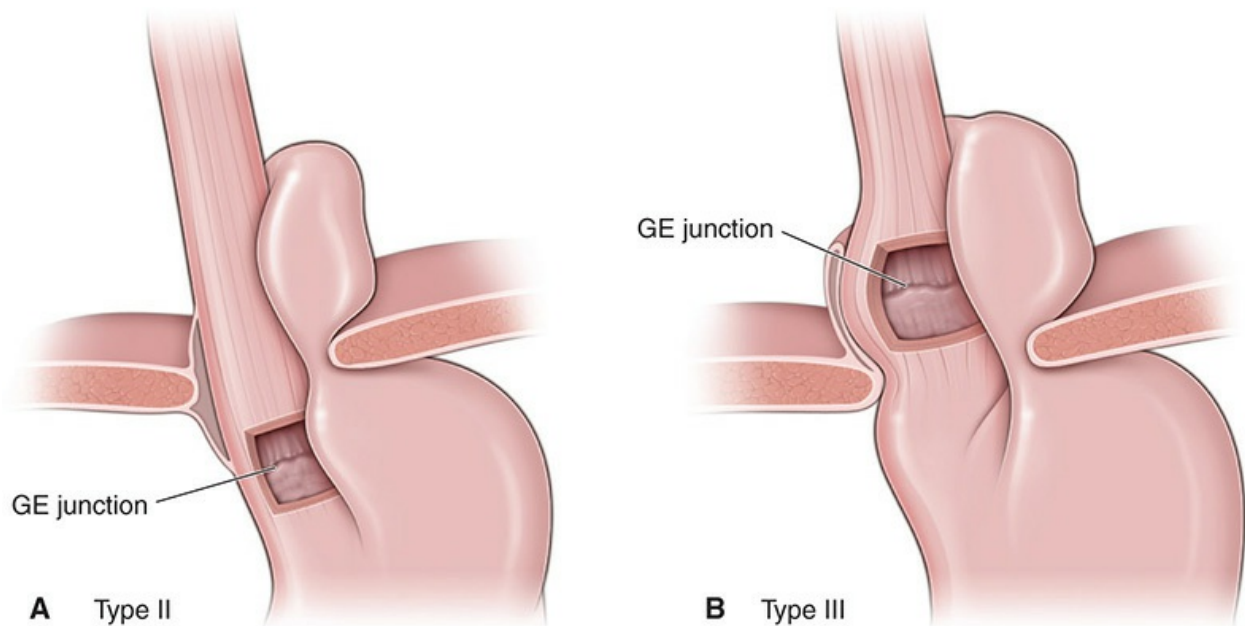

longer than 3 months, and the etiology should be investigated. Most cases of persistent postoperative dysphagia have some mechanical cause, such as transthoracic migration of the fundoplication, tight crural closure, or poor construction of the wrap, requiring reoperation.<sup>108</sup>

Intraoperative and early complications include esophageal and gastric perforation (<2%), pneumothorax, splenic injury, bleeding, and visceral injury. Mortality rates range from 0.008% to 0.8% while morbidity is also very low, at 2%.<sup>109</sup> The most common side effects of laparoscopic Nissen fundoplication are bloating, diarrhea, and dysphagia.<sup>110</sup> Of patients undergoing laparoscopic antireflux surgery, only 2% to 6% will eventually require reoperation. Of those, the majority are due to transthoracic herniation of the repair (10%-60%), with “slipped” fundoplications making up the majority of the remaining cases (15%-30%). Other reported indications for reoperation include tight fundoplication, missed motility disorder, and paraesophageal hernia.<sup>111</sup> Of those requiring reoperation, close to three-quarters will present within the first 2 years after initial operation.<sup>112</sup>

## PARAESOPHAGEAL HERNIAS

### Definition and Classification

Hiatal hernias are herniation of the stomach or other abdominal organs into the chest through the esophageal hiatus in the diaphragm. There are traditionally four types of hiatal hernias. Type I is defined as a migration of the GEJ into the chest secondary to an attenuated phrenoesophageal ligament. The “sliding” (type I) hernia and is the most common type of hiatal hernia. True paraesophageal hernias (PEH), or type II hiatal hernias, occur when the gastric fundus herniates anterior to the esophagus while the GEJ remains in the abdomen. Type III hiatal hernias are a combination of types I and II, in which both the GEJ and the gastric fundus herniate into the chest. Type IV hiatal hernias occur when not only the stomach, but other abdominal organs such as the colon, also herniates into the chest through the esophageal hiatus (Fig. 23-23). Of note, PEH (types II-IV) account for only about 14% of all hiatal hernias, with about 90% of all PEH being of the type III variety.<sup>113</sup>

**FIGURE 23-23** Types II and III paraesophageal hernia.

## Presentation

Patients with PEH can present with a variable set of symptoms, which can range from asymptomatic to life threatening. Symptoms of reflux such as heartburn are present in the majority of these patients. Other symptoms specifically associated with the anatomic location of the stomach after herniation through the hiatus into the chest can include dysphagia, postprandial bloating, nausea, vomiting, and even respiratory compromise.<sup>114</sup>

One important but less obvious symptom of PEH is chronic anemia. Anemia results from the development of Cameron's erosions or (ulcers) within the gastric folds secondary to repetitive movement through the esophageal hiatus. Cameron's erosions occur where the stomach slides over hiatal crura. At this region, the pressure of the stomach on the crura leads to ischemia of the gastric mucosa. More than one-third of patients with PEH can have an associated anemia, with about 60% having resolution after PEH repair.<sup>115</sup>

The life-threatening complication of PEH is gastric volvulus, which can lead to incarceration and subsequent strangulation. This is caused by abnormal rotation of the stomach  $>180$  degrees along one of two axes, creating a closed-loop obstruction. The first and most common type occurs when the stomach rotates along an imaginary line connecting the GEJ and the

pylorus, referred to as organoaxial rotation. The second type, mesoaxial rotation, occurs when the stomach rotates about an imaginary line between the greater and lesser curvatures. Of these, organoaxial volvulus is associated with a higher incidence of strangulation and is more often associated with PEH.<sup>116</sup> The classic symptoms associated with gastric volvulus are known as Borchartt's triad and include epigastric pain, nonproductive retching, and inability to pass a nasogastric tube. However, true strangulation of the stomach in a paraesophageal hernia is very rare.

## Evaluation

Evaluation begins with a history and physical examination, as PEH can have nonspecific symptoms which may be attributable to other pathology. Both contrast upper gastrointestinal (UGI) series and esophagogastroduodenoscopy (EGD) are implemented in assessing the extent and severity of PEH. The UGI study allows for visualization of the size of the hiatal defect, the amount of stomach herniated into the mediastinum, gastric volvulus, and presence of obstruction (Fig. 23-24). EGD is used to assess the presence of other esophageal/gastric pathology, such as a tumor, gastric bleeding, ulceration, and mucosal ischemia, suggestive of strangulation. Routine pH-monitoring or esophageal motility studies on patients with PEH are not necessary. However, in cases where dysphagia is a primary symptom, esophageal manometry is useful to assess for other motility disorders. In cases where reflux symptoms are the primary presenting symptoms, pH monitoring can confirm pathologic GERD as the cause, thereby better predicting surgical outcome.

**FIGURE 23-24** Contrast upper gastrointestinal series demonstrating a paraesophageal hernia.

## Management

Management decisions in patients with PEH can be complex. Generally, this is an older age group with multiple comorbidities. Patients with symptomatic PEH who are acceptable operative risk should be offered surgical repair, as it will improve symptoms and QoL.<sup>117</sup> Traditionally, all patients with PEH have been offered repair because of concern about life-threatening complications.<sup>118</sup> Recently, however, analysis of potential outcomes of asymptomatic or minimally symptomatic PEH patients concluded that after considering operative risk and surgical benefit to patients, watchful waiting would be more beneficial than elective PEH repair in approximately 83% of

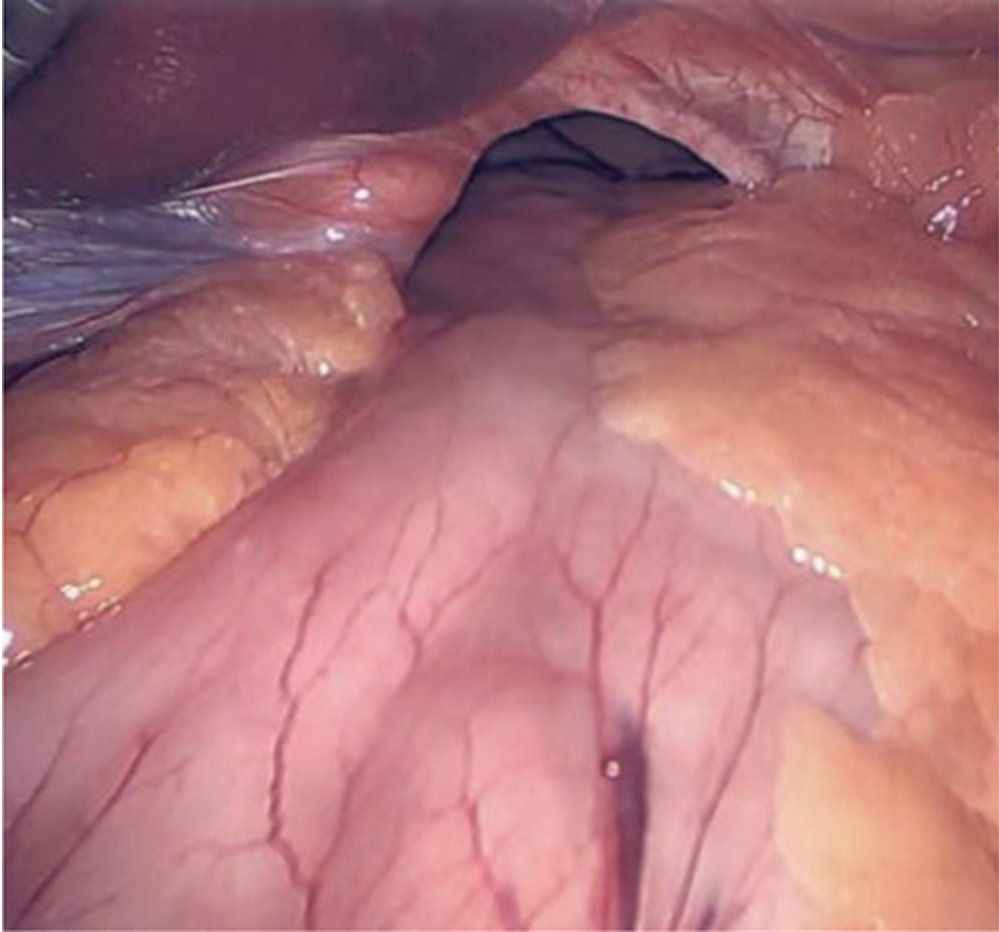

patients.<sup>119</sup> Therefore, a thorough assessment of symptoms and risks should drive the decision to operate.

## Operative Repair

While PEHs have traditionally been repaired through either a laparotomy or thoracotomy, today it is generally accepted that laparoscopy is the preferred method of repair. As this technique has evolved, laparoscopic repair is feasible in most patients.<sup>120</sup>

The patient is placed in the lithotomy position as with a standard laparoscopic antireflux operation. Attention is first turned toward the hernia sac, which is easily identified (Fig. 23-25). No attempt at reduction of the herniated stomach or other organs should be made, as stomach is attached to the hernia sac and traction on the stomach could lead to organ injury. The hernia sac is divided along the left crus to enter the plane between the hernia sac and mediastinum (Fig. 23-26). This is a critical step, as unlike other hernia sacs, the hernia sac of a PEH has two layers: the peritoneum and the phrenoesophageal ligament. The hernia sac can then be bluntly dissected from the mediastinum in a relatively bloodless plane between the hernia sac and pleura (Fig. 23-27). As the hernia sac is dissected from the mediastinum, the hernia contents will naturally come with it. Care needs to be exercised, as the hernia sac will overlie the esophagus (Fig. 23-28). Not uncommonly, the hernia sac may extend posterior to the esophagus. This portion must also be dissected and excised to allow for adequate visualization of the retroesophageal space. Once the hernia sac is reduced, it may be resected to improve visualization.<sup>121</sup> The esophagus is encircled with a Penrose drain and the right and left crura exposed (Fig. 23-29). The hiatal defect is repaired as previously described. The large defect can be problematic because of tension.

**FIGURE 23-25** Laparoscopic identification of the paraesophageal hernia.

**FIGURE 23-26** Beginning the dissection of the paraesophageal hernia sac.

**FIGURE 23-27** The proper plane between the hernia sac and pleura.

**FIGURE 23-28** Identification of esophagus as the hernia sac is reduced.

**FIGURE 23-29** Retroesophageal identification of right and left crura.

Adjuncts have been used to reinforce this repair. They include the use of a variety of biologic and prosthetic meshes and relaxing incisions. No adjunctive techniques have definitively led to reduction in hernia recurrence.<sup>122–124</sup> However, crural repair with prosthetic mesh has been associated with complications such as erosion into the esophagus or stomach, dysphagia, and pain. If esophageal foreshortening is encountered, a lengthening procedure such as a Collis gastroplasty can be performed.

Another controversy in PEH repair is the need for an antireflux procedure. Some patients who have undergone PEH repair without a fundoplication will have symptomatic improvement of their PEH; however, new symptoms of GERD may develop. Therefore, unless there is a specific contraindication to an antireflux procedure, most patients would benefit from a Nissen or Toupet fundoplication in addition to the hiatal hernia repair.

Finally, another technique that has been utilized in an effort to prevent recurrence is gastropexy/gastrostomy. The stomach can be anchored to the abdominal wall via these techniques. No proven benefit has been shown to date with any fixation of the stomach in the abdominal cavity, but some studies have shown relatively good outcomes.<sup>125</sup> Therefore, gastropexy can be considered a surgeon's preference, rather than a mandated principle.

## BARRETT ESOPHAGUS

Barrett esophagus (BE) is a change in the mucosa of the esophagus from squamous epithelium to metaplasia columnar epithelium as a result of GERD. The clinical significance of BE is its role as a risk factor in the development of esophageal adenocarcinoma (EA). Patients with BE are up to 40 times more likely to develop esophageal adenocarcinoma than the general population.<sup>126</sup> Prior to 40 years ago, BE was not a significant clinical problem because EA made up a small minority of esophageal cancers and cancers overall. However, the incidence of EA has increased since the late 1970s in the Western world,<sup>127</sup> most likely related to GERD and subsequent BE.

### Pathogenesis

Barrett metaplasia occurs as a result of exposure of esophageal epithelium to gastric and duodenal fluids. When native squamous esophageal mucosa is exposed to gastric acid and duodenal bile, it undergoes an adaptive metaplasia to become mucus-secreting columnar cells with interspersed goblet cells.<sup>128</sup> Following metaplasia, these cells can then undergo morphologic changes called dysplasia. Pathologically, dysplastic cells tend to be distorted and crowded. Furthermore, these cells have nuclear abnormalities, including increased nuclear to cytoplasmic ratios.<sup>129</sup> Based on pathologic appearance, dysplasia can be described as low grade (LGD), high grade (HGD), intermediate, or indeterminate (Fig. 23-30). At the genetic level, cells that have undergone Barrett metaplasia also demonstrate many properties of carcinogenesis including growth self-sufficiency, inhibition of antigrowth signals, escape from apoptosis, limitless replication, angiogenesis, invasion, and metastasis.<sup>130</sup>

Barrett metaplasia

Low-grade dysplasia

High-grade dysplasia

**FIGURE 23-30** Histologic grades of Barrett esophagus.

## Diagnosis

The typical patients with BE tend to be overweight, middle-aged white men with symptoms of reflux.<sup>131</sup> However, many patients can have “silent” reflux and can still have BE despite being completely asymptomatic. Only an upper endoscopy can confirm the diagnosis. Upon examination, BE is grossly appreciated as salmon-colored mucosa projecting proximally into the distal esophagus from the normal squamocolumnar junction (Fig. 23-31A). Endoscopic use of narrow-band imaging can enhance visualization of the BE (Fig. 23-31B). These suspicious areas must be biopsied to confirm the presence of intestinal metaplasia and goblet cells.<sup>132</sup> Endoscopic biopsy must be done using the Seattle protocol of four quadrant biopsies every 2 cm or less from the anatomic gastroesophageal junction. The extent of the endoscopic BE is described using the Prague classification system of length of circumferential BE (C) and total length of esophagus involving with the BE (M). For example, if the circumferential length involved was 3 cm and a “tongue” of BE extended an additional 2 cm cephalad, this would be reported as C3M5. Special note must be made of nodules and ulcers. These should be biopsied thoroughly.

A

B

**FIGURE 23-31** Endoscopic identification of Barrett esophagus. **A.** Barrett metaplasia with white light. **B.** Barrett metaplasia with narrow band imaging.

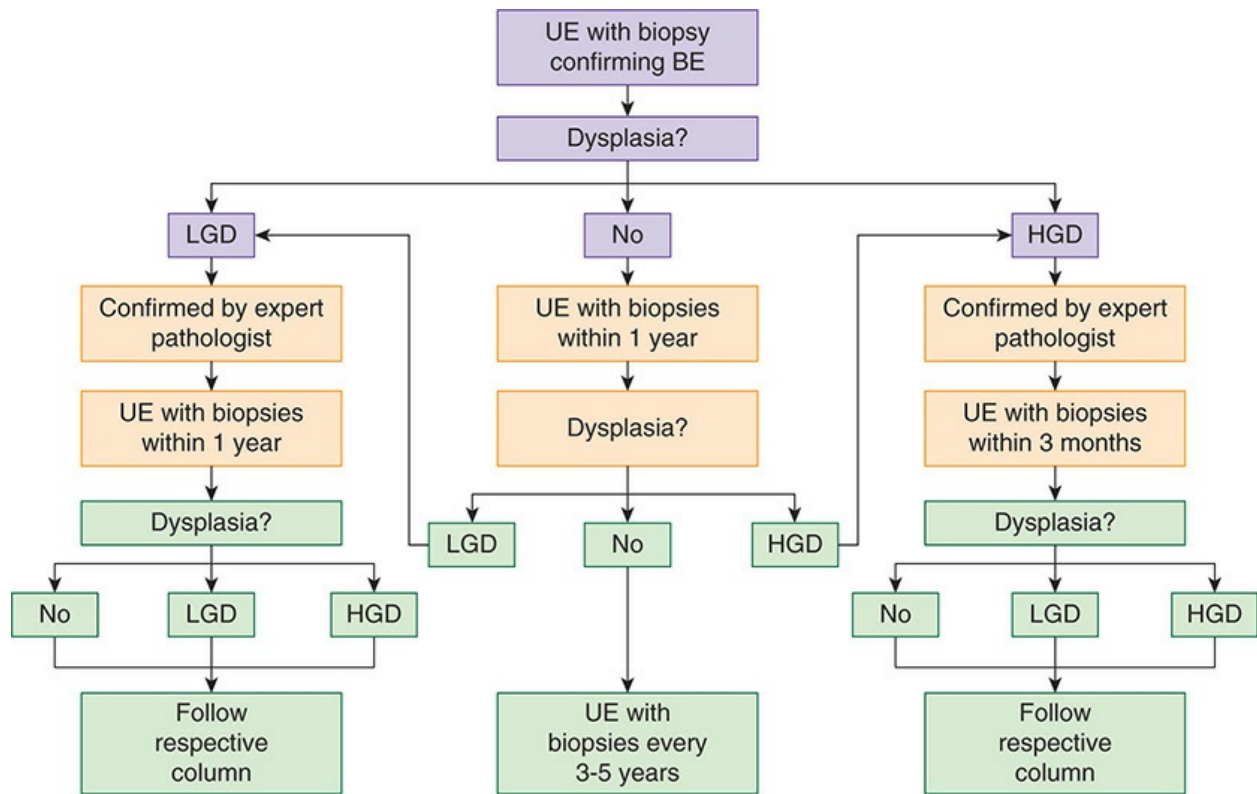

## Screening

Many groups have advocated screening patients considered high-risk for developing BE and subsequent EA. Some retrospectively designed studies have demonstrated benefits of screening certain patient populations,<sup>133</sup> but there is no level I evidence demonstrating an improvement in survival as a result of endoscopic screening. As cost is an issue with screening programs, groups have developed models to show that it is cost-effective to screen those patients deemed to be at high risk.<sup>134</sup> However, identifying the “high-risk” patient can be problematic and there is no consensus as to what makes a patient high-risk. Because of this, screening recommendations remain controversial. At this time, the American College of Gastroenterology does not recommend routine screening for BE or EA,<sup>131</sup> but the British Society of Gastroenterology states that it is acceptable to screen patients with chronic GERD and other risk factors including age >50 years, white race, male sex, and obesity.<sup>135</sup>

## Surveillance

After BE has been diagnosed, surveillance recommendations depend on the presence and degree of dysplasia present. Surveillance of nondysplastic BE (NDBE) remains the most controversial. Some suggest that surveillance is not required, as 97% of NDBE patients will be cancer-free in 10 years.<sup>136</sup> However, others argue that a progression to cancer rate of 0.4% to 0.6% per year justifies surveillance.<sup>137</sup> If no dysplasia is found by pathologic examination on the index endoscopy, then the patient should undergo repeat endoscopy with biopsies within 1 year. If this confirms NDBE, surveillance can be extended to every 3 to 5 years. If LGD is found, it should be confirmed by an expert gastroenterologic pathologist. Patients with LGD should continue to undergo surveillance annually until they have two consecutive dysplasia-free biopsies. Finally, if HGD is found on biopsy, it must again be confirmed by an expert gastroenterologic pathologist. If ablation is not done, then intense surveillance should be implemented for

HGD including repeat endoscopy with biopsies within 3 months (Fig. 23-32).

**FIGURE 23-32** Algorithm of surveillance for Barrett esophagus.

## Treatment of BE

The management of patients with BE is based upon the degree of dysplasia. The initial treatment strategy for all patients with BE should be geared at the treatment of reflux. PPI therapy is the mainstay in the management of BE. Acid-suppressing medications can lead to a 71% reduction in cases of EA and/or HGD transformation in patients with BE.<sup>138</sup> Although once a day or twice a day dosing is controversial, compliance with daily PPI is mandatory.

## ENDOSCOPIC ABLATION OF BARRETT ESOPHAGUS

There have been many techniques introduced to ablate BE in hopes of reducing EA risk. At one time, photodynamic therapy was widely used. However, it was associated with issues related to “buried glands” and severe stricture formation. Because of this, it has fallen out of favor and is not discussed in this chapter. Other techniques, such as a thermal

electrocoagulation, argon beam coagulation, and laser ablation have led to inconsistent results. Therefore, these are not part of the mainstay of treatment. The best studied techniques are radiofrequency ablation and, to a far lesser extent, cryoablation.

## **Indications**

***Nondysplastic Barrett Esophagus.*** The incidence of progression to EA in patients with NDBE is about 4 to 6 per 1000 patients per year. Ablation of NDBE is controversial, but some have advocated ablation for specific reasons.<sup>139</sup> At present, the consensus statement from the American Gastroenterological Association does not recommend the “routine” ablation of NDBE.<sup>140</sup> However, ablation can be considered in the “high-risk” patient for the progression to EA with NDBE. Risk factors to consider are a family history of EA, long BE length, difficult-to-control reflux, or patient preference.

***Low-Grade Dysplasia.*** The incidence of progression to EA in patients with LGD is about 7 to 8 per 1000 patients per year. As with NDBE, this has led to a recommendation against ablation. However, a recent randomized controlled trial demonstrated unequivocally that ablation reduces the incidence of progression to EA.<sup>141</sup> Given these new results, ablation of LGD may be considered appropriate.

***High-Grade Dysplasia.*** There is complete consensus that HGD should be ablated. The incidence to progression to EA is about 14 to 15 per 1000 patients per year. A randomized controlled trial demonstrated significant reduction in the risk to progression to EA with ablation.

## **Techniques of Endoscopic Ablation**

***Radiofrequency Ablation.*** Radiofrequency ablation (RFA) is the best studied of the ablative techniques. The device used most commonly is the BARRx™ system (Fig. 23-33; Covidien, Sunnyvale, CA). In this method, a complete upper endoscopy is done and the length of BE to be treated is determined. Circumferential BE is treated with the Halo-360 device, while “spot” ablative devices, such as the Halo-90, can be used for smaller areas. If the Halo-360 is used, the esophageal mucosa is cleared of any debris and a guidewire passed

into the stomach. A sizing balloon catheter is passed over the guidewire to the level to be treated. The balloon is inflated and the appropriate size ablation catheter chosen. An ablation catheter is passed over the guidewire and the endoscope passed alongside the ablation catheter. The top of the ablation coils are positioned cephalad to the top edge of the BE. The ablation balloon is inflated, suction applied to the endoscope, and the device activated. It delivers 10 Joules of energy. The ablation balloon is deflated, the coagulum is removed from the surface of the esophagus, and the process is repeated. This process is continued until the length of BE desired to be treated is ablated (Fig. 23-34). If one of the spot devices is used, this is done under direct visualization with the device either attached to the endoscope or through the endoscope. Complications such as chest pain, esophageal stricturing, and hemorrhage have been reported, but these complications are quite uncommon.<sup>142</sup>

**FIGURE 23-33** BARRx System for radiofrequency ablation of Barrett esophagus. (All rights reserved. Used with the permission of Medtronic.)

**FIGURE 23-34** Steps in radiofrequency ablation of Barrett esophagus.

**Cryotherapy.** Cryotherapy causes mucosal destruction through repeated freeze-thaw cycles using agents such as liquid nitrogen. The technique utilizes a catheter passed through the endoscope. Liquid nitrogen at  $-70^{\circ}\text{C}$  is applied under direct visualization to the area of BE to be ablated. A retrospective study has demonstrated that 97% of patients treated with cryotherapy had eradication of their HGD, 87% had eradication of all dysplasia, and 57% had eradication of their BE altogether.<sup>143</sup> This study revealed a few treatment-related complications, including chest pain and strictures. However, there have been no randomized trials documenting the effectiveness of cryoablation.

**Combining Ablation of BE with Antireflux Surgery.** The risk of recurrence of BE after ablation is related to persistent reflux.<sup>32</sup> Because of this, it is reasonable to consider antireflux surgery, especially in the symptomatic patient. This has led to a decrease in the recurrence of BE after successful ablation.<sup>144</sup>

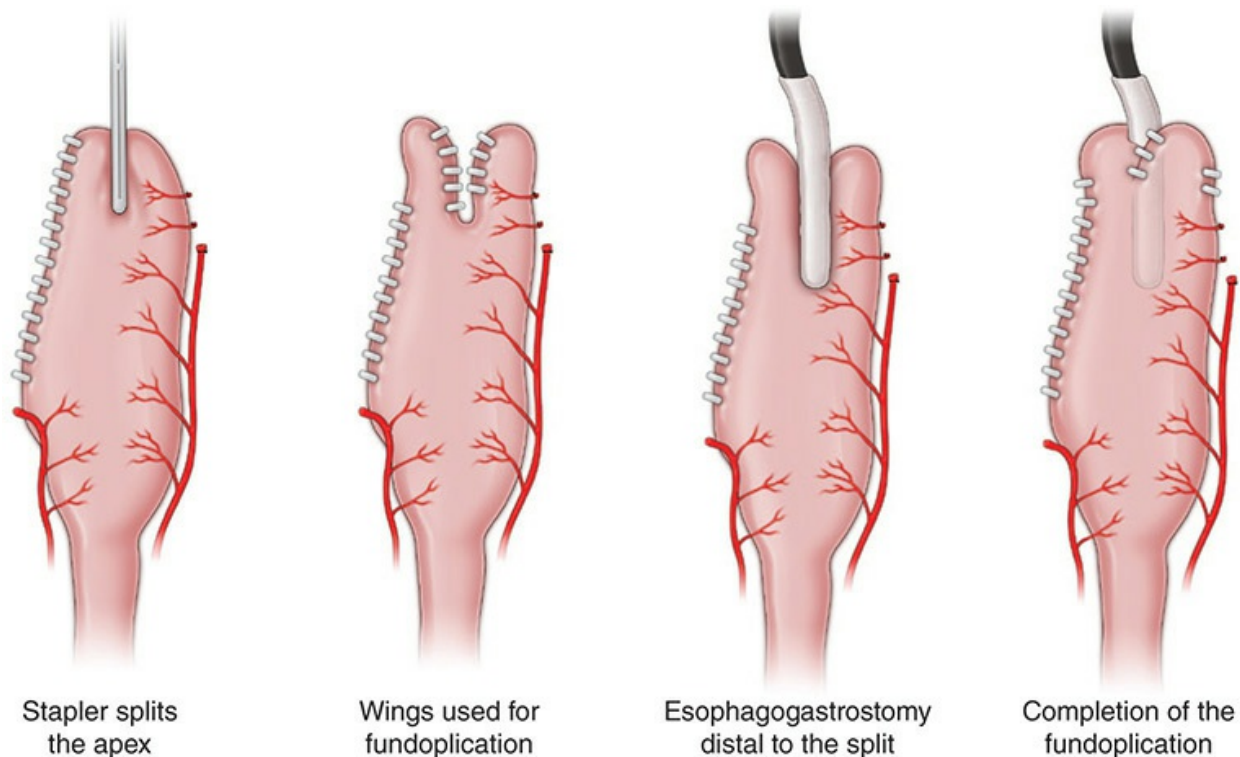

**Endoscopic Mucosal Resection.** The endoscopic counterpart to ablative therapy is endoscopic resection. This is achieved either via endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD). EMR is a technique that involves resecting both the mucosa and submucosa of an area of interest using snare cautery similar to how polypectomies are performed in the colon. The advantage of these techniques compared to ablative modalities is that they provide tissue specimens that can be sent to pathology for accurate staging. Because of the ability to obtain a pathologic specimen, EMR or ESD is the primary treatment of nodular BE, especially HGD, as nodules are more likely to harbor malignancy. EMR is the mucosal resection technique employed most frequently in the United States and Europe.<sup>145</sup> This can be preceded by submucosal elevation of the lesion using a combination of saline and epinephrine if need be.<sup>146</sup> A band similar to one used for variceal bleeding is placed at the base of the nodule after it is sucked into the banding cap. This creates a “pseudopolyp” that can be resected with a snare in a similar fashion to an endoscopic polypectomy. When patients with dysplasia and early-stage EA are treated with EMR, complete local remission rates range from 91% to 96%.<sup>147,148</sup> A drawback of EMR is that its use is restricted to lesions that are less than 15 mm.<sup>149</sup> EMR can be combined with RFA of the remaining flat BE.

With larger lesions, the advanced technique of ESD can be used. This technique uses endoscopic electrosurgical knives rather than a snare to resect the specimen en bloc. Complications seen in these procedures include bleeding, perforation, and stricturing, but mortalities are rare.<sup>128,149</sup>

## **ESOPHAGECTOMY**

Occasionally, BE will require an esophagectomy. Indications include BE nodules harboring a T1b (tumor invades submucosa) or greater EA, persistent BE with HGD despite multiple attempts at ablation, complicated strictures or ulcers intractable to conservative management, and the “burnt-out”

esophagus which leads to functional obstruction. Although esophagectomy is considered elsewhere in this book, consideration should be given to creation of a fundoplication with the esophagectomy to reduce the symptoms of reflux and the incidence of BE after an esophagectomy (Fig. 23-35).<sup>150</sup>

**FIGURE 23-35** Steps in the construction of the split-stomach

fundoplication. (Reproduced with permission from Velanovich V, Mohlberg N: The split-stomach fundoplication after esophagogastrrectomy, *J Gastrointest Surg.* 2006 Feb;10(2):178-183.)

## CONCLUSION

GERD is a commonly encountered medical problem, especially in the Western world. The importance of this condition and proper evaluation, treatment, and surveillance is highlighted by its potentially devastating complications, namely BE and EA. Physicians should have a high index of suspicion when evaluating patients, as GERD can present with varying clinical pictures. Diagnostic technology is continually advancing, and a comprehensive workup should be implemented in all suspected cases of GERD. Treatment options can range from lifestyle modification to open surgery, and varies on a case-by-case basis. The hope is that with the advent

of newer, less invasive treatment modalities such as endoluminal and laparoscopic interventions, efficacy will continue to improve while morbidity rates will decline.

# PARAESOPHAGEAL HERNIA REPAIR

*Jeffrey A. Blatnik • L. Michael Brunt*

Paraesophageal hernias comprise approximately 5% to 15% of all hiatal hernias and are challenging hernias to repair. Most commonly, these occur in patients age >50 to 60 years. The natural history of paraesophageal hernia repair has not been systematically studied, but, in general, many patients present with a longstanding history of hiatal hernia. Therefore, it's likely that these progressively enlarge over time. While they can be asymptomatic, some patients present with acute gastric outlet obstruction and/or gastric ischemia that requires emergency surgical intervention. In this chapter, the clinical presentation, diagnostic evaluation, and surgical technical aspects and resultant outcomes of paraesophageal hernia repair will be presented.

## BACKGROUND

The classification of hiatal hernia is illustrated by the radiographic studies shown in [Figure 24-1](#). Type I hernias are sliding hiatal hernias defined by the location of the gastroesophageal (GE) junction above the diaphragm. Types II, III, and IV are different types of paraesophageal hernias. In type II paraesophageal hernias (PEHs), the GE junction is in a normal position and a

portion of the upper stomach, usually the fundus, is herniated alongside the esophagus through the hiatus. Type II PEHs account for a relatively small percentage of cases. The most common type of PEH is type III, in which there is a combined sliding and paraesophageal component. These hernias can be quite large, with most of the stomach, if not the entire stomach, in the chest and associated volvulus. Type IV PEHs are those in which some other organ besides the stomach is herniated into the chest, most commonly the colon, but also possibly the small bowel, pancreas, and duodenum.

**FIGURE 24-1** Barium swallow that illustrates the 4 types of hiatal hernias. **A.** Type I sliding hernia. **B.** Type II paraesophageal hernia (PEH). **C.** Type III PEH. **D.** Type IV PEH with intrathoracic stomach; note the bowel gas in the left chest, which is due to herniated colon.

Because of the large size of the defect and extent of herniation, the stomach may undergo rotation within the hernia sac. Most commonly, this consists of organoaxial volvulus in which the stomach rotates along the axis of the organ. This type of volvulus results in the greater curvature being flipped upward and at a higher position in the mediastinum than the lesser curvature ([Fig. 24-2A](#)). The stomach can also rotate along the axis of its mesentery (mesoaxial volvulus). Mesoaxial volvulus is associated with a higher risk of gastric ischemia because of the twisting of the mesentery, which can compromise venous return and gastric blood flow ([Fig. 24-2B](#)).

**FIGURE 24-2 A.** Barium swallow that shows organoaxial volvulus. Note that the stomach is essentially upside down, with the greater curvature of the stomach positioned higher than the lesser curvature. **B.** Barium swallow that shows a PEH with mesoaxial volvulus.

## CLINICAL PRESENTATION

Patients with PEH may be completely asymptomatic, but more often, they have a variety of symptoms depending on the extent of the herniation. There may be a longstanding history of hiatal hernia that has been managed medically. Postprandial fullness, discomfort, and pain, especially after eating a larger meal, are some of the most common symptoms associated with PEH. These symptoms occur because the herniated segment does not empty properly, and therefore, with a larger meal, the stomach becomes distended, which leads to discomfort. Typical heartburn and regurgitation symptoms of gastroesophageal reflux disease (GERD) may be present but are less common, likely because these patients may still have a competent lower esophageal sphincter. Patients may also have dysphagia either because of associated esophageal dysmotility or because the large hernia compresses the distal esophagus. Approximately 25% of patients present with anemia from gastrointestinal bleeding. The bleeding is usually occult and discovered incidentally on a routine blood count. Anemia in this setting is typically due to Cameron lesions, which are superficial erosions or ulcerations in the proximal stomach that can be secondary to constriction of the stomach at the hiatal defect and friction from movement across the hiatus, which can lead to occult blood loss. PEH may also be detected incidentally on plain chest radiographs as shown in [Figure 24-3](#) or on computed tomography (CT) scan done for chest pain or other reasons ([Fig. 24-4](#)).

**FIGURE 24-3** Chest radiograph in a patient with a large paraesophageal hernia. Note the air fluid level in the chest from the herniated stomach.

**A**

**B**

**FIGURE 24-4** Computed tomography scan that demonstrates a large paraesophageal hernia: **(A)** axial images and **(B)** coronal view. The fluid-

filled stomach is seen on the coronal view and colonic gas along with stomach on the axial image.

Up to 20% of patients with PEH present with gastric volvulus. While gastric volvulus can be asymptomatic, it can also develop acutely and lead to gastric outlet obstruction with acute onset of chest or epigastric pain, nausea, and emesis. In some cases, the volvulus may lead to gastric ischemia and strangulation. Most patients who present with acute gastric outlet obstruction can be temporized with nasogastric decompression. However, some patients require emergency surgery to reduce the stomach and avoid progression to gastric strangulation. Inability to pass a nasogastric tube should raise concern for gastric volvulus with possible gastric ischemia.

## **DIAGNOSTIC EVALUATION**

The diagnosis and evaluation of a patient with a PEH typically involve a multistep process and numerous tests once the diagnosis is suspected.<sup>1</sup> When the diagnosis is suspected, the initial evaluation should consist of a barium esophagram and esophagogastroduodenoscopy (EGD). The barium swallow may be useful in defining the anatomy, the type of hiatal hernia, and in particular, the relationship of the GE junction to the diaphragm. If the GE junction is located more than 5 cm above the hiatus, then the patient may have a shortened esophagus (Fig. 24-5). This is a very useful initial test as it typically yields a significant amount of information about the anatomy and function of the esophagus and stomach.

**FIGURE 24-5** Barium swallow in a patient with a shortened esophagus. The gastroesophageal junction is not well visualized but was more than 5 cm above the hiatus, and at operation, an esophageal lengthening procedure was performed.

Further diagnostic evaluation should be carried out that consists of an upper gastrointestinal endoscopy to assess for mucosal lesions and other upper gastrointestinal pathology including the presence of Cameron ulcers and to evaluate the stomach. Factors evaluated at the time of EGD include the

size of the hernia, which is often appreciated with retroflexed view. In acute presentations, an EGD can be used to assess the viability of stomach if there is concern for ischemia.

Because patients with PEH may have associated esophageal dysmotility or hypomotility from longstanding reflux and the large hernia, high-resolution esophageal manometry is advisable for most patients to identify this condition and for selection of the proper type of fundoplication to be done at the time of repair. In some cases, it may be difficult for the manometry catheter to pass through the GE junction and assess the lower esophageal sphincter, which can be compressed by the herniated contents. In general, a 24-hour pH test is not indicated for PEH because the presence of the hernia is sufficient objective evidence of the underlying pathology and the results do not typically alter the surgical approach.

## OPERATIVE APPROACH

PEH repair can be challenging for a number of reasons, including the large amount of herniated contents, the presence of a large hiatal defect that must be closed, need to excise a large hernia sac, the possibility of a shortened esophagus, and often distorted anatomy. In addition, these patients are frequently older with more comorbidities and accompanying obesity, which can increase the difficulty and risks of surgical repair.

PEHs may be repaired either via an open abdominal, open thoracic, or laparoscopic transabdominal approach. Over the past 20 years, laparoscopic PEH repair has largely replaced these other approaches except in the rare, unstable patient who does not tolerate a pneumoperitoneum or the septic patient with gastric necrosis. The operation may be segmented into 3 primary steps, the details of which are provided in [Table 24-1](#): (1) dissection and reduction of the hernia sac and stomach into the abdomen; (2) closure of the crural/hiatal defect; and (3) creation of the fundoplication. Patient preparation should consist of a single dose of intravenous antibiotic (first-generation cephalosporin unless allergic), lower leg compression devices and subcutaneous heparin for thromboembolic prophylaxis, and placement of a urinary catheter. The patient is typically positioned on a bean bag mattress that is well padded and with the legs on spreader bars so the surgeon can stand between the legs.

---

**TABLE 24-1: SEQUENTIAL STEPS IN PARAESOPHAGEAL HERNIA REPAIR**

**Step 1: Dissection of hernia sac and reduction of herniated contents**

- Division of gastrohepatic ligament
- Incision of phrenoesophageal ligament and development of sac plane
- Division of phrenoesophageal and hernia sac attachments to crura
- Exposure of base of crura from right side
- Division of gastrosplenic ligament
- Completion of retrosophageal window
- Complete reduction of sac and herniated contents into abdomen
- Circumferential mobilization of esophagus in mediastinum with identification and preservation of vagal nerve trunks
- Excision of hernia sac
- Decision regarding adequacy of esophageal length
- If short esophagus present, perform wedge fundectomy to lengthen esophagus with 54- to 60-Fr bougie dilator in place

**Step 2: Closure of the hiatal defect**

- Crural closure starting posteriorly with interrupted nonabsorbable suture  $\pm$  pledgets
- Placement of bioresorbable mesh to reinforce hiatal closure if indicated according to surgeon judgment

**Step 3: Creation of fundoplication**

- Complete Nissen fundoplication; short floppy wrap over distal esophagus
- Partial fundoplication if inadequate peristalsis or contraction reserve is present
- Perform gastropexy if deemed necessary

---

## **Step 1. Dissection of the Hernia Sac and Reduction of the Herniated Contents**

At initial laparoscopic exploration, one may attempt to reduce the herniated contents, but this is often difficult to achieve without first dissecting the hernia sac (Fig. 24-6). One should use gentle traction and avoid forcible reduction because of the risk of tearing or perforating the stomach. An

advanced energy device (most commonly an ultrasonic coagulator) facilitates dissection of the hernia sac and mobilization of the upper stomach and esophagus. The dissection can begin either on the anatomic right or left side of the stomach. The authors prefer to begin by dividing the gastrohepatic ligament up to the right crus of the diaphragm. The hepatic branch of the vagus nerve can be divided, but one should take care to identify (and preserve) a replaced left hepatic artery, which can be present in up to 30% of cases. The phrenoesophageal membrane and edge of the hernia sac are then incised anteriorly, and the plane between the sac and the mediastinum should be developed and then extended toward the right and left crura (Fig. 24-7). This maneuver is critical for beginning to reduce contents out of the mediastinum and can largely be done by blunt dissection. The dissection of the sac continues along the right side down to the base of the crura and into the retroesophageal space until the left crus has been identified. It is important to preserve the thin fascial layer over the crura, which provides strength for the subsequent crural closure. Once the right side has been freed up and the retroesophageal window started, the left anterior phrenoesophageal and gastrophrenic attachments can be divided, which allows one to begin to reduce the sac out of the left side of the mediastinum. At this point, it is often preferable to open the gastrosplenic omentum beginning at the level of the upper body of the stomach and dividing it up to the left crus, taking the short gastric vessels with an ultrasonic coagulator (Fig. 24-8). With large PEHs, the short gastric pedicle is often elongated, which can make this step in the operation easier than with conventional hiatal hernia repair. The short gastrics should be taken close to the stomach to avoid injury near their entry into the spleen, which can be difficult to control, and also to avoid leaving redundant tissue on the fundus for the subsequent fundoplication. The attachments at the base of the left crus are then divided, and at this point, one should visualize a completed retroesophageal window (Fig. 24-9).

**FIGURE 24-6** Initial laparoscopic view of a large paraesophageal hernia.

**FIGURE 24-7** Incision of the paraesophageal hernia sac. This step is typically done with use of an advanced energy device (eg, ultrasonic coagulator) but also by blunt dissection within the sac plane.

**FIGURE 24-8** Division of the gastrosplenic ligament and short gastric vessels, which is typically done with an ultrasonic coagulator or other advanced energy device.

**FIGURE 24-9** Completed retroesophageal window with visualization of the right and left crura and aorta. A, aorta; E, esophagus; IVC, inferior vena cava;

LC, left crus; RC, right crus.

Next, the dissection is carried back into the mediastinum where the esophagus is mobilized circumferentially, taking care to identify and preserve both anterior and vagal nerve trunks, which can be distorted in their location by the large hernia (Fig. 24-10). Retraction on the esophagus and upper stomach during mediastinal mobilization can be accomplished either by placing a grasper in the retroesophageal window or by a Penrose drain placed around the esophagus at the hiatus.

**FIGURE 24-10** Mediastinal dissection with view of the posterior vagus nerve (arrow).

It is often helpful at this point to excise the hernia sac, which is usually larger on the left anterior side (Fig. 24-11). The hernia sac may serve as a lead point for possible hernia recurrence, and in some small studies, excision of the hernia sac has been associated with a reduced hernia recurrence rate.<sup>2</sup>

**FIGURE 24-11** Excision of the hernia sac on the left anterior side of the stomach. It is important to maintain traction and countertraction on the sac and stomach and to identify and avoid injury to the anterior vagus nerve, which can be in close juxtaposition to the medial edge of the sac and to the stomach itself.

When excising the sac, one must be careful to avoid injuring the anterior vagus nerve, which can be closely applied to the base of the sac. In some cases, there is also redundant sac to excise on the anatomic right side, and care should be taken there to identify and preserve the posterior vagus nerve during that step.

Once the contents are completely reduced and the esophagus has been extensively mobilized, a determination should be made as to whether or not there is adequate intra-abdominal length of 2.5 to 3 cm or more. If not, then an esophagogastric lengthening procedure may need to be performed, as described below. Other precautions include the importance of proper traction and countertraction to expose the relevant anatomy at each stage in the operation. One should also be careful with the use of energy near the

esophagus, stomach, and vagus nerves because of the risk of direct thermal spread to those structures.

## **Step 2: Closure of the Hiatal Defect**

Once the hernia has been reduced and the esophagus has been fully mobilized, the hiatal defect should be repaired. The crura should be closed with interrupted nonabsorbable sutures, preferably 0 polyester-type sutures (Fig. 24-12). The closure should begin posteriorly with either simple interrupted or figure of 8 sutures or a combination thereof. Some surgeons prefer to use pledgeted sutures to buttress the closure. If mesh is to be used, it should be placed at this step in the operation. It may be necessary with larger defects to also place a crural closure stitch anterior to the esophagus because of increasing tension posteriorly. In cases in which there is a wide defect that cannot be closed primarily, a relaxing incision can be made in the right crus to bring the crura together at the midline. This defect from the relaxing incision would then need to be covered with some type of mesh, as will be discussed below.

A

B

**FIGURE 24-12** **A.** Closure of the hiatal defect with interrupted figure-of-8 0 polyester sutures. **B.** Similar closure but with use of pledgets.

### **Step 3: Creation of Fundoplication**

After the hiatal defect has been closed, a fundoplication should be carried out and is typically done over a large, 54- to 60-Fr bougie dilator. The wrap should be located over the distal esophagus (or in the case of esophageal lengthening, over the neoesophagus). A short, floppy wrap of 3 sutures of interrupted 0 polyester is carried out with 1 or 2 of these sutures incorporating a bite of the esophageal wall to prevent the wrap from slipping (Fig. 24-13A). Pledgets should generally be avoided in the fundoplication because of the risk of fistulization. Upon completion of the fundoplication, one should be able to easily slide a blunt instrument beneath the wrap and alongside the esophagus. A gastropexy anchoring the posterior fundus to the diaphragm or the anterior stomach to the abdominal wall can be carried out, but there is no consensus on whether this impacts recurrence rates or not. For patients who have aperistalsis or profound hypomotility or inadequate contraction reserve on high-resolution manometry, a partial fundoplication should be performed (Fig. 24-13B). Typically, a posterior Toupet fundoplication is done, but some surgeons prefer an anterior Dor fundoplication instead.

A

B

**FIGURE 24-13** **A.** Standard Nissen fundoplication as a part of a PEH repair. **B.** Toupet posterior fundoplication in a patient with inadequate peristaltic function. PEH, paraesophageal hernia.

## Placement of Mesh

The use of mesh for the repair of large PEHs is an area of controversy that is unresolved. The one consensus among surgeons is that the use of permanent synthetic mesh at the hiatus should generally be avoided due to the rare but catastrophic risk of mesh erosion into the esophagus, which may require treatment with esophagectomy.<sup>3-6</sup> The use of biologic mesh gained considerable interest after the initial results of a randomized trial in 2006.<sup>7</sup> In this prospective, randomized trial, the authors compared hiatal reinforcement with biologic mesh (4-ply, porcine, small intestine submucosa) to primary hiatal closure only in 108 patients. At the 6-month radiographic follow-up, they found a significant reduction in the rate of recurrent hernia (24% vs 9%) in patients who underwent mesh reinforcement. However, when a subgroup of 60 of these patients was followed out to 5 years, the beneficial effect of biologic mesh reinforcement was lost, with recurrent hernia rates of 59% in the primary repair group versus 54% in the reinforced group.<sup>8</sup> A limitation of the long-term data of this study was that a substantial portion of the patient population was lost to follow-up. Despite the high anatomic recurrence rate in both groups, symptoms were significantly improved in the vast majority of cases, and only 2 patients (3%) required reoperation. Regardless, based on this and other studies, the current recommendation on the use of mesh reinforcement at the time of PEH repair is that it appears to reduce short-term recurrence rates but may not impact long-term recurrence outcomes. In a European consensus panel review on PEH management, a majority of experts felt that the use of mesh was important under specific circumstances such as large hiatal defect and the quality of the crura; there was no consensus, however, on the type of mesh that should be used.<sup>9</sup> Further studies with later generation biologic or other bioresorbable mesh options are needed before a definitive recommendation can be made.

In regard to the choice of biologic or bioresorbable mesh, a variety of materials are available for use, as illustrated in [Figure 24-14](#). In general, biologic meshes should be employed to buttress the primary crural closure

and not to bridge the crural defect because the material resorbs over time. Numerous fixation techniques have been used, including sutures, tacks, and glues.<sup>10,11</sup> Regardless of the method, great care should be taken to avoid injury to the pericardium or aorta when using penetrating fixation options, which has been reported during PEH repair.<sup>12-14</sup>

A

B

C

**FIGURE 24-14** Examples of biologic mesh used for hiatal reinforcement of the crural closure in PEH repair. **A.** Acellular porcine dermis. **B.** Porcine small intestine submucosa. **C.** Synthetic polyglycolic acid and trimethylene carbonate resorbable mesh. Note the combination of resorbable tacks and permanent suture (2-0 polyester) used to fixate the mesh.

## Use of Relaxing Incisions

During the repair of large hiatal hernias or when there is excessive tension on the hiatus during closure, it may be necessary to use a crural relaxing incision to reduce the radial tension and allow closure at the hiatal defect. The right crus may be especially thin and begin to tear during closure of very large, wide defects. While relaxing incisions can be performed on either the right or left crus, it is usually easier in the authors' experience to do this on the right side along the lines indicated in using an ultrasonic coagulator. The incision should be placed laterally near the inferior vena cava, preserving a cuff of crus that can be used to suture the mesh in place, and should extend more anteriorly, where tension is greater, than posteriorly. On the left side, the relaxing incision should start to the left of the hiatus and follow the course of the seventh rib. In a more recent study, Bradley et al<sup>15</sup> demonstrated that the addition of a left crus relaxing incision reduced tension by 35.8%, whereas a right crural relaxing incision reduced tension by 46.2%.<sup>15</sup> When combining both methods, the tension was reduced by 56.1%.

Most authors recommend covering the defect of the relaxing incision with a bioresorbable mesh. Short-term studies have shown acceptable results with the use of crural relaxing incisions when combined with biologic mesh reinforcement.<sup>16,17</sup> However, the use of biologic mesh for relaxing incisions in the left crus was associated with subsequent development of diaphragmatic hernias in one report.<sup>18</sup> Further long-term studies are needed to validate the success of this approach.

## Esophageal Lengthening

Most surgeons agree that adequate esophageal length is crucial for reducing the risk of hernia recurrence. With extensive mediastinal esophageal dissection, the goal is to bring the GE junction at least 3 cm into the abdomen

without tension.<sup>19</sup> When the appropriate amount of esophageal length cannot be obtained by additional esophageal mediastinal dissection, the addition of an esophageal lengthening procedure should be considered.<sup>20,21</sup> In the classic Collis gastroplasty, a linear stapler is fired alongside the esophagus onto the stomach at the angle of His to create a neoesophagus of 3 cm or more in length. This maneuver is difficult to perform laparoscopically, however, because of the angle of the stapler, and so more often, a wedge resection of the fundus<sup>22</sup> is done (as shown in Fig. 24-15). The wedge resection may require 2 or more applications of an articulating 6-cm stapler (blue cartridge load) and should always be done with a 54-Fr or larger bougie dilator in the esophagus to avoid narrowing of the GE junction. The stapler is maximally flexed and then first fired down across the top of the fundus toward the bougie. In some cases, a second load must be fired to get divide the fundus to the side of the bougie. The final staple load is fired cephalad, adjacent to the bougie alongside the GE junction. The staple line should then be incorporated into the fundoplication to minimize the risk of a leak.

A

B

C

D

**FIGURE 24-15** Collis gastroplasty technique using a wedge resection of the gastric fundus. **A.** With a 54-Fr bougie dilator in place, a 60-cm linear stapler is fired across the upper fundus toward the bougie. **B.** Second firing across the stomach to reach the bougie dilator in the proximal stomach. **C.** The stapler is then oriented angling cephalad alongside the bougie and fired to complete the wedge excision. **D.** The completed wedge resection line with an additional 3 cm of length added and creation of the “neoesophagus.”

A technical issue that should be considered when deciding to include a Collis gastroplasty is that the neoesophagus does not exhibit normal esophageal peristaltic actions, which may result in potential dysphagia.<sup>23</sup> In one study of 171 GERD patients, a short esophagus that required a Collis gastroplasty was found in 6.4% of patients. During a mean follow-up of 43

months, good symptom control was achieved in all patients and no reherniations were observed.<sup>24</sup> Another study found good long-term symptomatic outcomes in 52 patients who underwent Collis gastroplasty during hiatal hernia repair by either open transthoracic or laparoscopic approaches.<sup>25</sup>

## **Addition of an Antireflux Procedure**

The addition of a fundoplication has become standard in the repair of PEHs. The reason for this is that even if the patient did not have reflux preoperatively, the extensive mobilization and division of the phrenicoesophageal ligaments may predispose to reflux postoperatively, which has been demonstrated in up to 30% of patients after PEH repair with no prior history of GERD.<sup>26</sup> In addition, the fundoplication may help anchor the upper stomach intra-abdominally. Recently, a small, prospective, randomized trial was reported in which 40 patients were randomized during PEH repair using a mesh augmented hiatal repair to receive either fundoplication or a simple cardiophrenicopexy.<sup>27</sup> At the 12-month follow-up, reflux scores were lower in the fundoplication group, and esophagitis was present endoscopically in 54% of the cardiophrenicopexy patients versus 17% of patients who had a fundoplication. DeMeester scores were also significantly lower in the fundoplication group at 3 months. These findings further support routine fundoplication in PEH repair.

## **Other Considerations**

### **EMERGENCY PEH REPAIR**

A small percentage of patients with PEH may present acutely with symptoms of obstruction and possible strangulation. In one decision analysis model, the likelihood of developing acute symptoms that required emergency surgery was estimated to be 1.16% annually, and the lifetime risk of acute symptomatic presentation from the age of 65 at diagnosis onward was 18%.<sup>28</sup> The majority of patients who present acutely are clinically stable and can be managed by decompression with a nasogastric tube and subsequent elective surgery after a complete diagnostic evaluation has been done. In a study of

the National Surgical Quality Improvement Program (NSQIP) database of 3498 patients with PEH, only 5% required emergent surgery.<sup>29</sup> Emergency surgery has also been associated with an increased rate of morbidity and higher mortality, even when controlled for patient age and comorbidities, and is more often done in an open fashion.<sup>29-32</sup>

Emergent surgery for PEH is a challenging procedure and, therefore, should be carried out in high-volume centers if possible, which may also reduce the need for emergency surgery.<sup>33</sup> Most emergent cases can be done laparoscopically but require considerable experience due to the increased difficulty of managing an incarcerated, edematous stomach. If a patient cannot be decompressed by a nasogastric tube, then urgent endoscopic decompression can be attempted provided the patient is stable and does not have signs of ischemia. The indications for emergent surgical intervention include evidence of peritonitis or gastric perforation, inability to decompress the stomach by nasogastric tube or endoscopically, or suspicion of gastric ischemia (markedly elevated white blood cell count, concerning findings on CT scan, bloody emesis or nasogastric drainage, or ischemic endoscopic appearance). The operative steps are similar as for elective PEH repair. However, if the stomach cannot be reduced laparoscopically or if there is gastric necrosis, the operation should be converted to an open procedure via an upper midline incision.

## **ELDERLY PATIENTS**

An additional consideration in PEH repair is that many of the patients are elderly, which may impact recovery and outcomes. In one study that analyzed outcomes by age group, patients age 75 years and older had similar symptomatic outcomes to those under age 75 and without an increase in morbidity.<sup>34</sup> In another study of patients with giant PEH age 70 and older (median age, 78 years), the major morbidity rate after repair was 15.5% and repair resulted in significant symptomatic improvement.<sup>35</sup> Of note, 13% of patients in this series presented acutely and required urgent repair. Finally, an analysis of the NSQIP database identified 313 patients age 80 and older who underwent PEH repair. The analysis found that mortality and serious morbidity were not different between patients  $\geq 80$  years old versus those under age 80.<sup>36</sup> These results suggest that laparoscopic PEH repair can be safely performed in elderly patients without increased risk.

## GASTROSTOMY TUBE PLACEMENT

In patients with numerous underlying medical comorbidities who may not be candidates for definitive surgical repair, other techniques have been described that may reduce the patient's symptoms. The use of a percutaneous endoscopic gastrostomy (PEG) tube or laparoscopically placed G-tube has been advocated for some patients as a method to reduce the stomach and secure it within the abdominal cavity in patients who are too frail to undergo definitive surgery.<sup>37</sup> Alternatively, this method can also be used to temporize patients before definitive surgical repair, although that is rarely indicated.

## OUTCOMES

Laparoscopic PEH repair has been shown to be effective in controlling symptoms despite a high rate of recurrent hiatal hernia radiographically. These results appear similar to those seen with open PEH repair in terms of hernia recurrence rates.<sup>38</sup> A summary of selected laparoscopic series with long-term follow-up and outcomes is shown in [Table 24-2](#).<sup>34,39-47</sup> In the majority of series, recurrent hernias were seen in 20% to 35% of cases. However, the rate of observed recurrence also depends on whether radiographic evaluation was done, which detects more recurrences than if based on symptoms alone. Recurrences also appear to increase over time and, in one series, went from 16% at 1 year to 39% at 5 or more years of follow-up.<sup>45</sup> In Dallemagne's series of 85 patients with 10-year follow-up,<sup>42</sup> the observed recurrence rate was 65%; in the prospective, randomized trial carried out by Oelschlager, the radiographic recurrence rate was over 50%, both in the primary repair and biologic mesh groups.<sup>8</sup> Most series have shown that patients with recurrences are more likely to have symptoms than those who do not have a recurrent hernia. Despite these findings, the rate of reoperation has been low (<5%) in the majority of reported series.

**TABLE 24-2: SELECTED SERIES OF OUTCOMES OF LAPAROSCOPIC  
PARAESOPHAGEAL HERNIA REPAIR WITH LONG-TERM FOLLOW-UP**

Series	No. of Patients	Mean Age (years)	Recurrences	Reoperation	Follow-Up
Gangopadhyay 2006	171	65	40 (23.7%)	1 (0.6%)	25.3 months
White 2008	31	63	10 (32%)	2 (6.5%)	11.3 years
Luketich 2010	662	70 #	70/445 (15.7%)	21 (3.2%)	22 months <sup>a</sup>
Furnee 2010	70	60.6	18 (30%)	8 (11.4%)	45.6 months
Dallemagne 2011	85	66	23 (65%)	2 (3%)	99 months
Mittal 2011 <sup>b</sup>	73	70.6	4 (5.5%)	1 (1.4%)	1-5 years
Taragarona 2013	77	64	20/46 (46%)	3 (3.9%)	107 months
Jones 2015	209	57.6	35/166 (21%)	1 (0.6%)	25 months
Lidor 2015	111	61	19 (28%) <sup>c</sup>	4 (3.6%)	43.5 months
Wang 2015	115	64	41 (35.7%)	2 (1.7%)	5 years

<sup>a</sup>Represents median age and follow-up.

<sup>b</sup>Patients all had intrathoracic stomach defined as >75% stomach in the chest with associated organoaxial volvulus. Only 36 patients had follow-up beyond 1 year.

<sup>c</sup>Recurrence rate based on 70 patients who underwent radiographic evaluation at 1 year.

## MESH SERIES

As noted earlier, the role of mesh in repair of large hiatal hernias and PEHs is controversial. In the Oelschlager-led prospective, randomized trial that compared primary closure versus buttress with porcine small intestinal submucosa, the radiographic recurrence rate at 6 months was 24% in the primary closure group versus 9% in the biologic mesh group.<sup>7</sup> However, at 5-year radiographic follow-up in a subset of patients, the recurrence rates were 59% in the primary repair group and 54% in the biology mesh group.<sup>8</sup> A similar trial using 4-ply porcine small intestine submucosa and titanized polypropylene mesh that compared suture repair versus absorbable mesh versus nonabsorbable mesh showed recurrence rates of 23.1%, 30.8%, and 12.8%, respectively, at the 1-year follow-up.<sup>48</sup> Four systematic reviews and meta-analyses have analyzed this topic over the past 4 years, the results of which are shown in Table 24-3.<sup>49-52</sup> The number of studies and patients included varied in these reports, but overall appeared to favor mesh for a reduction in the rate of recurrent hiatal hernia. In the analysis by Memon and colleagues,<sup>51</sup> mesh placement was associated with a lower rate of reoperation but did not impact hernia recurrence rate or incidence of wrap migration. These findings suggest that the use of mesh for PEH repair should be individualized according to the local conditions at the hiatus and surgical expertise with the use of mesh in this location.

**TABLE 24-3: RESULTS OF SYSTEMATIC REVIEW AND META-ANALYSES OF MESH REPAIR FOR LARGE HIATAL HERNIAS**

Author	No. of Studies	Type of Analysis	No. of Patients	Recurrence Rates
Furnee 2013	26	Suture vs mesh	Suture: 247 Mesh: 451	Suture: 26.3% Me: 15.6%
Huddy 2016	9	Suture vs synthetic vs biologic mesh	Suture: 310 Synthetic mesh: 214 Biologic mesh: 152	Suture: 24.5% Synthetic mesh: 12.6% Biologic mesh: 17.1%
Memon 2016 <sup>a</sup>	4	Suture vs mesh	Suture: 186 Mesh: 220	Not reported
Tam 2016 <sup>b</sup>	13	Suture vs mesh	Suture: 382 Mesh: 354	Suture: 24% Mesh: 13%

<sup>a</sup>Analysis favored mesh placement for reoperation rate only, but not for recurrence rate and wrap migration.

<sup>b</sup>Analysis favored mesh placement for recurrence rate but not reoperation rate.

## COMPLICATIONS

Complications associated with PEH repair are those common to any foregut operation. These include gastric or esophageal perforation, bleeding, acute reherniation, and esophageal outflow obstruction, as well as general risks of thromboembolic, cardiac, and other complications. Perforation of the esophagus or stomach may result from excessive traction during the dissection, thermal injury to the esophagus or stomach, esophageal lengthening procedures, or insertion of a bougie dilator for calibration of the fundoplication. In an analysis of 379 patients who underwent primary PEH repair, the intraoperative perforation rate was 1.8%, and the most common mechanism was retraction injury to the stomach.<sup>53</sup> If a perforation occurs, it should be repaired with a 2-layer sutured closure, and a radiographic swallow should be obtained the following day. One must be careful to avoid contact of advanced energy devices (eg, ultrasonic coagulator) with the esophagus or stomach during or immediately after activation to avoid a thermal injury to the esophagus, stomach, or vagus nerves. The esophagus may be especially at risk of thermal injury because of the absence of a serosal layer.

Delayed esophageal perforation may also occur at the staple line following an esophageal lengthening procedure. This complication can often be managed by endoscopic clipping or stenting of the site of perforation. Nutrition can be delivered by either intravenous total parenteral nutrition or by feeding tube placement until healing has occurred. For patients who present with a leak postoperatively, if there are signs of peritonitis, mediastinitis, or sepsis, then emergent surgical exploration and drainage are indicated. If the leak is primarily into the chest and mediastinum, then a thoracotomy will likely be required for management.

Intraoperative bleeding most often results from injury to the spleen or splenic vessels. The best strategy is prevention by staying close to the stomach during dissection and division of the short gastric vessels, and avoiding excessive traction on the spleen. Minor splenic capsule injuries can often be controlled with tamponade and topical hemostatics. Major splenic bleeding should be managed by splenectomy. Another potential source of major and catastrophic hemorrhage during PEH repair is the aorta. Special care should be taken when dissecting posteriorly in the mediastinum, and one should avoid sweeping movements toward the aorta with the ultrasonic coagulator or scissors tips. One should also avoid placement of tacks (during mesh placement) in the hiatus in the vicinity of the aorta or deep sutures placed at the base of the crura. Cardiac tamponade has also been reported from tack placement anteriorly where the heart lies across the diaphragm.<sup>12-14</sup>

Acute reherniation of the wrap through the hiatus may occur in the immediate postoperative period, although this is uncommon. Most often, this occurrence is associated with an acute diaphragmatic stress event such as postoperative retching and emesis. For this reason, it has been our practice to administer routine emetics postoperatively to patients for the first day to minimize this risk. One should also be aware of the potential for acute reherniation in the operating room during emergence from anesthesia as the patient reacts to the endotracheal tube, which can result in vigorous Valsalva contractions with transfer of forces to the hiatus.

Esophageal outflow obstruction with symptomatic dysphagia may occur immediately after surgery or in a delayed fashion. Most commonly, this is due to obstruction at the fundoplication but can also be due to a tight crural closure or an underlying esophageal motility disorder that was not recognized preoperatively. Patients who are unable to tolerate clear liquids or who fail to empty their esophagus in the immediate postoperative period should be

evaluated by barium swallow and should be considered for early revision of the fundoplication (Fig. 24-16). For those who present in a delayed fashion, endoscopic dilation should be considered, which may provide sufficient relief of symptoms. Symptomatic dysphagia can also be a manifestation of recurrent hiatal hernia and is one of the primary reasons for reoperation after PEH repair.

**FIGURE 24-16** Acute esophageal outflow obstruction in a patient on postoperative day 1 following paraesophageal hernia repair and Nissen fundoplication. Minimal contrast passes through a narrowed gastroesophageal junction, and the esophagus is dilated proximally. This required a return to the operating room and conversion to a partial fundoplication.

## **RECURRENCES AND REOPERATIVE**

## CONSIDERATIONS

Despite the relatively high rate of recurrent hiatal hernia that can be seen after PEH repair, most patients are either asymptomatic or have symptoms that can be managed medically. This observation may be in part because a patient with a large PEH has been converted to a small type I recurrence. For this reason, most surgeons will defer reoperation on patients unless they have symptoms that cannot be managed medically. In addition, patients may also develop a recurrent PEH in the setting of prior laparoscopic antireflux surgery and repair of a type I hiatal hernia years previously (Fig. 24-17). When evaluating patients with symptomatic recurrence, the preoperative evaluation should include a barium esophagram to assess the anatomy, an EGD to assess for the nature of the recurrence and any strictures or mucosal lesions (Fig. 24-18), and high-resolution manometry. Twenty-four-hour pH testing is not usually necessary unless the symptoms are atypical. In addition, it is advisable to obtain and review any previous operative report(s) to determine the type of repair and fundoplication that was performed previously and whether any mesh was used, which may influence the operative planning.

**FIGURE 24-17** Barium swallow in a patient with a recurrent PEH after prior laparoscopic Nissen fundoplication and repair of a small type I hiatal hernia.

**FIGURE 24-18** EGD in the same patient with a recurrent PEH after prior laparoscopic Nissen fundoplication and repair of a small type I hiatal hernia.

Repair of recurrent PEHs should be carried out by surgeons with extensive experience in foregut surgery because these are challenging operations due to the extensive scarring at the hiatus.<sup>54</sup> In experienced centers, outcomes after reoperation may be similar to first-time PEH repair despite longer operative times and a higher rate of use of a Collis gastroplasty and temporary gastrostomy tubes.<sup>55</sup> Although initial port placement and operative approach are the same as for a first-time operation, often the left lateral section of the liver will be adherent to the lesser omentum, stomach, and diaphragmatic crus and must be freed to gain exposure to the hiatus and allow for retraction of the liver. Much of the dissection can be done with a laparoscopic Metzenbaum-type scissors using both sharp and blunt dissection techniques with minimal use of energy. All attachments at the hiatus should be freed and the esophagus mobilized within the mediastinum to the greatest extent possible. A determination should be made as to the mechanism of the recurrence (ie, whether it is due to failure at the hiatal closure, a short esophagus, or other technical and patient-related factors). It is generally recommended that any previous fundoplication be taken down completely at the time of the surgery to facilitate exposing the left and right crura and to allow the surgeon to have a full understanding of the anatomy and adequacy

of esophageal length. It is also more likely that additional techniques such as mesh reinforcement of the hiatal closure and the need for an esophageal lengthening procedure will be necessary to complete the repair and reduce the risk of subsequent recurrence.

The risk of esophageal or gastric perforation is increased in patients who undergo redo hiatal hernia repair and, in reported series, has been approximately 14%.<sup>53,54</sup> In most cases, these injuries can be repaired laparoscopically. It has been our practice to obtain a radiographic water-soluble contrast swallow study the morning after any redo PEH repair to exclude a leak and assess for esophageal emptying and anatomy.

## POSTOPERATIVE MANAGEMENT

Postoperatively, patients are usually started on clear liquids the morning after surgery and advanced to an esophageal diet as tolerated. Dietary instruction should be provided by a dietician before discharge. For patients who have undergone a difficult repair or redo surgery or if esophageal lengthening has been performed, a water-soluble contrast is done the morning after surgery prior to initiation of oral intake. Acid suppression medication is stopped unless the patient has undergone esophageal lengthening or had active esophagitis preoperatively. Most patients can be discharged between 1 and 3 days postoperatively depending on their age, medical comorbidities, and recovery status. After discharge, the diet may be liberalized after 2 to 3 weeks provided the patient is having no swallowing issues. Patients should be counseled about minimizing any major diaphragmatic stress long-term such as maintaining a healthy weight and avoiding severe coughing or emesis. Our practice has been to discharge patients with a prescription for an antiemetic in the event that they develop nausea. Follow-up should occur within 3 to 4 weeks. Our patients are seen subsequently at 1 year unless symptoms dictate sooner follow-up, at which time a barium swallow is obtained to document the anatomic integrity of the repair. Symptomatic assessment with a validated instrument such as the GERD Health-Related Quality of Life scale can be useful for monitoring and comparing symptoms prior to surgery and during follow-up.<sup>56</sup>

## SUMMARY

Laparoscopic PEH repair is a challenging operation that has good symptomatic outcomes as reported in high-volume centers. The foundational principles of management include a thorough preoperative diagnostic evaluation, careful risk assessment for surgery, and precise surgical technique with dissection and reduction of the hernia sac, primary crural closure with or without biologic mesh reinforcement of the hiatus, and creation of a fundoplication tailored to the patient's esophageal motility. Surgeons who undertake these operations should also be prepared for the possibility of a shortened esophagus and need for a crural relaxing incision to achieve hiatal closure. Further advancements are needed to reduce the rate of radiographic recurrences after PEH repair.

# **PERSPECTIVES REGARDING BENIGN FOREGUT DISEASES AND THEIR SURGERIES**

*Lee L. Swanstrom • Silvana Perretta*

This chapter is written by experts in the surgical treatment of a wide variety of benign esophagogastric diseases, and presents a comprehensive picture of a how to manage these patients. In this commentary, we discuss indications for operation, the surgical skill required, and the techniques required to address these benign conditions.

## **WHAT'S SO BENIGN ABOUT BENIGN ESOPHAGEAL DISEASES?**

There is a funny thing about digestive diseases, at least when it comes to their surgical treatment (perhaps their medical treatment as well—another subject....): that is that, in the universal scales of the gods of health, there seems to be an equal “disease burden” between benign and functional

diseases and cancer. This balance extends from anal/rectal disease (rectal cancer vs sphincter dysfunction, condylomata, hemorrhoids, etc), colon (colon cancer vs inflammatory bowel disease [IBD], irritable bowel syndrome [IBS], constipation, volvulus etc), small bowel (cancer vs IBD, bleeding small bowel obstruction [SBO]), Hepato-pancreato-biliary (HPB) (bilio/duodenal/pancreatic cancer vs ulcer, pancreatitis, etc.), gastric (gastric cancer vs gastroparesis, peptic ulcer disease [PUD], dyspepsia, bleeding, etc.) and esophageal (cancer vs motility disorders, achalasia, gastroesophageal reflux disease [GERD], hiatal hernia, non-cardiac chest pain, dysphagia, etc.). Obviously gastrointestinal (GI) cancer is not a good thing, and rightfully deserves a lot of attention. However, GI cancers are relatively rare when compared to functional and benign diseases. Furthermore, benign functional digestive diseases have been shown to often have a quality of life impact comparable to the worst chronic medical conditions such as diabetes, but also to debilitating acute problems such as trauma and cancer.<sup>1-4</sup> With IBD as a possible exception, the medical world, industry, and the public spends more time, money, and human resources on GI cancers than it does on the far more prevalent, costly, and often equally debilitating chronic/functional benign conditions. Of course, digestive cancers kill the majority of patients, and other than from narcotic drug overdose, the benign diseases seldom lead to death.

## **IS SURGERY THE BEST OPTION FOR PATIENTS WITH BENIGN OR FUNCTIONAL FOREGUT DISEASE?**

All of the conditions addressed in this section have a surgical option. It may be a radical surgery, minimally invasive, or endoscopic, but at some point some of these benign and essentially medical problems will need some sort of surgery. This is a daunting decision point: “...at *some* point, *some* of these, and *some* sort of surgery...” should give any sensible surgeon pause. For the surgeon and the patient with a benign foregut issue, particularly for the more chronic or functional diagnoses, the proper answer to these questions is essential. In general, a conservative initial approach is a good idea for most conditions. For the more functional conditions—noncardiac chest pain, dysphagia, gastroparetic symptoms, etc.—extensive attempts to treat

conservatively is *mandatory* before proceeding to surgery. This is because there is a substantial risk that surgery will not improve the patient's symptoms—and can even make them worse. For benign disease with a more objective definition or anatomic state, such as GERD, achalasia, and paraesophageal hernia (PEH), medical attempts at symptom control are less important but still might be required by third-party payers and offer a reassurance to the patient that the discomforts, costs, and side effects of the surgery were worth it.

## **BENIGN FOREGUT SURGERY AS AN ARTFORM**

A major problem with many benign foregut procedures is that they are reconstructive, and optimal techniques are not well described. In addition, there is a wide variety of patient anatomy, physiology, and psychology to which to adapt the surgery. Mistakes in this realm can lead to severely unhappy patients even in the face of objectively good results.<sup>5</sup> The other major problem with these surgeries is that “mastery” necessitates a holistic interest in the patient and therefore has a substantially long learning curve to achieve this highest degree of ability. Antireflux surgery provides a good example of this. In spite of being around since the 1950s, there remain a plethora of described surgical variations, both global (partial vs total fundoplication) and particular (construction with or without a bougie? etc.). Even in the face of level one evidence of the superiority or equivalency of technical approaches or details, practitioners will continue to argue and advocate their own “brand” of functional repair. In the end, it is probably more the experience of the practitioner that will determine the quality of the outcome more than particular technical details.<sup>6</sup> This is one reason that education in benign foregut operations is of critical importance, and probably justifies postgraduate fellowship training. Training for true mastery, in our opinion, should cover all aspects of the disease; diagnostics, endoscopy, minimally invasive surgery, open surgery, complication management, etc. rather than just the technical aspects of the operations.

## **NECESSITY/ADEQUACY OF THOROUGH**

## WORKUP

A common element of all benign digestive diseases being considered for surgical treatments is the need for comprehensive evaluation before crafting a surgical plan. This can include imaging, and almost always will include endoscopy. Optimally, the endoscopy should be performed by the surgeons themselves, as it is an excellent way to understand the personalized anatomy and evaluate the extent and severity of the patient's pathology. A fairly unique aspect of benign foregut disease is the interconnectedness of many of these functional disorders: diverticuli are often associated with spastic motility disorders, as is noncardiac chest pain; gastroparesis can be expressed by GERD symptoms, achalasia frequently presents as heartburn/reflux, and so forth. Because of this, comprehensive evaluation and testing is needed to achieve a total picture of the disease state and allow a treatment plan to be developed that addresses all aspects leading up to the presenting complaint. Nothing is more disappointing to the patient than having residual or new symptoms after a procedure for a benign issue. The important takeaway then is to be thorough—even redundant—in preoperative testing, and to address all discovered issues at the time of surgery.

## ARTISTIC TECHNIQUE

Many procedures for benign foregut disease, particularly antireflux surgery, suffer from wide variations in quality of outcomes. By and large, this is a result of either poor patient selection, inappropriate procedure choice, or technically poor procedure performance. These procedures, as opposed to extirpative or ablative procedures, attempt to restore or establish function of a rather complex and not totally understood part of the digestive tract. Consider all of the controversy that continues to exist regarding the physiology of the LES: Is it related to a decreased sphincter pressure or anatomic configuration of a flap valve? Where exactly does it start and stop in relation to external or internal landmarks? What is the contribution of the crura? How does hiatal hernia play into its function? And so forth. The same is true for many of the other benign diseases of the foregut—achalasia, peptic ulcer disease, gastroparesis, spastic disorders, and diverticula. These are all rather vague as to what constitutes “normal” and how exactly to get there surgically. This combination of a poor understanding of how things work and mediocre

landmarks for how to get there leads to poorly proscribed surgical recipes for reconstructive surgery. This explains why, many decades after first being described, there are many named techniques to perform antireflux or achalasia surgery (Nissen, Dor, Toupet, Hill, Lind, Watson, etc.) and even more variations within the named procedures. Such a diversity shows that these surgeries are more of a philosophic reflection or art form than a well-defined repair. The problem with this, of course, is that it makes teaching and learning these operations very difficult, and attaining mastery requires a particular focus on the disease and patient as well as many years of practice, and this knowledge may not be easily transferred to the next generation.

## COMPREHENSIVE FOLLOW-UP

Operations for benign diseases have a particular need for follow-up after surgery. This is primarily related to the subjective nature of their presenting symptoms and the frequent disconnect between subjective perception of symptoms after surgery and objective test results. It has been well documented for reflux diseases, achalasia, and gastroparesis that almost 50% of postoperative patients complaining of symptoms such as heartburn, dysphagia, and delayed gastric emptying in fact have completely normal studies.<sup>7,8</sup> And conversely, many patients with a perfect subjective result after functional restorative surgery will have abnormal results. Our philosophy, in the face of this disconnection, is to strongly urge all postoperative patients with benign reconstructive surgery to have objective testing at some point after the operation. [Table 25-1](#) lists our current follow-up recommendations for a variety of benign diseases.

**TABLE 25-1: FOLLOW-UP PARADIGMS**

	Early (<3 mo)	6 mo	12 mo	3 yr	5 yr
Reflux	SX	SX	SX, Mano, 24 hr pH	SX	SX, EGD
PEH	SX	SX, UGI	Mano, 24-hr pH, EGD	SX	SX, UGI
Achalasia	SX	SX, TBS, Mano, pH, EGD	SX	TBS	SX, EGD, 24-hr pH, TBS
Gastroparesis	SX	SX, EGD, GES	SX	GES	SX
PUD	SX	SX, EGD	SX	0	SX, EGD
Esophageal diverticula	SX	SX, UGI	EGD, 24-hr pH	0	SX, UGI
Submucosal tumor	0	EGD	0	0	EGD

Abbreviations: SX, symptom score/quality of life; Mano, manometry; 24-hr pH, 24-hour pH test; EGD, esophagogastroduodenoscopy; UGI, upper GI barium swallow; TBS, timed barium swallow; GES, gastric emptying study; PEH, paraesophageal hernia; PUD, peptic ulcer disease.

## CONCLUSION

Benign indications for surgery of the foregut represent a disease burden equal to if not greater than malignant indications. The highly subjective spectrum of presentation, the need for an artist-like approach to restoration of functional anatomy, and the unpredictable nature of symptomatic results make surgery for these indications somewhat daunting and frustrating. The surgeon's tools in this treatment are thorough evaluation and objective follow-up, meticulous technique, and the knowledge that great experience brings.

# CANCER OF THE ESOPHAGUS

*Daniel King Hung Tong • Simon Law*

## HISTORY

Historically, surgery is the mainstay of treatment for esophageal cancer. Czerny was the first who resected a cervical esophageal cancer in 1877. In 1913, Torek performed the first transthoracic esophageal cancer resection successfully.<sup>1</sup> A rubber tube was used as the esophageal substitute connecting the esophagostomy and gastrostomy for feeding in the patient, who lived for another 17 years. Reconstruction using stomach as a conduit after intrathoracic esophageal cancer resection was performed by Ohsawa, a Japanese surgeon in Kyoto, in 1933.<sup>2</sup> In 1946, Lewis described a 2-phase approach via right thoracotomy and laparotomy.<sup>3</sup> Tanner reported the same procedure in 1947.<sup>4</sup> McKeown later described the 3-phase esophagectomy via right thoracotomy, laparotomy, and cervical incision.<sup>5</sup>

In addition to surgical treatment, there has been a proliferation of treatment options, especially with regard to different combinations of chemotherapeutic agents and radiotherapy, in the past 2 decades. Significant divergence in the epidemiologic pattern between Western and Eastern

countries has been observed, which has had a major impact on the management of this disease.

## EPIDEMIOLOGY

Esophageal cancer is the eighth most common cancer worldwide and the sixth most common cause of death from cancer.<sup>6</sup> There is significant variation of incidence among different geographic regions and various ethnic groups. The disease is common in countries of the so-called “Asian esophageal cancer belt,” which stretches from eastern Turkey and east of Caspian Sea through northern Iran, northern Afghanistan, and southern areas of the former Soviet Union, such as Turkmenistan, Uzbekistan, and Tajikistan, to northern China and India. In high incidence areas, the occurrence of esophageal cancer is 50- to 100-fold higher than that in the rest of the world. It is the fourth most common cancer in China.<sup>7</sup> The age-standardized incidence rate of esophageal cancer in China is 27.4 per 100,000, compared to 10 in Japan, 7.9 in northern Europe, 7.6 in western Europe, 5.8 in North America, and 5.5 in Australia/New Zealand.<sup>6</sup> The crude age-adjusted mortality is up to 140 per 100,000, and esophageal cancer is the one of the most common causes of cancer death in China.<sup>8</sup> Esophageal cancer most commonly presents in the sixth and seventh decades of life. In most countries, esophageal cancer is a male-predominant disease.

Over the past three decades, there has been an epidemiologic shift from squamous cell cancers to adenocarcinoma of the lower esophagus and cardia in the white populations in Western countries. The incidence of adenocarcinoma has surpassed that of squamous cell cancers since the 1990s. In Eastern countries, however, squamous cell cancer remains the predominant type and is mostly located in the mid esophagus.

## ETIOLOGY

The etiologic factors for the development of esophageal cancer vary between the different histologies (Table 26-1). Smoking and drinking are independent contributing factors, as shown by prospective studies of patient who drink but do not smoke and, conversely, of patients who smoke but do not drink.<sup>9</sup>

---

**TABLE 26-1: ETIOLOGIC FACTORS OF ESOPHAGEAL CANCER**

<b>Factor</b>	<b>Squamous Cell Cancer</b>	<b>Adenocarcinoma</b>
Smoking	+++	+
Alcohol	+++	—
Hot beverages	+	—
N-nitroso-containing food (eg, pickled vegetables)	+	—
Chewing betel nut	+	—
Mate drinking	+	—
Deficiencies of fresh green vegetables, fruits, and vitamins	+	—
Low socioeconomic class	+	—
Fungal toxin or virus	+	—
History of radiation to mediastinum	+	+
Lye corrosive stricture	+	—
History of aerodigestive malignancy	+++	—
Plummer-Vinson syndrome	+	—
Achalasia	+	—
Obesity	—	++
Gastroesophageal reflux	—	+++
Barrett esophagus	—	++++

Genetic predisposition may be important in the pathogenesis of esophageal squamous cell cancer. Case-controlled studies have identified familial aggregation, suggesting that the cancer may be heritable.<sup>10</sup> Mitochondrial studies have proved historical population migrations from central-northern to southern-eastern China, where another high-incidence area is found,<sup>11</sup> again suggesting that hereditary factors may play a part. Genetic polymorphism is important in individuals with chronic alcohol consumption.<sup>12</sup> Approximately 36% of East Asians show a physiologic

response to drinking that includes facial flushing, nausea, and tachycardia. This facial flushing response is predominantly related to an inherited deficiency in the enzyme aldehyde dehydrogenase 2 (ALDH2). Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase and the acetaldehyde is, in turn, metabolized by ALDH2 to acetate. Two main variants for ALDH2 exist, resulting from the replacement of glutamate with lysine at position 487. Only individuals homozygous for the glutamate allele have normal catalytic activity. Homozygotes with the lysine alleles have no detectable activity, whereas heterozygotes with Glu/Lys alleles have much reduced ALDH2 activity. The inability to fully metabolize acetaldehyde results in its accumulation in the body, leading to the facial flushing and unpleasant side effects. Lys/Lys homozygotes could not tolerate much alcohol because of the intensity of the side effects, and so paradoxically, they do not have increased risk because they simply do not consume a significant amount of alcohol. Individuals who are Glu/Lys heterozygotes may become habitual drinkers because they can become tolerant to the side effects of alcohol and yet have suboptimal catalytic activity, and thus the acetaldehyde accumulates. These are the individuals most susceptible to the carcinogenic effects of alcohol consumption, which are related to acetaldehyde causing DNA damage and other cancer-promoting effects.<sup>13</sup> A simple questionnaire that elicits the history of a flushing response was shown to be useful in identifying at-risk individuals. They could be advised against drinking or to undergo screening endoscopy. The risk of developing cancer may be reduced or earlier diagnosis possible.<sup>14</sup>

For squamous cell cancer, in addition to drinking and smoking, dietary and environmental factors are important, especially in Asian countries. Nitrosamines and their precursors (nitrate, nitrite, and secondary amines), such as pickled vegetables, are incriminated.<sup>15</sup> Nutritional depletion of certain micronutrients, particularly vitamins A, C, and E, niacin, riboflavin, molybdenum, manganese, zinc, magnesium selenium, as well as inadequate consumption of fresh fruits, vegetables, and protein, predispose the esophageal epithelium to neoplastic transformation.<sup>16</sup> Changes in specific dietary habits, such as replacing traditional methods of food preservation and storage with refrigeration, together with consumption of vitamin-rich food, may have produced a drop in incidence rates in certain areas of China, especially in urban cities such as Shanghai.<sup>17</sup> Other dietary risk factors include consumption of hot beverages, opium smoking, chewing betel nuts,

and mate drinking in South American countries.

The human papillomaviruses<sup>18</sup> and certain fungi belonging to the genera *Fusarium*, *Alternaria*, *Geotrichum*, *Aspergillus*, *Cladosporium*, and *Penicillium* are infective agents variably found to be associated with esophageal cancer.

Patients with other aerodigestive malignancies have a particularly high risk of developing squamous cell carcinoma (SCC) of the esophagus, presumably because of exposure to similar environmental carcinogens and “field cancerization.” Using esophageal cancer as the index tumor, multiple primary cancers were found in 9.5% of patients, of which 70% were in the aerodigestive tract.<sup>19</sup> The overall incidence of synchronous or metachronous esophageal cancer in patients with primary head and neck cancer is estimated to be 3%.<sup>20</sup>

Diseases that are known to predispose to esophageal cancer are few. The risk from achalasia is estimated to be 7- to 33-fold, but symptoms of achalasia are present for an average of 15 to 20 years before the emergence of cancer.<sup>21</sup> Other diseases include lye corrosive strictures, Plummer-Vinson syndrome, tylosis, and celiac disease.

For adenocarcinoma, the reasons to account for the significant rising incidence can be attributed to the obesity epidemic, gastroesophageal reflux disease,<sup>22</sup> and Barrett esophagus, which are less common in Asian populations, with the reported prevalence of Barrett esophagus ranging from 0.06% to 19.9% in Asia.<sup>23</sup> Gastroesophageal reflux disease affects up to 44% of the general population in the United States, and approximately 5% to 8% will develop Barrett esophagus,<sup>24</sup> with an estimated annual rate of neoplastic transformation of 0.1% to 0.3%.<sup>25,26</sup> The degree of dysplasia is associated with the risk of malignant transformation, with an annual rate of 0.25% for patients without dysplasia and 6% for patients with high-grade dysplasia.<sup>27</sup> Epidemiologic data suggest a protective role of *Helicobacter pylori* against reflux. The high prevalence of *H pylori* infection in Eastern populations may guard against reflux and Barrett esophagus and may account for the difference in cancer cell type.<sup>28</sup> However, this association remains controversial.

## DIAGNOSIS

# Early Neoplastic Lesions

## SQUAMOUS CELL DYSPLASIA

Diagnosing esophageal cancer at an early stage is crucial in improving the prognosis. The 5-year survival rate is approaching 90%, and a 25-year survival rate of 50% can be achieved when cancer is diagnosed at an early stage.<sup>29</sup> In high-incidence countries such as China and Japan, national screening programs aim at early diagnosis.

The initial technique of screening in China was to use an inflatable balloon that was swallowed and retrieved to obtain abrasive cytology, whereas in Japan, a cytology sample was harvested using an encapsulated sponge.<sup>30,31</sup> This type of screening cytology has been replaced by primary endoscopic examination in high-risk areas or in populations at increased risk. Traditionally, chromoendoscopy using Lugol's iodine is a useful adjunct (Fig. 26-1). In addition, there is significant advancement of endoscopic technology to detect early neoplastic lesions. The development of narrow-band imaging allows optical chromoendoscopic examination. A high-resolution or magnifying endoscopy allows detail examination of mucosal capillary pattern and detection of early neoplastic neovascularization. A classification system of the intraepithelial papillary capillary loop (IPCL) has been introduced to grade the severity of these early neoplastic changes (Fig. 26-2).<sup>32</sup>

V-N IPCL. EMR, endoscopic mucosal resection; ESD, endoscopic submucosal dissection.

## **BARRETT ESOPHAGUS AND ADENOCARCINOMA**

Screening and surveillance for early cancer due to Barrett esophagus are controversial. Gastroesophageal reflux is prevalent among the white populations; approximately 20% of adults have heartburn at least once per week, 5% of whom have Barrett esophagus; thus, a very substantial number of patients will require screening. However, the absolute risk of adenocarcinoma is low even in subgroups of patient with severe reflux symptoms. Moreover, 40% or more of patients with esophageal adenocarcinoma have no prior reflux symptoms and therefore would not be detected through screening programs targeted to those with such reflux symptoms.<sup>22</sup> Current guidelines suggest that for patients with an established diagnosis of Barrett esophagus, surveillance is recommended. Systemic 4-quadrant, 2-cm biopsy protocol using jumbo biopsy forceps is recommended.<sup>33</sup> Dysplasia is so far the only reliable indicator of risk for development of invasive cancer. The recommendations given by the American College of Gastroenterology with regard to endoscopy interval and treatment are listed in [Table 26-2](#).<sup>34</sup>

**TABLE 26-2: MANAGEMENT PROTOCOL FOR BARRETT ESOPHAGUS**

## Flat columnar mucosa

### Systemic cold biopsy

Nondysplastic Barrett esophagus	Indefinite for dysplasia	Low-grade dysplasia	High-grade dysplasia	T1a early adenocarcinoma

—	EGD biopsy in 1 year, managed per new histology	—	—	—

### Endoscopically visible nodularity in Barrett esophagus

#### Endoscopic mucosal resection

Low-grade dysplasia	High-grade dysplasia	T1a early adenocarcinoma	T1b early adenocarcinoma	Low-grade dysplasia
Endoscopic ablative therapy	Endoscopic ablative therapy	Favorable histology? <sup>2b</sup>	Discussion at multidisciplinary oncology group	Endoscopic ablative therapy
		<div style="text-align: center;">             no →              ↓              yes           </div>		
		Endoscopic ablative therapy	Surgery	

Abbreviations: EGD, esophagogastroduodenoscopy; PPI, proton pump inhibitor.

<sup>a</sup>One year of surveillance is an acceptable alternative.

<sup>b</sup>Favorable histology: no lymphatic or vascular invasion; moderate to well-differentiated disease.

Data from Shaheen NJ, Falk GW, Iyer PG, et al: ACG Clinical Guideline: Diagnosis and Management of Barrett's Esophagus, *Am J Gastroenterol*. 2016 Jan;111(1):30-50.

Endoscopy and systemic biopsies remain the gold standard for diagnosis of Barrett esophagus, dysplasia, and early cancer. Other modalities such as cytology (with or without fluorescence in situ hybridization [FISH]), autofluorescence imaging, narrow-band imaging, optical coherence tomography, and confocal laser endomicroscopy are investigational techniques aimed at enhancing diagnostic capabilities.<sup>35</sup> It has been reported that acetic acid chromoendoscopy can increase diagnostic yield of Barrett esophagus by 6 times and the number of biopsies required to detect 1 neoplasia was 15 times fewer compared conventional protocol based biopsy approach.<sup>36</sup>

## Advanced Cancer

Evaluation of symptoms, physical signs, and demographic factors helps in the diagnosis of advanced cancer. Patients may present with different symptoms depending on the extent of disease. Elderly patients complaining of dysphagia must be assumed to have esophageal cancer until proven otherwise. Patients with chronic reflux symptoms who develop dysphagia must have tumor in the differential diagnosis in addition to reflux stricture.

In advanced disease, the most common presenting symptom is dysphagia (80%-95%) that is progressive in severity. Many patients delay seeking medical advice until severe dysphagia and weight loss have occurred.

Regurgitation is common, especially when the patient lies supine at night. Fluid regurgitation can lead to coughing, aspiration, and chest infection. Food boluses passing the tumor site may cause retrosternal pain (odynophagia). Hoarseness is the result of tumor invasion of the recurrent laryngeal nerve either by the primary tumor or nodal metastases.

The demographics of patients with SCC are different from those of patients with adenocarcinoma (Table 26-3). Patients with SCC are usually blue-collar workers with recent significant weight loss. Chronic smoking and alcohol consumption are common and lead to a higher prevalence of chronic lung disease and liver cirrhosis. A proximally located tumor more easily predisposes to aspiration pneumonia from regurgitated fluid and, in advanced cancer, tracheoesophageal fistula. Supraclavicular regions should be examined for the presence of nodal spread. Patients with adenocarcinoma usually come from a higher socioeconomic class. Adenocarcinomas are associated with obesity-related diseases such as gastroesophageal reflux disease and ischemic heart disease.

**TABLE 26-3: DEMOGRAPHICS OF SQUAMOUS CELL CARCINOMA AND ADENOCARCINOMA OF THE ESOPHAGUS**

	SCC	Adenocarcinoma
Tumor location	Mid and lower esophagus	Lower esophagus/ cardia
Comorbidity	Pulmonary disease Liver cirrhosis	Ischemic heart disease
Premalignant lesions	Dysplasia	Barrett esophagus and dysplasia
Screening/ surveillance	Balloon cytology Endoscopic with Lugol's iodine	Endoscopy surveillance
Surgical approaches	Predominantly transthoracic 2-/3-field lymphadenectomy Thoracoscopic ± laparoscopic	Transthoracic/ transhiatal 2-field or minimal lymphadenectomy Thoracoscopic ± laparoscopic or laparoscopic only

Abbreviation: SCC, squamous cell carcinoma.

## STAGING

Accurate staging allows stage-directed therapies and quality control for clinical trials. To achieve this, an evidence-based staging system and comprehensive modalities of investigation are crucial.

### Staging System

The most commonly used staging system worldwide is the American Joint Committee on Cancer (AJCC) staging and the International Union Against Cancer (UICC) TNM (tumor-node-metastasis) system.

The definitions of TNM, tumor grade, level of tumors, and nodal stations are shown in [Tables 26-4 to 26-11](#) and [Figures 26-3 and 26-4](#). The T stage advances as tumor invades from mucosa deep to muscle, adventitia, and beyond the esophagus. Regional nodes encompass areas from the neck and through the mediastinum to the upper abdomen, including the celiac nodes.

The segregation of N1 to N3 is by the number of involved lymph nodes. Location is defined by the position of the epicenter of the tumor in the esophagus and classified as X: location unknown; Upper: cervical esophagus to lower border of azygos vein; Middle: lower border of azygos vein to lower border of inferior pulmonary vein; and Lower: lower border of inferior pulmonary vein to stomach, including gastroesophageal junction. Squamous cell cancers are stage-grouped differently to adenocarcinoma. Stage-groups of both tumor types are further sub-classified as clinical (cTNM); post-neoadjuvant (ypTNM) and pathological (pTNM) stage according to the latest 8th edition of AJCC staging system.

**TABLE 26-4: DEFINITIONS OF TNM FOR ESOPHAGEAL CANCER**

## **T: Primary tumor**

Tx	Tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia, defined as malignant cells confined to the epithelium by the basement membrane
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa T1a: Tumor invades the lamina propria or muscularis mucosae T1b: Tumor invades submucosa
T2	Tumor invades the muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades the adjacent structures T4a: Tumor invades the pleura, pericardium, azygos vein, diaphragm, or peritoneum T4b: Tumor invades other adjacent structures, such as the aorta, vertebral body, or airway.

## **N: Regional lymph nodes\***

Nx	Regional nodal status cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one or two regional lymph nodes
N2	Metastasis in three to six regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes

## **M: Distant metastases**

M0	No distant metastasis
M1	Distant metastasis

---

TNM, tumor-node-metastasis.

\*Regional nodes extend from the neck to the celiac nodes.

**TABLE 26-5: DEFINITIONS OF HISTOLOGICAL GRADE (G) FOR ESOPHAGEAL CANCER**

### **Squamous cell carcinoma G category**

- GX Differentiation cannot be assessed
- G1 Well differentiated
- G2 Moderate differentiated
- G3<sup>a</sup> Poorly differentiated, undifferentiated

### **Adenocarcinoma G category**

- GX Differentiation cannot be assessed
- G1 Well differentiated, with >95% of the tumor composed of well-formed glands
- G2 Moderately differentiated, with 50-95% of the tumor showing gland formation
- G3<sup>b</sup> Poorly differentiated, with tumors composed of nest and sheets of cells with <50% of the tumor demonstrating glandular formation

---

<sup>a</sup>If further testing of “undifferentiated” cancers reveals a squamous cell component or if after further testing they remain undifferentiated, categorize as squamous cell carcinoma G3.

<sup>b</sup>If further testing of “undifferentiated” cancers reveals a glandular component, categorize as adenocarcinoma G3.

**FIGURE 26-3** Description of the different levels of esophageal tumor. Ae, abdominal esophagus; B, tracheal bifurcation; Ce, cervical esophagus; D, diaphragm; EGJ, esophagogastric junction; H, hiatus; Lt, lower third; Mt, middle third; O, esophagus; S, sternal notch; Te, thoracic esophagus; Ut, upper third.

**FIGURE 26-4** **A.** Lymph node stations according to the American Joint Committee on Cancer (AJCC) classification. **B.** Lymph node stations according to the Japan Esophageal Society.

Controversy exists regarding whether adenocarcinoma of the gastroesophageal junction (GEJ) should be staged as esophageal or gastric cancer. Adenocarcinoma of the cardia was staged as esophageal cancer according to the seventh edition of the AJCC staging system. However, assigning tumors at this location as esophageal or gastric is somewhat arbitrary. Since the launch of the seventh edition of the AJCC staging system in 2010, accumulating evidence, especially from the East (eg, Japan and Korea),<sup>37,38</sup> has suggested that type III tumors should be staged as gastric cancer instead of esophageal cancer. The definition of esophagogastric junction is thus revised in the 8th edition of AJCC system such that cancer involving it with epicenters no more than 2 cm into the gastric cardia are

staged as adenocarcinoma of the esophagus and those with more than 2cm involvement of the gastric cardia are staged as stomach cancer, even if the edges of the tumors invades the esophagogastric junction.<sup>39</sup>

In daily practice, an anatomic classification system for adenocarcinoma of the GEJ that is widely adopted is the Siewert classification. This assigns tumors 5 cm proximal and distal to the GEJ into types I to III (esophageal, cardiac, and subcardiac; Fig. 26-5). The three types of cancers differ in regard to patient demographics, possible etiology, histopathologic features, treatment approach, and prognosis. Although widely recognized with much data to support the classification, there are certain drawbacks to this system. First, assigning tumors to type I to III may lack accuracy preoperatively, especially when advanced tumors may have obliterated the landmarks endoscopically; the system classifies tumors by the epicenter of the tumor. Second, treatment, especially surgical approaches, would more depend on the proximal and distal extent of the tumors rather than the epicenter; for instance, a small tumor of 2 cm centered on the GEJ is approached quite differently from a 10-cm tumor that also centers on the GEJ. This has to be kept in mind before using this system.

C

**FIGURE 26-5** **A.** Classification of adenocarcinomas around the gastroesophageal junction (GEJ) according to Siewert. Type I, esophageal; type II, cardiac type III, subcardiac. **B.** A type I adenocarcinoma arising from Barrett esophagus. The *large arrow* points at the gastroesophageal junction (GEJ), whereas the *small arrow* points at the squamocolumnar junction. **C.** A type II cardia cancer removed as a total gastrectomy specimen and its corresponding barium contrast study. There is no evidence of Barrett esophagus.

## METHODS OF STAGING

The modalities to achieve precise staging include barium contrast studies, bronchoscopy, upper endoscopy, computed tomography (CT) scan, percutaneous ultrasound of cervical lymph nodes with or without fine-needle aspiration (FNA) cytology, endoscopic ultrasound (EUS) with or without FNA, 2-fluoro-2-deoxy-S<sub>D</sub>-glucose (FDG) positron emission tomography (PET) scan, and laparoscopy and/or thoracoscopy.

### Barium Contrast Studies

The availability of other new staging modalities makes barium contrast studies much less essential. Features indicative of presence of malignancy include mucosal irregularity, shouldering, stenotic lumen, and dilatation of proximal esophagus ([Fig. 26-6](#)). Other signs that are suggestive of advanced-stage disease include tortuosity, angulation, axis deviation from the midline, sinus formation, and fistulation to the tracheobronchial tree.

**FIGURE 26-6** Barium contrast swallow showing a stenotic tumor. Mucosal irregularities and proximal dilation with retention of contrast material are evident. A sinus often indicates infiltrative disease (*arrow*).

## **Bronchoscopy**

Bronchoscopy is performed to assess tumor invasion of the tracheobronchial tree, especially for proximally located tumors. Signs indicative of tumor involvement include widening of carina, extrinsic compression particularly from posterior tracheal wall, direct tumor infiltration, and fistulization.

Histopathologic confirmation of tumor invasion of the tracheobronchial tree precludes upfront surgical resection.

## Computed Tomography Scan

The main value of CT scan in the staging of esophageal cancer is its ability to detect distant metastasis, such as that in liver, lung, bone, and kidneys. The sensitivity for liver metastases larger than 2 cm is approximately 70% to 80%, but sensitivity is reduced to 50% if the lesion is <1 cm.<sup>39</sup> Lung metastasis is seldom a solitary lesion, and if it presents as a solitary mass, investigation should be directed to primary lung cancer or benign nodules.

In evaluation of the primary esophageal tumor, the precision of CT scan is inferior to EUS. In the diagnosis of T4 disease by CT scan, obliteration of the fat plane between the esophagus and the aorta, trachea and bronchi, and pericardium is suggestive of invasion, but the paucity of fat in cachectic patients makes this criterion unreliable. When the area of contact between the esophagus and the aorta extended for more than 90 degrees of the circumference, an 80% accuracy of infiltration was reported,<sup>40</sup> but this is by no means absolute.

The sensitivity of detecting mediastinal and abdominal nodal involvement is suboptimal with CT scans because only size alone can be used as diagnostic criterion. However, normal-sized lymph nodes may contain metastatic deposits, and enlargement of lymph nodes may be due to reactive and inflammatory hyperplasia. Studies using high-resolution helical CT scanning have demonstrated sensitivities of 11% to 77% and specificities of 71% to 95% for detection of regional nodal disease.<sup>41</sup> CT scanning is now commonly performed together with PET scanning; a composite picture is created in the same setting to correlate more accurate anatomy with metabolic uptake (Fig. 26-7).

**FIGURE 26-7** Combined positron emission tomography (PET) and computed tomography image. In addition to size of lymph nodes, the standard uptake value (SUV) often will help to determine if the lymph node is involved by cancer. A right pulmonary hilar node identified with its corresponding PET image. SUV was 3.1.

## Endoscopic Ultrasound and Percutaneous Ultrasound

EUS is the only imaging modality able to distinguish the various layers of the esophageal wall, usually seen as 5 alternating hyper- and hypoechoic layers (Fig. 26-8). The accuracy of EUS for tumor and nodal staging averages 85% and 75%, respectively, compared to 58% and 54% for CT scanning. In about one-third of patients, a conventional EUS probe cannot pass through the esophageal lumen due to tumor stricture. Miniaturized ultrasound catheter probes can be used to pass through the working channel of a conventional endoscope, which can achieve comparable accuracy to conventional EUS. A study found that predilation is safe in this situation, but the success rate of complete examination depends on the size of dilation (36% for 11-12.8 mm and 87% for 14-16 mm).<sup>42</sup>

**FIGURE 26-8** Endoscopic ultrasound (EUS) picture of an early tumor confined to the mucosa. Five layers of the esophagus can be seen; the 2 dark layers are the muscularis mucosae (inner layer) and muscularis propria (outer layer). In this tumor, the hyperechoic layer of the submucosa has not been reached. The tumor is at 6 o'clock. This lesion was removed with endoscopic submucosal dissection (ESD) technique.

Echo features of lymph nodes that suggest malignant involvement include echo-poor (hypoechoic) structure, sharply demarcated borders, rounded contour, and size greater than 10 mm, in increasing order of importance. A collective review showed that the overall accuracy of staging nodal disease was 77%.<sup>43</sup> The accuracy of EUS may differ for different lymph node locations and is related to the depth of penetration of EUS (about 3 cm). It is best for detecting paraesophageal nodes, and sensitivity varies inversely with the axial distance of the nodes from the esophageal axis. The ability to perform EUS-guided FNA cytology of suspicious nodes (such as celiac

nodes) is another factor that makes EUS superior to CT scanning.

Percutaneous ultrasound is particularly useful for obtaining FNA biopsies of cervical lymph nodes. In one large study of 519 patients, cervical lymph node metastasis was detected in 30.8% of patients (160 of 519 patients). The sensitivity, specificity, and accuracy of US diagnosis in patients who underwent subsequent cervical lymphadenectomy were 74.5%, 94.1%, and 87.6%, respectively. In those who did not undergo neck dissection, the chance of cervical nodal recurrence was low, at less than 5%.<sup>43</sup>

Information gained by combining preoperative cervical ultrasound and EUS can be highly prognostic. In one study, when the number of metastatic nodes was stratified into subgroups of 0, 1 to 3, 4 to 7, and 8 or more nodes, the number of involved lymph nodes was prognostically similar to the eventual subdivisions as determined by histologic diagnosis.<sup>44</sup> However, both percutaneous ultrasound and EUS are highly operator-dependent, and meticulous application is required to produce these results.

## **FDG-PET Scans**

PET is gaining popularity in esophageal cancer staging and is commonly used in conjunction with CT scans for better anatomic definition. For detecting the primary tumor, the sensitivity of PET ranges from 78% to 95%, with most false-negative tests occurring in patients with T1 or small T2 tumors.<sup>41,45</sup> Adenocarcinomas of the GEJ and proximal stomach sometimes show limited or absent FDG accumulation regardless of tumor volume (FDG nonavidity). Some investigators observed this phenomenon in as many as 20% of these patients, and it seems to be related to the diffusely growing subtype and poorly differentiated tumors.<sup>46</sup>

PET does not provide definition of the esophageal wall and thus has no value in determining T stage. For locoregional nodal metastases, its spatial resolution is also insufficient to separate the primary tumor from juxtatumoral lymph nodes because of interference from the primary tumor, and thus, most studies demonstrated poor sensitivity. This is especially true for nodes in the middle and lower mediastinum, where most primary tumors are found. In one study, the sensitivities of PET for detecting cervical, upper thoracic, and abdominal nodes were 78%, 82%, and 60%, respectively, but were only 38% and 0%, respectively, for the mid and lower mediastinum.<sup>41</sup> Specificity of

PET in detecting regional nodes is usually much better, reaching 95% to 100% in some studies.<sup>45,47</sup> The low rate of false-positive findings is important in preoperative staging.

A meta-analysis of 12 publications on PET scanning in esophageal cancer showed that the pooled sensitivity and specificity for the detection of locoregional metastases were 0.51 (95% confidence interval [CI], 0.34-0.69) and 0.84 (95% CI, 0.76-0.91), respectively. For distant metastases, the corresponding figures were 0.67 and 0.97. When 2 studies (out of 11) that had particularly low sensitivities for detection of distant metastases were excluded (probably because they included more early tumors), the pooled sensitivity improved to 0.72 and specificity to 0.95.<sup>48</sup> This study highlights that the accuracy of PET in locoregional nodes is only moderate.

## **Thoracoscopy and Laparoscopy**

Thoracoscopy and laparoscopy have their advocates. Thoracoscopic staging usually involves a right-sided approach, with opening of the mediastinal pleura from below the subclavian vessels to the inferior pulmonary vein with lymph node sampling. Laparoscopic staging can include celiac lymph node biopsy and the use of laparoscopic ultrasound for detecting liver metastases. One multi-institutional study (CALGB 9380) reported results in 113 patients, and the strategy was feasible in 73% of patients. Thoracoscopy and laparoscopy identified nodes or metastatic disease missed by CT scan in 50% of patients, by magnetic resonance imaging (MRI) in 40%, and by EUS in 30%. Although no deaths or major complications occurred, this approach did involve general anesthesia, one-lung anesthesia, a median operating duration of 210 minutes, and a hospital stay of 3 days.<sup>49</sup> Laparoscopy could be used in diagnosing metastases (especially peritoneal spread) or identifying unsuspected cirrhosis, which may contraindicate resection, and it could be performed as a preliminary procedure during the time of esophagogastrectomy. Its main contribution would be in lower esophageal and cardiac adenocarcinoma, whereas its value is expected to be minimal for more proximally located tumors.<sup>50</sup> Given their invasiveness, thoracoscopy and laparoscopy should be reserved for patients in whom positive confirmation of metastatic disease is not otherwise obtainable and is essential in deciding on treatment.

# TREATMENT

## Stage-Directed Therapy

Treatment options for esophageal cancer were limited in the past. Surgical resection, radiotherapy, and plastic stenting for palliation were the only 3 choices. With the advancement of technology, there has been a proliferation of therapeutic options. Staging has become increasingly more important in stratifying patients for different treatment methods, either alone or in combination with others.

## Early Squamous Cell Cancers

Early tumors include T1a-EP, LMP, MM and T1b-SM1, SM2, and SM3 lesions as defined in [Table 26-12](#). The risk of nodal metastases is the most important factor to consider in choosing the therapeutic option. The reported rates of nodal involvement in T1a-EP, T1a-LMP, and T1a MM tumors are 0%, 3.3%, and 12.2%, respectively. For T1b-SM1, SM2, and SM3 lesions, the respective rates of lymph node involvement are 26.5%, 35.8%, and 45.9%, respectively.<sup>51</sup> Five-year survival rates are 80% to 100% for mucosal cancers and 50% to 65% for submucosal cancers.

**TABLE 26-12: CLASSIFICATION OF T1 TUMORS ACCORDING TO THE JAPAN ESOPHAGEAL SOCIETY**

TX	Depth of tumor invasion cannot be assessed
T0	No evidence of primary tumor
T1a	Tumor invades mucosa
T1a-EP	Carcinoma in situ (Tis); formerly corresponds to M1
T1a-LMP	Tumor invades lamina propria mucosa (LMP); formerly corresponds to M2
T1a-MM	Tumor invades muscularis mucosa (MM); formerly corresponds to M3
T1b	Tumor invades submucosa
SM1	Tumor invades the upper third of the submucosal layer
SM2	Tumor invades the middle third of the submucosal layer
SM3	Tumor invades the lower third of the submucosal layer

---

Note. In endoscopically resected specimens, because the full thickness of the submucosa extending into the muscularis propria is not available for examination, a tumor invading the submucosa to a depth of 200  $\mu\text{m}$  is classified as SM1, whereas a tumor invading more than 200  $\mu\text{m}$  is classified as SM2.

Data from Japan Esophageal Society: Japanese Classification of Esophageal Cancer, 11th Edition: part I, Esophagus. 2017;14(1):1-36.

Tumors with minimal risk of nodal metastases, such as T1a-EP and LMP, are amenable to endoscopic mucosal resection (EMR). Circumferential mucosal resection may result in cicatricial stenosis. Therefore, EMR is indicated for lesions not exceeding two-thirds of the circumference of the esophagus. EMR can also be a feasible treatment for tumors of moderate risk of nodal metastases such as T1a-MM or T1b-SM1 (200  $\mu\text{m}$  deep from the muscularis mucosa) but without evidence of nodal spread in pretreatment staging investigation. SM2 and SM3 lesions are associated with significant risk of nodal metastases and should be treated with the same approach as in advanced cancers. The distinction of SM2/SM3 lesions from more superficial ones, however, is difficult, even with high-frequency EUS. In practice, therefore, these tumors are often resected endoscopically based on endoscopic appearance and the experience of the endoscopist. The resected specimens are then examined histologically to assess depth of infiltration and hence curability. A decision is then made regarding whether additional

treatment would be needed. The Japan Esophageal Society has published guidelines on the treatment for early cancers, especially regarding the indications for endoscopic resection.<sup>52</sup> Clinical trials are also being carried out to enhance local control and cure rate of endoscopic resection, such as the addition of radiotherapy in preventing local recurrence.<sup>53</sup>

Endoscopic resection techniques include EMR and endoscopic submucosal dissection (ESD). EMR is performed by injection of saline into the submucosal plane to raise the mucosal lesion. The lesion is then sucked into a cap fitted onto the tip of endoscope, looped by a snare wire, and cut by blend-current electrocautery. The limitation of this technique is that the size of the lesion should be less than the size of the cap, and the generally recommended size of the lesion should be less than 2 cm. For larger lesions, if resected by EMR, complete resection can only be achieved with piecemeal resection, which is associated with increased recurrence rate when compared to ESD.

ESD is more complex. There are several steps in ESD, as follows: (1) marking: the border of the lesion is marked by electrocautery; (2) submucosal injection: injection of solution into the submucosal tissue plane; (3) precut: cutting the mucosal edges along the line of marking; (4) submucosal dissection: dissecting the lesion from the submucosal bed; and lastly (5) hemostasis. There are various types of solutions used for submucosal injection; examples include glycerol, hyaluronic acid, hypertonic saline, and mannitol. The common feature of these solutions is that they can be retained in the tissue plane longer to delay dispersion. Methylene blue or indigo carmine can be added for better visualization and adrenaline to improve hemostasis. Different through-the-scope instruments are available for the cutting and dissection; the choice is mainly based on endoscopist preference. Comparing ESD with EMR, ESD has less chance of positive margins, more en-bloc resection, and lower recurrence rate, but it has slightly higher bleeding and perforation rates. The technique for ESD is more demanding, and the learning curve is longer.

For ablative therapy, radiofrequency ablation (RFA) has been applied for squamous esophageal dysplastic lesions.<sup>54</sup> The advantage is that it is technically easy to operate, but the drawback is that no surgical specimen for detailed histopathologic examination is available.

## Early Adenocarcinoma and High-Grade Barrett Dysplasia

Barrett high-grade dysplasia, synonymous with intraepithelial cancer, is the last preinvasive stage in the metaplasia-dysplasia-cancer sequence. Treatment options include intensive surveillance, mucosal ablation, and esophagectomy.

### INTENSIVE SURVEILLANCE

Proponents of endoscopic surveillance claim that such a strategy can diagnose invasive cancer at an early stage and treatment can be delayed until then without compromising prognosis. The assumed high morbidity and mortality rates of esophagectomy are also a deterrent to immediate surgical resection. Opponents of surveillance observe that the incidence of early adenocarcinoma or high-grade dysplasia is estimated at 1.1% to 6% annually, but some estimates are as high as 13.4% per year.<sup>25,26,55</sup> High-grade dysplasia is currently the only reliable marker of preinvasive cancer, but interobserver concordance is suboptimal in distinguishing invasive and noninvasive lesions. When esophagectomy is carried out in patients who have high-grade dysplasia, invasive cancer is identified in the surgical specimen in up to 42% of patients, even when patients have been recruited in surveillance programs. More recent evidence, however, suggests that this figure is an overestimate; a meta-analysis of histologic findings after esophagectomy for high-grade dysplasia revealed invasive adenocarcinoma (at least submucosal cancer) in 12.7% of patients, and most of these patients had visible lesions such as nodularity at endoscopy, a known risk for invasive cancer. In the absence of visible lesions, this figure is as low as 6.7%.<sup>56</sup> Most would regard the finding of high-grade dysplasia as a threshold for intervention. In patients who have visible lesions, such as raised nodules, and not just a flat Barrett mucosa, endoscopic resection is recommended to ensure no invasive cancer is present, followed by ablative therapy of the remaining flat columnar mucosa. Given the high incidence of progression from high-grade dysplasia to early adenocarcinoma, current guidelines recommend intervention, preferable with endoscopic therapy (Tables 26-2 and 26-13).<sup>34</sup>

**TABLE 26-13: PRACTICE GUIDELINES FOR BARRETT ESOPHAGUS FROM PROFESSIONAL BODIES**

Society, Year of Launch, Country	NDBE	LGD	HGD	Intramucosal Cancer
SAGES 2009 South Africa	Surveillance every 1-3 years	RFA		NA
NICE 2010 United Kingdom	Explain to patient about uncertainty of intervention			Offer endoscopic therapy as alternative esophagectomy
SAGES <sup>a</sup> 2010 United States	Treat endoscopically followed by surveillance			Endoscopic therapy as first line of treatment

Abbreviations: AGA, American Gastroenterological Association; HGD, high-grade dysplasia; LGD, low-grade dysplasia; NA, not applicable; NDBE, nondysplastic Barrett esophagus; NICE, National Institute for Health and Clinical Excellence; RFA, radiofrequency ablation, SAGES: South African Gastroenterology Society. <sup>a</sup>SAGES, Society of American Gastrointestinal and Endoscopic Surgeons.

## ENDOSCOPIC THERAPIES

The rationale of endoscopic mucosal treatments is that the incidence of nodal metastases is low in high-grade dysplasia or T1a (intramucosal) cancers, and therefore, treating the mucosal disease alone will result in cure. In T1a lesions, the rate of nodal metastases is low, reported as 0% to 6%. Once the submucosa is invaded (T1b lesions), this figure rises to around 20%.<sup>57</sup>

Several professional bodies have launched practice guidelines for endoscopic treatment for Barrett esophagus (Tables 26-2 and 26-9). The

options of endoscopic approaches for high-grade dysplastic Barrett esophagus and early adenocarcinoma include EMR, photodynamic therapy (PDT), and RFA.

EMR can be used to resect localized visible lesions in Barrett esophagus. A study of EMR reported by Ell and colleagues<sup>58</sup> included 100 patients, of whom complete local remission was achieved in 99%. Eleven percent of patients developed recurrence (6% locally and 5% at different locations), but successful repeated treatments were possible in all. The 5-year survival rate was 98%.<sup>58</sup> In this study, all patients had mucosal lesions of up to 20 mm, no lymphovascular invasion, and histologic grades of G1 and G2 arising in Barrett metaplasia.

In addition to resecting the localized lesions, circumferential EMR is possible to deal with the whole length of the Barrett mucosa. In one series, the complete resection rate was 76%. With a median follow-up of 32 months, however, recurrent or metachronous early cancer was found in 12% of patients.<sup>59</sup>

In addition to resectional therapy, ablative methods are available. A randomized trial demonstrated that PDT could reduce the cancer risk in Barrett esophagus. In this study, 208 patients with high-grade dysplasia were randomized to ablation using PDT with porfimer sodium plus a proton pump inhibitor (PPI) versus PPI only. High-grade dysplasia was eliminated in 77% of patients in the PDT group, although in 39% of patients in the PPI group, high-grade dysplasia was also lost on subsequent biopsies. Barrett epithelium elimination was achieved in 52% of patients in the PDT compared to 7% in the PPI group. Adenocarcinoma developed in 15% of the patients in the PDT group compared with 29% in the PPI group, with a longer time to progression to cancer favoring PDT.<sup>60</sup> The problems with PDT treatment include the need for repeated sessions, photosensitivity, stricture formation (6% in the series just described), and the phenomenon of buried glands or pseudo-regression, making continual surveillance necessary. This incidence can be as high as 51%. Because PDT does not treat nodal disease and there is no specimen for histologic examination, accurate pretherapy diagnosis of noninvasiveness is necessary.

RFA has been shown to be effective in treating both nondysplastic and dysplastic Barrett esophagus. RFA energy is delivered by bipolar electrode and the energy causes frictional heating of cellular water molecules. The

system comes with circumferential (HALO360) and focal ablative probes (HALO90). Technically, the procedure is performed under sedation. For HALO360, a sizing balloon is first introduced into the esophagus and an appropriate size of probe is chosen and inserted into the esophagus. For HALO90, the probe is mounted at the tip of an endoscope. The ablative surface is a 20-mm-long × 13-mm-wide articulated platform with an electrode array identical to the circumferential device. It is best used for ablating residual Barrett mucosa after first treatment. There are other new devices available including a similar focal HALO90 size probe that is inserted through the biopsy channel of the scope.

The Ablation Intestinal Metaplasia-II (AIM-II) trial examined the use of the HALO system in ablating nondysplastic Barrett esophagus of up to 6 cm in length. HALO360 treatment was performed at baseline and repeated at 4 months if there was residual intestinal metaplasia. Focal ablation with HALO90 was carried out after 12 months if needed. Complete remission of metaplasia was achieved in 48 (70%) of 69 patients at 12 months and in 60 (98%) of 61 patients at 30 months. No stricture or buried glands were found.<sup>61</sup>

Another trial examined the use of the HALO system in ablating dysplastic Barrett esophagus; 127 patients were randomly assigned in a 2:1 ratio to RFA or to a sham procedure. Randomization was stratified according to the grade of dysplasia and the length of Barrett esophagus. Primary outcomes at 12 months included eradication rates of dysplasia and intestinal metaplasia. In the intent-to-treat analyses, among patients with low-grade dysplasia, complete eradication of dysplasia occurred in 90.5% of patients in the ablation group compared to 22.7% in the control group. Among patients with high-grade dysplasia, the respective figures were 81% and 19%. Overall, 77.4% of patients in the ablation group had complete eradication of intestinal metaplasia, compared with 2.3% of patients in the control group. Patients in the ablation group had less disease progression (3.6% vs 16.3%) and fewer cancers (1.2% vs 9.3%). Stricture only developed in 6% of ablated patients.<sup>62</sup> A study recruited 1634 patients who achieved complete eradication for the investigation of recurrence. With an average follow-up of 2.4 years, 20% of patients had recurrence and the recurred length of Barrett mucosa was 0.6 cm, which was significantly shorter than the pretreatment length. The likelihood for recurrence was associated with increasing age, longer Barrett mucosal length, and nonwhite race.<sup>63</sup>

## ESOPHAGECTOMY

Surgical resection is the only method to ensure complete eradication of the dysplastic mucosa and the frequently undetected invasive cancer. Surgical resection was considered a standard treatment because of the high frequency of invasive cancers found in surgical specimens when resection was performed for high-grade dysplasia (up to 42%), although more recent evidence suggests that this figure is much lower, at 13%.<sup>64</sup> The supposedly high morbidity and mortality rates of esophagectomy are also deterrents against surgical resection. However, in specialized centers, the mortality rate from esophagectomy, especially in this group of patients, is minimal. Minimally invasive surgical methods, including thoracoscopy, laparoscopy, or esophageal stripping, further reduce the trauma of surgical access. Excellent long-term survival with good quality of life is reported.<sup>65</sup>

Vagal-sparing esophagectomy leaves the vagi intact and is another approach aimed at preserving quality of life; it has been shown to result in much fewer postvagotomy symptoms.<sup>66</sup> In the Merendino procedure, limited surgical resection of the distal esophagus and GEJ, together with lymphadenectomy of the lower mediastinum and upper abdominal compartment, has also been advocated. An isoperistaltic jejunal interposition graft is used to restore intestinal continuity. This method combines the adequacy of nodal dissection and improved quality of life, as the jejunal loop prevents gastroesophageal reflux.<sup>67</sup>

In summary, in patients with high-grade dysplasia or early intramucosal cancer, treatment is indicated, preferably with endoscopic modalities. When the histopathologic findings of the specimen indicate more advanced than T1a, a multidisciplinary approach of management, as for advanced-stage disease, should be considered. Recent data showed that the risk of low-grade dysplasia progressing to early adenocarcinoma is low. It is controversial regarding whether surveillance or mucosal ablative therapy should be offered. The risk of progression in patients without dysplasia is even lower, and according to clinical practice guidelines, a surveillance interval of 3 to 5 years is appropriate.

## Advanced Esophageal Cancer

Surgical resection remains the mainstay treatment for localized esophageal

cancer. Surgery in combination with multimodality treatment is also standard of care. Palliative methods have also improved when cure is not possible.

## **SURGERY FOR ADVANCED ESOPHAGEAL CANCER**

Excellent surgical outcome after esophagectomy is now achievable in dedicated high-volume centers; centralization of services also improves outcome.<sup>68,69</sup>

Important aspects to enhance better outcome after esophagectomy are (1) selecting appropriate patients for resection, (2) choice of surgical techniques and their execution, and (3) perioperative care.

**Patient Selection for Esophagectomy.** How stringently one selects patients for esophagectomy will influence the resection rate. Selection depends on many factors, including (1) the referral pattern of individual centers, (2) the prevailing treatment philosophy, (3) the availability of alternative therapies, and (4) the possible mortality that the surgeon and patient are prepared to accept. Reported resection rates range from 21% to 70% or 80%.<sup>70,71</sup> This wide variation suggests probable prereferral bias or a high prevalence of early cancers in those with high resection rates.

In studies that report on improvement of surgical results over time, more stringent patient selection often comes into play, either by excluding high-risk patients or by treating advanced disease by nonoperative means. Resection with a clear aim for palliation is becoming uncommon, and most would only operate on patients for potential cure.

The evaluation of the fitness of a patient to undergo esophagectomy is an imperfect science. Many poor-risk indicators have been identified, such as Karnofsky score of less than 80,<sup>72</sup> poor nutritional status as defined as more than 10% weight loss,<sup>73</sup> preexisting cirrhosis, and cardiopulmonary disease.<sup>72</sup> Other factors reported to be predictive of increased morbidity and mortality included advanced age, proximally located tumor, high alcohol intake, and heavy smoking.<sup>72,74</sup> Certainly, evaluating risk is important in patient selection and in preoperative counseling. In practice, however, although certain conditions can be medically optimized, there is a limit in how much the preexisting physiologic reserve of patients can be improved. Perhaps the only exception is that when significant coronary ischemia is discovered, coronary revascularization with angioplasty and stenting could be performed.

Antiplatelet agents may delay surgery. It is prudent then to treat the patient first with neoadjuvant therapy while waiting for surgery. Cessation of smoking and alcohol intake is beneficial, and chest physiotherapy and incentive spirometry should be instituted.

**Choice of Surgical Approaches.** There are many important variables in esophagectomy, such as surgical access, the extent of resection and lymphadenectomy, the type and method of preparation of the esophageal substitute, the route of reconstruction, and the technique of esophageal anastomosis. Many of these variables are interrelated and could affect immediate morbidity and mortality rates, long-term quality of life, and survival. Tumor location and stage, patient risk profile, and surgeon preference and experience are important variables in deciding the surgical procedure. The surgeon should be versatile and well versed with the many different techniques to adapt to different clinical situations.

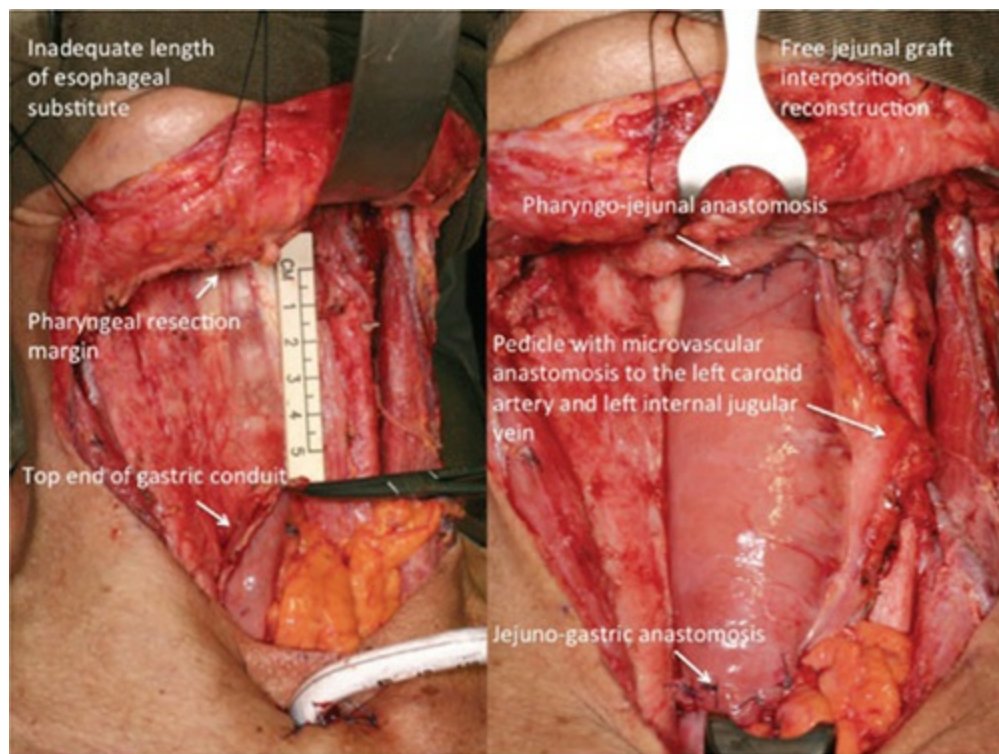

**Cervical Esophageal Cancer.** The incidence of cervical esophageal cancer accounts for 2% to 10% of all esophageal carcinomas.

Pharyngolaryngoesophagectomy (PLE), with or without adjuvant radiotherapy, has been the gold standard of treatment since first reported by Ong and Lee in 1960.<sup>75</sup> The procedure involves cervical and abdominal incisions and a thoracotomy. Tumors located at the hypopharyngeal and cervical esophageal regions were resected together with the whole length of the esophagus, and the gastric tube was pulled up to the neck via the posterior mediastinum for pharyngogastric anastomosis. A permanent end tracheostomy was created. Modern technique replaces the thoracotomy part with a transhiatal or minimally invasive approach.<sup>76</sup> The outcomes of PLE have significantly improved over the past few decades. In the authors' institute, the hospital mortality rate was brought down from 31% to 9%.<sup>77,78</sup> It is still a complex procedure with relatively high morbidity and mortality rates compared with esophagectomy for intrathoracic esophageal cancer.

For tumors confined to the cervical esophagus, other alternative reconstructive methods are available, including free jejunal interposition graft (FJ),<sup>79</sup> deltopectoral flap (DP), pectoralis major myocutaneous flap (PMF), free anterolateral thigh flap (ALT), and free posterior tibial flap (PTF) reconstruction. At the authors' institute, in a series of 202 patients who had circumferential pharyngeal defects, the leakage rates using PMF, ALT, and

FJ for reconstruction were 23.9%, 12.5%, and 4.6%, respectively. The late anastomotic stricture rates for PMF, ALT, and FJ were 27.2%, 12.5%, and 2.3%, respectively, and overall graft failure occurred in 2% of patients.<sup>79</sup> With manubrial resection, the distal extent of the FJ interposition is further lengthened, reaching the level above the aortic arch. FJ has become our preferred reconstructive method for circumferential pharyngeal defect since mediastinal dissection and its associated morbidities are avoided. FJ interposition can also be used when the gastric conduit is not long enough to reach the pharyngeal level, serving as a link between the gastric conduit and the pharyngeal defect above (Fig. 26-9).

**FIGURE 26-9** Free jejunal graft to bridge the gap between gastric conduit and pharynx.

With the possibility of laryngeal preservation when treated by chemoradiation therapy, however, surgery is often not the preferred first choice of treatment.<sup>78</sup> Therefore, the current role of surgery for cervical esophageal cancer is mainly for salvage after incomplete response or recurrent disease after chemoradiotherapy. Expectedly, surgery is made more complicated in heavily irradiated tissue when these situations arise.

***Intrathoracic Esophageal Cancer and Cardia Cancer.*** Surgical resection for tumors located in the intrathoracic segment of the esophagus entails resection of the diseased segment with adequate margin and thorough lymphadenectomy. Optimal surgical approach depends on the location of the tumor.

For upper third tumors, a 3-phase esophagectomy (MaKeown approach)<sup>80</sup> is an appropriate choice with the purpose of gaining adequate proximal margin. The intrathoracic segment of esophagus is first mobilized by right thoracotomy, followed by laparotomy for preparation of the gastric conduit, and lastly pull-up to the neck for esophagogastric anastomosis.

In Asia, most esophageal tumors are located in the middle third and are predominantly SCCs, whereas in the West, adenocarcinomas located at the lower third and around the GEJ have become the predominant type. Many surgeons prefer 2-phase esophagectomy (Lewis Tanner approach) for mid and lower third tumors.<sup>3,4</sup> The stomach is first prepared via the abdomen. This is followed by a right thoracotomy when the esophageal tumor and relevant draining lymphatics are resected. The gastric conduit is then brought to the chest for esophagogastric anastomosis near the apex of the thoracic cavity. For lower third or GEJ tumors, a left thoracoabdominal approach or a single left thoracotomy incision with diaphragmatic incision are alternatives. The transhiatal approach is more suitable for distally located tumors with anastomosis in the neck. For Siewert type II or III GEJ tumors, the lower mediastinum can be accessed by widely opening the hiatus, and this can be achieved by dividing the crus laterally and the diaphragm anteriorly. The lower esophagus can then be transected. Anastomosis is more easily constructed by using a mechanical stapler. When the proximal stomach is involved and a total gastrectomy is required, the reconstruction is then performed in Roux-en-Y manner in the lower mediastinum.

***Transthoracic Esophagectomy (TTE) Versus Transhiatal Esophagectomy (THE).*** This debate between TTE and THE remains controversial. THE avoids a thoracotomy at the expense of a thorough mediastinal lymphadenectomy, in particular the middle and superior mediastinum. Both approaches have advocates. Randomized controlled trials in the 1990s failed to demonstrate the superiority of either approach, and the main criticism was that these trials were too small to demonstrate significant differences.<sup>81,82</sup> The largest randomized controlled trial to date compared 106 patients who

underwent THE and 114 patients who underwent TTE for mid-lower third/cardia adenocarcinoma. Pulmonary complication rates were 27% for THE and 57% for TTE. The THE group had longer ventilation time, intensive care unit stay, and hospital stay. In-hospital mortality and overall 5-year survival rates were similar in both groups. Patients who underwent TTE had more lymph nodes harvested (31 vs 16). In those with 1 to 8 positive lymph nodes, TTE had a survival advantage (64% vs 23% at 5 years). However, survival rates were similar in patients without nodal metastases or with more than 8 nodal metastases.<sup>83</sup>

In choosing TTE or THE, there are several factors to consider, including the location and stage of the tumor, neoadjuvant treatment, and the intended extent of the lymphadenectomy. For upper or middle third tumors or advanced tumors closely related to the tracheobronchial tree, in patients who have had prior chemoradiation where tissue planes may have been obliterated, the THE approach may not be safe. However, THE can be more safely performed for distally located tumors where dissection can be performed under visual control. Oncologically, if extended nodal dissection is planned for the middle and superior mediastinum, THE would not be suitable, and this is only possible with TTE.

***Minimally Invasive Esophagectomy (MIE).*** Cuschieri and colleague first reported esophagectomy using video-assisted thoracoscopic surgery (VATS) in 5 patients in 1992.<sup>84</sup> Since then, various combinations of minimally invasive techniques for esophagectomy have developed. The most popular approach is the combination of thoracoscopy and laparoscopy. Other variations in methods include doing the thoracoscopic dissection in the left lateral or prone position and performing or not performing an intrathoracic or cervical anastomosis. VATS approach with intrathoracic anastomosis was reported in 1995.<sup>85</sup> Recently, the application of robotic-assisted thoracoscopic and/or laparoscopic esophagectomy using the da Vinci system has also been reported.<sup>86</sup>

The superiority of MIE compared to open approach has been investigated. Meta-analyses have shown some benefits with the minimally invasive approach. In one study, 672 patients who underwent MIE were compared with 612 patients who underwent open esophagectomy. The MIE group had reduced blood loss, less respiratory complications, shorter hospital stay, and lower morbidity rates.<sup>87</sup> The only multicenter randomized controlled trial of

MIE studied 59 patients who underwent MIE (combined thoracoscopy in prone position and laparoscopy) and 55 patients who underwent open esophagectomy. An almost 3-fold greater pulmonary complication rate was found with the open group, with no difference in mortality rate. Postoperative quality of life was also superior in the MIE group.<sup>88</sup> Oncologically, the number of retrieved lymph nodes and short-term survival were similar between MIE and the open approach.<sup>87,89</sup>

There are a limited number of reports on long-term outcome of MIE for esophageal cancer. A report from Japan that compared VATS esophagectomy versus open approach in historical cohorts found that there was no difference in 3- and 5-year survival between the 2 groups.<sup>90</sup> The 5-year stage-specific survival after MIE was reported as follows: stage I, 85%; stage IIA, 33%; stage IIB, 37%; and stage III, 16% (AJCC staging system sixth edition).<sup>91</sup> Despite the better short-term outcome of MIE, the oncologic benefit of MIE has not been proven because there has been no large-scale randomized controlled trial to verify the benefit. Conducting randomized controlled trials for esophageal cancer, especially involving MIE, was once believed to be difficult because of the small number of patients in each single institute, heterogenous surgical technique or lack of expertise to execute the procedure, and other reasons. Recently, a study group composed of 17 institutions conducted a prospective phase II trial (Eastern Cooperative Oncology Group [ECOG] 2202) to verify the feasibility of total MIE (total thoracoscopic or laparoscopic esophagectomy and esophagogastric anastomosis in the neck). A total of 95 patients underwent MIE. Anastomotic leak occurred in 8.6% of patients, acute respiratory distress syndrome in 5.7%, pneumonitis in 3.8%, and atrial fibrillation in 2.9%; the 30-day mortality rate was 2.1%; and the 3-year overall survival was 58.4%.<sup>92</sup> These results are comparable to that of open approach. Minimally invasive esophagectomy has become the standard of care at many institutions around the globe. Most reported similar, if not better, results compared with open surgery.

**Extent of Resection.** Curative (R0) resection in esophagectomy entails clear resection margins, including proximal, distal, and adventitial margins for the primary tumor, and radical clearance of the lymphatic drainage systems. Due to the differences in location between SCC and adenocarcinoma and to a certain extent their biologic behavior, the extent of lymphadenectomy performed is often different for the 2 cell types.

**Resection Margins of the Primary Tumor.** Esophageal cancer has a tendency to spread longitudinally. Studies have shown that the prevalence of intraepithelial and intramural spread could be as high as 46% and 53%, respectively, with multiplicity of tumor in 30% of patients.<sup>93</sup> The deeper the invasion of the primary tumor, the more likely this spread will happen. The chance of finding tumor histologically at the resection margin and also subsequent recurrence at the anastomosis is reduced with increasing length of the transected esophagus away from the primary tumor. An axial in situ margin of 10 cm (fresh contracted specimen of about 5 cm) is advocated, which leads to a less than 5% chance of anastomotic recurrence.<sup>94</sup> Intraoperative frozen section is one method to ensure a negative margin, although this does not guarantee absence of anastomotic recurrence later. In our experience, 7.5% of patients had a positive resection margin, 10.3% of whom developed anastomotic recurrence compared to 4.9% of patients with a negative margin.<sup>94</sup>

Positive adventitial margin increases local recurrence rate and jeopardize survival.<sup>95</sup> However, achieving a clear adventitial margin is difficult in esophagectomy because of the close relationship between the esophagus and adjacent indispensable organs. Neoadjuvant chemoradiation is increasingly being used to downstage tumor and increases the probability of R0 resection. En bloc resection is advocated in some centers and entails resection of the primary tumor together with the pericardium, thoracic duct, azygos vein, intercostal vessels, and bilateral pleurae overlying the primary tumor and a surrounding cuff of crura.<sup>95</sup> This approach, however, may not be applicable to middle or upper third tumors due to the proximity of the tracheobronchial tree and is more suitable for adenocarcinomas of the lower esophagus.

**Extent of Lymphadenectomy: Squamous Cell Cancers** The ability to perform lymphadenectomy is closely related to the surgical approach used. Lymphadenectomy for SCC is performed by transthoracic approach, either open or minimally invasive, unless only a limited lower mediastinal dissection is planned. In countries where SCCs are prevalent, transhiatal resection is uncommonly performed based on safety concerns and because the value of lymphadenectomy is less questioned. Evidence is accumulating in advocating extended lymphadenectomy. However, the risks and benefits must be balanced with the increased extent of the surgical procedure.

Different extents of lymphadenectomy for SCC have been described. The

nomenclature of mediastinal lymphadenectomy was standardized in the 1990s, although the terms are not widely adopted and are often misused. Standard 2-field lymphadenectomy involves dissection of the infracarinal lymphatic drainage system and lymph nodes around the celiac trifurcation. When additional superior mediastinal nodal dissection along the right paratracheal area and right recurrent laryngeal nerve is performed, it is called extended 2-field lymphadenectomy. If the lymphatic chain along the left recurrent laryngeal nerve is also resected, it is regarded as complete 2-field lymphadenectomy. The addition of bilateral cervical lymph node dissection is regarded as 3-field lymphadenectomy (Figs 26-10 to 26-15). For intrathoracic SCCs, detailed lymph node mapping of metastatic disease in Japan shows that lymph nodes can spread to the neck, mediastinum, and upper abdomen around the celiac trifurcation. The overall rate of cervical lymph node metastases is approximately 30%. In relation to the level of primary tumor, cervical lymph nodes are involved in 60%, 20%, and 12.5% of upper, middle, and lower third tumors, respectively. When nodes along the recurrent laryngeal nerves from the superior mediastinum are considered together with the cervical nodes as 1 entity, the “cervicothoracic” group nodes are involved in up to 63.4% of proximal third, 45.2% of middle third, and 42.0% of lower third cancers.<sup>96</sup> These data provide the rationale behind “3-field” lymphadenectomy, where the true value of extended lymphadenectomy does not lie with the addition of a cervical phase, but the completeness of the superior mediastinal dissection along the recurrent laryngeal nerves to the neck.

ligated; SA, splenic artery.

**FIGURE 26-15** For cervical lymphadenectomy, the cranial landmark is the cricoid cartilage and the caudal border is the upper margin of the clavicle. The most important nodes are the paratracheal nodes along the recurrent laryngeal nerves. Left neck dissection. CA, carotid artery; E, esophagus; IJV, internal jugular vein; LRN, left recurrent laryngeal nerve; S, stomach; T, trachea. The esophagogastric anastomosis is seen. Constructed with a 1-layer continuous suturing technique.

Three-field lymphadenectomy as practiced in Japan shows an overall hospital mortality rate of 4%. Although this very low mortality rate is achieved, most of these results come from experienced and specialized institutions, and such extensive surgery is expected to carry with it a more unfavorable outcome if it is more widely and unselectively applied. In addition, morbidity rates are substantial; septic complications were the most common at 26.8%, followed by pulmonary complications (21.3%). Recurrent laryngeal nerve injury can occur in more than 50% of patients, which

predisposes to pulmonary complications and impairs long-term quality of life.<sup>97</sup>

The realization that an extensive operation can result in substantial morbidity and that not all patients will benefit has driven the recent focus of research to further refine the indications for extended lymphadenectomy. A recent study evaluated an efficacy index (EI), which is defined as the incidence of metastasis to a region (%), multiplied by the 5-year survival rate (%) of patients with metastasis to that region, and then divided by 100. This is an assumptive figure, expressing the possible effect of dissection of a certain lymph node region to increase the 5-year survival rate of the whole group. It was found that cervical lymphadenectomy had a high EI for upper and middle third tumors but a low EI for lower third tumors.<sup>98</sup> Similarly, abdominal nodal dissection may not be beneficial for upper third tumors. In patients with demonstrable recurrent laryngeal lymph nodes preoperatively, cervical nodal dissection may be worthwhile even for lower third tumors. However, in patients without such nodes, cervical nodal dissection may not have a survival advantage. Other strategies include using intraoperative polymerase chain reaction to examine recurrent laryngeal nerve lymph nodes to predict the need for cervical dissection, similar to the concept of sentinel lymph node metastasis, and taking a 2-stage operative approach to select patients suitable for cervical lymphadenectomy. Replacing 3-field lymphadenectomy with neoadjuvant, adjuvant, or intraoperative radiotherapy is an alternative, but the role of radiotherapy remains controversial.

***Extent of Lymphadenectomy: Barrett Adenocarcinoma and Gastric Cardia Cancers.*** The lymphatic spreading behavior of Barrett adenocarcinoma and gastric cardia is different from SCC. Positive nodes are found in approximately 10% of patients with SCCs for T1a lesions, whereas in Barrett adenocarcinoma, this rate is only 0% to 6%. In T1b cancers, the respective figures are 30% to 50% for SCCs and 20% for adenocarcinomas. In addition, the pattern of lymphatic spread also differs; more than 85% of all positive nodes in early adenocarcinoma are located in close proximity to the primary tumor, in contrast to less than 60% in SCC.<sup>99</sup> Nodes are not commonly found in the superior mediastinum and, when present, probably indicate very widespread disease. Thus, lymphadenectomy is generally performed using a standard 2-field approach. The advent of transhiatal esophagectomy came at a time when esophagectomy was a high-risk operation with high mortality

rates, and this less invasive method probably contributed to reducing overall death rates. With improvement in surgical techniques and perioperative care, it seems that, in most experienced centers, when selected appropriately, both procedures can be carried out safely and the margin of benefit in reducing morbidity for most patients with the transhiatal operation is not overwhelming. In addition, more evidence has accumulated in recent years showing the benefits of radical lymphadenectomy.

Logan<sup>100</sup> and Skinner et al<sup>101</sup> first introduced the concept of en bloc resection for esophageal cancer. In en bloc resection, the thoracic esophagus is resected together with a fascial cylinder enclosing the tumor-bearing zone of the esophagus and the lymphatic drainage system. The structures for resection include the primary tumor, azygos vein, thoracic duct, pericardium, intercostal vessels and bilateral mediastinal pleurae. This approach increases clearance of the lateral margin and is most suitable for adenocarcinoma because of its tumor location. En bloc resection is less applicable for SCC, since most SCCs are located adjacent to the trachea-bronchial tree where extension of this lateral margin is not possible.

Excellent results are reported for en bloc resection in appropriately selected patients; a morbidity rate of 40%, mortality rate of less than 5%, and 5-year survival rate of 37% to 52% have been reported in dedicated centers.<sup>102</sup> Tumor recurrence rate was investigated in patients who underwent en bloc resection. The local recurrence rate is less than 5% within the field of dissection, and if nodal recurrence develops, it is mostly found outside the dissection field.<sup>103,104</sup>

For tumors of the gastric cardia (Siewert type II and III tumors), most surgeons would perform a total gastrectomy with a Roux-en-Y jejunal loop reconstruction, although some would prefer to preserve the distal stomach for anastomosis. An upper abdominal compartment nodal dissection around the celiac axis seems routine for all, but complete lower mediastinal nodal dissection is somewhat controversial. Some argue that thorough lower mediastinal dissection is needed, and this is only possible with the addition of a thoracotomy. Others believe that this is unnecessary, and mediastinal nodal involvement could indicate advanced disease for which survival is poor regardless of the extent of lymphadenectomy. The Japanese Oncology Group trial 9502 addressed this question. Patients whose tumors were Siewert II or III adenocarcinomas and that infiltrated into the esophagus for less than 3 cm were randomly assigned to a transabdominal (n = 82) or left

thoracoabdominal approach (n = 85). A more thorough mediastinal dissection was deemed only possible with the later approach. The trial was closed prematurely after the first interim analysis, when the predicted probability of the left thoracoabdominal approach having a significantly better overall survival than the transabdominal route at the final analysis was only 3.7%. The morbidity rate was worse after the left thoracoabdominal approach. Thus, a transabdominal approach seems adequate, but the surgeon must be prepared to add a thoracotomy when frozen section indicates a positive proximal resection margin.

Another pivotal trial is the Dutch trial comparing THE versus TTE for Siewert type I and II adenocarcinoma of the GEJ; the details have already been discussed earlier.<sup>105</sup> For type I cancers, TTE with mediastinal lymphadenectomy may impart a survival advantage in patients with limited nodal metastases.

Regardless of histology, more data have emerged supporting the benefits of radical lymphadenectomy. An international multicenter study involving 2303 patients showed that presence of nodal metastases, number of nodes involved, and number of nodes removed were important prognostic factors in addition to depth of tumor invasion, age, sex, and histologic type. The number of nodes removed (reflection of the extent of lymphadenectomy) correlated with overall survival. The optimal number of nodes resected in this study was 23.<sup>106</sup> The Worldwide Esophageal Cancer Collaboration (WECC) involving 4627 patients with either SCC or adenocarcinoma suggested the optimal number of nodes to be removed should be related to the pT stage: 10 for pT1 tumors, 20 for pT2, and 30 for pT3 or pT4.<sup>107</sup>

## **RECONSTRUCTION AFTER ESOPHAGECTOMY**

The reconstruction phase of an esophagectomy determines to a significant extent the postoperative morbidity and long-term quality of life. The main areas to consider in reconstruction are the choice of esophageal substitute and the route of reconstruction.

### **Choice of Esophageal Substitute**

The most commonly used conduit is the gastric tube, and of the many configurations, an isoperistaltic tube based on the greater curvature with preservation of the right gastric and right gastroepiploic vessels is most reliable. The simplicity of preparation, adequate length, and robust blood supply make it the first choice as the esophageal substitute (Fig. 26-16). Disadvantages of the gastric conduit include the fact that patients who have an intrathoracic stomach often experience postprandial discomfort and early satiety related to loss of normal gastric functions such as receptive relaxation. Patients can also suffer from acid reflux, possible gastric ulceration, and dysfunctional propulsion. The level of the esophagogastric anastomosis has a bearing on the severity of reflux. Patients who have a low intrathoracic anastomosis tend to have more severe reflux and esophagitis compared with the high intrathoracic or cervical anastomosis. Preserving a longer length of esophagus, on the other hand, theoretically may enhance swallowing function. Inadequate gastric emptying can be a problem. A pyloric drainage procedure is not universally practiced. In a randomized trial, 13% of patients who did not have a pyloroplasty had problems with gastric emptying.<sup>108</sup> A meta-analysis suggested that a drainage procedure lessens the chance of early postoperative gastric stasis, but long-term function is not affected.<sup>109</sup>

**FIGURE 26-16** Gastric conduit prepared for transposition to the neck for pharyngoesophagostomy after pharyngolaryngoesophagectomy. Ample length is evident.

Many other factors contribute to emptying of the intrathoracic gastric conduit. A smaller stomach enhances postoperative emptying. The straighter

position of the stomach, when delivered to the neck via the posterior mediastinal or the retrosternal route, may make the stomach empty more efficiently compared to one placed in the right pleural cavity, where the angulation at the diaphragmatic hiatus as the stomach continues from the right paravertebral gutter into the abdomen may produce relative obstruction. Rotation of the stomach at the hiatus should be avoided. With a gastric conduit, diet modifications and the use of acid suppressive and prokinetic drugs such as erythromycin may be useful.

There are instances when the stomach cannot be used, such as after previous gastric resection, and tumor involvement of a substantial part of the stomach dictating its removal. In these situations, the use of the colon is preferred. For most, colonic interposition remains an infrequently performed procedure and has the potential for more complications. Mobilization of the colonic loop is more complex; its blood supply is less reliable than the gastric conduit; 3 anastomoses are required; and when the colon becomes ischemic, the choice of alternative conduit is restricted. In our experience, use of a colon loop is associated with more blood loss, a longer operating time, and a higher anastomotic leak rate. Colon ischemia occurs in 1 of 42 patients (2.4%), which compares favorably to a rate of 3% to 10% reported in the literature.<sup>110</sup>

A colonic conduit provides good long-term swallowing function; it seems to have active peristalsis, and this is cited as an explanation for its superior function as an esophageal substitute when compared with a passive gastric conduit. Although peristalsis can be demonstrated immediately following surgery, long-term emptying likely relies on gravity. When the distal stomach is retained in the abdomen after a colon interposition with a cologastric anastomosis, the latter provides additional reservoir function. A recently published study demonstrated that the colon could be used as the first choice for esophageal substitute with acceptable outcomes when compared to using the stomach and also avoids the problem of acid reflux. The stomach is preserved for its reservoir function.<sup>111</sup>

The jejunum is used most frequently after distal esophagectomy and total gastrectomy for cancer of the lower esophagus and gastric cardia. A Roux-en-Y configuration seems best, as it prevents bile reflux to the esophagus. A jejunal loop used in a modified Merendino procedure to interpose between the esophagus and proximal stomach after limited resection of the distal esophagus and GEJ has also been advocated.<sup>112</sup> Excellent postoperative

quality of life and function are claimed. A long jejunal loop is sometimes used to reach the neck, but preparation is tedious and the vasculature may not be reliable; a “supercharge” using a microvascular anastomosis to cervical vessels may be required.<sup>113</sup> A free jejunal graft is used for reconstructing the defect after resection of the pharyngoesophageal segment in the neck, as previously discussed (Fig. 26-9).<sup>79</sup>

## Route of Reconstruction

The method of reconstruction is in part related to the surgical approach for resection. When a cervical anastomosis is chosen, one must decide whether to place the conduit via the orthotopic, retrosternal, or subcutaneous route. The subcutaneous route is rarely used because it is cosmetically unsightly. The retrosternal route was shown to be associated with increased or similar cardiopulmonary morbidity and mortality rates.<sup>114</sup> The retrosternal route is 2 to 3 cm longer compared to the orthotopic route, but this is rarely of relevance because the esophageal replacement conduit is usually of sufficient length. Some suggest that the tight space at the thoracic inlet in the neck could cause potential constriction on the conduit and recommend partial manubrial, clavicular head, and first rib resection; we have found this unnecessary. Functionally, although it was shown that there is a higher rate of gastric retention when the retrosternal route is used, quality of life is not adversely affected. The orthotopic route of reconstruction may maintain better nutritional status than the retrosternal route.<sup>114</sup>

When palliative resection is carried out for advanced tumor, recurrent tumor could infiltrate into the conduit placed in the posterior mediastinum. In a retrospective study of 209 patients who had undergone curative resection and orthotopic reconstruction, of 73 patients (35%) who had locoregional tumor recurrence, 46 (22%) had secondary dysphagia as a result. The authors concluded that in 27 patients (13%) dysphagia would likely have been prevented by using a retrosternal reconstruction route.<sup>115</sup> However, the site of the obstruction that produced dysphagia was not clearly stated. The stomach is usually spacious, and tumor infiltration will not readily result in dysphagia. Only at the thoracic inlet and in the cervical region, where there is limited space, can tumor involvement lead to obstruction. Using the retrosternal route will eliminate tumor involvement in the posterior mediastinum, but

infiltration from tumors in the neck cannot be avoided. The benefits of choosing the retrosternal route in reducing secondary dysphagia from recurrent tumor infiltration may be overemphasized. In our own study, only 4 (14%) of 28 patients developed tumor infiltration into the gastric conduit in the posterior mediastinum.<sup>116</sup> The main symptom was bleeding in 2 patients, and none had dysphagia. Therefore, it is our policy to only use the retrosternal route for reconstruction when resection is palliative, especially when postoperative radiotherapy is planned, or when the reconstructive phase of the operation precedes tumor resection.

## **PERIOPERATIVE CARE AND POSTOPERATIVE MORBIDITY AND MORTALITY**

Esophagectomy mortality has significantly improved in the past 3 decades, but it is still a major procedure with risk. In the West, the mortality rate is between 7% and 9%, and the overall complication rate ranges from 17% to 74%.<sup>117</sup> With adequate preoperative workup, however, serious cardiac events like myocardial infarction should be rare. Atrial arrhythmia is common, affecting about 20% of patients. In itself, atrial fibrillation is benign, but it serves as a marker for more serious underlying pulmonary and septic surgical complications.<sup>118</sup> Occurrence of atrial arrhythmia should prompt thorough search for a more ominous underlying cause.

Pulmonary complications remain the most common and serious postoperative morbidity. Major complications can affect 30% of patients; most series report a rate of about 20%.<sup>119</sup> Pneumonia and respiratory failure occurred in 15.9% of our patients and were responsible for 55% of hospital deaths. Predictive factors include advanced age, supracarinal tumor location (in part related to recurrent laryngeal nerve injury), and lengthy operating time. Neoadjuvant therapy did not lead to increased morbidity.<sup>74</sup> Measures to improve respiratory outcome include cessation of smoking preoperatively, chest physiotherapy, avoidance of recurrent laryngeal nerve injury, cautious fluid administration to avoid fluid overload, use of smaller chest tubes,<sup>120</sup> early ambulation, regular bronchoscopy, and early tracheostomy for sputum retention.<sup>121</sup> Epidural analgesia is invaluable in postoperative pain relief and

has been shown to improve outcomes.<sup>122</sup>

The most common surgical complication after esophagectomy is anastomotic leak. A leak rate of below 5% can be achieved in dedicated centers.<sup>123</sup> Most leaks are probably related to technical errors, such as tension between the conduit and the esophageal stump, ischemia of the conduit as a result of rough handling and poor preparation, and suboptimal technique. The intrinsic vascular perfusion of the stomach can be enhanced by certain methods, such as “ischemic preconditioning,” whereby partial mobilization of the gastric conduit is later followed by a second-stage anastomosis.<sup>124</sup> The perfusion of the stomach could be shown to improve in the interim period. Although an interesting concept and potentially useful, the existing wide range of reported leak rates (from 2%-3% to 30%) suggests that much improvement is possible by other means, even without ischemic conditioning.

A recently devised technique to assess conduit perfusion intraoperatively is laser-assisted fluorescence. Indocyanine green is injected intravenously, and angiography of the substitute is evaluated. A recently published study on 144 patients who underwent esophagogastric anastomosis showed that the leak rate was significantly less when the anastomosis was performed at the site of robust blood perfusion compared to a site that was less well perfused (2% vs 45%).<sup>125</sup>

The actual method of anastomosis is perhaps less important than its proper application. Stapled anastomosis is popular for intrathoracic anastomosis, whereas the hand-sewn technique is preferred in the neck. There is no evidence from randomized trials that leak rates differ between stapled and hand-sewn anastomoses, but the circular stapler may give rise to more strictures.<sup>126</sup> The linear stapler has also been advocated in the neck. One group reduced their cervical leak rate from 10% to 15% using a hand-sewn technique to 2.7% using linear staples with a side-to-side anastomosis.<sup>127</sup> With experience, however, the hand-sewn method is as safe, if not more so, and certainly less expensive.

As mentioned already, technical variables play an important role in the genesis of postoperative complications. Anastomotic leaks (largely technical) and recurrent laryngeal nerve injury, for instance, are related to higher incidences of postoperative pulmonary morbidities. At the author’s center, pulmonary complications occurred in 10% of patients without technical complications and in 38% of patients who developed such morbidities, and

mortality rates were 3.3% and 9.2%, respectively. Multivariate analyses also demonstrated that a long operating time is related to pulmonary complications, and increasing intraoperative blood loss is related to postoperative mortality. In sum, the meticulous and expeditious execution of an esophagectomy and its subsequent reconstruction are of paramount importance in lessening complication and mortality rates.

Vigilant and aggressive treatment of complications is important for good outcomes. Management of complications has improved with time. At the author's unit, the anastomotic leak rate was 16% in the 1960s to 1970s; 61% of these patients died, resulting in a leak-related mortality of 9.8%. In the 1980s, the leak rate was 3.5%, and 35% of these patients died, for a leak-related mortality of 1.2%, whereas in the late 1990s, leak occurred in 3.2% of patients and none died as a result. Leak rate has remained similar since.

Other surgical complications such as chylothorax and herniation of bowel through the diaphragmatic hiatus are rare but should be recognized early; both are corrected by surgical reexploration.

## **Standardization of the Definition of Perioperative Complications**

Variation in institutional practice may contribute to different outcomes. A recently published study shows that there is significant interinstitutional heterogeneity with regard to reporting of postesophagectomy complications.<sup>128</sup> Another study identified 210 different complications in 98 publications, more than 60% of which did not specifically define the reported complications.<sup>129</sup> A review of esophageal outcomes from 164 National Surgical Quality Improvement Project (NSQIP) hospitals in the United States demonstrated that operative results between centers varied by 161% for 30-day mortality and 84% for major morbidity.<sup>130</sup> To resolve this issue, an international consensus on standardization of data collection and definitions for complications of esophagectomy with participation of 13 countries has been launched.<sup>131</sup> Consistency in definitions of complications and survival allows more meaningful and accurate comparison of outcomes between centers and will possibly improve the quality of care in the future.

# MULTIMODALITY TREATMENT STRATEGIES

The past 3 decades have seen a proliferation of additional treatments for esophageal cancer. The rationale is based on the suboptimal long-term results of surgery or radiotherapy. Both the spatial and synergistic actions of chemotherapeutic agents and radiotherapy are explored in multimodality treatments. How surgical resection and these new combinations should be integrated into treatment programs is an active area of research.

## Neoadjuvant Radiotherapy

Neoadjuvant radiotherapy has not been shown to increase resection rate or improve survival when compared with surgery alone. The European Organization for Research and Treatment of Cancer (EORTC) study suggested improved local disease control but no better long-term outcome.<sup>132</sup> A Cochrane meta-analysis showed that if preoperative radiotherapy regimens do improve survival, the effect is likely to be modest, with an absolute survival benefit of 3% at 2 years and 4% at 5 years that was not statistically significant ( $P = .062$ ).<sup>133</sup>

## Adjuvant Radiotherapy

The largest randomized controlled trial on adjuvant radiotherapy recruited 495 patients with intrathoracic SCCs for analysis. Postoperative radiotherapy of 50 to 60 Gy was given in 220 patients to the entire mediastinum and bilateral supraclavicular fossae. Per-protocol analysis showed no overall difference in 5-year survival, which was 31.7% for the surgery-alone group and 41.3% for the radiotherapy group. A benefit in the radiotherapy group was observed in stage III patients; 5-year survival rates were 13.1% and 35.1%, respectively. In patients with node-positive disease, the difference in survival was of borderline significance. The chance of mediastinal, cervical lymph node, and anastomotic recurrence was also reduced.<sup>134</sup> Survival benefit was not demonstrated for the other trials. Postoperative radiotherapy may be beneficial to subgroups of patients, especially those who have palliative resections, to enhance local disease control.

## Neoadjuvant Chemotherapy

The role of preoperative chemotherapy was studied extensively. The 2 largest trials were the Intergroup (INT 0113) trial in the United States and the Medical Research Council (MRC) (OE02) trial in the United Kingdom. The first study randomized patients to undergo surgery alone or to have 3 cycles of cisplatin and fluorouracil before surgery and, in those who had stable or responsive disease, 2 additional postoperative courses.<sup>135</sup> Of 440 eligible patients, 213 were assigned to the neoadjuvant group. The median survival was 14.9 months for the chemotherapy group compared with 16.1 months for the surgery group. Two-year survival rates were no different at 35% and 37%, respectively. The MRC trial (OE02) involved 802 patients and similar preoperative regimens with 2 courses of cisplatin and fluorouracil.<sup>136</sup> Overall survival was better in the chemotherapy group. Median survival was 16.8 months versus 13.3 months, and 2-year survival rates were 43% and 34%. The long-term follow-up data have been reported; with a median follow-up of 6 years and 93% of patients followed to 5 years or death, 5-year survival rates were 23% in the chemotherapy group compared with 17% in the surgery group. Benefits were evident for both SCC and adenocarcinoma.<sup>137</sup>

Many differences between the 2 studies could explain the different outcomes, including the chemotherapy regimen, distribution of histologic cell types (66% adenocarcinoma in the MRC trial and 54% in the INT trial), the number of patients who underwent resection, time to resection, type of surgery performed, and number of patients who also had radiotherapy. The larger sample size in the MRC trial also could have facilitated the detection of a small improvement with chemotherapy.

A Japanese study conducted by the Japanese Clinical Oncology Group (JCOG 9907) randomized 330 patients with stage II or III SCCs (excluding T4 disease) to either 2 courses of preoperative cisplatin and fluorouracil or a similar regimen given after esophagectomy. Overall 5-year survival was significantly better at 60% in the preoperative chemotherapy group compared to 38% in the postoperative group.<sup>138</sup> Although this trial did not specifically compare preoperative chemotherapy to surgical resection alone, this has quickly become a standard-of-care treatment in Japan. In the United Kingdom, the MRC OE02 trial has also established preoperative chemotherapy as a widely practiced strategy.

OE05 compares the OE02 preoperative chemotherapy regimen (2 cycles of cisplatin and fluorouracil [CF]) to 4 courses of preoperative epirubicin, cisplatin, and capecitabine (ECX) in patients with adenocarcinoma of the esophagus and GEJ (Siewert type I and II; note that OE02 involved both SCC and adenocarcinoma), followed by esophagectomy with 2-field lymphadenectomy. From 2005 to 2011, 897 patients (CF, n = 451; ECX, n = 446) from 72 centers were randomized. ECX resulted in more toxicities, but postoperative complications and mortality rates were similar (90-day mortality rates were 4% for CF and 5% for ECX). Progression-free survival and disease-free survival favored ECX, but statistically, they were not significantly different; same was true for overall survival. Three-year survival rates were 39% for CF and 42% for ECX.<sup>139</sup>

The MRC Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial, a randomized study, included 503 patients with adenocarcinoma of the stomach, GEJ, and lower esophagus. Initially planned for gastric cancers, eligibility criteria were extended to include lower esophageal adenocarcinoma coinciding with termination of OE02. Thus, 14% of patients had lower esophageal tumors, and another 12% had GEJ tumors. Three courses of epirubicin, cisplatin, and infused fluorouracil (ECF) were given to patients before surgery, and 3 courses were repeated afterward; patient who received this regimen were compared to patients who underwent surgical resection alone. Both progression-free and overall survival rates were improved in the chemotherapy group.<sup>140</sup>

## Adjuvant Chemotherapy

This is an area perhaps least well studied, and trials on pure postoperative chemotherapy are limited. JCOG 9907, mentioned in the previous section, was in fact a follow-up study on JCOG 9204, which randomized 242 patients comparing surgical resection with and without the addition of 2 courses of postoperative cisplatin and fluorouracil. The 5-year disease-free survival rate was significantly different between the groups (45% with surgery alone and 55% with surgery plus chemotherapy). The overall 5-year survival rates were not significantly different, at 52% and 61%, respectively. The effect was more marked in the subgroup with lymph node metastases.<sup>141</sup>

## Neoadjuvant Chemoradiation

The Chemoradiotherapy for Oesophageal Cancer Followed by Surgery Study (CROSS) trial randomized 366 patients to chemoradiotherapy followed by surgery (n = 178) versus surgery alone (n = 188). It was shown that neoadjuvant chemoradiotherapy did not increase morbidity and the hospital mortality rate. The neoadjuvant chemoradiotherapy group had a significantly better median survival of 49.4 months versus 24 months in the surgery-only group. The 5-year overall survival also favored neoadjuvant chemoradiotherapy plus surgery over surgery alone with a median of 45 months of follow-up. Seventy-five percent of the population in this study had adenocarcinoma, 23% had SCC, and 2% had large-cell undifferentiated carcinoma. On subgroup analysis, neoadjuvant chemoradiotherapy for adenocarcinoma had a better survival than surgery alone, and similar findings were identified for SCC.<sup>142</sup> The long-term follow-up (a minimum of 5 years) results demonstrated that the median overall survival for patients with SCC was 81.6 months in the neoadjuvant chemoradiotherapy plus surgery group and 21.1 months in the surgery-alone group. For adenocarcinoma, the survival time was 43.2 months in the neoadjuvant chemoradiotherapy plus surgery group and 27.1 months in the surgery-alone group.<sup>143</sup>

Walsh and colleagues investigated neoadjuvant chemoradiation for adenocarcinomas only, but the trial was criticized for inadequate preoperative staging, unclear surgical procedures, and a large number of protocol violations, and survival from the surgery group was exceptionally poor (3-year survival rates were 32% and 6% for the preoperative treatment group versus surgery-alone group, respectively).<sup>144</sup>

Although it cannot be said conclusively that neoadjuvant chemoradiotherapy is superior to surgery alone in the treatment of localized esophageal cancer, it is widely practiced, especially in the United States. Neoadjuvant chemoradiotherapy does result in more pathologic complete responses compared with chemotherapy (25%-30% vs <10%). One trial compared preoperative chemotherapy with preoperative chemoradiation therapy in advanced adenocarcinoma of the lower esophagus and GEJ. More pathologic complete responses were observed in the chemoradiation group (16% vs 2%), and more patients had negative nodal involvement (64% vs 38%). A trend toward improved median survival (32.8 vs 21.1 months) and 3-year survival (47.4% vs 27.7%) was also seen, although these results did

not reach statistical significance.<sup>145</sup>

## **Definitive Chemoradiation**

The Radiation Therapy Oncology Group (RTOG 85-01) trial of chemoradiation versus radiotherapy provided convincing evidence of the superiority of chemoradiation.<sup>146</sup> The 5-year survival rate reported for the combined therapy group was 26% compared to 0% after radiotherapy (median survival, 14 vs 9 months). Data on recurrence patterns showed that both local and distant disease control were superior with combined treatment. Local persistence of disease and recurrence rates were 47% for chemoradiotherapy and 65% for radiotherapy. Intensification of radiation dose to beyond 50.4 Gy did not yield further advantage but potentially added complications.<sup>147</sup>

A Cochrane meta-analysis on 13 randomized trials that compared chemoradiation with radiation confirmed the superiority of chemoradiation. Concurrent chemoradiation provides a significant overall reduction in mortality at 1 to 2 years, an absolute reduction in death rate by 7%, and a reduction in local persistence/recurrence rate by 12%. The downside is a 17% increase in grade 3 and 4 toxicities. Sequential chemoradiation provides no benefit, perhaps demonstrating the need to maximize the radiosensitizing properties of chemotherapy.<sup>148</sup>

## **The Role of Surgery**

The RTOG trial suggested that, in patients with T1-3N0-1M0 disease, a 14% to 26% 5-year survival can be expected. It has been suggested that surgery may be of no additional value to chemoradiation and should be relegated to use as an adjuvant treatment.

Two clinical trials attempted to examine whether surgical resection was necessary after chemoradiation. A French study (FFCD 9102) treated 444 patients with both SCCs and adenocarcinomas of stage T3-4N0-1M0 with 2 cycles of fluorouracil, cisplatin, and concurrent radiation (46 Gy at 2 Gy/d or split course of 15 Gy in weeks 1 and 3). Only 259 patients who had at least a partial response were randomized to undergo immediate surgery or to have 3 more cycles of chemotherapy with 20 Gy at 2 Gy/d or split-course 15 Gy.

The death rate within 3 months after starting induction treatment was 9% for the surgery group compared with 1% in the chemoradiation group. Two-year survival rates (34% and 40%) and median survival (17.7 and 19.3 months) were not significantly different between the surgical and nonsurgical groups, respectively. Patients in the surgical arm, however, required stenting less often (13% vs 27%) and fewer dilations (22% vs 32%).<sup>149</sup> There was no difference in the long-term quality of life, but the surgery arm had transient deterioration in the immediate postoperative period.<sup>150</sup>

A German multicenter trial recruited 172 patients with SCC (T3-4N0-1M0). Three cycles of fluorouracil/leucovorin/etoposide/cisplatin were given followed by chemoradiation (cisplatin/etoposide + 40 Gy). Resection was then performed. This was compared to a control group administered the same chemotherapy, followed by definitive chemoradiation (cisplatin/etoposide + >60 Gy).<sup>151</sup> A nonsignificant trend toward better overall survival at 5 and 10 years was observed: 27.9% and 19.2% in the resection group, compared to 17.0% and 12.2% in the chemoradiation-alone group. Local tumor control was significantly worse in the nonsurgical arm. Three-year survival rate was 35% in nonresponders undergoing complete tumor resection compared to 11% in nonresponders who did not undergo resection. Both the French and German studies concluded that surgical resection may not be necessary after chemoradiation therapy.

It may be premature to negate the value of surgical resection. First, chemoradiation is by no means harmless, and surgical resection may not be as morbid as described. Treatment duration of chemoradiation is often long, and compliance is problematic. Only 68% of the patients in the RTOG 85-01 trial could complete the planned treatment.<sup>146</sup> In the control arm of INT 0123, acute grades 3 and 4 toxicity affected 43% and 26% of patients, respectively, and long-term grades 3 and 4 toxicity affected 24% and 13% of patients, respectively.<sup>147</sup> Treatment-related mortality was 5% to 9%, as reported by the INT trials.<sup>147</sup> In studies that showed a benefit for chemoradiation or questioned the value of surgical resection, the results of the surgical arm were often suboptimal. In the FFCD 9102 trial, the death rate within 3 months in the surgical arm was 9% compared to 1% in the nonsurgical arm<sup>149</sup>; in the German trial, the mortality rates were 10% and 3.5%, respectively.<sup>152</sup> The early surgical deaths likely biased the long-term survival results. Comparisons with nonoperative treatments will only be valid

when better results from high-volume centers are integrated into clinical trials.

Second, local disease control with chemoradiation alone is less than satisfactory. It can be shown that with increasing extent of lymphadenectomy, better local control is achieved with surgery; by comparison, nonoperative chemoradiation has a much higher local persistence/recurrence rate of over 50%.<sup>147</sup> The relief of dysphagia, the main symptom requiring palliation, is much more certain with surgical resection; the need to treat dysphagia with a stent occurred twice as often in the nonsurgical group in the FFCD 9102 trial.<sup>149</sup>

Third, residual disease exists for the majority of patients treated by chemoradiation. The pathologic complete response rate for most trials is in the region of 25% to 30%. Thus, it is logical to assume that surgical resection would enhance cure at least in the remaining 70% to 75% of patients who did not completely respond. In the German trial, the 3-year survival of nonresponding patients who underwent resection was 35% compared with 11% in those who did not.<sup>152</sup> In the FFCD 9102 trial, 192 patients were not randomized primarily because of lack of objective response but also because of medical contraindications or patient refusal. Of these, 112 patients had operations; among these patients, 80 had R0 resection (42%). The median survival for the patients who underwent surgery was 17.3 months, compared with 6.1 months for those who did not, and was comparable for those who were randomized. The data suggest that salvage surgery could benefit a subset of patients who do not respond to initial therapy.<sup>153</sup> Conversely, the role of surgery is less obvious in those with a complete response. However, ascertaining true complete response is difficult. Recent studies using fluorodeoxyglucose positron emission tomography (PET) scans show promise; however, although PET scan can more reliably distinguish responders and nonresponders, it is not accurate enough to pinpoint the complete pathologic responders.<sup>154</sup>

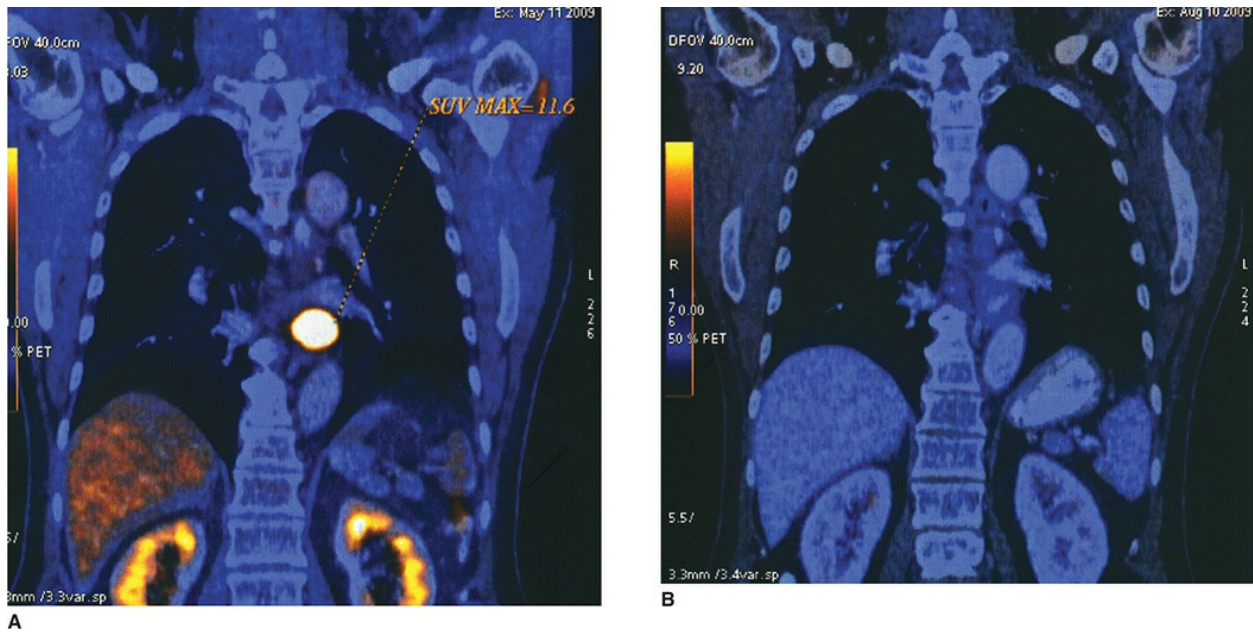

The dilemma of when surgery can be omitted remains when faced with complete clinical response after multimodality treatment. An ongoing multicenter trial in France (Esostrate) attempts to compare immediate surgery versus surveillance and rescue surgery for recurrence in esophageal cancer with complete clinical response after chemoradiotherapy.<sup>155</sup> Another equally important prerequisite element to answer the above question is the accuracy

of current diagnostic tools in defining real complete clinical response. A Dutch group proposed a study to test the accuracy of detecting residual disease after CROSS neoadjuvant chemoradiotherapy (Pre-SANO study). In this Pre-SANO study, two rounds of clinical response evaluations by endoscopy with biopsy and endoscopic ultrasonography with fine needle aspiration showed sensitivity and specificity for differentiation between tumor regression grade (TRG) 3-4 (residual viable cells >10%) and TRG 1 (no residual viable cell) were 90% and 72% respectively.<sup>156</sup> Follow this trial, SANO, if diagnostic tests are indeed accurate, then the concept to test “surgery as needed” (for recurrence after complete clinical response) approach (SANO trial) will be appropriate. Much interest will be generated with the results of these studies.

## **Prediction of Response and Response-Directed Therapy**

Reliable predictors for response to chemoradiation would be useful, because multimodality treatments are toxic, time consuming, and costly. Various markers have been explored, such as simple histology,<sup>157</sup> proliferative cell nuclear antigen (PCNA), epidermal growth factor receptor (EGFR), Ki-67, cyclin D1, thymidylate synthase, and microvessel density, both in tissue and in serum. To date, none has been proven to help clinical decision making.<sup>158</sup>

Metabolic imaging with PET scan has some promise. The degree of response detected by PET imaging has been shown by many studies to correlate with pathologic response after chemotherapy or chemoradiotherapy (Fig. 26-17).<sup>45,154</sup>

**FIGURE 26-17** Positron emission tomography/computed tomography before (A) and after (B) chemoradiation therapy; the tumor has become completely eumetabolic.

The MUNICON (Metabolic Response Evaluation for Individualization of Neoadjuvant Chemotherapy in Oesophageal and Oesophagogastric Adenocarcinoma) trial evaluated patients with locally advanced adenocarcinoma of the distal esophagus or type II cardia tumors undergoing neoadjuvant chemotherapy. Early metabolic response was defined as a reduction of 35% or more in the mean glucose standard uptake value (SUV) measured by serial PET scans at the beginning and at 2 weeks after commencement of treatment. Responders continued chemotherapy for an additional 12 weeks before resection, whereas nonresponders went directly to immediate surgery. Of 119 patients, 110 were evaluable for metabolic responses, of whom 54 (49%) were responders. Significantly improved R0 resection rate (96% vs 74%), major pathologic response rate (defined as <10% residual tumor; 96% vs 0%), longer median event-free survival (29.7 vs 14.1 months), and longer median overall survival (median, not reached vs 25.8 months) were found for metabolic responders versus nonresponders. More importantly, the outcomes for nonresponders were not different from previous results in such patients who completed 3 months of chemotherapy, indicating that such a strategy did not compromise these patients and could save them from suboptimal chemotherapy. <sup>159</sup>

The same investigators reported on their MUNICON-2 trial. Metabolic nonresponders as defined in MUNICON were switched to chemoradiotherapy (both chemotherapy and chemoradiotherapy were cisplatin based). Of 32 patients recruited, 13 (41%) were metabolic nonresponders. Subtotal histologic response (<10% residual tumor) after chemoradiotherapy was reported in 3 patients (23%), but no complete response was observed. In contrast, the complete histologic response rate in metabolic responders was 16%. Higher rates of R1/2 resections were also observed for nonresponders (31% vs 16%). One-year progressive-free survival was also inferior (46% vs 63%). The study suggested that merely adding radiotherapy to the same cisplatin-based chemotherapy in nonresponders was only marginally better. Another strategy may be to switch to alternative, non-cross-resistant chemotherapy during radiation.<sup>160</sup>

It seems that cisplatin- and fluorouracil-based chemoradiotherapy has reached its therapeutic limit in treating esophageal cancer. Paclitaxel has also become standard since the CROSS trial. More novel chemotherapeutic agents are being explored, including docetaxel, the topoisomerase I inhibitor irinotecan (CPT-11), vinorelbine, gemcitabine, Herceptin (trastuzumab), oxaliplatin, biomodulators such as interferon, and targeted therapies such as bevacizumab or cetuximab. This remains a very active area of research. In addition, advances in techniques in radiation delivery, such as intensity-modulated radiotherapy, may further reduce radiation toxicity.<sup>161</sup>

One ongoing multicenter phase III Japanese trial compares 3 regimens of neoadjuvant therapy: cisplatin and fluorouracil versus docetaxel, cisplatin, and fluorouracil versus chemoradiotherapy with cisplatin and fluorouracil (JCOG 1109, NExT Study). Although this study does not specifically look at VATS esophagectomy, it will probably shed light on the safety and effects of such procedure in the neoadjuvant setting. Minimally invasive esophagectomy is allowed in this study, but surgeons need to be credentialed by a committee in order to take part, thus ensuring quality control of the surgical procedure. It would be interesting to see whether the results will be different with the open versus minimally invasive approach and after chemotherapy versus chemoradiotherapy. This study commenced in November 2012 and aimed at recruiting 501 patients in 6.25 years, with 2 interim analyses after enrolling half the number of patients.<sup>162</sup>

## PALLIATION

Endoscopic palliative treatments for more advanced tumors include placement of an esophageal prosthesis, laser therapy, intralesional injection of various substances, and PDT. The most commonly employed technique is perhaps insertion of a prosthesis, especially self-expanding metallic stents (SEMS; Fig. 26-18). The smaller diameter of the delivery mechanism makes aggressive dilation of the tumor before insertion unnecessary. These stents are more flexible than conventional plastic prostheses; membrane-covered versions have been developed to seal esophagoairway fistulae and prevent tumor ingrowth. Perforation, pneumonia, bleeding, and migration rates were significantly lower with metallic stents. Because of the lower morbidity, metallic stents were also more cost-effective despite their higher initial cost. The choice of various metallic stents depends on their individual characteristics, in terms of flexibility, tensile force, and degree of shortening on deployment in relation to the site of placement. Compared with more conventional methods of palliation such as laser therapy, patients with SEMS spent less time in the hospital and required less frequent reinterventions.<sup>163</sup>

**FIGURE 26-18** A self-expanding metallic stent (SEMS) in situ. **A.** Posterior-anterior view. **B.** Right lateral view.

The main problems with SEMS are stent migration, tumor ingrowth or overgrowth, and, if placed across the GEJ, acid reflux. Placing uncovered stents across the cardia lessens the chance of migration, and stents have been developed with a 1-way flap valve to prevent reflux. It has also been shown that “tumor” ingrowth is sometimes due to granulation tissue or hyperplastic

reaction by the esophageal mucosa.<sup>164</sup> Patency can be achieved again by laser, argon beam application, or sometimes placement of a second stent within the first. One recent randomized trial compared the use of the Ultraflex stent (Boston Scientific, Marlborough, MA) with the Polyflex stent (Boston Scientific), and the Niti-S double stent (Taewoong Medical, Seoul, Korea). The Polyflex stent is a silicone device with an encapsulated monofilament braid made of polyester. The silicone and polyester material are designed to lessen nontumoral tissue overgrowth, a problem common with SEMS. The Niti-S stent has an inner polyurethane layer over its entire length and an outer uncovered nitinol wire tube to allow the mesh to embed itself in the esophageal wall. Success rates were similar for all 3 stents, but recurrent dysphagia was more common with the Ultraflex stent because of tissue ingrowth and overgrowth and, to lesser degree, the Niti-S stent. Polyflex stent had a higher chance of migration, not surprisingly, because the stent is also designed to be removable in benign esophageal stenosis.<sup>165</sup>

Another problem of stent insertion is placement near to the upper esophageal sphincter. Foreign body sensation, pain, odynophagia, and airway compression can be troublesome and demand accurate placement. This is illustrated in the situation when recurrent disease is found at the anastomosis or in the esophageal remnant after subtotal esophagectomy. Placement of SEMS is still possible and achieves good palliation.<sup>166</sup>

## **SUMMARY AND FUTURE PERSPECTIVES**

Significant improvement is evident in the management of esophageal cancer. Advancement of technology and proliferation of investigation and treatment modalities allow for precisely stratifying patients into various treatments. Surgeons play a key role in formulating therapeutic strategy for individual patients. More evidence-based staging systems and comprehensive staging modalities can help in patient selection. Data are evolving, and minimally invasive esophagectomy has been shown to be comparable, if not superior, to conventional approach for esophagectomy and has become standard surgical approach in many institutions. Neoadjuvant chemoradiotherapy integrated with surgery for locally advanced-stage disease seems better than either chemotherapy or radiotherapy alone, incorporated with surgery or as an adjuvant approach. Search for more effective and less toxic chemotherapeutic

agents and identification of predictors of chemoradiotherapy response should be the next direction of research in this area. The challenge for the future is for us to critically test our strategies in a scientific, unbiased manner and to explore other innovative treatments.

# SURGICAL PROCEDURES TO RESECT AND REPLACE THE ESOPHAGUS

*Jon O. Wee • Shelby J. Stewart • Raphael Bueno*

Billroth and Czerny described the first esophageal resections in the 1870s, and these consisted of resections of the cervical esophagus without reconstruction. Later, resection of gastroesophageal (GE) junction tumors was performed by laparotomy with gastroesophageal anastomosis to reestablish intestinal continuity. Because there were concerns over respiratory compromise, surgeons were hesitant to enter the chest to perform esophageal resection. In 1915, Torek described the first transthoracic esophageal resection.<sup>1</sup> He used a left thoracotomy to resect the esophagus but did not attempt reconstruction. Instead, a cervical esophagostomy and abdominal gastrostomy were performed. A 3-ft-long external rubber tube was used to connect the ostomies, and it allowed the patient to eat for 17 more years (Fig. 27-1). Turner performed the first transhiatal esophagectomy in 1933.<sup>2</sup> Oshawa reported the first transthoracic resection of the esophagus with esophagogastric anastomosis in 1933.<sup>3</sup> Knowledge of this procedure did not become widespread in the Western community until Adams and Phemister described the procedure in 1938.<sup>4</sup>

The patient lived 17 years after the surgery and died at age 80. B. Removable rubber tube conduit with beveled ends. (Reproduced with permission from Torek F. The operative treatment of carcinoma of the oesophagus, *Ann Surg* 1915;April;61(4):385-405.)

Ivor Lewis is credited with popularizing transthoracic resection of the esophagus. Initially, he performed the procedure in two stages: first, mobilizing the stomach via laparotomy, and several days later resecting the intrathoracic esophagus and reconstructing with the stomach. The Ivor Lewis approach (which is an upper midline laparotomy for mobilization of the gastric conduit followed by right thoracotomy for resection and reconstruction) and the transhiatal approach are currently the two most commonly used techniques of esophageal resection. In 1962, McKeown described a tri-incisional approach. He used a right thoracotomy to mobilize the esophagus. The patient was then repositioned in the supine position, the gastric conduit was mobilized by laparotomy, and the anastomosis was performed in the neck.<sup>5</sup> Minimally invasive options for surgical resection have also become increasingly popular.<sup>6,7</sup> Thoracoscopic and laparoscopic techniques, robotic surgery, as well as combined minimally invasive with open approaches have created a wider variety of experiences and are

discussed in other chapters.

## NEOADJUVANT TREATMENT

Historically, surgery has been the primary mode of treatment for localized esophageal cancer. Nonetheless, the long-term results of surgery alone for esophageal cancer are disappointing, with a 5-year survival of approximately 20%.<sup>8-10</sup> Given the poor results with surgery alone, preoperative chemotherapy with or without radiation has been proposed as a means of improving long-term survival. Twelve randomized trials have been performed using preoperative chemoradiation, while nine additional randomized studies have evaluated the benefit of preoperative chemotherapy without radiation. Although two of the larger randomized trials comparing preoperative chemoradiation followed by surgery to surgery alone showed no difference in survival,<sup>11,12</sup> several randomized trials have been used to support the use of preoperative chemoradiation.

Urba and colleagues looked at 100 total patients randomized to preoperative chemoradiation or surgery alone.<sup>13</sup> Median survival was approximately 18 months in both groups; however, there was a trend toward improved survival at 3 years (30% vs 16%), albeit statistically insignificant.

Walsh and associates randomized 113 patients, and at 3 years there was a 32% survival benefit for those receiving preoperative cisplatin plus 5-FU and radiation (40 Gy) versus 6% for those undergoing surgery alone ( $p = 0.01$ ).<sup>14</sup> This study, however, has been heavily criticized for its lack of adequate pretreatment staging and survival in the surgical arm that is far below other reported series.

Cancer and Leukemia Group B 9781 (CALGB 9781) by Tepper and colleagues, evaluated patients with stage I to III esophageal cancer. Patients were randomized to surgery alone or to preoperative cisplatin and 5-FU with concurrent radiation (50.4 Gy) followed by surgery. Poor accrual resulted in premature closure of this underpowered study of 56 patients. Nonetheless, with median follow-up of 6 years, 5-year survival was 39% for the trimodality group versus 16% for the surgery-alone group ( $p = 0.002$ ).<sup>15</sup>

The 2012 Chemoradiotherapy for Oesophageal Cancer Followed by Surgery Study (CROSS) by Van Hagen et al. is a large multicenter study of 366 patients, and has been the most significant contribution supporting

neoadjuvant chemoradiotherapy. The chemoradiotherapy cohort was dosed carboplatin/paclitaxel with 41Gy of concurrent radiation prior to surgery. Findings were encouraging, with the achievement of an R0 resection in 92% of patients randomized to preoperative chemoradiation versus 69% in the group managed with surgery alone ( $p < .001$ ). Five-year overall and disease-free survival were also significantly improved in the preoperative chemoradiotherapy group as compared to the surgery-alone cohort, with 47% and 34% overall survival. Median survival was 49 months in the neoadjuvant group versus 24 months in the surgery-only group. However, most of the benefit was seen in the squamous cell population. Survival in patients with squamous cell cancer had a hazard ratio of 0.422 ( $p < .007$ ). Adenocarcinoma patient survival had a hazard ratio of 0.71 but with a  $p$  value of 0.7, demonstrating a trend but not statistically significant difference.<sup>16</sup>

In an effort to settle controversies arising from several conflicting study results, there are a number of meta-analyses comparing neoadjuvant chemotherapy or chemoradiotherapy to surgery alone. The most recent is by Sjoquist and associates, a 2011 update of the 2007 study by GebSKI et al.<sup>17</sup> The 2007 analysis reported a significant survival benefit for neoadjuvant chemoradiotherapy as well as neoadjuvant chemotherapy in patients with esophageal cancer. The update, with nearly 4000 patients, strengthened previous results, returning a hazard ratio of 0.78 (95% CI 0.70-0.88;  $p < 0.0001$ ) corresponding to an absolute survival benefit at 2 years of 8.7% and a number-needed-to-treat of 11 with trimodality treatment.<sup>18</sup>

A 2004 meta-analysis by Fiorica and colleagues included 734 patients, and returned similar findings with a significant improvement in 3-year survival with preoperative chemoradiotherapy versus surgery alone. However, this study also reported a significant increase in postoperative morbidity including respiratory complications, heart failure, and anastomotic leak in patients treated with neoadjuvant therapy.<sup>19</sup>

Urschel and Vasan in 2003 combined the results of over 1100 patients from nine randomized controlled studies comparing neoadjuvant chemoradiotherapy followed by surgery versus surgery alone. This study also favored neoadjuvant chemoradiotherapy with surgery over surgery alone.<sup>20</sup> These studies have led to the most recent (2015) National Comprehensive Cancer Network (NCCN) guidelines for the use of neoadjuvant chemoradiation in medically and surgically fit patients diagnosed with

resectable, locally advanced esophageal cancer of the GE junction.<sup>21</sup>

Similar to the studies evaluating the potential survival gain with preoperative chemoradiotherapy, there is substantial comparative evidence of the benefit of neoadjuvant chemotherapy without radiation for locally advanced esophageal cancer. The largest of such studies is the Medical Research Council (MRC) esophageal cancer (OEO2) trial of 2002, which was updated in 2009.<sup>22,23</sup> Both the original and long-term studies demonstrated a statistically significant survival benefit (23% vs 17%) and progression-free survival in those patients who received preoperative chemotherapy. A comparable well-sized US study by Kelsen et al. was published in 1998. The original results of this study, however, were contradictory, displaying no evidence of a difference in the disease-free or overall survival between the two treatments.<sup>24</sup> Nonetheless, a 2009 update of this trial did report the necessity for complete resection with negative microscopic margins, as only patients who underwent an R0 resection had a substantial chance of long-term disease-free survival.<sup>25</sup>

These reports were followed by the Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial in 2006. This study looked at GE junction tumors including those that were considered gastric, an important group that had been excluded from many earlier studies. This trial demonstrated an improved survival at 5 years of 36% versus 23% in patients with GE junction adenocarcinoma treated with preoperative chemotherapy.<sup>26</sup>

Although many of these studies suggest that neoadjuvant treatment may prove beneficial, there still remains controversy about the use of chemotherapy versus chemoradiotherapy. Two head-to-head comparisons of neoadjuvant chemotherapy versus neoadjuvant chemoradiotherapy have been completed to date. Both studies, however, were underpowered and consequently unable to determine a statistically significant survival advantage. The first trial by the German Esophageal Cancer Study Group did display a trend toward improved survival with trimodality therapy.<sup>27</sup> The second study by Bermeister and colleagues did not share this trend.<sup>28</sup> Unfortunately, no clear determination has been made regarding which method is better. The relatively low incidence of esophageal cancer, the variable response to treatment between squamous cell carcinoma and adenocarcinoma, and the regional practice patterns make a large, randomized study difficult to envision.

## STAGING

It is important to recognize those patients with stage IV disease, because the mean survival in these patients is 6 to 10 months. In the past, palliative esophagectomy was thought necessary to restore swallowing and oral nutrition. With advances in photodynamic therapy, expandable endoscopic stents, and other endoluminal therapies, it is unusual for anyone to require esophageal replacement to reestablish swallowing ability. Hence, stage IV patients should be spared the perioperative mortality, morbidity, and recovery time associated with esophagectomy. The appropriate use of neoadjuvant treatment requires accurate staging. Patients with nodal involvement, invasion through the esophagus, or possibly even invasion into the muscularis often undergo preoperative chemoradiation, while patients with simple mucosal involvement generally proceed directly to endoscopic treatment or surgical resection.

The main staging modalities available today are computed tomography (CT) scan, positron emission tomography (PET) scan, and endoscopic ultrasound (EUS). CT scans are used mainly for detecting distant metastases in the lungs, liver, or other remote sites, including the brain. CT scan may be useful for excluding T4 tumors if a fat plane can be demonstrated between the adjacent structure and the esophagus. Such staging is often not possible if the patient is severely cachectic or if there are no natural fat planes, such as that between the trachea and esophagus. In regard to nodal status, CT is not as sensitive or as accurate as EUS.

PET scan is superior to CT scan for detecting distant metastatic disease. In a series of 91 patients, CT scan had a sensitivity of 46%, a specificity of 74%, and an overall accuracy of 73%. In contrast, PET scan had a sensitivity of 69%, specificity of 93%, and overall accuracy of 84%. All metastases that were missed by PET were less than 1 cm in size.<sup>7</sup> Other studies have shown similar results.<sup>29,30</sup> In addition, PET scan may aid in the diagnosis of primary tumor where it may be difficult to perform biopsy because of obstruction. Conversely, a certain percentage of nonbulky tumors of the esophagus may be PET-negative.

EUS gives detailed images of the esophageal wall and nearby structures (Fig. 27-2). Accurate identification of the layers of the esophageal wall is possible. Muscle layers tend to be hypoechoic with intervening hyperechoic mucosal layers. The first and second hypoechoic layers correspond to the

mucosa and muscularis mucosa, respectively. The third hyperechoic layer is submucosa. The fourth hypoechoic layer is the muscularis propria, and the fifth hyperechoic layer is the outside of the esophagus. Tumor infiltration of the wall disrupts the normal-layered appearance, and extent of penetration is usually clearly visible. EUS has an overall accuracy of 80% to 90% in ascertaining T status. The differentiation between T1 and T2 is most difficult. In addition, biopsy of deeper layers of tumor not accessible by traditional grasping forceps is possible. It should be noted that EUS is not accurate in defining postneoadjuvant treatment T status because of fibrosis induced by the chemoradiation.

**FIGURE 27-2** Endoesophageal ultrasound image of an adenocarcinoma of the esophagus (T3) and multiple lymph nodes suspicious for metastatic disease (N1). (Reproduced with permission from Van Dam J, Sivak MV, Catalano MF et al: High-grade malignant stricture is predictive of esophageal tumor stage: risks of endosonographic evaluation, *Cancer* 1993;May 15:71(10):2910-2917.)

Nodal status is determined by examining four characteristics. Malignant nodes tend to be round and hypoechoic. They have discrete borders and are larger than 1 cm in size. Nodes that meet such criteria have a 90% chance of being malignant. Fine-needle aspiration (FNA) further increases the accuracy in determining nodal status. If the tumor is from a node, the cytopathologist should be able to identify lymphoid tissue in the specimen. False positives can result with FNA if the needle passes through the primary tumor. The accuracy of EUS in N-status staging is between 70% and 80%. EUS is 10% to 15% more accurate than CT scan.<sup>31</sup>

Developments in EUS and PET scanning have lessened the enthusiasm for preresection operative staging of esophageal cancer patients. Operative staging involving laparoscopy and thoracoscopy is more invasive but may be superior to EUS. Luketich and associates studied 26 patients and detected N1 disease in a considerable number of patients staged N0 by EUS.<sup>32</sup> It should be noted, however, that the sensitivity of EUS in this series was only 60%, considerably lower than that described in other series. In addition, 15% of patients with no radiographic metastatic disease were found to have liver metastases by laparoscopic staging. The average cost of surgical staging was \$20,000 to \$25,000 versus \$2000 for EUS.

A common algorithm used in staging patients includes endoscopy for primary diagnosis, CT scanning with PET to evaluate for metastatic disease, and EUS if the patient is an operative candidate and neoadjuvant therapy is considered. In cases of esophageal obstruction, where EUS scanning is known to be less accurate, the incidence of lymph node metastasis is very high (90%), and neoadjuvant therapy should be considered.

## **APPROACH TO THE CERVICAL LESION**

The treatment of a cancer of the cervical esophagus is challenging and requires a multidisciplinary approach involving an otorhinolaryngologist, a thoracic surgeon, and occasionally a plastic surgeon. Frequently, radiation will be required preoperatively to maximize margins and spare the larynx, if possible. The neck incision is made along the anterior border of the sternocleidomastoid muscle and can be extended across the midline if additional exposure is needed. If the tumor is fixed to the spine or neck vessels, the procedure is aborted and palliative radiotherapy is considered. If

the larynx is involved, it is removed en bloc with the upper esophagus along with the upper paraesophageal nodes bilaterally. A radical neck dissection is not routinely performed. The dissection spares the jugular vein, sternocleidomastoid muscles, and spinal accessory nerves. The trachea is transected, leaving enough length to allow construction of a permanent end tracheostomy. The endotracheal tube is inserted into the distal trachea and the hypopharynx is divided sharply.

By this point, a separate midline abdominal incision will have been performed, and blunt dissection is begun on the esophagus from the abdomen. A two-team approach should be considered, with one team at the neck while the other prepares the gastric conduit. The gastric conduit is elevated to the neck with traction and the gastroesophageal junction is divided. The pharyngogastrostomy anastomosis is performed using a single-layer, interrupted hand-sewn anastomosis with a nonabsorbable suture. The cervical tracheostomy is performed above the sternal notch. If too much trachea has been resected to allow for this, manubrial resection will permit placement of the end tracheostomy lower in the midline.

## **STRATEGY FOR LESIONS BELOW THE THORACIC INLET**

Lesions below the thoracic inlet can be divided according to their location in the upper esophagus (below the thoracic inlet but above the carina), midesophagus (between the carina and inferior pulmonary vein), or lower esophagus (below the inferior pulmonary vein). While we favor the tri-incisional approach for all malignant lesions (for reasons discussed later), lesions in the upper thoracic esophagus generally must be approached with this technique to ensure adequate proximal margins. If the lesion is in the midthoracic esophagus, either the tri-incisional approach or the Ivor Lewis approach may be adequate. Lower esophageal tumors can be resected with either of these two approaches, or additionally with a transhiatal approach, or left thoracotomy and distal esophagectomy. With any resection, accommodation must be made for additional resection with reconstruction if frozen margins are involved with tumor.

## Transhiatal versus Transthoracic Techniques

Five prospective, randomized trials have been performed comparing transhiatal to transthoracic resection. The first was published in 1993 by Goldmine and associates.<sup>33</sup> Sixty-seven patients younger than 70 years with squamous cell cancer were randomized to Ivor Lewis resection or transhiatal resection. Operative time was longer (6 vs 4 hours) in the Ivor Lewis group. There was no difference in the incidence of pneumonia (20%), anastomotic leak, recurrent nerve injury, bleeding, perioperative mortality, or length of hospital stay. For those patients with nodal disease, however, none of the transhiatal patients were alive at 18 months, while 30% of the transthoracic patients were alive at 18 months.

The most recent randomized trial is from 2006. This study from Pakistan by Areja and associates found no significant difference between the two approaches. However, this study, like many before it, was limited, with only 30 patients.<sup>34</sup>

Chu and coworkers randomized 39 patients with lower-third esophageal cancers to either Ivor Lewis or transhiatal resection.<sup>35</sup> Limitations of the study were small sample size, short follow-up (mean 15 months), and patient exclusions. Patients undergoing neoadjuvant therapy or those with forced expiratory volume in 1 second (FEV<sub>1</sub>) less than 70% of expected were excluded. There were no perioperative deaths in either group. Intraoperative hypotension occurred in 60% of transhiatal patients but only in 5% of transthoracic patients. There was no difference in blood loss, pneumonia, or recurrent nerve injury. The mean proximal margin was 3 cm longer in the transhiatal group. No significant difference was seen in tumor recurrence or survival during the brief follow-up period.

A study comparing transhiatal resection to transthoracic, tri-incisional en bloc resection for distal adenocarcinoma of the esophagus or cardia was performed in the Netherlands. One hundred and six patients were randomized to transhiatal resection and 114 patients to transthoracic resection. In-hospital mortality was 2% to 4% in each group. Chyle leak was higher in the transthoracic resection group (10% vs 2%). Respiratory complications including atelectasis and pneumonia were higher in the transthoracic group (57% vs 27%). Although statistical significance was not reached, 39% of the transthoracic group was alive at 5 years, while only 29% of the transhiatal

group survived 5 years.<sup>36</sup> An update of this study following with a full 5-year follow-up continued to show no statistically significant overall survival in either approach.<sup>37</sup> However, in a subgroup of patients who had one to eight positive lymph nodes in the resection specimen, the transthoracic approach (TTE) demonstrated improved overall survival compared with the transhiatal approach (THE) (39% TTE vs 19% THE,  $p = 0.05$ ). Disease-free survival was similarly improved with the transthoracic approach (64% TTE vs 23% THE,  $p = 0.02$ ).

Thirty-two patients were included in a trial by Jacobi et al.<sup>38</sup> This trial sought to determine if there was a difference in perioperative pulmonary function between the two approaches by measuring several cardiopulmonary parameters. They found a significant increase in operative time, blood loss, and need for transfusion in the transthoracic approach. Although there was a slight increase in intraoperative pulmonary strain during single-lung ventilation in the transthoracic patients, this was well compensated and transient. Additionally, the pulmonary disturbance did not correlate to a significant difference in postoperative cardiopulmonary events, 30-day mortality, anastomotic leak, or 1-year survival (70% THE vs 77% TTE). Of note, the patients in this study were highly selected and included in the study only if they were aged less than 75 years and free of cardiac, pulmonary, or renal dyscrasia.

The randomized trials show no statistically significant difference in survival, but they are small, and trends toward improved survival are observed in patients undergoing transthoracic dissection. No difference in mortality have been detected in the completed trials thus far.

The analyses summarized above have been performed in an attempt to quell the debate of the superiority of either transhiatal or transthoracic approach. Three meta-analyses to date have attempted to determine the most appropriate approach to the surgical treatment of esophageal cancer. Boshier and colleagues reviewed 52 English-language studies between 1981 and 2009.<sup>39</sup> Comparable to other meta-analyses, there was no significant difference in 5-year survival, postoperative cardiac complications, hemorrhage, acute respiratory distress syndrome/acute lung injury, chyle leak, and renal insufficiency. Significant differences were found with the extent of lymphadenopathy, with a mean resection yield of eight more lymph nodes found with the TTE. Additionally, the TTE was found to have an

increased incidence of pneumonia (21% vs 17%), early (<30 days or in hospital), mortality (10% vs 7%), and a prolonged length of stay of 4 days as compared to the THE. The THE, however, was found to have a statistically significant increase in anastomotic leak (17% vs 10%), anastomotic stricture (25% vs 21%), and vocal cord paralysis (11% vs 5%). A subgroup analysis of 22 studies published after 1999 was also completed. Surprisingly, this analysis of more recent studies determined that the differences in anastomotic leak, vocal cord paralysis, and pneumonia were no longer significant.

Rindani and associates reviewed 44 trials involving either Ivor Lewis or transhiatal esophagectomy that were published in the English language between 1986 and 1996.<sup>40</sup> Overall, the incidence of bleeding, cardiac complications, or pneumonia was no different between the two groups. Differences were seen in the anastomotic leak rate (16% transhiatal vs 10% Ivor Lewis), stricture rate (28% transhiatal vs 16% Ivor Lewis), and incidence of recurrent nerve injury (11% transhiatal vs 5% Ivor Lewis). Mortality was higher after the Ivor Lewis approach (9.5%) than the THE (6.3%). Long-term survival was approximately 25% with either technique.

Hulscher and colleagues performed a meta-analysis of 50 studies published between 1990 and 1999 involving transthoracic and transhiatal resection.<sup>41</sup> Cardiac complications (20% vs 7%), anastomotic leakage (24% vs 7%), and vocal cord paralysis (10% vs 4%) were higher in the transhiatal group as opposed to the transthoracic group. Pulmonary complications (19% vs 13%), in-hospital mortality (9% vs 6%), and operative time (5 vs 4.2 hours) were higher in the transthoracic group. Overall long-term survival was similar between the two groups (23% for transthoracic and 21.7% for transhiatal resections).

It is important to note that these meta-analyses are retrospective and nonrandomized. In addition, reported surgical quality was suboptimal in both approaches, and the transthoracic group was noted to have more advanced cancer. Caution should therefore be used in applying these findings to individual institutions and patients.

Several patient factors must be considered when choosing the operative approach to esophageal resection. Some argue that transhiatal dissection may be less taxing on an elderly or debilitated patient (due to shorter operative time or avoidance of a thoracotomy). Many surgeons experience hemodynamic changes with transhiatal resection presumably due to compression during blunt dissection. Wong reported intraoperative

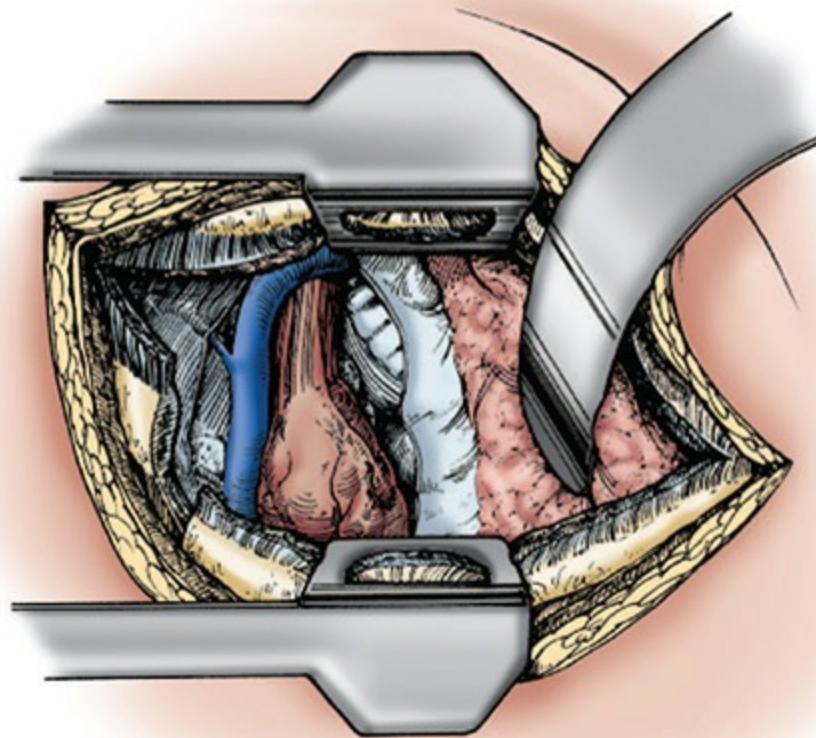

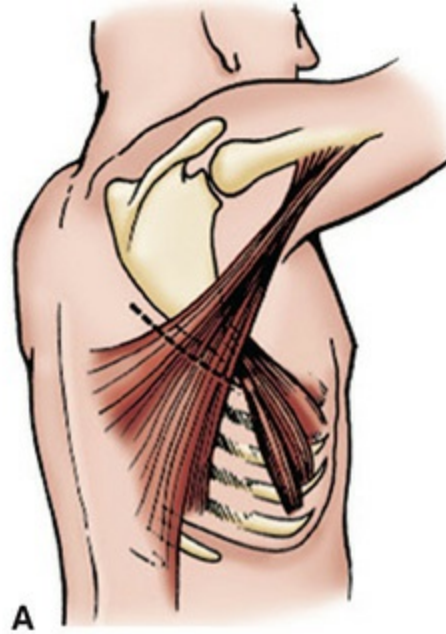

hypotension in 60% of transhiatal dissections, but in only 5% of transthoracic dissections,<sup>42</sup> suggesting that the transhiatal operation may be more taxing to a patient with severe cardiac valvular or atherosclerotic disease who cannot tolerate fluctuations in blood pressure. This finding, however, was not corroborated by the Jacobi study.

## **SURGICAL APPROACHES TO LESIONS BELOW THE THORACIC INLET**

### **Tri-Incisional Esophagectomy (McKeown Technique)**

The tri-incisional technique of esophageal resection combines the most attractive aspects of the Ivor Lewis and transhiatal approaches. It allows for dissection of the intrathoracic esophagus under direct vision with complete nodal resection and brings the anastomosis to the neck, allowing for maximal proximal margins and minimizing the risk of an intrathoracic leak.

Under general anesthesia, bronchoscopy is performed to rule out tracheal or bronchial (most commonly left main bronchial) involvement with tumor. Esophagogastroduodenoscopy is performed to localize the tumor and rule out disease of the stomach or duodenum. The patient is then reintubated with a double-lumen endotracheal tube and placed in the left lateral decubitus position. A right posterolateral thoracotomy incision is made large enough, approximately 10 cm in length, to introduce the surgeon's hand (Fig. 27-3). The serratus muscle is spared. Division of the intercostal muscles anteriorly and posteriorly often permits adequate rib spreading without the need to remove a small portion, or shingle, of rib. The chest is entered through the fifth or sixth interspace, depending on the location of the tumor. The inferior pulmonary ligament is divided using electrocautery, and the lung is retracted anteriorly.

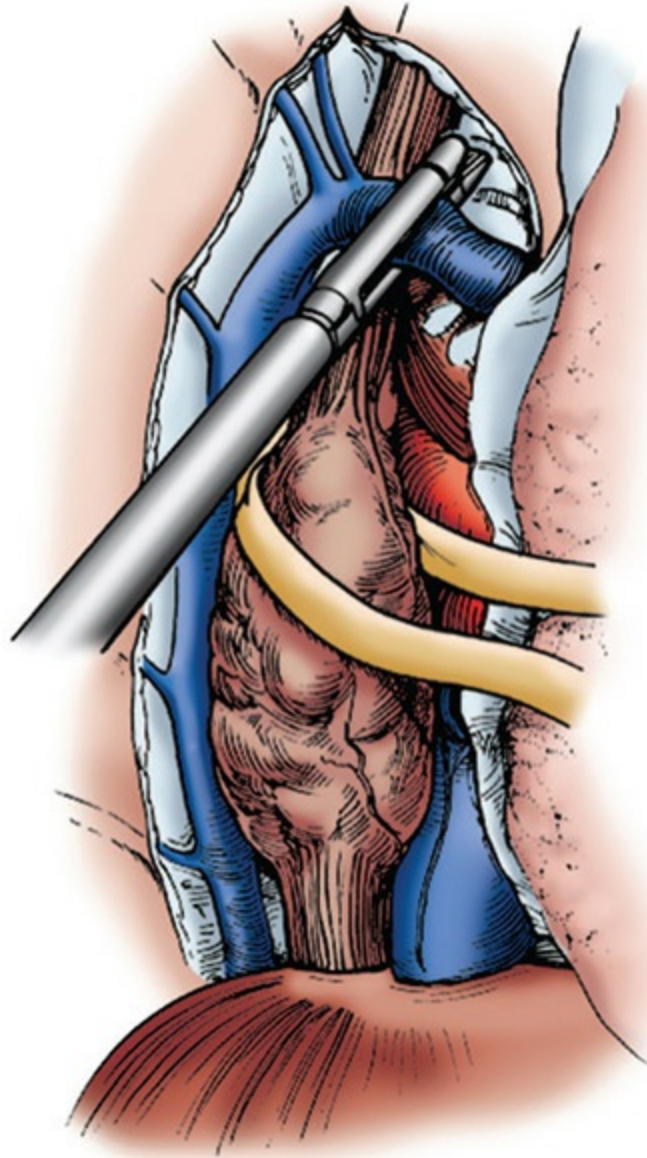

**B**

**FIGURE 27-3** **A.** The right chest has been entered through the fifth interspace. A piece of the posterior sixth rib has been “shingled” to aid in exposure. The lung is retracted anteromedially, and the mediastinal pleura has

been incised posteriorly to expose the esophageal tumor. *Inset:* The patient is placed in the left lateral decubitus position. The *dotted line* marks the skin incision for a right posterolateral thoracotomy. **B.** The latissimus muscle is divided as caudally as possible, and the serratus muscle is spared and reflected medially.

Dissection of the esophagus begins at a point away from tumor and any associated scarring, and the esophagus is encircled with a Penrose drain. Traction on the Penrose drain allows for cautery dissection encompassing all adjacent nodes. Arterial branches directly off the aorta are clipped or ligated. The settings on the electrocautery should be low when cauterizing near the trachea. The azygos vein is typically divided, although this is not always necessary ([Fig. 27-4](#)). At this level, the vagus nerves are identified. Dissection cranial to this level involves the vagus nerves; the vagus nerves are peeled off and away from the esophagus to avoid injury to the recurrent vagus branches.

**FIGURE 27-4** The esophagus has been isolated circumferentially at a point superior to the tumor and encircled with a Penrose drain. An endostapling device is used to divide the azygos vein near its caval connection.

Dissection between the trachea and esophagus must be done with care and with low cautery dissection to avoid injury to the membranous trachea. Much of the dissection high in the chest can be done bluntly (Fig. 27-5). The cranial aspect of the dissection is complete when one's fingers reach easily above the first rib. The Penrose drain is knotted and passed into the lower neck with the knot against the vertebral body for later retrieval during the neck phase of the dissection (Fig. 27-6).

**FIGURE 27-5** With countertraction applied to the Penrose drain encircling the esophagus above the tumor, blunt finger dissection is used to develop the tracheoesophageal plane to and above the thoracic inlet.

**FIGURE 27-6** The knotted Penrose drain is pushed up through the thoracic inlet and left to lie beneath the omohyoid muscle on the left side of the neck.

Another Penrose drain is used to gain traction on the lower esophagus, and dissection continues caudally. All tissue between the pericardium, aorta, and azygos vein is dissected and incorporated into the specimen. No effort is made to resect the thoracic duct, although it is sometimes injured. For tumors near the gastroesophageal junction, a rim of diaphragm is incorporated into the specimen. The knotted Penrose drain is placed in the abdomen for later retrieval (Fig. 27-7). At this point, careful inspection is made for hemostasis and injury to the thoracic duct. Often, injury to the thoracic duct is evident when slightly cloudy or crystallized fluid is seen pooling in the region of the duct. If an injury to the duct is seen, it should be closed with a pledgeted fine suture such as 5-0 Prolene. Mass ligation of the duct, as it enters the chest, is then performed by encompassing all tissue between the spine, aorta, and azygos vein at the level of the hiatus with a 0-silk suture. A 28-Fr straight

chest tube is inserted via a separate stab incision and directed to the apex of the chest. An additional hole in the tube can be made to facilitate dependent fluid drainage. The ribs are reapproximated with 2-0 Vicryl sutures. The latissimus layer is closed using a running 0 Vicryl suture. A subdermal layer is closed with 2-0 Vicryl and the skin is closed in subcuticular fashion.

**FIGURE 27-7** The lower Penrose drain is pushed down onto the gastroesophageal junction below the diaphragm. The thoracic duct is shown ligated, and a rim of the diaphragmatic hiatus encircles the lower esophagus.

The patient is placed in the supine position and is reintubated with a single-lumen tube. A roll is placed under the back to permit neck extension, and the head is turned to the right. A midline laparotomy is performed from the umbilicus to the xiphoid. Exploration of the abdomen should include a careful palpation of the liver and inspection of the serosal surfaces for tumor implants. Palpation of the GE junction and proximal stomach should be

performed to rule out gastric spread of tumor. The left lobe of the liver is mobilized and retracted to the right. The Penrose drain left from the chest dissection is used for retraction of the GE junction (Fig. 27-8). The gastroepiploic artery is identified and palpated. The pulse should be easily palpable provided the patient has a physiologic blood pressure. Staying at least 2 cm away from the gastroepiploic artery, the lesser sac is entered. Dissection continues cranially on the stomach along the greater curvature. Dissection may be performed by dividing tissue and ligating with 2-0 silk ties or by using an ultrasonic scalpel. The stomach is retracted medially and the omentum laterally. The artery itself should not be grasped or used for retraction. The gastroepiploic arcade ends near the point where the short gastric arteries begin. A pack placed behind the spleen often aids in exposure of the short gastric vessels (Fig. 27-9). The short gastric vessels can be ligated, double-clipped, or divided with an ultrasonic scalpel. Large vessels should be tied. Care should be taken not to incorporate stomach wall in the ligature, as this may result in delayed necrosis of stomach wall and a postoperative intrathoracic leak. Dissection on the greater curvature proceeds to the hiatus and is complete when the Penrose drain is reached.

**FIGURE 27-8** Exposure achieved by upper midline laparotomy. The large Balfour retractor is on the lateral abdominal walls, and the upper hand

retractor reflects the liver to the right, exposing the hiatus and lower Penrose drain around the GE junction.

**FIGURE 27-9** Gastric mobilization is begun at the superior greater curvature near the hiatus. A rolled Mikulicz pad is placed behind the spleen to aid in exposure. The short gastric vessels between the spleen and the stomach are divided, and the transition zone between the left and right gastroepiploic arteries is identified. Mobilization proceeds at least 2 cm away from the right gastroepiploic arcade (*dotted line*).

Proximal dissection on the greater curvature of the stomach proceeds in likewise fashion. The gastroepiploic artery migrates farther from the stomach as one dissects toward the pylorus, and care must be taken not to injure the vessel. The gastrohepatic ligament is divided with cautery up to the GE junction. The stomach is lifted anteriorly, and thin adhesions between the

stomach and pancreas are divided with cautery. The left gastric vessels are approached from behind the stomach (Fig. 27-10). The vessels are skeletonized, and lymph nodes are swept up onto the specimen. The vessels are clamped with a vascular endoscopic 30-mm stapler. The gastroepiploic pulse should be palpated at this time to ensure that the celiac axis itself has not been clamped, and the stapler is then fired. The duodenum is then mobilized using a Kocher maneuver, bringing it to the midline (Fig. 27-11). A pyloromyotomy or pyloroplasty may be performed with equivalent efficacy in aiding gastric emptying. If a pyloroplasty is performed, it is best to close it in a single layer with interrupted (3-0 silk) sutures. A leak is exceedingly rare.

**FIGURE 27-10** After the greater curvature is mobilized, the stomach is reflected superiorly and to the right, exposing the left gastric artery and coronary vein. These are ligated and divided with an endostapler, near their origin, from the celiac axis.

**FIGURE 27-11** A Kocher maneuver to mobilize the duodenum and a pyloromyotomy are performed.

A neck incision is then made 6 cm in length along the anterior border of the left sternocleidomastoid muscle starting at the sternal notch. Deep to the platysma, dissection proceeds medial to the sternocleidomastoid muscle and carotid sheath and lateral to the thyroid. The omohyoid can be divided with cautery (Fig. 27-12). Blunt dissection is then used to approach the vertebral bodies (Fig. 27-13). Lying along the vertebral body, the Penrose drain is grasped and brought out into the neck wound with the encircled esophagus. Proximally, the esophagus can be gently mobilized. The nasogastric tube is removed, and the esophagus is divided with a GIA 75-mm stapler (Fig. 27-14). A 2-silk suture is attached to the proximal margin, and the specimen is drawn out into the abdomen (Fig. 27-15). The cervical end of this tie is fastened to a clamp.

**FIGURE 27-12** Anatomic structures of the left neck below platysma level. The incision line along the medial border of the sternocleidomastoid muscle is shown. Division of the omohyoid muscle along with ligation of the middle thyroid vein allows for exposure of the underlying esophagus.

**FIGURE 27-13** Left cervical incision with the sternocleidomastoid muscle reflected laterally. Finger dissection beneath the omohyoid muscle develops a plane to the knotted Penrose drain. The patient is placed supine for the neck and abdominal incisions (*inset*).

**FIGURE 27-14** A GIA stapler is used to divide the cervical esophagus. Note the ligated middle thyroid vein and divided omohyoid muscle. *Inset:* Traction is placed on the Penrose drain around the cervical esophagus.

**FIGURE 27-15** The specimen is removed through the abdominal incision with a long heavy silk suture attached to the end of the esophagus.

The gastric tube is then constructed by resecting the GE junction and the lesser curvature of the stomach down to the crow's foot of veins with a series of thick tissue 75-mm gastrointestinal anastomosis (GIA) staplers (Fig. 27-16). A narrow gastric tube is believed to aid in emptying; however, a diameter of less than 5 to 6 cm may compromise conduit perfusion. The right gastric artery along the lesser curvature can be divided in order to allow elongation of the conduit (Fig. 27-17). The specimen is removed, and frozen

sections are performed on the margins. Inspection for hemostasis is made of the gastric bed. The esophageal hiatus should admit four fingers. One ampule of IV glucagons is administered to ensure relaxation and lengthening of the gastric conduit. The silk tie that traverses the mediastinum is then attached to the valved end of a Foley catheter with a 30-cc balloon (Fig. 27-18). An endoscopic camera bag is secured around the 30-cc balloon (Fig. 27-19). The conduit is advanced into the bag, ensuring appropriate orientation. Suction is applied to the bag via the Foley catheter, and the conduit is drawn up into the neck incision (Fig. 27-20). The assistant must actively guide the conduit through the hiatus. At the end, the pylorus should sit at the hiatus.

**FIGURE 27-16** The stomach is mobilized as a pedicle based on the right gastroepiploic vessels. *Inset:* Incisions illustrated.

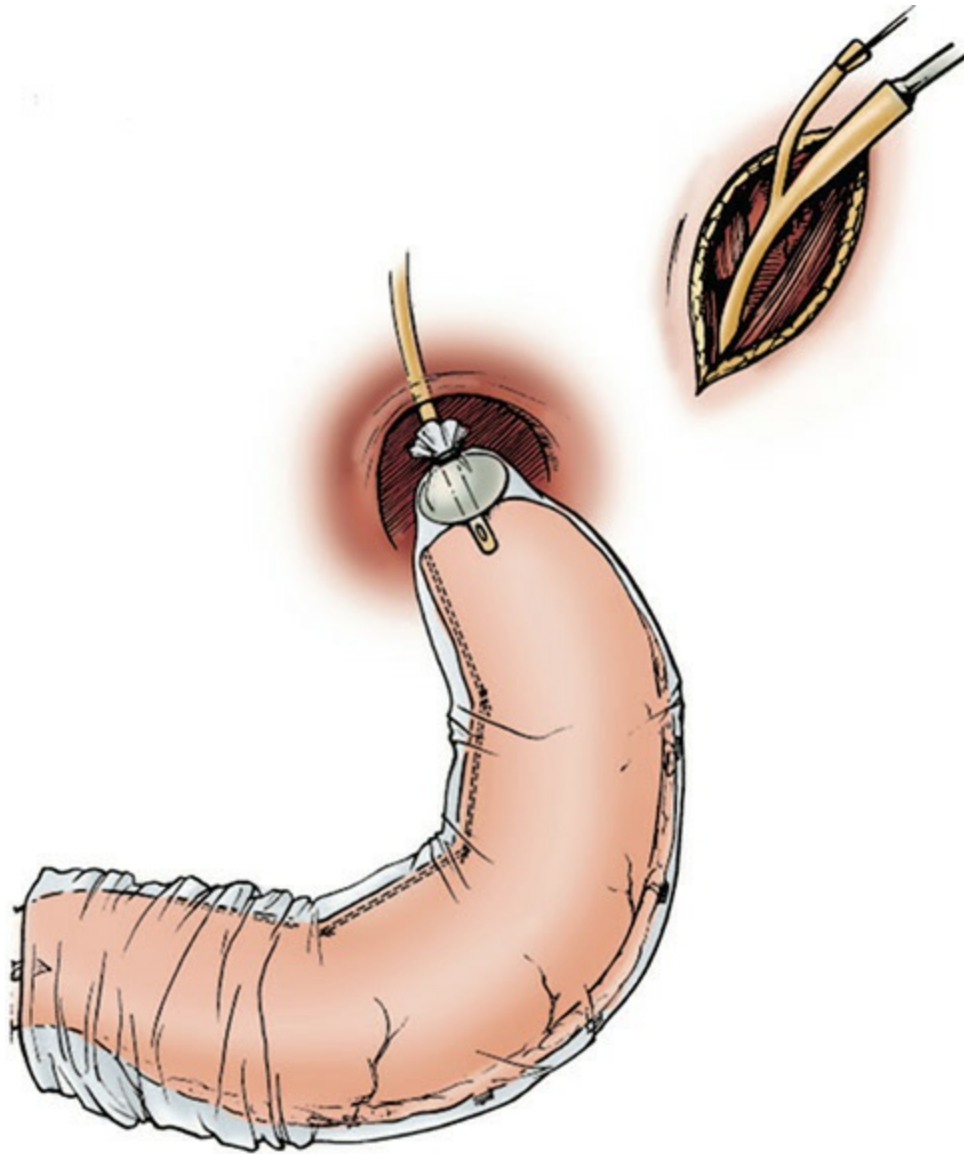

**FIGURE 27-17** The right gastric artery and lesser omentum are divided with an endostapling device. *Inset:* A GIA stapler divides the stomach along the lesser curvature, creating the gastric conduit.

**FIGURE 27-18** The heavy silk is tied to the port of a 30-cc balloon Foley catheter and is pulled up partially through the neck incision.

**FIGURE 27-19** An arthroscopy camera bag is tied around the Foley catheter balloon and the gastric conduit is placed in the folded-up arthroscopy bag ensuring the proper axial orientation. *Inset:* A Yankauer suction is attached to the Foley catheter to collapse the bag around the neoesophagus.

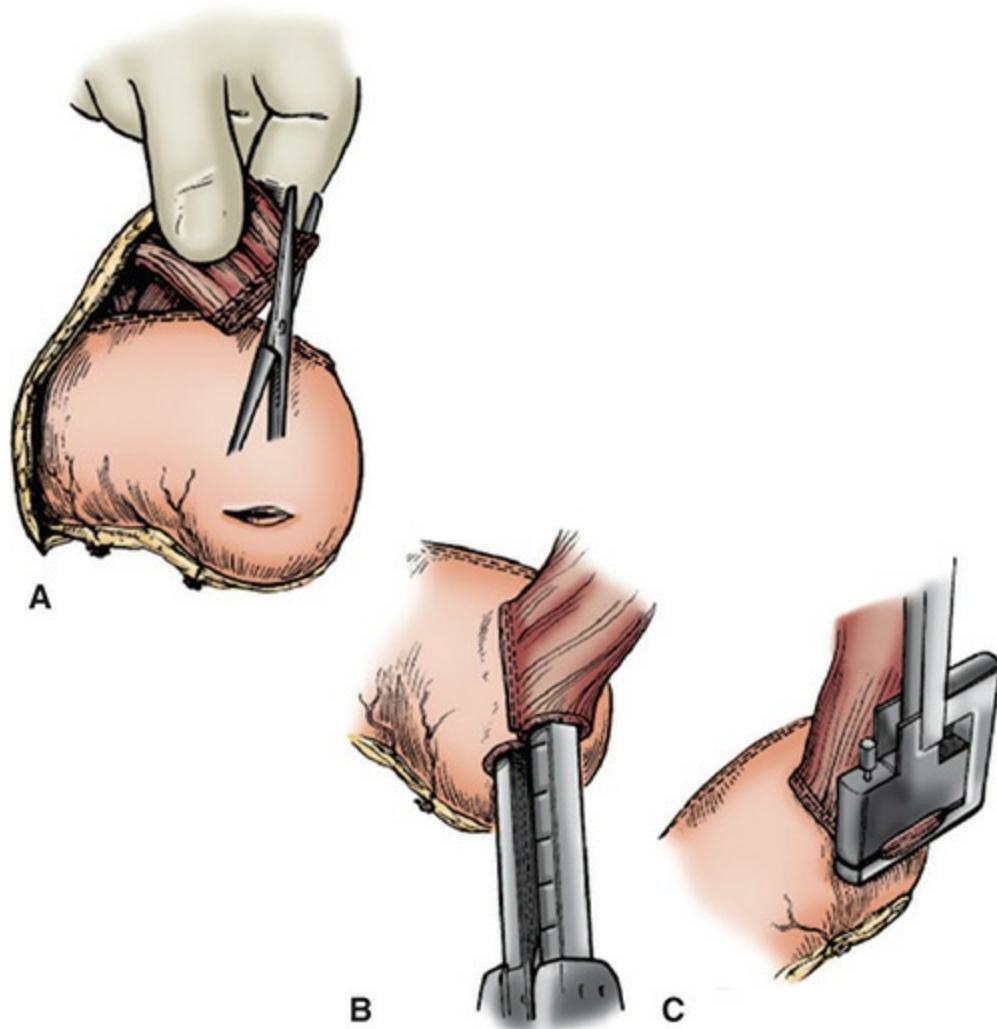

**FIGURE 27-20** The gastric conduit is atraumatically pulled through the posterior mediastinum into the cervical wound.

The neck anastomosis can be hand-sewn using interrupted full-thickness 3-0 silk sutures (Fig. 27-21). The anastomosis may also be stapled in side-to-side, functional end-to-end fashion. A portion of the esophageal staple line is removed, an enterotomy is created on the posterior aspect of the gastric tube, and a linear GIA 75-mm stapler is inserted to create the anastomosis (Fig. 27-22). An additional fire of an endoscopic 30-mm stapler may be used to gain additional length on the anastomosis. The enterotomy is usually closed with a TA 30 or 60 stapler after guiding the nasogastric tube down toward the

hiatus. Hybrid anastomosis has been described with the back wall of the anastomosis created using a 30-mm stapler and the anterior wall closed with sutures. A soft drain should be placed posterior to the anastomosis, and the platysma and skin are closed separately. It is wise to use an interrupted closure, as this will allow for reopening of a portion of the wound should a cervical leak develop. Before closing the abdomen, a J-tube should be inserted at a point approximately 40 cm distal to the ligament of Treitz. The fascia is closed using a #2 running monofilament suture and the skin is closed with staples.

**FIGURE 27-21** The esophagogastric anastomosis is performed with a single layer of full-thickness interrupted nonabsorbable sutures. The Silastic sump drain is shown emanating from the fundus of the gastric conduit. A Jackson-Pratt drain is shown positioned alongside the gastric conduit inferiorly and exiting from a separate stab wound above the clavicle.

**FIGURE 27-22** A. and B. The stapled functional end-to-end anastomosis is performed using the GIA stapler to approximate the side of the esophagus to the anterior wall of the stomach. C. The TA linear stapler is then used to close the defect between the two free walls.

## Ivor Lewis Technique

The patient is placed in the supine position. Bronchoscopy to rule out tracheobronchial invasion and esophagoscopy to confirm the location of the tumor are performed. An upper midline incision is made from the umbilicus to the xiphoid. The abdominal phase of this operation is identical to the previously described tri-incisional technique. Enlargement of the hiatus and dissection of the lower esophagus are more easily performed through the abdomen than through a high thoracotomy incision. The GE junction and

lesser curvature of the stomach are resected using a GIA stapler. The specimen is left attached to the esophagus to facilitate mobilization into the chest. A J-tube is placed before closing the abdomen.

A double-lumen endotracheal tube is placed and the patient is repositioned in the left lateral decubitus position. A right posterolateral thoracotomy is performed, and the chest is entered through the fourth or fifth interspace. The azygos vein is divided and the intrathoracic esophagus is dissected. All lymphatic tissue is included with the esophagus. Because a gross margin of 5 cm, and ideally 10 cm, is desired, the anastomosis is usually performed high in the chest at or above the level of the azygos vein. The proximal esophagus is dissected only several centimeters above the proposed level of transection to preserve its blood supply. The mobilized stomach is pulled up into the chest. The anastomosis can be constructed using an EEA stapler or hand-sewn technique. If a hand-sewn anastomosis is chosen, a double-layer technique is advisable (Fig. 27-23). In 1942, Churchill and Sweet described a method of double-layer anastomosis that is still often used today.<sup>43,44</sup> A point on the gastric tube at least 2 cm away from the staple line is chosen for the anastomosis. A circle of stomach serosa 2 cm in diameter is scored and the underlying gastric vessels are ligated with 4-0 silk sutures. The back outer layer of the anastomosis is constructed with interrupted 4-0 silk horizontal mattress sutures. These are placed 4 mm away from the serosal edge. Full-thickness stomach and esophageal wall are used. The esophagus is opened with a sharp instrument and the inner layer is constructed with interrupted suture incorporating esophageal mucosa and full-thickness stomach edge. The nasogastric tube is passed after completion of the posterior wall. A continuous Connell suture may also be used. The anterior outer layer anastomosis is constructed with 4-0 silk horizontal mattress sutures. The anastomosis should be wrapped or buttressed with omentum. At all times, atraumatic handling of mucosal edges and tying of sutures without crushing of tissues are advised. Some surgeons advise tacking the edge of the stomach wall to mediastinal tissue or paravertebral fascia to decrease tension on the anastomosis, although it is not clear if this is necessary. A 28-Fr straight chest tube is placed into the apex of the chest via a separate stab incision. The chest is closed with interrupted #2 Vicryl paracostal sutures, followed by a 0 Vicryl running latissimus layer, a 2-0 Vicryl running subdermal layer, and a 3-0 Vicryl subcuticular layer. Postoperative toilet bronchoscopy should be performed.

**FIGURE 27-23** View through a right thoracotomy incision showing an esophagogastric end-to-side anastomosis in the apical right chest. Note the tacking sutures from stomach to the posterior chest wall to avoid torsion.

## Transhiatal Technique

### CONSIDERATIONS

We believe that a tri-incisional approach gives better exposure to the thoracic esophagus, allowing for a safer and wider resection and better lymphadenectomy. As discussed, there may be survival advantages to the radical resection permitted by the transthoracic technique, although trials to date have not shown a statistically significant survival advantage using this approach. In cases in which the thoracic esophagus is not involved with tumor (either high-grade dysplasia or a laryngeal tumor involving the proximal esophagus), the transhiatal technique may be performed with equivalent oncological efficacy.

### TECHNIQUE

The patient is placed in the supine position with the head rotated 45 degrees to the right. The abdominal phase of the operation is performed in identical fashion to that described in the tri-incisional section above. An upper-hand retractor is useful in elevating the sternum and costal margin. The

phrenoesophageal ligament is divided using cautery, and the lower esophagus is encircled with a 1-in wide Penrose drain. The phrenic vein must first be identified and ligated. This will also enlarge the window for dissection of the intrathoracic esophagus. The hiatus is dilated to allow entry of the surgeon's hand. Arterial branches from the aorta are clipped on the aortic side and divided using cautery. Thin handheld malleable retractors are used to retract either side of the pleura during the dissection. Dissection under direct vision is usually possible up to the level of the inferior pulmonary veins.

At this point, an incision is made in the left neck along the anterior border of the sternocleidomastoid muscle starting at the sternal notch and extending 6 to 8 cm. The platysma is divided. The sternocleidomastoid muscle and carotid sheath are retracted laterally. The omohyoid is often divided. The middle thyroid vein is ligated and divided. A retractor may be used but must not rest on the recurrent nerve in the tracheoesophageal groove. The esophagus is palpated anterior to the spine and posterior to the trachea. Sharp dissection is carried out immediately on the esophagus, separating the esophagus from the membranous trachea and recurrent nerve. The esophagus is looped with a 1-in Penrose drain.

Blunt dissection of the posterior plane of the esophagus is performed first. From the abdomen, the surgeon's hand is placed in between the spine and esophagus with the palmar aspect of the fingertips immediately against the esophagus (Fig. 27-24). This is performed in conjunction with raising the esophagus anteriorly with the aid of the Penrose drain. An identical maneuver is performed through the cervical incision. When sufficient dissection has been done from either side, both hands are introduced simultaneously and an attempt is made to touch fingertips. Intervening loose areolar tissue must then be torn, uniting the fingertips. If the surgeon's fingertips will not reach from the neck, a sponge stick can be used. While the surgeon's hand is behind the heart, there must be constant communication between the surgeon and the anesthesiologist. Hypotension often results from compression of the left atrium and impairment of left ventricular filling. It is wise to have the arterial line tracing and numbers in direct view of the surgeon; the surgeon's eyes should be on these numbers as he/she performs the blind dissection with his/her fingers.

**FIGURE 27-24** Lateral view of the blunt dissection posterior to the esophagus in the chest. A sponge stick is used, as it may be difficult to insert one's hand completely through the cervical incision. (Reproduced with permission from Orringer MB, Sloan H: Esophagectomy without thoracotomy, *J Thorac Cardiovasc Surg* 1978;Nov;76(5):643-654.)

Dissection anterior to the esophagus is then performed in nearly identical fashion. The palmar aspect of the hand is again kept directly against the esophagus (Fig. 27-25). As dissection approaches the carina from below, the surgeon will note an increase in the tenacity of the anterior attachments to the esophagus. Dissection must be gentler in this area. A gentle side-to-side motion of the fingertips will also separate the trachea from esophagus. Eventually the fingertips from both hands are united. Once the anterior and posterior dissection has been completed, the lateral attachments are then divided. From the neck incision, as much blunt dissection of the lateral attachments as possible is performed under direct vision. Next the surgeon's hand is introduced anterior to the esophagus with the palmar aspect of the hand facing the esophagus. The hand is inserted until the first and second fingers are above the level of dissection of the lateral attachments. These attachments are pressed against the spine, and using a raking motion the surgeon pulls his hand back toward the abdomen, releasing the lateral attachments (Fig. 27-26). Care must be taken in the region of the azygos vein and its branches.

**FIGURE 27-25** Anterior blunt dissection of the esophagus in the chest. Dissection must be gentle and deliberate around the level of the carina to avoid tracheal as well as azygos vein injury.

**FIGURE 27-26** The esophagus has been freed from the trachea, and the lateral attachments are avulsed from a cranial to caudal direction.

The remainder of the operation, including the anastomosis, is identical to that of the tri-incisional technique. After removing the specimen, it is wise to pack the mediastinum with a lap pad (without compressing the heart) to facilitate hemostasis. Prior to drawing the conduit into the neck, a final inspection is made for hemostasis and for entry into either pleural space. If either pleural space is entered, a chest tube should be placed.

# Left Thoracoabdominal Approach

## CONSIDERATIONS

Limited resection of the distal esophagus via left thoracotomy is almost always a compromise procedure. Only the distal esophagus is readily accessible via the left chest, as the aortic arch obscures much of the upper esophagus. A tumor that extends more proximally than 30 cm should not be approached through the left, as a difficult dissection behind the aortic arch will be required. In addition, placement of the esophagogastric anastomosis low in the left chest can be associated with severe GE reflux. This approach is best reserved for a GE junction cancer that involves a significant portion of the proximal stomach and when there is concern that the residual stomach may be of insufficient length to reach the neck.

A variety of incisions or a combination of left thoracic and abdominal incisions can be used for this approach. An upper midline laparotomy can be extended across the costal margin. This is the least versatile approach and its use is limited to instances in which use of the esophagus is unexpected, as with proximal extension of a gastric tumor. A second approach involves placing the patient in full right lateral decubitus position and taking the diaphragm down in radial fashion 2 to 3 cm from the chest wall to gain exposure to the abdomen. This approach permits good exposure to the upper abdomen, although exposure to the pylorus and duodenum may be difficult.

## TECHNIQUE

The most versatile thoracoabdominal approach involves positioning the patient in the right lateral decubitus position with the hips rotated posteriorly 45 degrees. A left sixth interspace thoracotomy is performed beginning at the tip of the scapula and extending across the costal margin toward the abdominal midline. The costal margin is divided with a rib cutter. The left lung is deflated. The diaphragm is incised circumferentially 2 to 3 cm away from the chest wall (Fig. 27-27). Doing so avoids injury to the radial branches of the phrenic nerve. A novel technique is to use the endo GIA staplers along the periphery of the diaphragm. This provides some structure to sew to when reconstructing the diaphragm. The abdomen is explored for metastatic disease. Cautery is used to divide the inferior pulmonary ligament.

The mediastinal pleura overlying the esophagus is incised, and the esophagus is encircled in the lower chest including all tissue from the aorta to the pericardium. The esophagus is dissected proximally behind the inferior pulmonary vein. A proximal gross in situ margin of 10 cm is ideal, though lesser margins, if confirmed negative by frozen section, may be adequate. A point of division of the proximal esophagus is identified and mobilization above this point is minimized to preserve blood supply to the anastomosis. The thoracic duct can be located at this level and ligated if desired.

**FIGURE 27-27** Left thoracoabdominal approach; delineate the circumferential diaphragmatic incision as well as the hiatal margin incision. A Penrose drain encircles the esophagus above the tumor.

The incision permits excellent exposure of the short gastric vessels, which are ligated starting at the hiatus. Care is taken along the greater curvature, where the short gastric vessels end and the right gastroepiploic vessel begins.

The right gastroepiploic artery is preserved. The gastrohepatic ligament is divided. The left gastric artery is identified and all celiac lymph nodes are swept up onto the specimen. The stomach is retracted anteriorly and the left gastric artery is divided with a vascular endoscopic stapler. The gastric tube is constructed by sequential fires of GIA staplers starting at the fundus and extending down to the crow's foot of veins. Six centimeters of distal margin is desirable. A Kocher maneuver and pyloroplasty or pyloromyotomy are performed, and the tube is passed through the enlarged hiatus into the chest. The anastomosis is typically constructed inferior to the aortic arch and may be hand-sewn as described in the previous section or stapled.

If needed, the dissection can be carried to the neck with this incision with some difficulty. The proximal esophagus can be dissected bluntly under the aortic arch, and provided the neck has been prepped into the field, a left cervical incision is made as in the tri-incisional technique and the conduit pulled into the neck. Closure begins with careful reapproximation of the diaphragm with interrupted horizontal mattress 0 silk sutures followed by solid reapproximation of the costal margin with figure-of-eight wire or heavy nonabsorbable suture such as no. 1 Prolene. Some surgeons prefer not to divide the costal margin, and instead perform all intra-abdominal work through the divided diaphragm.

## **ALTERNATIVE METHODS OF RECONSTRUCTION: COLON AND JEJUNUM**

### **Colonic Interposition**

The stomach is the preferred organ for esophageal replacement because of its blood supply, the resistance of these vessels to atherosclerotic disease, the need for a single anastomosis, and the ability of the stomach to reach the neck without difficulty. Prior gastric surgery, scarring from peptic ulcer disease, or involvement with tumor may preclude use of the stomach as a conduit. In this instance, colon interposition may be employed. The left colon is preferred over the right colon for several reasons. Its diameter more closely resembles that of the esophagus, its vascular supply has less variation, and greater length can be obtained. Unfortunately, atherosclerotic disease most

commonly affects the inferior mesenteric artery, and the left colon is often more affected by diverticular disease than the right.

Preoperative preparation includes colonoscopy or barium enema to ensure normal anatomy and the absence of any intrinsic colonic disease. Patients older than 40 years or any patients with atherosclerotic risk factors should undergo mesenteric angiography. Significant vascular disease of the conduit vessel would preclude its use as a conduit. A complete bowel prep and oral antibiotics are necessary prior to operation.

## **LEFT COLON**

After completion of the thoracic phase of the operation, the patient is placed in the supine position and a midline laparotomy is performed. After a careful search for metastatic disease, the left colon is mobilized by dividing the white line of Toldt and by dividing the attachments to the spleen and omentum. The colon is freed proximal to the hepatic flexure. A careful inspection is made of the vascular supply, including the marginal artery of Drummond ([Fig. 27-28](#)). A pulse should be palpable in the left colonic artery as well as the marginal artery. The middle colic artery supplying the hepatic flexure is clamped with a soft bulldog clamp and its perfusion is inspected for 10 minutes.

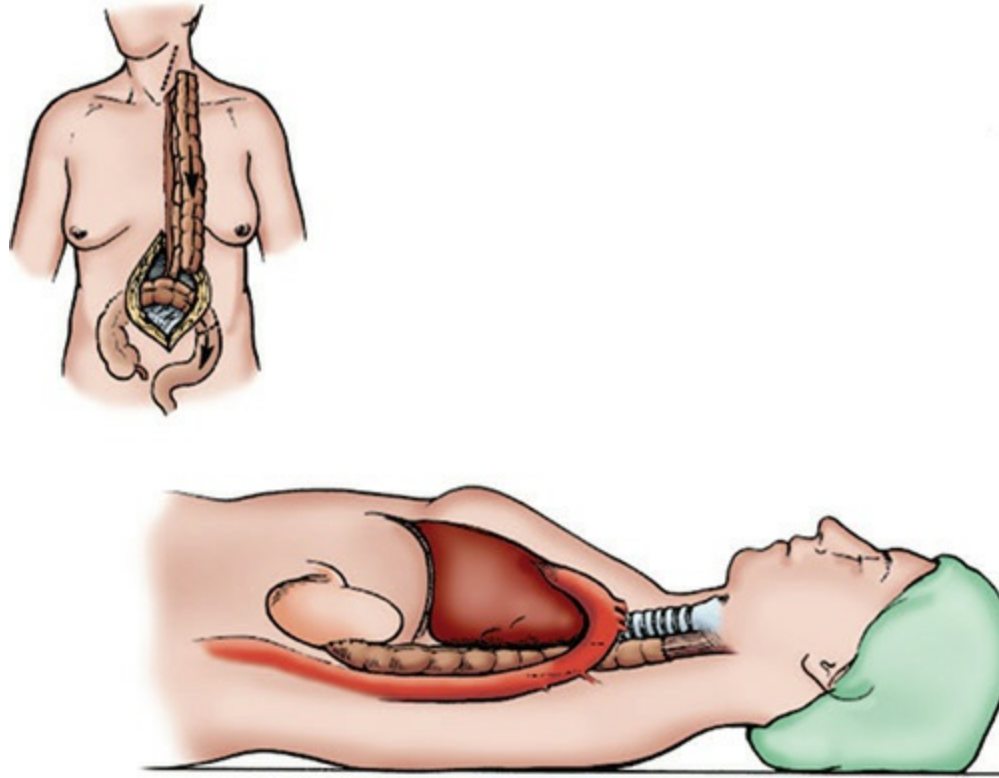

**FIGURE 27-28** The mobilized colon is elevated, and the arterial supply and venous drainage are examined. The arterial and venous ligation sites and the mesenteric incision lines are illustrated for an isoperistaltic conduit based on a left colic artery supply.

Prior to conduit isolation, the GE junction is isolated and the cardia and lesser curvature are dissected with division of the phrenoesophageal ligament and the gastrohepatic ligament. The stomach is divided using a GIA stapler. A pyloric drainage procedure is performed. The length of colon needed is estimated by placing an umbilical tie along the proposed route of colonic interposition. This tie is placed alongside the colon and the length of required colon is determined.

After ensuring adequate blood supply to the conduit, the marginal artery is

ligated distal to both branches of the left colic artery. The middle colic artery is divided near its origin. The mesentery is scored and divided between clamps. The colon is divided with GIA staplers and the conduit is packed in moist gauze. The colocolonic anastomosis is most easily stapled in side-to-side functional end-to-end fashion. The mesenteric defect is closed with a running suture to avoid internal herniation. The esophagus is identified in the neck and the esophagectomy is completed as previously described in the tri-incisional esophagectomy section.

The colon can be brought to the neck via either the anterior mediastinum (substernal) or the in situ route (bed of the resected esophagus). The in situ route is preferred, as it provides the shortest route to the neck ([Fig. 27-29](#)). In instances of prior infection or scarring (as seen with gastric conduit necrosis or leak), the in situ route may be scarred and unusable. The substernal route may then be used with resection of the manubrium required to prevent acute angulation and possible obstruction in the neck. The colon is oriented in isoperistaltic position and drawn to the neck in an endoscopic camera bag as described previously. The proximal anastomosis is most easily performed using a single-layer interrupted technique with fine 4-0 silk sutures. An EEA or functional end-to-end stapled anastomosis is also acceptable. The nasogastric tube is guided through prior to completion of the anastomosis. The cologastric anastomosis is then performed onto the posterior aspect of the stomach. The easiest method of anastomosis employs an EEA stapler. The handle is placed through an anterior gastrotomy and creates the anastomosis in the posterior wall of the stomach. The gastrotomy is then closed with a TA stapler. The nasogastric tube must be guided through the anastomosis into the stomach. Any excess length in the conduit should be pulled into the abdomen; if it remains in the chest, obstruction may result. The colon is sutured to the left crus of the diaphragm at the hiatus using seromuscular sutures in a two-third circumferential fashion in order to prevent herniation of abdominal contents into the chest.

**FIGURE 27-29** Lateral view of the colonic conduit in the posterior mediastinal esophageal bed. Cervical esophagocolonic and posterior cologastric anastomoses are shown. *Inset:* Neck incision marked and left colon conduit mobilized on the anterior chest wall, based on the marginal artery pedicle of left colonic artery and placed in isoperistaltic position.

## RIGHT COLON

There are numerous conditions that may make the left colon unsuitable as a conduit, including extensive diverticular disease, stricture from ischemia or infection, atherosclerotic occlusion of the inferior mesenteric artery, or splenic vein thrombosis and thrombosis of the inferior mesenteric vein. In these instances, the right colon may be used as a conduit to reach the neck. The right colon is mobilized by lysis of its retroperitoneal attachments. The length of colon needed is estimated with an umbilical tape as described previously. The greater omentum is removed from the hepatic flexure and proximal half of the transverse colon. Its mesentery is transilluminated revealing the ileocolic, right colic, middle colic, and marginal arteries. The ileocolic and right colic arteries are clamped in preparation for division of these vessels and mobilization of the conduit based on the middle colic

artery. If perfusion appears adequate, these vessels are ligated. The peritoneum overlying the base of the mesentery is scored, and the remainder of the mesentery is divided between clamps and ligated. The proximal and distal ends of the conduit are divided with a linear cutting stapler. Some surgeons incorporate the ileocecal valve and distal ileum in the conduit because the diameter of the ileum closely approximates that of the esophagus. Others prefer not to use distal ileum in the anastomosis, as the valve may contribute to dysphagia.

The colocolonic anastomosis is performed with staplers. The right colon conduit is then rotated in clockwise fashion (as the surgeon looks into the abdomen) in preparation for isoperistaltic transfer into the chest. As stated earlier, the preferred route is via the esophageal bed. This route is often unavailable for use in colon transposition, as one of the most common indications is a failed gastric conduit placed in the esophageal bed. The retrosternal route is most often used. The diaphragm is bluntly detached from its inferior sternal attachments, and blunt dissection with the hand is performed to enlarge the tract. Division of cartilaginous attachments behind the manubrium is also necessary. The conduit is drawn into the neck via a plastic endoscopy bag as described previously. If the thoracic inlet is thought to be too constricting, the head of the clavicle, manubrium, and anterior aspect of the first rib may be resected. The proximal and distal anastomoses are performed as described for left colon conduits. The conduit may also be passed to the neck via the transpleural or subcutaneous route (with great cosmetic deformity).

## **Jejunal Interposition**

Jejunal interposition may be applied as a free graft, pedicled graft, or Roux-en-Y replacement. Jejunum is often the third choice (after stomach and colon) for esophageal replacement, because it cannot replace the entire esophagus to the neck, but can be used to replace a portion of the distal or proximal esophagus. When distal esophagectomy is necessary for peptic stricture, jejunum or colon interposition is preferred, as both conduits are relatively resistant to reflux. The isoperistaltic conduits are believed to have a lower incidence of recurrent reflux than the simple gastric pull-up procedure. Free jejunal grafts are used in limited reconstructions of the cervical esophagus. Patients undergoing jejunal interposition should receive preoperative

antibiotics. Although a mechanical bowel preparation is not needed, it should be used if it is possible that colon may be needed.

## **ROUX-EN-Y REPLACEMENT**

Roux-en-Y replacement is most commonly used after total gastrectomy and distal esophagectomy (Fig. 27-30). Unlike stomach, it will not reliably reach to the cervical esophagus. The jejunum is divided approximately 20 to 30 cm beyond the ligament of Treitz. The jejunum and its mesentery are held up and its arcade is transilluminated. The proposed point of division is identified, as are the mesenteric vessels to be divided. The first few arcades are not divided to preserve blood flow to the native jejunum. Up to 60 cm of jejunum can be mobilized using this technique. The mesentery is scored and these vessels are clamped near their origin from the superior mesenteric artery with soft bulldog clamps. The conduit is observed for about 10 minutes for evidence of ischemia. The vessels are then ligated and divided. A hole is made in the transverse mesocolon to the left of the middle colic artery, just large enough to pass the jejunum and its mesentery. For replacement after total gastrectomy, the proximal anastomosis is made to the very distal esophagus in the upper abdomen. If resection of the distal esophagus is required, the incision is usually extended across the costal margin to the sixth or seventh interspace. If additional length is needed on the conduit, the next vessel in the arcade is identified, test-clamped, and then divided. The anastomosis can be performed by stapled or hand-sewn technique. The stapled anastomosis is most easily performed with an EEA stapler. The largest EEA stapler possible should be used for the anastomosis. The distal esophagus may first be dilated with a lubricated metal dilator. A full-thickness 2-0 Prolene suture is used to create a purse string in the distal esophagus. The shaft may be introduced by opening the stapled end of the jejunum. It can then be passed out the side of the jejunum and united with the anvil. Care must be taken not to occlude the ongoing lumen of the jejunum with the stapler. Two full-thickness anastomotic doughnuts should be verified. After removing the stapler, the jejunal end is closed with a TA 60 stapler. A hand-sewn anastomosis in one or two layers can also be performed. The jejunum is tacked to the hiatus at several points using interrupted silk sutures. This prevents herniation of abdominal contents into the chest and limits tension on the esophagojejunal anastomosis. Likewise, defects in the colonic mesentery should be closed to

prevent an internal hernia. The distal anastomosis can be hand-sewn or more rapidly performed with a side-to-side functional end-to-end stapled anastomosis.

**FIGURE 27-30** Roux-en-Y jejunal replacement of the distal esophagus.

## **PEDICLED JEJUNAL INTERPOSITION**

Pedicled jejunal interposition is most often used to replace a strictured distal esophagus (Fig. 27-31). A left thoracoabdominal incision is employed with a left seventh interspace incision extended across the costal margin and rectus muscle. The jejunum is transilluminated and an appropriate length of jejunum is selected, beginning 20 cm beyond the ligament of Treitz. A single large vessel is chosen as the conduit feeder vessel. The jejunum is transected

proximally and distally using a GIA stapler, and the mesentery is divided down each side toward the feeder vessel (Fig. 27-32A). The jejunum is reconnected using a side-to-side functional end-to-end stapled anastomosis (Fig. 27-32B). The pedicled jejunum is tunneled through the colonic mesocolon and brought up to the left chest through an enlarged hiatus. (Fig. 27-33) The proximal anastomosis can be constructed with an EEA stapler (usually 28 cm in size, but a larger anastomosis may be more resistant to postoperative stricture). The jejunogastric anastomosis is easily performed using an EEA stapler (inserting the handle through a separate gastrotomy). A two-layered hand-sewn anastomosis may also be used.

**FIGURE 27-31** Pedicled jejunal replacement of the distal esophagus. The

jejunum is brought through an incision in the transverse mesocolon.

**FIGURE 27-32** **A.** The jejunum is prepared in an isoperistaltic fashion (*arrows*) based on a distal mesenteric branch and proximal marginal arcade. The *dotted line* illustrates the line of resection of mesentery and the division of vessels. **B.** After dividing the mesentery and preserving the pedicle, jejunal continuity is restored and the mesenteric defect closed.

**FIGURE 27-33** Jejunal interposition graft to reconstruct the lower esophagus. An end-to-side esophagojejunostomy is performed to avoid tension on the vascular pedicle. A posterior jejunogastric anastomosis avoids tortuosity of the conduit while an 8- to 12-cm segment of the jejunal graft situated below the hiatus aids in the control of reflux.

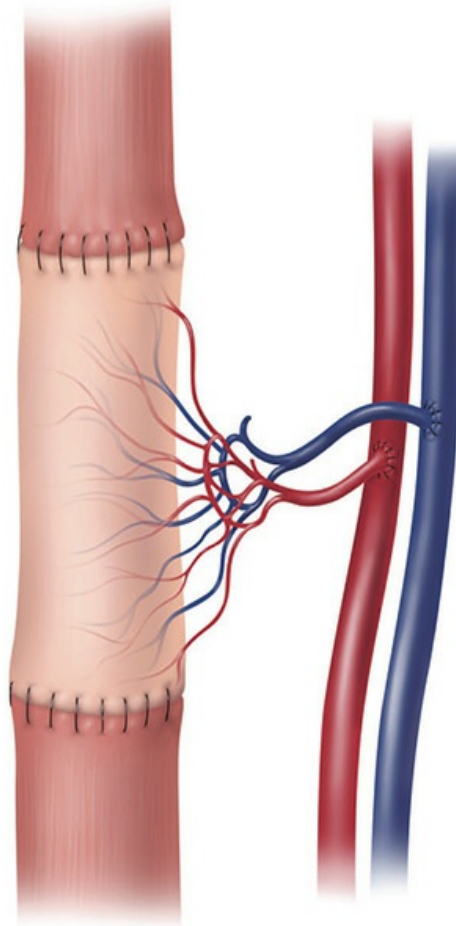

### **FREE JEJUNAL TRANSFER**

Free jejunal transfer is needed if the pedicle is not of sufficient length, such as in replacement of a portion of the cervical esophagus for benign disease. It is not clear whether use of a free jejunal transfer is preferable to total esophagectomy and gastric pull-up. The use of jejunum does carry a lower

incidence of postoperative reflux and avoids dissection of the thoracic esophagus; however, there is increased risk of graft ischemia and gangrene. Two anastomoses are required and there is an increased risk of anastomotic leak. As with a pedicled jejunal graft, a short segment of jejunum is chosen for harvest. A left cervical incision is made, and the esophagus as well as the carotid artery and jugular vein are isolated. A dominant feeder vessel in the jejunal segment is identified and divided with a scalpel. The artery and vein are flushed with heparinized saline. The proximal anastomosis is constructed first and is performed with a two-layer end-to-side hand-sewn anastomosis. An operating microscope is then used to perform the arterial and venous anastomosis to the carotid artery and jugular vein with 9-0 or 10-0 Prolene suture. The distal anastomosis is then performed in a fashion identical to the proximal anastomosis (Fig. 27-34). Typically, a meshed skin graft is placed over the conduit for continuous postoperative monitoring. A feeding jejunostomy tube is placed as with every case of esophageal replacement.

A

B

**FIGURE 27-34** Free jejunal graft used as a cervical esophageal replacement. It is typically covered with a meshed skin graft so that conduit health can be observed postoperatively.

## COMPLICATIONS AND HOW TO AVOID THEM

### Anastomotic Leak

The incidence of anastomotic leak is higher following cervical anastomosis (10%-17%) than intrathoracic anastomosis (5%-10%).<sup>39,40,44,45</sup> The incidence of leak is believed to be higher in the cervical position for several reasons. First, increased length is needed and this may place increased tension on the anastomosis. The tip of the stomach, which is used in the cervical anastomosis, may have a more tenuous blood supply, as it is farther from the gastroepiploic artery. Additionally, venous engorgement due to a tight thoracic inlet may impair blood supply. An analysis of anastomotic leaks found that albumin level below 3 g/dL, positive margins, and cervical anastomosis were risk factors for anastomotic leak following esophagectomy.<sup>46</sup> A randomized comparison of hand-sewn versus stapled anastomosis in 102 patients undergoing Ivor Lewis esophagectomy did not show any significant difference in the incidence of anastomotic leak. The incidence was 5% after a single-layer monofilament anastomosis and 2% after a stapled anastomosis.<sup>47</sup> The incidence of leak following hand-sewn anastomosis is more operator-dependent, and those who perform few of these procedures may wish to use a stapled technique.

Anastomotic leak following Ivor Lewis esophagectomy is a feared complication that in the past was associated with a 50% mortality rate. Centers that routinely employ this technique have refined their techniques, resulting in very low leak rates in the 2% range. Early detection and aggressive management can reduce the high mortality rate usually associated with this complication. Unexplained fever, elevated white cell count, respiratory failure, delirium, hypotension, or low urine output may signal the onset of an intrathoracic leak. Confirmation is usually possible by Gastrografin swallow or instillation of contrast through the nasogastric tube.

Immediate intervention is required, and attempts at direct repair with muscle flap reinforcement and wide drainage are often successful. Patients who are unstable or severely ill should be diverted with a spit fistula, and either excluded at the hiatus or have the conduit closed and returned to the abdomen. In rare instances, a clinically silent, small, contained leak that is not adjacent to vital structures such as the trachea or aorta may be observed and treated with strict NPO status and enteral feeds.

Although leak is more common following cervical anastomosis, it is rarely life threatening. Occasionally a cervical anastomosis may leak into the chest and must be treated like an intrathoracic leak. Initially, mortality from a cervical leak was estimated at 20%, though recent series have shown that the mortality is much lower.<sup>48</sup> Cervical anastomotic leak is usually signaled by fever, erythema, and fluctuance in the neck incision. Opening of the neck incision and probing down to the prevertebral fascia (with placement of a drain) is usually all that is needed. Patients can be allowed clear liquids by mouth and may be fed via jejunostomy tube until the leak is sealed. Barium swallow following esophagectomy may miss 10% of cervical leaks. Giving patients purple grape juice to drink and observing the drain during swallow may detect leaks missed by barium swallow.

## **Anastomotic Stricture**

The same risk factors that predispose to anastomotic leak also predispose one to stricture. Indeed, it is very common to present with stricture following treatment for an anastomotic leak. Retrospective meta-analyses have shown that the incidence of stricture is higher after cervical reconstruction (28%) than after Ivor Lewis reconstruction (16%).<sup>40</sup> The definition of stricture is not precise and is usually determined by the need for intervention (ie, dilation). As some surgeons are more aggressive than others with regard to dilation, this value may be misleading. A retrospective analysis of transhiatal esophagectomy patients revealed that the use of a stapled anastomosis, anastomotic leak, and the presence of cardiac disease were the only risk factors associated with the development of stricture.<sup>49</sup> Other studies have mentioned intraoperative blood loss and poor conduit vascularization as risk factors. A unifying theme in anastomotic stricture (other than mechanical stapler issues) is impaired blood supply to the region of anastomosis. In an

effort to avoid ischemia, it is wise to not place the anastomosis too close to the tip of the gastric conduit. Careful handling of the gastroepiploic artery, ensuring systemic oxygen delivery, and avoidance of congestion all are important in avoiding anastomotic leak and stricture.

Mechanical factors may also contribute to development of stricture, especially when an EEA-stapled anastomosis is performed. In a randomized evaluation of the EEA stapler for Ivor Lewis anastomosis, the incidence of stricture was found to be 40% with a stapled anastomosis versus 9% with a hand-sewn anastomosis. When a small (25-mm) EEA stapler was used, the incidence of stricture was 43% as opposed to a 12.5% incidence with a 29-mm stapler, and no strictures were seen with a 33-mm stapler.<sup>47</sup>

Postoperative strictures may nearly always be managed by bougie dilation. Repeat dilations are often needed. In the aforementioned study of strictures following Ivor Lewis esophagectomy, 53% of patients needed one dilation, 20% required two, 12% required three, and 8% required four. No patient was treated with reoperation. In Honkoop and associates' study of anastomotic stricture following transhiatal esophagectomy, the average patient required three dilations to achieve normal swallowing. Perforations occurred in 2 of the 519 patients requiring dilation.<sup>49</sup>

## **Recurrent Laryngeal Nerve Injury**

The clearest risk factor for recurrent nerve injury is cervical anastomosis. In retrospective analyses by both Rindani et al. and Boshier et al., the incidence of recurrent nerve injury with a cervical anastomosis was double (11%) than that for intrathoracic anastomosis (5%).<sup>38,39</sup> The recurrent nerve can be injured at any point, from its "recurrence" from the vagus nerve (around the subclavian artery on the right and around the aortic arch on the left), to its course in the tracheoesophageal groove, to its insertion into the larynx. Although an Ivor Lewis resection should not touch the recurrent nerve, traction or cautery injury to the vagus nerve may cause injury to the recurrent nerve.

A left neck incision is often used to approach the cervical esophagus. The right recurrent nerve is farther from the esophagus than the left, and it is easier to avoid the right nerve from a left neck incision than it is to avoid the left nerve from a right neck incision. During neck dissection, it is important

to stay immediately against the esophagus in order to avoid injury to the nerve. In a review of tri-incisional esophagectomy by Swanson and colleagues, refinements in technique resulted in a reduction of recurrent nerve injury from 14% to 7%.<sup>50</sup> In the Brigham and Women's Hospital technique, the vagus nerves are divided at the level of the azygos vein, and cranial dissection of the esophagus proceeds within the nerves. A Penrose drain is used to surround the esophagus and is positioned in the neck for later retrieval during the cervical phase of the operation to ensure isolation of the esophagus inside the recurrent nerves.

Early recognition and aggressive treatment are necessary to minimize respiratory complications from recurrent nerve injury. Recurrent nerve injury prevents cord apposition, making an effective cough impossible and interfering with protective reflexes involved in swallowing. Hoarseness is present with recurrent nerve injury but may be present after any intubation. Loss of effective cough is another hallmark of recurrent nerve injury but may not be present immediately following extubation, because there may be swelling of the cords after use of a double-lumen tube, a prolonged operation, and large fluid shifts. Effective cough may be lost between 24 and 48 hours after extubation as cord swelling decreases. Any patient with hoarseness and ineffective cough should undergo fiberoptic laryngoscopy. Immediate injection of the affected cord with gelfoam will allow an effective cough and clearance of secretions.

## **Respiratory Complications**

In early series, anastomotic leak and infection were the most common cause of death following esophagectomy. In modern series, the most common cause of death is respiratory failure. The incidence of pneumonia following esophagectomy ranges from 2% to 57%.<sup>36,45,51</sup> The assumption that the incidence of pneumonia is higher with transthoracic esophagectomy than with transhiatal esophagectomy has not been definitively borne out by the literature. A large meta-analysis by Rindani and coworkers showed no difference in incidence of pneumonia between the two techniques.<sup>40</sup> Conversely, a more modern yet sizable meta-analysis of studies published between 1980 and 2006 did report a significantly higher incidence in pneumonia in the transthoracic group (21% transthoracic vs 17% transhiatal).

The authors, however, performed a subgroup analysis of 16 studies published after 1999, and this analysis no longer returned a significant difference in pneumonia between the two approaches.<sup>39</sup> Two randomized trials, one by Goldmine and associates and one by Chu and colleagues, also showed no difference in the incidence of pneumonia.<sup>33,35</sup> A larger randomized trial comparing tri-incisional, en bloc esophagectomy with transhiatal esophagectomy did show a higher incidence of combined atelectasis and pneumonia in the tri-incisional group (57%) versus the transhiatal group (27%). The unexpectedly high incidence of pulmonary complications in the transthoracic group should, however, be questioned, as reported rates are typically around 20% to 35%.<sup>31,32</sup>

A variety of modifications and maneuvers can be employed to limit the incidence of pulmonary complications. All efforts must be made to spare injury to the recurrent nerve, and if injured, aggressive intervention including cord medialization is necessary. Efforts at limiting pain associated with thoracotomy, including a limited muscle-sparing thoracotomy, are helpful. The use of thoracic epidurals has been shown to decrease the incidence of pulmonary complications in thoracotomy patients. Early ambulation and aggressive pulmonary toilet are necessary.

## Bleeding

Bleeding following esophagectomy occurs about 5% of the time regardless of the technique used. Meta-analyses have shown that estimates of blood loss are slightly higher with the transthoracic group as opposed to the transhiatal group.<sup>36,38</sup> Preoperatively, antiplatelet agents should be stopped well in advance of surgery. Low-dose subcutaneous heparin or low-dose low-molecular-weight heparin should not increase the incidence of perioperative bleeding. Intraoperatively, arterial branches from the aorta to the esophagus should be clipped whenever possible. If blunt dissection is used, staying immediately against the esophagus should help avoid larger arteries, as the esophageal arterioles tend to form a fine plexus of vessels approximately 1 to 2 cm away from the wall of the esophagus. A notorious site of bleeding during the transhiatal dissection is the azygos vein or one of its branches. This bleeding usually occurs at about the level of the carina and, as always, extra care should be taken at this level. A common site of bleeding after any

thoracotomy is the chest wall itself, including intercostal vessels; these should be inspected after removing the retractor.

## Chyle Leak

The thoracic duct enters the chest through the aortic hiatus and lies between the spine, azygos vein, and aorta at the level of the diaphragm. At approximately the T6 level, it crosses to the left side and eventually empties into the left subclavian vein. The incidence of chyle leak following esophagectomy ranges from 2% to 10% and is at greatest risk during en bloc resection. If the thoracic duct is taken during en bloc dissection, the duct is ligated at the hiatus and inspected for leak. It is wise to inspect the area of the thoracic duct at the end of any transthoracic dissection of the esophagus. Often, clear fluid (in the unfed patient) can be seen welling up in the area and may lead one to a laceration of the thoracic duct. In such instances, the leak should be repaired directly with pledgeted 4-0 Prolene sutures. Prophylactic ligation of the thoracic duct following esophagectomy is sometimes performed. In this maneuver, all tissues between the aorta, spine, and azygos vein at the level of the hiatus is ligated with a large (0 or 1) ligature.

The diagnosis of a thoracic duct leak should be suspected if chest tube output remains high (>800 mL/d) in a patient despite a normal volume status. Definitive diagnosis may be difficult, because chyle is not milky unless the patient has been fed fats. Fluid should be sent for Gram stain, triglyceride level, cell count, and cholesterol level. A triglyceride level greater than 1 mmol/L is strongly suggestive of a chyle leak, as is a lymphocyte count greater than 90%. If chylomicrons can be confirmed by electrophoresis, the diagnosis can also be established. A good bedside test involves feeding the patient cream enterally 200 to 300 mL over 2 hours and observing for a change in character of chest tube effluent, from serous to milky white.

Chyle leak following esophagectomy must be repaired. These patients are recovering from major surgery and most are malnourished. The loss of protein and lymphocytes associated with a chyle leak may be associated with infections and may interfere with healing. Once the diagnosis is confirmed, or even if it is strongly suspected, patients should be treated. They can be brought to the operating room and the thoracotomy incision reopened. The patient is given enteral cream 1 hour before the procedure to help locate the leak. The defect is repaired with a pledgeted 4-0 or 5-0 Prolene suture. A

Careful inspection for other leaks should be performed before closure, and mass ligation of the duct at the hiatus should be considered as well.

CT- or MRI-guided noninvasive methods have been proposed for repairing chyle leaks. The cisterna chyli can sometimes be located under CT guidance, cannulated, and injected with either coils or glue. In a published trial of 42 patients (including 9 postesophagectomy patients), the thoracic duct could be embolized in 26, and 16 of these cases were cured.<sup>52</sup>

## Impaired Conduit Emptying

Numerous factors affect conduit emptying postesophagectomy. These include vagotomy, drainage through the pylorus, width of the conduit, redundancy and/or kinking of the conduit, and postoperative swelling. Studies objectively looking at conduit emptying following esophagectomy give conflicting results as to the effect of pyloroplasty on gastric conduit emptying time. A prospective trial studied 200 patients and randomized half to pyloroplasty and half to no pyloroplasty following Ivor Lewis esophagectomy.<sup>53</sup> The average daily postoperative nasogastric drainage was no different between the two groups. Thirteen patients who did not undergo pyloroplasty had symptoms from delayed gastric emptying, and two died of aspiration pneumonia. There were no complications from the pyloroplasty procedure. Six months after the procedure, gastric emptying was 6 minutes in the pyloroplasty group versus 24 minutes in the group without pyloroplasty. These patients had more symptoms attributable to delayed emptying as well. The same group conducted a randomized trial of pyloroplasty versus pyloromyotomy and found both to be equally effective and safe.

Width of the gastric conduit may also affect emptying. A thin gastric tube has been shown to have a lower incidence of symptoms related to poor gastric emptying (3%) than patients either with the whole stomach (38%) or distal two-third stomach (14%) acting as the conduit.<sup>54</sup> A conduit diameter of 5 to 6 cm is probably ideal. Excess conduit length or angulation may also impair emptying, and excess colon conduit length or angulation is known to cause immediate or delayed problems with emptying. However, a conduit that is too thin can lead to an increased anastomotic leak rate.<sup>55</sup>

## CONCLUSION

Esophagectomy can be a technically challenging operation. Mortality rates can vary greatly with experience. Hospital volume and surgeon experience play significant roles. Analysis of the relationship between volume and mortality shows a large variance in mortality from almost 25% in low-volume and low-experience centers to as low as 2.5% in high-volume centers.<sup>56,57</sup> With improvements and increased penetration of minimally invasive techniques, mortality has been reported as low as 1.4%.<sup>55</sup> Careful patient selection, preoperative preparation, and choice of operation, as well as meticulous surgical technique, excellent anesthetic and intensive care, and aggressive management of postoperative complications can limit the morbidity and mortality of this operation.

# **PERSPECTIVE ON CANCER OF THE ESOPHAGUS AND SURGICAL PROCEDURES TO RESECT AND REPLACE THE ESOPHAGUS**

*Joshua A. Boys • Tom R. DeMeester*

It was a pleasure to receive a letter from Dr. Michael Zinner inviting us to write a prospective on the chapters from Drs. Daniel Tong and Simon Law from Hong Kong on cancer of the esophagus and Drs. Jon Wee, Shelby Steward, and Raphael Bueno from The Brigham and Women's Hospital, Harvard Medical School, on surgical procedures to resect and replace the esophagus. We begin by stating both chapters are exceedingly well written, informative, and enlightening. Our reading identified areas where we were moved to comment based on our personal experience. The comments usually take the form of additional thoughts or alternatives. Occasionally, we raise a note of caution or take a controversial point of view.

## THE PROBLEM OF BARRETT ESOPHAGUS

The specific reason for the dramatic increase in adenocarcinoma of the esophagus continues to remain a mystery, even though it represents the largest epidemiologic change ever recorded for a solid cancer.<sup>1</sup> Reasons proposed for the significant and continuous increase in incidence of esophageal adenocarcinoma are the epidemics of obesity and gastroesophageal reflux disease (GERD).<sup>2</sup> The latter can result in the complication of Barrett esophagus and its subsequent development into high-grade dysplasia. As Tong and Law point out, high-grade dysplasia is the last preinvasive stage in the metaplasia–dysplasia–cancer sequence and has become the focus of efforts to combat the problem. Intensive surveillance of patients with Barrett esophagus is proposed as a strategy to identify high-grade dysplasia prior to the evolution of cancer and treat it with endoscopic mucosal resection or ablation. To date, the results of intensive surveillance have been disappointing, and the work involved in ablation and its required unlimited follow-up is extremely expensive. Further, Tong and Law indicate a 20% recurrence rate after an average follow-up of 2.4 years, and the median length of Barrett mucosa in which the recurrent lesion occurred was only 0.6 cm, which is significantly shorter and more difficult to identify than the pretreatment length.

Disappointment with intensive surveillance as a solution to the Barrett esophagus problem has stimulated an interest in the possibility of surgically preventing the development of Barrett esophagus. The progression of GERD to Barrett esophagus in patients who are receiving treatment with proton pump inhibitors (PPIs) has been reported by several investigators.<sup>3-5</sup> This has led to concerns that PPI therapy does not address all aspects of the disease and patients who are at risk of progression need to be identified early in the course of their disease in order to prevent the development of visible Barrett esophagus. Recently, it has been reported that biopsies of the squamocolumnar junction that show microscopic intestinalized metaplastic cardiac mucosa in endoscopically normal patients with GERD are predictive of the evolution of visible Barrett esophagus.<sup>6</sup>

A further indicator of progression toward visible Barrett esophagus is a permanent structural alteration of the lower esophageal sphincter (LES) on manometry, resulting in uncontrollable reflux.<sup>5,7</sup> Acid suppression therapy is

notably effective in patients who have a normal LES but less so in those who have a structurally defective LES. Permanent structural alterations of the LES are difficult to correct without surgical intervention. The likelihood of symptom control and prevention of progression to Barrett esophagus in patients with persistent symptoms on PPI therapy is greater if surgical correction of a compromised LES is carried out earlier rather than later.<sup>7</sup>

A proposed solution to the rising incidence of esophageal adenocarcinoma is to apply the principle: Where there is no Barrett esophagus, there is no cancer. A competent Nissen fundoplication has been shown to prevent Barrett esophagus if performed before it develops.<sup>8</sup> Early fundoplication in patients with microscopic intestinal metaplasia just below the squamocolumnar junction, in the absence of endoscopically visible Barrett esophagus, results in complete regression of the intestinal metaplasia and no evidence of visible Barrett esophagus in 74% of patients.<sup>9</sup> In a separate control group of patients with endoscopically visible Barrett esophagus, only 4% of patients showed regression of the Barrett esophagus after fundoplication.<sup>9</sup>

Despite the ability of the fundoplication to induce regression of microscopic intestinal metaplasia and prevent development of visible Barrett esophagus, the side effects of the procedure (ie, dysphagia, bloating, and the inability to burp and vomit) have discouraged the use of this approach to avert the evolution of the precancerous lesion. Over the past decade, minimally invasive outpatient LES augmentation procedures have been developed. These procedures avoid the side effects associated with Nissen fundoplication and may therefore be appropriate for early surgical intervention.<sup>10</sup> The effectiveness of these procedures to induce regression of microscopic intestinal metaplasia at the squamocolumnar junction and avert the development of Barrett esophagus and a subsequent adenocarcinoma should be investigated in future clinical studies.

The burden of esophageal adenocarcinoma is predicted to continue to rise dramatically in high-income countries.<sup>11</sup> It is incumbent on both gastroenterologists and surgeons to work together to stop the rising incidence of Barrett esophagus, the premalignant lesion of esophageal adenocarcinoma. By 2030, it is predicted that 1 out of every 100 European men will be diagnosed with esophageal adenocarcinoma before the age of 75.<sup>11</sup>

## THE ERROR IN CLINICAL STAGING OF ESOPHAGEAL CANCER

Tong and Law have rightly pointed out that “accurate staging allows stage-directed therapies and quality control for clinical trials.” They could not be more correct; however, there is an emerging problem. Clinical studies based on clinical staging have up to an 84% error rate for specific staging of a patient<sup>12</sup> and a 24% error rate for staging a patient above or below a specified stage.<sup>13</sup> Such a degree of error could affect proper randomization between the arms of a clinical study if the size of the study population is insufficient. As a consequence, the results of randomized studies between different treatment regimens that are based on clinical staging become suspect.

Superficial esophageal adenocarcinomas, particularly T1a lesions, are nearly always staged correctly and cured by endoscopic mucosal resection. Similarly, advanced locoregional disease (cT2-3N2-3 in the updated staging system) is usually staged correctly, and although neoadjuvant therapy has been shown to be of benefit, cure of this advanced disease is rare. The problem with clinical staging arises in patients with limited locoregional disease (cT2-3N0-1 in the updated staging system) who fall between these 2 extremes. The accuracy of staging cT2-3N0-1 disease correctly by clinical staging is between 13% and 25%.<sup>12,13</sup> In such patients, the assessment of nodal metastases remains problematic and is culpable for the staging error.

Complicating things further, it is now recognized that the number of involved lymph nodes is a critical factor in survival.<sup>14</sup> The updated seventh edition of the American Joint Committee on Cancer (AJCC) staging system has N0 (no positive nodes), N1 (1-2 positive nodes), N2 (3-6 involved nodes), and N3 (7 or more involved nodes) categories. Currently, there is little information on the accuracy of clinical N staging using the updated staging system. Treatment algorithms would be simplified and clinical staging would be of little significance if neoadjuvant therapy was beneficial for all resected patients other than those with superficial tumors amenable to treatment by endoscopic resection alone. However, multiple studies have failed to show a benefit for neoadjuvant therapy in patients with limited locoregional disease.<sup>12,15-18</sup>

A recent study by Worrell et al reported the accuracy of clinical staging and survival of patients treated with primary esophagectomy for limited

locoregional disease defined as cT1-3 and N0-1 (in the updated staging system, disease limited to 0-2 involved nodes).<sup>13</sup> Using endoscopic resection, endoscopic ultrasound, and/or computed tomography/positron emission tomography scan, the final pathology confirmed accurate clinical staging ( $\leq$ T3N1) in 76% of patients with limited locoregional disease. The remaining 24% of patients were understaged ( $>$ T3N1), and in all cases, understaging was based on advanced nodal (N2 or N3) disease. Overall, 65% of the patients were node negative (T1-2N0), and the survival rate in these patients was 82% at 5 years and would likely not have been improved with induction therapy. These results compare favorably to the 64% 5-year survival rate for similarly clinically staged patients who received neoadjuvant chemoradiotherapy before esophagectomy in a series reported from the MD Anderson Cancer Center.<sup>19</sup> This comparison and other reported experiences are providing accumulating evidence that neoadjuvant therapy is not beneficial in node-negative patients.

There are now 2 studies that show the risk of systemic disease can be correlated with the number of involved lymph nodes and exceeds 50% when 3 or more nodes are involved.<sup>12,14</sup> Consequently, it remains to be determined whether systemic induction therapy would be beneficial for patients with N1 disease (0-2 involved nodes based on the staging system) if they have less than a 50% chance of systemic disease recurrence.

In the study by Worrell et al 24% of patients were understaged, all on the basis of unsuspected N2-3 disease.<sup>13</sup> The overall 5-year survival rate in correctly staged patients was 67%, compared with 33% for patients who were understaged ( $P < .0001$ ). Consequently, understaged patients with advanced nodal disease are at high risk for systemic metastases, and resection alone is inadequate treatment.

Ideally, clinical staging would identify patients with advanced nodal disease so that they can be offered neoadjuvant therapy before resection. Toward this goal, Worrell et al performed a multivariable analysis on their studied population to identify independent factors that were statistically associated with an increased risk for nodal understaging. Three factors proved significant: dysphagia at presentation, tumor size  $>3$  cm, and poor differentiation.<sup>13</sup> When none of these factors were present, 97% of patients were correctly staged. Conversely, when all 3 factors were present, 92% of patients were understaged. Patients with 1 or 2 risk factors had an

intermediate risk of understaging. These findings suggest that, in addition to the results of imaging studies, these 3 factors can be used to select patients at high risk for nodal disease and for consideration of neoadjuvant therapy. Further, if these additional clinical factors are used, the number of understaged patients would be reduced from 24% to 12.5%.<sup>13</sup> At this level, more definitive results of trials with neoadjuvant therapy would be forthcoming and help to properly select patients who should receive neoadjuvant therapy and those who should be protected from the potentially toxic and immunosuppressive effects of neoadjuvant therapy.

## CHOICE OF ESOPHAGECTOMY

In their respective chapters, both groups of authors tackle the ongoing debate between transhiatal and transthoracic esophagectomy. Their discussions are excellent and point out the various factors to consider in choosing one or the other procedure. It is important to keep in mind that not all transthoracic esophagectomies are en bloc esophagectomies. Consequently, the basis for the debate between the 2 procedures is the principle that surgical cure of esophageal cancer is dependent upon early detection and complete surgical removal of all tumor and potential tumor-bearing lymph nodes. To appreciate the topic in both chapters, it is important for the reader to understand the historical development of the en bloc esophagectomy.

The en bloc esophagectomy was first described by Andrew Logan in 1963.<sup>20</sup> The borders of Dr. Logan's dissection were the esophageal hiatus and costovertebral angle inferiorly; the aorta and thoracic spine posteriorly; the trachea, pericardium, and diaphragm anteriorly; and the arch of the azygos vein superiorly. In the abdomen, the proximal stomach and greater omentum are removed along with the node-bearing tissue along the right crus, left crus, porta hepatis, portal vein, common hepatic artery, celiac artery, left gastric artery, splenic artery, and splenic hilum. Although the extensive procedure was effective in curing some patients with cancer of the esophagus, the rate of cure was barely more than the mortality of the procedure.

Early treatment paradigms viewed esophageal carcinoma as a systemic problem at the time of diagnosis. This encouraged the concept of palliation rather than cure as the goal of the surgical procedure and persuaded surgeons to perform the thoracic portion of the dissection from the abdomen through

the esophageal hiatus as a means of providing palliation with less morbidity and mortality.<sup>21</sup> Other surgeons were performing the en bloc dissection for early cancers and reserving the palliative transhiatal dissection for more advanced disease in order to reduce morbidity and mortality when there was a low probability of cure. The policy of reserving the en bloc dissection for early cancers was first challenged in 1997 by David Skinner and colleagues.<sup>22</sup> Their retrospective study showed the 4-year and overall median survival after an en bloc esophagectomy was significantly improved over that achieved with a more limited resection with no difference in mortality and morbidity. Some surgeons argued that the improvement was a result of selection bias because more patients with a lower stage were in the en bloc group. However, when patients with stage III disease were analyzed, there was a significant improvement in the 4-year survival of 11% after the limited resection compared to 34.5% after the en bloc resection.

As retrospective evidence in favor of the en bloc dissection was emerging, the controversy over the 2 techniques grew among surgeons, and the scientific community was encouraged to perform a robust randomized controlled trial comparing resection techniques. A flaw of this methodology was pointed out by Altorki and colleagues, when they stated that “a randomized trial, however, can only compare potentially comparable strategies. The unquestionable deficiency of limited resections in providing adequate staging will not vanish in a randomized setting.”<sup>22</sup> This was proven by van Lanschoot’s group in 2002, who performed a randomized controlled trial comparing transhiatal and en bloc resections in patients who were American Society of Anesthesiology (ASA) class I or II and did not receive neoadjuvant chemotherapy and/or radiation therapy.<sup>23</sup> The en bloc patients had significantly more nodes resected than the patients who underwent transhiatal resection (median,  $31 \pm 14$  vs  $16 \pm 9$  nodes). Further, the patients who had the en bloc resection had more stage III and IV disease than those who had a transhiatal resection. Despite their advanced stages, the patients who had the en bloc resection were trending toward an improved 5-year disease-free survival compared to those who had the transhiatal dissection. The difference, however, was not statistically significant.

Because a randomized controlled trial is unable to make an appropriate comparison between resection methods due to the difficulty of having a population of patients with the same tumor stage, the next best method is a

matched comparison. This was done by Johansson and associates in 2004.<sup>24</sup> They compared patients receiving transhiatal or en bloc R0 resection for T3 adenocarcinoma with at least N1 disease,  $\geq 20$  lymph nodes removed, and no neoadjuvant therapy. The patients were followed for a minimum of 5 years or until death from recurrent cancer. The only significant differences between the groups were median age (71 years for transhiatal vs 57 years for en bloc) and the median number of resected nodes (29 for transhiatal vs 52 for en bloc). The 5-year overall survival was improved with en bloc resection compared to transhiatal resection; however, the survival advantage was limited to patients with 8 or fewer positive nodes. All patient with evidence of 9 or more involved lymph nodes had a similar survival regardless of resection technique. On Cox analysis, only the number of involved lymph nodes and the type of resection were significant factors for improved survival.

In light of the evidence put forth by the report of Johansson et al in 2004, van Lanschot and associates reanalyzed their randomized study data to assess differences in survival by resection type and number of involved nodes.<sup>25</sup> When this was done, those with 1 to 8 involved lymph nodes had an improved overall survival after an en bloc resection (39%) compared to those who had a transhiatal resection (19%). Patients who had an en bloc resection also had reduced locoregional recurrence rate (42% for transhiatal vs 25% for en bloc) and an improved 5-year disease-free survival (23% for transhiatal vs 46% for en bloc;  $P = .002$ ). Just as Johansson's report found in 2004, there were no survival difference between resection techniques in patients with 0 or  $\geq 9$  involved lymph nodes.

The proposed explanations for the poor survival of patients with 1 to 8 involved lymph nodes who had the transhiatal resection are as follows: (1) After a transhiatal resection, there remains more undetected patients with  $>8$  involved lymph nodes; (2) the transhiatal resection is less able to remove involved lymph nodes in patients with  $\leq 8$  involved lymph nodes; and (3) a combination of both explanations. To investigate these possible explanations, a multinational study was performed in 2008 by Peyre and associates to determine if the number of involved lymph nodes could predict the risk of systemic disease after esophagectomy irrespective of the resection technique.<sup>14</sup> The study showed that patients with systemic disease were more likely to have T3 tumors, and 3 or more involved lymph nodes. Patients with only 1 or 2 involved lymph nodes were significantly less likely to develop

systemic disease compared to patients with 3 to 7 involved lymph nodes (44% vs 69%, respectively;  $P < .001$ ). The relationship of nodal disease to systemic disease in this study indicated that when 3 or more nodes are involved, the likelihood of systemic disease is >50% and approaches 100% with 8 or more involved lymph nodes.

Based on the above studies, the goal to improve the survival of patients with esophageal cancer by surgery should be to remove all diseases in patients with <8 involved nodes. To determine how many nodes need to be resected at the time of surgery to accomplish this task was studied in a second trial by Peyre and associates in 2008.<sup>26</sup> They identified the top 3 independent predictors associated with survival using Cox regression analysis. The number of involved lymph nodes was the strongest predictor of outcome, followed by the depth of invasion (T) and the total of number of nodes removed. A linear association with improved survival occurred with increasing number of lymph nodes removed. The resection that took out the maximal number of nodes was an en bloc resection, with a median of 30 nodes removed. In contrast, the median numbers of nodes taken out by other resection techniques were as follows: transhiatal, 12 nodes; Ivor-Lewis, 13 nodes; transthoracic, 13 nodes; and thoracoabdominal, 14 nodes. Of the 3 predictors of survival (ie, the number of involved nodes, the depth of tumor invasion, and the number of nodes removed), only the number of nodes removed can be influenced by the surgeon. To maximize the outcome of surgical resection for esophageal cancer, a lymphadenectomy that removes a minimum of 23 to 29 nodes needed to be performed.<sup>26</sup> The operation most likely to achieve this threshold is an en bloc resection.<sup>26</sup> In an era when esophagectomy can be performed safely, emphasis must now be placed on performing an adequate oncologic procedure. From a logical perspective, the en bloc resection appears to do this the best.

A study by Koenig and coworkers in 2009 showed that the reason for improved survival following the removal of more lymph nodes was the likelihood of taking out lymph nodes containing micrometastases.<sup>27</sup> The lymph nodes containing micrometastases were identified by immunohistochemistry after a curative resection without neoadjuvant or adjuvant therapies. In patients with T2 or T3 disease, 36.8% had micrometastases, compared to 11% of patients with T1 tumors. The 5-year survival of patients with detected occult micrometastases in lymph nodes was significantly worse than that of patients without nodal micrometastases (30%

vs 76%, respectively). The en bloc resection achieves the highest number of lymph nodes removed, and as a consequence, it removes a greater number of lymph nodes containing micrometastases; for this reason, it is associated with a better survival.

Some may argue that with the use of neoadjuvant therapy and en bloc resection is not necessary. Rizzetto et al<sup>28</sup> showed in a 2008 study that, in patients with locally advanced adenocarcinoma of the esophagus, all of whom were treated with neoadjuvant therapy, there was a significant improvement in overall survival and survival with residual disease in patients who underwent an en bloc esophagectomy compared to those who had a transhiatal resection. The study clearly showed that even after neoadjuvant therapy, the extent of resection is an important determinant of long-term survival from esophageal adenocarcinoma. The explanation for this finding relates to the higher locoregional failure rate with the transhiatal resection and likely to the removal of both known and unknown (micrometastatic) disease with the extended lymphadenectomy performed by the en bloc resection.

## **STOMACH AND DUODENUM**

# BENIGN GASTRIC DISORDERS

*Ian S. Soriano • Kristofell R. Dumon • Daniel T. Dempsey*

## INTRODUCTION

Most benign gastric disorders are either inflammatory or neoplastic. A variety of vascular, mechanical, congenital, and traumatic disorders also affect the stomach. Some of these are covered in other chapters of this book. Surgical management of benign gastric disorders has evolved significantly over the last 40 years. Elective peptic ulcer surgery for intractability has largely been replaced by medical management, though urgent operation for perforation is not uncommon, and occasional elective ulcer operation is still necessary for obstruction or nonhealing. Most elective (and even urgent) gastric procedures can now be performed with laparoscopy (and in some cases with robotic assistance) if local expertise is available. Intraoperative endoscopic guidance with or without ultrasound allows accurate lesion localization and can help the surgeon perform a more targeted resection when wide margins are not necessary.

## HELICOBACTER PYLORI INFECTION

*Helicobacter pylori*-induced chronic gastritis is the most important risk factor for peptic ulcer and gastric adenocarcinoma, a major cause of cancer death worldwide. Successful *H pylori* treatment largely eliminates recurrent peptic ulcer in infected patients, and eradication of *H pylori* worldwide would eliminate most cases of gastric adenocarcinoma. *H pylori* infection is also associated with mucosa-associated lymphoid tissue (MALT) lymphoma, dyspepsia, hyperplastic gastric polyps, and even idiopathic thrombocytopenic purpura (ITP). When Marshall and Warren elucidated the relationship between *H pylori* and peptic ulcer disease, a discovery for which they were later awarded the Nobel Prize in medicine, they rekindled the hypothesis that this common clinical malady was an infectious disease. It is now clear that most gastric adenocarcinoma is also related to chronic *Helicobacter* gastritis.

*H pylori* is a gram-negative spiral flagellated organism that currently infects more than half of the people in the world. The prevalence of *H pylori* infection varies among populations and is strongly correlated with socioeconomic conditions. In a number of developing countries, *H pylori* infection affects more than 80% of middle-aged adults, and reinfection risk after curative treatment is high. Infection rates are lower in industrialized countries. Epidemiological data indicate that the prevalence of infection in the United States has been declining since the second half of the 19th century, with the decreases corresponding to improvements in hygiene and sanitation. Nonetheless, *H pylori* infection is predicted to remain endemic in the United States for the next century. Human beings are the only reservoir for *H pylori*. Infection is presumed to occur by oral ingestion of the bacterium. Family members of infected individuals are at increased risk of infection. In developing countries, most people become infected during childhood. A number of occupations also show increased rates of *H pylori* infestation, notably healthcare workers. Infection with *H pylori* is a chronic disease and does not resolve spontaneously without specific treatment. Worldwide, *H pylori*-induced gastritis accounts for 80% to 90% of all gastritis.

*H pylori* has evidently adapted to the hostile gastric environment and displays a number of features that permit its entry into the surface mucus layer, attachment to gastric epithelial cells, evasion of host immune responses, and persistent colonization of the surface epithelium and gastric

pits despite luminal acidity. Up to 15% of the protein in a *Helicobacter* organism is composed of cytoplasmic urease that converts periplasmic urea into CO<sub>2</sub> and ammonia, the latter buffering the surrounding acid. *H pylori* infection is not invasive of the gastric mucosa, and the host immune response is triggered by the attachment of bacteria to gastric epithelial cells. The initial inflammatory response is characterized by recruitment of neutrophils, followed sequentially by T and B lymphocytes, plasma cells, and macrophages. The resultant chronic gastric inflammation in affected individuals is characterized by enhanced mucosal expression of multiple cytokines and the presence of reactive oxygen and nitrogen species, and long-term infection is associated with mucosal cell DNA damage and chromosomal instability.

The relationship between *H pylori* infection and peptic ulceration is overwhelmingly strong and multiple observations establish *H pylori* as a factor in the pathogenesis of peptic ulceration. Unfortunately, an effective vaccine has not yet been developed. *H pylori* infection is invariably followed by the development of chronic gastritis, and the organism is the primary cause of chronic active gastritis worldwide. The infectious response to *H pylori* is characterized by non-erosive inflammation of the gastric mucosa. Antral gastritis is present histologically in patients with peptic ulcer, and *H pylori* can be isolated from inflamed gastric mucosa of ulcer patients. Postprandial hypergastrinemia and elevated basal acid secretion are common. Gastric metaplasia of the duodenal bulb develops after infestation of the antral mucosa. Metaplastic gastric epithelium in the duodenum is colonized by *H pylori* from gastric sources, and this gastric metaplasia is extremely common in duodenal epithelium surrounding areas of peptic ulceration. Eradication of *H pylori* with antibiotics that have no effect on acid secretion leads to ulcer healing, and treatment of peptic ulceration with bismuth compounds, which inhibit *H pylori*, is associated with reduced rates of ulcer relapse relative to acid suppression therapy. Relapse of duodenal ulcer after eradication of *H pylori* may be preceded by reinfection of the gastric mucosa by the organism.

However, it is clear that infection by *H pylori* alone does not cause peptic ulceration in most individuals, suggesting the existence of other pathogenetic factors. Up to half of patients evaluated for dyspepsia have histologic evidence of *Helicobacter* infection but no ulcer. In developed countries, one-fifth of healthy volunteers harbor the bacteria, and the incidence of bacterial

infestation increases with age in the healthy, asymptomatic population. The occurrence of peptic ulcers in only a fraction of individuals who harbor the organism suggests that other factors must also act to induce ulceration. Even in the presence of active *H pylori* infection, strong acid suppression usually heals peptic ulcer, an observation consistent with the old dictum “no acid, no ulcer.” However long-term proton pump inhibitor (PPI) use in patients with active *Helicobacter* infection is associated with corpus predominant gastritis, which leads to atrophic gastritis and increases the risk of gastric cancer.

Testing for *H pylori* infection should be performed in patients with peptic ulcer, gastritis, significant dyspepsia, MALT lymphoma, and early gastric cancer. Noninvasive methods for diagnosis of *H pylori* infection include the urea breath test, serology, and detection of stool antigen. The urea breath test is based on production of urease by *H pylori* in the gastric mucosa, and a positive test indicates active infection. C 14-labeled urea is ingested and C 14-labeled CO<sub>2</sub> is produced and excreted in the breath. This test has a sensitivity and specificity of greater than 90%. The urea breath test is useful for initial diagnosis of infection and for follow-up after eradication therapy, since unlike serology, it is positive only in the presence of active infection. The stool antigen test is another noninvasive test to detect active *H pylori* infection. Both polyclonal and monoclonal kits have been developed. Different kits are available for both outpatient and inpatient settings. These tests may perform differently in different geographic locations according to the antigenic composition of the circulating strains, so it is recommended that only locally validated tests be used. Because *H pylori* induces a strong immunologic response, serological testing is useful but may not be as accurate as the urea breath test or the stool antigen test, and a positive serology persists after eradication of *H pylori* infection. Consideration should be given to confirming a positive *H pylori* serology with another more accurate test. *H pylori* infection can also be diagnosed by histologic evaluation of gastric biopsies and/or the rapid urease test on fresh biopsies. Culture of *H pylori* is not routine and is usually reserved for recurrent infection and for antibiotic sensitivity testing when second-line therapy has failed. All of these tests for *H pylori* have a false negative rate.

Patients with a positive test should be treated, and in the appropriate clinical scenario, some patients with a negative test should probably be treated as well (unexplained gastritis; recurrent or intractable peptic ulcer). Documented eradication of *H pylori* infection is the goal of treatment in each

patient. An enormous worldwide experience has developed relating to *H pylori* eradication. More than 2000 articles report the results of antibiotic trials, and a large number of summary articles and meta-analyses are available. It is important to note that none of the therapeutic regimens reported to date cure *H pylori* infection in 100% of patients. To be effective, antimicrobial drugs must be combined with gastric acid secretion inhibitors or bismuth salts (Table 29-1). In the absence of treatment, eradication of *H pylori* infection is very rare. The Maastricht V/Florence Consensus Report provides current recommendations for diagnosis and treatment of *H pylori* infection in various clinical scenarios, including recommendations for areas with high metronidazole and clarithromycin resistance (Fig. 29-1). The United States currently demonstrates high clarithromycin resistance but low to intermediate metronidazole resistance, similar to the patterns for most of central and southern European countries. Ideally, a treatment regimen is chosen with 90% effectiveness, and repeat noninvasive testing to confirm eradication is performed. Treatment failure requires an alternative course of therapy. Failure to eradicate infection after two tries should prompt *Helicobacter* culture and sensitivity testing, and referral to a specialist. With assiduous treatment, *Helicobacter* eradication can be achieved in nearly every patient. Patients with atrophic gastritis require endoscopic surveillance.

**TABLE 29-1: COMMON TREATMENT REGIMENS FOR *H PYLORI***

Triple therapy (10-14 days)

PPI BID

Amoxicillin 1 gm BID or metronidazole 500 BID

Clarithromycin 500 mg BID

Quadruple therapy option 1 (14 days)<sup>a</sup>

PPI BID

Bismuth subsalicylate 524 mg QID

Metronidazole 250 mg QID

Tetracycline 500 mg QID or doxycycline 100 BID

Quadruple therapy option 2 (14 days)

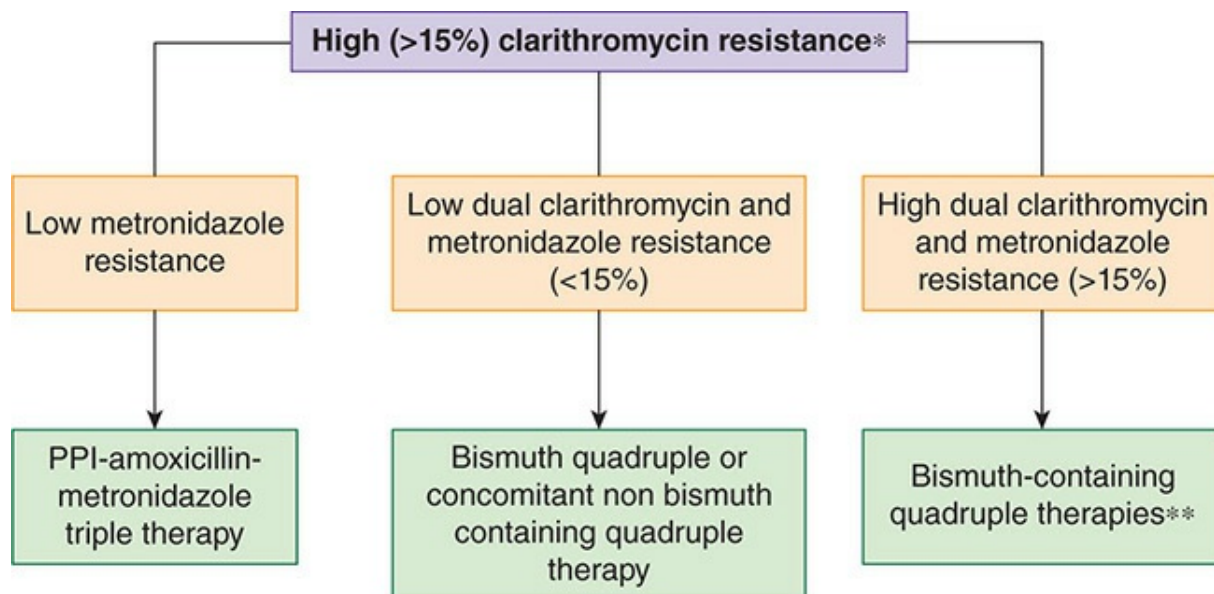

PPI BID

Amoxicillin 1 gm BID

Metronidazole 500 BID

Clarithromycin 500 mg BID

<sup>a</sup>Recommended for failures of triple therapy and in areas with high *Helicobacter* resistance to clarithromycin.

\* Regardless of their population expectations, individuals who have previously taken clarithromycin and/or metronidazole should be considered high-risk patients for dual resistance.

\*\* If bismuth is not available, levofloxacin, rifabutin and high dose dual (PPI + amoxicillin) therapies might be considered. If tetracycline is not available, bismuth-containing quadruple therapy combining furazolidone-metronidazole or amoxicillin-metronidazole can be considered.

**FIGURE 29-1** Treatment algorithm for *Helicobacter pylori* in areas with high clarithromycin resistance.

## FUNCTIONAL DYSPEPSIA

Dyspepsia is a very common symptom complex characterized by pain and discomfort centered in the upper abdomen. Up to 50% of patients who present with dyspepsia may have *Helicobacter* infection, depending on the regional prevalence of the latter. Patients with dyspepsia and alarm symptoms require esophagogastroduodenoscopy (EGD). Testing and treatment for *Helicobacter* should be considered. Functional dyspepsia is diagnosed when there are no endoscopic or histologic findings, or when chronic symptoms persist after *Helicobacter* eradication has been documented, but it is important to note that *Helicobacter*-associated dyspeptic symptoms may persist for a while after eradication. When a dyspeptic patient has no diagnostic workup, the condition is classified as “non-investigated dyspepsia.” For surgeons, the importance of non-ulcerative dyspepsia relates to its place in the differential diagnosis of epigastric pain. There is no role for surgery in the treatment of this disorder.

## ATROPHIC GASTRITIS

Atrophic gastritis is characterized by shrinkage or disappearance of gastric glands along with loss of parietal and chief cells. By far the most common cause is chronic *H pylori* infection, particularly the corporal distribution (as opposed to the antral distribution, which is more typically associated with peptic ulcer disease). Autoimmune destruction of cells (pernicious anemia) and chemical irritation (eg, bile reflux) can also result in atrophic gastritis. Some patients with atrophic gastritis develop intestinal metaplasia in the gastric mucosa, which may progress to dysplasia and then to gastric cancer. Numerous cofactors have been implicated including diet, altered gastric microbiome, genetics, and hypergastrinemia. Patients with atrophic gastritis are at risk for gastric cancer and some warrant endoscopic surveillance. Patients with metaplastic atrophic gastritis are at higher risk for gastric cancer, and those with dysplastic metaplasia even higher. Patients with high-grade dysplasia may benefit from gastrectomy. The cancer risk is related to the extent of the atrophic gastritis and intestinal metaplasia, and grading systems have been developed to stratify cancer risk based on endoscopic findings. Two such systems are the operative link on gastritis assessment (OLGA) and the operative link on gastric intestinal metaplasia (OLGIM)

assessment. These systems define the severity (stage) of atrophic gastritis based on the histologic grading of at least five gastric biopsies (lesser and greater curve antrum; lesser and greater curve corpus; angularis incisura) (Table 29-2). Since pathologists are more likely to agree on the histological diagnosis of intestinal metaplasia than they are on atrophic gastritis, the latter tool (OLGIM) may be more useful in stratifying gastric cancer risk. Patients stratified as Stage 3 or 4 gastritis and those with pernicious anemia may benefit from surveillance endoscopy every 3 years. Serum markers are also useful in helping to identify patients with atrophic gastritis, who usually have increased serum gastrin and iron deficiency due to parietal cell loss and hypochlorhydria or achlorhydria, decreased pepsinogen I levels due to chief cell loss, and B<sub>12</sub> deficiency due to parietal cell loss and concomitant loss of intrinsic factor.

**TABLE 29-2: GASTRITIS STAGING BY OLGA SYSTEM**

	Corpus Atrophy			
	Grade 0	Grade 1	Grade 2	Grade 2

None = grade 0	Stage 0	Stage 1	Stage 2	Stage 2
Mild = grade 1	Stage 1	Stage 1	Stage 2	Stage 3
Moderate = grade 2	Stage 2	Stage 2	Stage 3	Stage 4
Severe = grade 3	Stage 3	Stage 3	Stage 4	Stage 4

## PEPTIC ULCER DISEASE

### Epidemiology

Peptic ulcer disease (includes duodenal, gastric, and marginal ulcers) is a major public health problem in the United States and a source of substantial health care expenditure (Table 29-3). Overall, peptic ulcer mortality and hospitalization rates have declined from over 200,000 admissions in 1993

down to about 150,000 in 2006. Hemorrhage continues to be the most frequent presentation at hospital admission, followed by perforation and obstruction, but perforation is by far the most common indication for operation nowadays. Currently bleeding peptic ulcer is typically treated successfully with endoscopic techniques, occasionally with help from interventional radiology, and emergency operation for bleeding is unusual. Although overall mortality rates in patients hospitalized for peptic ulcer decreased slightly (2.7%, down from 3.8%), no change was seen in the determinants of mortality. Perforation is still associated with the highest mortality, followed by obstruction and then bleeding. The mortality from surgical intervention decreased over the time period but remains high compared to endoscopy and embolization. In parallel with the discovery of *H pylori* and the subsequent development of improved therapies for its eradication, surgical treatment of peptic ulcer has changed dramatically, with the virtual elimination of elective operations for intractable peptic ulcer disease. Operative therapy is now used mostly for urgent or semi-elective treatment of complications from the disease; ie, perforation, obstruction, bleeding, and rarely nonhealing.

**TABLE 29-3: HOSPITALIZATION FOR PEPTIC ULCER IN USA 2006**  
(NATIONAL INPATIENT SAMPLE)

Location of ulcer

<sup>a</sup>9.7% of patients admitted were operated upon.

## Pathophysiology

The pathogenesis of peptic ulceration is multifactorial but increasingly understood to be a consequence of *H pylori* infection and nonsteroidal anti-inflammatory drug (NSAID) use. Before recognition of the role of *H pylori*, ulcer disease was conceived as an imbalance between acid and pepsin secretion and mucosal defense, with the balance shifted toward peptic injury and disease. In groups of patients, increases in acid secretion are well documented, and although gastric acid is crucial in the development of ulcers, an acquired defect in mucosal defense exists to tip the balance away from health. Mucosal infestation of the antrum with *H pylori* is the factor that contributes to ulceration in most patients both by weakening local defenses and increasing acid secretion. Aspirin and NSAID use is the second most important factor in ulcer pathogenesis, largely via weakened mucosal defenses. Other factors such as exogenous steroids and acute stress undoubtedly play a role in ulcer formation (Table 29-4). Substantial evidence implicates cigarette smoking as a significant risk factor in the development of

chronic peptic ulcers. Smokers appear to have an increased risk of developing *H pylori* infection relative to nonsmokers. Cigarette smoking impairs ulcer healing and increases the risk of recurrent and/or marginal ulceration. Continued smoking blunts the effectiveness of active ulcer therapy. Cigarette smoking increases both the probability that surgery will be required and the risks of operative therapy. When *H pylori* is eradicated in smokers, they appear to have no greater risk of peptic ulceration than nonsmokers. This observation suggests that smoking is probably not an independent risk factor for ulcer disease but acts by increasing the harmful effects of bacterial infection. Cessation of smoking is a key goal of anti-ulcer therapy.

**TABLE 29-4: RISK FACTORS FOR DEVELOPMENT OF PEPTIC ULCER**

*Helicobacter pylori* infection

---

Abnormalities of gastric acid secretion in patients with peptic ulceration have been recognized for more than 50 years. The formation of peptic ulcers clearly depends on gastric secretion of acid and pepsin. This association is emphasized by the dictum “no acid—no ulcer,” and *H pylori* infection is known to secondarily induce alterations in gastric acid secretion.

Abnormalities of mucosal function have been invoked as contributing factors to peptic injury. In support of this concept, several agents that are used to treat peptic ulceration are cytoprotective. The ability of such agents to heal ulcers suggests that abnormalities in mucosal defense, in addition to abnormalities in acid secretion, cause ulceration. Most cytoprotective agents act via mucosally secreted bicarbonate or on mucosal prostaglandin production.

NSAIDs are a major risk factor for the development of acute ulceration and for hemorrhagic complications of ulceration. NSAIDs produce a variety of lesions, ranging from superficial mucosal erosions to deeper ulcerations. While the mucosal injury caused by NSAIDs is more common in the stomach than in the duodenum, ulcer complications occur with equal frequency in these two sites. *H pylori* and NSAID use independently increase the risk of peptic ulcer and ulcer bleeding. These agents also act synergistically. In the duodenum, it appears likely that invasive *H pylori*-associated ulcers are compounded by the direct injurious effects of NSAIDs. The injurious actions of NSAIDs are secondary to suppression of prostaglandin production. Numerous experimental models have demonstrated that NSAIDs injure the gastroduodenal mucosa. Ulcers resembling those occurring in humans can be produced by administration of NSAIDs to animals, and NSAID-associated gastric ulcers can be prevented by the coadministration of prostaglandin analogues. Ulcers associated with NSAIDs heal rapidly when the drug is withdrawn, corresponding temporally to reversal of antiprostaglandin effects. Clinically significant ulceration of the stomach and duodenum is estimated to occur at a rate of 2% to 4% per patient-year in NSAID users. The risks of long-term NSAID use are increased by *H pylori* infection and cigarette smoking. The incidence of NSAID-related ulcer complications is highest in older patients, as is attendant mortality rate. Peptic ulcer disease is rare in individuals who are *H pylori*-negative and who do not receive NSAID medications.

## Diagnosis

Peptic ulceration is typically characterized by nonradiating epigastric pain described as burning, stabbing, or gnawing. Referral of pain to the back may indicate posterior penetration of the ulcer. The pain is usually related to eating, with duodenal ulcer pain relieved by eating, which sometimes makes

gastric or marginal ulcer pain worse. Ingestion of antacids or initiation of antisecretory agents (H<sub>2</sub> antagonists or PPIs) usually provides prompt relief. In uncomplicated cases, physical examination is usually normal. The differential diagnosis includes a variety of diseases originating in the epigastrium and upper GI tract. Common disorders to be distinguished include non-ulcer dyspepsia, gastritis, gastric neoplasia, cholelithiasis and related diseases of the biliary system, neoplastic lesions of the liver, and both inflammatory and neoplastic disorders of the pancreas. In dyspeptic patients, especially those older than 50 years of age, the most important differential diagnoses are peptic ulceration and gastric cancer.

The evaluation of patients with suspected peptic ulceration usually involves endoscopic examination of the esophagus, stomach, and duodenum. In controlled trials, endoscopy was both more sensitive (92% vs 54%) and more specific (100% vs 91%) than radiographic examination, but the latter should be considered if perforation is suspected. The most frequent site for duodenal peptic ulceration is the first portion of the duodenum, with the second portion less frequently involved. Peptic ulceration of the third or fourth portions of the duodenum is distinctly unusual and raises the possibility of gastrinoma or nonpeptic causes of ulceration such as cancer or ischemia. Peptic ulcers in the pyloric channel or the prepyloric area are similar in appearance to duodenal ulcers and should be treated as such (type 3 gastric ulcers). Endoscopic demonstration of a duodenal ulcer does not require duodenal biopsy but should prompt mucosal biopsy of the gastric antrum to demonstrate the presence of *H pylori* and guide subsequent therapy.

## Peptic Ulcer Location

The three typical locations for peptic ulcer are duodenal, gastric, and marginal or anastomotic, and the pathophysiology and treatment vary by location. In the United States, benign gastric ulcers are found in approximately 90,000 new patients a year, about one-fifth that of duodenal ulceration. The opposite is found in Japan, where gastric ulcers are 5 to 10 times more common. Gastric ulcer is more common in men than women and occurs in a patient cohort approximately 10 years older than that of duodenal ulceration. In symptomatic patients, upper GI endoscopy is the preferred method for diagnosing peptic ulcers, though radiologic studies are often

complementary. About 10% of gastric ulcers are malignant or associated with malignancy, so aggressive biopsy and brushings, as well as careful follow-up to demonstrate healing, are mandatory. All gastric ulcers should undergo multiple biopsies, obtained from the perimeter of the lesion. The addition of endoscopic brushings to multiple biopsies increases diagnostic accuracy to approximately 95%. Although benign gastric ulcers may occur in any location in the stomach, more than half are located along the lesser curvature proximal to the incisura angularis. Fewer than 10% of benign ulcers are located on the greater curvature. Most benign gastric ulcers lay within 2 cm of the histologic transition between fundic and antral mucosa. Gastric ulcers are classically categorized as type 1 (lesser curvature near angularis incisura), type 2 (gastric ulcer associated with active or inactive duodenal ulcer), type 3 (prepyloric ulcer), type 4 (juxtacardia ulcer), and type 5 (greater curvature ulcer). Similar to duodenal ulceration, *H pylori* infection plays an important role in the pathogenesis of benign gastric ulcers. Antibiotic *Helicobacter* treatment regimens useful for duodenal ulcer have also been used for benign gastric ulceration. The response of gastric ulcers to *Helicobacter* treatment is equivalent to that of duodenal ulcers. Recurrence or persistence of gastric ulcers after *H pylori* eradication may indicate persistent or recurrent infection, but more likely represents persistence of other risk factors such as smoking and/or NSAID use. In addition to *H pylori* infection, alterations in gastric motility have been demonstrated in some patients with benign gastric ulcers. Motility defects include delayed gastric emptying, abnormal pyloric sphincter function, prolonged high-amplitude gastric contractions, duodenogastric reflux, and alterations in the gastric migrating motor complex. These alterations have not been definitively demonstrated to be pathogenic, and their relevance to gastric ulceration is unsettled.

Marginal ulcers are peptic ulcers which characteristically occur on the jejunal side of the gastrojejunostomy following distal gastrectomy, gastric bypass, or simple gastrojejunostomy. The risk of marginal ulceration is related to the acid/peptic load delivered into the jejunum (a site unaccustomed to any acid), and luminal jejunal buffering (largely absent in Roux gastrojejunostomy). So risk factors for marginal ulceration include Roux gastrojejunostomy, large gastric pouch after distal gastrectomy or Roux-en-Y gastric bypass (RYGBP), gastrogastic fistula after RYGBP, retained or excluded antrum, and incomplete or inadequate vagotomy. Other factors to consider are ischemia and permanent suture material. Marginal

ulcers are prone to the same complications that bedevil duodenal or gastric ulcer including perforation, obstruction, bleeding, and nonhealing. Cancer is usually not a concern with marginal ulcer unless the anastomosis was performed many years ago, and then stump cancer becomes a consideration.

## Operative Treatment of Peptic Ulcer Disease

It is well recognized that elective operation for intractable peptic ulcer disease has largely disappeared. Operative intervention is now performed primarily for the treatment of ulcer complications which are (in decreasing order of operative frequency): perforation, obstruction, bleeding, and nonhealing (Table 29-5). The role of the traditionally “definitive” ulcer operations (parietal cell vagotomy, vagotomy and drainage, vagotomy and antrectomy) is less clear. Both surgeon questionnaire and evaluation of administrative database suggest that vagotomy for ulcer nowadays is unusual, as is definitive ulcer operation in the setting of perforation or bleeding. Cancer remains an important part of the differential diagnosis in gastric ulcer, obstructing peptic ulcer disease, and marginal ulcer if (it occurs many years after gastrojejunostomy). Ultimately, recurrent peptic ulcer is almost inevitable if one or more of the following persist: *Helicobacter* infection, NSAID use, smoking, inadequate acid suppression. Lifelong acid suppression should be considered in all patients hospitalized for peptic ulcer. The operative mortality for emergency ulcer operation is 10% to 20%. This speaks to the frailty and degree of chronic illness seen in many patients requiring peptic ulcer surgery today.

TABLE 29-5: SURGICAL OPTIONS FOR PEPTIC ULCER

Indication	Type of Peptic Ulcer		
	Duodenal	Gastric <sup>a</sup>	Marginal
Perforation	Patch	Biopsy and patch	Patch <sup>b</sup>
	Patch+HSV	Excise ulcer/close defect <sup>c</sup>	Resection of GJ
	Patch+TV/D	Distal gastrectomy w ulcer	
	TV+A		
Bleeding	Oversew alone	Biopsy and oversew	Oversew alone <sup>b</sup>
	Oversew+TV/D	Distal gastrectomy w ulcer	Resection of GJ
	TV+A		
Obstruction	HSV+GJ	HSV+GJ/ulcer biopsy	Resection of GJ
	TV+GJ	TV+GJ/ulcer biopsy	
	TV+A	TV+A	
Nonhealing <sup>d</sup>	HSV+GJ	Wedge resection	Resection of GJ
	TV+A <sup>e</sup>	Distal gastrectomy <sup>e</sup>	

<sup>a</sup>Unless excised, gastric ulcers should be biopsied.

<sup>b</sup>If GJ done many years ago, biopsy should be considered.

<sup>c</sup>Depends on location of ulcer.

<sup>d</sup>Whenever possible, operation should be delayed until smoking and NSAIDs are eliminated. Autonomous hypergastrinemia secondary to gastrinoma or retained antrum should be ruled out.

<sup>e</sup>Historically, distal gastric resection has been the operation of choice for nonhealing duodenal or gastric ulcer. This operation should be avoided in thin patients, particularly in those who continue to smoke and/or take NSAIDs.

## Perforated Peptic Ulcer

Patients with perforated peptic ulcer have a hospital mortality risk of 10% to 20%. Most patients with perforated peptic ulcer are adequately treated by peritoneal washout and omental patch, with subsequent elimination of risk factors (ie, treat *Helicobacter*; stop smoking; stop NSAIDs; take acid suppression). The postoperative elimination of risk factors is very important. In the absence of peritonitis and systemic inflammatory response, nonoperative management may be considered *if* careful radiologic evaluation confirms that the ulcer has sealed. However, the large majority of patients with perforated ulcer need urgent operation, which can be done laparoscopically or open. Biopsy to rule out cancer should be done in patients with perforated gastric ulcer, and perforated marginal ulcer if the gastrojejunostomy was done many years ago. Wedge resection may be preferable to omental patch for some perforated gastric ulcers. In the setting of shock, perforation >48 hours, or dangerous medical comorbidity (eg, recent MI, pulmonary hypertension, multisystem organ failure [MSOF], cirrhosis), definitive ulcer operation should be eschewed. In the stable patient, definitive operation may be considered for chronic ulcer which has failed medical management and if postoperative elimination of risk factors is unlikely.

Though simple omental patch with postoperative *Helicobacter* treatment has been shown to eliminate recurrent or persistent ulcer symptoms in most patients with perforated duodenal ulcer, some patients will fail *H pylori* eradication or have other significant risk factors such as smoking and NSAID use. Furthermore, extrapolation from duodenal ulcer to gastric or marginal ulcer may be inappropriate. Thus it is reasonable to consider definitive operation on a case-by-case basis in the stable patient with peptic ulcer perforation. For perforated duodenal ulcer, definitive procedures include parietal cell vagotomy, truncal vagotomy and drainage (pyloroplasty incorporating the perforation or gastrojejunostomy), and truncal vagotomy and antrectomy (perhaps most appropriate for giant duodenal perforations). For perforated gastric ulcer, definitive operations include distal gastrectomy to include the ulcer, and wedge resection with vagotomy and drainage. For marginal ulcer, definitive operation includes resection of the gastrojejunostomy with the perforation, along with additional stomach if deemed appropriate.

## Obstructing Peptic Ulcer

By far the most common cause of gastric outlet obstruction is cancer (pancreas, duodenum, stomach), and it is worthwhile keeping this in mind when treating patients for peptic ulcer obstruction. All three peptic ulcer varieties (duodenal, gastric, marginal) can cause chronic scarring resulting in intractable gastric outlet obstruction manifested by chronic nausea, vomiting, epigastric pain, weight loss, food intolerance, and even sitophobia. Patients with suspected obstructing peptic ulcer should have upper endoscopy with biopsy and CT scan. Traditional barium fluoroscopic studies may also be revealing. Endoscopic balloon dilation can be transiently helpful in up to half of these patients, but multiple dilations are usually necessary and most patients eventually require operation. The gold standard procedure for obstructing duodenal or prepyloric gastric ulcer is distal gastrectomy with Billroth 2 gastrojejunostomy, and truncal vagotomy. An acceptable alternative operation is laparoscopic gastrojejunostomy and selective vagotomy, which can be done minimally invasively. If the obstructing ulcer disease is primarily prepyloric, attempt should be made to obtain luminal biopsies at the site of obstruction. Subsequently, if indicated, the gastrojejunostomy can be reversed (eg, for severe dumping if the pyloric

channel is patent) or converted to distal gastrectomy with Billroth 2 or Roux gastrojejunostomy (eg, for persistent symptoms or concern about malignancy). However, this “lesser operation” may miss or delay the diagnosis of an unexpected obstructing cancer. The hospital mortality for patients with obstructing peptic ulcer is 2% to 3%.

## Bleeding Peptic Ulcer

Although bleeding remains the most common reason for hospitalization in peptic ulcer patients, with a hospital mortality around 3%, it is no longer a common indication for surgery due to the efficacy of endoscopic treatment and occasionally radiologic embolization. Aggressive treatment with IV acid suppression is important too. Bleeding peptic ulcer is the most common cause of clinically significant upper GI bleeding. Most patients (75%) have low-risk bleeds, but 25% of patients have high-risk bleeds, and essentially all the deaths from bleeding ulcer occur in this latter group. Clinical and endoscopic parameters can identify this high-risk group (Table 29-6), which should be managed by a multidisciplinary team in a special unit or intensive care unit. After initial resuscitation, early endoscopy should be performed and bleeding sites treated with epinephrine injection and an energy source. Endotracheal intubation for airway protection is considered on a case-by-case basis. Rebleeding should prompt repeat endoscopic treatment or angiography. Surgery should be considered for refractory bleeding requiring multiple transfusions, especially if associated with episodes of hemodynamic instability, and for high-risk lesions, such as deep penetrating ulcer with a subjacent named artery. Bleeding from erosion of the ulcer into the gastroduodenal, left gastric, or splenic artery is very likely to persist or recur after endoscopic therapy alone.

**TABLE 29-6: ULCER STIGMATA AND REBLEEDING IN PEPTIC ULCERS**

	Prevalence (%)	Rebleeding (%)
Active arterial bleeding	12	88
Nonbleeding visible vessel	22	50
Nonbleeding flat clot	10	33
Oozing	14	10
Nonbleeding flat spots	10	7
Clean ulcer base	32	3

Reproduced with permission from Machicado G: Thermal probes alone or with epinephrine for the endoscopic haemostasis of ulcer haemorrhage, *Baillieres Clin Gastroenterol* 2000;June:14(3):443–458.

Bleeding marginal ulcers are best treated with resection. Occasionally the ulcer has eroded into named vessels such as the splenic artery or middle colic artery, so the surgeon should be prepared for these contingencies. Bleeding gastric ulcer can be treated with oversewing, wedge resection, or definitive gastrectomy to include the ulcer. Traditionally, vagotomy for gastric ulcer has been deemed unnecessary. Though hemigastrectomy and damage control remains an option, it is best to avoid definitive ulcer operation in the setting of shock or profound coagulopathy. Surgical options for the management of bleeding duodenal ulcer include oversewing, either alone or with definitive ulcer operation, usually vagotomy and drainage. Classically the pyloroduodenotomy, which is made to access the bleeding ulcer, is incorporated into a pyloroplasty. Alternatively, the pyloric incision is closed and gastrojejunostomy performed. Then truncal vagotomy is done. Antrectomy with truncal vagotomy can be considered in stable patients, especially those with giant bleeding duodenal ulcer. However, management of the duodenal stump can be challenging since the ulcer must be securely oversewn or resected.

Regardless of operation performed, certain and secure ulcer hemostasis by suture ligation should be the most important goal of any operation for bleeding peptic ulcer. Much has been written about the proverbial and useful “U-stitch” to secure hemostasis in a deep duodenal ulcer with a hole in the gastroduodenal artery near a large pancreatic side branch. Deep “over-and-over” sutures may accomplish the same thing. Extraluminal ligation of the gastroduodenal or left gastric artery may occasionally also be helpful. Compared to simple oversewing and vagotomy and drainage, rebleeding may

be less common after distal gastrectomy for bleeding peptic ulcer, but the operative mortality is higher. Overall, current hospital mortality in patients requiring operation for bleeding peptic ulcer is 10% to 20%.

## Intractable or Nonhealing Peptic Ulcer

Operation for nonhealing peptic ulcer should be performed only after careful deliberation and diagnostic evaluation. Nonhealing or intractability should indeed be a rare indication for ulcer operation today, and the patient referred for surgical evaluation of intractable peptic ulcer disease should raise red flags for the surgeon. Since acid secretion can be totally blocked and *H pylori* eradicated with modern medication, it is important to ask why the patient has a persistent ulcer diathesis. All causes of nonhealing peptic ulcer should be considered prior to operative treatment (Table 29-7).

Surgical treatment may be considered in patients with nonhealing or intractable peptic ulcer disease who have multiple recurrences, large ulcers

(>2 cm), complications (obstruction, perforation, or hemorrhage), or suspected gastric cancer. Though nonhealing ulcers may represent an undiagnosed malignancy, this is unusual nowadays. Typically patients with intractable or nonhealing peptic ulcer experience suboptimal outcomes after ulcer operation, which may result in chronic weight loss of up to 10% to 20%. Before embarking on an ulcer operation in a patient for intractability or nonhealing, it is prudent for the surgeon to envision this degree of weight loss, since this is what the patient might look like after an ill-conceived ulcer operation. The obvious corollary is that operation for intractability or nonhealing ulcer should be avoided in asthenic patients. Sadly, the thin patient can be an easy target for a big ulcer operation in the hands of the inexperienced ulcer surgeon.

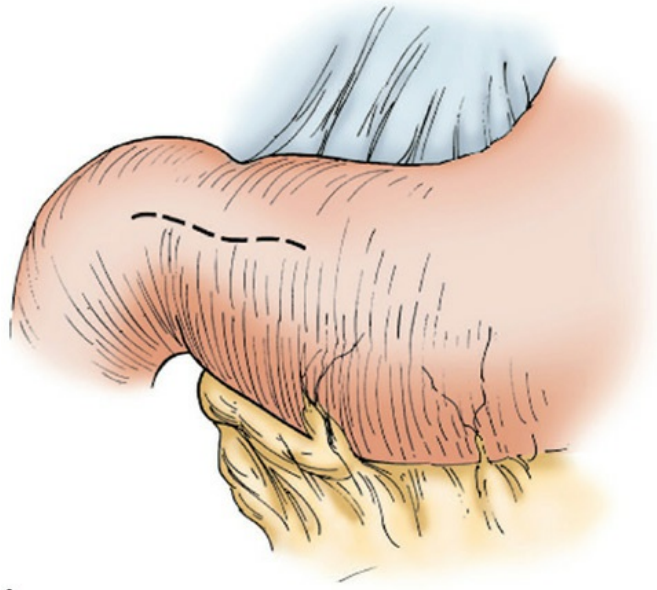

Prior to operation for intractable or nonhealing peptic ulcer, empiric *Helicobacter* treatment should be administered; smoking and NSAIDs should be stopped. Patient, family, surgeon, and gastroenterologist should understand the risks and likely outcomes of operation. It is important to realize that operative results for ulcer intractability today will not mirror those obtained 40 to 50 years ago, since the surgical populations are different. Formal distal gastric resection should be avoided if possible. For intractable duodenal ulcer, consideration should be given to parietal cell vagotomy, with or without gastrojejunostomy, which is reversible. For intractable or nonhealing gastric ulcer, wedge excision with or without parietal cell vagotomy should be considered as an alternative to distal gastrectomy when technically feasible.

It is important that the surgeon not fall into the trap of performing a large, irreversible operation on these patients based on the unproven theory that if all other methods have failed, a larger operation is required. Today's patients are different than those of three or four decades ago. One might argue that modern medical care has healed the minor ulcer, and that patients presenting with true intractability or nonhealing will be more difficult to treat and are likely to have chronic problems after a major ulcer operation. If surgery is necessary, less is often better. It is the practice of the authors never to perform a gastrectomy as the initial elective operation for intractable duodenal ulcer in the thin or asthenic patient. Instead, the preferred operation for this group of patients is HSV. In patients with nonhealing gastric ulcer, wedge resection with HSV should be considered in thin or frail patients. Otherwise distal gastrectomy (to include the ulcer) is recommended. It is

unnecessary to add a vagotomy in patients with type I gastric ulcer.

## Technical and Physiological Considerations

Transection of both vagal trunks at the esophageal hiatus, termed truncal vagotomy, severs vagal input to the abdominal viscera. Truncal vagotomy eliminates the cephalic phase of gastric acid secretion and alters antral and pyloric motor function, often (but not always) resulting in delayed gastric emptying. Thus, truncal vagotomy is usually combined with a procedure to eliminate or bypass pyloric sphincter function, for example pyloroplasty or gastrojejunostomy. Several methods of pyloroplasty have been developed. The Heineke–Mikulicz pyloroplasty (Fig. 29-2) consists of a longitudinal incision of the pyloric sphincter extending into the antrum and the duodenum. The incision is closed transversely, eliminating sphincteric closure and increasing the lumen of the pyloric channel. The Finney pyloroplasty (Fig. 29-3) extends the pyloric incision 5 cm onto the duodenal wall, forming an inverted U-shaped incision after the placement of superior and inferior traction sutures. Once traction is applied, the two limbs of the inverted U-shaped incision are lined up and sutured to each other to complete the procedure, with the inferior suture line forming the posterior wall and the superior suture line forming the anterior wall of the pyloroplasty. A Jaboulay gastroduodenostomy (Fig. 29-4) requires more extensive dissection, beginning with a Kocher maneuver followed by corresponding incisions on the stomach and the duodenum proximal and distal to the pylorus, respectively. Traction sutures are then placed between the stomach and duodenum to approximate the two incisions, and the anastomosis is then performed.

**FIGURE 29-4** Jaboulay gastroduodenostomy.

Truncal vagotomy can be combined with resection of the gastric antrum to further reduce acid secretion by removing antral sources of gastrin. The limits of antral resection are defined by external landmarks. The stomach is divided proximally along a line from a point above the incisura angularis on the lesser curvature to a point somewhere along the greater curvature midway between the pylorus and the inferior tip of the spleen. Reconstruction via a gastroduodenostomy is called a Billroth I procedure. A Billroth II procedure

uses a gastrojejunostomy to restore GI continuity.

Proximal gastric vagotomy, also termed highly selective vagotomy (HSV), differs from truncal vagotomy in that only the nerve fibers to the acid-secreting fundic mucosa are transected (Fig. 29-5). The hepatic and celiac divisions are not divided, and vagal nerve fibers to the antrum and pylorus remain intact. The operation has also been called parietal cell vagotomy to emphasize the intended functional consequence. Proximal gastric vagotomy is a safe operation with an elective operative mortality rate of less than 0.1% in a good risk patient. Truncal vagotomy and pyloroplasty has an accepted mortality rate of 0.5% to 0.8%, whereas operative mortality after truncal vagotomy and antrectomy approximates 1.5%. Note that these statistics, acquired decades ago, represent the results of elective operations on mostly good risk patients with peptic ulceration and may not accurately reflect expected results when similar procedures are performed urgently in patients with multiple comorbidities.

**FIGURE 29-5** Technique of proximal gastric vagotomy. The distal 6 cm of the esophagus is skeletonized. Denervation spares the antrum and pylorus by stopping 7 cm proximal to the pylorus.

Division of vagal nerve fibers alters gastric acid secretion by reducing cholinergic stimulation of parietal cells. Vagal denervation also decreases parietal cell responsiveness to gastrin and histamine. Basal acid secretion is diminished by approximately 80% in the immediate postoperative period and

is maintained over time. The maximal acid output in response to secretagogues such as pentagastrin is reduced by approximately 70%. After 1 year, pentagastrin-stimulated maximal acid output increases to 50% of pre-vagotomy values but remains at this level on subsequent testing. Acid secretion due to meal stimulation is reduced by 60% to 70% relative to normal subjects. The inclusion of antrectomy to truncal vagotomy further reduces acid secretion. Maximal acid output is reduced by 85% relative to values recorded before antrectomy.

Operations that involve vagotomy affect gastric emptying. Both truncal vagotomy and proximal gastric denervation abolish vagally mediated receptive relaxation that normally allows the ingestion of a meal with no increase in intragastric pressure. After vagotomy, the intragastric pressure rise is greater for any given volume ingested, and the gastroduodenal pressure gradient is higher than in normal subjects. As a result, emptying of liquids, which depends on the gastroduodenal pressure gradient, is accelerated. Because nerve fibers to the antrum and pylorus are preserved with proximal gastric vagotomy, the function of the distal stomach to mix solid food is preserved, and emptying of solids is nearly normal. Truncal vagotomy affects the motor activity of the distal stomach, and solid and liquid emptying rates are usually increased when truncal vagotomy is accompanied by pyloroplasty.

Though uncommonly performed today, gastric ulcer in the good risk well-nourished patient is perhaps best treated with distal gastrectomy (including the ulcer in the specimen) (Fig. 29-6) with either gastro-duodenal (Billroth I) or gastrojejunal (Billroth II) anastomosis. Performed electively, operative mortality approximates 2% to 3%, and ulcer recurrence rates are less than 5%. Unlike antrectomy for duodenal ulcer, inclusion of vagotomy does not decrease recurrence rates for gastric ulcer, which is not surprising given the variability of acid secretion in patients with gastric ulcers. The occurrence of a benign ulcer near the gastroesophageal junction (type IV ulcer) represents a difficult surgical problem. The ulcer may be excised via a distal gastrectomy with an extension along the lesser curvature into the cardia and reconstruction with Roux gastrojejunostomy (Csendes operation). Alternative procedures to deal with proximal gastric ulcers include the Pauchet gastrectomy and the Kelling-Madlener procedure (Fig. 29-7). Type V gastric ulcers occur along the greater curvature and are best treated with wedge resection.

## POSTGASTRECTOMY SYNDROMES

Perhaps up to 30% of patients who have had operations on the stomach have some chronic symptoms, commonly referred to as “postgastrectomy syndromes.” However, the occurrence of permanent disabling postgastrectomy syndromes is uncommon (5% or less) and usually unpredictable. Symptoms typically include one or more of the following: diarrhea, vomiting, abdominal pain, and malnutrition or nutritional deficiency. These patients have had operations on the stomach for peptic ulcer, cancer, obesity, or gastroesophageal reflux disease (GERD). The frequency with which post-gastrectomy symptoms and syndromes are found

depends on how hard they are looked for. The incidence is high early postoperatively, but most patients report improvement within 1 year after surgery. The management of patients with these symptoms can be challenging but appropriate therapy can have a significant impact on the patient's long-term outcome.

## Dumping Syndrome

Dumping syndrome (DS) is a constellation of gastrointestinal and vasomotor symptoms that present postprandially due to rapid gastric emptying. It is caused by loss of pyloric regulation of gastric emptying and/or decreased gastric compliance. Early dumping symptoms occur within 1 hour of ingestion of a meal and include nausea, epigastric discomfort, tremulousness, and sometimes dizziness or syncope. Late dumping symptoms follow a meal by 1 to 3 hours. Late symptoms are usually due to reactive hypoglycemia.

The human stomach has the capability of adapting to large volumes of orally administered liquids and solids through vagally mediated accommodation and receptive relaxation. Procedures that alter the normal intragastric pressure/volume relationship (proximal gastric vagotomy, sleeve gastrectomy, fundoplication) or outflow resistance (pyloroplasty, gastrojejunostomy) predispose to DS. Procedures that alter both have the highest incidence of dumping (eg, distal gastrectomy, gastric bypass). Dumping symptoms have been reported in up to 70% of Billroth II patients and up to 75% of patients after RYGBP for obesity. Similarly, after gastrectomy for cancer, 67% of patients present with early dumping symptoms and 38% with late dumping. The role of surgically induced microbiome changes in the etiology of DS is unknown.

Early dumping is more common and includes systemic and abdominal symptoms. Systemic manifestations include palpitations, tachycardia, fatigue, a need to lie down following meals, flushing or pallor, diaphoresis, lightheadedness, hypotension, headache, and possibly syncope. Abdominal symptoms include early satiety, epigastric fullness or pain, diarrhea, nausea, cramps, bloating, and borborygmi. Early dumping begins within 30 min following a meal and is attributable to bowel distention, relative hypovolemia, gastrointestinal hormone hypersecretion, and autonomic dysregulation. Late dumping is characterized by symptoms that occur 1 to 3 h postprandial. Symptoms of late dumping consist of perspiration, faintness,

decreased concentration, and altered levels of consciousness, among others. These symptoms are related to a reactive hypoglycemia that occurs 1 to 3 h postprandial. Patients with late dumping often have early dumping as well. Most patients with DS have mild to moderate symptoms, but some patients have disabling symptoms that may be severe enough to cause protein–energy malnutrition.

An oral glucose challenge will confirm the diagnosis of DS. The diagnosis can also be made with a scintigraphic gastric emptying study, in which greater than 50% of an isotope-labeled solid meal has emptied within 1 hour. Early dumping tends to improve with time, whereas late dumping tends to persist or exacerbate.

In most patients with DS, symptoms are not severe and medical management is successful. Dietary modification such as frequent small meals and separating liquids and solids are the first line of treatment. Diets should be high in protein and fiber. Fat, milk, and simple sugars should be avoided.

A number of pharmacologic options exist for the treatment of DS. Octreotide, a somatostatin analogue, should be considered for patients with severe postgastrectomy DS refractory to diet therapy (Table 29-8). Octreotide can markedly improve the quality of life in DS patients. Long-term octreotide therapy may lose efficacy over time, as side effects, such as diarrhea and steatorrhea, and cost lead to lack of compliance. Acarbose is an  $\alpha$ -glycosidase hydrolase inhibitor that delays carbohydrate digestion and absorption and is efficient in the treatment of late dumping. Diazoxide is a potassium channel activator that inhibits the secretion of insulin. Thus, diazoxide has showed success in treating late dumping hypoglycemia and can be used when acarbose and lifestyle modifications are insufficient.

---

Most patients improve with time (months and even years), dietary management, and medication. Therefore, the surgeon should not rush to reoperate on the patient with DS. Only a small percentage of patients with dumping symptoms ultimately require surgery. The results of remedial operation for dumping are variable and unpredictable. A variety of surgical approaches exist, none of which work consistently well. In addition, there is not a great deal of experience reported in the literature with any of these methods and long-term follow-up is rare. Patients with disabling refractory dumping after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that the pyloric channel is patent endoscopically. For dumping following pyloroplasty, distal gastrectomy with Roux reconstruction is an option. For severe dumping after BI or BII gastrectomy, conversion to Roux-en-Y gastrojejunostomy may be considered, since dysmotility of the Roux limb tends to slow gastric emptying. In the presence of a sizable (>40%) gastric pouch with intact vagal innervation, lifelong acid suppression may be prudent in the setting of Roux gastrojejunostomy.

## **Postvagotomy Diarrhea**

Truncal vagotomy is initially associated with clinically significant diarrhea in 5% to 10% of patients, but symptoms improve with time. The incidence of long-lasting postvagotomy diarrhea is 1% to 2%. The cause of postvagotomy diarrhea is unclear. Contributing factors include intestinal dysmotility with accelerated small bowel transit, bile acid malabsorption, rapid gastric emptying, altered microbiome, and bacterial overgrowth. Some patients with postvagotomy diarrhea respond to cholestyramine, while for others codeine or loperamide may be useful. In the rare patient who is debilitated by postvagotomy diarrhea unresponsive to maximal medical management for at least 1 year, surgery might be considered, but outcomes can be problematic. The 10-cm reversed jejunal interposition placed in continuity 100 cm distal to the ligament of Treitz has been described but can cause obstructive symptoms and/or bacterial overgrowth.

## **Gastric Stasis**

In the rare patient with *acute gastric stasis* after gastric surgery, persistent nausea and vomiting prevent removal of the nasogastric tube in the absence of mechanical obstruction. If the symptoms persist beyond a period of 7 to 10 days after surgery, a gastrostomy can be placed and a J tube should be considered for enteral nutrition. In patients who are not candidates for enteral nutrition, total parenteral nutrition is an alternative. Reoperation should generally be delayed for at least 3 months, as the majority of patients will regain satisfactory GI function without surgery.

*Chronic gastric stasis* following gastric surgery may be due to a problem with gastric motor function or caused by an obstruction. Chronic gastric stasis presents with vomiting (often of undigested food), bloating, epigastric pain, and weight loss. Symptoms are usually improved by a liquid diet, and always improved by prolonged fasting. The evaluation includes EGD, upper GI series, gastric emptying scan (scintigraphy), and gastric motor testing. Endoscopy shows gastritis and retained food or bezoar in the stomach. The gastroenteric anastomosis and efferent limb should be evaluated for stricture or narrowing. A dilated efferent limb suggests chronic stasis, either from a motor abnormality (eg, Roux syndrome) or mechanical small bowel obstruction (eg, chronic adhesion). If the problem is thought to be primarily a disorder of intrinsic motor function, newer diagnostic techniques such as electrogastrography and GI manometry should be considered.

Once mechanical obstruction has been ruled out, medical treatment is successful in most patients. Management consists of dietary modification and promotility agents such as metoclopramide, domperidone, and erythromycin. Intermittent oral antibiotic therapy may be helpful in treating bacterial overgrowth. Probiotics should be tried, since alterations in gut microbiome are likely. Operation is reasonable when chronic postoperative gastric stasis is severe and resistant to medical management. At operation, small bowel obstruction and efferent limb obstruction should always be ruled out. Gastroparesis following vagotomy and drainage procedures may be treated with subtotal (75%) gastrectomy. Billroth II anastomosis with Braun enteroenterostomy may be preferable to Roux-en-Y reconstruction after subtotal gastrectomy in this setting, since Roux reconstruction may result in persistent gastric emptying problems (Roux syndrome). Gastroparesis following subtotal gastric resection is best treated with near-total (95%) or total gastric resection and Roux-en-Y reconstruction. High-frequency gastric electrical stimulation (GES) may be an effective treatment for patients with

postsurgical gastroparesis who failed standard medical therapy, but long-term data are lacking.

## **Afferent and Efferent Loop Obstruction**

Afferent loop obstruction is a mechanical complication that typically occurs after Billroth II or loop gastrojejunostomy. Etiologies include (1) entrapment, compression, and kinking of the afferent loop by postoperative adhesions; (2) internal herniation, volvulus, and intussusception of the afferent loop; (3) scarring due to marginal ulceration of the gastrojejunostomy; (4) locoregional recurrence of cancer (lymph nodes, peritoneum, gastric remnant, anastomotic sites); (5) radiation enteritis of the afferent loop; and (6) enteroliths, bezoars, and foreign bodies impacted in the afferent loop. Although both acute and chronic forms of afferent loop syndrome have been described, chronic partial obstruction is the more common clinical manifestation. The classic presentation of chronic afferent loop syndrome is postprandial abdominal pain relieved by bilious vomiting. A meal elicits pancreatic, biliary, and duodenal secretion into the obstructed afferent limb. Eventually the pressure in the partially obstructed afferent limb overcomes the obstruction (usually 30-60 minutes postprandial), delivering a large volume of bilious secretions into the stomach or Roux limb. This leads to bilious vomiting and prompt relief of the pain, which was caused by the afferent limb distention. Obstruction of the biliopancreatic limb following RYGBP must also be considered an afferent loop obstruction and typically presents with postprandial abdominal pain; bilious vomiting is usually lacking because of the long Roux limb.

If the obstruction is high grade or complete, the distended afferent loop may not sufficiently decompress, leading to acute afferent loop obstruction. In this scenario, vomiting, if present, will be nonbilious, and a clinical picture of “closed loop obstruction” manifested as an acute abdomen will result. If this condition is not recognized early, the afferent loop may actually perforate and result in peritonitis. Urgent intervention or surgery is necessary to correct this problem. Abdominal CT is the diagnostic study of choice. CT appearance of the obstructed afferent loop consists of a C-shaped, fluid-filled tubular mass located in the midline between the abdominal aorta and the superior mesenteric artery (c-loop sign) with valvulae conniventes projecting into the lumen (keyboard sign).

Although endoscopic interventions and/or percutaneous approaches may be useful in special cases (eg, carcinomatosis or extremely high operative risk), the cornerstone of treatment for afferent loop obstruction is operation. In contrast to the relatively stereotypical manifestation of afferent loop obstruction, efferent loop obstruction generally mimics proximal small bowel obstruction. It is most commonly caused by adhesions, but internal hernia must also be considered.

## **Alkaline (Bile) Reflux Gastritis**

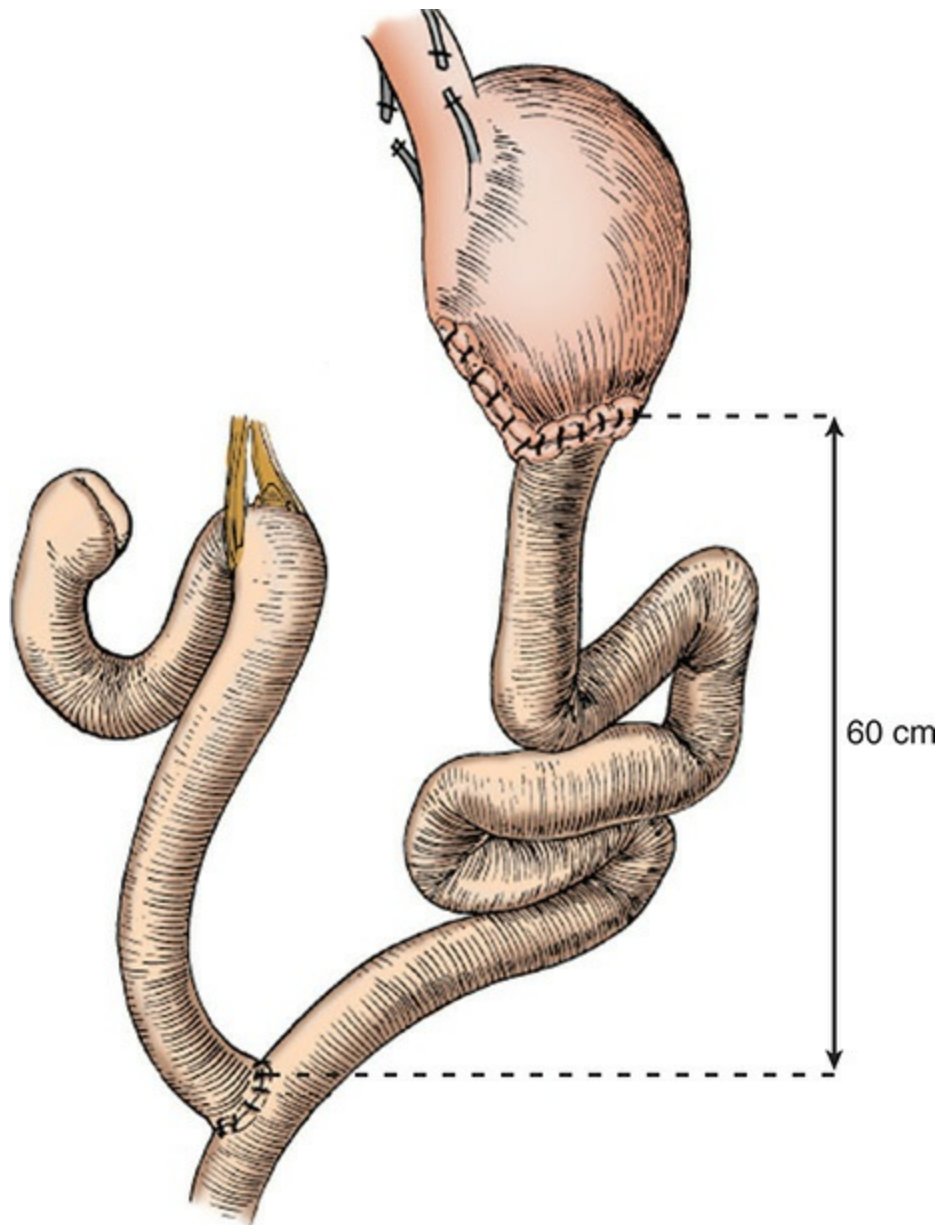

Alkaline reflux gastritis is presumably caused by the longstanding presence of an abnormal amount of duodenal content in the stomach or gastric remnant, a situation that often occurs in patients after pyloroplasty or loop gastrojejunostomy with or without gastric resection. A distinction must be made between *histologic* bile gastritis, which is present in many patients after gastric surgery (up to 85% in Billroth II patients), most of whom are asymptomatic, and the presence of clinical bile gastritis leading to significant symptoms, a much more unusual situation. Gastric stasis may potentiate the damaging effects of duodenal contents on the gastric mucosa. Smoking and NSAIDs also may contribute. In a subset of patients, bile gastritis leads to metaplasia and dysplasia, and some of these patients progress to gastric cancer (“stump cancer”). Many patients have histologic gastritis after gastric surgery, but clinically significant bile reflux gastritis is not common and the relationship of chronic gastric mucosal inflammation to symptoms in this setting is not well defined. The most common symptoms attributed to chronic bile gastritis are abdominal pain and bilious vomiting. The pain is typically not relieved by antacids or acid suppressive medication. Unlike afferent limb syndrome, the pain does not resolve after vomiting.

The diagnosis of alkaline reflux gastritis is essentially a diagnosis of exclusion and is largely based on symptomatology. The first step in patient evaluation is endoscopy. Inflammatory changes in the stomach involving more than just the peristomal area are supportive, but not specific for bile reflux. Mucosal biopsies will show the characteristic histologic features of bile reflux. However, the endoscopic and histological features of bile gastritis are frequently observed in asymptomatic patients, and the extent of the findings does not correlate well with the severity of symptoms. Hepatobiliary iminodiacetic acid (HIDA) scans can provide a semiquantitative assessment

of bile reflux/stasis in the stomach. Upper gastrointestinal barium study, ultrasound, and CT scan may also be useful.

Medical management includes cholestyramine, antacids, H<sub>2</sub> blockers, proton pump inhibitors, sucralfate, or promotility agents to enhance clearance of refluxate from the gastric remnant. When these measures fail, surgery is considered for patients with incapacitating symptoms, a reasonably secure clinical diagnosis, and realistic expectations. Preoperative nutritional support may be required and jejunostomy tube placement should be considered strongly during remedial operation, the aim of which is diversion of duodenal contents away from the stomach.

The Roux-en-Y gastrojejunostomy is the surgical reconstruction most frequently chosen to treat patients with alkaline reflux gastritis (Fig. 29-8). Conversion of BI or BII to Roux-en-Y gastrojejunostomy with a 60-cm Roux limb reliably diverts intestinal contents from the gastric remnant and improves symptoms in up to 85% of patients. This procedure also results in significant improvement of endoscopic findings. Although Roux-en-Y gastrojejunostomy achieves satisfactory symptom relief following surgery, during long-term follow-up epigastric pain may persist, particularly in those patients using narcotics preoperatively. The only symptom that is consistently relieved is bilious vomiting, but some patients develop worsening delayed gastric emptying. Other surgical options for postoperative bile gastritis include Braun enteroenterostomy between the afferent and efferent limbs of BII or loop gastrojejunostomy, Henley isoperistaltic jejunal interposition between stomach and duodenum, and duodenal switch. The latter was described to treat primary bile reflux gastritis, which occurs rarely, and absent any previous operation of the stomach or duodenum, but it might be a reasonable surgical option in the rare patient who has acquired debilitating bile reflux gastritis after pyloroplasty or B-I gastroduodenostomy.

**FIGURE 29-8** Roux-en-Y gastrojejunostomy used to treat alkaline reflux gastritis. (Reproduced with permission from Schwartz SI, Ellis H: *Maingot's Abdominal Operations*, 9th ed. Stamford, CT: Appleton & Lange; 1989.)

## **Roux Stasis Syndrome**

After distal gastrectomy with Roux-en-Y reconstruction, some patients experience symptomatic delayed gastric emptying of solids. This phenomenon has been termed the “Roux stasis syndrome” since it has generally been attributed to measurable abnormalities in Roux limb motility.

Of note, Roux syndrome is more common in the presence of a large gastric remnant or after vagotomy, and quite uncommon after Roux-en-Y gastric bypass.

Symptoms of Roux syndrome include abdominal pain and distention, postprandial bloating, nausea, and vomiting. Typically the vomitus contains solid food and is nonbilious. Bacterial overgrowth, with diarrhea and nutrient malabsorption, may result. Endoscopically, the gastric remnant may be dilated with retained food and mucosal irritation. The anastomosis is patent and the Roux limb may also be dilated. There is no evidence of mechanical obstruction on CT or upper GI series. Scintigraphy shows markedly delayed emptying of solids. Liquid emptying is usually not delayed.

Most patients with the Roux syndrome can be successfully managed conservatively with dietary manipulations and use of prokinetic agents, but some patients require revisional operation in an attempt to relieve debilitating symptoms and improve nutritional status. In general, the operation of choice is near-total or total gastrectomy with anastomosis to a new Roux limb (usually the original Roux should be resected). The addition of a feeding jejunostomy is prudent. Pacing of the intestine and/or stomach has been investigated as potential nonsurgical treatment, but this has not yet been proven effective as long-term treatment.

## Marginal Ulcers

Marginal ulceration (ie, juxta-anastomotic ulceration) is a well-described complication of gastrojejunostomy and must be considered as part of the differential diagnosis for many of the more traditional post-gastrectomy syndromes. The incidence of marginal ulcer ranges from 0.6% to 25%. It is more common after Roux-en-Y anastomosis than after Billroth II because the former arrangement lacks the buffering afferent limb contents that counteract the noxious effect of gastric acid on the jejunal mucosa (usually the ulceration is on the jejunal side of the anastomosis). Chronic ischemia and permanent suture material may also be contributing factors. NSAIDs (including aspirin) and smoking predispose to marginal ulcer. Incomplete vagotomy, *Helicobacter* infection, and hypergastrinemia must also be considered. In most cases, marginal ulcers can be adequately treated with PPIs, the elimination of NSAIDs, *Helicobacter* treatment, and smoking cessation. Vagotomy and/or lifelong PPI therapy should also be considered.

Hypergastrinemia after distal gastrectomy can be caused by gastrinoma or retained antrum. In the latter there is residual antral tissue left in continuity with the duodenal stump after gastric resection with Billroth II anastomosis. A similar situation can be created inadvertently during revisional gastric bypass operation if the proximal bypassed stomach is resected and the distal bypasses stomach left in situ. Clinical suspicion of retained antrum may be confirmed by technetium 99 scan, and resection is curative. Gastrinoma is suspected when secretin infusion leads to significant further elevation of gastrin level. CT, endoscopic ultrasound (EUS), and octreotide scan may be helpful, but exploration by an experienced surgeon is the best way to find the tumor(s) if operation is indicated.

## **Nutritional Abnormalities**

Weight loss is common in patients who have had a gastric operation for tumor or ulcer. The degree of weight loss tends to parallel the magnitude of the operation and should be considered as part of the preoperative decision making. Anemia is also a common finding in postgastrectomy patients, occurring in up to one-third of patients. This is generally secondary to nutrient malabsorption, but can also be caused by decreased nutrient intake or chronic blood loss due to ulcer, tumor, or mucosal inflammation. Iron, B<sub>12</sub>, and folate deficiencies are the most common cause of chronic nutritional anemia after gastric surgery. Chronic calcium deficit and osteoporosis may occur after gastric operation. Calcium absorption occurs primarily in the duodenum, so any gastric operation that diverts the food stream away from the duodenum will disturb calcium homeostasis. Finally, any gastric procedure that predisposes to bacterial overgrowth or inadequate mixing of food and digestive enzymes may interfere with the absorption of fat-soluble vitamins, including vitamin D. Thus, it is likely that both calcium and vitamin D malabsorption contribute to metabolic bone disease in patients following gastric surgery.

## **STRESS ULCER DISEASE**

Gastritis and gastric ulceration can be induced by physiologic stress, which compromises mucosal defenses against acid peptic injury. Though some

acute stressors (eg, intracranial hypertension) may be surprisingly associated with increased gastric acid secretion, decreased gastric mucosal blood flow is a major factor in the development of “stress gastritis,” which has largely disappeared as an indication for operation owing to advances in critical care and probably also to stress ulcer prophylaxis. Usually occurring in hospitalized patients with critical illness (Table 29-9), stress gastritis can be demonstrated endoscopically in the majority of patients recovering from shock. While occult bleeding in this population is common, clinically significant hemorrhage defined by the need for blood transfusion, hypotension, or alteration in other vital signs occurs in only 0.5% to 5% of patients. In four recent surgical series comprising more than 28,000 patients, the incidence of clinically significant stress ulceration was 0.4%. In another series of 16,612 hospitalized patients, the incidence of overt stress bleeding was only 0.1%. In a review of patients admitted to both surgical and medical intensive care units (ICUs), the incidence of clinically significant and endoscopically proven stress ulceration was 0.17%.

**TABLE 29-9: RISK FACTORS FOR STRESS ULCER BLEEDING**

Respiratory failure  
Coagulopathy  
Hypotension  
Sepsis  
Hepatic failure  
Renal failure  
Steroids  
Injury Severity Score >16  
Spinal cord injury  
Age >55 y

Major trauma (especially if accompanied by hypotension) sepsis, respiratory failure, hemorrhage, or multiple injuries predispose to acute stress gastritis. Acute stress gastritis is also common after thermal injury with greater than 35% total body surface area burned. A form of gastritis similar to that following trauma may complicate central nervous system (CNS) injury

or intracranial hypertension. When viewed endoscopically, multiple ulcerations are observed in the proximal, acid-secreting portion of the stomach. Fewer lesions are found in the antrum, and only rare ulcerations in the duodenum.

The major complication of stress gastritis is hemorrhage. Patients with coagulopathy and those requiring mechanical ventilation are at increased risk of hemorrhage. Patients without these two risk factors have been reported to have an overall risk of hemorrhage of only 0.1%, while those with both demonstrate clinically significant bleeding in 3.7% of cases. Respiratory failure is defined as greater than 48 hours on a mechanical ventilator. Coagulopathy is defined as a platelet count less than 50,000/ $\mu$ L, an international normalized ratio greater than 1.5, or a partial thromboplastin time greater than two times control.

Admission to an ICU does not by itself place patients at risk for hemorrhage, and patients undergoing major GI surgery do not have an increased risk of stress-related bleeding in the absence of complications. Increased patient age, emergency surgery, need for reoperation, and the occurrence of hypotension are risk factors for postoperative gastric bleeding. The occurrence of sepsis and respiratory failure are also risk factors. Multiple regression analysis has shown that mechanical ventilation and coagulopathy impart the greatest risk.

The diagnosis of stress ulceration requires endoscopic examination. Acute mucosal ulcerations may be observed as early as 12 hours post-insult—lesions appear as multiple shallow areas of erythema and friability, accompanied by focal hemorrhage. Histologically, the lesions consist of coagulation necrosis of the superficial surface epithelium with infiltration of leukocytes into the lamina propria. Signs of chronicity, such as fibrosis and scarring, are absent. With resolution of injury or sepsis, healing is accomplished by mucosal restitution and regeneration.

Stress ulcer prophylaxis is unnecessary in most elective surgery patients but should be considered in ICU patients with mechanical ventilation >48 hours, coagulopathy, burns, CNS injury, recent history of peptic ulcer or upper GI bleeding, and shock. Most commonly H<sub>2</sub> blockers or PPIs are used; both enteral or parenteral routes of administration are acceptable. Suppression of gastric acid secretion has been implicated in the development of nosocomial pneumonia and *Clostridium difficile* infection, so indiscriminate or unnecessary use of these agents in hospitalized patients should be avoided.

A survey of Society of Critical Care Medicine members showed that ranitidine, famotidine, sucralfate, and cimetidine were the drugs used most commonly for prophylaxis. The presence of bright red blood in the nasogastric tube was considered by most to define prophylaxis failure, and the addition of a second drug from a different therapeutic class was the preferred mode of treatment. Because hemorrhage does not occur in all patients, studies that use bloody nasogastric discharge as a sign of stress gastritis underestimate the true incidence in critically ill patients. In one endoscopically controlled study, 100% of patients with life-threatening injuries had evidence of gastric erosions by 24 hours. A high prevalence of gastric erosions is also noted in burn patients, while GI hemorrhage occurs in only 25% to 50% of patients with burn wound infection. Barium contrast examinations have no role in the diagnosis of stress gastritis and interfere with endoscopic examination.

## GASTRIC EPITHELIAL POLYPS

Gastric epithelial polyps ([Table 29-10](#)) are the most common benign tumors of the stomach, and they are usually found incidentally on EGD or upper GI. The two most common gastric polyps are fundic gland polyps and hyperplastic polyps. Both tend to be multiple.

**TABLE 29-10: MANAGEMENT OF COMMON GASTRIC EPITHELIAL POLYPS**

### Fundic gland polyps

Commonly seen in patients on chronic PPI; typically multiple, in proximal stomach

Biopsy for diagnosis

Total polypectomy if >1 cm, ulcerated, or antral location

Suspect polyposis syndrome if associated with gastroduodenal adenomas in young patient

High-grade dysplasia in fundic gland polyp possible w polyposis syndromes

Stop PPI if >20 fundic gland polyps or if fundic gland polyp >1cm

### Hyperplastic polyps

Occur in the setting of atrophic gastritis due to Helicobacter, autoimmune, bile reflux

Up to 20% have focus of dysplasia; 2% have cancer (mostly polyps >2 cm)

Remove all hyperplastic polyps >0.5 cm and repeat EGD in 6 months

Periodic surveillance EGD is prudent for extensive or advanced atrophic gastritis

### Adenomatous polyps

Usually solitary, sessile, and distal in stomach

Associated with atrophic gastritis and gastric metaplasia/dysplasia

Definite cancer risk, both in polyp and remotely in stomach

All adenomatous polyps should be removed and remote gastric biopsies done

Endoscopic surveillance for all patients with adenomatous gastric polyp(s)

---

*Fundic gland polyps* are most commonly associated with chronic PPI use but they may occur as part of polyposis syndromes. They are thought to have very low malignant potential, but a substantial percentage of fundic gland polyps arising in patients with familial adenomatous polyposis (FAP) may show dysplasia. Progression to cancer is rare. Polyposis syndrome should be considered when numerous fundic gland polyps are encountered in young

patients and/or when concomitant distal gastric polyps or duodenal adenomas are found. Fundic gland polyps should be removed and PPIs stopped if the polyp(s) exceeds 1 cm in size or is ulcerated, or is distally located (we also stop PPIs for >20 fundic gland polyps). Otherwise, simple confirmatory biopsy is adequate. Routine endoscopic surveillance is unnecessary unless the patient has a polyposis syndrome or there is something unusual about the findings (large or distal polyps).

*Hyperplastic polyps* occur in the setting of chronic inflammation; eg, chronic gastritis or around a gastrojejunostomy. Up to 20% of hyperplastic polyps may have a focus of dysplasia, and larger polyps (>1 cm) or pedunculated lesions may contain cancer. Lesions >0.5 cm should be completely removed and the stomach should be assessed for metaplasia and dysplasia. *H pylori* should be eradicated, and follow-up endoscopy exam performed in about 6 months to assess any missed or new polyps. Subsequent endoscopic surveillance is based on the assessment of gastric cancer risk using a risk assessment tool (eg, OLGA) since virtually all of these patients have chronic gastritis.

*Adenomatous gastric polyps (gastric adenomas)* are usually solitary and most often occur in a background of chronic gastritis. Like colon adenomas, gastric adenomatous polyps have malignant potential and should be completely resected. The stomach should be diligently assessed endoscopically for metaplasia and dysplasia. Synchronous gastric cancer is not unusual with gastric adenomas, particularly if the adenoma contains a focus of adenocarcinoma. *Helicobacter* should be eradicated if present. Sessile and larger lesions are more likely to harbor dysplasia or cancer. Repeat endoscopy should be performed to ensure that other synchronous lesions were not missed and to assess adequacy of polypectomy. Subsequent endoscopic surveillance should be considered with frequency based on assessed gastric cancer risk.

*Hamartomas* can occur in the stomach in patients with Peutz–Jeghers (PJ) syndrome and PTEN hamartoma tumor syndrome (includes Cowden syndrome). If amenable to endoscopic removal this is not unreasonable, since carcinoma arising from hamartoma has clearly been described. Patients with PJ syndrome are at increased risk for gastric cancer (about 30% lifetime risk) but there is no evidence that removal of hamartomas decreases this risk, and the lifetime risk for colon cancer or pancreas cancer is even higher.

## GASTRIC SUBEPITHELIAL TUMORS

Subepithelial gastric tumors include GIST (see [Chapter 33](#)), leiomyoma, lipoma, cyst, schwannoma, ectopic pancreas, and carcinoid (see below). They are identified on EGD or barium upper GI, and can best be evaluated by EUS and endoscopic needle biopsy with specimen evaluation by specialized immunohistochemical techniques. Symptomatic lesions should be removed. Incidentally discovered lipoma and cyst have characteristic EUS findings and do not require removal or close follow-up. GIST and leiomyoma have similar echo characteristics and both are spindle cell tumors on standard H&E stain, as is the less common schwannoma. These lesions are differentiated by immunohistochemistry: GIST is positive for c-kit; leiomyoma for desmin; and schwannoma for S100 protein. Regardless of symptoms, GIST is removed whenever possible either by endoscopic submucosal resection for small lesions, or laparoscopic or open gastric wedge resection. In the absence of worrisome EUS features such as irregular borders and internal heterogeneity, small leiomyomas (<2 cm) may be observed, but large leiomyomas (>5 cm) should be removed because of the risk of current or future malignancy. Intermediate lesions (2-5 cm) should be removed unless inconveniently located for wedge resection (eg, gastric cardia or prepyloric antrum), in which case diligent follow-up may be recommended on a case-by-case basis. Any change in the tumor is an indication for resection.

## GASTRIC NEUROENDOCRINE TUMORS (CARCINOIDS)

The majority of gastric carcinoids (70%) are type 1 carcinoids and are enterochromaffin-like (ECL) neuroendocrine tumors that occur in the presence of hypergastrinemia due to atrophic gastritis, usually autoimmune ([Table 29-11](#)). They tend to be small and multiple with a low risk of malignancy. Endoscopic removal with biopsy of background gastric mucosa to confirm atrophic gastritis, and surveillance, is recommended. Antrectomy to remove the source of tumor-stimulating gastrin may be considered when there are multiple type 1 carcinoids larger than 1 cm or when recurrence is problematic. Type 2 carcinoids occur in the setting of gastrinoma and MEN-1. These lesions also tend to be multiple with a slightly higher risk of

malignancy, and the oxyntic mucosa is hyperplastic, not atrophic. Treatment is removal of the gastrinoma. If EUS and biopsy of type 1 or type 2 carcinoid show high-risk features (invasion of muscularis propria, angioinvasion, high mitotic count), gastrectomy is indicated. Type 3 carcinoid tumors are sporadic solitary tumors that occur in the setting of normogastrinemia. Malignant potential is high, and treatment is surgical resection with lymphadenectomy after clinical staging. Interestingly, there have been a few case reports of solitary and sizable gastric carcinoid tumors occurring in patients with hypergastrinemia without atrophic gastritis, associated with long-term PPI use.

**TABLE 29-11: MANAGEMENT OF GASTRIC NEUROENDOCRINE TUMORS  
(CARCINOIDS)**

## Gastric neuroendocrine tumors (NETs)

Derived from ECL cells

### Type 1 (70%-80% of gastric carcinoids)

Occur in setting of hypergastrinemia from chronic atrophic gastritis usually autoimmune

Typically multiple and small (<1 cm), commonly w background ECL hyperplasia

Low malignant potential (5-year survival 95%)

Consider EUS and endoscopic resection\*

Antrectomy to remove gastrin source in some patients

### Type 2 (5%)

Occur in the setting of hypergastrinemia associated w gastrinoma and MEN I

Oxyntic mucosa is hyperplastic, not atrophic.

Moderate malignant potential (5-year survival 70%)

Consider EUS and endoscopic resection\*

Remove gastrinoma

### Type 3 (20%)

Usually solitary and large, often symptomatic, gastrin normal

High malignant potential (5-year survival <50%)

Poorly differentiated NET = "type 4" (1-year survival 50%)

Perform EUS<sup>a</sup> and metastatic workup

Consider gastrectomy with lymphadenectomy

---

<sup>a</sup>Gastrectomy and lymphadenectomy should be considered for lesions with high-risk features (vascular invasion, invasion of muscularis propria, high mitotic count, nodal involvement) which rarely may be present with type 1 carcinoid, and may be present in up to 30% of type 2 carcinoids.

## GASTROPARESIS

Gastroparesis is a chronic gastric motility disorder defined by delayed gastric emptying of solids without evidence of mechanical obstruction. Diabetes is a recognized cause of gastroparesis. Primary idiopathic gastroparesis affects mostly young and middle-aged women who present with nausea, abdominal pain, early satiety, vomiting, fullness, bloating, anorexia, and weight loss, with nausea and vomiting being the most disquieting of all the symptoms.

Gastroparesis is diagnosed by symptom assessment and delayed gastric emptying of a solid meal. Gastric retention of more than 10% of the standard solid test meal at 4 hours is abnormal, with retention of more than 30% at 4 hours indicating severe gastroparesis.

Severe gastroparesis may result in recurrent hospitalizations, malnutrition, and significant mortality. Patients failing medical therapy (special diet and trial of promotility agents such as metoclopramide, erythromycin, and domperidone) are often considered for a variety of endoscopic and/or surgical interventions. In general, the therapeutic progression should start with the least aggressive interventions. Recent emphasis has been on reducing pyloric resistance with Botox, laparoscopic pyloromyotomy, or per oral endoscopic pyloromyotomy. Implantable gastric stimulators have helped some patients. Other options include gastrostomy, jejunostomy, gastrojejunostomy, and sleeve gastrectomy. Completion gastrectomy seems to provide symptom relief in post-surgical gastroparesis but this is generally considered a last resort.

## **BEZOARS AND FOREIGN BODIES**

Bezoars are collections of undigestible matter that accumulate in the stomach and small bowel. They are the most common foreign body found in the stomach and may be seen in patients who have undergone prior gastric surgery, including after bariatric surgery. The most common bezoar is composed of hair (trichobezoars). It occurs most commonly in young women. Phytobezoars are composed of vegetable matter and are usually seen in association with gastroparesis or gastric outlet obstruction. Other types of bezoars include lactobezoars (concentrated milk formula), mixed medication bezoars (pharmacobezoars), and food bolus bezoars. Bezoars may present with obstruction, ulceration, or bleeding, and rarely as intussusception. Diagnosis is suggested by upper GI series and confirmed by endoscopy. Enzyme therapy with papain, cellulase, or acetylcysteine may be used, but most patients will need endoscopic or surgical disruption and extraction.

Foreign body ingestion in adults is usually associated with psychiatric or developmental disorder, intoxication, or incarceration. Repeated episodes of foreign body ingestion are common in some patients. Ingested foreign bodies are usually asymptomatic, but removal of sharp or large objects in the

stomach should be considered to avoid bleeding, perforation, or obstruction. Endoscopic removal of ingested foreign bodies is usually possible and is thought to be necessary in about 70% of intentional ingestions, while it is less frequently performed for accidental ingestion. Operation, open or laparoscopic, is performed in about 15% of adult patients with ingested foreign bodies, which most often are retrieved from the stomach. AP and lateral radiographs, and CT scan are helpful localizing studies. Contrast studies are avoided until the need for urgent endoscopy or operation is determined. For gastric foreign bodies, urgent removal is typically recommended for sharp pointed objects, objects longer than 6 cm, and magnets. Prompt but nonurgent removal is recommended for batteries and objects >2.5 cm. Airway protection is key, since aspiration of the foreign body during removal may occur. Retrieval of drug packets from the stomach of drug smugglers (“body packers”) is usually done surgically rather than endoscopically because the risk of rupture and dangerous overdose is thought to be lower with operation.

## MISCELLANEOUS GASTRIC CONDITIONS

### Dieulafoy Lesion

Dieulafoy lesion is a congenital arteriovenous malformation of the proximal stomach, typically on the lesser curve where it derives its supply from branches of either the left or right gastric artery. It is seen in middle-aged or elderly men and characterized by an unusually large, tortuous submucosal artery. Prior to widespread endoscopy, Dieulafoy lesions were diagnosed postoperatively but are now becoming diagnosed and treated routinely via endoscopy.<sup>57</sup> It clinically presents as an upper GI bleed if eroded, and on endoscopy appears as a stream of arterial blood emanating from what appears grossly to be a normal gastric mucosa. Patients may also present with intermittent episodes of mild upper GI bleeding, and endoscopy can miss the lesion if it is not actively bleeding. Most lesions are now treated via endoscopic therapy (injection of epinephrine or other sclerosants, electrocoagulation, hemoclipping, rubber band ligation, and photocoagulation) or via angiographic embolization. Surgery is sometimes necessary, at which time the lesion may be oversewn or resected. Endoscopic

submucosal resection has also been reported. Dieulafoy lesions may occasionally be seen in the duodenum and jejunum as well as in the colon. These lesions have also been successfully managed via endoscopy or surgery.

## **Gastric Diverticula**

Gastric diverticula are typically solitary and may either be congenital or acquired. Congenital diverticula are rare, true diverticula that typically occur near the gastroesophageal junction and are found on the lesser curve or in the posterior area. They will demonstrate all three layers of the gastric wall on endoscopic ultrasound. Acquired or pseudodiverticula usually have a negligible outer muscle layer and are due to either pulsion or traction, and most are found in the antrum. Symptoms are due to inflammation and may produce pain or bleeding, but perforation is rare. Symptomatic lesions should be removed, and this can be done laparoscopically.

## **Mallory–Weiss Syndrome**

The Mallory–Weiss lesion is a longitudinal tear in the mucosa of the gastroesophageal junction, usually due to forceful vomiting and/or retching, and is commonly seen in alcoholics. It has also been reported after instrumentation of the esophagus and stomach. It typically presents with impressive upper GI bleeding. Endoscopy confirms the diagnosis and may be useful in controlling the bleeding, but 90% of patients stop bleeding spontaneously. In patients who continue to bleed, balloon tamponade, angiographic embolization, or selective infusion of vasopressin, systemic vasopressin, and surgery are other treatment options. At surgery, the bleeding lesion is oversewn via a long gastrotomy.

## **Gastric Volvulus**

Gastric volvulus occurs when the stomach twists around one of its axes, usually seen with a large hiatal hernia. It can also occur in the unusually mobile stomach without a hiatal hernia. Typically, the stomach twists along its long axis (organoaxial volvulus), and the greater curvature flips up. Less frequently, it occurs around the transverse axis, called mesoaxial volvulus. It

is usually a chronic condition that can be surprisingly asymptomatic, and expectant nonoperative management is usually advised, especially in the elderly. The risk of strangulation and infarction has been overestimated in asymptomatic patients.

Surgery is recommended for symptomatic patients, especially if symptoms are severe and/or progressive. These patients complain of pain and pressure related to the intermittently distending and poorly emptying twisted stomach. Dyspnea, palpitations, and dysphagia may be seen due to compressive effects of the distended stomach on the surrounding organs. Symptoms are often relieved with vomiting or, if possible, passage of a nasogastric tube. The patient who presents moribund most likely has an infarcted stomach requiring urgent operation and resection, but this is quite unusual. Elective operation may often be done laparoscopically and usually involves reduction of the stomach, repair of hiatal hernia, and gastropexy. Gastropexy alone may be considered for high-risk patients or patients with short esophagus.

## **MINIMALLY INVASIVE GASTRIC OPERATIONS**

The use of minimally invasive surgery in benign gastric diseases has seen a significant increase over the past decade. Minimally invasive techniques combined with either intraoperative endoscopic or radiologic localization are now routinely used for most localized, benign lesions such as leiomyomas, gastrointestinal stromal tumors (GISTs), and gastric diverticula. Combined endoscopic and laparoscopic techniques have also been described. The number and location of ports are determined by triangulating around the target organ, and most procedures can be performed using four to five ports. The benefits of laparoscopic surgery (less postop pain, quicker recovery, and decreased hospital stay) are all realized without compromising surgical principles of adequate resection and tension-free suture lines for many benign gastric disorders. Vagotomy (any type), patch closure of perforation, gastrojejunostomy, pyloroplasty, pyloromyotomy, and gastric wedge resection are all procedures that can and should be considered by the surgeon with advanced laparoscopic skills for the appropriate indication. Also, laparoscopic intragastric resection of large polyps or subepithelial tumors is a good option for lesions that are close to the pylorus or GE junction. An

anterior gastrotomy is made, the lesion identified and elevated, a GIA stapler placed across the base with apparent grossly negative margin, and then a 50-Fr bougie is passed per os through the GE junction to confirm patency. The stapler is fired, the lesion removed, and the anterior gastrotomy closed.

With the introduction followed by rapid improvements of the da Vinci robotic platform, the use of robotic technology, first in urology and gynecology, has now found increasing use in general surgical procedures. Despite its size, cost, and the lack of tactile feedback, the reported advantages over conventional laparoscopic surgery of improved ergonomics, tremor filtering, motion scaling, stable visual platform, and (wrist-like) instrument articulation, especially with the latest generation models (Xi system) have led to widespread adaptation in practice. Decreased conversions rates to open surgery (compared to laparoscopy) as well as expanding indications for a minimally invasive approach in more complex procedures (intracorporeal suturing, mediastinal/pelvis procedures) may be additional reasons for using the robot in gastric resection and reconstruction procedures, particularly those close to the pylorus or GE junction.

# GASTRIC ATONY

*Rian M. Hasson • Scott A. Shikora*

## INTRODUCTION

In addition to being essential for adequate nutrient absorption, normal gastrointestinal motility is crucial for maintaining an appropriate balance of microorganisms and proper function within the gut.<sup>1</sup> It also serves as a major defense mechanism against infection of the gut, and limits the propagation of bacteria to pathologic levels.<sup>1</sup> Gastric atony, also referred to as gastroparesis, can be defined as the inability of the stomach to contract normally, causing a delay in the movement of food out of the stomach. Causal factors for gastric atony can be classified as either medical or idiopathic. The most common medical cause is diabetes mellitus, whereas less common medical conditions include neurologic disorders, connective tissue disorders, critical illness, and surgery.

In the nonsurgical patient with medical comorbidities, disruption of the normal motility can lead to atony, resulting in often devastating symptoms that severely impact nutrition and quality of life. Diabetic gastroparesis is thought to be the result of the dysregulation of the autonomic nervous system, a system that is intimately related to the neural functioning of the stomach. Similarly, the impact of neurologic disorders on gastric motility is often a

consequence of the parallel functioning of neurotransmitters within the central nervous system and those found in enteric neurons. Disturbance of the former can lead to disruption of the latter and gastric atony. With connective tissue disorders, gastric atony is of critical importance, given the tendency of these patients to develop severe and complicated reflux resulting from lower esophageal sphincter hypotension and significantly impaired esophageal peristaltic amplitude. Critical illness greatly impairs the use of enteral nutrition and results in a sustained catabolic state that depletes the patient's caloric reserves, leading to decreased immune function, impaired wound healing, and ultimately increased morbidity and mortality.<sup>2</sup> This disruption can further result in bacterial overgrowth, translocation, pneumonia, and sepsis. While multiple therapeutic options exist for medical gastric atony, patients may often spend a majority of their life with discomfort and in search of the appropriate management.

In the postoperative setting, gastric atony, or failure of the stomach to empty, must, by definition, not be related to any other common postsurgical complication such as wound infection, intraperitoneal abscess, electrolyte disturbances, pancreatitis, thromboembolic disorders, pneumonitis, or cardiovascular complications. While a variety of factors may cause postoperative ileus, the specific categorization of atony must include “dysfunction causing a prolonged postoperative course defined as more than 14 days elapsing between the primary surgical intervention and planned discharge of the patient from the hospital.”<sup>3</sup>

In general, there are a variety of techniques employed to treat gastric atony including medical management, endoscopic techniques, and surgical intervention. Future directions will focus on greater development of these treatment strategies either alone or in combination to improve the daily functioning of these patients. The purpose of this chapter is to review the biology, physiology, diagnosis, treatment options, and persistent clinical challenges that describe this often complex and debilitating disorder.

## **NORMAL GASTRIC MOTILITY**

Research investigating the specific mechanisms through which the intestinal tract functions has revealed a well-designed balance between management of the intestinal microbiome and intestinal motility.

## Historical Perspective

The role of the stomach in nutrient digestion and health maintenance has interested man since early times.<sup>4-6</sup> The ancient Greeks often detailed the “bitter-sour” nature of gastric contents, and in the 16th century, both Paracelsus<sup>7</sup> and van Helmont<sup>8</sup> believed acid to be present in the stomach and a necessity for digestion. Subsequent observations by Reaumur<sup>9</sup> and Spallanzani<sup>10</sup> further described the “solvent” effects of gastric juices. However, the role of gastric acid was not well understood until 1823 when William Prout published his work on the effects of gastric acid secretion.<sup>4</sup> Three years later, observations made by William Beaumont of his patient afflicted with a gastrocutaneous fistula, Alexis St Martin, were published in 1826.<sup>10</sup> His detailed observations over almost a decade of the gastrocutaneous fistula described gastric digestion in a human during normal life experiences including the effects of stress.

In the early 20th century, the multifaceted nature of the control of gastric acid secretion was explored by experiments using ablation of the celiac axis and vagotomy as therapeutic intervention for peptic ulcer disease. This led to a rapid increased interest in gastric acid secretion and spurred the work of Dale and Laidlaw on histamine.<sup>12</sup> This seminal research led to the critical discovery by Popielski of histamine’s effect on gastric secretion,<sup>13</sup> Bayliss and Starling’s discovery of secretin,<sup>14</sup> and Edkins’ discourse on gastrin.<sup>15</sup> These discoveries ushered in a new era in our understanding of gastric disease and specifically led to remarkable advances in the pharmacologic management of peptic ulcer disease starting with the discovery of the H<sub>2</sub>-receptor antagonists by Sir James Black in 1972.<sup>16</sup>

The emphasis on acid-related disease preoccupied research in the middle and latter half of the 20th century until the groundbreaking discovery of *Helicobacter pylori* in 1983 by Marshall and Warren.<sup>17</sup> This was counterintuitive to the then current thinking that the stomach was microbiologically sterile, despite the many observations of numerous bacterial populations in gastric secretions described by Jaworski<sup>18</sup> and the Nobel Prize–winning contribution of Metchnikoff in 1908 for his work describing *Lactobacillus* and gut immunity.<sup>19</sup> As a consequence, the importance of the gastric microbiome and its relationship to *H pylori* revolutionized our understanding of gastric diseases, specifically cancer,

especially in terms of prevention. Current neurohormonal research has led to a better understanding of the control of appetite, food absorption, metabolism and obesity. Furthermore, increasing evidence supports a vital role for gastric motility in the maintenance of the several processes mentioned earlier in completing digestion and ultimately absorbing nutrients.

## **Current Understanding and the Migrating Motor Complex**

Despite these many advances demonstrating the complexity of the stomach, it is still often viewed as “just” the hollow muscular organ that initiates the second phase of digestion<sup>4</sup> (the first being mastication and transport of the food bolus through the esophagus). However, all ingested materials, specifically nutrients and orally dosed medications, have to negotiate the stomach, and as such, the stomach is now recognized to be one of the most important components within the gastrointestinal (GI) tract. Furthermore, the stomach facilitates many unique functions that are crucial to the continued transport of ingested materials, digestion, and the uptake of nutrition, roles that may also have a secondary purpose of maintaining homeostasis.<sup>1,19,20</sup>

It is now confirmed that gastric motility is one of the most important factors necessary for normal digestion. In the interdigestive state, upper GI motility can be described by the recurrent contractility pattern of the migrating motor complex (MMC) (Fig. 30-1).<sup>21</sup> The MMC is thought to serve a “housekeeping” role by sweeping residual undigested material through the digestive tract, out of the stomach, and into the small intestine. The MMC is a distinct 4-stage pattern of electromechanical activity that takes place in GI smooth muscle between meals. Although well preserved across mammalian species, the specific role of the MMC in humans has remained unclear. However, using manometry, Björnsson and Abrahamsson<sup>22,23</sup> demonstrated that apart from the intestinal contractions migrating in the distal direction observed in phase II, phase III of the MMC also behaves as a retroperistaltic pump in the duodenum, creating intermittent alkalization of the stomach. While acidity of the stomach has always been a key component of homeostasis, recent observations have also identified a role for this alkalization in maintaining normal physiologic balance and signaling the return of hunger after meals.<sup>24,25</sup> Conversely, impaired GI motility impedes

the absorption of drugs and nutrients introduced into the stomach, decreases the hunger stimulus, and can also be the nidus from which the symptoms of poor digestion, including nausea, vomiting, distention, and early satiety, begin.

**FIGURE 30-1** Migrating motor complex (MMC). The 2 panels refer to the gastric and intestinal wall, respectively. *Black arrows* indicate induction (*full line*) or permissive effects (*dotted line*). *Red arrows* indicate inhibitory effects. Interestingly, it seems that phase III contractions of the MMC with gastric and duodenal origin are under different control mechanisms. The peptide hormones motilin and ghrelin and the vagus nerve seem to be important regulators for phase III contractions originating in the antrum, while somatostatin and serotonin seem to be involved in the regulation of phase III contractions with a duodenal origin. Peaks in xenin concentration are also associated with duodenal phase III activity in humans. Motilin levels (or activity) are inhibited by pancreatic polypeptide, somatostatin, 5-HT<sub>3</sub> antagonists, and low pH. 5-HT, 5-hydroxytryptamine (serotonin; this could originate either from enterochromaffin cells or from neurons in the enteric nervous system); ACh, acetylcholine; M, motilin-producing M cell; NOR, noradrenaline; P/D1, ghrelin-producing P/D1 cell; PP, pancreatic polypeptide; SOM, somatostatin-producing cell; X, putative xenin producing cell. (Reproduced with permission from Deloose E, Janssen P, Depoortere I, et al: The migrating motor complex: control mechanisms and its role in health and disease, *Nat Rev Gastroenterol Hepatol*. 2012 Mar 27;9(5):271-285.)

GI motility serves as a major means to prevent infection of the intestinal tract. Normally, microorganisms are rarely encountered in the esophagus, stomach, and duodenum because of peristaltic contractions that continually move their contents toward the colon. While fairly low in the esophagus and stomach, the quantity of bacteria increases significantly as the GI contents reach the terminal ileum and eventually the bacterial-laden colon. Multiple “normal” physiologic processes within the gut limit the proliferation of these microorganisms to pathologic levels.<sup>26</sup> While gastric acid is directly toxic to bacteria, resulting in minimized overgrowth, inhibiting gastric acid secretion in the face of normal motility does not seem to affect bacterial counts. Conversely, when motility is disrupted, with or without normal acid secretion, small intestinal bacterial overgrowth occurs. Hence, it is now recognized that patients with impaired GI motility are also at risk of bacterial overgrowth in the proximal gut with pathogenic organisms and subsequent translocation of these organisms or their toxins into the bloodstream.

We can conclude that normal GI motility is vital to the initial desire to eat, natural and timely digestion, the specific uptake of nutrients to maintain

health and well-being, and the regulation of bacterial flora whose structured concentration is also necessary for digestive stability. Disruption in motility at any step can have major consequences impacting overall health and nutrition in multiple ways.

## **CLASSIFICATION, PATHOPHYSIOLOGY, AND EPIDEMIOLOGY OF GASTRIC ATONY**

Gastric atony can arise in multiple situations, including medical, postsurgical, and idiopathic settings, each related to specific derangements in normal motility ([Table 30-1](#)). The management of these patients presents several challenges and is best conducted in the context of a dedicated and skilled multidisciplinary team.

**TABLE 30-1: DIFFERENTIAL DIAGNOSES OF GASTRIC ATONY**

**Endocrine and Metabolic Disorders**

- Diabetes mellitus
- Hypothyroidism
- Parathyroid dysfunction
- Adrenal insufficiency
- Chronic renal insufficiency
- Electrolyte abnormalities

**Neurologic Disorders**

- Parkinson disease
- Cerebrovascular disease
- Muscular dystrophy
- CNS tumors
- Spinal cord lesion
- Migraine

**Postsurgical**

- Postoperative ileus
- Vagotomy
- Nissen fundoplication
- Post bariatric surgery
- Partial gastric resection
- Pancreatic surgery/ Whipple
- Transplantation: lung/ heart-lung

**Gastrointestinal Disorders**

- Achalasia
- Gastric ulcer
- Gastroesophageal reflux disease/ functional dyspepsia
- Celiac disease
- Gastroenteritis (viral)
- Atrophic gastritis
- Pseudo-obstruction
- Hiatal hernia

**Connective Tissue Disorders**

- Scleroderma
- Systemic lupus erythematosus
- Raynaud disease
- Amyloidosis
- Dermatomyositis, polymyositis

**Others**

- Idiopathic
  - Eating disorders
  - Medications (ie, narcotics, anticholinergics, nicotine, dopaminergics, calcium channel blockers, tricyclic antidepressants)
  - Liver disease
- 

## Medically Related Atony

### DIABETES MELLITUS

Even though the relationship between diabetic gastroparesis and other complications of longstanding diabetes mellitus (DM) is incompletely understood, it has been established that there is an association with autonomic neuropathy.<sup>27</sup> Additionally, although acute hyperglycemia delays gastric emptying,<sup>28</sup> the relationship between long-term control of glycemia

and gastric emptying is unclear, and results from investigation have been conflicting at best. For example, although increased glycosylated hemoglobin (HbA1c) levels have been associated with GI symptoms in people with type 2 DM (T2DM),<sup>29</sup> HbA1c levels were not found to be significantly different among patients with T2DM with GI symptoms and delayed gastric emptying, patients with T2DM with GI symptoms and normal gastric emptying, and patients with T2DM without GI symptoms. In addition, improved glycemic control did not improve gastric emptying in subjects with delayed gastric emptying and type 1 DM or patients with T2DM and delayed gastric emptying.<sup>30</sup> These findings are in contrast to those of the Diabetes Control and Complications Trial (DCCT),<sup>31</sup> in which 6.5 years of intensive insulin therapy reduced the risk of other complications such as diabetic retinopathy, nephropathy, and peripheral and cardiac autonomic neuropathy by 40% to 60% when compared with conventional insulin therapy. Furthermore, the differences between the former intensive and conventional treatment groups persisted for as long as 14 years despite the loss of glycemic separation.<sup>32-34</sup> In the only community-based study, symptoms of peripheral or autonomic neuropathy were not associated with diabetic gastroparesis.<sup>35</sup> Nevertheless, despite uncertainty in the causal factors for gastric atony, diabetic patients are still the cohort most commonly afflicted with medically related gastric atony, and are often most afflicted with gastric atony–related symptoms second only to patients with postsurgical gastric atony.<sup>36</sup>

## **NEUROLOGIC DISORDERS**

As populations age, the prevalence of neurologic disease continues to increase and consultations involving GI motility problems in the patient diagnosed with a neurologic disorder become ever more common. The high prevalence of gastric atony and other disturbances of gut motor function in neurologic diseases is based on similarities in morphology and function of the neuromuscular apparatus of the gut and that of the somatic nervous system.<sup>36</sup> Furthermore, the basic organization of the enteric nervous system (ENS) (neurons, ganglia, glia, and ENS-blood barrier) and the ultrastructure of its components are similar to those of the central nervous system (CNS). Almost all neurotransmitters identified within the CNS are also found in enteric neurons. Thus, the concept of ENS involvement in neurologic disease should not come as a great surprise.

Dysfunction of the autonomic nervous system (an important modulator of enteric neuromuscular function) can be commonly seen in several neurologic syndromes. In addition to the presence of several primary and secondary disorders of autonomic function, disturbed autonomic modulation of gut motor function, in some cases, may be an important factor that contributes to symptom development. It is also evident that the gut has important sensory functions. Sensory input is fundamental to several reflex events in the gut, such as the viscerovisceral reflexes that coordinate function along the gut. Even though these functions are usually subconscious, gut sensation may be relayed to and perceived within the CNS. Because the role of sensory dysfunction in the mediation of common symptoms such as abdominal pain and nausea in the patient with CNS disease with GI manifestations has not been extensively investigated, this does offer a future area of study.<sup>36</sup>

The two predominant neurologic disorders often encountered in GI practice are cerebrovascular disease and parkinsonism. In addition, patients with multiple sclerosis, autonomic and peripheral neuropathies including that associated with diabetic autonomic neuropathy, Guillain-Barré syndrome, myotonic dystrophy, and Duchenne muscular dystrophy have all been shown to demonstrate signs and symptoms suggestive of gastric atony. Regardless of the specific neurologic diagnosis, the use of a multidisciplinary team that is aware of the wishes and needs of the family and mindful of the nature and the natural history of the underlying disease process is best practice. Together, the team, including a neurologist and/or neurosurgeon, nutritionist, gastroenterologist, and specialty nurse, can assess and manage gastric atony and other GI problems in the patient with neurologic disease.<sup>36</sup>

## **CONNECTIVE TISSUE DISORDERS**

Gastric atony is also seen with scleroderma, one of the most common causes of pseudo-obstruction. Gastric involvement in scleroderma tends to parallel the same clinical course as the esophagus.<sup>37</sup> In the Olmstead County study,<sup>38,39</sup> 10.8% of all cases of definite gastric atony were associated with the presence of a connective tissue disorder. In scleroderma, gastric involvement has been documented in anywhere from 10% to 75% of all patients, and delayed gastric emptying has been seen in 50% to 75% of those patients with scleroderma who demonstrated GI symptoms.<sup>36</sup> Gastric atony in itself has important clinical consequences in scleroderma, including

exacerbation of gastroesophageal reflux and malnutrition. The former is of critical importance, given the tendency of these patients to develop severe and complicated reflux resulting from significantly impaired esophageal peristaltic amplitude and lower esophageal sphincter hypotension. Using the relatively noninvasive <sup>13</sup>C-octanoic acid breath test, Marie et al<sup>40</sup> documented delayed gastric emptying in 47% of 57 consecutive patients with scleroderma. Furthermore, they described a close correlation between GI symptoms and a delay in gastric emptying.<sup>40</sup>

Using the same approach, Hammar et al<sup>41</sup> discovered atony in 29% of their 28 patients with primary Sjögren syndrome. Most recently, a reported association between Ehlers-Danlos syndrome type III (the joint hypermobility syndrome) and a variety of functional GI symptoms, including those that may be based on gastric emptying delay, have begun to emerge,<sup>42-44</sup> with the frank documentation of gastric atony in some of the studies.<sup>42</sup>

## **CRITICAL ILLNESS**

The prevalence of delayed gastric emptying in the intensive care unit (ICU) setting has been estimated to range from 38% to 57%, depending on the method used to define it.<sup>45,46</sup> Using the <sup>13</sup>C-octanoate acid breath test and measuring <sup>13</sup>CO<sub>2</sub> in end-expiratory breath samples, Ritz et al,<sup>47</sup> found that 40% to 45% of the patients in an intensive care setting had delayed gastric emptying. Factors that can contribute to delayed gastric emptying in critical care patients include the supine position, coughing, suctioning, obesity, and advanced age, and the extent of the delay is directly related to the severity of critical illness. Nguyen et al<sup>48</sup> found that, after controlling for other factors, admission diagnoses had only a modest impact on the risk for gastric atony in the ICU, with those at the highest risk being patients with head injuries, multisystem trauma, sepsis, and burns. That being said, a number of comorbid conditions may increase gastric emptying time, including raised intracranial pressure, hiatal hernia, gastric cancer, gastric resection, liver cirrhosis, and chronic pancreatitis. Interestingly, Lam et al<sup>49</sup> observed in a retrospective study that a history of diabetes was not an independent risk factor for gastric emptying delay in critically ill patients despite its high prevalence in modern hospital populations. Additionally, proximal gastric motor responses to feeding were similar in diabetic patients to those of

healthy individuals.<sup>50</sup> Nevertheless, hyperglycemia does impair gastric contractility and, along with electrolyte disturbances, may lead to gastric atony.<sup>51,52</sup> Hence, in the critically ill setting, the continued need for optimization of both of these parameters is vital. Treatment has thus focused on the correction of electrolyte disturbances, withdrawal of medications that may impair gut motility, hypoglycemic monitoring, the addition of prokinetics, and the placement of feeding tubes (gastrostomy or jejunostomy) as needed.

## Postsurgical Atony

Although many surgical procedures originally associated with gastroparesis or gastric atony are less commonly performed today, several more recently developed upper abdominal procedures may be complicated by the development of gastric atony (Table 30-1). Acute gastric atony may be the result of the “ileus syndrome,” which can complicate many surgical procedures. Most often, it is a transient event that usually resolves in a short period of time. Occasionally, this gastric dysmotility can become chronic and result in significant symptoms. In contrast to chronic medical gastric atony, whose pathophysiology is often poorly understood, in the acute form of postsurgical atony, inflammatory processes seem central to the inhibition of motility. The frequency of postsurgical gastric atony can vary widely depending on many factors including the site and nature of the surgical procedure.<sup>36</sup> Again citing the prominent Olmstead County studies of the community prevalence of gastric atony, 7.2% of all cases were related to prior gastrectomy or fundoplication.<sup>39</sup> More specifically, Dong and colleagues<sup>53</sup> noted that the rates of atony ranged from 0.4% to 5% after gastrectomy, 20% to 50% after pylorus-preserving pancreaticoduodenectomy, and 50% to 70% after cryoablation therapy for pancreatic cancer.

## VAGOTOMY

Although vagotomy is now infrequently performed for the management of peptic ulcer disease, the effect of inadvertent vagal injury underscores the continued relevance of a complete understanding of the complex effects of

vagotomy on gastric motor function.<sup>36</sup> Loss of vagally mediated reflexes impairs receptive relaxation of the gastric fundus, leading to acceleration of the early phase of liquid emptying. This acceleration causes rapid emptying of hyperosmolar solutions into the proximal small intestine and may result in dumping syndrome. Conversely, and as a consequence of impaired antropyloric function, vagotomy prolongs the later phases of liquid and solid emptying. Other motility effects of vagotomy include impairment of the motor response to feeding, which contributes to the pathophysiologic mechanisms of postvagotomy diarrhea, and a suppression of the antral component of the MMC, which is particularly common among individuals with symptomatic postvagotomy gastroparesis.<sup>36,46,52,53</sup>

Currently, standard practice includes the addition of a drainage procedure, such as a pyloroplasty or gastroenterostomy, which tends to only negate the effects of vagotomy and results in little alteration in the gastric emptying of liquids or solids. Interestingly, prolonged postoperative gastroparesis (ie, lasting longer than 3-4 weeks) is, in fact, rare (<2.5% of patients after either vagotomy and pyloroplasty or vagotomy and antrectomy).<sup>54</sup> In contrast, significant postoperative gastric atony may occur in patients who have a prior history of prolonged gastric outlet obstruction. In these cases, normal gastric emptying may not return for several weeks. That being said, longitudinal studies suggest that vagotomy-related gastroparesis trends toward resolution over time. One study has suggested gastric emptying in those who had undergone either a truncal or a highly selective vagotomy (previously thought to have very different long-term results) being similar in clinical features by 12 months after the procedure.<sup>55</sup>

When postsurgical gastric motor dysfunction persists, it can often present an arduous management challenge. Responses to medical therapies such as prokinetic agents have proved particularly disappointing in this group, and in these resistant cases, a completion gastrectomy may be the best alternative. It should be noted, however, that this intervention may still lead to frustration, as results in a large series deemed this approach successful in only 43% of patients.<sup>56</sup>

## **ANTIREFLUX OPERATIONS**

Multiple studies have documented that fundoplication affects sensorimotor function of the proximal stomach.<sup>57-59</sup> Furthermore, most, but not all,<sup>60</sup>

studies have demonstrated that following fundoplication, there is impaired relaxation of the proximal stomach in response to meal ingestion. Instances of gastric atony have been described following antireflux surgery and endoscopic antireflux procedures,<sup>61</sup> even though the usual effect of fundoplication is to accelerate, rather than delay, gastric emptying.<sup>58</sup> It should come as no surprise that Nissen fundoplication was the most common cause of postsurgical gastroparesis in the audit conducted by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Gastroparesis Consortium. Despite the high frequency with which this procedure is now performed,<sup>62</sup> the pathophysiologic process leading to postfundoplication gastroparesis remains unclear. It has been proposed that some cases of postsurgical gastric atony have been secondary to an unrecognized preoperative disorder. In other cases, there is compelling evidence to implicate vagal nerve injury, which also has a higher occurrence in redo procedures and may contribute to persistent gas and bloating symptoms.<sup>63</sup>

In rare instances, postfundoplication gastric atony may be severe and persistent. Although gastric resection does not seem to offer much help for these situations,<sup>64</sup> some success has been reported with an approach that combines pyloroplasty with the conversion to a partial fundoplication.<sup>65</sup> In an uncontrolled trial, endoscopic injection of the pylorus with botulinum toxin A produced symptomatic improvement in a small series of patients with postvagotomy gastroparesis, which in the vast majority was thought to result from fundoplication.<sup>66</sup>

## **ROUX-EN-Y SYNDROME, OR ROUX SYNDROME**

Patients undergoing creation of a Roux-en-Y gastroenterostomy can develop severe symptoms of postprandial abdominal pain, bloating, and nausea. This has often been associated with a specific clinical entity referred to as the Roux syndrome.<sup>67</sup> Studies have inconsistently described impaired gastric motor function<sup>68</sup> and a functional obstruction within the roux limb as a result of motor asynchrony,<sup>67,69</sup> with the latter demonstrated by manometry. Regardless of these associations, for the most part, the overall impact of these motility patterns in the pathophysiologic processes of this syndrome still remains unclear.<sup>70</sup>

## **BARIATRIC SURGERY**

Ardila-Hani and Soffer<sup>71</sup> comprehensively reviewed the impact of bariatric (or metabolic) surgical procedures on GI motor function and found that esophageal problems were by far, the most common. Gastric emptying did not appear to be affected by laparoscopic adjustable gastric banding, whereas Roux-en-Y gastric bypass and sleeve gastrectomy tended to accelerate gastric emptying. The few instances of gastric atony reported have often been described as severe and persistent and likely secondary to an anastomotic stricture, small bowel obstruction due to anastomotic edema of either the gastrojejunostomy (most common) or jejunojunctionostomy, hernia, or behavioral problems such as disordered eating. Medical therapy appears to be the first-line approach; however, this too can result in lackluster alleviation of symptoms. Interestingly, Salameh et al<sup>72</sup> described successful treatment using gastric electrical stimulation in 6 patients with intractable gastroparesis following Roux-en-Y gastric bypass for morbid obesity. More investigation will be needed before consistent solutions to this rare problem can be offered.

## **GASTRECTOMY**

Symptomatic “dumping” may occur in up to 50% of patients after Billroth I or II gastrectomy. By removing the antral mill, antral resection often renders the stomach incontinent to solids, leading to accelerated emptying.<sup>73</sup> Late dumping symptoms occur 90 to 120 minutes after a meal and are a consequence of reactive hypoglycemia. In addition, the accommodation reflex is impaired among symptomatic patients.<sup>74</sup> Delayed gastric emptying sometimes occurs after a Billroth II gastrectomy as a result of a large atonic gastric remnant.<sup>73</sup> Meng et al<sup>75</sup> reported a 6.9% frequency of gastric atony among 563 patients who underwent radical gastrectomy for gastric cancer in their hospital in Shanghai, China. The principal risk factors for the occurrence of atony included preoperative gastric outlet obstruction and anastomotic function following reconstruction. While others have proposed laparoscopy-assisted, pylorus-preserving gastrectomy as a less radical operative approach to early gastric cancer, gastric atony was still the most common complication of this procedure, occurring in 6.2% of cases.<sup>76</sup> Interestingly, Meng et al<sup>75</sup> also observed a similar rate of gastric atony

(3.7%) among a smaller group of patients who underwent a laparoscopic gastrectomy. Reassuringly, in contrast to the previously mentioned experience with completion gastrectomy following vagotomy, completion gastrectomy has been shown to result in significant symptomatic improvement among subjects with postgastrectomy gastric atony.<sup>77</sup>

## **PANCREATECTOMY**

Pancreatectomy, pancreas transplantation,<sup>78</sup> and pylorus-preserving pancreaticoduodenectomy, in particular, have been associated with a high incidence of postoperative gastric atony. Over time, it has been concluded, that while operative technique generally seems to be of less importance, the principal predictor of gastric emptying delay after these operations is the occurrence of other postoperative complications.<sup>79,80</sup> Parmar et al,<sup>81</sup> in what has been the largest series (N = 711) to date, documented an overall rate of delayed gastric emptying specifically following pancreaticoduodenectomy of 20%. Furthermore, they observed that the occurrence of gastric atony was associated with complications such as fistula formation, postoperative sepsis, and reoperation, and did not seem to be influenced by technical factors such as pylorus preservation or whether the gastrojejunostomy was antecolic or retrocolic. In contrast, results of a prior systematic review<sup>82</sup> found that an antecolic reconstruction was in fact linked to lower rates of gastroparesis. Others have suggested that the use of a Billroth II rather than a Roux-en-y gastrojejunostomy for reconstruction following this procedure may reduce the risk of gastric emptying delay.<sup>83</sup> Either way, decreasing the complication rate while paying attention to surgical technique may be helpful in decreasing postsurgical atony. Interestingly, the presence of preoperative diabetes has also been identified as an additional risk factor for this postsurgical cohort.<sup>84</sup>

## **OTHER PROCEDURES**

It has been demonstrated that virtually any procedure that can affect upper GI motor function or compromise the vagus nerve can result in gastric atony. Clinically significant atony or gastroparesis has been reported not only in association with a wide range of gastric procedures but also in relation to esophageal procedures including botulinum toxin injection for achalasia<sup>85</sup> and esophageal resection,<sup>86</sup> lung transplantation, and even hepatic surgery.

Sutcliffe et al<sup>86</sup> noted a 12% rate of gastric conduit emptying delay in a series of patients following esophagectomy. In another report, gastric atony was more commonly seen after minimally invasive than open esophagectomy.<sup>87</sup> Gastric atony in the setting of lung transplantation is especially worrisome, as its presence preoperatively has been associated with an increased risk for the development of bronchiolitis obliterans syndrome.<sup>88</sup> Although common even before surgery,<sup>69</sup> new-onset gastric atony has also been observed in up to 6% of subjects after transplantation<sup>88,89</sup> and may trigger or exacerbate gastroesophageal reflux from which these patients have no protection. For this reason, there is a low threshold in this patient population to proceed with fundoplication in combination with gastric electrical stimulation to address concomitant gastric atony.<sup>90</sup>

## Idiopathic Atony

Among patients who do not have underlying disorders or have not undergone any of the surgical procedures described above, the pathogenesis of idiopathic gastric atony is poorly understood, but often still has some link to illness or remote surgery. In a tertiary referral series of patients with idiopathic gastric atony, it was observed that the onset of symptoms was consistent with a viral origin in 23% of participants.<sup>91</sup> In the NIDDK Gastroparesis Clinical Research Consortium, approximately 19% of participants with idiopathic gastric atony and 14% with either type 1 DM or T2DM and gastric atony demonstrated symptoms of an infectious prodrome before diagnosis.<sup>92</sup> Although cholecystectomy, per se, has not been incriminated as a cause of gastric atony,<sup>36</sup> a prior cholecystectomy seems to negatively affect the natural history of both diabetic and idiopathic gastroparesis. The previously mentioned tertiary study found that gastroparesis symptoms began after a cholecystectomy in 8% of participants,<sup>93</sup> and 36% of patients with idiopathic or diabetic gastric atony had undergone a cholecystectomy in the NIDDK study.<sup>92</sup> Whether cholecystectomy is an independent risk for atony is unclear; however, patients with cholecystectomy had more comorbidities, particularly chronic fatigue syndrome, fibromyalgia, depression, and anxiety.

## Hospitalization and Economic Burden

Hospitalizations with gastroparesis as the primary diagnosis increased from 3977 in 1995 to 10,252 in 2004 (+158%), whereas hospitalizations with gastroparesis as the secondary diagnosis increased from 56,726 to 134,146 (+136%).<sup>94</sup> In contrast, smaller changes were seen in diabetes-related hospitalizations (+53%), all hospitalizations (+13%), and hospitalizations with gastroesophageal reflux disease (GERD), gastric ulcer, gastritis, or nonspecific nausea/vomiting as the primary diagnosis (−3% to +76%).<sup>94</sup> Furthermore, comparing 4 of the most common GI conditions (GERD, gastric ulcers, gastritis, and nonspecific nausea/vomiting), when gastric atony or gastroparesis was listed as the primary diagnosis, the length of stay was longer (increase of 15.4%-66.2%; all conditions vs gastroparesis,  $P < .001$ ) and had the highest or second highest total charges (−7.2% to +60.6%, all  $P < .01$ ) in 2004, with similar results in 1995.<sup>94</sup> Although more recent trends have yet to be published, similar trends for gastric atony versus other diagnoses have been previously observed.<sup>66,95</sup>

Bielefeldt et al<sup>96</sup> pointed at an indirect economic impact of the chronic illness with high rates of un- or underemployment and likely, as a result, a high number of patients with low household incomes. Parkman et al<sup>97</sup> more recently published a study of nearly 400 patients demonstrating that while patients reported median household incomes close to the national average, less than half of the patients were employed at the time of enrollment and nearly one-third had high rates of work absenteeism due to their disease.

## CLINICAL PRESENTATION

### Signs and Symptoms

As previously mentioned, the symptoms of gastric atony can be frustrating and debilitating for the patient. While some are able to find intermittent relief, others may toil for years, resulting in a substantial decrease in quality of life.

## NAUSEA AND VOMITING

Regardless of the etiology, nausea and vomiting are the most common symptoms in patients with gastric atony, with over 40% of patients reporting that these symptoms are among the most bothersome.<sup>98</sup> Accordingly, the pathogenesis of these symptoms is heterogeneous and often multifactorial. It is known that the receptor site for vomiting is centrally located in the area postrema at the base of the fourth ventricle in the brain (chemoreceptor trigger zone). Peripheral receptor sites include the vagus nerve and vestibular apparatus. Stimulation of the vagal afferents from either gastric distention or deregulated gastric motility triggering emesis<sup>99</sup> can lead to a repeated cycle of vomiting following the first episode.

## **EARLY SATIETY AND FULLNESS**

Early satiety and fullness are common symptoms among patients with both idiopathic and diabetic gastric atony, especially in those with T2DM.<sup>91</sup> Impaired gastric accommodation, known as the reduction in gastric tone and increase in compliance that follows ingestion, has been found in 43% of patients with idiopathic gastric atony, and it contributes to patients' inability to completely tolerate a normal meal.<sup>100</sup> Similarly, impaired gastric accommodation was found in 40% of patients with functional dyspepsia.<sup>101</sup> A smaller study of 10 diabetic gastroparesis patients, who were refractory to prokinetic therapy, found that 90% of these patients had impaired gastric accommodation.<sup>102</sup>

Several medications have been shown to increase gastric accommodation in healthy subjects as well as patients with functional dyspepsia. Notably, buspirone was shown to result in improvements in functional dyspepsia symptoms, particularly postprandial fullness, bloating, and early satiety.<sup>103</sup>

## **BLOATING**

Bloating is another common symptom seen in functional GI disorders such as irritable bowel syndrome (IBS) and functional dyspepsia along with gastroparesis.<sup>104</sup> Although there has been no association found between the rate of gastric emptying and severity of bloating,<sup>98</sup> the presence of bloating with gastroparesis has been associated with a poor response to medical therapy.<sup>105</sup> A large multicenter study including 335 patients found that

bloating was present in 76% of patients with gastric atony, with 41% suffering severe symptoms.<sup>96</sup> Interestingly, it was found that there was also an association between the use of norepinephrine reuptake inhibitors (predominantly tricyclic antidepressants) and symptoms of mild bloating.

## **ABDOMINAL PAIN**

Although abdominal pain is a common feature of gastric atony, studies have consistently shown that the severity of pain also does not correlate with the severity of the delay in gastric emptying. Specifically in diabetic patients, pain predominance was found in approximately 20% of patients referred to the NIDDK Gastroparesis Clinical Research Consortium.<sup>96</sup> Visceral hypersensitivity, defined as a lowered threshold for eliciting visceral pain, is common among functional GI disorders, including functional dyspepsia, IBS, and gastroparesis. The presence of visceral hypersensitivity was found in 29% of patients with idiopathic gastric atony and 55% of patients with diabetic gastric atony.<sup>102</sup> The presence of hypersensitivity to intragastric balloon distention was associated with a higher prevalence of abdominal pain, early satiety, and weight loss. Similarly, among these gastroparesis patients, the presence of hypersensitivity was also associated with greater symptom severity.

## **DIAGNOSIS**

### **Radiologic (Gastric Emptying and Scintigraphy)**

The gold standard for quantifying gastric emptying is gastric emptying scintigraphy, and the consensus recommendations for the procedure involve technetium-99m sulfur-colloid labeled, low-fat, egg-white meal with imaging at 0, 1, 2, and 4 hours.<sup>106</sup> The diagnosis of delayed gastric emptying is confirmed if there is >90% gastric retention at 1 hour, >60% at 2 hours, and >10% at 4 hours.<sup>107-109</sup> This test is noninvasive, widely available, and easy to perform. Other routine tests include upper abdominal x-ray and esophagogastroduodenoscopy (EGD) to rule out mechanical obstruction. Real-time magnetic resonance imaging (MRI) has also been shown to be a reliable tool for the assessment of gastric motion; however, the study itself is

expensive, time intensive, and not widely available.<sup>108,110,111</sup>

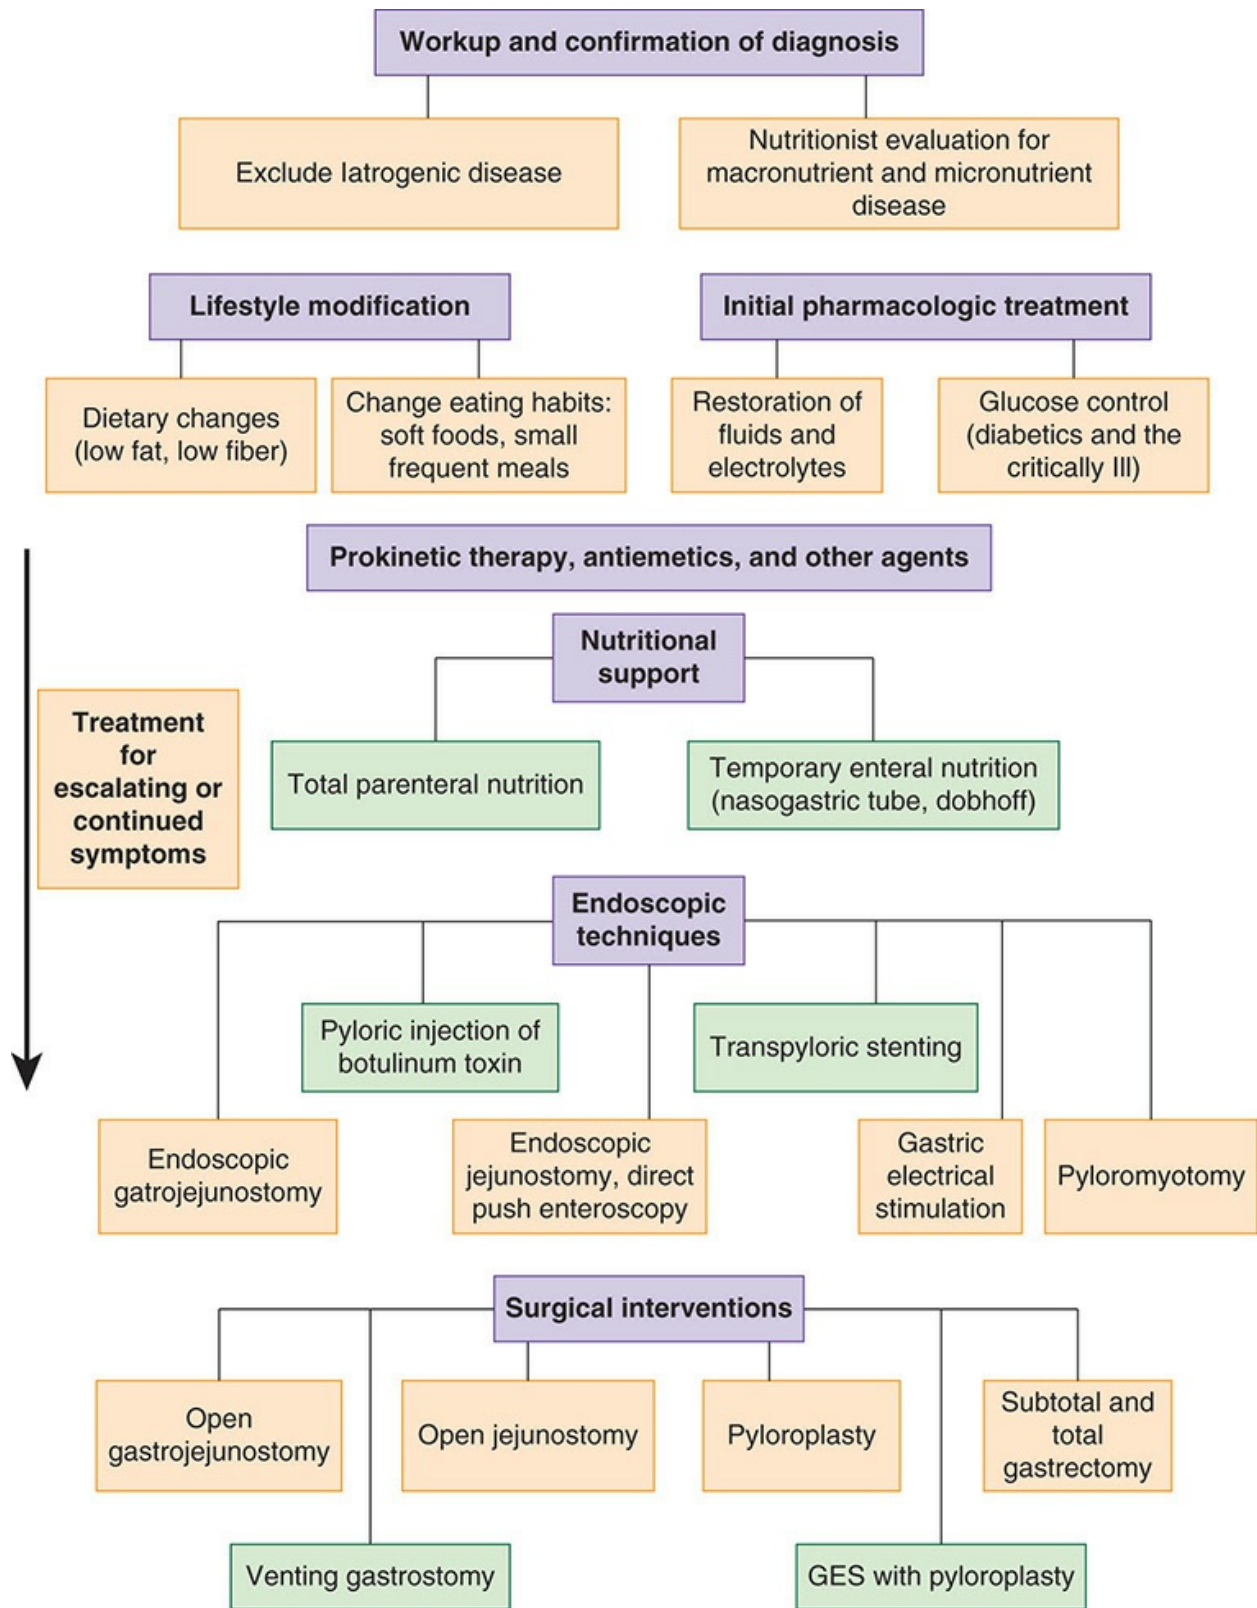

## **Manometry and Electrogastrography**

Gastric manometry is an invasive test that measures motility patterns of the gut. This test requires expertise to perform and evaluate the results. Gastric manometry can reveal characteristic patterns that suggest a neuropathy, myopathy, or intestinal mechanical obstruction.<sup>111</sup> Electrogastrography, a noninvasive measurement of electrical activity of the gastric smooth muscle, is used predominantly in research to evaluate for gastric arrhythmias.<sup>109</sup> Electrogastrography measures electrical rhythms, but because it requires expertise to evaluate results, it is not widely available.<sup>108,111</sup>

## **TREATMENT OPTIONS**

Optimal treatment can only be achieved once a careful investigation has taken place to properly diagnose gastric atony, exclude iatrogenic causes, correct electrolyte or metabolite imbalances, and modify eating habits and diet to achieve the peak level of noninvasive symptom relief possible. While medical management has been the gold standard initial treatment for most cases of gastric atony, the emergence of minimally invasive techniques has created attractive alternative options for patients who do not respond to medical management. When all else fails, conventional surgical remedies can be considered. [Figure 30-2](#) offers a treatment algorithm for patients with symptomatic gastroparesis.

**FIGURE 30-2** Treatment algorithm for gastric atony. While medical management has been the gold standard regarding initial treatment for most

cases of gastric atony, the emergence of minimally invasive techniques has created attractive alternative options for patients who do not respond to medical management. Conventional surgical remedies can be considered if other options fail. GES, gastric electrical stimulation.

## Medical Therapy

Although a multitude of pharmacologic therapies exist for the treatment of gastroparesis, prokinetic agents are by far the most recognized agents. It has been approximately 30 years since the first randomized controlled trials of the conventional prokinetic agents, metoclopramide, domperidone, and erythromycin, have been published. Despite this, they are still the first-line agents for the treatment of gastroparesis.<sup>112</sup> Much like many other investigated areas of gastric atony, the majority of data regarding the efficacy of conventional prokinetic agents for the treatment of gastric atony are outdated.<sup>113-117</sup> Metoclopramide has been the most extensively studied and has been associated with less improvement in gastric emptying when compared to the macrolide antibiotic erythromycin.<sup>117</sup> A meta-analysis assessing the benefits of 4 different medications in 514 patients in 36 clinical trials reported erythromycin as the most potent stimulant of gastric emptying. Both erythromycin and the dopamine receptor antagonist domperidone (not available in the United States) are best at reducing the symptoms of gastric atony.<sup>118</sup> Currently, several novel pharmacotherapies such as ghrelin receptor agonists (TZIP-101, TZIP-102, RM-131), mitemincin, prucalopride, velusetrag, and levosulpiride are in development; however, their clinical efficacy and safety still need to be determined.<sup>112,119,120</sup> While it is generally accepted that a significant percentage of patients require additional therapy beyond prokinetic agents, no clear data exist to determine the percentage of patients who fail medical management. Nevertheless, the use of promotility drugs in all patients is a relatively safe and effective means to circumvent the problem of gastric atony and improve patient recovery. Furthermore, understanding the drugs available and their interaction with the receptors involved in neuromuscular transmission within the GI tract can often aid the clinician in selecting the optimal therapy.

## Endoscopic Techniques

Gastric atony has traditionally been a largely medically managed disease with refractory symptoms typically falling under the umbrella of the surgical domain. Advancements in the field have included the endoscopic management of gastroparesis, which most commonly involves intrapyloric botulinum toxin A injection and gastric electrical stimulation implantation. Furthermore, on the horizon are novel endoscopic approaches that have the potential to radically improve the standard of care. Endoscopic management of gastroparesis seeks to treat delayed gastric emptying with a less invasive approach compared to traditional surgical approaches.<sup>121</sup> New endoscopic procedures offer a minimally invasive alternative to more radical options and should probably be more widely adopted. However, a progressive algorithm needs to be followed in challenging cases: starting with medical treatment and diet modification, then progressing through endoscopic treatments including new interventions such as per-oral pyloromyotomy, and finally using laparoscopic and/or open interventions including gastrectomy for truly refractory cases.<sup>122</sup>

## **BOTULINUM TOXIN A (BOTOX)**

Botulinum toxin A inhibits neuromuscular transmission. It has become a drug with many indications for several neurologic and nonneurologic conditions. One of the most recent achievements in the field is the observation that botulinum toxin A provides benefit in diseases of the GI tract. The toxin blocks cholinergic nerve endings in the autonomic nervous system but does not block nonadrenergic noncholinergic responses mediated by nitric oxide. This has promoted further interest in using botulinum toxin A as a treatment for overactive smooth muscles and sphincters. The introduction of this therapy has made the treatment of several clinical conditions, including gastroparesis, easier in the outpatient setting, at a lower cost and without permanent complications.<sup>123</sup> However, the benefits of botulinum toxin injections in gastric atony have been unclear. Several retrospective and open-label studies have shown clinical advantages of intrapyloric botulinum toxin type A injections, whereas other smaller randomized trials did not show positive results. Overall, the available published studies have yielded conflicting results, leading to a fading out of Botox therapy for gastroparesis.<sup>124</sup> Currently, the American Gastroenterological Association (AGA) does not recommend the use of endoscopic Botox for patients with

gastroparesis.<sup>125</sup> However, given the small sample size of existing studies with conflicting data, there is a continued need for larger randomized trials in the future before a definitive decision or treatment guidelines can be established.

## ENDOSCOPIC GASTRIC STIMULATOR IMPLANTATION

In 2000, gastric electrical stimulation (GES) was approved by the US Food and Drug Administration (FDA) as a humanitarian device exemption in patients with refractory symptoms of diabetic or idiopathic gastroparesis.<sup>126</sup> Often referred to as a gastric pacer, GES uses an implantable device consisting of a pulse generator that allows for electrical stimulation at a variety of frequencies. Permanent GES for gastroparesis typically requires a surgical implantation under general anesthesia. Several case series and small randomized controlled trials, the most important being the Worldwide Anti-Vomiting Electrical Stimulation Study (WAVESS), have shown clinical benefit from GES.<sup>127-133</sup> A subsequent meta-analysis by Chu et al<sup>134</sup> in 2012 confirmed significant improvement in symptom severity and gastric emptying times, although many of the analyzed studies were low-quality observational studies lacking control groups. A more recent study by McCallum et al<sup>130</sup> also demonstrated improvement in weekly vomiting frequency among all patients with idiopathic gastric atony with a median reduction of 61.2%. The National Institute of Health and Care Excellence issued guidelines in 2014 that stated that the current evidence is adequate to support the use of GES.<sup>135</sup>

Up until 2012, surgery was the only available means to implant the GES device. Endoscopic placement of temporary gastric stimulators has been proven as a concept and is often used to determine whether a patient will respond to GES before undergoing a permanent implant surgery. The lack of a permanent endoscopic solution and the reliance on surgical implantation for symptomatic improvement has at present limited further endoscopic utilization.<sup>136,137</sup> However, Deb et al<sup>138</sup> designed 5 innovative endoscopic gastric implantation techniques and developed a novel, wirelessly powered miniature gastrostimulator. Although this early model has only been evaluated in pig investigations, the studies provide a promising prototype for

other dysmotility treatment paradigms and exciting new options that may translate in the future to less invasive endoscopic placement in gastroparetic patients.<sup>139</sup>

## **SURGICAL IMPLANTATION OF GASTRIC ELECTRICAL STIMULATION**

The implantation procedure of the GES can be performed via laparotomy or a laparoscopic approach. Two intramuscular leads containing electrodes (Model 4351; Medtronic) are inserted into the muscularis propria of the stomach.<sup>140,141</sup> The 2 electrodes are sutured 9 and 10 cm from the pylorus on the greater curvature of the stomach and connected by leads of 35 cm in length to the pulse generator, which is placed subcutaneously in the abdominal wall, usually in the right upper quadrant. The programming parameters are usually set as the default at surgery and are then reevaluated approximately 3 months after surgery. While some investigators have proposed specially designed algorithms,<sup>142,143</sup> due to the lack of any controlled trials, these have only been used for clinical nonresponders. In a 10-year observation,<sup>144</sup> it has been shown that the electrical current is increased approximately 20% to 30% during follow-up interrogations based on a clinician observation that symptoms are not optimally controlled and more voltage might help. However, this practice has not been based on any supportive evidence.

## **ENDOSCOPIC PYLOROMYOTOMY**

Rao et al<sup>145</sup> demonstrated that phasic motor activity in the antrum and duodenum can be stimulated by fundic balloon distention. While there are no such studies to determine the effect of pyloric channel distention on the interstitial cells of Cajal in the stomach or gastric emptying, endoscopic pyloromyotomy and manipulation of the pylorus may improve gastroparesis refractory to medical management. Khashab et al<sup>146</sup> demonstrated the feasibility and efficacy of this approach with a case report of the first human gastric per-oral endoscopic myotomy in a patient with severe refractory gastroparesis. The procedure was well tolerated with vast improvement in gastroparetic symptoms noted at 12-week follow-up.

This technique is similar in principle to the submucosal dissection and

myotomy performed for the treatment of achalasia.<sup>147</sup> With this technique, endoscopy is performed and myotomies of the inner circular and oblique muscle bundles 2 to 5 cm proximal to the pylorus on the anterior wall of the stomach are performed. The longitudinal muscle layers are preserved. Endoscopic pyloromyotomy is then performed by dissecting the pylorus until deeper layers become evident with full separation of the pyloric ring.<sup>146,148</sup>

Complications of endoscopic pyloromyotomy include GI bleeding, leak, and pneumonia.<sup>148</sup> Despite these complications, the endoluminal pyloromyotomy technique could provide an incision-less, less invasive alternative with similar functional outcome as compared to standard laparoscopic or open pyloroplasty.<sup>148</sup> While the small number of cases certainly limits the ability to determine the true impact of this procedure in the management of gastroparesis, with more frequent use, increasing technical experience, and more data, endoscopic pyloromyotomy has exciting potential to be at the forefront in the endoscopic management of gastroparesis.

## **ENDOSCOPIC DECOMPRESSION OR BYPASS: PERCUTANEOUS GASTROJEJUNOSTOMY AND JEJUNOSTOMY**

Enteral nutrition and feeding is sometimes required for more severe symptoms of gastric atony and can be seen in up to 30% of patients with grade 3 gastric atony.<sup>149,150</sup> Specifically, a feeding jejunostomy is a critical adjunct to the treatment of gastroparesis as a means to maintain hydration, nutrition, and glycemic control. While surgical gastrojejunostomy is a potential treatment option for patients with refractory gastric atony, the procedure is associated with substantial morbidity and mortality when patients are in a less than ideal clinical condition.<sup>151-154</sup> Furthermore, although surgical gastrojejunostomy has been shown to improve gastroparetic symptoms, endoscopic ultrasound-guided gastrojejunostomy using a stent has been developed but warrants further investigation due to unknown long-term stent safety and patency issues.<sup>152</sup> Ideally, the stent can be removed after an interval of time, leaving a permanent fistula tract. However, studies are needed to determine the necessary pressure gradient and initial gastrojejunostomy tract diameter in order to maintain long-term fistula

patency after stent removal. The minute amount of data available to date, while optimistic and potentially transformative, requires repeat analysis and trials with human study before implementation into the gastroenterologist's everyday arsenal. However, given the technical success reported in the studies above, the future of endoscopic gastrojejunostomy using EUS-guided lumen-apposing metal stents is bright, with the potential to diminish the need for invasive surgeries and improve symptoms of gastroparesis refractory to medical management.

Percutaneous endoscopic gastrostomies with jejunal extensions (PEGJ) are technically less demanding to perform but plagued with the difficulties of tube migration back into the stomach. One of the major negatives of percutaneous endoscopic jejunostomies (PEJs) is that the tube is generally positioned in the distal duodenum or very proximal jejunum and the force of active vomiting often leads to displacement or coiling of the tubing back into the proximal duodenum or the stomach, resulting in the enteral fluid being vomited. It also partially compromises the lumen size of the pylorus. This specific aspect is relevant because, as oral intake is introduced and PEJ feedings are being tapered off, the usually 14- to 16-Fr tube is still located in the pylorus, interfering with the gastric emptying process and the mechanism of the pylorus. The skin site is often also more difficult to manage because of the larger tube diameter with seeping or discharge of very acidic fluids onto the skin. The tube is large and needs to be secured to the skin and is painful and very cosmetically obtrusive.<sup>155</sup>

Direct percutaneous endoscopic jejunostomy (DPEJ) is a push enteroscopy technique that was first described by Shike et al<sup>156</sup> and offers another option of providing direct postpyloric enteral nutritional support. In the largest cohort study to date, Maple et al<sup>157</sup> reported clinical outcomes with DPEJ and included 307 attempts at PEJ placement with a success rate of 68%. Although this study included multiple indications for DPEJ placement, gastric atony comprised 21% of the cases. A case series by Toussaint et al<sup>158</sup> showed a PEJ technical success rate of 78.6% with no immediate complications reported. However, this was based on a small sample size of only 14 patients. Based on these data, PEJ should be considered in the algorithm of enteral access for nutritional support before considering surgical jejunostomy. The main limitation of DPEJ is the technical difficulty of the procedure as the jejunum is narrow, making it more difficult to advance a needle directly into the

lumen.<sup>159</sup> This difficulty can be alleviated with balloon-assisted enteroscopy (BAE).<sup>160</sup>

PEJs are technically more difficult to place but provide a more direct route for enteral alimentation without the need for laparotomy. Fan et al<sup>161</sup> reported the outcomes of PEGJ versus PEJ with findings for reintervention rates of 39.5% versus 9.0%, respectively. Toussaint et al<sup>162</sup> reported on the use of PEJ for gastroparesis with a success rate of 78.6% and a complication rate of 36.4%, including jejunal volvulus and jejunocolic fistula. In summary, jejunostomies are a critical adjunct to the management of gastroparesis but need knowledgeable medical support to minimize long-term complications.<sup>155</sup>

## **SURGICAL GASTROSTOMY AND JEJUNOSTOMY TUBE PLACEMENT**

The theory that gastric tube placement is needed to provide venting in patients with gastroparesis to alleviate symptoms has not been proven to be beneficial. The abdominal bloating that patients with gastric atony experience has now been determined to be secondary to small bowel bacterial overgrowth, rather than the accumulation of air. Tube venting may also cause electrolyte imbalance, particularly potassium, which can become a major health risk. More importantly, patients may claim they have the ability to eat a meal, but the process of draining their intestinal contents by suction or venting can be a misleading indication of the patients' progress. Additionally, it can often become an addictive habit. Intestinal venting can compromise the patient's nutritional status by draining out the consumed nutrients and may also inhibit the stomach itself by not allowing it to adequately reeducate itself and regain motor function.<sup>155</sup>

Gastrostomy and jejunostomy tubes can also be placed surgically through a mini-laparotomy, laparoscopically or endoscopically as previously mentioned. The largest series of gastroparesis (26 patients) followed with jejunostomy was studied by Fontana and Barnett,<sup>163</sup> who demonstrated subjective perception of improved health with improved nutrition in 57% of patients and decreased hospitalizations in 52%. However, this series notably had 23 major complications requiring hospitalization and surgery, including intestinal obstruction, tube dislodgement, wound abscesses, and cellulitis,

reiterating that morbid complications can still occur despite the ease with which these tubes are placed.<sup>164</sup>

Surgical jejunostomy tube placement can be performed concomitant to gastric surgery for gastroparesis. The 3 most common techniques are a longitudinal Witzel tunnel, the Roux-en-Y technique, and the needle catheter technique. The Witzel technique involves creating a longitudinal tunnel in the small bowel wall that covers a several-centimeter length of tube so that inadvertent tube dislodgement facilitates the collapse and sealing off of the enterostomy.<sup>165</sup> Gerndt and Orringer<sup>166</sup> demonstrated that the routine use of the Witzel tunnel resulted in complications in only 2.1% of 523 patients. These complications included intestinal obstruction, intraperitoneal leak, and local and intra-abdominal abscesses.<sup>166</sup> The Roux-en-Y jejunostomy has few indications and is mostly used for pediatric patients with severe injury and neurologic malformations.<sup>167</sup> However, a high rate of complications was described, with 15% stoma prolapse and 6% leakage rates.

The needle catheter technique involves the use of the Seldinger technique whereby a needle is tunneled through the intestinal serosa and submucosal space for a distance of 5 cm before entering the enteric lumen. A wire is then passed through the needle followed by a narrow lumen catheter. Needle catheter jejunostomies are often used for feeding after oncologic procedures but are also plagued by complications, including tube blockage, tube dislodgement, and pneumatosis. However, Meyers and colleagues<sup>168</sup> reported on the findings of 2022 patients with needle catheter jejunostomies and noted complications in only 1.5% of patients. The laparoscopic approach can also use the needle catheter technique for jejunostomy placement, resulting in small incisions and early return of bowel function with similar complications.

## **TRANSPYLORIC STENTING**

An innovative approach recently described by Clarke et al<sup>169</sup> involves the use of through-the-scope transpyloric stent placement as a treatment for gastric atony. In this small case series (n = 3), double-layered, fully covered Niti-S self-expandable metallic stents (TaeWoong Medical, Seoul, South Korea) were used and shown to successfully improve symptoms of gastric atony. The procedure entails the placement of a self-expandable stent across the pyloric channel. The stent is placed using endoscopic guidance without fluoroscopy. The stent is then fully deployed in the transpyloric position with

its proximal end in the gastric antrum. In all 3 cases, patient symptoms markedly improved or became asymptomatic at 115, 122, and 174 days of follow-up, respectively. While this was a case series of only 3 patients, the stark improvement and lasting results at follow-up after the procedure suggest that transpyloric stent placement may improve symptoms associated with impaired gastric emptying.<sup>169</sup>

A major concern with transpyloric stenting is stent migration leading to intestinal obstruction or the recurrence of symptoms. Several stent-securing methods such as endoscopic clips (through-the-scope clip and over-the-scope clip) and endoscopic suturing have been described to reduce stent migration. However, at present, the question still remains regarding which stent-securing method is superior.<sup>170</sup> Future studies are required to truly ascertain the long-term durability, utility, and preferred method for transpyloric stenting and fixation. Until that time, transpyloric stenting will remain a limited option for endoscopists in the management of patients with refractory gastroparesis.

## **SURGICAL TREATMENT**

Surgical therapies for patients with intractable gastric atony have traditionally been reserved for patients who have failed diet modification, medical therapy, and/or endoscopic therapy. However, depending on the precipitating factor, surgical treatment may at times be warranted. Surgical options including pyloroplasty and gastrectomy (subtotal or total), along with electrical stimulation, or placement of gastrojejunostomy or jejunostomy feeding tubes are viable solutions.<sup>171</sup>

### **Pyloroplasty**

Pyloroplasty is beginning to emerge as a successful drainage procedure for refractory gastric atony in the surgical management of diabetic and nondiabetic gastric atony. A retrospective study was performed of 46 patients undergoing pyloroplasty for refractory gastroparesis.<sup>172</sup> Modifiers of improvement included pre- and postoperative assessment using gastric emptying scintigraphy and the Gastroparesis Cardinal Symptom Index. Laparoscopic pyloroplasty was performed in 42 patients, open pyloroplasty was performed in 3 patients, and 1 patient was converted from a laparoscopic

to open pyloroplasty. Studies were repeated during the 6- to 12-month postoperative intervals. The postoperative gastric emptying scintigraphy improved in 90% of patients and normalized in 60%. Postoperative half-emptying time was significantly reduced ( $P = .001$ ), as was the 4-hour retention ( $P < .001$ ). The Gastroparesis Cardinal Symptom Index showed statistically significant reduction in symptom severity for all 9 categories ( $P < .0005$ ) as well as total symptom score ( $P < .005$ ), and no patients developed dumping syndrome. This has led to the conclusion that pyloroplasty is a highly effective therapy for refractory gastroparesis, offering significant reduction in symptom severity, improvement in quality of life, and acceleration of gastric emptying.

## **Surgical Implantation of Gastric Electrical Stimulation with Pyloroplasty**

The lack of acceleration of the delayed gastric emptying by GES begs the question as to how much better the outcome would be if gastric emptying could be accelerated. This is the rationale for the addition of a surgical pyloroplasty (PP) performed at the time when GES is implanted. This approach can be supported by the following data in the literature: first, the injection of Botox into the pylorus causes a transient but substantial decrease in symptoms and gastric retention rate, with this effect being the most pronounced in the postvagotomy subset<sup>173</sup>; second, surgical investigation<sup>174,175</sup> has suggested that PP alone could have a role in patients with gastroparesis; and finally, pyloric spasm is hypothesized to be present in diabetes.<sup>176</sup> A subset of patients with idiopathic gastroparesis was suspected of having pyloric dysfunction based on pyloric motility findings.<sup>177</sup>

Only 1 clinical investigation has tested whether PP combined with GES could enhance the outcomes of GES.<sup>164</sup> This study showed that gastric emptying improved in all subgroups, especially in postsurgical patients with gastroparesis. In fact, >50% of patients normalized their gastric emptying test. No adverse events related to the additional surgery were observed. In addition, oral intake and nutritional status were improved after PP with GES, along with a continued reduction in nausea and vomiting. A randomized, double-blind study would be beneficial to further confirm these excellent results. In general, it may be concluded that the addition of a Heineke-

Mikulicz PP to the standard GES procedure markedly improves and often normalizes delayed gastric emptying, especially in postvagotomy gastroparetic patients, thus enhancing long-term symptom control and augmenting the central mechanism of nausea and vomiting by GES.<sup>163</sup> Furthermore, the data would support that PP should be recommended to be routinely added to the standard GES procedure.

## Total and Subtotal Gastrectomy

Gastrectomy has traditionally been reserved for patients who have experienced severe refractory postsurgical gastric atony.<sup>178,179</sup> Common operations resulting in postsurgical gastric atony include vagotomy for ulcer disease, Nissen fundoplication for severe GI reflux, the Billroth I and II gastric reconstructions for ulcer disease and gastric cancer, and the Whipple procedure, as previously discussed. Forstner-Barthell et al<sup>180</sup> reported that extensive subtotal or completion gastrectomy provides symptomatic improvement in 67% of gastroparesis patients but has not always been shown to be beneficial in terms of weight gain. Nausea, the need for total parenteral nutrition, and retained food at endoscopy were negative prognostic factors for patient outcome following the procedure. Like other surgical adjuncts, complications were common (40%) and included narcotic withdrawal syndrome (18%), ileus (10%), wound infection (5%), intestinal obstruction (2%), and anastomotic leak (5%). Symptoms were relieved in 43% of participants (Visick grade I or II); however, 57% of candidates remained in Visick grade III or IV. Nausea, vomiting, and postprandial pain were shown to be reduced from 93% to 50%, 79% to 30%, and 58% to 30%, respectively ( $P < .05$ ); however, chronic pain, diarrhea, and dumping syndrome were not significantly affected.<sup>180</sup>

Subtotal gastrectomy involves resection of approximately 70% of the stomach including the antrum and pylorus, with closure of the duodenum and reestablishment of continuity with a Roux-en-Y jejunal segment. Watkins et al<sup>181</sup> reported the largest longitudinal experience with subtotal gastrectomy in diabetic patients with gastric atony. They demonstrated that 6 of 7 patients had immediate resolution of vomiting symptoms and improvement in quality of life, which persisted up to 6 years postoperatively.<sup>181</sup> Zehetner et al<sup>182</sup> compared 2 groups treated with GES, laparoscopic subtotal gastrectomy, or a

combination of the 2 if GES failed. Thirty-one patients received laparoscopic subtotal gastrectomy, whereas 72 received GES. Evaluation demonstrated that 30-day morbidity was significantly greater in the gastrectomy group than the GES group (23% vs 8%), but this difference decreased over time.

Although two-thirds (63%) of the GES group attained symptom improvement, 87% of those in the gastrectomy group reported significant improvement in nausea, vomiting, and epigastric pain. Nineteen (26%) of the GES group had to have the device removed because of device malfunction, infection, or failure to respond. These patients received laparoscopic subtotal gastrectomies, with 100% reported symptom improvement. This success with laparoscopic gastrectomy prompted Lipham and colleagues<sup>182</sup> to propose this approach as first-line therapy for the surgical treatment of gastric atony.

Recent observations of increased gastric emptying in bariatric surgical patients have prompted multiple case reports and case series describing the use of longitudinal sleeve gastrectomy for the treatment of patients with atony. Sleeve gastrectomy involves removal of the body and fundus of the stomach and stapling along the lesser curvature to create a tubular stomach. Bagloo and colleagues<sup>183</sup> reported an initial case series of sleeve gastrectomy in 4 patients with diabetes with atony. Three of the 4 patients had resolution of their symptoms after a minimum follow-up of 6 months. Similarly, Meyer and colleagues<sup>184</sup> demonstrated, in 9 morbidly obese patients with diabetes and gastroparesis, that laparoscopic sleeve gastrectomy resulted in the resolution of gastroparesis symptoms and improved gastric emptying studies. The introduction of laparoscopic gastric resection with reconstruction has allowed for decreased morbidity in populations with complex diabetic histories prone to complications and morbidity secondary to chronic malnutrition.

McCallum and colleagues<sup>166</sup> reported their experience on 8 patients with gastroparesis who underwent completion gastrectomy after failing to respond to both available and experimental medical therapies with prokinetic agents. They concluded that although completion gastrectomy is a radical approach, it can provide reliable relief of symptoms in a select group of patients with chronic refractory gastroparesis after partial gastric resection for gastric outlet obstruction secondary to peptic ulcer disease. Subsequently, these authors reported on their own experience at a GI motility referral center. They reported on 9 of 200 patients (4.5%) who received GES for gastric atony who then underwent a total gastrectomy with placement of a jejunostomy tube as a

last resort to control their symptoms. Nausea and vomiting improved by an average of 55%; all patients became nutritionally stable, previously placed jejunostomy tubes were able to be removed, and the quality of life was such that they all would recommend the procedure. Furthermore, all patients had a significant reduction in the number of emergency room visits and hospitalizations.

## OUTCOMES

### Natural History

In the Olmsted County epidemiology study,<sup>39</sup> one-third of all patients with incident gastric atony died, and another one-third required hospitalization, medications, or tube feeding related to atony. Furthermore, overall survival in patients with gastroparesis was significantly lower than that of the Minnesota white population, reiterating the vast impact it can have on patient morbidity and mortality.

### Impact on Quality of Life

As stated earlier, the impact of gastroparesis on quality of life can be severe and debilitating. Although nausea and vomiting are the cardinal symptoms of gastroparesis, data from the NIDDK Gastroparesis Clinical Research Consortium suggested that upper abdominal pain or discomfort is not uncommon and is often severe.<sup>185</sup> Moderate to severe pain was associated with more severely delayed gastric emptying, worse quality of life, depression, and anxiety.<sup>185</sup> Moreover, among patients with moderate to severe pain, 48% were chronically taking opiates. To what extent this impact is related to GI symptoms per se versus comorbid conditions (eg, depression) and/or medications (eg, opiates) is unclear.

Data on the impact of GI symptoms on quality of life among patients with gastric atony in the community are limited. Among a community cohort of people with T2DM, the physical and mental quality of life as assessed by the Short Form-36 were lower in patients with diabetes with GI symptoms compared with population norms.<sup>186</sup> The quality-of-life scores in all

subscales decreased markedly with increasing numbers of distinct GI symptoms, and the association between GI symptoms and poorer quality of life in DM was independent of age, sex, smoking, alcohol use, and type of DM.<sup>186</sup>

Race has also been shown to be associated with the impact of GI symptoms on quality of life in patients with DM. One study reported that nonwhite patients with gastroparesis had more severe symptoms, poorer quality of life, and used more health care resources than white patients.<sup>187</sup> The 2 groups differed in health care use, with 49% of nonwhite patients reporting more than 4 gastroparesis-related emergency department visits and 42% reporting more than 4 gastroparesis-related hospitalizations, compared with 20% and 14% of white patients, respectively. In this study, nonwhite race, sex, age, and age of onset were independently associated with symptom scores, whereas the causes of gastroparesis and GE times were not. High unemployment rates, lower household income, and work absenteeism are also variably associated with gastroparesis.<sup>96,150</sup>

## **Mortality Rates**

Overall survival in patients with idiopathic gastroparesis was significantly lower than the age- and sex-specific expected survival computed from the Minnesota white population.<sup>39</sup> A review of several case series observed that the mortality rates in patients with gastroparesis range from 4% and 38%.<sup>188</sup> The best outcomes were observed in a largely outpatient-based group of patients followed for approximately 2 years, and the highest death rates were reported in patients with diabetes with gastroparesis requiring nutritional support.<sup>30,189-192</sup> In a study of 86 patients with diabetes, approximately 25% had died during follow-up of at least 9 years, but gastroparesis was not associated with mortality after adjustment for other disorders.<sup>193</sup> However, this study did not ascertain the relationship between diabetic gastroparesis and other medical conditions. Whether this increased mortality is driven by gastroparesis is unknown. Data on long-term natural history in the community are lacking.

## **FUTURE DIRECTIONS**

Chronic disturbances of GI function encompass a wide spectrum of clinical disorders that range from common conditions with mild-to-moderate symptoms to rare diseases characterized by a severe impairment of digestive function, chronic pain, vomiting, bloating, and severe constipation.<sup>194</sup> Patients at the clinically severe end of the spectrum such as those with gastric atony can specifically experience profound changes in gut transit and motility. In a subset of these patients, histopathologic analyses have revealed abnormalities of the gut innervation, including the ENS, termed enteric neuropathies, and offer a possible future direction of study to increase our arsenal of treatment targets.<sup>194</sup> At the other end of the spectrum, medical treatment options continue to be first-line therapy for those with “manageable” symptoms. Nevertheless, acquisition of knowledge regarding this disease can hopefully enable the future development of novel targeted therapeutic approaches to help relieve the symptomatic and emotional burden of those afflicted.

## CONCLUSION

Gastric atony continues to be a medical problem with significant effects. The causes are multifactorial and may have mild to severe symptoms. Acquisition of consistent cure rates will undoubtedly require early diagnosis, prompt workup, and more effective, yet minimally invasive medical treatment options.

# GASTRIC ADENOCARCINOMA AND OTHER NEOPLASMS

*Waddah B. Al-Refaie • Young K. Hon • Jennifer F. Tseng*

## INTRODUCTION

Tumors of the stomach are diverse in presentation, symptoms, and prognosis. In this chapter, the authors will first describe the epidemiology, presentation, and management of gastric adenocarcinoma. Subsequently, gastric polyps, mesenchymal tumors (eg, gastrointestinal [GI] stromal tumors), and the rare gastric sarcoma and lymphoma will be discussed.

## GASTRIC ADENOCARCINOMA

### Historic Background

The first description of stomach cancer documented in Western literature is generally thought to be that of Avicenna (980-1037). Many years later, in

1761, Morgani published a manuscript on malignancies of the stomach. In 1879, Pean was believed to perform the first gastric resection for cancer, followed by Billroth performing the first described pyloric resection in 1881, and Schlatter successfully performing the first total gastrectomy (TG) in 1897. In 1951, McNeer et al recommended a more extensive resection for cancer, including TG with distal pancreatectomy and splenectomy.<sup>1</sup>

## Incidence and Pathology

While gastric cancer (GC) is the third leading cause of cancer-related death worldwide, significant differences in its incidence exist across the continents.<sup>2</sup> Specifically, a higher incidence is found in Japan and Eastern Asia (approximately 18-25 cases/100,000) than in Europe and North America (approximately 8-10 cases/100,000).<sup>3</sup> The incidence of GC in the United States is low as it is currently the 15th most prevalent cancer. In 2015, 24,500 patients were diagnosed with GC, and nearly 10,000 persons are projected to die from GC in 2016. The estimated overall 5-year survival approaches 30%.<sup>4</sup>

Gastric cancer is a malignant solid organ tumor of older adults (>65 years). The median age of diagnosis is 69 years of age. Similar to other solid organ cancers, older adults are primarily affected.<sup>5</sup> In recent years, the incidence of GC has been rising in younger adults (age <50 years). Initially, their outcomes were mistakenly perceived to be worse than older adults. However, a recent large population-based study showed that younger patients were more likely to present with advanced or metastatic disease; however, they have a more favorable stage for stage prognosis than their older counterparts.<sup>6</sup>

In addition to age, race and ethnicity also impact the presentation, treatment, and prognosis of GC. In the United States, Caucasians typically present with proximal GC, often involving the gastroesophageal junction (GEJ), whereas Asians tend to present with early stage disease, distal tumors, and have a more favorable prognosis. In contrast, African Americans and Hispanics are more likely to present with advanced stage disease and harbor worse outcomes, likely due to a combination of issues related to access to care and multiple morbidities.<sup>7,8</sup>

## Gastric Cancer Risk Factors

The development of GC has been attributed to several risk factors. The most significant appears to be an infection with *Helicobacter pylori*. This is particularly an issue in developing countries and is more often observed in GC outside the cardia, as supported by a robust meta-analysis of 42 observational studies.<sup>9</sup> Diets that contain salt, smoked or poorly preserved foods, nitrates, nitrites, and secondary amines have been shown to contribute to development. In contrast, diets that are rich in raw vegetables, fresh fruits, vitamin C, vitamin A, calcium, and antioxidants have been found to be protective.<sup>10</sup> Cigarette smoking is another major environmental risk factor with 2- to 3-fold increased risk for GC. Excessive alcohol consumption may also pose an increase.<sup>11</sup> Finally, GC is associated with a wide host of hereditary GC syndromes outlined below.

### HEREDITARY GASTRIC CANCER SYNDROMES

Ten percent of GCs concentrate in families, and less than 3% are due to an inherited cancer syndromes.<sup>12-14</sup> In evaluating these patients, close attention should be paid to the family history along with the pathology to uncover those with hereditary GC. Features suggestive of hereditary risk include GC in two or more first-degree relatives and/or second-degree relatives, cancers in multiple generations, signet ring cell histology, and early age of onset (<45 years).<sup>15</sup>

Hereditary diffuse gastric cancer (HDGC) was the first hereditary GC to be identified. HDGC is caused by germline mutations in *CDH1*, the gene that encodes the E-cadherin protein.<sup>16</sup> The average age of onset for HDGC is 38 years (range 14-69 years); premenopausal lobular breast cancer can occur as well<sup>16,17</sup> By the age of 80 years, 70% of men and 56% of women with HDGC developed diffuse gastric cancer (DGC); lobular breast cancer develops in 42% of women.<sup>18</sup>

To better manage these risks, the International Gastric Cancer Linkage Consortium has proposed criteria for HDGC. Germline *CDH1* testing is recommended in three groups: (1) families with two or more patients with GC at any age and one confirmed DGC, (2) individuals with DGC before the age of 40, and (3) families with diagnoses of both DGC and lobular breast

cancer (one diagnosis before the age of 50). *CDH1* testing should also be considered in the following three groups: (1) patients with bilateral lobular breast cancer or a family history of two or more cases of lobular breast cancer occurring before the age of 50, (2) patients with a personal or family history of cleft lip/palate and DGC, and (3) tumors with in situ signet ring cells and/or the pagetoid spread of signet ring cells.

In addition to the early age of onset, one of the key challenges when families with HDGC is the relative ineffectiveness of endoscopic surveillance in detecting DGC alone. In this regard, TG for DGC patients and prophylactic gastrectomy (for at-risk family members) is appropriate for *CDH1* carriers. These recommendations are less clear in managing families who meet established criteria but in whom no mutation is present.

Other different hereditary cancer syndromes with increased risk of GC include Lynch syndrome, Li-Fraumeni syndrome, familial adenomatous polyposis (FAP), Peutz-Jeghers syndrome (PJS), juvenile polyposis syndrome, *MUTYH*-associated polyposis, hereditary breast, and ovarian cancer syndrome.<sup>19</sup> As such, it is imperative to refer at-risk patients and their families to cancer genetics professional to discuss options for management.

## **Prognostic Factors and Surgical Outcomes**

### **OVERALL SURVIVAL OUTCOMES**

In western populations, patients predominantly present with advanced stage disease and an overall 5-year survival rate of less than 30%.<sup>4</sup> Nearly 65% of GC patients, collected in the US National Cancer Database, are found to have advanced disease (T3/T4). Indeed, up to 85% of these patients harbor nodal metastases at the time of diagnosis.<sup>11</sup> The median survival in persons who undergo curative gastrectomy is 24 months (5-year survival 20%-30%). However, when palliative or no GC therapy is performed, these median survival rates drop to 8 and 5.4 months, respectively.<sup>11</sup>

In this current era of personalized cancer medicine, the prognosis after R0-gastric cancer resection has been examined across several externally validated and electronically available patient-centered nomograms. The nomograms go beyond elements of the current American Joint Committee on Cancer (AJCC) staging system to also account for the patients' age, sex, tumor location, tumor size, negative/positive lymph node status, and

pathologic features/classification of the tumor(s).<sup>20,21</sup>

## GASTRIC CANCER SURGERY OUTCOMES

Due to regionalizing complex surgical care, including major cancer surgery, mortality rates after gastrectomy (namely TG) have become relatively very low (<2%). A high hospital volume with at least 11 gastrectomies per year is predicted to have a 3% to 6% lower in-hospital mortality than lower volume centers.<sup>22,23</sup>

While postgastrectomy mortality rates are low, the postoperative morbidity rate remains high, approaching 40%.<sup>24</sup> These complications include systemic (pulmonary embolism, pneumonia, myocardial infarction, deep vein thrombosis) and technically-related issues (anastomotic leak, anastomotic stricture).

Postgastrectomy readmission rates are estimated to range from 7% to 20%. These readmissions are largely driven by operative GI complications. It was noted that within this subset of patients, those with a higher preoperative nutritional risk and postoperative infections were found to be at the highest risk of complications requiring readmission.<sup>25,26</sup>

## PATHOLOGIC STAGING

The pathologic staging is a T-, N-, M-based AJCC staging system ([Table 31-1](#)).

**TABLE 31-1: AJCC 8TH EDITION TNM STAGING FOR GASTRIC ADENOCARCINOMA**

### Primary Tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i>
T1	Tumor 2 cm or smaller in greatest dimension without extraparenchymal extension
T2	Tumor larger than 2 cm but not larger than 4 cm in greatest dimension without extraparenchymal extension
T3	Tumor larger than 4 cm and/or tumor having extraparenchymal extension
T4	Moderately advanced or very advanced disease
T4a	Moderately advanced disease Tumor invades skin, mandible, ear canal, and/or facial nerve
T4b	Very advanced disease Tumor invades skull base and/or petrygoid plates and/or encases carotid artery

### Regional Lymph Node (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(-)
N2	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(-); <i>or</i> metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(-); <i>or</i> in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(-)
N2a	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(-)
N2b	Metastasis in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(-)
N2c	Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(-)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(-); <i>or</i> metastasis in any node(s) with clinically overt ENE(+)
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(-)
N3b	Metastasis in any node(s) with clinically overt ENE(+)

### Pathological N (pN)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(-)
N2	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(+); <i>or</i> larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(-); <i>or</i> metastases in multiple ipsilateral lymph node(s), none larger than 6 cm in greatest dimension and ENE(-); <i>or</i> in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(-)
N2a	Metastasis in single ipsilateral node 3 cm or smaller in greatest dimension and ENE(+); <i>or</i> a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(-)
N2b	Metastasis in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(-)
N2c	Metastasis in bilateral or contralateral lymph node(s), none larger than 6 cm in greatest dimension and ENE(-)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(-); <i>or</i> in a single ipsilateral node larger than 3 cm in greatest dimension and ENE(+); <i>or</i> multiple ipsilateral, contralateral, or bilateral nodes any with ENE(+); <i>or</i> a single contralateral node of any size and ENE(+)
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(-)
N3b	Metastasis in a single ipsilateral node larger than 3 cm in greatest dimension and ENE(+); <i>or</i> multiple ipsilateral, contralateral, or bilateral nodes any with ENE(+); <i>or</i> a single contralateral node of any size and ENE(+)

### Distant Metastasis (M)

M0	No distant metastasis
M1	Distant metastasis

When T is...	And N is...	And M is...	Then the stage group is...
Tis	N0	M0	0
T1	N0	M0	I
T2	N0	M0	II
T3	N0	M0	III
T0, T1, T2, T3	N1	M0	III
T4a	N0, N1	M0	IVA
T0, T1, T2, T3, T4a	N2	M0	IVA
Any T	N3	M0	IVB
T4b	Any N	M0	IVB
Any T	Any N	M1	IVC

## CLINICAL MANIFESTATIONS

Gastric cancers can present with specific or nonspecific GI symptoms.

Specific symptoms include early satiety, dysphagia, or weight loss, often prompting the treating caregiver to request an upper endoscopy for diagnosis and further workup.<sup>10</sup> However, when patients present with nonspecific symptoms that are easily mistaken for benign conditions (eg, gastroesophageal reflux, peptic ulcer disease), the diagnostic process can be considerably delayed. Indeed, the relatively low incidence rates and lack of cost effective screening program for GC in the United States only add to the difficulty of diagnosing these patients early. Patients with advanced disease can present with a palpable abdominal mass, cachexia, ascites, or bowel obstruction.

The cardinal physical examination findings of metastatic disease, such as an enlarged supraclavicular node (Virchow node) or a drop metastasis in the pouch of Douglas (Blumer shelf), are typically rare.<sup>11</sup> Overall, most physical examination findings are unfortunately found to be nonspecific and unreliable in making a definitive diagnosis.

## Pretherapy Workup

### HISTORY AND PHYSICAL EXAMINATION

The workup should start with a thorough history and physical examination. Specific questions in the history should include whether the patient has experienced unintentional weight loss, anorexia, early satiety, vomiting, bleeding, epigastric burning, pain, or discomfort. The surgeon should also ask about social factors, such as tobacco and alcohol use, and the consumption of large amounts of nitrate-rich or smoked/preserved foods. A previous history of *H. pylori* infection or a family history of GC are also important considerations.<sup>10</sup> Finally, assessing the patients' performance status and frailty are also critical to predict their ability to tolerance GC therapies.

### LABORATORY WORKUP

In addition to a thorough history and physical examination, the pretherapy evaluation in patients with GC should include:

- Complete blood count (CBC): To evaluate and treat GC- or treatment-related anemia

- Basic metabolic panel (BMP): To detect electrolyte abnormalities, especially in gastric outlet obstruction, and to detect renal functional abnormalities prior to receiving contrast-enhanced imaging and/or preoperative systemic therapy
- Liver function panel: To check prior to the induction of preoperative systemic therapy
- Albumin and prealbumin: To uncover malnutrition especially since approximately 30% to 80% of patients diagnosed with GC are malnourished.<sup>25</sup>

**Genetic Testing for Hereditary Gastric Cancer.** As previously described, the operating surgeon should be aware of potential features in the history or pathology report that are suggestive of hereditary GC. As part of the multidisciplinary approach to GC, a referral to a professional cancer genetic counselor is imperative to better manage this unique cohort of patients and their families with potential hereditary GC.

In family carriers of the *CDH1* mutation, a shared decision is made around prophylactic TG. Furthermore, support from a social worker and a psychologist should be available to address and manage the burden of dealing with such major life-changing treatment decisions.

## **Diagnostic and Staging Modalities**

### **SCREENING FOR GASTRIC CANCER (EAST VS WEST)**

Unlike the United States and Europe, screening esophagogastroduodenoscopy (EGD) is typically performed in countries with a high prevalence of GC, such as Japan and South Korea. The overall goal is to improve overall outcomes. However, in regions outside of Asia with a lower prevalence, endoscopic screening has not been shown to be beneficial for primary prevention in the general population.<sup>27</sup>

As previously discussed in other parts of this chapter, screening should be considered in certain cases of hereditary GC syndromes.<sup>28</sup> For example, in persons with adenomatous polyposis syndromes (eg, FAP), screening EGD is recommended starting at age 25 to 30 years and repeated every 0.5 to 4 years based on the Spigelman stage of duodenal polyposis.<sup>29</sup> In cases of HDGC, prophylactic TG is the recommended approach at a young age, obviating the

need for screening EGD and potentially preventing the development of GC.

**Endoscopy and Endoscopic Ultrasound for Gastric Cancer.** Upper GI endoscopy plays a key role in establishing the diagnosis and in treatment planning of GC. However, upper endoscopy lacks standardized quality measures for adequate endoscopy similar to colonoscopy for colonic polyps or cancer (eg, caecal intubation, time for completions). As such, surgeons and their GI counterparts need to work collaboratively to identify key GC-relevant elements including: (1) the exact location of the cancer within the stomach to determine the extent of gastrectomy, (2) the relation of the cancer to the esophagus to ascertain the need for distal esophageal resection, and (3) the presence of linitis plastica as a marker of systemic disease pointing toward the need for preoperative systemic therapy.

Experienced endoscopists can leverage several other techniques to assist with identifying high-risk lesions using magnifying endoscopy, chromoendoscopy, narrow band imaging, flexible spectral color enhancement endoscopy (FICE), and confocal laser endomicroscopy (CLE). These techniques have shown promise in improving the endoscopic detection of worrisome lesions and in guiding biopsy site selection.<sup>30</sup>

Endoscopy also represents an opportunity for tissue collection and molecular profiling (eg, Her2neu) for advanced and progressive GC for possible enrollment in emerging GC immune therapy trials (eg, tissue for PD1 status). When preoperative systemic therapy is employed, this diagnostic tool can also provide useful treatment and prognostic information, such as the status of the response to preoperative therapy or distal esophageal involvement.

Nearly 10% of gastric patients diagnosed before the age of 50 years also have synchronous colon cancer, and a preoperative screening colonoscopy should be performed on all these patients.<sup>31</sup>

Endoscopic ultrasound (EUS) has also emerged as an accurate staging tool in GC to compliment high-resolution cross-sectional imaging and staging laparoscopy.<sup>32,33</sup> By placing the EUS probe directly over the primary tumor, EUS can distinguish T1 (early GC) from T2 (invasion of muscularis propria) lesions with a sensitivity of 85% and a specificity of 90%. Additionally, the distinction between T1 and T2 (superficial) versus T3 and T4 (advanced) lesions can be achieved with a sensitivity of 86% and a specificity of 90%.<sup>34</sup>

N-staging is also important. EUS is used to confirm the presence of nodal involvement with a sensitivity of 83% and a specificity of 67%. Nodal areas of particular interest include the paracardial, superior gastric, inferior gastric, and pancreaticolienal regions.<sup>34</sup> EUS is highly operator-dependent and provides accurate loco-regional staging of gastric adenocarcinoma that can inform decisions regarding preoperative systemic therapy versus surgery-first followed by adjuvant therapy.

**Contrast-Enhanced Cross-Sectional Imaging.** In addition to EUS, high-resolution multidetector computed tomography (CT) is the preferred imaging modality for the staging and post-treatment surveillance of gastric adenocarcinoma. Because of its thin slices and multiplanar capabilities, this modality provides accurate visualization of the primary tumor and surveys the chest, abdomen, and pelvis for metastatic disease.

At our institution (MedStar Georgetown University Hospital), we developed a gastric tumor protocol CT for patients with suspected or known gastric masses; the stomach is distended with oral contrast material or water prior to performing the CT. Distention of the stomach helps differentiate a collapsed gastric wall from tumor. It has been shown that the combination of focal or eccentric wall thickening greater than 1 cm and intravenous contrast enhancement is highly specific.<sup>35</sup> This gastric tumor protocol CT is extremely useful when considering the laparoscopic resection of other gastric neoplasms, such as gastric GI stromal tumors or neuroendocrine tumors. Further details are found in other parts of this chapter. We also recommend taking advantage of the coronal and sagittal reconstructions, which display helpful gastric anatomy and, in some cases, the optimal planes for visualizing tumors with adjacent organ involvement.

Overall, the accuracy of CT for staging is estimated to range from 66% to 93%.<sup>36</sup> The limitations of CT are its inability to detect subtle serosal invasion, metastatic disease in normal-sized lymph nodes, and small peritoneal deposits that may be below the resolution of CT. Hence, our strong preference is to also add staging laparoscopy to overcome these known limitations.

Positron emission tomography (PET) with 2-deoxy-w-(<sup>18</sup>F) fluoro-D-glucose (FDG PET) combined with CT (FDG PET CT) is valuable in some patients for the detection of occult disease. However, it lacks accuracy in mucinous or diffuse disease, such as linitis plastica.

## **DIAGNOSTIC LAPAROSCOPY AND PERITONEAL CYTOLOGY**

Diagnostic laparoscopy (DL) is highly recommended as an additional staging tool. DL was found to upstage 20% to 25% of patients and thus can prevent nontherapeutic laparotomies in patients with subradiographic or occult hepatic or peritoneal metastasis.<sup>37</sup> The risk of peritoneal disease is much higher in those with linitis plastica and AJCC stage T3+, N+ disease; DL can inform the treatment strategy of a patient with suspected stage IV disease. DL can also be utilized to re-evaluate disease response to systemic therapy, to obtain peritoneal cytology, or to place a preoperative feeding tube.<sup>38,39</sup>

The use of peritoneal cytology continues to be an area of controversy. Peritoneal cytology that is positive for tumor cells has been shown to be a poor prognostic marker in the absence of visible tumor spread (C1 disease).<sup>40,41</sup> The estimated median survival in patients with C1 disease was only 20 months.<sup>39,40</sup> At our institution, we employ a selective approach for peritoneal cytology in the following situations: (1) linitis plastica, (2) borderline performance status, or (3) evidence of AJCC T4 disease on imaging.

In summary, our multidisciplinary staging approach is to employ the following three tools: (1) EUS performed by an experienced gastroenterologist, (2) high-resolution CT of the chest, abdomen, and pelvis, and (3) staging laparoscopy with or without cytology.

## **Multidisciplinary Treatment Strategy for Operable Gastric Cancer**

A multidisciplinary treatment strategy is crucial in patients newly diagnosed with GC. We recommend a stage-dependent treatment approach informed by the three patient-centered aspects:

1. The patient's suitability to undergo curative gastrectomy
2. Accurate three-tool pretherapy staging
3. Sequence of GC therapy (surgery-first vs perioperative therapy)

## **SUITABILITY TO UNDERGO CURATIVE**

## **GASTRECTOMY**

The operating surgeon should consider several important preoperative variables prior to undertaking surgical therapy. Evaluating the underlying comorbidities and performance status are key preoperative considerations. Managing the burden of existing comorbidities is also important to enhance operative recovery after gastrectomy. As previously mentioned, reversing preoperative malnutrition and electrolyte abnormalities will lead to better operative outcomes. In some regards, improving some factors, such as frailty or performance status, may not be an achievable goal. However, a preoperative rehabilitation stay prior to surgical treatment may reduce the impact of frailty on operative outcomes.<sup>42,43</sup>

## **ACCURATE THREE-TOOL PRETHERAPY STAGING**

Up to 30% of newly diagnosed GC patients harbor occult radiographic metastases. As such, we recommend accurate stage-dependent treatment using a combination of EUS, high-resolution contrast-enhanced cross-sectional imaging, and DL. Together, patients can avoid the pitfalls of nontherapeutic laparotomy for GC.

## **SEQUENCE OF GASTRIC CANCER THERAPY (SURGERY-FIRST VERSUS PERIOPERATIVE THERAPY)**

Margin-negative (R0) gastrectomy and adequate lymphadenectomy together represent the pillars of surgical therapy for operable GC. Level I evidence continues to strongly support a multimodal approach in persons with GC to enhance their overall and disease-free survival. In this regard, most patients with AJCC T2+ or N+ operable GC are offered one of the following two treatment sequences: (1) surgery-first, followed by adjuvant chemotherapy and/or chemoradiotherapy, or (2) perioperative systemic therapy. The latter is gaining more traction in Europe in light of emerging evidence that shifts the operable GC treatment paradigm to that of a perioperative approach. Additional details will be provided in parts of the current chapter.

At our institution, we take patient- and tumor-related factors into consideration to guide the sequence of therapy. Factors such as the presence of linitis plastica and the tumor location are considered during the treatment

strategy planning. For example, a proximal GC location, the presence of linitis plastica, or borderline performance status all favor perioperative therapy. In those with proximal GC, prolonged operative recovery and higher operative complication rates are to be expected after TG; hence the rationale for perioperative therapy. In contrast, factors including an early stage GC or distal GCs (and their subsequent tumor-related complications, including bleeding or obstruction) favor a surgery-first approach.

## **Surgical Approaches for Operable Gastric Cancer**

### **TOTAL GASTRECTOMY**

Total gastrectomy is typically performed in patients with proximal GCs (cancers of the cardia or fundus). This operation entails the extirpation of the entire stomach, GEJ, and omentum, with subsequent restoration of intestinal continuity using a Roux-en-Y reconstruction (Figs 31-1 A and B). The stomach is carefully dissected and mobilized free of all attachments. The arterial supply of the stomach is then ligated at its origin, followed by the removal of the stomach. TG is considered complete when normal esophageal and duodenal mucosa is included in the margins.<sup>11,44</sup>

**A**

**FIGURE 31-1A** Subtotal gastrectomy with D2 lymphadenectomy for gastric adenocarcinoma with pathology demonstrating pT4a, pN3b, 24/44 lymph nodes positive.

**B**  
**FIGURE 31-1B** Roux-en-y reconstruction after total gastrectomy.  
(Reproduced with permission from Zinner MJ: *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone/Elsevier; 1992.)

## **SUBTOTAL GASTRECTOMY**

A subtotal gastrectomy (STG) is recommended for patients with midbody or distal GCs (Fig. 31-2). Unlike TG, STG entails the removal of 70% to 80% of the stomach. Adequate negative resection margins (ie, 4-6 cm proximal and 2 cm distal margins) are necessary to ensure an appropriate oncologic resection. In line with TG, it is imperative to ligate the gastric arteries at their origins, with the exception of the short gastric vessels; these should be maintained to prevent remnant ischemia. Gastrointestinal continuity is restored either via a Roux-en-Y gastrojejunal reconstruction (our preference) or a loop gastrojejunostomy. The rationale behind the use of a Roux-en-Y gastrojejunal reconstruction instead of a loop gastrojejunostomy is to avoid bile reflux into the gastric remnant.<sup>11</sup> Hand-sewn or a stapled anastomosis is considered safe and appropriate.

## FIGURE 31-2 Subtotal gastrectomy.

Equivalent overall and disease-free survival have been noted after TG versus STG for distal GC (overall 5-year survival rate of 62.4% vs 65.3% for TG vs STG, respectively).<sup>22</sup> When compared to TG, STG has been shown to provide more favorable nutritional outcomes and quality-of-life.<sup>45</sup>

## Extent of Lymphadenectomy for Gastric Cancer

While adequate lymphadenectomy with histopathological nodal evaluation are important components of GC staging and therapy, the extent of lymphadenectomy has been an area of significant debate and controversy.<sup>46</sup>

The classification of lymphadenectomy for operable GC falls into two categories: (1) the topographic location of the lymph node stations and (2) the extent of nodal removal, extending away from the stomach. The Japanese Research Society for Gastric Cancer has described the topographic classification of histopathological and nodal evaluations. This classification is based on nodal stations within various parts of the stomach and its arterial supply, and extends to the para-aortic nodal region.<sup>47,48</sup> The second classification is based on the extent of nodal removal and is also known using the “D” nomenclature. As such, four tiers of lymphadenectomy exist: (1) D0 denotes incomplete removal and therefore is considered an inadequate nodal dissection, unless palliative gastric resection is considered; (2) D1 entails the removal of the perigastric lymph nodes; (3) D2 is D1 combined with the removal of the nodal stations around the celiac trunk, along with a distal pancreatectomy and splenectomy; and (4) D3 includes D2 + resection of the nodes from the celiac axis to the inferior mesenteric artery.<sup>48</sup>

The evaluation of lymphadenectomy for GC has progressed in Europe. Initially, two large European trials from the United Kingdom and Netherlands demonstrated no survival differences between D1 versus D2 lymphadenectomy (Fig. 31-3). In both trials, enrollees suffered worse operative outcomes after D2 lymphadenectomy.<sup>49–51</sup> However, the long-term results from the Dutch Gastric Cancer Group trial demonstrated a more favorable survival benefit for D2 nodal dissection. Specifically, the 15-year overall survival (OS) rates were 21% and 29%, respectively, for the D1 and D2 groups ( $P = 0.34$ ). Lower rates of local (12% vs 22%) and regional

recurrence (13% vs 19%) were also associated with D2 lymph node dissection.<sup>50,52,53</sup> Contemporary European studies are currently evaluating survival benefits with D2 compared to D1 lymphadenectomy in the setting of improved D2 operative outcomes.<sup>54–56</sup>

**FIGURE 31-3** D1 versus D2 Lymphadenectomy. D1 lymphadenectomy is resection of perigastric lymph nodes (brown nodes). D2 lymphadenectomy is an extended resection of nodes surrounding celiac artery area (green nodes) with splenectomy and distal pancreatectomy (not shown).

To better answer this question of survival benefit of D2 lymphadenectomy in the Asian population where GC is more prevalent, JCOG9501 was a Japanese randomized controlled trial conducted to compare D2 dissection alone versus D2 with para-aortic nodal dissection (PAND) for operable T2b–T4 GC (T2b, T3, or T4). D2 nodal dissection with PAND did not improve the overall and relapse-free survival rates compared to D2 dissection alone (5-year OS rates were 70.3% and 69.2%, respectively).<sup>57,58</sup> Recent meta-analyses of D1 versus D2 trials have demonstrated that D2 dissection is associated with a significantly higher postoperative risk, but with equivalent

long-term survival rates between D1 versus D2 lymphadenectomy.<sup>59,60</sup>

A Cochrane review meta-analysis of over 2500 patients enrolled in eight Asian and European lymphadenectomy (D1, D2, or D3) GC trials showed no difference in survival between D2 and D3 even in Asian lymphadenectomy trials. Furthermore, no significant differences were found in the overall and disease-free survival in trials of D1 versus D2 lymphadenectomy. However, D2 lymphadenectomy was associated with a significantly improved disease-specific survival rate compared to D1, albeit with two higher operative mortality rates.<sup>61,62</sup>

The differences in Asian versus western results are perhaps attributable to differences in disease biology, surgical expertise, variations in where GC surgery is performed (especially in the United States), and differences in BMI in Eastern versus Western GC patients.<sup>51,63</sup>

In light of this mixed level of evidence, most current western guidelines recommend at least a D1 lymphadenectomy with a total nodal yield of 15 or more lymph nodes. A modified D2 (also known as pancreas and spleen-preserving D2 lymphadenectomy) remains an approach in expert centers.

## **Minimally Invasive Gastrectomy for Gastric Cancer**

In addition to open GC surgery, minimally invasive gastrectomy (MIG) has emerged as an investigational surgical therapy. Nonrandomized and observation studies, using propensity score case-matching, have shown that MIG is associated with reductions in surgical site pain, the length of hospital stay, the use of narcotics, and postgastrectomy complication rates.<sup>64,65</sup> In a small prospective randomized investigation of laparoscopic versus open STG, operative mortality rates (3.3% vs 6.7%, respectively), 5-year OS (58.9% vs 55.7%, respectively), and disease-free survival rates (57.3% vs 54.8%, respectively) were more favorable for MIG, although the difference was not statistically significant.<sup>66,67</sup>

While emerging investigations point toward improved outcomes with MIG in operable GC, several studies have included subjects with smaller tumor sizes or early-stage GC. This observation should be factored into comparisons of MIG with open GC surgery in western populations that typically have larger tumor sizes and more advanced disease.

There are two ongoing large prospective randomized MIG versus open gastrectomy trials in Asia. The first is a multihospital phase III Japanese study to assess the OS of laparoscope-assisted distal gastrectomy compared to open distal gastrectomy in patients with early-stage GC.<sup>68</sup> Klass 01 is another ongoing large Korean prospective randomized trial of laparoscopic versus open gastrectomy for distal GC.<sup>69</sup>

To date, MIG for GC in the United States remains in its infancy and will require additional larger randomized clinical trials for more adoption among the surgical community in the United States.

## **SYSTEMIC CHEMOTHERAPY**

Multimodality therapy for GC is designed to provide patients and their family with better care by prolonging the survival outcomes, reducing the risk of recurrence along with minimizing the burden of the disease. In this regard, the benefit of integrating surgical therapy (gastrectomy and lymphadenectomy) with systemic therapy has been demonstrated to reduce the recurrence risk of GC following surgical resection. In one meta-analysis, the use of any form of chemotherapy as adjuvant therapy to surgical resection for GC produced an 18% overall reduction in the risk of cancer recurrence.<sup>70</sup> Currently postoperative chemotherapy and radiation therapy is being compared to the perioperative use of chemotherapy alone.

**Adjuvant Chemotherapy and Radiation Therapy.** In 2001, the US Intergroup trial (INT-0116) established the combination of chemotherapy with radiation therapy as one possible adjuvant care standard for operable GC. In this randomized, phase III, open-label trial, patients were eligible for enrollment if their tumor was stage Ib to stage IVM0; patients were assigned to the treatment arm (5-fluorouracil and leucovorin, concurrent with radiation) versus surgery alone.<sup>71</sup> In the adjuvant chemotherapy and radiotherapy arm, OS was statistically better (36 months), in comparison to the control arm (27 months,  $P = 0.005$ ).

In the Intergroup trial, only 64% of patients assigned to the treatment arm were able to complete therapy, underscoring the toxicity of adjuvant therapy especially in the context of the morbidity and operative recovery associated with the necessary surgical therapy. In addition, 77% of enrolled patients had a distal tumor location within the stomach. While specific histologic subtypes

were not reported, a distal location is typically associated with the less aggressive intestinal histology of gastric adenocarcinoma.<sup>72</sup> Thus, the tumor location and biology could explain some of the benefit of this adjuvant approach. Finally, this trial was also notable for the lack of adequate nodal evaluation in as many as 50% of trial participants, thus raising questions about whether adjuvant therapy compensated for inadequate GC surgery or unrecognized node-positive disease.

**Perioperative Chemotherapy.** In 2006, the Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial in the United Kingdom established an alternative approach to adjuvant therapy for resectable GC through the use of perioperative chemotherapy alone. This phase III, open-label study randomized patients deemed to have resectable GC to either six cycles of chemotherapy (three each, presurgery and postsurgery) or to surgery alone.<sup>73</sup> Patients with nonmetastatic gastric adenocarcinoma of stage II or higher were eligible. Unlike the Intergroup trial, chemotherapy in the MAGIC trial consisted of a triple regimen of epirubicin, cisplatin, and 5-fluorouracil. Modifications to this regimen, using oxaliplatin instead of cisplatin, and capecitabine instead of 5-fluorouracil, have been shown by the Randomized ECF for Advanced and Locally Advanced Esophagogastric Cancer 2 (REAL-2) study to be acceptable, affording similar outcomes but with reduced toxicity.<sup>74</sup>

In the MAGIC trial, the use of perioperative chemotherapy was associated with a significant survival benefit versus surgery alone (5-year survival rates of 36% and 23%, respectively;  $P = 0.009$ ). As in the case with the Intergroup trial, several characteristics of the MAGIC trial need to be highlighted. First, while 90% of patients assigned to the treatment arm were able to complete the preoperative cycles of chemotherapy, only 57% began the postoperative chemotherapy cycles and only 43% completed them. While again highlighting the challenge of adjuvant therapy postoperatively, the relatively consistent ability of patients to tolerate neoadjuvant therapy is also noted. Second, the majority of tumors were located proximally, including 15% that were at the GEJ and 11% that were in the distal esophagus. While the histologic subtypes were not reported in the MAGIC trial either, the more aggressive diffuse subtype tends to predominate in this proximal tumor location.<sup>72</sup> Together, these data suggest that the perioperative approach to adjuvant therapy could be optimal for a proximal tumor location and

histology.

**Treatment Recommendations.** Because of the difficulties in directly comparing the MAGIC and Intergroup trials to inform the sequence of GC therapy, the adjuvant chemotherapy or chemoradiotherapy in resectable gastric cancer (CRITICS) trial was conducted in Europe.<sup>75</sup> In the CRITICS trial, all patients received neoadjuvant chemotherapy (consisting of three cycles of epirubicin, cisplatin or oxaliplatin, and capecitabine) followed by adequate surgical therapy (gastrectomy and lymphadenectomy). After surgery, patients randomly received either an additional three cycles of the same chemotherapy or concurrent chemotherapy and radiation therapy (45 Gy combined with cisplatin and capecitabine). While the analysis is ongoing, preliminary results presented in 2016 suggest that there is no significant difference in OS between these two postoperative adjuvant approaches.<sup>76</sup> It is important to recognize that these results cannot be generalized into one approach, and that the selection decisions must consider the individual characteristics of the patient's tumor. As previously described, in patients with a proximally located, diffuse-histologic subtype of cancer, perioperative chemotherapy akin to the MAGIC and CRITICS approach should generally be recommended. Moreover, given the observed effect of operative recovery on tolerance of adjuvant therapy, preoperative chemotherapy is perhaps an attractive approach in those with an advanced tumor stage (T3/T4 or any node-positive). Conversely, in those with a distally located, intestinal-histologic subtype of cancer, postoperative chemotherapy and radiation therapy akin to the Intergroup trial is more appropriate. Additionally, those patients whose symptoms would not allow for surgical delay while neoadjuvant chemotherapy is administered (eg, tumor-related bleeding or obstruction that cannot be relieved by other methods) should generally proceed directly to surgery. The interplay of these different factors underscores the need for a multidisciplinary consultation to establish the treatment sequence and adjuvant plans prior to any therapeutic intervention.

## **RADIATION THERAPY FOR OPERABLE GASTRIC CANCER**

Local and regional failure after surgical therapy for operable GC is relatively common and detrimental to patients' quality of life. In the aftermath of

gastrectomy, several retrospective studies have shown that 40% of patients will develop a recurrence and in nearly 26% recurrence is local-regional alone.<sup>77,78</sup> These failures have stimulated investigation into integrate radiotherapy with surgery along with systemic therapy.

As previously described, the INT-0116 trial remains one of the largest randomized studies in the United States to evaluate the role of adjuvant chemoradiation.<sup>71,79</sup> The updated results of 10-year follow-up demonstrate a strong benefit from chemoradiation with significant improvements in OS and relapse-free survival (hazard ratio [HR] 1.32, 95% confidence interval [CI], 1.1-1.60;  $P < 0.0046$  and HR 1.51, 95% CI, 1.25-1.83;  $P < 0.001$ , respectively). Fifty-two percent of patients who received chemoradiation relapsed, compared to 76% of patients who received surgery alone. There were similar numbers of distance relapses in both arms, which suggests that improved locoregional control with adjuvant chemoradiation might impact survivals. Moreover, no difference in long-term treatment-related toxicity was observed between the two arms.

Recently, the Korean Adjuvant Chemoradiation Therapy in Stomach Cancer (ARTIST) trial tested the role of adjuvant radiation therapy in patients with D2-resected GC.<sup>80,81</sup> The study randomized 458 patients (stage IB–IV) to either six cycles of capecitabine and cisplatin, or two cycles of capecitabine and cisplatin, followed by chemoradiation, followed by two cycles of capecitabine and cisplatin. At a median follow-up of 7 years, there was no significant difference in disease-free survival (HR 0.74, 95% CI, 0.520-1.050;  $P = 0.0922$ ) or OS (HR 1.130, 95% CI, 0.775-1.647;  $P = 0.5272$ ). Locoregional failures were reduced from 13% to 7% in the chemoradiation arm. In the subgroup analysis, there was significant improvement in disease-free survival with the addition of radiation in patients with node-positive disease. Furthermore, the addition of radiation therapy to systemic chemotherapy for resectable GC was found to be of benefit over chemotherapy alone (46.7 months vs 20.9 months;  $P < 0.001$ ) in a retrospective study of seven US hospitals.<sup>82</sup> Patients with N1 disease and those with lymphovascular invasion benefited the most from radiation therapy.

While emerging evidence continues to support the use of perioperative systemic chemotherapy as the standard of care for operable GC, postoperative chemoradiation remains an alternative approach for those who

receive surgery first (with no preoperative therapy). The greatest benefit for adjuvant chemoradiation was observed in patients with node-positive disease and intestinal-type histology.

## **PALLIATION AND SYMPTOM MANAGEMENT**

Surgeons also play an important role in scenarios of advanced GC, especially when up to 30% of patients present with locally advanced or metastatic GC.<sup>83,84</sup> In these situations, patients are typically at a higher risk for malnutrition from possible tumor-related obstruction with symptoms of dysphagia or gastric outlet obstruction. In these situations, palliative procedures include gastrectomy or GI bypass, which are often reserved for the palliation of ongoing (or pending) bleeding, perforation, or obstruction.

It is important that the treating team discuss the overall goals of palliative GC surgery. While patients' desires are prioritized, these goals should also seek to improve quality of life and allow them to continue (or not) systemic chemo-, targeted-, or immune therapy.

The impact of palliative STG versus systemic therapy alone on OS has been previously evaluated in 285 patients who were not amenable to therapeutic resections in the Dutch Gastric Cancer Trial.<sup>52</sup> Of these, 129 patients did not undergo resection and had either a gastroenterostomy or an exploratory laparotomy alone, while 156 patients underwent a palliative resection. Patients in the palliative resection cohort (>70 years of age with limited metastasis to one other site) only derived a nearly 3-month survival benefit over patients who underwent a gastroenterostomy or exploratory laparotomy alone at the time of the initial DL for local or metastatic GC. This short survival benefit, however, was associated with higher morbidity (38% vs 12%) and a longer length of stay (15 days vs 10 days) in the palliative resection cohort.

In this regard, palliative GC surgery decisions should be highly personalized and driven by the patients' goals of care, the extent of their disease progression, performance status, and multidisciplinary input from medical oncology, radiation oncology, and the palliative care teams.

## **GASTRIC CARCINOID**

## Background

Gastric carcinoids, commonly termed neuroendocrine neoplasms, are derived predominantly from mostly histamine-secreting enterochromaffin-like (ECL) cells but also serotonin-secreting ECL cells or ghrelin cells.<sup>85</sup> They are classified as either a gastrin-dependent (Type I/II) or gastrin-independent (Type III) gastric carcinoids. Type I are associated with chronic atrophic gastritis (80%) whereas Type II are due to Zollinger-Ellison syndrome (ZES) (6%), often as part of the multiple endocrine neoplasia type 1 (MEN1).<sup>86</sup> Type III are considered sporadic and are not associated with any syndromes nor hypergastrinemia caused by either proton pump inhibitors or by ZES. There has been an association between gastric carcinoids formation and longstanding treatment with histamine blockers which results in a hypergastrinemic state that stimulates the CCK-2 receptors on ECL cells, causing hyperplasia; in this setting, there is also a potential association of gastric carcinoids with GC.<sup>87</sup> The gastrin-dependent carcinoids (Type I/II) are generally benign or low grade with a low rate of metastasis (9%-30%) whereas, sporadic gastrin-independent Type III carcinoids are more aggressive neuroendocrine carcinomas having higher rates of metastasis (54%-66%).<sup>86,88</sup> Gastric carcinoids do not invade beyond the mucosa or submucosa and there are generally no signs of angioinvasion.<sup>89</sup> They are graded based upon the World Health Organization 2010 classification for neuroendocrine tumors which utilizes the number of mitosis per 10 high-power fields (HPF) and the percent Ki-67 proliferation index (Fig. 31-4). Aggressive features include greater than 2 mitoses per HPF, a Ki-67 index greater than 2%, angioinvasion, and transmural invasion.<sup>87</sup>

**FIGURE 31-4** Ki-67 proliferation index in 50 high-power field represented by the dark brown immunohistochemistry staining.

## INCIDENCE

While carcinoids can affect various organ systems, the most common site of carcinoid involvement is the GI tract (67.5%), with small intestine in 41.8%, rectum in 27.4%, and stomach in 8.7%. The age-adjusted incidence was highest in black males (4.48 per 100,000 population per year).<sup>90</sup> Gastric carcinoids are generally diagnosed between the fifth and seventh decades with a higher overall incidence in women. The incidence of gastric carcinoid has been increasing over the past 30 years due to either improved detection with endoscopic surveillance techniques or the common use of over-the-counter proton pump inhibitors.<sup>90,91</sup>

## Presentation

Patients with gastric carcinoids often present with gastric bleeding/ulcer as presenting symptoms and are not known to be associated with carcinoid

syndrome. Type I gastric carcinoids are associated with chronic atrophic gastritis and therefore can have vitamin B12 and iron deficiency.<sup>92</sup> Type I gastric carcinoids present with polyps or a mass in the fundus or body of the stomach where the gastrin-dependent ECL cells are located. Type II gastric carcinoids are associated with ZES and therefore can present with peptic ulcer disease with bleeding. Both Type I and II gastric carcinoids present generally with more than 1 tumor but these tend to be subcentimeter on initial EGD while Type IIIs are generally single tumors greater than 1 cm.<sup>93</sup> Type III gastric carcinoids are generally sporadic and gastrin-independent; therefore, they are not likely to be associated with peptic ulcer disease but rather with a mass or bleeding or as an incidental finding.<sup>94</sup> Gastric carcinoids are evaluated by EGD and/or EUS for level of invasion. These tumors generally stain for argyrophil, argentaffin, and chromogranin A for all types of gastric carcinoids (Fig. 31-5). Type I gastric carcinoids have a low incidence of lymphatic metastases while Type III gastric carcinoids have a high incidence (33.3% vs 71%, respectively).<sup>95</sup>

## Management

The management of gastric carcinoids is optimized by a multidisciplinary approach. Gastric carcinoids are initially detected by EGD with biopsies with subsequent EUS to determine the depth of the tumor. Plasma gastrin, chromogranin A level, a 24-hour 5-hydroxyindoleacetic acid (5-HIAA) urine or fasting plasma 5-HIAA collection, and pancreastatin are obtained to complete the laboratory workup and determine the type of gastric carcinoid. Chromogranin A levels can be affected by impaired renal function, hepatic failure, chronic atrophic gastritis, or proton pump inhibitors whereas, pancreastatin is unaffected by proton pump inhibitors and is often the only elevated marker in GI carcinoids.<sup>96</sup> Staging of gastric carcinoids is performed with multiphasic abdominal CT, somatostatin receptor-based imaging, and/or the recent <sup>68</sup>Ga-labeled dotatate PET/CT. In a recent meta-analysis of the impact of <sup>68</sup>Ga-Dotatate imaging on the management of neuroendocrine tumor, there was an overall change of 39% (range 16%-71%) even after an octreotide scan was performed.

Treatment of gastric carcinoids is based upon type of carcinoid, size, depth of invasion, presence of metastasis, and the patient's ability to tolerate surgery.<sup>97</sup> Somatostatin analogue is the medical treatment of choice for patients who are not surgical candidates due to either patient frailty or the presence of metastases.<sup>98</sup> Type 1 gastric carcinoids are usually benign growths in the body or fundus of the stomach with clustering of tumors that are usually subcentimeter in size. Endoscopic mucosal resection (EMR) is the accepted treatment of choice for gastric carcinoids less than 1cm with less than five lesions without invasion beyond the submucosa. If the lesions are greater than 1cm or there are greater than five lesions, antrectomy, wedge resection, or TG are surgical options with preoperative staging CT scans performed when the lesion is greater than 2cm in size. While antrectomy may not surgically resect all the tumor, it does lower the gastrin production which can cause the tumor to regress; it is eliminated in 70% to 85% of patients.<sup>93,99</sup> The management of Type II is similar to Type I with endoscopic, surgical, or medical treatment options but with the main focus on resecting the

gastrinoma that is the driving stimulus for these carcinoids.<sup>100</sup> Type III gastric carcinoids have the worst prognosis of the three types with 5-year survival less than 50%. While EMR has been shown to be effective for tumors under 2 cm,<sup>101</sup> lesions greater than this should be treated like a gastric adenocarcinoma with subtotal or TG with en bloc resection lymphadenectomy.<sup>87</sup> Endoscopic surveillance is performed annually after resection or medical therapy with octreotide or lanreotide.

## GASTRIC POLYPS

### Background

As the use of endoscopy has increased, the incidence of gastric polyps has risen. While they are asymptomatic in more than 90% of patients, there are cases of larger polyps that cause bleeding, anemia, dyspepsia, pain, or obstruction.<sup>102</sup> There are several types of gastric polyps that may appear similar grossly but differ in histology with varying neoplastic potential depending on the type and corresponding variation in appropriate initial management and follow-up.

### Fundic Gland Polyp

Fundic gland polyps can be sporadic or be associated with FAP. Fundic gland polyps present as multiple transparent sessile polyps that are small (1-5 mm in diameter) and often located in the body and fundus of the stomach. Histopathology demonstrates cystically dilated glands lined by gastric body-type mucosa (Fig. 31-6). These lesions are benign with a low incidence of dysplasia (<1%) and are generally not associated with chronic atrophic gastritis or *H. pylori* infection. Clinical management of these polyps can include polypectomy with endoscopic surveillance, or simply surveillance alone. Sporadic fundic gland polyps do not need subsequent genetic testing for FAP as isolated polyps are not harbingers of FAP.<sup>103</sup>

**FIGURE 31-6** Hematoxylin and eosin stain of a fundic gland polyp.

Fundic gland polyps are also associated with autosomal dominant FAP in 25% to 41% as a result of the mutation of the APC gene on chromosome 5q21;<sup>104</sup> gastric adenomatous polyps are only associated 5% of the time. Unlike the sporadic fundic gland polyps, FAP-associated polyps can be innumerable, covering the lining of the stomach; this is often referred to as familial gastric polyposis (FGP). Endoscopic surveillance including the duodenum with biopsy sampling of more than five polyps is required every 1 to 2 years until the age of 50 to determine FGP versus adenoma and to remove polyps more than 1 cm.<sup>105</sup>

## Hyperplastic Polyps

Hyperplastic polyps are sessile or pedunculated polyps less than 2 cm in diameter that can present as single polyp or in multiple polyps throughout the stomach (Fig. 31-7). Histologically, they are distinguished by proliferation of surface foveolar cells lining elongated, distorted pits that extend deep in to the lamina propria that contain pyloric glands, chief cells, and/or parietal cells which can overlap with the histology of hamartomas and inflammatory conditions.<sup>105</sup> The significance of hyperplastic polyps is not their neoplastic transformation over time but rather the increased risk of synchronous GC elsewhere in the gastric mucosa. The most common clinical setting of

hyperplastic polyps is chronic autoimmune gastritis (51.3%) and chronic infection with *H. pylori*. Less common are pernicious anemia, and reactive or chemical gastritis (37.3%).<sup>102,106</sup> It is clinically important to biopsy locations elsewhere in the stomach at the time of biopsy of the hyperplastic polyp to rule out *H. pylori* infection or other synchronous conditions. The management of hyperplastic polyps is often debated in regards to the size cut off for polypectomy ranging from 0.5 to 2 cm given the possible faulty forceps biopsy sampling of dysplastic lesions and incidence of carcinoma in situ under 2 cm in size.<sup>107</sup> Once a hyperplastic polyp has been noted on initial endoscopy, surveillance of the lesion is recommended at 1-year follow-up.<sup>105</sup>

**FIGURE 31-7** Endoscopic image of a hyperplastic polyp.

## Adenomatous Polyps

Adenomatous polyps are precursor lesions to GC. While they are commonly seen in high GC countries in Asia (Korea, China, and Japan), they only account for 6% to 10% of gastric polyps in the Western population. They are

generally solitary lesions that are usually present in the antrum but not restricted to that location; they can be present anywhere in the stomach. These lesions present histologically with tubular, villous, or tubulovillous features associated intestinal metaplasia and chronic atrophic gastritis but are not due to *H. pylori*<sup>102</sup> (Fig. 31-8). Villous lesions that are greater than 2 cm in diameter have the highest risk of malignant transformation (28.5%-40%).<sup>108</sup> The management of these lesions is complete resection given that these are precursors. Repeat 6-month surveillance is recommended to detect incomplete resection and with aggressive features; 1 year is appropriate for complete resection without such features.<sup>105</sup>

**FIGURE 31-8** Hematoxylin and eosin staining of an adenomatous gastric polyp.

## Inflammatory Fibroid Polyps

Inflammatory fibroid polyps are lesions that arise in the submucosa as gastric submucosal granulomas with eosinophilic infiltration. They are commonly located in the antrum or in the prepyloric region (Fig. 31-9). They present more frequently in female patients in the fifth to sixth decades of life. These lesions have the characteristics of CD34- and fascin-positive immunoreactive spindle and stellate stromal cells mixed with inflammatory cells and edema.<sup>102</sup> These lesions are benign but can present with bleeding, anemia, and/or obstruction, often mimicking other types of malignancies such as gastrointestinal stromal tumors (GIST).<sup>109</sup> Inflammatory fibroid polyps have

recently been shown to be driven by alpha-platelet derived growth factor but have a low neoplastic potential.<sup>110</sup> These lesions are often amenable to endoscopic resection unless they extend into deeper layers of the gastric wall which may require wedge resection if symptomatic.

**FIGURE 31-9** Hematoxylin and eosin staining of an inflammatory gastric polyp with eosinophilic infiltration.

## Hamartomatous Polyps

Hamartomatous polyps are rare lesions that include juvenile polyps, PJS, and Cowden disease.

### JUVENILE POLYPS

Juvenile polyps are solitary hamartomatous polyps found in the antrum that are benign and have low neoplastic potential. They are defined histologically by irregular cysts lined by normal gastric epithelium with possible stromal hemorrhage, surface ulceration, and chronic inflammation due to torsion. However, when there are multiple polyps associated with these histological findings, they are considered juvenile polyposis.<sup>105</sup> Unlike solitary juvenile

polyps, juvenile polyposis carries a malignancy risk of more than 50% due to numerous mutations (BMP1A, 10q22.3, SMAD4, 18q21.1).<sup>111</sup> Patients with SMAD4 mutation have a high probability of the combined syndrome of juvenile polyposis syndrome and hereditary hemorrhagic telangiectasia.<sup>112</sup> Routine endoscopic surveillance and polypectomy is important to reduce the risk of cancer, bleeding, anemia, and obstruction. When there is polyposis of a segment of the stomach, surgical resection may be required.

## **PEUTZ-JEGHERS POLYPS**

Peutz-Jeghers polyps are the result of a rare autosomal dominant inherited condition characterized by hamartomatous GI polyps and mucocutaneous pigmentation of the lips, buccal mucosa, and digits. The incidence of Peutz-Jeghers syndrome is estimated to be from 1 in 8300 to 1 in 280,000 individuals.<sup>113</sup> These polyps are histologically characterized by hyperplastic glands lined by foveolar epithelium and broad bands of smooth muscle fibers the branch out. The risk of GI cancer is significantly increased; in addition, there is a 15-fold increase in extra-GI malignancies such as breast, endometrial, pancreatic, ovarian, testicular and lung cancer.<sup>102</sup> Routine endoscopic surveillance with double balloon enteroscopy (DBE) and polypectomy for polyps greater than 1 cm decreases the incidence of gastric bleeding, anemia, and/or obstruction. For extra-GI malignancies, lifelong surveillance colonoscopy, CT, magnetic resonance imaging (MRI), mammography, pelvic ultrasounds in women, and testicular examinations in men are recommended.<sup>113</sup>

## **COWDEN SYNDROME**

Cowden syndrome is an autosomal dominant syndrome that includes mucocutaneous hamartomatous tumors; GI polyps; abnormalities of the breast, thyroid, genitourinary system; intramucosal lipomas; and ganglioneuromas.<sup>114</sup> Histological findings include cystically dilated glands with papillary infoldings with a connective tissue component. The GI polyps are generally benign with low risk of malignant transformation but there is a risk of malignancy of the thyroid, colon, small bowel, genitourinary tract, breast and of non-Hodgkin lymphoma and acute myelogenous leukemia (AML).

# MESENCHYMAL TUMORS

## Gastrointestinal Stromal Tumors

### BACKGROUND

Gastrointestinal stromal tumors are tumors that arise from the interstitial cells of Cajal and represent the most common type of mesenchymal tumors of the GI tract with the stomach being the most common site of origin. GIST has been historically misdiagnosed as GI sarcoma, leiomyoma, leiomyosarcoma, leiomyoblastomas, plexosarcoma, or malignant fibrous histiocytoma and this underestimates the true incidence in the literature in the past.<sup>115</sup> Historically, the diagnosis often was associated with poor prognosis with median OS of 60 months for primary disease and 19 months for metastatic disease; however, there have been considerable advances in the diagnosis and management of GIST within the past 20 years.<sup>116</sup> Since the landmark discovery of the role of proto-oncogene tyrosine kinase receptor CD117 mutations associated with GIST in 1998 by Hirota et al, the diagnosis has been significantly facilitated.<sup>117</sup> Subsequent to the discovery of c-kit proto-oncogene, a new era of targeted therapy using imatinib mesylate has shaped the current management of GIST after it obtained Food and Drug Administration (FDA) approval for treatment of advanced metastatic GIST in 2002 on the basis of early clinical trials demonstrating increased progression-free survival compared to historical controls.<sup>118</sup> The use of imatinib mesylate has been expanded for use in the adjuvant setting after the American College of Surgeons Oncology Group (ACOSOG) Z9001 trial demonstrated improved recurrence-free survival for 1 year after complete resection for GIST more than 3 cm.<sup>119</sup> A subsequent randomized clinical trial was performed comparing administering imatinib mesylate for 3 years versus 1 year adjuvant treatment. The trial demonstrated an improved 5-year recurrence free survival (65.6% vs 47.9%;  $P < 0.001$ ) and OS (92% vs 81.7%;  $P = 0.02$ ) for patients with GIST tumors having high risk features such as tumor diameter more than 10 cm, tumor diameter more than 5 cm and mitotic count more than 5/HPF, tumor rupture at time of surgery, or mitotic count more than 10 mitoses/50 HPF);<sup>120</sup> on this basis, the current recommendation is to extend adjuvant therapy to 3 years.

## CLINICAL PRESENTATION

Patients may present with symptoms of bleeding from submucosal ulceration of the tumor, obstructive symptoms of gastric outlet obstruction, or abdominal pain. Often asymptomatic tumors are incidentally discovered during endoscopy, radiographic imaging, or surgery for other reasons. The most common site of involvement is the stomach (60%) and small intestine (30%) with other sites along the GI tract (colon, esophagus) and extra GI tumors being less.<sup>121</sup> The average size of symptomatic GIST tumors was 6 cm compared to asymptomatic tumors measuring 2 cm.<sup>122</sup> Advanced GIST can present with metastatic liver lesions, invading surrounding organs, or with diffuse peritoneal involvement. Generally, GIST does not spread to the lymphatic system with exception of succinate dehydrogenase (SDH)-deficient GIST which can often have lymphovascular invasion and lymph node metastases.<sup>123</sup> SDH-deficient GIST is more prevalent in pediatric GIST patients with a higher predilection for females compared to non-SDH-deficient GIST.<sup>124</sup>

## DIAGNOSTIC EVALUATION

Patients who present with symptoms of GI bleeding or obstruction can be initially evaluated by endoscopy with or without EUS and biopsy that can provide tissue for diagnosis of GIST and exon mutation analysis. If possible, core needle biopsy is more informative than fine needle aspiration as it provides a mitotic index profile for risk stratification. However, patients who are asymptomatic are often found incidentally on radiographic imaging for other unrelated symptoms and do not necessarily require biopsy if imaging is consistent with GIST. Contrast-enhanced CT is an appropriate staging modality to evaluate the tumor size, level of displacement of surrounding organs, heterogeneity of tumor, and metastatic disease. If there is suspicion of liver involvement, MRI of the abdomen can identify metastases. Response to targeted treatment with imatinib mesylate cause changes in resolution of enhancing tumor nodules, decreased tumor vascularity on CT, and a decrease in the [18F] fluorodeoxyglucose (FDG) PET avidity without a change in the traditional size criteria according to Response Evaluation Criteria in Solid Tumors (RECIST).<sup>125</sup>

## PROGNOSIS

The prognostic variables in patients with GIST have been analyzed with risk stratification systems that attempt to predict recurrence and OS. While there have been several nomograms developed by Memorial Sloan-Kettering Cancer Center (MSKCC), National Institutes of Health (NIH), and Armed Forces Institutes of Pathology (AFIP), they all reflect the variables of tumor size, mitotic count, location, and whether or not there was rupture.<sup>126–128</sup>

Overall prognosis after initial diagnosis can be predicted using the latest nomogram by Rossi et al that factors in site of disease (stomach, small intestine, colon/rectum, other), size of tumor, and a continuous range of mitotic index to determine the 10-year OS. This had higher discriminative ability (C-index 0.72) than NIH risk stratification (C-index 0.64) or the NCCN (C-index 0.63).<sup>129</sup>

In addition to prognostic variables of size, location, and mitotic index, genomic mutational status can provide additional prognostic information. It is important to perform a mutational analysis with exon sequencing of GIST tumors as it can predict the likelihood of response to systemic treatments. Imatinib mesylate and sunitinib are two systemic treatments available for c-kit and platelet-derived growth factor receptor alpha (PDGFRA) mutation GIST patients. Imatinib is the first-line treatment while sunitinib is second-line therapy reserved for imatinib-resistant tumors. For patients with c-kit exon-9 mutant GIST, the recommendation is to start at the higher 800 mg/d dose rather than 400 mg dose. One caveat is that wild type or PDGFRA exon 18-mutant GIST will have no response to imatinib mesylate or sunitinib.<sup>130</sup> GIST tumors that have exon 11 mutations will also have a higher risk of recurrence and worse overall prognosis when compared to other GIST mutations.<sup>131</sup> However, of the patients with GIST diagnosis, 10% to 15% present as wild type GIST that lack the c-kit or PDGFRA mutation. These patients have the worst prognosis due to lack of efficacy of imatinib mesylate.<sup>132</sup> Furthermore, 4% to 13% of all GIST patients present with BRAF mutation,<sup>133–135</sup> a well-known oncogenic driver mutation that is also resistant to imatinib mesylate because the BRAF signaling pathway is downstream of the c-kit pathway. These patients can instead benefit from BRAF inhibitors rather than imatinib.<sup>136</sup>

## MANAGEMENT

The primary treatment for patients with resectable GIST without evidence of metastases is primary R0 surgical resection with consideration of adjuvant targeted therapy with imatinib mesylate after analysis of tumor size, mitotic rate, and location of the tumor. The indication for resection of primary GIST depends on the size with tumors more than 2 cm with EUS every 6 to 12 months if there are no concerning features (ie, large size, irregular extraluminal border, heterogeneous echo pattern, or cystic spaces) according to the National Comprehensive Cancer Network Task Force report.<sup>137</sup>

Patients who are candidates for resection should undergo careful CT inspection of the tumor for signs of metastatic disease as well as surrounding organ involvement. The surgical approach should focus on en bloc resection of the stomach and surrounding involved organs to minimize the chances of positive margins or tumor spillage. A key oncologic principle is the prevention of tumor rupture given their friable, cystic tumor structure. Patients with tumor rupture at the time of resection have a worse overall prognosis and survival when compared to those without.<sup>138</sup> Given the low likelihood of lymph node involvement in GIST tumors, routine lymphadenectomy is not indicated; however pediatric GIST (SDH-deficient) tumors have a higher incidence of lymph node involvement and should undergo routine lymphadenectomy.

There is emerging data that minimally invasive approaches for resection of GIST are associated with lower length of stay (3 vs 8 days), fewer grade III complications (3% vs 14%), and no difference in OS versus laparotomy. There was a 10% conversion rate in 167 minimally invasive surgery (MIS) cases compared to 230 cases that began as laparotomies (Fig. 31-10).<sup>139</sup> At MedStar Georgetown University Hospital, preoperative planning includes gastric-tumor protocol CT to better localize the tumor and to plan port placements for a laparoscopic approach to gastric resection. We also routinely utilize a laparoscopic-assisted approach because it permits removal of gastric or small GISTs with the option to extend to a slightly longer incision, without using a longer laparotomy incision. The laparoscopic-assisted approach minimizes the risk of tumor rupture during extraction. Intraoperatively, we routinely utilize endoscopy to improve localization of the tumor during laparoscopy, confirm adequate margins during resection, and avoid narrowing the stomach when deploying a stapling device across a

lesion near the proximal or distal aspect (Fig. 31-11). While the laparoscopic approach is preferred, open surgical resection remains an accepted and safe approach. For example, patients with large GIST who are poor responders to preoperative tyrosine kinase inhibitors (TKIs), wild-type GIST, or BRAF mutated tumors usually undergo an open resection (Fig. 31-12).

**FIGURE 31-10** Laparoscopic-assisted gastrectomy with port placements demonstrate a less invasive method of gastric resection.

**FIGURE 31-11** Laparoscopic wedge resection of extraluminal GIST tumor performed with intraoperative endoscopy is a minimally invasive method of resection.

**FIGURE 31-12** Open resection of a large GIST lesion that was not amenable to laparoscopic excision.

**Adjuvant Therapy.** The role of adjuvant imatinib mesylate was defined in the landmark ACOSOG Z9001 trial, a phase III, double-blind, placebo-controlled, multicenter trial that randomized patients with more than 3 cm GIST with positive c-kit mutations to daily 400 mg imatinib mesylate daily compared to placebo. After median follow-up of 19.7 months, the imatinib mesylate group had a significant improvement in recurrence-free survival when compared to control (98% vs 83% at 1 year;  $P < 0.0001$ ). A subsequent randomized clinical trial of 3 years versus 1 year of adjuvant treatment demonstrated improved 5-year recurrence free survival (65.6% vs 47.9%;  $P < 0.001$ ) and OS (92% vs 81.7%;  $P = 0.02$ ) in patients with high risk features (tumor diameter  $>10$  cm, tumor diameter  $>5$  cm and mitotic count  $>5$ /HPF, tumor rupture at the time of surgery, or mitotic count  $>10$  mitoses/50 HPF) for patients treated 3 years.<sup>120</sup> The most recent trial looking at 5-year

adjuvant therapy, PERSIST-5, has now concluded. This single-arm, phase II, nonrandomized, open-label multicenter study analyzed the survival benefit of 5-year adjuvant imatinib mesylate in patients that underwent resection of primary KIT (+) GIST with high risk of recurrence within 12 weeks. The primary endpoint of the trial was recurrence-free survival. The 5- and 8-year estimated RFS rates were 90% (95% CI, 80-95) and 81% (95% CI, 62-91), respectively. The 5- and 8-year OS rate was 95% (95% CI, 86-99). Forty-five of 91 patients discontinued treatment; common reasons included patient choice (20%), adverse events (AEs, 17%), protocol deviation (4%), and loss to follow-up (4%). Of the patients that had recurrences, this occurred after discontinuing the imatinib.<sup>140</sup> They concluded that patients with exon 9 or PDGFRA mutations should be started at the higher 800 mg daily dose since there was no significant benefit at 3 years at the 400 mg dose.<sup>141</sup>

**Metastatic Disease.** Patients with metastatic disease are candidates for imatinib mesylate as the primary targeted therapy with the option of second-line tyrosine inhibitor, sunitinib, for disease progression after dose escalation of imatinib from 400 to 800 mg regimen.<sup>142</sup> The mode of imatinib resistance has been determined to be second c-kit exon mutations in exon 13 which can be targeted by sunitinib.<sup>143</sup> Patients can also develop resistance to imatinib mesylate therapy through new BRAF mutations in patients with c-kit and PDGFRA-mutant GIST.<sup>144</sup> A third-line TKI, Regorafenib, is an oral multitargeted inhibitor with activity against multiple kinases including KIT, RET, RAF1, BRAF, vascular endothelial growth factor (VEGF), and PDGFR that is recommended after progression through imatinib mesylate escalation and sunitinib.<sup>145,146</sup>

Select patients with GIST tumors that have a treatment response without signs of multifocal progressive disease (MPD) can undergo cytoreductive metastasectomy with an outcome comparable to sunitinib in highly select patients.<sup>147</sup> The liver is the most common site of synchronous and metachronous metastases for patients; the incidence is 15% to 20% incidence and there is a solitary site of disease in 50% of cases.<sup>116</sup> Patients selected for surgical metastasectomy are those that have stable disease who have primary or secondary resistance on first-, second-, and third-line of TKIs (imatinib mesylate, sunitinib, and regorafenib); those who have resectable disease with R0 margins; those who have good performance status (Eastern Cooperative

Oncology Group [ECOG] score 0); and those presenting with hemorrhage, perforation, obstruction, or abscess. The ability to obtain negative R0 margins enhances both progression-free survival (29 months vs 7 months;  $P = 0.002$ ) and OS (100% vs 37.5% at 1 year;  $P = 0.001$ ).<sup>148,149</sup> While there is no consensus on the timing of metastasectomy, selection of patients who have favorable response to TKI is critical. Recent data suggests that patients who underwent resection at the period of maximum tumor response to TKIs had improved surgical outcome compared to those who were operated on after the development of primary or secondary resistance (1-year survival of 95% with stable disease, 86% with limited progression, and 0% for generalized progression;  $P < 0.0001$ ).<sup>150–152</sup> Given the morbidity of metastasectomy, it is critical to select patients with the best probability of progression-free and OS based on the type of mutation and response to TKI.

## SARCOMA

**Leiomyoma and Leiomyosarcoma.** Leiomyoma and leiomyosarcoma are rare mesenchymal tumors that arise from the muscularis propria and muscularis mucosa layers of the stomach and small intestine (Fig. 31-13). The diagnosis is made by immunohistochemistry. These tumors stain positive for desmin and actin but are negative for CD117 (c-kit and CD34) which distinguishes them from GIST. Leiomyosarcoma can be distinguished from leiomyoma clinically—leiomyosarcomas are typically solitary, larger, and frequently display areas of hemorrhage and necrosis. Symptoms are often delayed due to their extramural growth until there is ulceration, bleeding, obstruction, or incidental finding of metastatic disease noted in the liver and peritoneum during imaging workup for a different cause. The prognosis of patients with metastatic disease at initial presentation is poor. Management should be focused on R0 resection.<sup>153,154</sup>

**FIGURE 31-13** Hematoxylin and eosin staining of a leiomyoma.

**Fibrosarcoma and Angiosarcoma.** Fibrosarcoma is a malignant tumor composed of fibroblasts with variable collagen production, classically with a herringbone architecture. Fibrosarcomas stain positively for vimentin and very focally for smooth muscle actin. Fibrosarcomas are rare, accounting for 1% to 3% of all sarcoma diagnoses. They present in the middle age but can also develop in infancy without any predilection for gender.<sup>155</sup> They are more commonly in the extremities, head and neck, than in the viscera. Fibrosarcomas are the least differentiated type of mesenchymal malignancy and are defined as spindle cell malignant neoplasms lacking any specific differentiation and therefore are the least heterogeneous of the sarcomas.<sup>156</sup> The tumors have a white or tan mass appearance with a firm texture due to the collagen content. Fibrosarcomas tend to exhibit resistance to systemic chemo- and radiotherapy.

Angiosarcomas are malignant vascular tumors that arise from normal endothelium. They comprise only approximately 2% of all sarcomas and are highly aggressive with early recurrence and metastasis. The majority develop as cutaneous tumors associated with lymphedema; less than a quarter present as deep soft tissue masses of the arm, trunk, and abdominal cavity.

Histologically, angiosarcomas have components of both epithelioid and spindled areas with a predominance of the former and are composed of sheets, small nests, cords, or rudimentary vascular channels. Immunohistochemistry positive for CD31, CD34, and von Willebrand factor confirms the diagnosis.<sup>157</sup>

**Hemangiopericytoma.** Hemangiopericytoma is a diagnosis used to describe a wide array of neoplasms that have a thin-walled branching vascular pattern. Patients generally present with tumors of the deep soft tissue or abdominal cavity and less commonly in the limbs; symptoms are due to the mass effect from these slow growing tumors. Hypoglycemia noted in these patients when tumors secrete insulin-like growth factor.<sup>158</sup> They are well-circumscribed masses with yellowish or tan cut surface and a fleshy or spongy consistency ranging in size from 5 to 15 cm in diameter at presentation. The overall prognosis of hemangiopericytoma is generally favorable as the majority are benign although an aggressive malignant clinical course is sometimes reported.

**Schwannoma.** Schwannoma is a benign neoplasm of Schwann cell origin. These are benign lesions that have a rubbery, yellow trabeculated appearance macroscopically. They are characterized by lymph node aggregates around their periphery, with nuclear palisading Verocay bodies and hyalinized vessels similar to schwannomas found elsewhere in the body. They grow slowly along the outer covering of the myelin sheath of the peripheral nerves and are generally contained within a capsule, permitting successful surgical removal<sup>159</sup> (Fig. 31-14). These tumors can be monitored if asymptomatic and the diagnosis is secure.

**FIGURE 31-14** CT imaging of a gastric schwannoma (A) without and (B) with IV contrast.

## GASTRIC LYMPHOMA

### Background

There are two major types of Non-Hodgkin lymphoma—nodal involvement versus extranodal disease. Gastric lymphoma is an extranodal Non-Hodgkin lymphoma defined by the presence of the majority of the lymphoma in the stomach with variable involvement of the surrounding lymphatic drainage. The two main subtypes of gastric lymphoma are diffuse large B-cell lymphoma (DLBCL) (Fig. 31-15) or mucosa associated lymphoid tissue (MALT). Gastric lymphoma arises from the mucosa or submucosal layer, most often from the lymphoid tissue in the lamina propria.

**FIGURE 31-15** Hematoxylin and eosin stain of a gastric diffuse large B cell lymphoma.

## INCIDENCE

There is estimated to be 500,000 new cases of gastric lymphoma in the United States each year; this comprises 5% of all lymphoma diagnoses.<sup>160</sup> Gastric lymphoma is the most common site of GI lymphoma followed by small intestine, ileocecum, and colon/rectum.<sup>161</sup> Patients initially present in their sixth decade of life with more males and Caucasians than females and blacks. There are several risk factors associated with gastric lymphoma including celiac disease, *H. pylori* infection, immunosuppression, human immunodeficiency virus (HIV) or Epstein-Barr virus (EBV), and inflammatory bowel disease.<sup>162,163</sup>

## PRESENTATION AND DIAGNOSIS

The clinical symptoms of patients with gastric lymphoma are nonspecific but not limited to fever, nausea, vomiting, epigastric abdominal pain, anorexia, unintentional weight loss, night sweats, hematemesis, and melena.<sup>164,165</sup> Staging studies includes contrast-enhanced CT, MRI, EGD biopsies, EUS,

and 18F-fluorodeoxyglucose PET (18FDG-PET).<sup>163</sup> Additionally, peripheral blood smear and bone marrow biopsy are required in the staging workup to exclude metastatic disease. Patients should also be tested for *H. pylori* given its essential role in the pathogenesis of MALT. There are several proposed staging systems that are available, including the Ann Arbor Staging System with Musshoff Modification and the Lugano Staging System. In the Ann Arbor Staging System with Musshoff Modification, stage IE is lymphoma restricted to the GI tract, stage IIE is lymphoma infiltrating lymph nodes on the same side of diaphragm, stage III is lymphoma involving both sides of the diaphragm, and stage IV is disseminated disease. Using the Lugano system, stage I is lymphoma confined to the GI tract, stage II is lymphoma extending into the abdomen, and stage III/IV is disseminated extranodal involvement or a GI tract lesion with supradiaphragmatic nodal involvement.<sup>166</sup>

## MANAGEMENT

The approach for patients with gastric lymphoma should be multidisciplinary, involving the medical oncologist, radiation oncologist, and surgical oncologist to determine the best treatment options. The treatment of choice for DLBCL is chemotherapy alone. A trial in Mexico randomized 589 patients to chemotherapy alone, chemotherapy plus surgery, surgery only, and surgery plus radiation therapy with 10-year survival rates of 96%, 91%, 54%, and 53%, respectively.<sup>167</sup>

In contrast, there was no difference in treatment outcomes in a randomized trial of 241 patients with low-grade MALT lymphoma comparing surgery, radiation therapy, and chemotherapy with 10-year survival rates of 80%, 75%, and 87%, respectively;  $P = 0.40$ ). Therefore, patients with low-grade MALT are offered chemotherapy with or without radiation therapy if antibiotic treatment does not cause complete regression of the MALT lesion.<sup>168</sup> MALT lymphoma was first associated with *H. pylori* infection in 1991; nearly 92% of patients with MALT lymphoma are positive for *H. pylori* infections. This association is based on the T-cell activation of MALT lymphoma by *H. pylori* itself.<sup>169</sup> Treatment of *H. pylori* with triple therapy (amoxicillin or metronidazole, clarithromycin, and proton pump inhibitors) has produced complete remission of MALT lymphomas and is considered the first line treatment.<sup>170,171</sup> Surgery is reserved for those with emergency presentation of uncontrolled refractory bleeding, perforation, and/or fistula

formation.

# PERSPECTIVE ON GASTRIC CANCER

*Hisashi Shinohara • Mitsuru Sasako*

## THEORETICAL BACKGROUND FOR D2 GASTRECTOMY

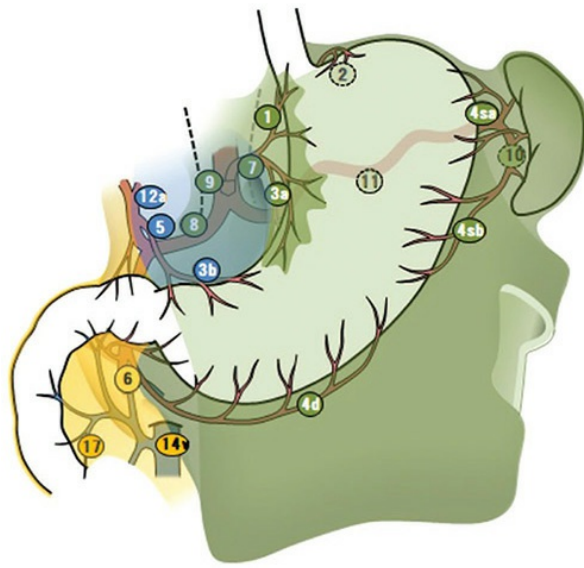

Gastric cancer remains a major health problem in East Asia. In contrast, in the United States and Western Europe, the incidence of gastric cancer has declined but is often diagnosed at an advanced stage. Thus, the number of operations that a surgeon performs annually varies according to region, so it is not easy to define which type of gastric cancer surgery should be considered the global standard. Nevertheless, a consensus that D2 dissection is the most appropriate way to treat resectable advanced gastric cancer has been reached based on the results of long-term follow-up of the Dutch D1 versus D2 trial<sup>1</sup> and the Japan Clinical Oncology Group (JCOG) 9501 study,<sup>2</sup> which confirmed no survival benefit with more extensive lymphadenectomy.

Radical surgery for gastrointestinal cancer focused on en bloc removal of the primary tumor along with lymphovascular drainage by excising organ-specific mesenteries. This general concept is widely accepted in colorectal cancer surgery and is realized as total mesorectal excision (TME) or complete

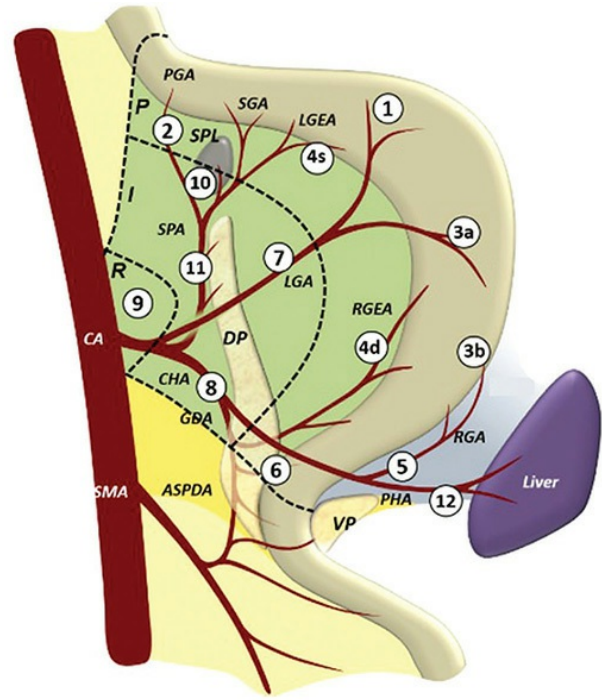

mesocolic excision (CME).<sup>3,4</sup> D2 gastrectomy entails systematic dissection of all the nodes along the celiac axis (CA) and its named branches as well as the perigastric nodes. Based on embryologic principles, D2 gastrectomy is essentially a realization of mesentery-based surgery despite the anatomic restrictions inherent to the mesogastrium.<sup>5</sup>

## UNIQUE ANATOMIC STRUCTURE OF THE MESOGASTRIUM

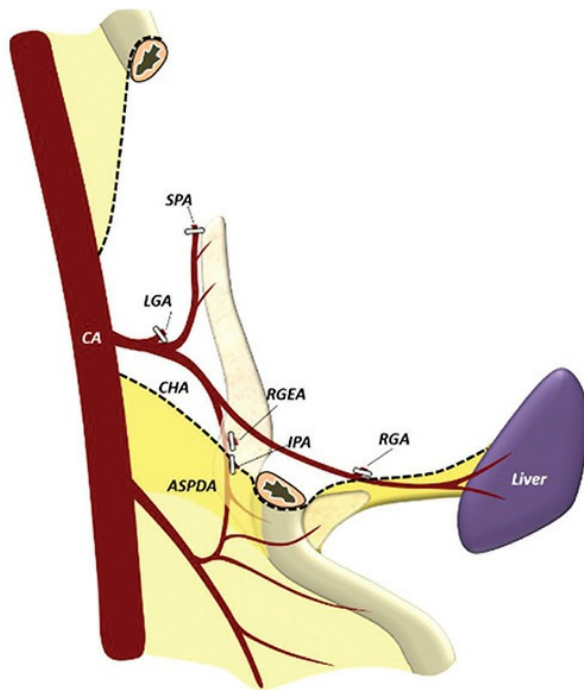

The basic technique of lymph node dissection is common for all gastrointestinal cancers. However, because of the high incidence of tumor deposits in the adipose tissue and significant tendency of developing peritoneal metastasis in gastric cancer, dissection without destroying the intact fascial package surrounding the fatty tissue where all nodes and tumor deposits are imbedded is of paramount importance.<sup>6</sup> To perform a proper lymph node dissection of the stomach, an understanding of the unique anatomic structure of the mesogastrium is essential. The stomach has 2 mesenteries: the dorsal mesogastrium and the ventral mesogastrium. During the rotation of the intestinal system, the ventral mesogastrium becomes the lesser omentum and the dorsal mesogastrium becomes the greater omentum. The mesoduodenum and the transverse mesocolon are eventually overlaid by the greater omentum. The dorsal pancreas arises from the duodenal wall, grows into the mesoduodenum, and eventually extends into the dorsal mesogastrium. The anterior surface of the mesoduodenum is then overlaid by the proper transverse mesocolon and the greater omentum. These fetal events produce certain anatomic restrictions to conduct mesentery-based gastric cancer surgery. From the viewpoint of mesenteric structures, however, it is important to recognize that regional lymph node stations can be embedded in the dorsal or ventral mesogastrium, as shown in [Figure 32-1A](#).

A

B

C

**FIGURE 32-1.** A. Development of omentum, mesogastrium, and mesoduodenum. Numbers in circles indicate lymph node stations according to the Japanese classification of gastric carcinoma. Blue nodes belong to the ventral mesogastrium, green nodes to dorsal mesogastrium, and yellow nodes

to mesoduodenum. **B.** The simplified mesogastrium whose embryonic concrescences were restored. The gastric mesentery can be divided into 3 sectors: the root (R), intermediate (I), and perigastric (P) sectors. **C.** D2 lymphadenectomy based on mesogastric excision concept by resection of the mesogastrium while excluding the pancreas and major branches of the celiac axis (CA). ASPDA, anterior superior pancreatoduodenal artery; CHA, common hepatic artery; DP, dorsal pancreas; GDA, gastroduodenal artery; IPA, infrapyloric artery; LGA, left gastric artery; LGEA, left gastroepiploic artery; PGA, posterior gastric artery; PHA, proper hepatic artery; SGA, short gastric artery; SMA, superior mesenteric artery; SPA, splenic artery; RGA, right gastric artery; TM, transverse mesocolon; VP, ventral pancreas.

## **D2 DISSECTION BASED ON MESOGASTRIC EXCISION CONCEPT**

The simplified mesogastrium after restoration of embryonic concrescences is shown in [Figure 32-1B](#). The dorsal mesogastrium can be divided into 3 sectors: the root, intermediate, and perigastric sectors. Station no. 9 surrounding the CA would be equivalent to the root sector of the whole gastric mesentery. The intermediate sector, which envelopes the pancreas, would include nodes along the left gastric artery (no. 7), common hepatic artery (no. 8), splenic hilum (no. 10), and splenic artery (no. 11). The perigastric sector would include nodes situated at the right (no. 1) and left cardia (no. 2) and lesser (no. 3a) and greater curvature (no. 4). The no. 6 infrapyloric station lies within the mesoduodenum beyond the boundary of the mesogastrium. The remaining few stations, that is, nos. 3b and 5, along the right gastric artery, and 12, along the proper hepatic artery, are originally included in the ventral mesogastrium.

The dissection of N2 nodes by “complete” mesogastric excision with central vascular ligation like CME is disturbed by the presence of the pancreas and some branches arising from the CA. Ligation of the CA in radical gastrectomy is anatomically possible since the blood supply to the liver is secured in most cases by the pancreatoduodenal arcades from the superior mesenteric artery. However, by preserving the gastroduodenal artery, even Appleby’s operation cannot realize complete mesogastric excision. Further, the division of the CA entails combined

splenopancreatectomy even when the organs are not directly invaded. Instead, as shown in [Figure 32-1C](#), D2 gastric cancer surgery should aim at systematic mesogastric excision, that is, en bloc excision of the mesogastrium while excluding the pancreas and its associated vessels.<sup>5</sup> This concept is expected to aid the universalization of the operative strategy for gastric cancer, as is currently the case for TME and CME in colorectal cancer.

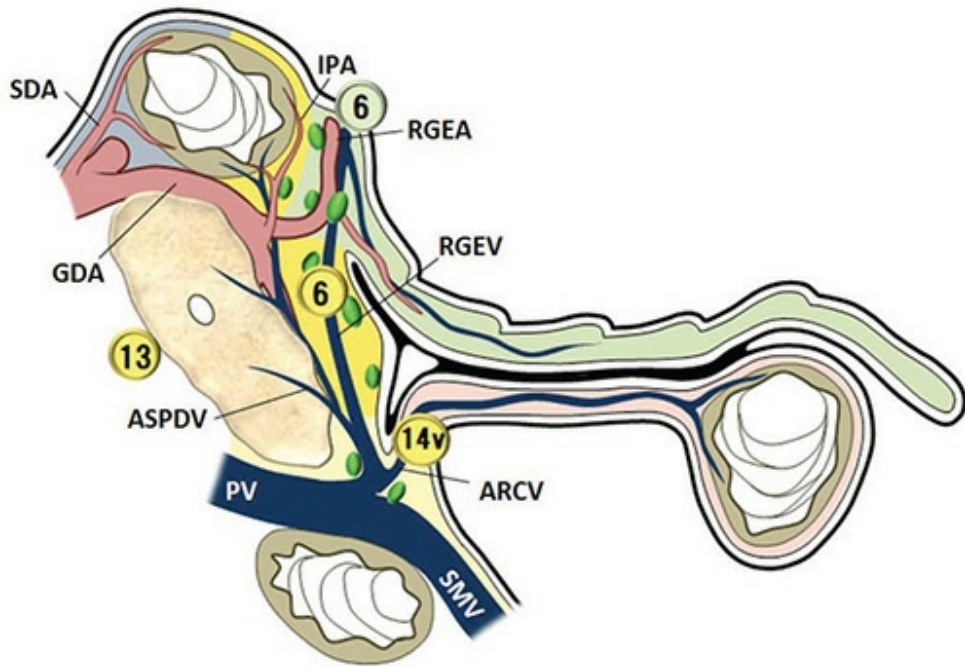

## **PRACTICAL MODIFICATIONS OF D2 GASTRECTOMY**

Prognostic relevance of other components of the standard D2 dissection such as combined splenectomy in case of cancer of the upper third stomach (JCOG 0110) and bursectomy (JCOG 1001) has more recently been addressed by randomized phase III trials. In the past, when most of gastric cancers were large and accompanied by large nodal metastasis surrounding the left gastric, splenic, and celiac arteries, en bloc resection of the entire tumor required the combined resection of the pancreatic tail with the spleen. This procedure, which had been carried out for prophylactic dissection of the splenic artery and hilar lymph nodes, was abandoned because of the higher mortality and morbidity with limited survival benefit compared with pancreas-preserving total gastrectomy.<sup>7</sup> Now, such extended surgery is used only for T4b tumors invading the pancreas or splenic vessels. JCOG 0110, a randomized controlled trial comparing a total gastrectomy with or without splenectomy for advanced gastric cancers not involving the greater curvature, proved the noninferiority of spleen preservation for such tumors,<sup>8</sup> while 2 other small sized trials did not show any statistically reliable results.<sup>9,10</sup> To carry out a D2 dissection without splenectomy, meticulous dissection along the splenic vessels is needed. For safe dissection of this area, accurate knowledge of the basic anatomy and its variations is essential. The branch-off point of the posterior gastric artery varies widely; it is sometimes at 3 to 4 cm from the root of the splenic artery and sometimes close to the splenic hilum. We should know that the upper pole artery to the spleen sometimes has a common trunk with the posterior gastric artery, which should be divided not at the root of the common trunk but at the branching off from the upper pole artery. There are 3 or 4 short gastric arteries, each of which tracks ventrally from the final branches of the splenic artery into the splenic parenchyma. The

left gastroepiploic artery is usually the most caudal branch of the splenic artery. Often, it has a common trunk with the inferior pole branch to the spleen. As demonstrated in [Figure 32-2A](#), all nodes are included in the dorsal mesogastrium that expanded into the upper abdomen to form the omental bursa. The role of bursectomy dissecting the peritoneal lining covering the pancreas and the anterior layer of the transverse mesocolon for preventing peritoneal metastasis had long been controversial. However, a phase III trial (JCOG 1001) failed to demonstrate a significant role of bursectomy in survival of patients with T3/T4 gastric cancer.<sup>11</sup>

A

B

**FIGURE 32-2. A.** Sagittal transaction near the root of the splenic artery and 3-dimensional scheme of the structures left lateral to the transection. All lymph nodes along the splenic vessels and posterior gastric vessels and in the splenic hilum are included in the dorsal mesogastrum that was expanded into the upper abdomen to form the omental bursa. Numbers in circles indicate lymph node stations according to the Japanese classification. Ao, aorta; LGEA, left gastroepiploic artery; LRV, left renal vein; PEA, posterior epiploic artery; PGA, posterior gastric artery; SPA, splenic artery. **B.** Sagittal transactional scheme near the origin of the right gastroepiploic vessels. Anatomic structures of the greater omentum, transverse colon and mesocolon, pancreas head, and duodenum are shown with vessels surrounding the organs. The ventral mesoduodenum includes the supraduodenal vessels, and the dorsal mesoduodenum includes infrapyloric vessels. The origins of the dorsal mesoduodenum and mesogastrum share the common root that joins with the right gastroepiploic vein (RGEV), the anterosuperior pancreaticoduodenal vein (ASPDV), and the accessory right colic vein (ARCV), making Henle's common trunk. GDA, gastroduodenal artery; IPA, infrapyloric artery; PV, portal vein; RGEA, right gastroepiploic artery; SDA, supraduodenal artery; SMV, superior mesenteric vein.

The last part of the antrum (4-6 cm) and the first portion the duodenum (duodenal bulb) are dually supplied by the infrapyloric vessels in the dorsal mesoduodenum<sup>12</sup> and by the supraduodenal vessels in the ventral mesoduodenum (Fig. 32-2B). To treat an antral cancer, proper dissection of both the mesogastrum and the mesoduodenum is essential. The incidence of metastasis to the infrapyloric node station is nearly 50% for distal cancers of T2 or more, and more than 40% of those having such metastasis will survive more than 5 years after proper D2 dissection.<sup>13</sup>

## THE PLACE OF LAPAROSCOPIC AND ROBOTIC SURGERY

Reflecting the result from the JCOG 0703 phase II study that explored the feasibility of the laparoscopic distal gastrectomy for stage I gastric cancer, the Japanese Guidelines for the Treatment of Gastric Cancer revised the position of laparoscopic distal gastrectomy for stage I gastric cancer in 2014 from a promising but experimental treatment to a valid option in daily clinical practice.<sup>14</sup> Thereafter, surgeons in East Asia have proceeded to conduct large

randomized controlled trials comparing open versus laparoscopic surgery and have gradually extended the indication to more advanced cancers.<sup>15,16</sup> In many respects, however, laparoscopic surgery has limitations, including lack of tactile sensation; difficulty in widely spreading out the membranes, which is essential for proper D2 dissection; and longer learning curve. Considering the high tendency to develop peritoneal metastasis and extranodal metastasis in the adipose tissue,<sup>6</sup> application of laparoscopic surgery for T3/4 tumors should be carefully considered until noninferiority of this approach to open surgery is proven. The recent development of surgical robotics represented by the da Vinci System may have overcome several shortcomings inherent to the laparoscopic approach. This system has advantages compared with conventional laparoscopic surgery systems, such as the EndoWrist, including additional degrees of freedom, elimination of the fulcrum effect, and high-resolution 3-dimensional images that can be magnified and reduce human tremor. Decrease in the incidence of surgical complications when compared with laparoscopic surgery has been reported from a leading Japanese institution.<sup>17</sup> However, a nonrandomized prospective study that compared robotic surgery with laparoscopic surgery in Korea has shown morbidity to be extremely low in both approaches, but the robotic surgery required a longer operating time and was significantly more expensive.<sup>18</sup> Another retrospective comparison of robot-assisted and laparoscopy-assisted pylorus-preserving gastrectomy also demonstrated no benefit of robotic over laparoscopic surgery.<sup>19</sup> Given the shorter learning curve for acquisition of relevant surgical skills,<sup>20</sup> easier access to robotic surgery and more frequent opportunities for training will be indispensable for the future progress of this promising modality.

# GASTROINTESTINAL STROMAL TUMORS

*Nicole J. Look Hong • Chandrajit P. Raut*

## INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare neoplasms. Although they represent only 0.1% to 3% of all gastrointestinal malignancies,<sup>1-4</sup> they account for 80% of gastrointestinal mesenchymal neoplasms.<sup>5</sup> Approximately 5000 to 6000 new cases are diagnosed per year in the United States, for an annual incidence of 14.5 per million and prevalence of 129 per million.<sup>6</sup> In the last 15 years, the understanding and treatment of GIST has witnessed remarkable advances due to two key developments: (1) the identification of constitutively active signals (oncogenic mutation of the *c-KIT* and *platelet-derived growth factor alpha* [*PDGFRA*] gene-encoding receptor tyrosine kinases) and (2) the development of therapeutic agents that suppress tumor growth by specifically targeting and inhibiting these signals. These developments in the management of GIST illustrate the principle of translational therapeutics in oncology, confirming that specific inhibition of tumor-associated receptor tyrosine kinase activity is an effective cancer treatment. The advent of effective targeted medical therapy for GIST has

increased the complexity of management and opened new dialogues regarding the need for integrated multimodality therapy. This chapter reviews the biology, treatment, and emerging clinical challenges of these mesenchymal neoplasms.

## PATHOLOGIC FEATURES

### Historical Background

The term “GIST” was initially coined in 1983 by Mazur and Clark to describe intra-abdominal nonepithelial neoplasms which lacked the ultrastructural features of smooth muscle cells and the immunohistochemical characteristics of Schwann cells.<sup>7</sup> GISTs typically exhibit heterogeneous histologic features. They are most commonly composed of long fascicles of spindle cells with pale to eosinophilic cytoplasm and rare nuclear pleomorphism, but may occasionally exhibit epithelioid characteristics, including sheets of round- to oval-shaped cells with abundant eosinophilic cytoplasm and nuclear atypia (Fig. 33-1). As such, they are typically classified as spindle cell type, epithelioid type, or mixed type. The majority of GISTs are of spindle cell appearance (70%), while epithelioid (20%) and mixed (10%) cell morphology are less common.

**FIGURE 33-1** GIST histology. Staining of tumor paraffin sections with hematoxylin and eosin (H&E) reveals three patterns of GIST histology: (A) spindle cell, (B) mixed cell, and (C) epithelioid cell type.

In 1995, Miettinen and colleagues discovered that 70% of GISTs were positive for CD34 by immunohistochemistry, a myeloid progenitor cell

antigen also present in endothelial cells and fibroblasts.<sup>8</sup> Based upon their histologic features, GISTs are believed to arise from the interstitial cells of Cajal, components of the intestinal autonomic nervous system that serve as intestinal pacemakers and also express CD34.<sup>9</sup> Nonetheless, until the late 1990s, there were no objective criteria to classify GISTs. They were frequently misclassified as leiomyomas, leiomyoblastomas, leiomyosarcomas, Schwannomas, gastrointestinal autonomic nerve tumors, or other similar soft tissue histologies.<sup>10</sup> Consequently, interpretation of clinical results for reports on “GISTs” published before 2000 is challenging.

## Receptor Tyrosine Kinase Mutations

In a landmark publication in 1998, Hirota and colleagues reported two critical findings: (1) near-universal expression of the transmembrane receptor tyrosine kinase KIT in GISTs and (2) presence of gain-of-function mutations in the corresponding *c-KIT* proto-oncogene.<sup>11</sup> The KIT receptor is activated by binding its cytokine ligand, known as steel factor or stem cell factor,<sup>12</sup> which then causes receptor homodimerization, phosphorylation, and cellular proliferation. KIT plays a critical role in the development and maintenance of components of hematopoiesis, gametogenesis, and intestinal pacemaker cells.<sup>13–15</sup> Oncogenic *KIT* mutations have been identified as molecular drivers of neoplasms corresponding to these functions, including mast cell tumors, myelofibrosis, chronic myelogenous leukemia, germ cell tumors, and GIST.<sup>13</sup> Mutated KIT remains constitutively active even in the absence of ligand binding and results in both unregulated cell growth and malignant transformation.<sup>11</sup>

GISTs are identified by immunohistochemical staining for the CD117 antigen, part of the KIT receptor (Fig. 33-2). CD117 expression is characteristic of most GISTs, but not of other gastrointestinal smooth muscle tumors such as leiomyosarcoma, which are more likely to express high levels of desmin and smooth muscle actin.<sup>13–16</sup> Application of CD117 staining as a diagnostic criterion for GIST has heightened understanding of disease prevalence but is an imperfect isolated surrogate for GIST diagnosis. Some GISTs may stain strongly for KIT (CD117) by immunohistochemistry (KIT-positive) yet lack *KIT* mutations,<sup>13</sup> while others that do not stain for KIT (KIT-negative) may nevertheless harbor *KIT* mutations.<sup>17</sup>

**FIGURE 33-2** Immunohistochemistry to detect c-KIT expression. Immunohistochemistry to detect expression of KIT (CD117) is present in approximately 95% of GIST and varies among tumors from predominantly cytoplasmic (left), to perinuclear and dot-like (right). Variable expression within a given tumor also occurs (right).

Over 85% of GISTs have activating *KIT* mutations (Fig. 33-3).<sup>13</sup> These mutations commonly occur in exon 11 (in 57% to 71% of cases), exon 9 (10% to 18%), exon 13 (1% to 4%), and exon 17 (1% to 4%).<sup>18–21</sup> GISTs with *KIT* exon 9 mutations predominantly arise in the small intestine, and homozygous mutant GISTs are often associated with recurrent disease. Mutations in exon 11 may include deletions, insertions, single-base substitutions, and various combinations of these and are associated with variable rates of disease recurrence following complete resection.<sup>22–25</sup> Deletion mutations in exon 11 are an independent adverse prognostic factor, with worse prognosis than those with point mutations.<sup>26–28</sup> Deletions specifically involving codon 557 and 558 are considered mutational “hotspots” and are associated with more aggressive and often metastatic behavior.<sup>29–30</sup>

**FIGURE 33-3** KIT and PDGFRA mutations in GIST. KIT and PDGFRA mutations in GIST produce constitutive ligand-independent receptor activation. Response to tyrosine kinase inhibitors correlates with the location of the activating mutation, with best response in patients whose tumors contain mutations in KIT exon 11.

Approximately 35% of neoplasms lacking *KIT* mutations have activating mutations in a gene encoding a related receptor tyrosine kinase, the platelet-derived growth factor receptor alpha (*PDGFRA*).<sup>31–33</sup> *PDGFRA* mutations have been identified in exon 12 (1% to 2% of GISTs), exon 18 (2% to 6%), and exon 14 (<1%).<sup>31,34</sup> *KIT* and *PDGFRA* mutations are mutually exclusive events in GIST pathogenesis. However, no differences in the activation of downstream signaling intermediates have been observed between *PDGFRA*-mutant and *KIT*-mutant tumors, suggesting that both pathways result in parallel oncogenic molecular signals. Substitution of valine (V) for aspartic acid (D) at codon 842 in exon 18 accounts for 70% of all *PDGFRA* mutations and is associated with imatinib resistance.<sup>35</sup> GISTs harboring a *PDGFRA* exon 18 D842V mutation have been shown to have a gastric location predilection, have a lower risk of recurrence than GISTs with *KIT* mutations, and tend to have a more indolent course.<sup>36</sup>

Finally, wild-type (WT) GISTs exhibit no detectable *KIT* or *PDGFRA* mutations, and have alternate pathways for pathogenesis. Additional putative mutations have been identified to molecularly characterize this group of emerging GIST tumors. These include mutations in *BRAF* V600E exon 15 and insulin-like growth factor-1 receptor overexpression.<sup>37,38</sup> Mutations in

succinate dehydrogenase (SDH) subunits and type 1 neurofibromatosis (NF1) genes have also been linked with GIST oncogenesis (see discussion below).<sup>39</sup>

## EPIDEMIOLOGY

### Incidence

Investigators have attempted to determine the true incidence of GIST using the Surveillance, Epidemiology, and End Results (SEER) database from the National Cancer Institute. However, these data are difficult to interpret since many GISTs were previously misclassified as other gastrointestinal mesenchymal neoplasms.<sup>40</sup> Although a near doubling of the incidence of all gastrointestinal mesenchymal tumors (over 80% were GIST) has been reported (0.17/100,000 in 1992 to 0.31/100,000 in 2002), this may be due to a combination of increased recognition, increased screening, and/or true increased incidence.<sup>40</sup> The annual incidence in the United States is estimated to be approximately 5000 new cases per year.<sup>41</sup> European population-based studies identify annual incidence rates ranging from 11 to 14.5 cases per million population.<sup>6,42</sup>

### Age

The median age at diagnosis of GIST is 60 years (range 58-65 years).<sup>2,6</sup> There is a slight male predominance, and there is no significant racial or ethnic predilection. GIST does occur rarely in children (1.4%-2.6% of cases), often as a familial syndrome or as part of Carney's triad (see below).<sup>43,44</sup> The clinical presentation is typically different in children and tends to present with multifocal epithelioid gastric GISTs, harbor wild-type *KIT/PDGFR*A genes, and have a higher incidence of lymph node metastases.<sup>37</sup>

### Hereditary GIST

The overwhelming majority of GISTs are sporadic. Nevertheless, families with germline *KIT* and *PDGFR*A mutations have been reported.<sup>45-53</sup> Individuals with GISTs secondary to familial germline *KIT* mutations are

usually younger than those with sporadic GISTs, manifest multifocal disease at presentation, and rarely develop metastatic disease.<sup>52</sup> This phenotype includes skin hyperpigmentation and diffuse hyperplasia of the intestinal myenteric plexus and is associated with a germline *KIT* exon 11 mutation.<sup>54</sup> Mutations in exons 8, 13, and 17 have also been identified at the germline level with constitutive activation resulting in variable phenotypes including dysphagia, urticarial pigmentosa, and macrocytosis.<sup>55–57</sup>

Germline *PDGFRA* mutations are less common and have been reported to affect exon 12.<sup>53</sup> These individuals have congenitally enlarged hands, small intestinal polyps, fibroid tumors, and lipomas.

Von Recklinghausen neurofibromatosis type 1 (NF1) is the most common autosomal dominant inherited disorder and is characterized by a spectrum of clinical features including cutaneous neurofibromatosis, café-au-lait macules, axillary and inguinal freckling, ocular hamartomas, and benign and malignant intestinal tumors.<sup>55</sup> Approximately 7% of these individuals have multifocal GISTs, most commonly in the small intestine.<sup>56–58</sup> In addition to their *NF1* mutations, these individuals express *KIT* and *PDGFRA* point mutations in 8% and 6% of GISTs, respectively.<sup>59</sup> Conversely, *NF1* mutations have not been identified in non-NF1 individuals with sporadic GISTs.<sup>60</sup>

Gastric GISTs are components of both Carney's triad and Carney–Stratakis syndrome. Fewer than 100 cases of Carney's triad, consisting of gastric GISTs, pulmonary chondromas, and extra-adrenal paragangliomas, have been reported.<sup>44,61</sup> Esophageal leiomyomas and adrenal cortical adenomas have recently also been added as elements of this syndrome.<sup>44</sup> Approximately 85% of cases occur in women and 80% are diagnosed before age of 30. Patients with Carney's triad lack germline *KIT* or *PDGFRA* mutations; however, chromosome 1 deletions of 1q12 to 1q21 involving the *SDH* gene and the 1p region have been implicated in the pathogenesis of this syndrome. GISTs seen in these patients are typically multifocal and are more likely to manifest lymph node metastases.

The similarly eponymous Carney–Stratakis syndrome describes familial cases expressing the dyad of gastric GIST and paraganglioma.<sup>46</sup> Recently, inactivating germline mutations in several *SDH* subunits have been reported in Carney–Stratakis syndrome kindreds and are reflected as a characteristic clinical picture.<sup>62</sup>

## CLINICAL PRESENTATION

Primary GISTs commonly arise in the stomach (50% to 70%), small intestine (25% to 35%), colon and rectum (5 % to 10%), mesentery or omentum (7%), and esophagus (<5%).<sup>10,63</sup> Occasionally, GISTs may arise in the duodenal ampulla, appendix, gallbladder, and urinary bladder.<sup>64–69</sup>

GISTs are generally found due to symptoms. In a large population-based study, 69% of tumors were symptomatic, 21% were discovered incidentally at surgery, and 10% were discovered at autopsy.<sup>6</sup> Primary extragastrointestinal GISTs are rare (<10% of cases) and may be the sequela of a yet unrecognized primary gastrointestinal tumor. These GISTs usually present in the omentum or mesentery and have a more aggressive clinical course compared with similar-sized gastric counterparts.<sup>70</sup>

GISTs are often highly vascular, soft, and friable, and bleeding is therefore a common complaint. Other common presenting symptoms may include abdominal pain, distension suggestive of obstruction, or a palpable mass. GISTs may cause life-threatening hemorrhage by erosion into the gastric or bowel lumen. Alternatively, tumor rupture may cause potentially catastrophic intraperitoneal bleeding and/or dissemination by peritoneal seeding. Intestinal obstruction may lead to perforation. Small tumors may remain asymptomatic and be incidentally detected on radiographic studies, endoscopy, or laparotomy.

Between 15% and 47% of patients with GIST have metastatic disease at diagnosis.<sup>2,71</sup> Common sites of metastasis include liver, peritoneum, and omentum; lymph node metastases are rare.<sup>5</sup> Extra-abdominal metastases (lung, bone, subcutaneous tissues, and brain) are rare, observed in approximately 5% of patients.<sup>72</sup>

## DIAGNOSIS

### Radiographic Studies

The initial imaging study for a suspected or confirmed GIST is a contrast-enhanced computed tomography (CT) scan of the abdomen and pelvis.<sup>73</sup> Primary GISTs are typically well-circumscribed masses located within the

wall of hollow viscera and may appear heterogenous due to the presence of necrosis or intratumoral hemorrhage, particularly in large tumors (Fig. 33-4). Magnetic resonance imaging (MRI) may help to characterize metastases to the liver or primary perirectal disease (Fig. 33-5). [<sup>18</sup>F]fluoro-2-deoxy-D-glucose positron emission tomography combined with CT (FDG PET-CT) may be helpful to characterize masses that are ambiguous on CT, to monitor response to tyrosine kinase inhibitor therapy, and to detect emergence of drug-resistant clones. However, its diagnostic test characteristics are sensitive but not specific, a profile that is not recommended for initial identification or staging of suspected primary disease.<sup>74-76</sup>

**FIGURE 33-4** CT image of primary gastric GIST presenting as an exophytic mass (arrow) off of the greater curvature of the stomach.

**FIGURE 33-5** MRI image of GIST along right posterolateral rectal wall (arrow).

## **Endoscopy, Fine-Needle Aspiration, and Biopsy**

Endoscopically, a primary GIST may appear as a submucosal lesion, with or without ulceration, present in the upper or lower gastrointestinal tract. They are often indistinguishable from other gastrointestinal tumors of smooth muscle origin, such as leiomyomas (Fig. 33-6). Endoscopic ultrasound (EUS) is not necessary to evaluate a confirmed GIST. However, EUS-guided fine-needle aspiration (FNA) may be attempted to establish diagnosis. Nevertheless, EUS-FNA is not consistently diagnostic, with sensitivity approaching 80%.<sup>77</sup> Additional cytologic morphology, immunohistochemistry, and reverse-transcriptase polymerase chain reaction analysis for *KIT* mutations may be required to confirm a diagnosis.<sup>78</sup>

**FIGURE 33-6** Endoscopic image of incidentally identified primary gastric GIST, presenting as an asymptomatic submucosal mass in the proximal stomach along the lesser curvature.

A preoperative biopsy is not routinely necessary for a primary, resectable neoplasm suspicious for GIST, particularly in the setting of ongoing symptoms. In fact, preoperative biopsy, either endoscopic or percutaneous, may rupture a suspected GIST and increase risk of dissemination and bleeding. However, if the differential diagnosis includes entities such as nonoperatively treated lymphoma, if preoperative diagnosis is required for targeted neoadjuvant therapy, or if there is suspected metastatic disease, biopsy is warranted.

## STAGING

The American Joint Committee on Cancer (AJCC) implemented formal staging for GISTs in 2010.<sup>79</sup> This schema is divided into two main groups based on location: gastric GISTs (also used for omentum), and small intestine GISTs (also used for esophagus, colorectal, mesentery, and peritoneum). This dichotomy is based on evidence of prognostic differences based on anatomic location.<sup>80-82</sup> The tumor, node, metastasis (TNM) classification is combined

with mitotic rate to determine individual tumor stage. Germline mutational status is not included in the current AJCC classification. This staging system has been validated and correlates with disease-free survival and overall survival, with tumor size and mitotic index being the most important prognostic factors.<sup>83</sup>

## PROGNOSTIC FACTORS AND RISK STRATIFICATION

The three established pathologic prognostic factors related to the risk for GIST metastases are tumor size, mitotic index (per 50 high-power field [HPF]), and tumor site of origin, with mitotic count being the most contributory (Table 33-1).<sup>16,80,84</sup> While tumors under 1 cm appear to be at a low risk of recurrence and progression, no tumors can be definitively called benign and most have malignant potential. Individuals with small bowel or colorectal GISTs have a higher risk of progression than those with gastric GISTs of comparable size and mitotic count. Several risk stratification schema have been suggested to categorize patient prognosis and recurrence risk based on pathologic features (Table 33-2).<sup>82,85-87</sup> However, predicting tumor behavior based on pathologic elements alone is suboptimal, and contemporary risk stratification aims to combine these features with molecular analysis in order to glean a more complete picture of biologic potential.

**TABLE 33-1: RISK ASSESSMENT FOR PRIMARY GASTROINTESTINAL STROMAL TUMORS**<sup>84</sup>

		% of Patients with Progressive Disease/Risk Classification, Based on Site of Origin			
Mitotic Rate	Tumor Size	Stomach	Duodenum	Jejunum/Ileum	Rectum
≤5 per 50 HPF	≤2 cm	0	0	0	0
	>2, ≤5 cm	1.9/very low	8.3/low	4.3/low	8.5/low
	>5, ≤10 cm	3.6/low	*	24/moderate	—*
>5 per 50 HPF	>10 cm	12/moderate	34/high	52/high	57/high
	≤2 cm	—*	—*	—*	54/high
	>2, ≤5 cm	16/moderate	50/high	73/high	52/high
	>5, ≤10 cm	55/high	—*	85/high	—*
	>10 cm	86/high	86/high	90/high	71/high

Risk of recurrence is based on data from the pre-imatinib era.

Additional adverse prognostic factors suggested include high cellular proliferation index (Ki-67),<sup>88</sup> aneuploidy,<sup>88,89</sup> telomerase expression,<sup>90,91</sup> *KIT* exon 9 mutations,<sup>80</sup> and *KIT* exon 11 deletions involving amino acid W557 and/or K558.<sup>92</sup> Point mutations and duplications of *KIT* exon 11 appear to have a favorable prognosis.<sup>80</sup> Exon 9 and 11 mutational status have also been shown to predict response to medical therapy and thereby influence clinical rates of progression and survival. In advanced GIST with *KIT* exon 11 mutations, approximately 90% of patients will respond to imatinib, whereas only 50% of exon 9 mutations will have a similar response, although dose-related response rates may be observed in the latter. Most GISTs with

*PDGFRA* mutations have a lower risk of recurrence and respond to imatinib, with the exception of the D842V substitution in exon 18.<sup>35</sup> Despite these mutational correlations with recurrence risk, evidence suggests that standard pathologic prognostic factors, particularly mitotic count, predict clinical outcomes more accurately than mutational analysis status, suggesting that no individual factor should be used in isolation.<sup>25</sup>

Completeness of surgical resection has also been suggested as a prognostic indicator. However, the ideal margin of resection is unknown. While a macroscopically complete resection with negative or positive microscopic margins (R0 or R1 resection, respectively) is associated with a better prognosis than a macroscopically incomplete resection (R2 resection), there are no data to confirm that a positive microscopic margin (R1 resection) impacts survival.<sup>2</sup>

## THERAPY FOR PRIMARY DISEASE

The modern management of GISTs is a multidisciplinary task. Patients should be treated in a center offering expertise in the surgical and medical management of disease, with available multidisciplinary cancer conferences to discuss nuances in clinicopathologic and immunohistochemical tumor profile and its influence on multimodality treatment sequencing.

### Active Surveillance

The management of gastric GISTs less than 2 cm in diameter is controversial, as their natural history is not known with certainty but is thought to be favorable. Two studies have shown that sub-centimeter gastric GISTs (microGISTs) are relatively common, detected in 22.5% of autopsies in adults over the age of 50 in Germany, and in 35% of patients undergoing gastrectomy for gastric cancer in Japan.<sup>93,94</sup> Despite their relative frequency, few of these neoplasms appear to become clinically relevant. Until further data are available, the most appropriate management of such small tumors remains uncertain.

In an Italian study comparing 170 GISTs  $\leq$  2 cm in size to 101  $>$  2 cm, the frequency of mitoses observed in individual tumors increased from 20% in  $<$  6 mm GISTs to 75% in 1.7- to 2.0-cm GISTs to 100% in  $>$  2-cm GISTs.<sup>95</sup>

Of the 170 small GISTs, 135 underwent mutational analysis. Key findings compared to larger GISTs were that 74% of small GISTs had *KIT* or *PDGFRA* mutations with an excess of wild-type cases, *KIT* exon 11 mutations were less common, and novel mutations were observed that have not been reported in clinically relevant GISTs >2 cm.<sup>95</sup>

Gastric tumors stratified as low risk based on clinical, pathologic, and molecular features may be considered for active surveillance alone. Decisions for surveillance alone should involve a multidisciplinary discussion with risks and benefits provided to the patient and documented in the medical record. Clinical and radiologic parameters invoking a transition to more aggressive management should also be reviewed.

If active surveillance is undertaken, current National Comprehensive Cancer Network (NCCN) guidelines suggest endoscopy with esophagogastroduodenoscopy (EGD) +/- EUS every 6 to 12 months. Presence of lesional growth to >2 cm, irregular extraluminal borders, ulceration, heterogenous echogenic foci, presence of cystic spaces, and/or development of symptoms should prompt reconsideration of the management strategy.<sup>96</sup> European Society for Medical Oncology (ESMO) guidelines recommend annual surveillance with EUS for presumed <2 cm GISTs, and EUS-FNA may be offered.<sup>97</sup> If a diagnosis of GIST is confirmed, then surgery should be offered. If the patient prefers no surgery, then observation should continue, though an evidence-based optimal surveillance policy is lacking.<sup>97</sup>

Japanese guidelines have been developed based on extensive population-based endoscopic surveillance for gastric cancer and distinguish between EGD and EUS findings. Gastric submucosal tumors <2 cm without the malignant findings on EGD of ulceration, irregular margins, or rapid growth may be followed with EGD surveillance once or twice per year.<sup>98,99</sup> Tumor growth or presence of malignant findings on EGD warrants either surgery or further workup, including CT, EUS, or EUS-FNA. Malignant findings on EUS (heterogeneous parenchyma or irregular margins) or confirmation of GIST by EUS-FNA are indications for surgery. Patients with submucosal lesions without confirmation of a diagnosis of GIST and without malignant findings on EUS may be offered surgery or ongoing surveillance.

## **Surgery**

Surgery remains the standard of care and the only potentially curative option for patients with primary, resectable, localized GISTs. All patients with GISTs  $\geq 2$  cm, symptomatic tumors, and all GISTs of non-gastric origin should be considered for surgical resection and adjuvant medical treatment. Oncologic principles of safe surgical practice prevail, and the primary goal of the operation is to resect all tumor with macroscopically and microscopically negative margins (R0). Tumors should be handled with a “no-touch” technique, as rupture or violation of the tumor pseudocapsule during surgery is associated with increased risk of recurrence and bleeding. Formal lymphadenectomy is rarely required, except in pediatric populations where lymph node metastases may be more prevalent.<sup>100,101</sup>

The extent of surgical resection is governed by the size of the tumor in relation to anatomic location, and the ability to safely restore gastrointestinal continuity. Sphincter and organ preservation is preferred, although locally advanced GISTs should be approached with an en bloc resection of adjacent organs in order to minimize potential violation of the tumor, if necessary. In such cases, surgical resection is often preceded by medical therapy to promote tumor shrinkage and minimize the extent of resection, as described below. The extent of surgery is usually a wedge or segmental resection of the involved stomach or bowel, without the wide margins necessary for corresponding adenocarcinoma. In a series of 140 patients with gastric GISTs, wedge resections were performed in 68%, partial gastrectomies in 28%, and total gastrectomies in only 4%.<sup>102</sup> Occasionally, more extensive resection (total gastrectomy for a large proximal gastric GIST, pancreaticoduodenectomy for a periampullary GIST, or abdominoperineal resection for a low rectal GIST) may be necessary.

Regardless of whether an open or laparoscopic resection is planned, GISTs are approached in a similar fashion using preoperative imaging as a guide. The abdomen is first thoroughly explored to identify involved organs and remove any previously undetected peritoneal metastatic deposits. Although primary GISTs may demonstrate inflammatory adhesions to surrounding structures, they do not generally invade other organs beyond the site of origin, despite ominous CT appearance. Nasogastric suction, preoperative tattooing, and intraoperative EGD can be considered as adjuncts to assist in the accurate localization of the GIST and in the achievement of R0 resection.

Although endoscopic resection of small gastric GISTs has been reported,

this is not recommended.<sup>103</sup> Unlike early gastric adenocarcinomas limited to the mucosa and amenable to endoscopic mucosal resection, GISTs involve the muscularis propria. Therefore, endoscopic resection risks leaving a positive deep margin, and due to the depth of the lesion may result in gastrointestinal perforation. Such endoscopic resections have been reported for the most part for small GISTs, a group of tumors for which surgery may not even be indicated.<sup>104</sup> Therefore, such techniques should be approached with a great deal of caution and are not recommended by any major international guidelines.

Laparoscopic or laparoscopy-assisted resection of primary GISTs continues to evolve and may be considered if standard oncologic principles can be maintained (Fig. 33-7). Two early studies confirmed both the safety and feasibility of a laparoscopic approach.<sup>105,106</sup> A recent meta-analysis by Koh et al. supports laparoscopic resection as a safe and feasible approach with no differences in margin positivity, recurrence-free survival (RFS) or overall survival (OS) when compared to open resections. Additionally, laparoscopic resections frequently had shortened stays in hospital and lower intraoperative blood loss.<sup>107</sup> However, decisions for technical operative approach must balance perioperative factors with oncologic safety. Evaluation of patient comorbidity, anatomic tumor location, surgeon expertise, and ability to convert to an open approach should be included in preoperative decision-making. When laparoscopic and laparoscopy-assisted approaches are undertaken, modified lithotomy or split-leg positioning should be considered for heightened visualization and organ manipulation. In addition, an angled camera and roticulating laparoscopic stapler may assist in the safe resection and extraction of the tumor.

**A**

**B**

**FIGURE 33-7** Laparoscopic image of gastric GIST along greater curvature of stomach (arrows) isolated between traction sutures (**A**) and with stomach

partially divided using linear stapler (**B**).

The goal of surgery for GIST is to perform a margin-negative resection. However, unlike for visceral adenocarcinomas or sarcomas at other sites, wide margins are unnecessary. Wide margins beyond a R0 resection have not been definitively linked with improvements in survival or recurrence, particularly in the era of effective medical therapy. There are also no data indicating that patients with an R1 (microscopically involved) resection require re-excision.<sup>41</sup> Margins may retract after resection and chemical fixation, and the pathologist may resect a staple line ex vivo, thereby converting a microscopically negative margin into a positive one. As such, all cases of positive microscopic margins should be reviewed by a multidisciplinary team to assess the need for re-excision with careful consideration of anatomic feasibility, biologic risk profile, and patient comorbidity.

## **OUTCOMES**

Despite macroscopically complete resection, as many as 50% of individuals may develop recurrent disease at a median of 24 months.<sup>2,108</sup> An R0 or R1 resection is associated with 5-year OS rates of 34% to 63%, whereas R2 resection is associated with 5-year OS as low as 8%.<sup>1,2,109,110</sup> However, these series do not apply current standards of adjuvant medical therapy and are likely underestimates of contemporary survival rates.

## **Neoadjuvant Therapy for Primary Disease**

The development of the effective, well-tolerated, orally available targeted tyrosine kinase inhibitor (TKI), imatinib mesylate (STI571, Gleevec, Novartis Pharmaceuticals) has revolutionized the treatment of GIST. This agent was initially developed for the management of patients with metastatic disease; however, suggested efficacy in neoadjuvant and adjuvant settings has greatly expanded its clinical utility. Imatinib selectively inhibits several tyrosine kinases, including KIT, PDGFRA, and BCR-ABL.<sup>20,111,112</sup> Several clinical trials have confirmed that up to 80% of patients with metastatic GIST achieve a complete or partial response or demonstrated stable disease on imatinib.<sup>113,114</sup> This prompted initial consideration of imatinib use as a tool to

promote tumor shrinkage and facilitate surgical resection.

There are several scenarios to support the neoadjuvant use of TKI in GISTs. While neoadjuvant therapy may not change the extent of gastric resection required, it may convert an operation requiring an open laparotomy to one performed laparoscopically or laparoscopy-assisted. In addition, in cases with locally advanced and/or unresectable tumors, imatinib is the first-line therapy, with intent to reconsider the role of surgical therapy after at least 6 months. After tumor shrinkage, individuals may be amenable to R0 resection, sphincter preservation, and/or organ sparing.

The role of neoadjuvant therapy with imatinib followed by surgical resection has been explored in several trials.<sup>115–119</sup> In 2009, the Radiation Therapy Oncology Group (RTOG) 0132 phase II trial was the first multi-institutional, prospective study evaluating the use of neoadjuvant and adjuvant imatinib in the treatment of primary GIST (tumors  $\geq 5$  cm; group A) and recurrent or metastatic GIST (tumors  $\geq 2$  cm; group B).<sup>88</sup> Patients were treated with imatinib (600 mg/day) for 8 to 12 weeks prior to surgery and then maintained on adjuvant imatinib for 2 years (Table 33-3). Preoperative imatinib therapy resulted in stable disease in 83% and 91% of patients in group A ( $n = 30$ ) and group B ( $n = 22$ ), respectively. Long-term follow-up results have shown an estimated 5-year progression-free survival (PFS) and OS of 57% in group A, 30% in group B, and 77% in group A, 68% in group B, respectively.<sup>119</sup> Two- and 5-year disease-specific survival (DSS) rate estimates for group A were 93.5% and 76.9% and for group B were 90.9% and 68.2%, respectively. Of note, in group A, 7 of 11 patients, and in group B, 6 of 7 patients who exhibited disease progression did so after discontinuation of imatinib following 2 years of treatment.

McAuliffe and colleagues from M.D. Anderson Cancer Center (MDACC) reported results of a phase II, single-institution trial investigating neoadjuvant imatinib in patients with primary and metastatic GIST  $\geq 1$  cm.<sup>116</sup> With a

hypothesis that molecular mechanisms of imatinib efficacy are initiated *prior* to detectable histopathologic cytoreduction, 12 patients with primary GIST and 5 patients with metastatic GIST were randomized to receive 3, 5, or 7 days of preoperative imatinib (600 mg/day) followed by 2 years of postoperative adjuvant imatinib. In addition to a radiographic response in all patients within the first week of treatment, tumor cell apoptosis was increased in treated patients when compared to treatment-naïve patients, and this also correlated with duration of treatment.

The German APOLLON study is a prospective, phase II, open-label trial that investigated the overall tumor response and progression rate of disease in patients with locally advanced, non-metastatic KIT- or PDGFRA-positive GISTs.<sup>117</sup> Patients received neoadjuvant imatinib (400 mg/day) for 6 months and *no* postoperative adjuvant therapy. Thirty-four patients underwent resection, 30 with a R0 resection. Results demonstrate that when compared to imaging performed after the first 2 months of neoadjuvant treatment, the operation required was significantly downstaged in the majority of patients after 6 months of neoadjuvant imatinib treatment.

The largest retrospective study to date comprises 161 patients pooled from 10 European Organization for Research and Treatment of Cancer (EORTC) and Soft Tissue and Bone Sarcoma Group (STBSG) databases.<sup>118</sup> All patients were treated with neoadjuvant imatinib (400 mg/day) until a “maximal response” was achieved, defined as two consecutive CT scans showing stable disease (median 40 weeks; range 6-190 weeks). A R0 resection was obtained in 83% of patients and adjuvant therapy was continued in 56% of patients for at least 1 year. Five-year disease-free survival (DFS) was 65% and 5-year OS and DSS from the start of imatinib therapy were 87% and 95%, respectively.

Neoadjuvant trials of advanced GIST have demonstrated that maximal radiographic response to imatinib generally required 6 to 9 months of treatment.<sup>113,120,121</sup> Thus, the optimal preoperative imatinib regimen may be 6 months or more as long as continued radiographic response is observed (Fig. 33-8).

**A**

**B**

**FIGURE 33-8** Patient with primary gastric GIST before (**A**) and after (**B**) 9 months of neoadjuvant imatinib. Neoadjuvant therapy resulted in dramatic tumor shrinkage.

A recent retrospective review by Tirumani and colleagues identified the timing of the earliest, best, and plateau response to neoadjuvant imatinib.<sup>122</sup> Of 20 patients receiving neoadjuvant imatinib (400 mg/day), 16 showed a partial response and 4 showed stable disease during a median treatment course of 32 weeks. The best response to neoadjuvant imatinib was an 83% reduction in volume at a median interval of 28 weeks, irrespective of tumor size and location. Ten patients who reached a plateau response did so at a median interval of 34 weeks, with the best response noted at 19 weeks. The authors conclude that once a tumor response reaches a plateau, a patient should be considered for surgery, as further tumor response is unlikely and thus the scope of the resection is likely not to change further.

Current NCCN guidelines recommend initial starting dose of imatinib at 400 mg/day, with consideration of 800 mg/day for patients with *KIT* exon 9 mutation to improve response rates. Monitoring of response to neoadjuvant imatinib by PET-CT or CT is completed at 3-monthly intervals until there is stable disease on two consecutive scans or when progression is documented despite escalation of imatinib dose (plateau response).<sup>96</sup> These recommendations lack supporting evidence and do not provide an optimal time frame for surgical resection. Decisions to proceed to surgery or remain on imatinib should be made jointly by surgeon and medical oncologist using PET-CT or CT scan as evidence of stability, response, or progression. If surgical therapy is planned, imatinib may be stopped just prior to surgery and reinitiated with the resumption of gastrointestinal function.

At present, there have been no trials specifically addressing the use of other TKIs including sunitinib malate (SU11248, Sutent, Pfizer, Inc.) or regorafenib (Stivarga, Bayer) in the neoadjuvant setting. Although data from the metastatic setting and algorithms for progressive use of TKIs are applied to locally advanced tumors, the isolated and/or additive effect of these second- and third-line agents on DFS and/or OS is yet undefined.

## **Adjuvant Therapy for Primary Disease**

The role of adjuvant therapy with imatinib combined with surgical resection of primary disease has been explored in several prospective randomized multiinstitutional trials. The trials tested durations of adjuvant imatinib of 12 months (American College of Surgeons Oncology Group Z9000,<sup>92</sup> ASOSOG

Z9001,<sup>93</sup> China Cooperative Group<sup>94</sup>), 24 months (EORTC 62024, Korean trial<sup>95</sup>), 12 versus 36 months (Scandinavian Sarcoma Group [SSG] XVIII), or 5 years (ongoing phase II multi-institutional trial, PERSIST/CSIT571BUS282) (Table 33-3).<sup>123–125</sup>

The American College of Surgeons Oncology Group (ACOSOG) trial Z9000 was the first phase II trial to investigate the use of adjuvant imatinib (400 mg/day) for 12 months after complete resection in patients with high-risk GISTs.<sup>123</sup> High risk was defined as tumor diameter of 10 cm or more, intraperitoneal tumor rupture, or up to four peritoneal implants. At a median follow-up of 7.7 years, RFS rates at 1, 3, and 5 years were 96%, 60%, and 40%, respectively, and OS rates were 99%, 97%, and 83% at 1, 3, and 5 years, respectively. The authors concluded that adjuvant imatinib for 12 months in patients with primary GIST who are at a high risk of recurrence prolongs overall survival when compared to historical controls. However, the optimal duration of adjuvant therapy could not be determined.

In 2009, results from the ACOSOG trial Z9001, the first phase III, randomized, placebo-controlled, multicenter trial were published.<sup>124</sup> In this trial, 713 patients who underwent resection of a primary GIST  $\geq 3$  cm were randomized to receive imatinib (400 mg/day) or placebo for 12 months after surgery. RFS was significantly longer in the imatinib arm compared to the placebo arm in all risk categories (97% vs 83%,  $p = 0.0000014$ ). The trial was stopped early due to encouragingly positive results at interim analysis, with a shortened median follow-up of 19.7 months. Interestingly, once recurrences were observed, the slopes of the Kaplan–Meier survival curves for both treatment arms were similar. This suggests that adjuvant imatinib delays recurrence, but overall disease trajectory remains unchanged. No significant difference in overall survival was observed between the two arms. The results of this study led to the approval of imatinib in the adjuvant setting by the US Food and Drug Administration for GISTs  $\geq 3$  cm, but with poor guidance on optimal treatment duration.

The SSG XVIII trial is a phase III prospective, randomized, open-label trial that evaluated 12 versus 36 months of adjuvant imatinib (400 mg/day) following resection of high-risk GISTs.<sup>126</sup> High-risk GISTs in this study were defined as tumor diameter  $>10$  cm, mitotic count  $>10/50$  HPF, tumor size  $>5$  cm with mitotic rate  $>5/HPF$ , or tumor rupture. With a median duration of follow-up of 54 months, patients treated with 36 months of imatinib had a

significantly longer 5-year RFS compared to 12 months of treatment (66% vs 48%,  $p < 0.01$ ). Most importantly, overall survival was found to be significantly better in the 36-month treatment group (92% vs 82%,  $p = 0.02$ ), which was the first time an overall survival benefit associated with the use of adjuvant imatinib was reported. However, there was no difference in DSS.

The Intergroup EORTC 62024 trial is a phase III, randomized, open-label trial comparing 2 years of adjuvant imatinib with observation in patients with intermediate- or high-risk GISTs.<sup>127</sup> Following surgical resection, patients were randomized to receive imatinib (400 mg/day) or observation alone. With a preliminary reported median follow-up of 4.7 years, no significant difference was observed in the 5-year imatinib failure-free survival ( $p = 0.23$ ). However, a subset analysis of patients with high-risk GIST showed a trend in favor of imatinib treatment ( $p = 0.11$ ). RFS at 3 and 5 years was significantly longer in the imatinib treatment group ( $p < 0.001$ ), but there was no difference in 5-year OS.

The PERSIST-5/CSIT571BUS282 trial is a phase II trial examining the use of imatinib (400 mg/day) after complete surgical resection in patients with primary GIST  $\geq 2$  cm with a mitotic rate  $\geq 5/50$  HPF or non-gastric primary GIST  $\geq 5$  cm. Accrual is complete but preliminary results on RFS have yet to be reported.<sup>128</sup>

The results of the Z9001 and SSG XVIII trials led to guideline recommendations of adjuvant imatinib for at least 3 years for patients with intermediate or high risk of GIST recurrence.<sup>96</sup> However, optimal adjuvant imatinib treatment length is still unknown.

Perhaps the most important question is whether administration of imatinib after complete resection of primary disease or after disease recurrence delays time to second- or third-line therapy. In addition, combining the data for sequential targeted medical therapies with more granular data on the behavior of different mutational subtypes lends increasing complexity to this clinical scenario.

## **THERAPY FOR ADVANCED DISEASE**

The majority of GIST recurrences occur in the first 5 years following surgical resection. In a pooled analysis of 10 series including 1625 patients undergoing surgical resection in the absence of adjuvant imatinib treatment,

the 5-, 10-, 15-, and 20-year recurrence-free survival rates were 70.5%, 62.9%, 59.9%, and 57.3%, respectively.<sup>126</sup> Up to two-thirds of these patients with a recurrence will have liver metastases and approximately half will have peritoneal disease.<sup>129</sup> Historically, patients with recurrent and metastatic GIST have been treated by a combination of the three traditional cancer therapeutic modalities: surgery, intravenous chemotherapy, and radiotherapy. Surgery may be effective for patients with resectable disease, but disease may recur in as many as 50% of individuals at a median of 24 months. Traditional intravenous chemotherapy (including standard sarcoma regimens employing doxorubicin +/- ifosfamide) and radiotherapy show poor efficacy.<sup>1,2,121</sup>

## **Imatinib Therapy for Recurrent and Metastatic Disease**

To date, three TKIs have been approved for the treatment of metastatic GIST: imatinib mesylate, sunitinib malate, and regorafenib. Imatinib is the first-line therapy for advanced (unresectable primary, recurrent, or metastatic) GIST, based on data from international phase I, II, and III trials.<sup>75,113,114,120,130</sup> The initial report of successful treatment of metastatic GIST in 2001 determined the efficacy and optimal dosing of imatinib.<sup>131</sup> Subsequently, the Intergroup B2222 trial, a phase II, randomized, open-label, multicenter trial that compared imatinib doses of 400 mg/day and 600 mg/day in patients with advanced disease, was completed.<sup>121</sup> With a median follow-up of 63 months, 2 of 147 patients (1.4%) achieved a complete response and 98 of 147 patients (67%) demonstrated a partial response, with no significant difference in response rates between the two doses. There was no difference in PFS and OS between the two groups. Median time to progression was 24 months and median OS was 57 months for all patients.

The subsequent phase III, randomized, open-label S0033 trial compared outcomes of imatinib 400 mg/day to 800 mg/day in patients with advanced GIST.<sup>113</sup> A total of 746 patients were enrolled in this multicenter study with a median follow-up 4.5 years. There were no significant differences in response rates between the two treatment arms. Median PFS was 18 months for patients on 400 mg/day dosing and 20 months for the high-dose arm ( $p = 0.13$ ) and the median OS rates were 55 and 51 months for lower and higher dosing arms, respectively ( $p = 0.83$ ). After progression on low-dose imatinib,

33% of patients who crossed over to the high-dose regimen achieved either objective response or stable disease. Subgroup analysis of this crossover group demonstrated a further median PFS of 5 months and an additional median OS of 19 months after dosage increase.

The similarly designed EORTC phase III randomized trial compared daily imatinib 400 to 800 mg dosing.<sup>114</sup> With a median follow-up of 760 days, the 2-year PFS rates were 56% and 50% ( $p = \text{NS}$ ) and 2-year OS rates were 69% and 74% ( $p = \text{NS}$ ) for low- and high-dose regimens, respectively. There was no significant difference in response rates between the two groups.

A meta-analysis combining the results from the EORTC and S0033 trial (MetaGIST) demonstrated a slight advantage in PFS in patients initially treated with the higher, 800 mg/day, imatinib dose ( $p = 0.17$ ).<sup>132</sup> This PFS advantage was only demonstrated in patients with *KIT* exon 9 mutations, and that was the only factor predicting benefit from the high-dose regimen in multivariable analysis. There was no significant difference in OS. The PFS curves demonstrated that the majority of the improvement appeared within the first 2 years of high-dose treatment. It should be noted that almost 50% of patients in the high-dose treatment arm required dose reduction within 6 months due to medication intolerance or toxicity.

Based on the results of these clinical trials, the current standard of care for advanced GIST is imatinib starting at a dose of 400 mg/day. Imatinib at 800 mg/day (dosed as 400 mg twice daily) should be considered as starting dose for patients with advanced GIST with a confirmed *KIT* exon 9 mutation. Correlation of kinase genotype and dose selection has been confirmed by analysis of data from both the S0033 and EORTC trials.<sup>133,134</sup> Of note, these two studies found that patients with *KIT* exon 11 mutations are more likely to have a partial response and have a longer PFS than those with a *KIT* exon 9 mutation or WT GIST.

Once imatinib therapy is initiated for the treatment of advanced GIST, it should be continued indefinitely. The French BFR14 trial was a phase III, randomized, open-label, multicenter trial evaluating the effect of imatinib interruption in patients with advanced GISTs.<sup>135,136</sup> Patients with nonprogressive disease who were randomized to interruption of imatinib therapy after 1 and 3 years had a much higher rate of disease progression than those who continued therapy. Of those patients randomized to the imatinib continuation treatment arm after 1 year of treatment, progression was noted in

31% of patients compared to 81% in the interruption arm. When imatinib was reintroduced in the interruption arm, 92% responded. Following 3 years of treatment with imatinib, the 2-year PFS was 80% in the continuation group and 16% in the interruption group ( $p < 0.0001$ ) after a median follow-up of 35 months. Data presented for interruption of imatinib treatment after 5 years demonstrated that 45% of patients relapsed during the first year of follow-up, whereas no further progression was noted in any patient assigned to the continuation treatment arm ( $p = 0.032$ ).<sup>137</sup> Based on these results, it is clear that imatinib should be continued until disease progression or treatment-related toxicities become intolerable.

A recent phase III, randomized, double-blind, single institution trial was completed to assess the efficacy of imatinib rechallenge in patients who progressed on TKI.<sup>138</sup> After a short median follow-up of 5.2 months, median PFS was 1.8 months with imatinib compared with 0.9 months with placebo ( $p = 0.005$ ). The median PFS improved to 1.7 months in 37/40 patients randomized to the placebo group who crossed over to imatinib treatment. No significant difference, however, in OS was demonstrated between imatinib and placebo groups (8.2 vs 7.5 months, respectively;  $p = 0.92$ ). The authors concluded that in patients with GISTs that are refractory to treatment with all standard tyrosine kinase inhibitors, the disease may continue to harbor clones that are still sensitive to kinase inhibitors, and continued imatinib treatment may slow progression.

## Therapy for Imatinib Resistance

While imatinib benefits the majority of patients with advanced GISTs, there is a subset of patients who fail to demonstrate an initial response, and/or who progress while on imatinib. Primary resistance is defined as evidence of clinical progression during the first 6 months of imatinib therapy, and occurs in approximately 14% of patients with advanced GISTs.<sup>75</sup> Primary resistance is most commonly seen in patients with WT-GISTs, with mutations involving *KIT* exon 9, or with a D842V mutation in *PDGFRA* exon 18.<sup>139</sup> Eventually, most patients develop secondary resistance, which occurs in patients who have been treated with imatinib for longer than 6 months with an initial response who then develop progressive disease. Secondary *KIT* mutations most commonly occur in *KIT* exons 13, 14, and 17 and a D842V mutation in

*PDGFRA* exon 18.<sup>139–143</sup> Acquisition of secondary KIT mutations has been shown to confer imatinib resistance by either directly altering the adenophosphate triphosphate (ATP)/drug-binding pocket or by interfering with access to this pocket through conformational changes in the activation loop of the kinase. Other mechanisms of imatinib resistance involve the KIT-dependent and -independent process by KIT gene amplification and complete loss of KIT expression. Resistance is managed by increasing imatinib dose to 800 mg/day or switching to a second- or third-line agent.

Sunitinib is indicated as a second-line therapy for patients with advanced GISTs who progress on or become intolerant to imatinib. Sunitinib is a tyrosine kinase inhibitor that targets KIT, PDGFR, vascular endothelial growth receptor (VEGFR1, VEGFR2, VEGFR3), the ret proto-oncogene receptor (RET), and Fms-like tyrosine kinase-3 receptor (Flt3). A phase III, randomized, placebo-controlled trial evaluated outcomes in patients receiving sunitinib for advanced GISTs after failure and discontinuation of imatinib.<sup>139</sup> Significant improvement in time-to-progression in patients treated with sunitinib was demonstrated when compared to those treated with placebo (27.3 weeks vs 6.4 weeks, respectively;  $p < 0.0001$ ), as well as PFS and OS. Sunitinib in this study was administered for 4 weeks followed by 2 weeks off treatment. A phase II, open-label, single arm study has since evaluated the efficacy of continuous, daily dosing of sunitinib at a dose of 37.5 mg/day.<sup>144</sup> The study reported a complete response rate of 53%, partial response 13%, and 40% achieved stable disease greater than 24 weeks. The median PFS was 34 weeks and the median OS was 107 weeks. Based on these studies, sunitinib is now considered the standard of care in patients who have progressed on or are intolerant of imatinib, and is administered in 37.5 mg daily dosing.

Regorafenib is now approved as third-line treatment in patients with advanced GIST who progress on imatinib and sunitinib. Regorafenib is a tyrosine kinase inhibitor that inhibits VEGF1, 2, and 3; PDGFRB; KIT; RET; fibroblast growth factor receptor (FGFR); and BRAF.<sup>145</sup> The recent phase III, randomized, double-blind, placebo-controlled GRID trial evaluated efficacy and safety of regorafenib in patients with advanced GIST who had evidence of progression after failure of at least imatinib and sunitinib.<sup>146</sup> The median PFS of patients randomized to regorafenib was 4.8 months compared to 0.9 months for the placebo group ( $p < 0.0001$ ). The rate of durable stable disease

lasting for greater than 12 weeks was 52.6% and 9.1% in the regorafenib and placebo groups, respectively. The results of this study led to the approval of regorafenib by the US Food and Drug Administration as the preferred third-line drug for GISTs.

Sorafenib is a tyrosine kinase inhibitor that is selective for KIT, PDGFRB, VEGF (isoforms 1-3), and Flt3, among others, that has shown clinical benefit in retrospective studies and phase II trials in patients who failed other TKIs.<sup>147-149</sup> The largest retrospective review by Montemurro and colleagues was a multicenter review that included 124 patients treated with sorafenib (400 mg/day) as a third- or fourth-line treatment for advanced GIST.<sup>149</sup> Partial response was observed in 10% of patients and stable disease in 57%. Median PFS was 6.4 months and median OS was 13.5 months. Preliminary results for a multicenter phase II trial also showed similar beneficial outcomes.<sup>150</sup> Of the 38 patients enrolled, 13% demonstrated a partial response and 55% of patients experienced stable disease over a median follow-up of 31 months. Median PFS was 5.2 months and median OS was 11.6 months, with a 1-year OS of 50%. While these studies suggest that sorafenib is a reasonable third- or fourth-line treatment, additional data from phase III clinical trials is needed to clearly define its role.

Nilotinib is a second-generation TKI that was originally designed for the treatment of chronic myelogenous leukemia due to its activity against bcr-abl.<sup>151</sup> Nilotinib has additional activity against PDGFRA and KIT and has been shown to improve outcomes in patients with imatinib- and sunitinib-resistant GISTs.<sup>152-154</sup> The use of nilotinib alone or in combination with imatinib was initially shown to be tolerable with clinical activity in imatinib-resistant GISTs in a phase I trial.<sup>153</sup> Of the 52 enrolled patients, 38 patients exhibited a stable disease and 2 patients a partial response. A phase III, randomized, open-label trial did not show an improvement in PFS with a median of 109 days in the nilotinib arm and 111 days in the best supportive care control arm.<sup>154</sup> It is important to note that 93% of patients in the control arm were receiving imatinib or sunitinib as part of best supportive care. In the post hoc subset analyses, patients receiving nilotinib after progression on imatinib and sunitinib demonstrated a significantly longer OS with a median of 405 days versus 280 days ( $p = 0.02$ ). A multicenter, phase III, randomized trial is currently ongoing to investigate the efficacy and safety of nilotinib versus imatinib as a first-line treatment in patients with advanced GIST.<sup>155</sup>

Multiple additional tyrosine kinase inhibitors are currently under investigation including dasatinib,<sup>156</sup> vatalanib,<sup>157</sup> mastinib,<sup>158</sup> dovitinib,<sup>159</sup> pazopanib,<sup>160</sup> and crenolanib.<sup>161</sup> Crenolanib is of particular interest as it is a kinase inhibitor of PDGFRA and has been found to be 135-fold more potent than imatinib against the PDGFRA D842V mutation in vitro. A multicenter phase II trial investigating the use of crenolanib for treatment of PDGFRA D842V-mutant GIST is ongoing.

In addition, other non-TKI agents are being investigated, including panobinostat,<sup>162,163</sup> heat shock protein-90 inhibitors,<sup>163,164</sup> and mTOR inhibitors such as everolimus.<sup>165</sup> Investigators are also exploring the role the immune response plays in the antitumor effects of imatinib in GIST. Using a mouse model of spontaneous GIST, investigators have found that imatinib therapy results in activation of CD8<sup>+</sup> T cells and induces regulatory T cell apoptosis within the GIST tumor by reducing tumor cell expression of the immunosuppressive enzyme indoleamine 2,3-dioxygenase (Ido)<sup>22</sup> Addition of cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) blockade potentiated the effects of imatinib in this model. This immunotherapeutic approach with the combination of imatinib and CTLA-4 blockade is a promising approach in improving outcomes in patients with advanced GIST.

## Cytoreductive Surgery

Cytoreductive surgery for advanced or metastatic disease is an accepted practice for disseminated solid tumors originating in the colon, appendix, ovary, and testicle. With the advent of targeted TKIs prolonging DFS and OS, clinicians are exploring the benefits of aggressive cytoreductive surgery in patients with advanced GIST. Three biologic tenets support this approach. First, the majority of patients experience durable periods of PR or SD on imatinib, lasting months to years. Second, pathologic complete responses are rare, noted in fewer than 5% of patients.<sup>166,167</sup> Third, response to imatinib is not maintained indefinitely; the median time to progression due to the development of secondary resistance is 18 to 24 months.<sup>113,114</sup> Once drug resistance develops, disease progression may be either limited (progression at one site of tumor, with other tumor deposits showing ongoing response to TKI) or generalized (progression at more than one site).<sup>168,169</sup>

Given these patterns of tumor behavior, cytoreductive surgery has several

purported biologic benefits. Surgery may reduce the burden of clonal variability in the tumor population and may prevent the formation of drug-resistant clones. This in turn may render the individual's remaining tumor burden again responsive to first- or second-line therapies. Furthermore, cytoreductive surgery may have a role in reducing symptoms and the development of complications such as perforation and bleeding. However, challenges lie in determining the optimal time for surgical intervention and the extent of surgery required to achieve meaningful clinical changes in outcomes.

The goal of cytoreductive surgery is to safely perform a macroscopically complete (R0 or R1) resection. Unfortunately, only 12% to 23% of patients with advanced GISTs on imatinib are considered surgical candidates.<sup>170,171</sup> The integration of surgery with multiple new emerging medical therapies is evolving.

There have been no fully completed randomized controlled trials comparing TKI therapy and cytoreductive surgery with medical therapy alone in the setting of advanced GISTs. Phase III trials to answer this question were designed and/or initiated in China, Europe, and the United States but remain unsuccessful due to poor accrual. Further phase III trial attempts are unlikely to occur. The Chinese group published results from their initially accrued patients with 19 patients in the surgery and imatinib arm and 22 patients in the imatinib-alone (400 mg/day) arm.<sup>172</sup> Patients in the surgery were treated with 3 to 12 months of medical therapy. Two-year PFS was 88.4% and 55.7% in the surgery with imatinib and imatinib-alone arms, respectively ( $p = 0.089$ ), suggesting no significant difference with these early and poorly powered results. However, several single-institution retrospective studies have documented promising PFS and OS rates following extensive cytoreductive surgery in patients with advanced GIST pretreated with TKI therapy.<sup>168–171,173,174</sup>

A study from the Brigham and Women's Hospital/Dana-Farber Cancer Institute (BWH/DFCI) evaluated outcomes in 69 patients who underwent cytoreductive surgery while receiving kinase inhibitors.<sup>169</sup> In this study, following surgery, there was no evidence of disease in 78%, 25%, and 7% of patients with stable disease, limited progression, and generalized progression, respectively ( $p < 0.0001$ ). For patients with stable, limited progression, and generalized progression, the 1-year PFS was 80%, 33%, and 0%,

respectively, and 1-year OS was 95%, 86%, and 0%, respectively. The authors concluded that patients with stable or limited disease progression are more likely to benefit from debulking procedures than those with generalized progression, particularly if an R0 or R1 resection is completed or tumor burden is reduced such that no individual nodule greater than 1 cm in diameter remains.

A study from Memorial Sloan Kettering Cancer Center (MSKCC) found similar results when evaluating outcomes following imatinib therapy and cytoreduction for advanced GISTs.<sup>168</sup> Patients with responsive disease, defined as having had a partial response or stable disease on kinase inhibitor therapy, had a 2-year PFS of 61% and a 2-year OS of 100%. Those patients with focal resistance or radiologic evidence of growth in one tumor progressed after surgery at a median of 12 months and had a 2-year OS of 36%. Patients who exhibited growth in more than one tumor progressed at a median of 3 months and had a 1-year OS of 36%. The majority of patients underwent liver resection (43%), and 68% of patients required resection of peritoneal metastases without resection of a major organ, which is similar to the BWH/DFCI study.

These results support the role of cytoreduction surgery in a subset of carefully selected resectable patients with continuation of TKI up to the surgery and also postoperatively. However, these series alone do not establish the superiority of surgery plus TKI over medical therapy alone. In light of current data, surgery should not be the first-line treatment for advanced GISTs, barring an impending emergency. These patients should be treated with imatinib for a minimum of 6 months prior to consideration of surgery. Patients with disease that is stable or with limited progression should be individually assessed by a team of GIST specialists to determine if as they may benefit from prolonged PFS or OS following cytoreductive surgery (Fig. 33-9). Patients with generalized progression have not been shown to benefit from cytoreductive surgery and are best treated nonoperatively (Fig. 33-10). If surgery is not a viable option, symptomatic patients or patients with limited progression may be considered for other targeted but less invasive therapies such as radiofrequency ablation or (chemo)embolization for liver disease, radiation for isolated bony metastases, or transition to other protocol-based therapies.

B

**FIGURE 33-9** Patient with duodenal GIST metastatic to the liver (arrows)

before (**A**) and after (**B**) eight months of imatinib, demonstrating partial response to therapy. The patient underwent resection of his intact primary disease, a right hepatectomy, and wedge resection of a left hepatic lesion.

A

B

**FIGURE 33-10** Patient with unresectable metastatic GIST (**A** and **B**). Therapy with imatinib failed to control growth of the disease. The patient underwent a palliative debulking to relieve proximal gastric obstruction, but the resection as anticipated was macroscopically incomplete.

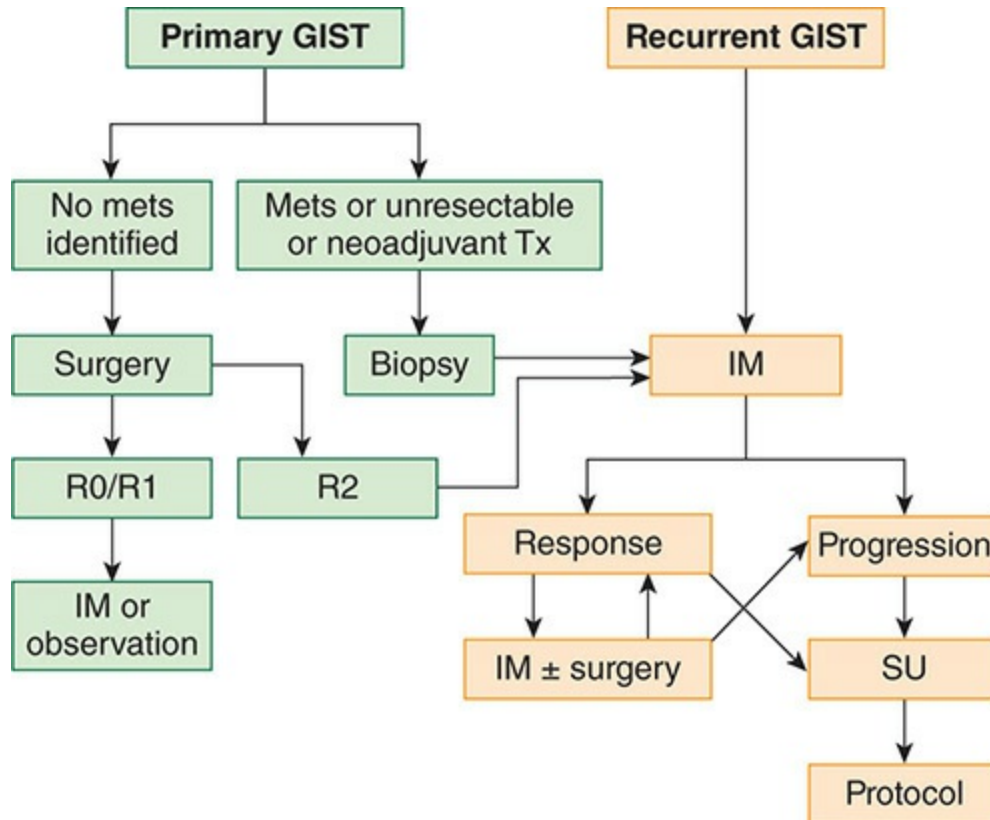

## SURVEILLANCE

There is no established prospective data to define optimal surveillance for patients with GISTs. However, follow-up schedules have been developed based on evidence that most recurrences occur within the first 5 years following surgery. NCCN guidelines recommend patients who have undergone surgical resection of a GIST undergo contrast-enhanced surveillance CT imaging of the abdomen/pelvis every 3 to 6 months for the first 3 to 5 years, then annually thereafter.<sup>96</sup> The ESMO guidelines recognize that follow-up schedules differ across institutions and that the risk of recurrence should guide the follow-up schedule.<sup>175</sup> High-risk patients should undergo routine follow-up with CT scan every 3 to 6 months for 3 years, every 3 months for 2 years (closer follow-up after cessation of adjuvant imatinib therapy), every 6 months until 5 years, and then annually until 10 years. For low-risk tumors, patients require less rigorous follow-up and could have CT imaging every 6 to 12 months for 5 years. Very low-risk GISTs probably do not even need to be followed. CT imaging is the preferred modality, as it is more readily available than MRI or FDG-PET-CT scan imaging; however, these modalities can be considered when CT findings are inconclusive. Routine imaging of the chest or brain is unnecessary.

## CONCLUSIONS

The principal and only potentially curative treatment for GIST is surgery. However, recurrences are common. Historically, survival in the setting of recurrent or metastatic disease has been poor. However, TKI therapy has dramatically transformed the natural history of this disease, and the role of mutational analysis in the type and dose of TKI administered is actively evolving. The role of imatinib has been expanded in patients with primary GIST to include use in the neoadjuvant setting and adjuvantly following complete macroscopic and microscopic resection in intermediate- to high-risk

patients<sup>177</sup> (Fig. 33-11). Ongoing studies will address the optimal length and dose of these therapies, define the subset of candidates most likely to benefit, and determine the long-term impact on OS.

**FIGURE 33-11** Schema for management of primary and advanced gastrointestinal stromal tumor.

TKIs are the mainstay of treatment for locally advanced, recurrent, and metastatic GIST. However, cytoreductive surgery may be considered in a subset of patients with advanced disease, although superiority over medical therapy alone is uncertain. Future work aims to add to the understanding of the complex integration of an individual’s molecular tumor characteristics with surgery and targeted therapy. With an improved understanding of this landscape, strategies can then be fashioned to battle drug-resistant GISTs and improve survival for these patients.

# PERSPECTIVE ON GASTROINTESTINAL STROMAL TUMORS

*Michael J. Cavnar • Ronald P. DeMatteo*

## INTRODUCTION

In [Chapter 33](#), Drs. Look Hong and Raut review gastrointestinal stromal tumor (GIST). Historically, metastatic GIST carried a median survival of 12 months, but this has improved to 5 years with the introduction of tyrosine kinase inhibitors (TKIs).<sup>1,2</sup> The landmark finding of the effectiveness of imatinib in GIST has transformed a disease for which little treatment beyond surgery existed into a chronic disease for which multimodality therapy can give patients prolonged survival with good quality of life and possibly even cure. Following the success of imatinib in GIST, the paradigm of targeted molecular therapy has rapidly expanded, with US Food and Drug Administration (FDA) approval of orally available targeted molecular therapy agents for multiple targets in multiple solid tumors. Initial success with targeting tyrosine kinase receptors in non–small-cell lung cancer (EGFR and later ALK) and renal cell carcinoma (VEGFR) has now been broadened to

include approval of drugs for breast cancer, colorectal cancer, thyroid cancer, soft tissue sarcoma, and pancreatic neuroendocrine tumor. In some instances, just 1 or 2 kinases are targeted, whereas in others, multiple kinases are inhibited. Additional available agents are now also widely used for targets downstream of tyrosine kinases, including BRAF in melanoma; mTOR in breast cancer, angiomyolipoma, and pancreatic neuroendocrine tumors; CDK4/6 in breast cancer; PARP in ovarian cancer; and Hedgehog in basal cell carcinoma.<sup>3</sup> While experience gained in the treatment of GIST has paved the way for the introduction of targeted therapy in many other cancers, it has also taught us valuable lessons as to complex issues that may arise. The simplicity of targeting KIT or PDGFRA in GIST has turned out to be far more complex than initially thought, with response to therapy dependent on the specific mutation and the nearly inevitable development of secondary mutations and other mechanisms of resistance in advanced and recurrent disease.

While molecular therapy is highly effective, it is important to recognize that surgery remains the only chance for cure in patients with GIST. We now know from the placebo arm of the American College of Surgeons Oncology Group (ACOSOG) Z9001 trial that 70% of patients with GISTs  $\geq 3$  cm appear to be cured by surgery with 74 months of follow-up.<sup>4</sup> Given the diverse anatomic locations of primary and metastatic disease, a variety of technical issues must be mastered for appropriate and safe treatment of GIST. Although surgical resection is the central component of treating GIST with curative intent, the surgeon treating GIST must also become knowledgeable in 3 key elements of the molecular therapy for this disease, which we highlight here: (1) appropriate patient selection and duration of neoadjuvant therapy; (2) adjuvant therapy in an increasingly well-defined subset of intermediate- and high-risk patients; and (3) surgical resection in well-selected patients with recurrent or metastatic disease.

## **SPECIFIC SURGICAL ISSUES**

For the surgeon planning to resect a GIST, it is important to understand a number of unique surgical principles. GISTs are extremely friable, especially after neoadjuvant imatinib, and thus may rupture if not handled with great care. Tumor rupture must be avoided as it may lead to early peritoneal

recurrence and is known to worsen outcome. As such, tumor handling during laparoscopy is best achieved by minimal direct contact with the tumor, and once resected, the tumor must be removed via a retrieval bag to prevent tumor seeding. GISTs are particularly vascular, with the potential for significant blood loss if the extensive venous and arterial collateral vessels are not carefully dissected and ligated. While GISTs do not typically invade into adjacent organs and instead push them aside, any organ adherent to a GIST should be removed at least partially en bloc.

Since GISTs arise in diverse locations, with highest frequency in the stomach followed by small intestine, rectum, and occasionally other sites, site-specific considerations are numerous. Laparoscopic (and possibly robotic) surgery is appropriate in each of these sites for small- to medium-sized tumors if the surgeon has adequate expertise and the appropriate equipment. When these tumors are small and have a low mitotic rate, cure by surgery alone is possible, particularly for gastric GISTs. During laparoscopic exploration, exophytic gastric tumors are readily identified, especially along the greater curvature and anterior stomach. Tumors that grow into the stomach lumen instead of exophytically can be identified by intraoperative endoscopy, or by filling the stomach with water and using laparoscopic ultrasound, although this is rarely necessary. Posterior gastric tumors are usually still amenable to minimally invasive resection but require extensive mobilization of the stomach, which is further facilitated by retracting the left lateral segment of the liver to the right. Formal anatomic gastrectomy is typically not required; rather, partially gastrectomy with a 1-cm margin is adequate.

Partial gastrectomy is frequently possible using surgical staplers, unless doing so will lead to unacceptable compromise of the gastric lumen. In this case, a gastrotomy is made and the tumor resected with a 1-cm margin using cautery, followed by hand-sewn closure of the defect. For GISTs arising from the gastroesophageal junction (GEJ), we prefer open surgery, especially for posterior tumors. We typically remove these tumors by gastrotomy and hand-sewn closure; however, if staplers are used, a bougie should be placed in the esophagus to avoid narrowing the GEJ. Total gastrectomy is rarely required for massive gastric tumors, and the postoperative complications should be considered and discussed with the patient preoperatively. Such large tumors may be intimately associated with other organs including the distal pancreas, spleen, and even the splenic flexure of the colon, possibly requiring en bloc

resection. When the extent of the tumor is recognized preoperatively, neoadjuvant imatinib (as discussed below) is highly recommended and may result in organ preservation.

The small intestine is the next most frequent site of primary GIST. Jejunal and ileal GISTs are readily removed laparoscopically, unless very large. They are easily identified by systematically running the small bowel from the ligament of Treitz to the terminal ileum. Duodenal GISTs are perhaps the most complex to deal with. Tumors located in the second portion of the duodenum may require a pancreaticoduodenectomy, unless small and arising from the lateral wall. In that case, local resection may be possible either using primary closure of the defect or reconstruction with a Roux-en-Y jejunal limb. GISTs in the third or fourth portion of the duodenum can be resected after appropriate mobilization and reconstructed either with a direct anastomosis to jejunum or with closure of the distal duodenum and creation of a Roux-en-Y limb of jejunum to the lateral second portion of the duodenum. For a duodenal tumor that is larger than a few centimeters, neoadjuvant imatinib should be considered if it may reduce the extent of the operation required.

GIST rarely arises in the colon, but rectal GISTs make up approximately 5% of primary tumors and thus deserve discussion. Akin to adenocarcinoma of the rectum, an organ-preserving neoadjuvant approach should be employed. This may allow avoidance of abdominoperineal resection and permanent colostomy. Likewise, it may allow local transanal resection for very distal tumors.

Many patients with GISTs already have a tissue diagnosis by the time of referral. However, for tumors with a classic radiologic appearance, biopsy may not be necessary, although the patient should be counseled preoperatively that other tumors such as Schwannoma, leiomyoma, or even ectopic pancreas are possible. Biopsy should be performed if identification of a benign tumor may avoid an otherwise morbid resection, such as an esophagectomy for a GEJ tumor. Likewise, if neoadjuvant therapy is being considered for a large tumor, biopsy is generally recommended to confirm the tumor is a GIST.

Given that GIST only rarely spreads to lymph nodes, it is not necessary in any of the typical sites to perform a lymphadenectomy, unless preoperative imaging indicates lymphadenopathy (in which case one should suspect the tumor is likely not a GIST) or enlarged nodes are palpated at operation.

## NEOADJUVANT THERAPY

We now have considerable experience with neoadjuvant imatinib therapy to improve resectability of locally advanced primary tumors and recurrent/metastatic disease. Patient selection for neoadjuvant therapy is based on several factors. Size is not an absolute indication, especially if primary resection is feasible (eg, a large primary jejunal or ileal tumor). However, if multivisceral resection will be required based on size, then neoadjuvant treatment should be considered. Neoadjuvant therapy may also allow a laparoscopic approach instead of laparotomy. Location at the GEJ, duodenum, or rectum often warrants neoadjuvant therapy with tumors larger than a few centimeters. Recurrent tumors and metastases that are also larger than a few centimeters also benefit if reduction in size or vascularity will facilitate less morbid resection.

While the neoadjuvant strategy is widely employed for other cancers such as esophageal, gastric, and rectal cancer, unlike cytotoxic chemotherapeutic agents used in those diseases, which have to be stopped many weeks before surgery, imatinib (and other TKIs such as sunitinib, regorafenib, and others) can be stopped a day or 2 prior to surgery without concern for adverse effect on wound healing or immune suppression. Response Evaluation Criteria in Solid Tumors (RECIST) are used to assess response in most cancers, but these criteria do not work well in GIST, where the tumor may swell temporarily after treatment. Instead, the Choi criteria, which incorporate density and size, are useful to detect early treatment response.<sup>5</sup> Generally, we perform a computed tomography (CT) 2 to 4 weeks after starting imatinib to check for tumor response. Because size is not the best indicator of response, it is important that the surgeon personally review the images, as the radiologist may not report changes in tumor density. The optimal length of imatinib therapy remains to be determined. After initiation of therapy, it is our practice to repeat scans at 3 and 6 months, and attempt resection at 6 to 8 months if there is no progression of disease. Meaningful shrinkage is unlikely past this time period.

While prospective randomized trials of neoadjuvant therapy compared to immediate surgery are lacking, the authors cite a small but growing literature of retrospective studies and single-arm or nonplacebo controlled prospective trials showing that the neoadjuvant strategy allows R0 resection in the majority of patients with well-selected locally advanced primary tumors or

recurrent/metastatic disease. Although some of these studies report survival data, without a matched comparison group, the value of these data is uncertain. Still, neoadjuvant therapy may improve organ preservation independent of progression or survival, affecting morbidity and quality of life. Given that the patients who warrant neoadjuvant therapy are typically at high risk of recurrence, continuation of adjuvant imatinib therapy after surgery is prudent, although this has not been rigorously studied. After surgery, imatinib and others TKIs can be resumed once the patient is tolerating a regular diet and having bowel function.

## ADJUVANT THERAPY

As covered by the authors, high-level evidence now supports prolonged adjuvant therapy with imatinib after resection for a subset of intermediate- and high-risk primary, localized GISTs. The initial results of a prospective randomized phase III trial of 1 year of adjuvant imatinib compared to placebo (ACOSOG Z9001) showed prolonged recurrence-free survival (RFS) with a median follow-up of 19.7 months, leading to FDA and European Medicines Agency approval of imatinib in GIST.<sup>6</sup> We subsequently reported long-term follow-up (median, 74 months) from this cohort, which demonstrated persistence of prolonged RFS.<sup>4</sup> This result was evident even without censoring placebo-treated patients who crossed over into the imatinib arm. This is remarkable given that the patients only received 1 year of therapy and the study included many patients with tumors that we now know were at low risk for recurrence. However, 1 year of imatinib was not enough to prevent recurrence, as patients in the imatinib arm began to experience recurrences after discontinuation of the drug. Another large prospective randomized phase III trial (SSG XVIII) showed superior RFS with 3 years compared with 1 year of adjuvant imatinib.<sup>7</sup> This study showed slight improvement in overall survival (OS), but not disease-specific survival (DSS). In general, OS benefit in these studies has been difficult to prove given the low event rate of death from disease and, more importantly, because imatinib is a highly effective salvage therapy.

Study of extended therapy is ongoing. PERSIST-5 is a single-arm phase II trial of 5 years of imatinib in patients at high risk of recurrence from primary GIST including any site  $\geq 2$  cm with  $\geq 5$  mitoses/50 high-power fields (HPFs)

or any nongastric GIST  $\geq 5$  cm. At a planned 3-year interim analysis, of 91 eligible patients, only four (4%) had experienced recurrence.<sup>8</sup> Of those 4 patients, 3 had discontinued the drug prior to recurrence and 1 was found to have an imatinib-resistant *PDGFRA* mutation. Thus, extended adjuvant therapy in high-risk patients appears appropriate, possibly indefinitely, in absence of progression or significant adverse effects. It is our practice to discuss with high-risk patients the goals of care; if the goal is to prolong RFS, understanding that OS and DSS may not be affected, we prescribe chronic imatinib therapy.

Long prospective follow-up of the ACOSOG Z9001 cohort allowed detailed analysis of treatment effect stratified by specific mutation.<sup>4</sup> Surprisingly, the improvement in RFS was only seen in patients with *KIT* exon 11 deletions, but not exon 11 insertions or point mutations. RFS was not improved in patients with *PDGFRA* mutations, *KIT* exon 9 mutations, or wild-type tumors. That the non-exon 11 groups showed limited response is not surprising. The majority of *PDGFRA* mutations were D842V, which is known to be imatinib-resistant. There were too few non-D842V *PDGFRA* mutations to make a conclusion about RFS in that group. The small group of *KIT* exon 9 mutants had equivocal outcome; however, they may have required higher dose imatinib, akin to metastatic disease.<sup>9</sup> Similarly, the small wild-type group, which was not further broken down but typically comprised of *SDH*, *BRAF*, *NF1*, *RAS*, and other mutations, did not show improved RFS. Still, it was not anticipated that exon 11 insertions and deletions would not show a benefit. Further prospective study will be needed to validate these findings. Nevertheless, it is increasingly clear that molecular stratification will be an important part of selecting patients for therapy.

Despite meticulous surgical technique and R0 resection, many patients will develop tumor recurrence. Using tumor size, location, and mitotic rate, we developed a nomogram to estimate the RFS for patients after resection of primary GIST (<http://www.mskcc.org/mskcc/html/98103.cfm>).<sup>10</sup> This nomogram has since been validated by a second group in a cohort of 289 patients and had superior predictive accuracy compared to National Institutes of Health and Joensuu criteria.<sup>11</sup> Results obtained from this nomogram can help the surgeon discuss postoperatively with the patient whether adjuvant imatinib therapy would be appropriate. As the influence of specific mutations on imatinib sensitivity is clarified, we will update the nomogram to further

assist in selecting patients for adjuvant therapy or close observation.

## **SURGERY FOR METASTATIC GIST**

For metastatic or recurrent GIST, treatment with imatinib has a proven survival benefit and is the standard of care. However, in well-selected patients with limited disease, we and others have advocated surgery when all residual disease can be removed. The authors do cite retrospective series including one from our institution that indicate that resection in patients with TKI-responsive disease have higher progression-free survival (PFS) and OS compared to those with focal resistance or generalized progression on therapy. However, these studies are limited by selection and lead time bias. Several trials to resolve this have been limited by poor accrual, and as cited by the authors, results from initial accrual in a Chinese study (although vastly underpowered) show a trend toward improved PFS that approaches significance.<sup>12</sup> While the true benefit of surgery in recurrent/metastatic GIST remains unproven, in the absence of randomized data, it seems reasonable to perform surgery for metastatic GIST in well-informed patients when the disease has responded to TKIs and complete resection can be achieved. This is supported by the fact that patients with metastatic disease treated with imatinib alone develop progression at a median of 24 months<sup>13</sup> through secondary mutations<sup>14</sup>; thus, R0 resection, if possible, seems prudent. In addition, with appropriate close follow-up of patients after resection of a primary GIST that is high risk, recurrent disease will now frequently be identified early when it may be amenable to resection. After R0 resection of metastatic or recurrent disease, patients should be continued on appropriate TKI, likely indefinitely. For patients with unresectable metastatic disease, second- and third-line TKIs show some effect; however, the benefit is less due to emergence of further resistance. This highlights our need for alternate treatment strategies including immunotherapy, which has substantial scientific rationale in GIST.<sup>15,16</sup> Indeed, a phase I trial of imatinib plus ipilimumab (anti-CTLA4) in metastatic GIST is ongoing at our institution.

# STOMACH AND DUODENUM: OPERATIVE PROCEDURES

*Joyce Wong • David I. Soybel • Michael J. Zinner*

## HISTORICAL PERSPECTIVE

The earliest recorded operations on the stomach were performed for penetrating injuries.<sup>1</sup> In the late 1800s, experimental studies in the surgical laboratories of Billroth confirmed the feasibility of removing the pylorus, a concept developed by Michaelis in the early part of that century. In 1881, Rydygier performed the first successful pylorotomy, and in 1884 he performed the first gastroenterostomy. Both of these operations were performed for complications of benign peptic ulcer disease. In 1881, Billroth performed the first successful pylorotomy for malignancy. In this case, the duodenum was anastomosed to the lesser curvature of the stomach and the greater curvature was oversewn. The patient initially did well but died from disseminated abdominal carcinomatosis 4 months later. In 1885, Billroth performed a resection of a large pyloric carcinoma, using an anterior gastrojejunostomy for the reconstruction. In subsequent years, Billroth, his

students, and others devised several approaches to gastroduodenal and gastrojejunal reconstruction.<sup>1-3</sup> Following popularization of gastrojejunostomy for reconstruction after gastric resection or palliation of unresectable gastric malignancy, surgeons were confronted with early complications such as bleeding, anastomotic leak, intestinal obstruction, and late complications such as stomal ulceration, bilious vomiting, afferent and efferent limb obstructions, and dumping.<sup>4,5</sup> At present, these problems remain only partially understood and controllable.

Pyloroplasty was initially devised by Heineke for treatment of congenital hypertrophic pyloric stenosis, and the results were poor. Jaboulay's side-to-side anastomosis of the distal greater curvature and duodenum in 1892 and the Faience extension of this anastomosis to include the pylorus itself were subsequently refined by Kocher. Kocher improved the technical ease of the operation by including a mobilization of the duodenum from its lateral peritoneal attachments. The first pyloromyotomy was performed for this lesion in 1912 by Ramstedt.

In the early part of the 20th century, a dramatic rise was observed in the incidence of duodenal ulceration. A period of intense clinical and laboratory investigation from 1920 through 1940 led to the recognition that surgically performed vagotomy could reduce gastric acidity under resting conditions and in response to luminal and humoral stimuli. The use of vagotomy for patients with complications of ulcer disease was pioneered by Latarjet, who reported 24 such cases in 1922. Latarjet himself recognized that vagotomy might lead to delayed gastric emptying and had added a drainage procedure, gastrojejunostomy. Confusion regarding the role of delayed gastric emptying in the pathogenesis of peptic ulcers, however, led many surgeons away from vagotomy and drainage as a treatment for recurrent peptic ulceration. It remained for Dragstedt and his colleagues at the University of Chicago to resurrect this concept in the 1940s.<sup>5</sup> Subsequently, Farmer, Smithwick, and others introduced the combination of truncal vagotomy (TV) and hemigastrectomy, an operation that also removed the gastrin-producing antral mucosa.<sup>3</sup> In the 1950s, Harkins' group in Seattle began to evaluate forms of vagotomy that left intact the celiac and hepatic branches (proximal selective vagotomy), along with or in combination with the preservation of vagal motor branches to the antrum (highly selective vagotomy [HSV] or parietal cell vagotomy). These modifications arose from an appreciation of the contributions of antral motility to proper digestion as well as improved

understanding of specific postvagotomy complications such as dumping and diarrhea. The popularization of HSV is largely attributable to the efforts of Johnston, Goligher, Amdrup, and others, who in the 1960s and 1970s demonstrated the feasibility of obtaining ulcer recurrence rates as low as those of conventional TV without the incidence of dumping and diarrhea that was associated with TV with drainage or gastrectomy.<sup>6,7</sup> It is worth noting that surgeons have done more than developing new and interesting operative approaches to acid peptic disease. They have played a major role in advancing current concepts of pathophysiology in ulcer disease and recurrence, and in understanding the physiological consequences of ulcer treatments, both medical and surgical.<sup>4,5</sup>

## VAGOTOMY

Even though the increasing use of medications that inhibit gastric acid secretion, such as proton pump inhibitors, has made elective antisecretory operations essentially nonexistent, these medications remain part of the surgeon's armamentarium in dealing with patients who remain refractory to maximal medical therapy for ulcer disease, and in some selected cases for patients with ulcer perforation and bleeding. To understand the importance of the technical details in the execution of antisecretory operations, it is necessary to fully appreciate the anatomy of the vagus nerve and the gastric microvasculature, as well as the physiology of acid secretion, mucosal barrier function, and gastric motility, which are expanded upon in the following text.

## Tests of Vagal Control of Acid Secretion

Historically, vagal control of acid secretion has been assessed by measuring acid secretion in response to various stimuli. Acid secretion can be measured directly by the placement of a tube into the stomach, through which gastric juice is aspirated and the titratable acidity is measured by adding known quantities of 0.1 N NaOH. Gastric output is measured at baseline and after stimulation with pentagastrin or sham feeding. Measurements of gastric acid output pre- and post-vagotomy operations can be measured to assess the efficacy of vagotomy.<sup>8,9</sup> Acid secretion also can be assessed semiquantitatively, using pH-sensitive dyes, such as Congo red, that coat the

mucosa and turn color when acid is being secreted from the gastric glands.<sup>10,11</sup> Although the former analytic methods permit accurate and quantitative assays of secretory capacity before and after the operation, the latter colorimetric methods can provide relatively rapid means of assessing secretory capacity of the stomach during the operation itself. These tests are rarely used today with the increasing use of medications that inhibit gastric acid secretion such as proton pump inhibitors and the consequent rarity of performing elective antiulcer gastric acid-reducing operations.

## **Vagal Regulation of Gastric Motility and Emptying**

As stated by Professor David Johnson in a previous edition of this book, "... Only when one fully understands the physiologic rationale of highly selective vagotomy will be one sufficiently motivated to do it well." This statement was made not in reference to the innervation of parietal cells that secrete HCl, but to the neural regulation of gastric motor function and emptying. The vagus dominates the motor activity of the normally functioning stomach in three ways. First, it mediates receptive relaxation and gastric accommodation; that is, the relaxation of the gastric fundus when intraluminal pressures in the proximal esophagus and stomach are increased by the presence of chyme. Second, the vagus mediates increases in antral myoelectrical activity that result from distention of the proximal stomach by chyme. Third, the vagus appears to mediate coordination of pyloric emptying with antral myoelectrical activity in response to changes in proximal gastric motor activity, and perhaps in response to changes in composition and pH of duodenal content.<sup>12</sup>

It should be recognized that while truncal or selective vagotomy interrupts the vagal pathways to the antrum and pylorus, all three forms of vagotomy (truncal, selective, and highly selective) abolish receptive relaxation and gastric accommodation. It has been claimed that in the absence of pyloric scarring or stenosis, vagotomy only temporarily impairs gastric emptying. This rationale has been used to justify combinations of selective and relatively nonselective approaches, such as a posterior truncal and anterior highly selective (or anterior seromyotomy) vagotomy. Such arguments become important in thinking about potential adverse consequences of laparoscopic approaches to the vagus and the need for, and choice of, drainage procedures. The assumptions that antral/pyloric coordination will

return after truncal vagotomy or that gastric emptying after pyloromyotomy is as good as that after pyloroplasty now seems valid.<sup>13-15</sup> In addition, the spectrum of complications following such mixtures of approach has now been characterized and is not substantially different than those reported in symmetric operations.<sup>15,16</sup> Nevertheless, for open or laparoscopic procedures, it is advisable to use the same caution in utilizing mixtures of approach or dispensing with drainage procedures after truncal or selective vagotomy.

## **Open Approaches to the Vagus**

### **PATIENT POSITION, INCISIONS, AND EXPOSURE**

To perform a complete vagotomy, access to the upper part of the stomach and lower esophagus is crucial. It is helpful for the operating surgeon, standing on the patient's right, to wear a headlight. When access to the duodenum is required, as in a gastrectomy, excellent exposure is available through a chevron incision. However, in most patients, both thin and obese, a midline incision carried up along the xiphoid will be adequate. In the obese, extension of the incision below the umbilicus facilitates exposure. Placing the patient in reverse Trendelenburg position is helpful. A nasogastric (NG) tube is placed with its tip at the most dependent portion of the greater curvature. The NG tube helps to keep the position of the esophagus in mind. A self-retaining retractor is required. We use an upper abdominal self-retaining retractor that provides excellent accessories for securing wide exposure to the upper abdomen, and by means of well-placed Mikulicz's pads, for holding the small bowel and transverse colon in the lower abdomen (Fig. 35-1). Some surgeons advocate routine mobilization of the left lobe of the liver by dividing the left triangular ligament. This mobilization is not always necessary, and when the lobe is floppy, can impede exposure. If this maneuver is performed, the lateral segment of the left lobe is held upward and to the right by a Richardson or Herrington-type retractor accessory. Care must be taken to place sponges or a pack between the retractor attachment and liver, and not to put much tension on the liver to avoid fracture of the liver parenchyma and bleeding.

**FIGURE 35-1** The use of the Bookwalter retractor for exposure of the upper abdomen.

## TRUNCAL VAGOTOMY

Truncal vagotomy (TV) is performed in conjunction with some form of drainage procedure. In the elective setting, it is used in conjunction with antrectomy for definitive management of refractory symptoms of duodenal ulcer, pyloric channel ulcer (gastric ulcer type III), or gastric ulcers combined with duodenal (Dragstedt) ulcers. In the current era of highly effective antisecretory therapies such as omeprazole, and anti-*Helicobacter* antibiotics,

the main indication for TV and antrectomy is in the setting of pyloric outlet obstruction with a longstanding history of ulcer symptoms or complications such as bleeding and perforation. TV and pyloroplasty are reserved for emergency operations for complications such as bleeding or perforation. Occasionally, TV plus gastroenterostomy will be an appropriate compromise when the duodenum is too scarred to permit safe antrectomy and duodenal closure. The anatomy of the vagal trunks and nerves of Latarjet has been reviewed<sup>17</sup> and is shown schematically in [Figures 35-2](#) and [35-3](#).

**FIGURE 35-2** The distribution of the anterior vagus nerve is shown. The *dotted line* indicates the line of dissection. Note that it goes around the incisura to within about 6 cm of the pylorus. The gastrocolic omentum has been partially divided to permit access to the posterior nerve of Latarjet and to allow the stomach to be grasped and used as a retractor. Note that the gastroepiploic arteries are carefully preserved.

**FIGURE 35-3** The posterior wall of the stomach and posterior nerve of the Latarjet are shown. The terminal Y fork of the nerve is preserved, and all of the branches to the stomach are divided, leaving about 5 cm of the distal portion of the stomach innervated.

Using a Mikulicz pad or carefully applied Babcock clamps, the assistant places downward traction on the greater curvature of the stomach, thereby placing traction on the gastroesophageal junction and lower esophagus. The first step is to incise the peritoneal covering of the gastroesophageal junction. The peritoneum is opened horizontally, from the angle at the lesser curvature to the cardiac notch at the greater curvature. The surgeon's thumb and right index finger are used in a blunt dissection to encircle the esophagus. When teaching this maneuver, it is not uncommon for the trainee to confuse the right crus of the diaphragm with the esophagus itself or even the posterior vagal trunk. Extra time spent at this juncture to correctly identify all structures is an essential aspect in teaching the operation. A Penrose drain can be passed around the junction in order to place more effective downward traction on the gastroesophageal junction. When encircling the esophagus, the

surgeon stays wide of the esophagus in order to prevent inadvertent entry into the lumen and to include the vagal trunks. In the course of this maneuver, the posterior vagal trunk usually will be palpated as a taut cord.

A single anterior vagal trunk is usually identified in the anterior midportion of the esophagus, 2 to 4 cm above the gastroesophageal junction (Fig. 35-4). At this level, however, it is not uncommon for vagal fibers to be distributed between two or three smaller cords. These cords are palpable as much as they are visible and can be separated from surrounding esophageal muscle fibers using a nerve hook. These trunks are individually lifted up, and 2- to 4-cm segments of each are separated from surrounding tissues. A medium-sized clip is applied at the most superior end, and a clamp is applied inferiorly. The 2-cm length of nerve is resected and a clip is applied below the clamp; small bleeders are cauterized precisely. If it has not been done, the esophagus should be more widely mobilized for a distance of 4 to 5 cm above the gastroesophageal junction. Smaller, individual vagal fibers that ramify from the main trunks toward the lesser curvature and the cardiac notch then can be identified and cut or cauterized. The “criminal nerve” of Grassi, discussed in more detail in the section describing parietal cell vagotomy, also may be identified here, wrapping around the cardiac notch from its origin in the posterior trunk. The posterior vagal trunk itself usually will have been identified along the right edge of the esophagus. If the anterior vagus has already been divided, the esophagus is more mobile. This mobility allows the surgeon to place downward traction on the gastroesophageal junction, or along the most caudal portion of the greater curvature, thereby applying gentle tension on the EG junction, which causes the posterior vagus to “bowstring” and make it easier to identify. A 2- to 4-cm segment is separated from surrounding tissues, its margins marked with clips, and resected. Major branches of the anterior vagus and the posterior vagal trunk should be sent to pathology for examination in frozen section. Care should be taken to note the results of the pathologist’s frozen section diagnosis in the dictated operative note.

**FIGURE 35-4** Division at both vagus nerves.

## **SELECTIVE VAGOTOMY**

Selective vagotomy (SV) is not commonly practiced in the United States, but it has found favor with European surgeons, who prefer not to cut the

posteriorly derived vagal branch that innervates the small intestine and pancreas and anteriorly derived vagal branch that supplies the gallbladder and liver. There is evidence that preservation of such branches can avoid alterations in gallbladder motility that might lead to stasis and stone formation.<sup>18</sup> However, it is not clear whether preservation of the small intestinal and pancreatic nerves protects against some symptoms of the dumping syndrome.<sup>19-22</sup> SV involves interruption of both nerves of Latarjet and therefore does not avoid the need for a drainage procedure.<sup>22</sup> Thus the main indication for SV may be in patients undergoing elective antrectomy with vagotomy for refractory ulcer symptoms or obstruction.

Exposure to the vagus, gastroesophageal junction, and esophagus is obtained in the same way that the surgeon would perform TV. Anteriorly, the nerve of Latarjet is identified by following the anterior vagal trunk as it descends from the esophagus to the lesser curvature of the stomach. Frequently, the descending branch of the left gastric artery is in close proximity to the site where the hepatic/gallbladder branches take off toward the liver in the gastrohepatic (lesser) omentum. A segment of the nerve of Latarjet is severed between clips and sent for examination on frozen section. The most expeditious way to perform this maneuver is to cross-clamp the portion of the lesser omentum that contains the artery and nerve, ligating and dividing these structures together (Fig. 35-5). The dissection continues upward along the lesser curvature, gastroesophageal junction, and esophagus. Division and ligation of blood vessels and nerves in this bundle avoids the hepatic/gallbladder branches and denervates the cardia, as was described for TV. This dissection opens up the plane for dissection and ligation of the posterior nerve of Latarjet.

**FIGURE 35-5** Selective vagotomy. The descending branch of the left gastric artery has been divided, and the anterior gastric branches of the anterior vagus are about to be divided.

## **HIGHLY SELECTIVE VAGOTOMY**

Generally accepted indications for highly selective vagotomy (HSV) include elective management of intractable symptoms of duodenal ulcer disease, emergency treatment for perforated duodenal ulcer, and emergency treatment of perforated gastric ulcer when the ulcer is to be excised in a wedge rather than resected in continuity with the distal stomach. HSV also has been advocated for management of bleeding gastric or duodenal ulcers, but this has not been widely practiced. Finally, there is published experience in

pyloric outlet obstruction using HSV in combination with finger or endoscopic balloon dilation,<sup>19,23-25</sup> but systematic audits of long-term persistence or recurrence rates of obstructing symptoms have yet to be reported.

A number of variations of the technique have been described, and all are not reviewed here. However, it is worth cataloguing the decisions that the surgeon must make in preparing for and performing this operation. In the past, Congo red dye has been utilized for intraoperative testing of the completeness of vagotomy. Currently, it is not approved for use in the United States and is generally unavailable except on protocol. Along these lines, it may be difficult, and sometimes contraindicated, to perform endoscopy in the setting of acute bleeding or perforation. Thus, the use of Congo red is not encouraged except where specific protocols of investigation might require its use.<sup>26</sup> Conceptually then, the operation is divided into four phases: (1) exposure and gastric mobilization; (2) dissection of the anterior leaf of the lesser omentum; (3) dissection of the posterior leaf of the lesser omentum; and (4) dissection of vagal fibers traveling to the stomach along the distal esophagus.

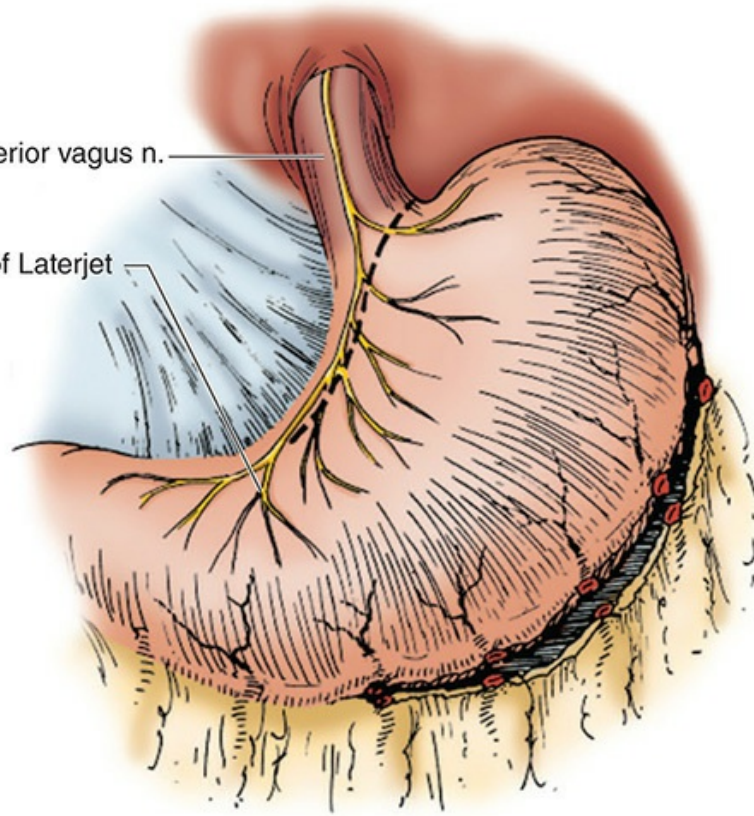

**Exposure and Gastric Mobilization.** Exposure of the vagus nerves, esophagus, and gastroesophageal junction is obtained as described previously. A wide-bore (18F) NG tube should be placed by the anesthesia team. A number of authors have emphasized the importance of the stomach as a retractor in this operation. We recommend mobilization of the distal part of gastrocolic omentum. The dissection should be carried outside the gastroepiploic arcade, in order to avoid loss of any blood supply to the greater curvature. Congenital adhesions between the stomach and peritoneum overlying the pancreas are divided sharply. The goal of this dissection is to obtain sufficient mobility of the stomach so that it can be rotated upward and to the patient's right, thus permitting visualization of the posterior leaf of the lesser omentum and the posterior nerve of Latarjet through the lesser sac. The nerve can be seen running close to the descending branch of the left gastric artery. Vagal fibers can be seen running transversely toward the lesser curvature.

**Dissection of the Anterior Leaf of the Lesser Omentum.** The anterior leaf of the lesser omentum now is dissected. The next decision point is to define the distal margin of the dissection of the branches of the nerve of Latarjet (Fig. 35-6). An important landmark is the incisura angularis. The

“crow’s foot” is the neurovascular bundle that innervates the junction of the corpus and antrum, and has three characteristic branches from which its name derives. These nerves contain motor branches to the antrum and secretory branches to the oxyntic mucosa. Thus, leaving this bundle intact makes the antisecretory operation less complete, but fully severing it may lead to disturbances in gastric emptying. Two approaches for defining the distal margin of the dissection have been advocated. First, one may arbitrarily begin the dissection at a predetermined point 6 to 7 cm proximal to the pylorus, a distance that usually corresponds to the most proximal of the three branches of the crow’s foot. Alternatively, one may identify this most proximal branch and begin the dissection there. It is helpful to begin the dissection a few centimeters proximal to the agreed-upon distal margin, because strong traction during subsequent parts of the operation may cause traction injury on the antral motor branches and vessels that accompany them. These last few centimeters are dealt with last.

Anterior vagus n.

N. of Latarjet

A

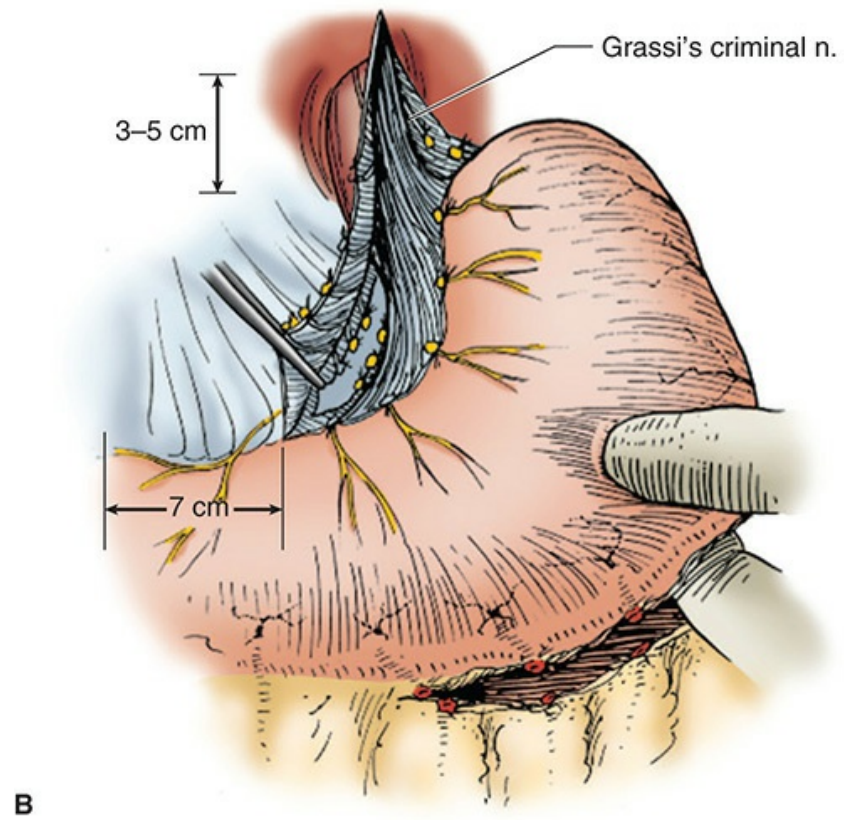

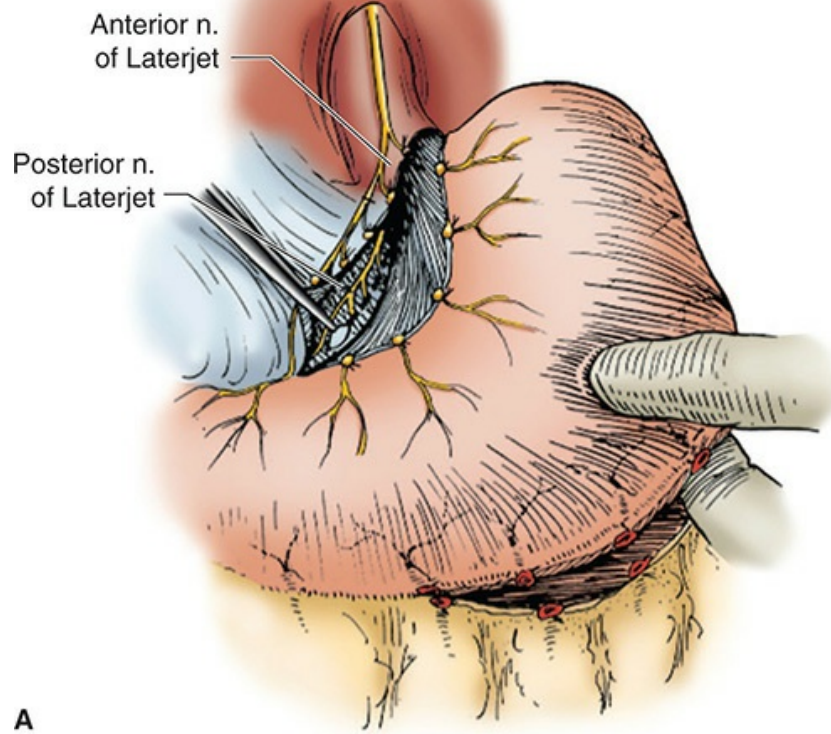

B

**FIGURE 35-6** Highly selective vagotomy. **A.** Planned line of dissection of the anterior leaf of the gastrohepatic ligament. **B.** The dissection is carried out, beginning just proximal to the crow's foot and extending upward, to the left of the gastroesophageal junction.

The assistant provides downward and leftward traction on the greater curvature, thus placing tension on the anterior nerve of Latarjet as it runs along the lesser curvature. The hepatic fibers usually are visualized without difficulty in the upper part of the lesser omentum. It is helpful to “score” the serosa of the lesser curvature, from the incisura to the cardia, and then transversely across the gastroesophageal junction. The incision is performed with dissecting scissors or a no. 15 knife, not electrocautery. This maneuver widens the gap between the nerve and the gastric wall. Individual vessels run transversely from the lesser omentum onto the lesser curvature. These structures are ligated in continuity with 3-0 silk ligatures before division. (We avoid the use of hemostats in this dissection.) This part of the operation is performed gently and should not cause blood loss. The dissection proceeds along the lesser curvature until the gastroesophageal junction is reached. The left anterior aspect of the esophagus is now uncovered, and, for the moment, the dissection stops. Care should be taken not to continue up the right side to avoid interrupting the main anterior vagus.

**Dissection of the Posterior Leaf of the Lesser Omentum.** The posterior leaf of the lesser omentum is then dissected. Care should be taken in setting up exposure for this part of the operation. In one approach, the stomach is rotated upward and to the patient's right. Alternatively, the posterior leaf can be reached by working through the anterior leaf as illustrated in [Figure 35-7](#). Using the thumbs and fingers, the gastroesophageal junction is “rolled” counterclockwise so that the posterior wall moves to the right and the anterior wall moves to the left. The nerve branches and their accompanying vessels then are ligated in continuity and divided. The dissection should not be carried to less than 6 cm from the pylorus. To avoid the main left gastric vessels, this approach to the dissection should be carried about two-thirds of the distance along the lesser curvature. After reaching the left gastric vessels, the surgeon returns to the anterior approach, ligating and dividing the remainder of the posterior leaf through the window in the anterior leaf.

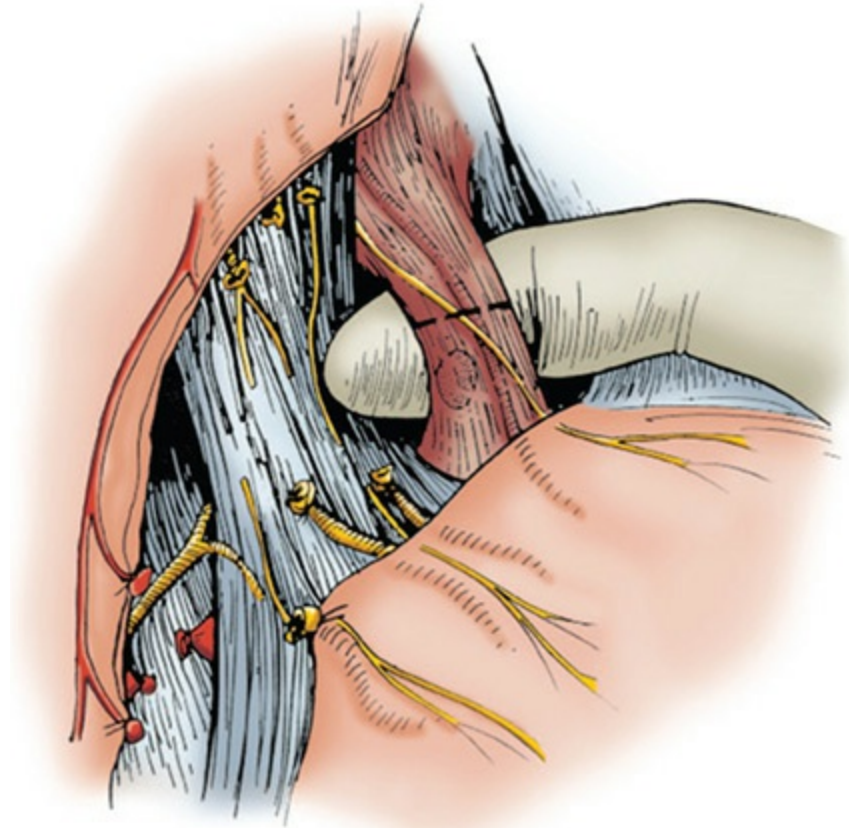

**FIGURE 35-7** Parietal cell vagotomy. **A.** The line of dissection of the posterior leaf of the gastrohepatic ligament is illustrated. **B.** The dissection is carried out through the window created by prior dissection of the anterior leaf.

**Dissection of the Distal Esophagus.** The goal of this dissection is to clear the distal esophagus of all nerve fibers for a distance of approximately 5 cm above the gastroesophageal junction. The importance of this part of the dissection is well documented.<sup>27</sup> It should be noted that the prior dissection of the lesser omentum has allowed the main vagal trunks to move upward and to the patient's right, thereby minimizing the risk of damaging the main trunks in this part of the dissection. The operative technique requires that this dissection stay close to the lesser curvature and esophagus. Any dissection toward the tissues to the right (ie, toward the main vagal trunks) should be avoided.

This part of the procedure begins with the dissection of the left side of the esophagus (Fig. 35-8). Denuding the surface can be performed gently, using a finger or "peanut" dissector to isolate the adventitia that contains nerves, vessels, and lymphatics. This dissection is where the criminal nerve of Grassi is likely to be encountered. Tissues are ligated in continuity and divided. This dissection should also clear 2 or 3 cm of the cardia, just distal to the gastroesophageal junction, and small fibers running to the greater curvature will be divided here. It is usually not necessary to divide any of the short gastric arteries.

**FIGURE 35-8** The serosa has been cut to the left of the esophagus, and fatty areolar tissue to the left of the esophagus, containing nerve fibers, blood vessels, and lymphatics, is hooked up by the right index finger. The angle of His and the adjacent esophagus with a 2- to 3-cm portion of the fundus of the stomach are thoroughly cleaned. In this way, small nerve fibers running to the proximal 3-cm portion of fundus (“criminal nerves of Grassi”) are eliminated.

The anterior aspect of the esophagus is now cleared of vagal fibers ([Fig. 35-9](#)). Gentle traction and lifting of the fibers will isolate them for division between ligatures or by cautery. We prefer ligation in continuity with fine (4-0 or 5-0) silk to avoid injury to the esophageal muscle. The posterior aspect is now re-exposed with downward traction of the gastroesophageal junction and a counterclockwise rotation of the distal esophagus. Working through the window of the anterior leaflet, the upward branches of the left gastric artery are visualized as they pass to the cardia and the gastroesophageal junction. They are ligated in continuity and divided. The dissection continues upward along the cardia and gastroesophageal junction until it is possible to encircle

the lower esophagus with a Penrose drain. Downward traction on the gastroesophageal junction is provided by this drain, and additional nerve fibers are seen in the adventitia. Smaller fibers are cauterized while held away from the esophageal muscularis, whereas larger ones are ligated with clips or fine silk and divided. Throughout this dissection, the positions of the nerves of Latarjet and the main trunks should be checked.

**FIGURE 35-9** Anterior gastric branches of the anterior vagal trunk running downward on the anterior surface of the esophagus are gently lifted with a hemostat and either ligated or clipped before being divided or destroyed with diathermy.

The final part of the operation involves completion of the distal dissection to the crow's foot and checks for hemostasis. A number of authors have in the past suggested that reperitonealization of the lesser curvature be

performed. Although we do not routinely do this, the rationale for this maneuver is that the devascularization that is part of HSV may lead to small areas of necrosis of the gastric wall and localized perforations. Such leaks have been reported in about 0.2% of patients.<sup>28,29</sup> Also, it has been argued that reperitonealization might impede reestablishment of vagal nerve connections to the gastric wall.<sup>30</sup> The reperitonealization would thus protect against such leaks. The reperitonealization can be performed by inversion of the serosa of the lesser curvature with running or continuous 3-0 long-acting absorbable suture. Alternatively, a vascularized pedicle of omentum can be used to cover the deserosalized lesser curvature. Bleeding complications have been reported with this latter method, but it minimizes tension within the gastric wall.

## **REOPERATIVE APPROACHES TO THE VAGUS NERVES**

Approximately two-thirds of patients with duodenal or pyloric channel ulcer recurrence after an initial antisecretory operation (TV, SV, or HSV) have evidence of persistent (or possibly reestablished) vagal innervation.<sup>9,31,32</sup> Although many such recurrences are amenable to medical regimens, a small fraction ultimately may be considered for reoperation, especially if surgery is required to control an acute complication such as bleeding or perforation following a period of ulcer-related symptoms. Prior surgery will have made the standard approaches to the lesser curvature and gastroesophageal junction hazardous, which is often caused by dense adhesions to a previously mobilized left lobe of the liver. Thus, two approaches to the vagus, both nonselective, may be considered for completion of the failed vagotomy, especially if it was performed in conjunction with antrectomy. It should be stressed that when such a reoperation is contemplated, especially in a nonemergent setting, it is prudent to obtain some form of acid secretion profile to document the hypersecretory state. Also, because of the nonselective nature of the completion vagotomy, an antrectomy or drainage procedure must be performed.

In the setting in which standard access is difficult due to prior surgery, Barroso and associates have utilized a transabdominal suprahepatic approach to the vagi.<sup>33</sup> A high midline incision is used, with mechanical retraction to elevate the subcostal margin. An 18F NG tube is placed. The triangular, left coronary, and falciform ligaments and adhesions are divided, permitting

downward retraction of the left lobe. Using the NG tube, the esophagus and hiatus are located. The esophagus and vagi are dissected at the level of the diaphragm at the hiatus and incised anteriorly for a distance of 3 to 5 cm, exposing the esophagus at the lower mediastinum. The trunks are easily identified and ligated in the untouched lower thoracic esophagus. The hiatus is closed with interrupted nonabsorbable sutures.

A transthoracic approach to this region has also been used,<sup>34</sup> and with the advent of thoracoscopy it may become increasingly attractive for this limited set of patients. Specific issues in anesthesia for this approach have been reviewed.<sup>35</sup> The operation is performed through the left chest, entered via the eighth intercostal space. An NG tube is positioned with its tip in the stomach. After division of the inferior pulmonary ligament, the base of the left lung is retracted upward and laterally. The mediastinal pleura overlying the esophagus is incised for a distance of 8 cm. The esophagus is then mobilized and encircled with a Penrose drain. Vessel loops are used to retract individual vagal trunks as they are identified. The supradiaphragmatic anterior vagus nerve may have multiple branches above the level of the diaphragm, but rarely are there multiple branches at a level 4 cm above the diaphragm.<sup>30</sup> In contrast, the posterior vagus has multiple branches above the level of the diaphragm but is a single trunk at this level more than 90% of the time (Fig. 35-10). Thus, the best opportunity for a complete vagotomy lies 4 cm above the diaphragm for the posterior trunk. A circumferential dissection of the 6 cm of esophagus just above the diaphragm is carried out, with technique similar to that performed during the HSV. Tube thoracostomy is required for 2 to 3 days postoperatively.

**FIGURE 35-10** Anatomy of the anterior (**A**) and posterior (**B**) vagus nerves above the diaphragm in 50 cadavers. Incidence of each anatomic group is indicated by percentage. (Reproduced with permission from Jackson RG: Anatomy of the vagus nerve in the region of the lower esophagus and stomach, *Anat Rec* 1949;Jan;103(1):1-18.)

## DRAINAGE PROCEDURES

In the context of bilateral truncal or selective vagotomies, the purpose of a drainage procedure is to preserve the pylorus but bypass it or render it ineffective. The options for drainage include (1) gastroenterostomy; (2) pyloric dilation; (3) pyloromyotomy; and (4) pyloroplasty. Generally, these techniques are used when TV or SV is performed, but they also may be used with HSV in order to treat obstruction resulting from peptic acid scarring. We discuss techniques for performing gastrojejunostomy in the subsequent discussion of gastric resection.

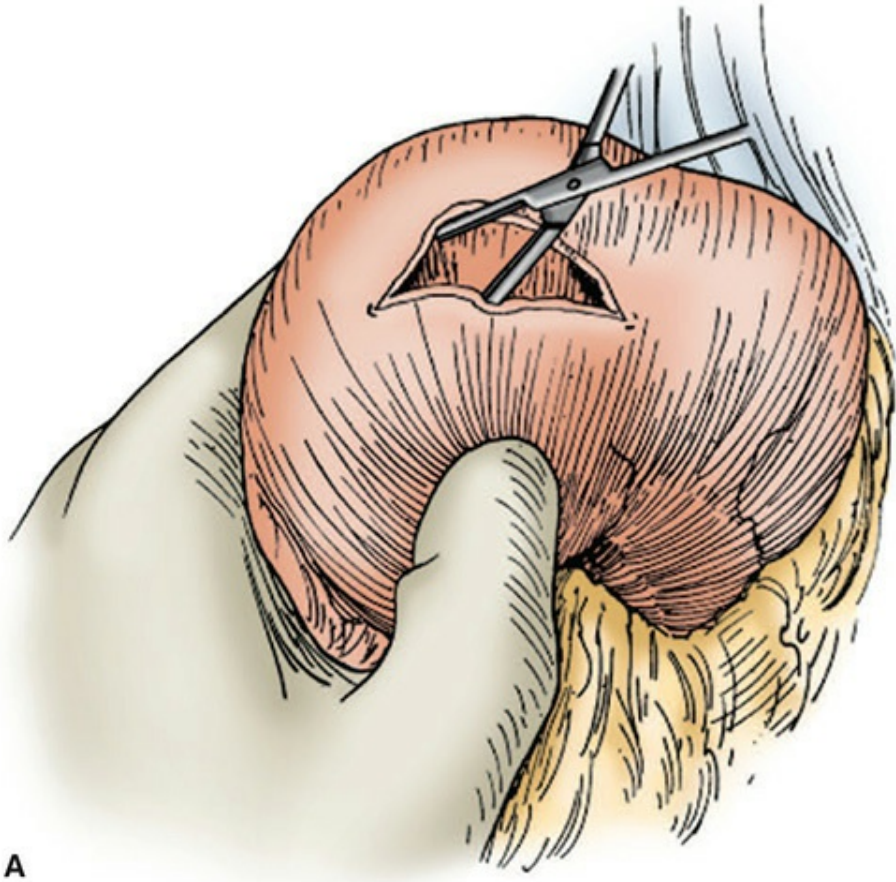

## Pyloric Dilation

In open procedures, the simplest technique reported for performing pyloric dilation is to perform a small gastrotomy, approximately 3 to 4 cm in length, proximal to the pylorus. A finger is introduced through the pylorus, forcing it to widen. The gastrotomy then is used with a single layer of 3-0 silk interrupted sutures or staples. A second technique, advocated for use in laparoscopic cases, is to use a balloon. The balloon, 15 mm in length, may be positioned through a gastrotomy, endoscopically, or with radiologic control, and inflated to 45 psi (pounds per square inch) for 10 minutes.<sup>25,36,37</sup> Other dilators are available for positioning over a wire and inflation to higher pressures, which may prevent pyloric spasm. Advocates of pyloric dilation after laparoscopic TV or SV have suggested that a drainage procedure is not required as often as previously thought or may only be necessary in the early postoperative phase and not permanently.<sup>25,36-38</sup> Thus, it is argued that dilation can be repeated postoperatively and in the outpatient setting. Most surgeons, however, subscribe to the need for some form of formal drainage procedure after SV or TV.

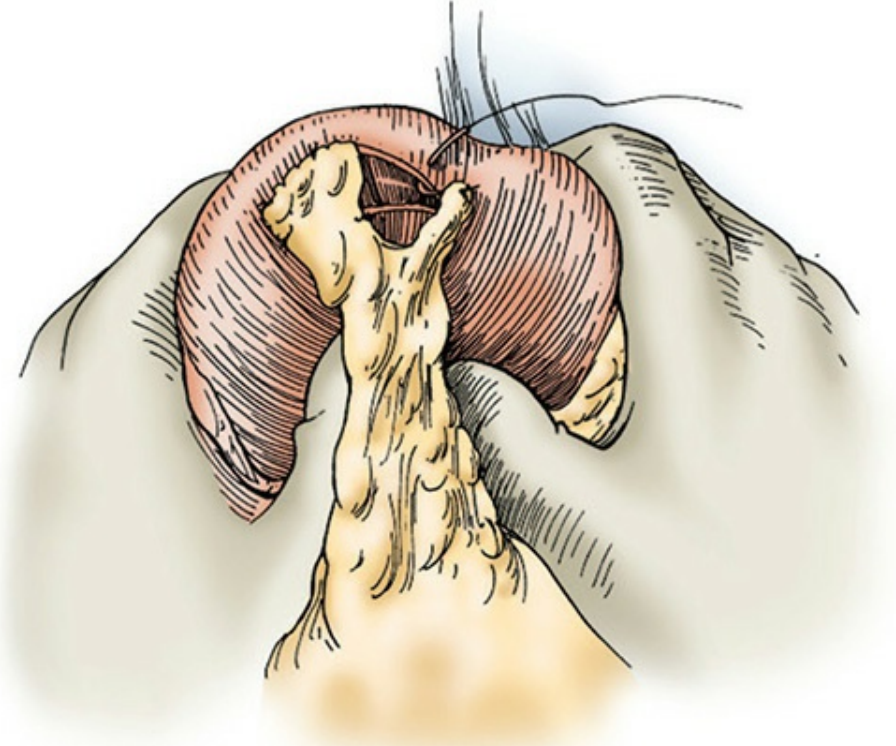

## Pyloromyotomy

Pyloromyotomy is performed using the same techniques as those described in the setting of hypertrophic pyloric stenosis in the infant (Fig. 35-11). An incision is made to score the anterior surface of the stomach from 1 to 2 cm proximal to 1 cm distal to the pyloric ring. The separation of pyloric muscles is accomplished mainly with a fine-tip hemostat and the knife. Cautery is avoided and only used in the muscularis, not the submucosa. When this procedure is performed in the setting of esophagogastrectomy, the pylorus is usually soft and unscarred. In the setting of chronic duodenal ulcer disease, the pylorus is often scarred, and it is difficult to perform the gentle, meticulous dissection of muscle layers, which is required, and at the same time to avoid entering the mucosa. Laparoscopic versions of this procedure also have been advocated in the setting of laparoscopic TV or SV.<sup>39</sup> Occasionally omentum is placed over the myotomy.

A

B

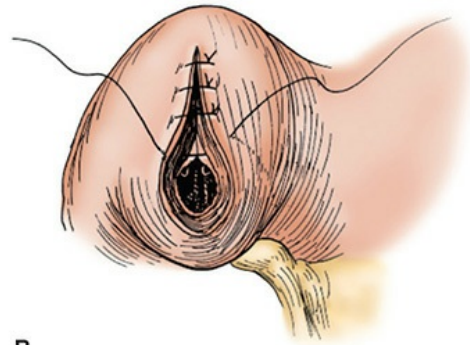

**FIGURE 35-11** Pyloromyotomy. **A.** Dissection of seromuscular layers, avoiding entry into bowel. **B.** An omental patch is used to cover the dissected area.

## Pyloroplasty

The most expeditiously performed pyloroplasty is the Heineke–Mikulicz procedure (Fig. 35-12).<sup>40</sup> This is difficult to perform if the pyloric region is very scarred. The operation usually is performed in the setting of emergency surgery for bleeding or perforation of a gastric or duodenal ulcer. A vagotomy is performed, usually after bleeding has been controlled. If the indication is a bleeding or perforated duodenal or pyloric channel ulcer, the incision for pyloroplasty may include the ulcer or be used to gain access to the ulcer. The incision is thus the planned pyloroplasty incision.

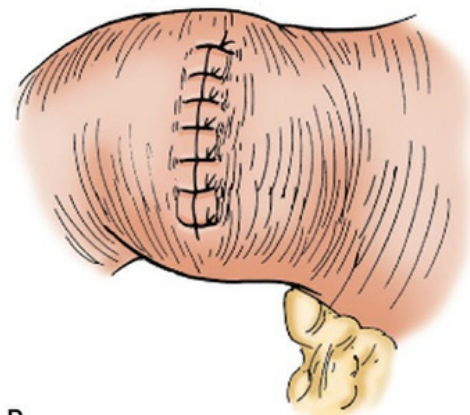

A

B

C

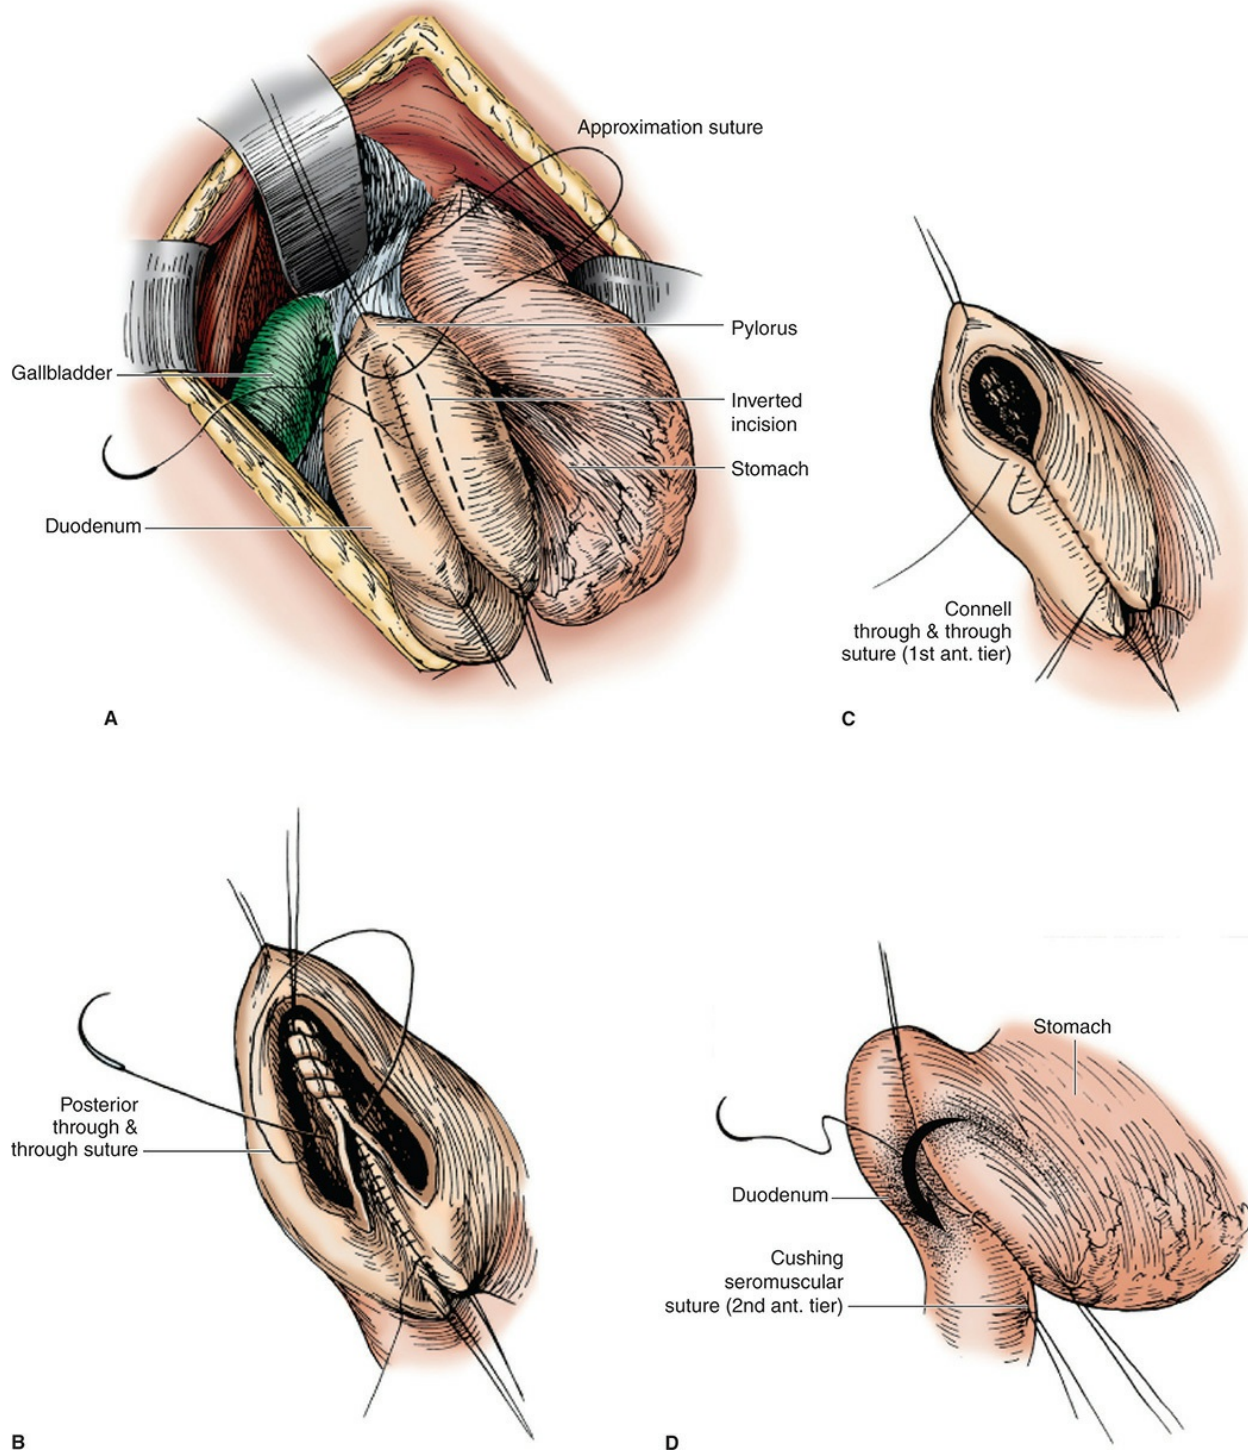

D

**FIGURE 35-12** Heinecke–Mikulicz pyloroplasty. **A.** Full-thickness incision extends from 2 cm proximal to 1–2 cm distal to the pyloric ring. **B.** The incision is closed vertically. **C.** Illustration of Gambee stitch. **D.** Finished pyloroplasty.

It is not always necessary to perform a Kocher maneuver; however, duodenal mobilization is usually helpful in relieving any tension on the intended suture line. Unless the duodenal bulb is unusually mobile, we recommend this as the initial step. In this maneuver, the peritoneum along the right border of the duodenum is incised from the lateral border of the common bile duct to the junction of the second and third portions of the duodenum. After duodenal mobilization, 3-0 silk stay sutures are placed untied, superior and inferior to the site of the intended incision, which then is made on the anterior surface in a longitudinal direction, using electrocautery, from 2 cm distal to the pyloric muscle to 3 cm proximal to the pylorus. The closure of the pyloroplasty is performed vertically, in order to minimize narrowing of the lumen. The Gambee stitch (see [Fig. 35-12](#)) is a single-layer inverting suture used in this setting. The suture, usually performed with 3-0 or 2-0 silk, begins on the outside and is (1) placed full thickness (serosa to mucosa) on the same side; (2) brought, on the same side, back through the mucosa to the submucosa; (3) carried through the submucosa to the mucosa on the opposite side; and (4) brought full thickness from mucosa to serosa on that side. When the pylorus is scarred and the tissues inflexible, it is often helpful to tie the sutures after they have been placed rather than as they are being placed. The stay sutures then are removed after completion of the pyloroplasty. A tongue of vascularized omentum (as shown for pyloromyotomy in [Fig. 35-11](#)) may be brought up to cover the closure and is sutured to the gut wall with 3-0 absorbable (polyglactin 910) sutures.

The Finney pyloroplasty<sup>1</sup> can be used when scarring has involved the pylorus and duodenal bulb and would not permit a tension-free, patulous Heinecke–Mikulicz pyloroplasty. The Finney pyloroplasty is in essence a side-to-side gastroduodenostomy ([Fig. 35-13](#)). When this operation begins, dense adhesions often are encountered surrounding the pylorus and duodenal bulb. These must be lysed systematically. The Kocher maneuver then is performed, carrying the mobilization distally. Complete mobility of the duodenum and freedom from surrounding adhesions are essential to this operation.

**FIGURE 35-13** Finney U-shaped pyloroplasty. **A.** The distal stomach and proximal duodenum are aligned with traction strands and their adjacent walls approximated with a Cushing suture; the inverted U-shaped incision into the lumens of the stomach and duodenum is indicated. **B.** Suture of the posterior septum of the stomach and duodenum. **C.** The first anterior tier of sutures

(Connell) is placed. **D.** The operation is completed with a reinforcing tier of Cushing sutures.

A 2-0 silk stay suture is placed on the upper anterior surface of the pyloric ring. Another stay suture is placed on the greater curvature of the stomach approximately 10 cm proximal to the pylorus, and a third stay suture is placed approximately 10 cm distal to the pylorus. Traction cranially on the pyloric suture and caudally on the other two sutures brings the anterior surfaces on the stomach and duodenum into apposition. The apposed surfaces are sutured together using interrupted 3-0 silk Lembert seromuscular sutures. Using electrocautery, an inverted U-shaped incision is made beginning on the gastric side just distal to the traction suture, traveling longitudinally through the pylorus, then distally to a point just proximal to the traction suture. If the ulcer is present on the anterior surface of the duodenal bulb, it is excised. The posterior inner layer between the stomach and the duodenum then is sutured closed with a continuous over-and-over 3-0 Vicryl, chromic catgut suture, or DDS. This closure is begun at the superior edge, carried caudally, and then converted into a Connell inverting technique as the suture is brought around the inferior edge to begin closing the anterior portion of the inner layer. The anterior outer layer then is closed using interrupted 3-0 seromuscular inverting sutures (Lembert) sutures. Some surgeons use 3-0 Maxon or PDS suture material for single-layer continuous closure, as additional insurance against a suture line leak.

## GASTRIC RESECTIONS

The common indications for gastric resections include peptic ulcer disease and tumors of the stomach. Safe performance of gastric resection requires an understanding of the following: (1) the physiology of vagal innervation and gastric emptying; (2) the surface and vascular anatomy of the stomach; (3) the principles of reconstruction following resection, specifically the Billroth I (B-I) gastroduodenostomy, the Billroth II (B-II) gastrojejunostomy, and the Roux-en-Y configuration; (4) the principles of surgical stapling techniques as well as hand-sewn suturing techniques; and (5) the specific early and late postoperative complications that arise from different gastric resections and different forms of reconstruction. Degrees of resection are correlated to the surface anatomy, as shown in [Figure 35-14](#). This discussion is divided into

three sections. The first section describes techniques for performing wedge resections and closure of gastric wall for ulcers, polyps, or tumors derived from neuroendocrine elements or stromal tissue. Carcinomas are not amenable to wedge resection, and curative resection should involve formal regional gastrectomy and lymphadenectomy. Palliative resection, however, for bleeding or obstruction, may involve either a wedge resection or formal resection. The second section describes techniques for distal gastric resection, focusing on antrectomy or hemigastrectomy (with or without vagotomy) for peptic ulcer disease and when the major decision involves the choice of B-I or B-II reconstruction. The third section describes techniques used in management of gastric carcinoma, focusing on proximal, subtotal, or total resection, and the techniques of regional node dissection.

**FIGURE 35-14** Amount of stomach removed in antrectomy or hemigastrectomy: 60% to 75% for partial gastrectomy and 80% or over for subtotal gastrectomy. Note that most of the lesser curvature of the stomach is excised in all these resections.

## Wedge Resection of the Stomach

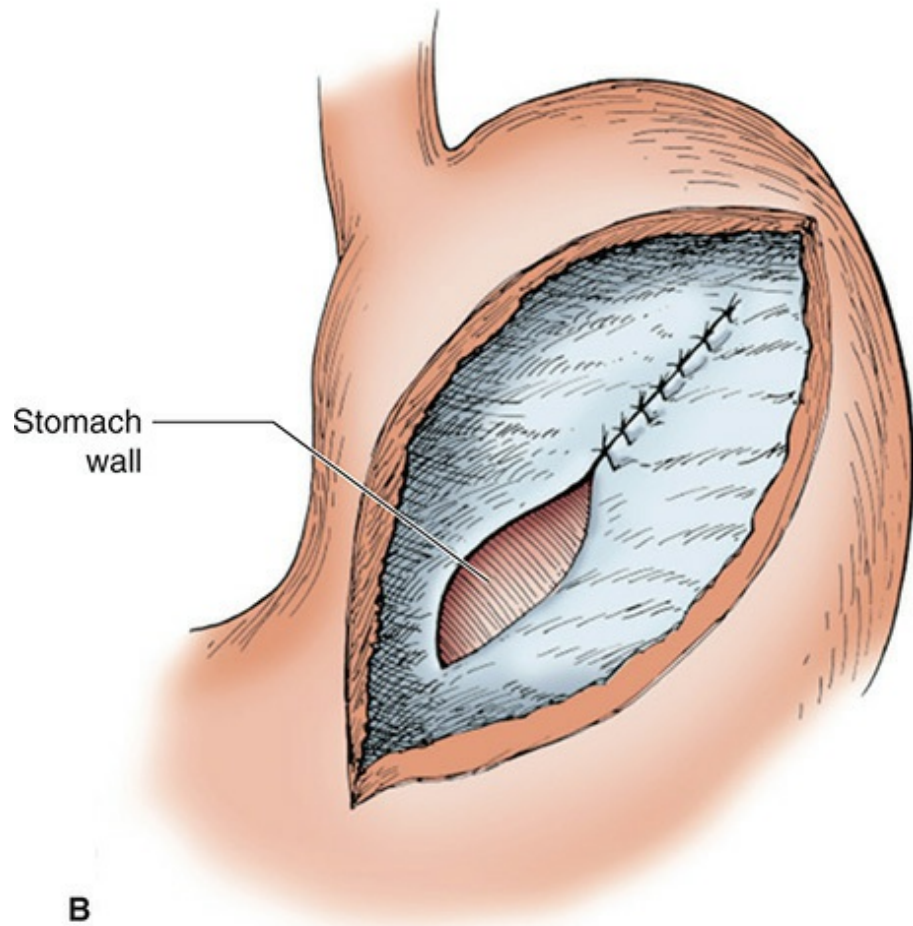

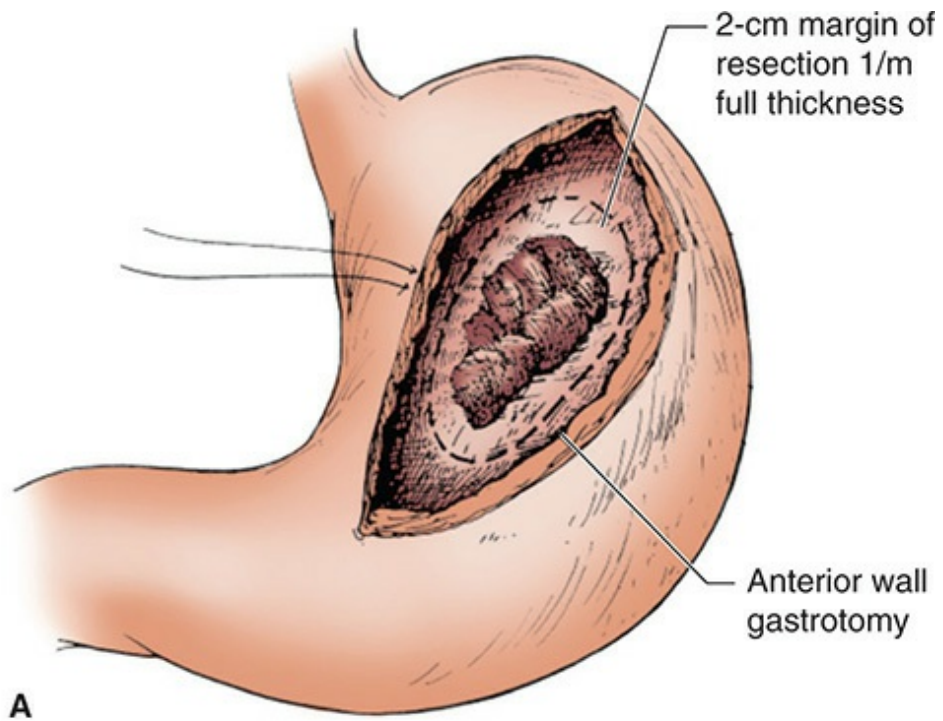

Exposure is gained through an upper midline incision, carried from the xiphoid to the umbilicus. A Bookwalter or other self-retaining mechanical retractor is highly desirable, especially for lesions located on the lesser

curvature or the proximal stomach. The technique of wedge resection depends on the location of the lesion. When a gastric tumor, such as a carcinoid or gastrointestinal stromal tumor (GIST), is located on the greater curvature of the stomach, it is important to note the proximity to the pylorus or gastroesophageal junction. Wedge resection may not be possible if the lesion lies too close (within 2 cm) to these borders, because the closure might narrow the lumen and cause partial obstruction to the flow of chyme. Formal resection may then be necessary. If proximity to these borders is not a problem, omental adhesions to the tumor are left in contact with the lesion. Farther away from the tumor, the portion of the omentum that is adherent is divided between clamps and will come with the specimen. Branches of the gastroepiploic arteries that supply the gastric wall adjacent to the tumor are ligated in continuity with 3-0 silk ligatures and divided. The gastroepiploic artery need not be divided unless it is adherent to the surface of the tumor. At a distance of 2 cm from the base of the tumor, the serosa of the gastric wall is scored using cautery, inscribing a circle. The cautery is then used to deepen the incision through the muscularis. As the muscularis is divided, submucosal bleeders will pop through, requiring precise cauterization to secure hemostasis. When the tumor and the surrounding gastric wall have been excised, the gastrotomy is closed longitudinally in two layers. The inner layer is a full-thickness hemostatic layer sewn continuously using 3-0 chromic or Vicryl suture and the outer layer used interrupted seromuscular 3-0 silk Lembert sutures. An omental patch is not necessary unless there are specific concerns about the blood supply to the closure. When situated favorably, such lesions are also amenable to laparoscopic resection<sup>41-43</sup> and to combined endoscopic-laparoscopic approaches involving intraluminal resections.<sup>44,45</sup> As long as the lumen is not compromised, stapled or open excision is possible.

When tumors are located on the lesser curvature or it is necessary to perform a gastrotomy in order to stop ongoing bleeding from a gastric ulcer, the excision can be performed from the mucosal side of the lesion (Fig. 35-15). Once the inside borders of the lesion have been identified, it is important to obtain optimal exposure of the lesion from the serosal aspect. It may be necessary to sacrifice one or both nerves of Latarjet or the left or right gastric arteries, and this determination can only be made from the outside of the stomach. A stapled option also exists if the lesion can be excised without narrowing the lumen. If the lesion is located on the lesser curvature and

cannot be removed without sacrifice of both nerves of Latarjet, a pyloroplasty should be performed. In such cases, our preference is that the resection is extended to include the distal stomach and a B-I or B-II reconstruction (Fig. 35-16). One variation on this latter approach for high-lying bleeding or perforated gastric ulcers is Pauchet's operation, a modification of an operation described by Shoemaker. This procedure involves removal of the antrum and a tongue of the corpus that extends upward to include the ulcer (Fig. 35-16E).<sup>46</sup>

**FIGURE 35-15** Small tumors or polyps not amenable to endoscopic polypectomy can be excised with surrounding wedge of normal gastric wall. **A.** A 2-cm margin is advisable. **B.** The gastrotomy can be closed in one or two layers, using 2-0 nonabsorbable sutures sewn in interrupted fashion.

## Distal Gastric Resections and Reconstruction

### VAGOTOMY AND ANTRECTOMY

An antrectomy for duodenal or pyloric channel ulcer removes about 35% of the distal stomach and must include the entire non-acid-secreting portion. The incision is made in the upper midline and a Bookwalter or other self-retaining mechanical retractor is helpful. An NG tube is positioned under the

surgeon's guidance, with its tip in the midportion of the stomach. TV is performed first, as described earlier. The incisura is a reasonable landmark for the proximal margin of resection on the lesser curvature, while the terminal portions of the right gastroepiploic artery indicate the margin on the greater curvature.

The distal stomach is mobilized in the following fashion: first, the lesser sac is entered by incising the gastrocolic ligament. These attachments are sometimes avascular but usually are divided between clamps and ligated with 3-0 silk ligatures. The stomach may thus be lifted upward, revealing the posterior gastric wall. Congenital adhesions from the posterior wall and pancreas capsule are divided sharply. The dissection is carried distally along the greater curvature (Fig. 35-17), dividing the small branches of the gastroepiploic artery to the gastric wall. The dissection reaches the main right gastroepiploic artery, which sometimes has to be divided between Kelly clamps and ligated with 2-0 silk ligatures. When possible, the dissection should be carried between the gastric wall and artery, thereby preserving the main gastroepiploic artery as additional collateral blood supply to the suture lines and coming anastomosis. When the dissection reaches the pylorus, small bleeders should be divided between fine hemostats and ligated with fine silk ligatures. The dissection should be meticulous and gentle, because pancreatic tissue lurks in this area and inflammation can be activated in this dissection. The dissection should be carried about 1 cm past the pylorus if a B-I reconstruction is anticipated. If B-II is anticipated, the dissection need only be carried far enough to comfortably place the transverse linear stapler past the pylorus or to oversee the duodenum by a hand-sewn technique.

**FIGURE 35-17** Billroth I operation. **A.** Use of the ligate-divide-stapler, LDS II. This instrument, employing a disposable cassette, applies two stainless steel clips and cuts between, thus reducing operating time and effort significantly. **B.** Extent of dissection of lesser curvature. **C.** Division of vessels entering the lesser curvature in much the same way as when performing proximal gastric vagotomy.

The assistant's left hand is used to lift the distal stomach forward and inferiorly. The more flimsy tissues of the lesser omentum are divided along the lesser curvature, using electrocautery. Starting at the incisura and working toward the pylorus, the tissues of substance are divided between clamps and ligated with 3-0 silk ligatures. This dissection generally will include the

descending branch of the left gastric artery. When the right gastric artery is reached, it is divided and ligated with 2-0 silk ligatures. At this point (Fig. 35-18), we prefer to divide the stomach. This is accomplished with a 90-mm GIA stapler or the gastric TA-90. If the latter stapler is used, the stomach distal to the staple line is occluded with a crushing intestinal clamp and the gastric wall is divided. The clamp is then used as a handle for manipulating the distal stomach. The final portion of the dissection involves gentle dissection of the posterior duodenal wall from the pancreas. Because this dissection may involve separation of pancreas elements from the posterior duodenal wall, cautery is used minimally or not at all and tissues are separated gently with fine hemostats and ligated with 4-0 silk. If a B-I anastomosis is anticipated, the duodenum is divided using the electrocautery, just distal to the pyloric ring. If a B-II anastomosis is anticipated, the transverse TA-30 stapler is placed flush with the pyloric ring. After firing the stapler, a knife is used to sever the pylorus from the staple line. The specimen then is removed to a sterile table. The staple line can be inverted with 3-0 silk Lambert sutures or covered with an omental patch if there is a concern about vascular supply or tension in the staple line. The specimen can then be opened and turned inside out to reveal the gastric mucosa. The proximal border of the resection should contain transverse and obliquely oriented rugae characteristic of the acid-secreting gastric corpus and distinguishable from the longitudinally oriented antral folds. This maneuver verifies complete removal of the antrum.

**FIGURE 35-18** Billroth I operation. Division of stomach beyond the incisura. The gastric 90 stapler facilitates this maneuver. Note the truncal vagotomy has already been performed.

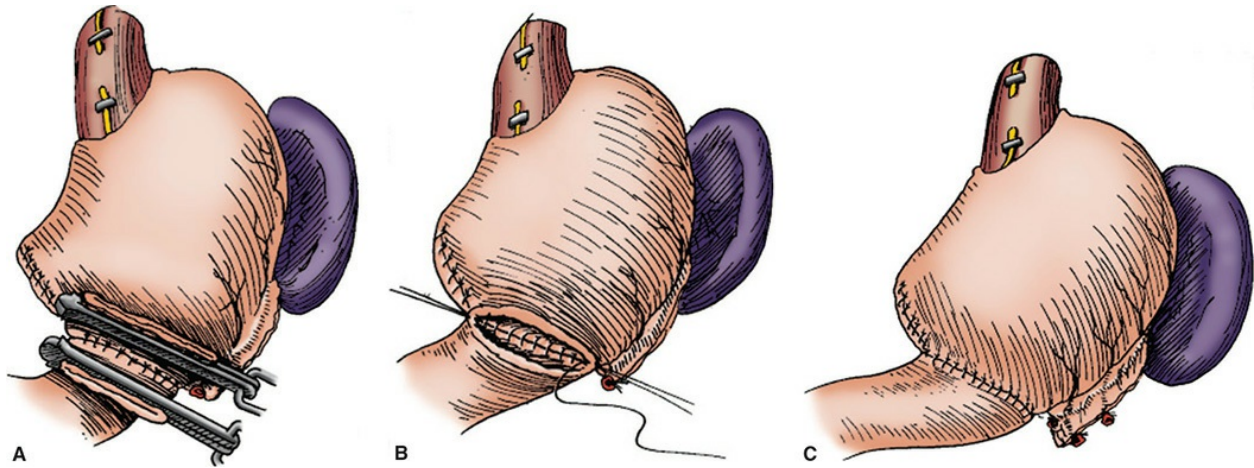

**Billroth-I Reconstruction.** When distal gastrectomy is performed for type I gastric ulcer, B-I anastomosis is preferable. A B-I anastomosis can be used safely for duodenal or pyloric channel ulcer if scarring of the duodenal bulb and pylorus are minimal. If this form of reconstruction is planned, a Kocher maneuver should be performed prior to distal gastrectomy. This will help to minimize tension on the anastomosis. As shown in [Figure 35-19](#), the lower portion of the gastric staple line is removed by excision of gastric wall just posterior to the staple line. The length of the staple line to be removed is the width of the duodenal stump. The gastroduodenostomy is performed in two layers ([Fig. 35-20](#)). The posterior layer of interrupted 3-0 silk Lembert

seromuscular sutures is placed first. The inner 3-0 Vicryl sutures are placed next to each other, sewn away from each other in an over-and-over fashion until the sutures are brought around the edges to the anterior aspect. Connell sutures are used to invert the inner anterior layer. The anterior outer layer is closed with interrupted 3-0 silk Lambert sutures. The junction of the sewn anastomosis and superior portion of the gastric staple line has been called the “angle of sorrow” because of the complication of leakage where these suture/staple lines meet. A number of authors recommend inversion of the upper staple line by 3-0 silk Lambert sutures and a special covering suture for this junction. A second strategy is to cover this area with a tongue of omentum.

**FIGURE 35-19** Billroth I operation. Division of the lower portion of the suture line. **A.** The line of transection from the greater curve to the mid portion of the staple line. **B.** With the stomach clamped a scalpel blade is used to incise the stomach. **C.** Completion of the transection where the anastomosis will be performed.

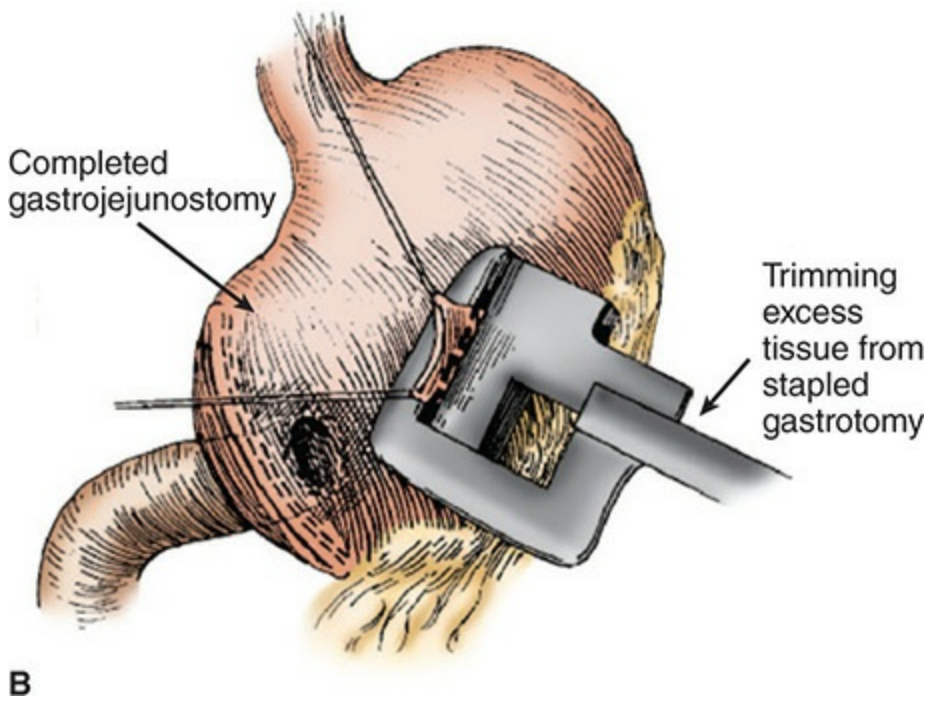

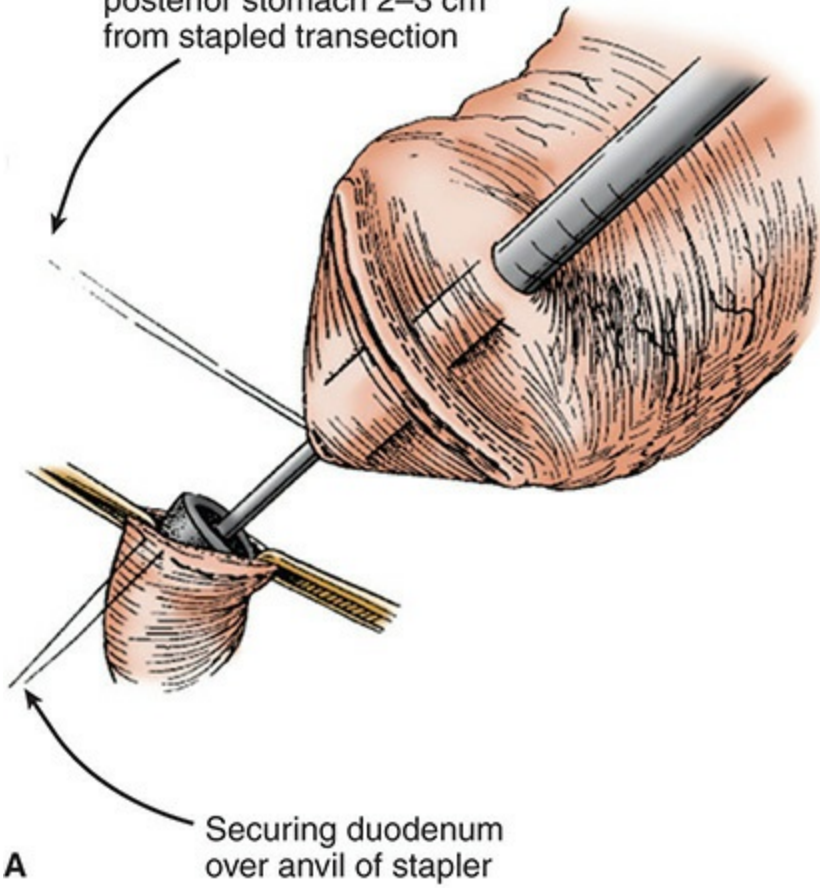

**FIGURE 35-20** Billroth I operation. The construction of the gastroduodenostomy is performed end to end in two layers. **A.** The posterior row of interrupted sutures. **B.** The posterior row of the inner layer using a running suture. **C.** The completed anastomosis.

A B-I anastomosis also may be performed using mechanical stapling techniques. As shown in [Figure 35-21](#), the duodenum is transected just distal to the pylorus with the knife and a purse-string suture is positioned circumferentially around its edge. The anvil of the circular stapler, usually a size 25 mm, is secured in the duodenal stump by the purse string. The circular stapler is inserted through an anterior gastrotomy and fired through the posterior wall of the stomach ([Fig. 35-22](#)). It is important that the margin of the stapled suture line be placed 3 cm proximal to the stapled gastric closure, to provide maximum blood supply to both staple lines. The anterior gastrotomy then is closed with a TA-55 stapler or sutured closed in two layers.

**FIGURE 35-21** **A.** A Dennis clamp can be placed across the proximal duodenum, and the purse-string device can be placed at the selected site of duodenal division. **B.** A gastrostomy is made with the cautery on the anterior surface of the stomach, carefully avoiding large vascular arcades. This should be done at least 3 cm proximal to the row of staples. The gastrostomy should be large enough to accommodate the end-to-end stapling device easily.

Arm of stapler penetrating posterior stomach 2-3 cm from stapled transection

**FIGURE 35-22 A.** The gastrotomy edges should be grasped with two Babcock clamps, and the end-to-end stapling device, minus the anvil, should be passed into the lumen of the stomach. The center rod should be gently pressed against the posterior wall of the stomach approximately 4 cm from the gastric line, and cautery should be used to permit passage of the rod through the posterior wall of the stomach. A purse-string suture will ensure that the stomach does not tear at the site of center rod penetration. The selected anvil size should be applied, and the open end of the duodenum should be grasped with Allis clamps. The duodenal wall should be gently pulled over the anvil, and the purse-string suture should be snugly tied around the center rod. **B.** The cartridge and the anvil should then be approximated, being certain that no extraneous tissues are caught between the anvil and the circular cartridge. The instrument should be fired, and the anastomosis should then be carefully observed by direct visualization to ensure that hemostasis is adequate. The surgeon should then remove the anvil and check the circular tissue doughnuts are intact. If the doughnuts are defective, external Lambert sutures will need to be applied to secure a complete anastomosis. The gastrotomy is closed by grasping each end with Allis clamps and incorporating the entire thickness of the stomach wall through the jaws of the 55-mm stapler.

**Billroth-II Reconstruction.** When scarring or undue tension precludes B-I anastomosis following distal gastrectomy, a B-II gastrojejunostomy is indicated. Before describing our technique, it is worth pointing out the decisions that one will make in performing this reconstruction.

**Closure of the Duodenal Stump.** The first set of decisions focuses on the technique used for closure of the duodenal stump. Careful attention should be given to mobilizing the duodenal stump and obtaining a secure tension-free closure. If the duodenum is relatively free of scar or inflammation, this presents no problem and the TA-55 or TA-60 stapler may be used for closure as described previously. If heavily scarred, dissection of the duodenum and performance of the antrectomy may be abandoned in favor of a safer vagotomy and gastroenterostomy.

If one is committed to the antrectomy and scarring prevents mobilization of the pylorus and duodenal bulb, one may rarely find a need to perform a Bancroft procedure, in which the most distal portion of the pyloric channel and antrum are left in situ after resection of the more proximal antrum (Fig.

35-23). The mucosa of the retained segment is stripped,<sup>47</sup> removing all gastrin-secreting tissue that could cause a retained antrum syndrome. In the classic approach for this procedure, the greater and lesser curvatures are mobilized without dissecting too far into the tissues surrounding the pylorus. About 7 to 8 cm from the pylorus, the seromuscular coat of the antrum is incised circumferentially down to the level of the submucosa. Using sharp dissection, the muscle coat is separated from underlying mucosa. This dissection can be facilitated by submucosal injection of 1:100,000 epinephrine solution, as has been described for the mucosal proctectomy in ileal pouch–anal anastomosis procedures.<sup>48</sup> When the pyloric channel opening is reached, a fine purse-string absorbable suture (3-0 chromic catgut or Vicryl) picks up small bites of submucosa at the pyloric ring. Transfixion and ligation of the mucosa is tempting, but it should be avoided as this would lead to mucosal ischemia and subsequent perforation. A small margin of mucosa is left to be invaginated into the pylorus as the purse string is gently closed and tied. The proximal margins of the seromuscular cuff are excised, leaving just enough to close over the purse string. Omentum is used to cover this closure, if possible.

**FIGURE 35-23** Bancroft procedure. **A.** Dissection of the mucosal from the pylorus and antral muscular layers. **B.** The site of mucosal transection and preservation of the pyloric musculature. **C.** Oversewing of the duodenal stump.

One other important circumstance to be prepared for is the closure of the duodenum distal to a posteriorly perforated or deeply penetrating ulcer. In this setting, the ulcer crater is left in situ (Fig. 35-24). In other settings, the anterior wall of the duodenum can be sutured to the ulcer base, with care being taken to suture-ligate any exposed vessels. The suture line can be protected by a vascularized tongue of omentum.

**FIGURE 35-24** Closure of a chronic, ulcer-scarred duodenal stump. **A.** The ulcer crater is opened and the duodenum sutured closed. **B.** The anterior edge of the ulcer crater is used to oversew the duodenal closure. **C.** A tongue of omentum is tied down to this layer of suture.

**Position of the Jejunal Loop: Antecolic or Retrocolic.** The second decision in performing a B-II reconstruction is whether to bring the loop of jejunum behind (retro) or in front of (ante) the transverse colon. In performing the gastrectomy for benign disease, there is no clear evidence that this makes any difference, and we prefer the retrocolic position. For malignant disease, it has generally been held that the retrocolic position may be predisposed to obstruction owing to enlargement of lymph nodes or serosal implants in the transverse mesocolon. Whether or not this predisposition exists, positioning the jejunal limb in front of the colon requires a somewhat longer mesentery. As long as the anastomosis will not be under tension, the antecolic position will permit emptying as effective as that through a retrocolic anastomosis. If a retrocolic position is chosen, the window in the transverse mesocolon should be wide enough to permit both the afferent and efferent limbs of the jejunum to slide comfortably through. When this window is closed following construction of the anastomosis, it is preferable to tack the mesentery above, on the gastric side, rather than on the jejunal side. This will prevent kinking and obstruction of the jejunal limbs and positions the anastomosis below the mesentery.

**Length of the Afferent Limb.** The third decision is the choice of the segment of jejunum used for the anastomosis. In general, the segment should be as close to the ligament of Treitz as possible and still reach the stomach without tension. This generally leaves 10 to 20 cm of the proximal jejunum as the afferent limb. The shorter this length, the less likely the possibility of an afferent limb syndrome developing. The incidence of other complications such as alkaline reflux gastritis, dumping, or postvagotomy diarrhea should not be influenced by the length of the afferent limb.

**Anastomosis: Site on the Gastric Wall and Technique.** Schematically illustrated in [Figure 35-25](#) are a number of described variations on the B-II reconstruction. We describe here one hand-sewn and one stapled technique for anastomosis. As shown in [Figure 35-26](#), a portion of the gastric staple line is excised with electrocautery, taking a small wedge of stomach behind the staple line. The superior portion of the staple line can be reinforced with 3-0

silk Lembert sutures at this time or can be reinforced later by tacking the afferent limb of jejunum, just beyond the anastomosis, to the gastric wall. The proximal jejunal limb is brought, untwisted, through a window in the transverse mesocolon (Fig. 35-27). Traction seromuscular sutures (2-0 or 3-0 silk) are placed at both corners of the anastomosis. The gastrojejunal anastomosis is performed in two layers (Fig. 35-28), between the most caudal part of the stomach and the jejunal limb. The outer layer is composed of 3-0 silk Lembert seromuscular sutures. The inner layer is performed in the posterior row by running two 3-0 Vicryl sutures in opposite directions around the corners and then in Connell fashion for the anterior row. Placement of the anastomosis on the posterior gastric wall, about 2 to 3 cm from the gastric staple line, also will provide a suitably dependent position for drainage of gastric contents. The window in the transverse mesocolon is closed, as illustrated in Figure 35-29.

**FIGURE 35-25** Billroth II operation and some of its modifications.

**FIGURE 35-26** Billroth II operation. The antrum is resected as in a Billroth I operation. The distal portion of the resection line is excised. **A.** The line of transection from the greater curve to the mid portion of the staple line. **B.** With the stomach clamped a scalpel blade is used to incise the stomach. **C.** Completion of the transection where the anastomosis will be performed.

**FIGURE 35-27** Billroth II operation. The jejunal segment, located 10 to 20 cm beyond the ligament of Treitz, is brought through a window in the retrocolic mesentery.

**FIGURE 35-28** Billroth II operation. The gastrojejunal anastomosis is constructed in two layers, as described in the text.

**FIGURE 35-29** Billroth II operation. The retrocolic window in the mesentery is closed in order to avoid herniation of other viscera. The mesentery is linked to gastric wall, positioning the anastomosis below the closure.

Illustrated in [Figures 35-30](#) and [35-31](#) is the technique for stapled gastroenterostomy. As before, the jejunal limb is placed in the retrocolic position. Traction sutures are placed on the gastric wall posterior to the anastomosis, bringing the jejunal limb into apposition. The 55-mm GIA stapler is fired after its two limbs are placed through a small gastrotomy and small enterotomy, respectively. The open end of the anastomosis is then closed with a TA-55 stapler. It should be noted that these staple lines, especially from the TA-55, are difficult to reinforce without undue tension. The blood supply of the gastric and intestinal walls is ample, and reinforcement with Lembert sutures generally is not necessary.

**FIGURE 35-30** Stapling technique for Billroth II gastrojejunostomy. **A.** A gastrostomy and enterotomy are made to accommodate the stapler. **B.** The stapler is positioned to create the anastomosis.

**FIGURE 35-31** A. Billroth II operation. B. and C. The transverse stapler is used to close the common opening over the gastrojejunal anastomosis.

## Subtotal and Total Gastric Resections

The main indications for subtotal (70%-80%) gastric resection are carcinoma of the antrum or pylorus or primary gastric lymphoma, although resection for lymphoma is quite rare given the increasing success of medical therapy. However, in cases of ulcers that lie very proximal on the lesser curvature, the proximity to the gastroesophageal junction prevents excision without significant narrowing of the gastric inlet. Similarly, the main indication for

total gastric resection is a bulky carcinoma of the body or distal fundus or a carcinoma of the proximal stomach, and rarely, otherwise unmanageable symptoms of an unresectable gastrinoma. Indications for near-total (>90%) gastric resection include the uncommon settings of the Roux stasis syndrome and gastroparesis unresponsive to medical management, as well as carcinoma or lymphoma of the body of the stomach. The approaches for subtotal and near-total gastrectomy are discussed here only briefly, focusing on issues of exposure and techniques for resection of the stomach itself and reconstruction. The principles of resection for gastric carcinoma will be presented subsequently in conjunction with the discussion of radical total gastrectomy for carcinoma.

## **SUBTOTAL AND NEAR-TOTAL GASTRIC RESECTIONS**

In principle, a subtotal gastrectomy is simply an extended antrectomy or hemigastrectomy. A few technical issues are worth noting. First, the exposure provided by a midline incision is usually adequate, although some surgeons may prefer a chevron incision. Second, the left gastric artery always is ligated and divided in this dissection, and once the level of gastric transection has been determined, the branches of the left gastroepiploic artery and short gastric arteries are ligated in continuity and divided up to this predetermined level. Third, in opting for a near-total gastric resection, a 1- to 2-cm cuff of gastric wall is left behind and is the margin for the anastomosis. For this operation, it is desirable to preserve the uppermost one or two short gastric vessels in order to ensure the adequacy of the blood supply for the gastric side of the anastomosis.

One final issue is that a greater extent of lymph node dissection has shown improvement in survival for gastric cancer after resection,<sup>49,50</sup> although with increased morbidity in some<sup>51</sup> but not necessarily in all<sup>52</sup> centers. Extended lymphadenectomy (D2 resection) involves dissection and removal of the perigastric lymph nodes as well as those of the named vessels of the celiac axis, and the hepatoduodenal ligament.<sup>53,54</sup> Skeletonization of the celiac artery and its branches (left gastric artery, common hepatic artery, and splenic artery) is required to achieve adequate lymphadenectomy. While performance of a D1 versus D2 lymphadenectomy had previously been debated, modified D2 lymphadenectomy (which excludes distal pancreatectomy or splenectomy for retrieval of lymph nodes) has now become standard of care in resections

for carcinoma and has been shown to contribute to improved survival.<sup>55,56</sup> Finally, although it is often possible to reconstruct with a standard gastrojejunostomy, we prefer a Roux-en-Y reconstruction because this minimizes tension on the suture line, incidence and symptoms of bile reflux, and theoretically reduces the risk of anastomotic obstruction by persistence or recurrence of tumor.

## **TOTAL GASTRECTOMY FOR CARCINOMA**

The goals of total gastrectomy for carcinoma are (1) clearing of margins on both esophageal and duodenal sides; (2) removal of local and regional lymph node-bearing tissues, including those surrounding the right and left gastric arteries, celiac axis, and named branches of the celiac axis, right gastroepiploic artery, and short gastric arteries; (3) removal of the omentum en bloc with the stomach; and (4) removal of the lymphatic tissues overlying the pancreatic capsule. Extended lymph node dissection (modified D2 resection) should be done here as described in earlier.<sup>40-43</sup> After total gastric resection, we favor a Roux-en-Y reconstruction with a direct esophagoenterostomy rather than a jejunal pouch, although the techniques for both forms of reconstruction will be described.

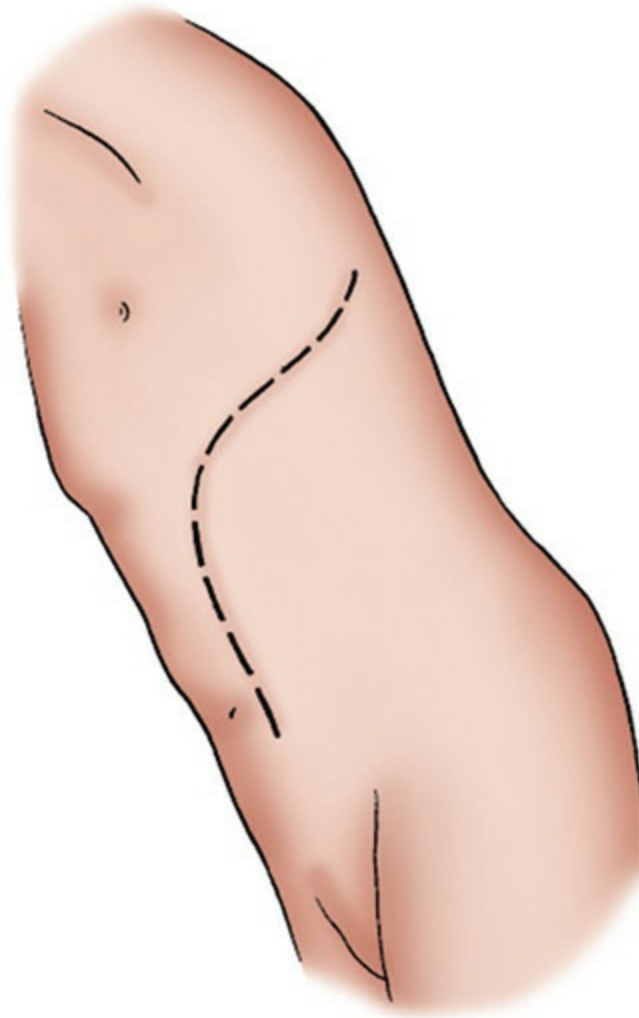

Illustrated in [Figure 35-32](#) is the final specimen in an en bloc resection. Generally, an upper midline or chevron incision will provide good exposure. A thoracoabdominal incision ([Fig. 35-33](#)) is rarely necessary but can provide better exposure when the patient's habitus suggests a deep hiatus. This latter incision also should be considered when preoperative endoscopy suggests that the tumor is close enough to the cardia so that the distal thoracic portion of the esophagus might be included with the resection. If this latter approach is chosen, the abdominal portion of the incision is performed first, in order to assess resectability. The patient is placed in a left thoracotomy position. The incision is carried from the line of the eighth rib obliquely toward the umbilicus. If resection appears feasible, the incision is extended over the eighth rib to the posterior angle. Occasionally, the seventh rib will provide better exposure. A separate rib retractor for the chest and a self-retaining retractor without a ring for the abdominal portion provide the best retraction. The diaphragm is divided toward the hiatus, but the muscle does not always have to be divided completely. Thus, it may be possible to spare the neurovascular bundle. Significant bleeding is encountered and this requires

suture ligation with 2-0 or 0-0 Vicryl.

**FIGURE 35-32** Anatomy relevant to resections for gastric carcinoma.

**FIGURE 35-33** Thoracoabdominal incision for radical total gastrectomy for carcinoma of the stomach. The incision is carried along the seventh or the eighth interspace.

In the abdominal approach, the Bookwalter retractor is used. A thorough examination of the entire abdomen must be undertaken to exclude subradiologic metastatic disease. Extra care in positioning retractors on the left lobe of the liver, diaphragm, and small intestine for optimal exposure of the hiatus is time well spent. The dissection is begun by dividing the omentum from the transverse colon (Fig. 35-34). This relatively avascular plane can be separated using the electrocautery. Deviation from this plane will injure the colon or require tedious ligation and division of omental or mesenteric blood vessels. The lesser sac is then entered, allowing assessment of the retroperitoneum with regard to local tumor extension and lymph node

involvement. The distal portion of the gastrectomy is then performed. The origin of the right gastric artery at the common hepatic artery is identified, ligated in continuity with 2-0 silk ligatures, and divided.

**FIGURE 35-34** Resection for gastric carcinoma. The gastrocolic omentum is detached from the transverse colon using electrocautery.

Lymphatic-bearing tissues are swept toward the gastric side. The right gastroepiploic artery is identified, usually by palpation, and traced as far to its base as possible. It is usually possible to trace the artery to its origin at the gastroduodenal artery, which is similarly ligated in continuity and divided. Using the electrocautery, the gastrohepatic ligament is incised near the liver and its tissues are swept toward the lesser curvature, from the duodenum to the esophagus. Any small vessels are ligated with 3-0 ligatures. The dissection is carried onto the peritoneal surface of the esophagus. The duodenum may then be divided using the GIA stapler or a TA-55 stapler that is fired twice, once on the duodenum and once directly on the pylorus. The

duodenum is divided just distal to the pyloric ring (Fig. 35-35).

**FIGURE 35-35** Resection for gastric carcinoma. The duodenum is divided beyond the pylorus. Either the linear cutter or transverse stapling instruments are appropriate. If feasible, the duodenal staple line is reinforced using 3-0 silk Lambert sutures.

With the distal portion of the stomach divided, full access to the left gastric artery is obtained posteriorly through the lesser sac. This approach optimizes visualization of the celiac axis and its branches. With the assistant retracting the stomach upward and anteriorly, a number of congenital adhesions between the posterior gastric wall and the peritoneum overlying the pancreas are observed (Fig. 35-36). If tumor is invading this plane, a

decision must be made regarding inclusion of the body and tail of the pancreas in the specimen. The plane made by the peritoneum overlying the pancreas is a natural plane, and there may be sense in taking this peritoneum with the en bloc specimen. This layer can be dissected off the anterior face of the pancreas and swept gently to the front toward the left gastric vessels and splenic hilum. If a curative resection appears to be feasible but would require removal of the body and/or tail of the pancreas, this is not a contraindication to resection. The origin of the left gastric artery is then identified at the celiac axis, ligated in continuity using 2-0 silk, and divided (Fig. 35-37). The stump of the artery is suture-ligated as well. From the celiac axis side, the tissue surrounding the artery contains lymphatics and is swept toward the lesser curvature. Lymphatic bearing tissues overlying the individual celiac axis branches, including the common hepatic artery, left gastric artery, and splenic artery, must be included within the specimen. When the tumor is located in the more proximal body and corpus, the case for inclusion of the spleen with the en bloc specimen has not been persuasive<sup>57,58</sup>; a recent meta-analysis suggested no oncologic benefit<sup>59</sup> for removal of a spleen not apparently involved by direct extension. Inclusion of the spleen is indicated if there are obvious tumor-bearing nodes or if there is direct invasion of the splenic hilum. Through the lesser sac, the tail of the pancreas is identified. The splenic artery and vein are separated, suture-ligated, and divided individually. At this point, the short gastric vessels are then part of the en bloc specimen and are not dissected or divided.

**FIGURE 35-36** Resection for gastric carcinoma. With the lesser sac fully visualized, the thin layer of tissue overlying the pancreas is exposed and can be removed with the en bloc specimen.

**FIGURE 35-37** Resection for gastric carcinoma. Exposure of the left gastric artery through the lesser sac.

The posterior aspect of the esophagus then comes into view as the stomach and spleen are lifted upward. Posteriorly, the front of peritoneal tissue can be dissected bluntly until the superior border of the pancreas is reached. The peritoneum is continuous with the peritoneum investing the gastric side of the gastroesophageal junction. If this layer has not been included with the dissection, the peritoneum must be divided here, exposing the gastroesophageal junction posteriorly. [Figure 35-38](#) demonstrates the stomach completely mobilized except for its attachment to the esophagus. A noncrushing clamp is placed on the mobilized esophagus and the specimen is resected. To minimize spillage of luminal contents, a second clamp is placed on the gastric side or the TA-55 stapler may be fired below the line of resection and above the gastroesophageal junction.

**FIGURE 35-38** Gastric resection for carcinoma. The esophagus is transected just above the gastroesophageal junction.

Our preferred technique for reconstruction is a simple Roux-en-Y, with an end-to-side esophagojejunal anastomosis with the Roux limb. Using the GIA stapler, a section of jejunum is divided 10 to 15 cm beyond the ligament of Treitz ([Fig. 35-39](#)). The Roux limb is brought antecolic up to the esophagus. An enteroenterostomy is constructed between the jejunum on the duodenal side of the Y and the jejunum, 40 to 45 cm distal to the Roux limb staple line ([Fig. 35-40](#)). The enteroenteral anastomosis can be performed using hand-sewn two-layer technique or stapling technique. The esophagojejunal anastomosis is performed using interrupted 3-0 silk sutures for both the inner and outer layers, as shown in [Figure 35-41](#), or by the use of an EEA stapler.

The completed reconstruction is shown in [Figure 35-42](#). This figure emphasizes the antecolic position of the anastomosis when the operation is performed for malignant disease. Areas of potential internal herniation in the mesentery are closed with absorbable 3-0 sutures.

**FIGURE 35-39** Gastric insert for carcinoma. Construction of Roux-en-Y limb begins with division of the jejunum beyond the ligament of Treitz.

**FIGURE 35-40** Construction of Roux-en-Y anastomosis. The enteroenterostomy is performed in two layers. The length of the Roux limb measures 40 cm.

**FIGURE 35-41** Roux-en-Y reconstruction following total gastrectomy. The

anastomosis is prepared using two layers of interrupted 3-0 silk sutures. **A.** Outer layer of posterior sutures. **B.** Site of enterotomy. **C.** Posterior inner row of sutures **D.** Completed esophagojejunal anastomosis.

**FIGURE 35-42** Roux-en-Y reconstruction completed. NG, nasogastric.

A jejunal pouch (Hunt-Lawrence pouch) also may be constructed, with the idea of anastomosing the esophagus in end-to-side fashion with the antimesenteric border of the pouch.<sup>60,61</sup> The technique is illustrated in [Figures 35-43](#) through [35-45](#) and can be performed expeditiously using surgical staplers. The pouch is constructed with the goal of providing a

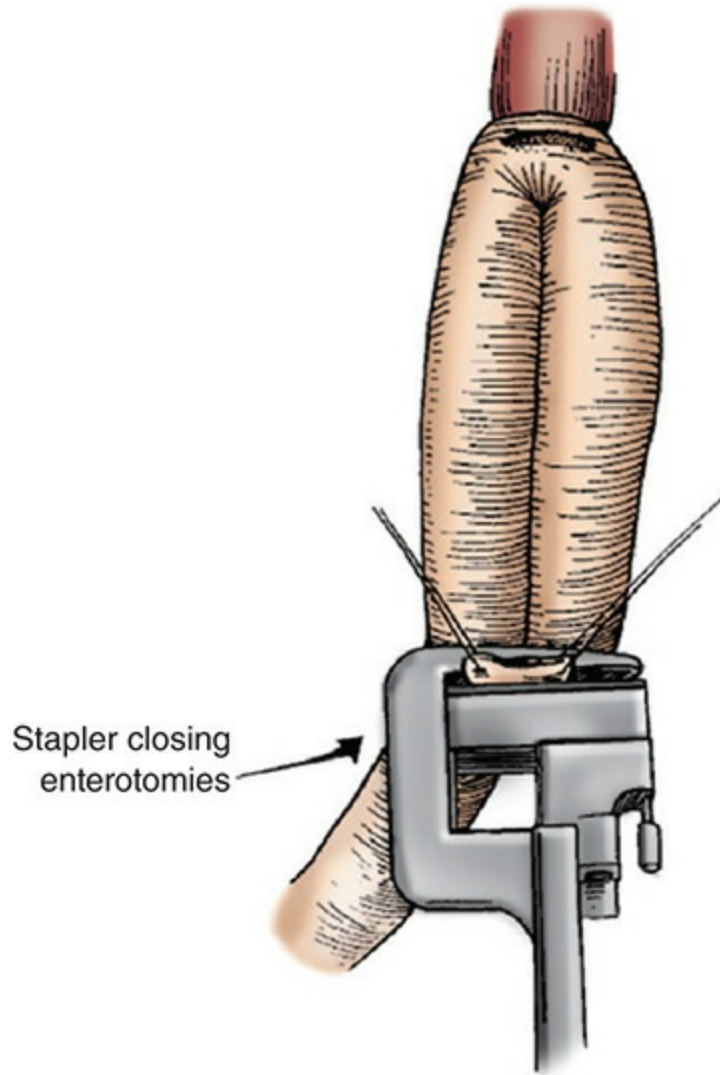

reservoir function. Alternatively, a number of surgeons expressed a preference for leaving an island of undivided intestine at the bend in the pouch. This should theoretically optimize the blood supply to the anastomosis. The circular stapler can be passed through the open end of the Roux limb in order to perform the end-esophagus to side-jejunum anastomosis. The linear stapler then can be fired in such a way as to leave the island of undivided intestine. One important point is that the pouch can be made too long, giving rise to stasis and ineffective clearance of food from the pouch into the intestine. The pouch should not be more than 15 cm in length.

**FIGURE 35-43** Total gastrectomy with jejunal pouch reconstruction.

**FIGURE 35-44** Total gastrectomy. The circular stapler is positioned via the enterotomies. The center rod is pushed through the antimesenteric border of the jejunum using cautery to prevent tearing.

**FIGURE 35-45** Completed pouch and esophagojejunal anastomosis. The enterotomy is closed with the transverse 55-mm stapler.

## Laparoscopic Approaches

### LAPAROSCOPIC APPROACHES TO THE VAGUS NERVE

As noted previously, the advent of laparoscopic approaches has led surgeons to reconsider traditional approaches to peptic ulcer disease. The advantages of minimally invasive approaches revolve largely around the minimal postoperative discomfort and rapid recovery, with a potential benefit in reduced cost of surgery versus the cost of long-term medication.<sup>62</sup> At the same time, rapid advances have occurred in our understanding of the role of

*Helicobacter pylori* and mucosal growth, and angiogenic factors in ulcer healing and recurrence. In addition, limitations in access and suturing techniques have increased the difficulty of access to the lesser sac and of performing drainage procedures. These considerations have led surgeons to question the rationale for routine drainage whenever TV has been performed.<sup>15,37</sup> A number of approaches have evolved to address these difficulties and have been given credibility in the laparoscopic experience. One such approach has been to combine truncal vagotomy with pyloric dilation or seromyotomy.<sup>26,16,21</sup> Another has been to combine a posterior truncal vagotomy with an anterior highly selective vagotomy or with an anterior seromyotomy.<sup>16</sup> The important elements of the laparoscopic approach to the vagi are discussed here.

## **PATIENT POSITION AND PORT PLACEMENT**

The patient is placed on the operating room table with legs in stirrups and apart (Fig. 35-46). Video monitors are placed on either side at the head; the surgeon often works best when standing between the legs, with the camera operator on the right and the first assistant on the patient's left. The scrub nurse/technician and instrument table are placed at the patient's right foot. A large esophageal tube or even a gastroscope is placed in the stomach to facilitate visualization of the distal esophagus. Frequent aspiration of the gastric contents is crucial to maintain total collapse of the stomach and the best visualization. We recommend an open technique to gain access to the peritoneum, insufflating to a pressure of 14 mm Hg. Five ports are placed in the following locations: (1) a 12-mm laparoscope port at the superior edge of the umbilicus or placed 5 cm above and lateral to the left of midline; (2) a 5-mm irrigation/suction and dissection port in the subxiphoid position, just to the right of midline; (3) a 10-mm port for retraction and grasping forceps midway between the umbilicus and xiphoid, to the right of the rectus, and possibly as far as the midclavicular line; (4) a 10-mm port for grasping forceps midway between the umbilicus and xiphoid, almost to the anterior axillary line on the left; and (5) a 12-mm operating port just lateral to the rectus 3 cm above the umbilicus. A number of surgeons prefer the angled 30-degree laparoscope for this operation.

**FIGURE 35-46** Setup for laparoscopically-assisted vagotomy.

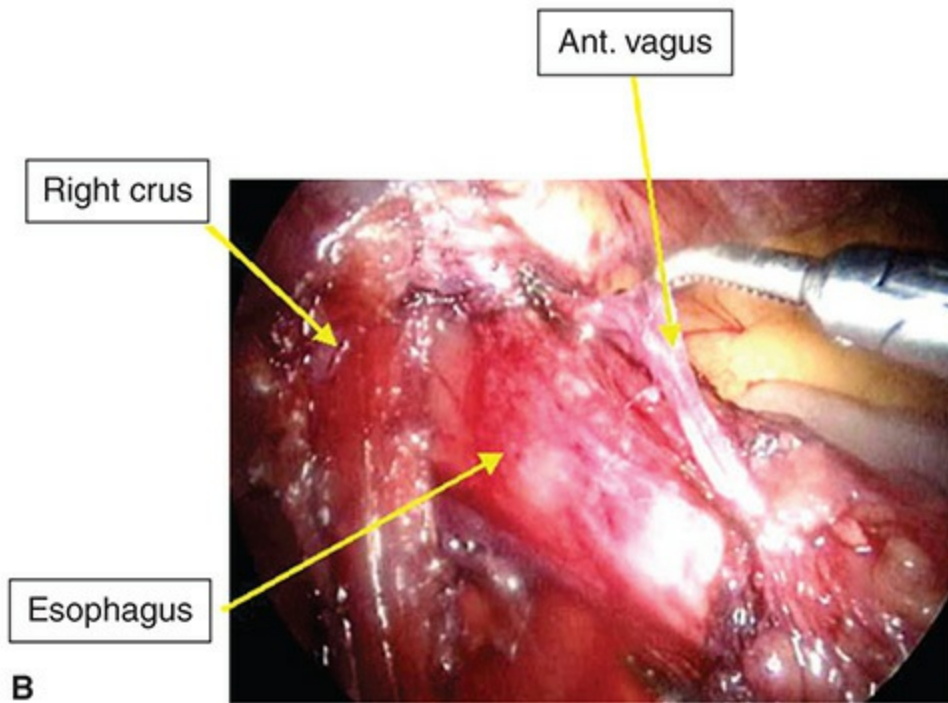

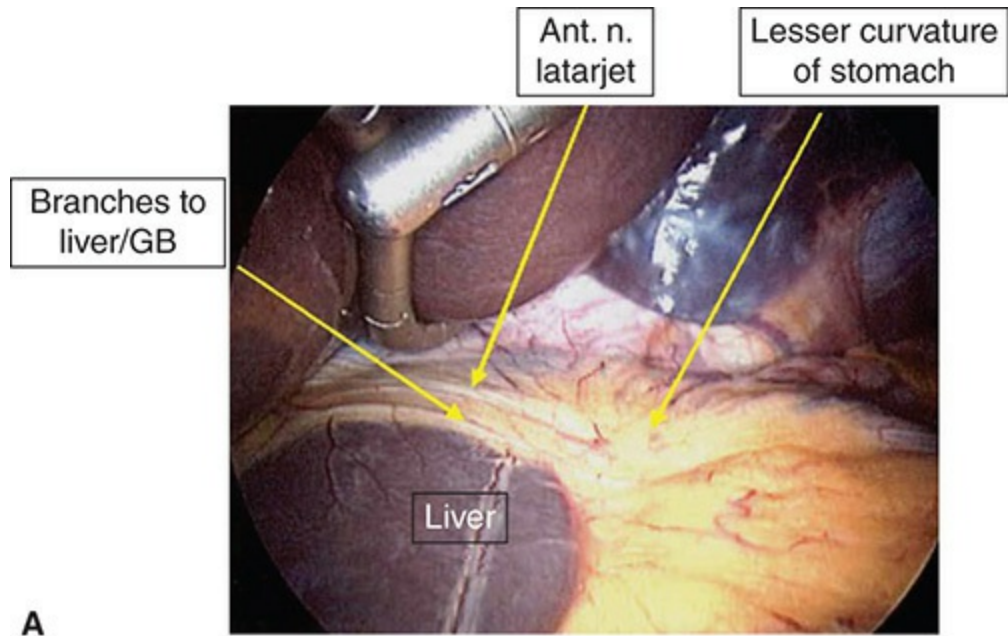

## LAPAROSCOPIC TRUNCAL VAGOTOMY

The left lobe of the liver is retracted using a probe placed via the subxiphoid port or the 10-mm fan retractor placed via the higher right-side port (Fig. 35-47). Visualization is improved when tissues from the hiatus are dissected away from the esophagus and lesser curvature (Figs 35-48 and 35-49). One can encounter a coronary hepatic vein or accessory hepatic artery in this dissection. These do not always need to be sacrificed. The right crus of the diaphragm usually is seen here and can be retracted with one of the blades of the liver retractor (Fig. 35-50). A Babcock clamp or other atraumatic grasper

is used to retract the anterior greater curvature (distal to the cardia) to the patient's left. A hook coagulator or dissecting forceps is used to incise the lesser omentum, entering the lesser sac just above the takeoff of the hepatic branch of the anterior vagus nerve. A plane is developed between the right crus and the esophagus and continued posteriorly. Continued dissection along the wall of the esophagus reveals the posterior trunk, which is ligated between clips and divided (Fig. 35-51). The excised nerve segment is sent for frozen-section examination. The next step is identification of the anterior vagal trunk(s). The phrenoesophageal membrane usually has been entered and incision is extended toward the left, first by scoring the membrane with scissors and then bluntly pushing away the membrane with a cotton dissector. The visualization of major anterior trunks is often easier in the laparoscopic approach, owing to magnification and excellent video optics. These branches also are ligated and divided between clips (Fig. 35-52), with frozen-section confirmation of the nerve segment. Smaller anterior branches are identified and cauterized after being held away from the esophageal wall. It is possible to dissect tissues on either side of the esophagus for a distance of 5 to 6 cm, thereby ensuring division of any nerve branches to the lesser curvature and cardia. The main difficulty can occur in visualizing the angle of His and possibly missing major vagal branches, including the "criminal nerve." With the use of a traction forceps placed through the subxiphoid port and a cotton dissector placed via the left grasping forceps, it is possible to expose the left edge of the gastroesophageal junction and cauterize or clip any branches.

**FIGURE 35-47** Laparoscopic view of the hiatus.

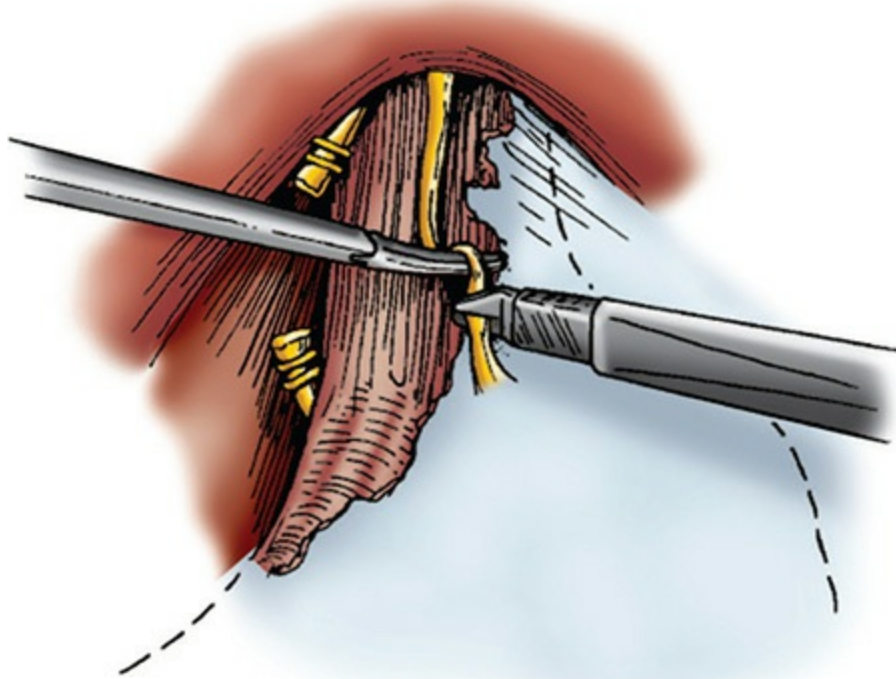

**FIGURE 35-50** Laparoscopically assisted vagotomy. The crus of the

diaphragm is retracted to the patient's right. The anterior vagal trunk is exposed at the gastroesophageal junction.

**FIGURE 35-51** Laparoscopically assisted vagotomy. The posterior trunk is ligated between clips and divided.

**FIGURE 35-52** Laparoscopically assisted vagotomy. Ligation and division of the anterior vagus between clips.

## **ANTERIOR PROXIMAL VAGOTOMY OR SEROMYOTOMY**

A laparoscopic dissection of the posterior leaf is feasible.<sup>63,64</sup> However, the combination of posterior TV and an anterior selective operation is appealing because it avoids the difficult maneuver of working through the lesser sac in order to visualize the posterior lesser omentum and nerves accompanying the ascending left gastric artery branches. For HSV, dissection is begun at the crow's foot, approximately 6 cm from the pylorus. Retraction of the greater curvature is performed using a Babcock clamp (Fig. 35-53). With the magnification available through the scope, the proximal branch of the crow's foot is often, but not always, relatively easy to identify. The anterior leaf of the lesser omentum is approached by dividing and ligating the neurovascular bundle between clips. Electrocautery is used sparingly, and preferably not at all. The serosa overlying the gastroesophageal junction is scored as in the open procedure. Dissection of the distal 5 cm of esophagus and cardiac branches is carried out as described previously for TV.

**FIGURE 35-53** Laparoscopically assisted parietal cell vagotomy. Dissection of the anterior leaf of the gastrohepatic ligament.

The goal of an anterior seromyotomy, as described originally by Taylor et al.<sup>65</sup> and then others,<sup>13,26,66</sup> is to sever the neurovascular bundles dividing the serosa and muscularis that transmit these nerves to the mucosa. The anterior surface of the stomach is retracted using the right and left grasping ports. The outline of the seromyotomy is scored using a coagulator hook or spatula, on the anterior surface of the stomach, 1 cm from the visible border of the lesser curvature. Moving caudad and parallel to the lesser curvature, a line is traced from the gastroesophageal junction to the first branch of the crow's foot, or arbitrarily 6 cm from the pylorus. The hook coagulator is most suitable for performing the seromyotomy, using monopolar current for electrocoagulation. The hook cuts through successive layers of gastric wall, the serosa, outer oblique muscle fibers, middle longitudinal fibers, and inner circular fibers. The two grasping ports then are used to place traction on the two edges of the gastric wall, exposing the deep circular fibers that may split as much from traction as from cautery. The darker submucosa/mucosa layer

pops through the muscularis. This layer is inspected for any evidence of full-thickness cautery injury or perforation. With a complete seromyotomy, the gap between the cut edges should be about 6 to 8 mm. Alternatively, a laparoscopic surgical stapling device can be used for creation of a modified seromyotomy.<sup>26</sup>

A number of decent-sized vessels may be encountered in the dissection. Prolonged cauterization may provide hemostasis but risks a full-thickness burn and subsequent perforation. The hook can be used to isolate these vessels and lift them for clipping in continuity. Recent advances in the design of needle holders may make it possible to suture these vessels in continuity before division by scissors. Surgical stapling devices can be used for this purpose as well as newer devices such as the harmonic scalpel, which utilizes ultrasonic energy for coagulating vessels, or electrothermal bipolar coagulator devices. After creation of the seromyotomy, the integrity of the mucosa should be verified by moderate expansion of the stomach using the NG tube for insufflation. Some authors use methylene blue solution (1 vial per 200 mL), placed intragastrically, for this maneuver. The seromyotomy then is closed using a continuous suturing technique. A tongue of omentum may be mobilized and secured over the seromyotomy as a patch, secured with sutures placed through either edge of the seromyotomy.

## **MINIMALLY INVASIVE APPROACHES TO GASTRIC RESECTION**

The patient is positioned the same way as for laparoscopic antisecretory surgery, with the patient supine with legs in stirrups and apart as shown in [Figure 35-46](#). Port placement is similar with five ports placed in the following locations: (1) a 12-mm laparoscope port at the superior edge of the umbilicus or placed 5 cm above and lateral to the left of midline; (2) a 12-mm port in the right midclavicular line; (3) a 12-mm port in the left midclavicular line; (4) a 5-mm port for grasping forceps at the anterior axillary line on the left; and (5) a 5-mm port almost at the anterior axillary line on the right. A 30- or 45-degree angled laparoscope is useful for gastric resections, as it allows improved visualization of the stomach from multiple perspectives. If resections high in the lesser curvature are planned, retraction of the left lobe of the liver using a probe placed via the subxiphoid port or the 10-mm fan retractor placed via the higher right-side port (see [Fig. 35-51](#)) is useful as

described for laparoscopic TV.

Wedge resections of benign but symptomatic masses on the greater curvature can be done by grasping the greater curvature with a Babcock or other atraumatic grasper and use of a laparoscopic stapling device to resect the involved portion of stomach. Occasionally intraoperative endoscopic confirmation of the position of intraluminal masses not readily apparent intraoperatively is useful. Wedge resections on the lesser curvature are more difficult due to the presence of the left lobe of the liver, which usually needs to be retracted, and the proximity of the esophagus and vagus nerves. However, with careful attention to the gastroesophageal junction, wedge resections of the lesser curvature can be done. Intraluminal approaches can also be utilized.<sup>44,45</sup> If the vagus nerve or its major branches are sacrificed in lesser curvature resections, a laparoscopic or endoscopic drainage procedure is recommended (endoscopic pyloric dilation or laparoscopic pyloric seromyotomy). Robotic-assisted gastric wedge resections may be performed in a similar manner, although the wristed instrumentation also allows for ease in circumferentially obtaining a full-thickness resection. The authors prefer to perform this resection with cauterized shears, and to repair the defect with a two-layer suture closure (Fig. 35-54).

**FIGURE 35-54** Robotic view of gastric wedge resection. **A.** Development of the wedge. **B.** Excision and margins prior to closure. **C.** Two-layer suture closure with braided absorbable suture for the outer layer (or absorbable monofilament).

Distal, subtotal, and total gastrectomy procedures have all been adapted for laparoscopic or, more recently, robotic approaches. With advances in equipment and concentrated experience, all approaches seem to be finding increasing application, with promising results in selected patients.<sup>67-70</sup> In minimally-invasive subtotal or total gastrectomy, port placement is similar to

that for wedge resections and antisecretory procedures (Fig. 35-55). Gastric mobilization, resection, and reconstruction are done in a similar fashion to that of the open procedures, although en bloc resections are typically not performed. After entry into the abdominal cavity and port placement, the left lobe of the liver is retracted laterally with a fan retractor or probe through the right lateral port if the lesser curvature cannot be adequately visualized or if extensive dissection of the lesser curvature is required. With a robotic approach, the third arm can often be utilized for liver retraction. The stomach is grasped with a laparoscopic Babcock clamp, and the distal stomach is mobilized by incising the gastrocolic ligament, which is taken with the harmonic scalpel or electrothermal bipolar coagulator device. The dissection is carried distally along the greater curvature to the duodenal bulb, dividing the small branches of the gastroepiploic artery to the gastric wall, similarly with the harmonic scalpel or electrothermal bipolar coagulator device. The duodenal bulb can be dissected away from the anterior aspect of the pancreas, allowing for circumferential clearance. Proximal dissection is carried out in a similar way, with division of the short gastric vessels until the left diaphragmatic crus is visualized, in the case of a total gastrectomy. Others have used endoscopic vascular staplers to take much of gastrocolic omentum and its vessels. Once the proximal portion of the gastric dissection is reached, the stomach is divided with laparoscopic staplers at our institution. The gastric resection is then completed by division of the distal stomach just past the pylorus with a laparoscopic stapler. An omentectomy is then performed, with mobilization of the omentum off of the transverse colon utilizing cautery or the electrothermal bipolar coagulator device. Reconstruction is completed as a B-II gastrojejunal anastomosis. Babcock clamps are used to locate the jejunum at the ligament of Treitz and bring a freely mobile portion of jejunum, typically 20 to 30 cm distal to the ligament of Treitz, up to the proximal gastric remnant in an antecolic or retrocolic fashion through an avascular window in the transverse colon mesentery. The gastric remnant and jejunum are aligned together, being careful not to twist the jejunal mesentery, and then secured to each other at the proximal and distal suture lines by interrupted 3-0 Vicryl sutures placed either with an Endo Stitch (Auto Suture Company, Norwalk, CT) or with a laparoscopic needle driver. After the gastric and jejunal limbs are aligned, Bovie cautery is used to place enterotomies in the proximal gastric remnant and jejunum. It is the author's preference that a retrogastric anastomosis be created, with approximation of

the jejunum to the posterior wall of the stomach. A laparoscopic stapler is placed into the gastric and jejunal limbs and then deployed to form the anastomotic staple line. The proximal portion of the anastomosis is then closed using a laparoscopic stapler or suture-closed using an Endo Stitch device or with a laparoscopic needle driver. For total gastrectomy, the esophagojejunal anastomosis is performed using the stapling device as illustrated in [Figure 35-56](#). The mesenteric defect in the transverse colon is then closed if a retrocolic anastomosis has been performed. For total gastrectomy, a laparoscopic feeding jejunostomy tube is also placed, generally 10 cm distal to the jejunojejunostomy anastomosis.

**FIGURE 35-55** Port placement for laparoscopic subtotal or total gastrectomy.

**FIGURE 35-56** Schematic view of laparoscopic total gastrectomy. The esophagojejunal anastomosis is performed using the stapling device.

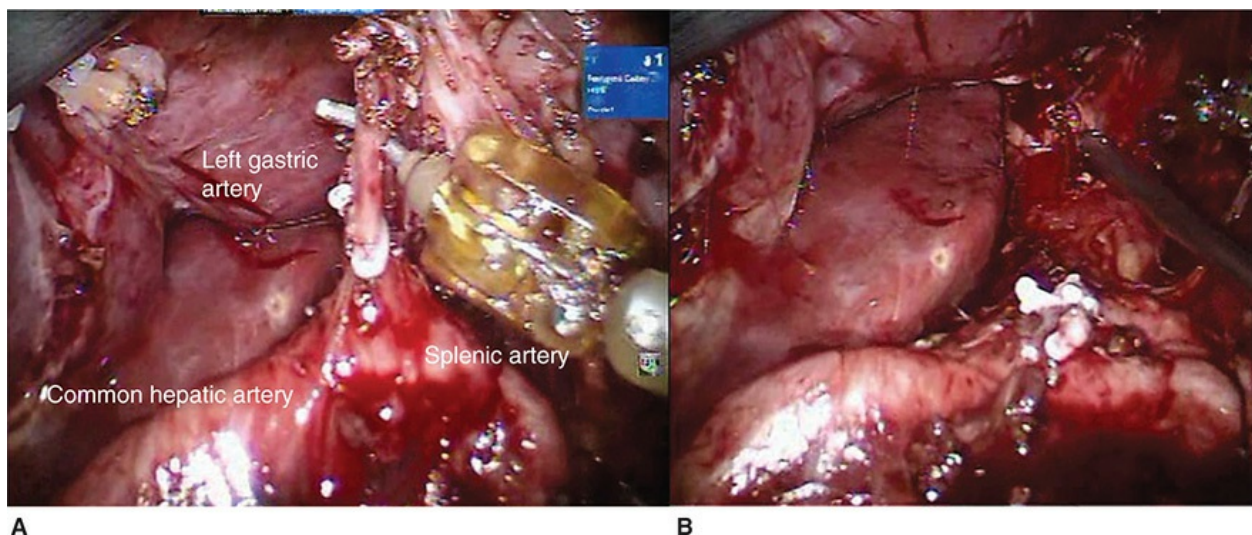

## Laparoendoscopically Assisted Sentinel Node Navigation

One of the concerns with laparoscopic gastrectomy procedures, done in patients with gastric cancer, is to determine whether a radical lymphadenectomy would be required. For early-stage gastric lesions (clinical and radiologic stage T1N0), sentinel node identification and so-called “sentinel node navigation” of the operation<sup>71-73</sup> have been advocated. Both single- and double-tracer methods have been described.<sup>74</sup> For complementary tracer injection, a method similar to that described recently by Orsenigo et al. would be utilized.<sup>75,76</sup> On the day prior to operation, endoscopy is performed to inject radioactive tracer (<sup>99</sup>Tc-colloid, 2 mL total) at four equally spaced points in direct proximity to the tumor; at the beginning of the actual operation, blue dye (2% patent blue, 2 mL divided among four sites) is injected endoscopically. The accumulation of radioactive tracer in the nodal

basin occurs over a period of 2 to 20 hours, while the transfer of blue dye to the sentinel node occurs very quickly. As a result, the sentinel node seems reliably identified when the blue node contains at least 10-fold higher radioactive counts than background.<sup>75</sup> It has been suggested that the radical lymphadenectomy may be limited to a D1 dissection if the sentinel node is clearly identified and clearly negative, but long-term outcomes in controlled trials are not yet fully known.<sup>77</sup>

## Minimally Invasive Lymphadenectomy

Modified D2 lymphadenectomy, excluding the routine resection of the distal pancreas and spleen, has become standard of care in gastric resections for cancer, per recent National Comprehensive Cancer Network guidelines. Increasing experience with minimally-invasive techniques has decreased the morbidity previously associated with lymphadenectomy. The author's preference is for a robotic approach, with its enhanced optics, which gives the operator an ability to skeletonize the celiac axis and named vascular branches of lymphatic tissue with greater dexterity than the laparoscopic approach as well as the ability to ligate the left gastric artery at its origin from the celiac axis (Fig. 35-57). Experienced laparoscopic surgeons, however, can achieve similar results.

**FIGURE 35-57** Robotic view of the celiac axis during lymphadenectomy with ligation of the left gastric artery. **A.** isolated left gastric artery before division **B.** View of origin of the celiac axis after division of the left gastric

artery.

# MORBID OBESITY, METABOLIC SYNDROME, AND NONSURGICAL WEIGHT MANAGEMENT

*Ali Tavakkoli*

The human life expectancy has steadily increased over the past few centuries; however, the current generation may be the first with a shorter life expectancy than their parents. The reason behind this unfortunate reversal is not increasing cancer rates or development of resistant bugs or new viruses, but a global increase in obesity and associated comorbidities.<sup>1</sup>

Obesity is defined as an excess accumulation of body fat and is commonly defined as a body mass index (BMI) of  $>30 \text{ kg/m}^2$ . In the United States, obesity affects 40% of women, 35% of men, and 17% of children and adolescents. In 2014, there were 600 million obese patients worldwide, with several countries having obesity rates greater than those in the United States. The highest rates of obesity can be found in some of the Pacific Island nations where obesity rates are greater than 40%. Obesity has been classified into several subcategories, as summarized in [Table 36-1](#), with estimated prevalences from the National Health and Nutrition Examination Survey

(NHANES) 2013 to 2014 data.<sup>2</sup> Severe obesity is often regarded as BMI  $\geq 40$ , or  $\geq 35$  with obesity-related comorbidities. Superobesity is defined as a BMI  $\geq 50$ .

**TABLE 36-1: PREVALENCE OF OBESITY AND SUBCLASSES IN THE US POPULATION**

BMI	Classification	US Prevalence		
		Overall %	Men%	Women %
$\geq 30$	Obesity	37.7	35	40.4
30.0-34.9	Class I obesity	30	29.5	30.5
35.0-39.9	Class II obesity			
$\geq 40.0$	Class III obesity (morbid)	7.7	5.5	9.9

With the growing obesity epidemic, there has also been an increase in the prevalence of morbid obesity over the past decade, with a linear growth in the rate of morbid obesity in women.

Although BMI is easy to calculate and has become the universally accepted measure for defining and classifying obesity, it is not ideal and has several limitations because it does not directly measure excess fat accumulation. As a result, a 70-inch muscular and fit athlete who weighs 215 pounds and has a BMI of 31 will be regarded as obese even though they have little excess fat accumulation. Although one can define obesity as percent body fat  $>32\%$  in women and  $>25\%$  in men, these calculations are difficult. More importantly, neither BMI nor percent body fat calculations provide any information on the regional body fat distribution. This is important because intra-abdominal and visceral obesity is associated with greater risk of insulin resistance, hyperlipidemia, hypertension, cardiovascular disease (CVD), and stroke than peripheral fat distribution. This difference is important because those with central obesity (android or apple pattern of obesity) have a greater risk of diabetes and CVD than those with fat accumulation in the subcutaneous tissue of buttock areas (gynoid or pear pattern of obesity). This difference in fat distribution may explain why individuals of Asian origin have a greater risk of diabetes at a lower BMI.<sup>3</sup> As a result, many have proposed lowering the BMI threshold at which weight management interventions, including surgery, are recommended in this population group.

The global epidemic of obesity is multifactorial and has genetic,

environmental, and epigenetic roots. It is thought that the recent exposure of man to an environment with excess and readily available food leads to an imbalance between caloric intake and energy expenditure, resulting in excess fat deposition. The reduction in physical activity and our new sedentary lifestyle have a significant role to play in the current obesity epidemic. Obesity is strongly and inversely related to degree of moderate physical activity, with small changes in daily levels of moderately vigorous physical activity leading to large differences in risk of obesity. Of all sedentary behaviors, prolonged television (TV) watching appears to be the most predictive of obesity and diabetes risk. In the Nurses' Health Study, after adjustment for age, smoking, exercise level, and dietary factors, every 2-hour increment spent watching TV was associated with a 23% increase in obesity and a 14% increase in the risk of diabetes.<sup>4</sup> The detrimental effect of TV on weight is in large part due to frequent snacking while watching TV and the associated increase in calorie intake, rather than decrease in physical activity alone.

Many studies have also confirmed that genetic factors influence obesity. In a meta-analysis of genomewide association studies (GWAS) and Metabochip studies involving nearly 34,000 patients, 97 loci were identified that were associated with BMI and accounted for approximately 2.7% of BMI variation. The GWAS analysis suggested that common variation accounts for about 21% of BMI variation.<sup>5</sup> Thus, although in rare cases such as leptin deficiency, a genetic mutation may be the primary factor in the development of obesity, the more common situation is where susceptibility genes interact with environmental factors to predispose individuals to obesity.<sup>6</sup> As an example, in a recent study of nearly 9000 people, the association between BMI and a polygenic risk score was higher in recent birth cohorts compared with earlier birth cohorts, likely due to the earlier exposure of the more recent cohort to our "obesogenic" environment.<sup>7</sup>

## **ADVERSE CONSEQUENCES OF OBESITY**

Although there is ongoing debate as to the etiology of the current obesity epidemic, there is little doubt over its adverse impact on health, quality of life, and life expectancy, with individuals who have a BMI >40 having a reduced life expectancy of 8 years. The adverse effect of obesity on mortality

rate has been confirmed in differing population cohorts across the world where each 5-unit increase in BMI increased mortality rate by 39% in Europe, 29% in North America, 39% in East Asia, and 31% in Australia and New Zealand. For the 4 populations combined, all-cause mortality risk increased with increasing BMI when compared to individuals with a BMI between 22.5 and 25 as baseline: 7% for BMI of 25.0 to <27.5, 20% for BMI of 27.5 to <30.0, 45% for BMI of 30.0 to <35.0, and 94% for BMI of 35.0 to <40.0.<sup>8</sup>

The increase in mortality in obese individuals is due to increased risk of many serious and chronic conditions including type 2 diabetes, heart disease, hypertension, stroke, hyperlipidemia, cancer, and sleep apnea (Table 36-2). The prevalence of these comorbidities often increases even with modest further weight gain. This observation is most striking when looking at type 2 diabetes. Compared with women with stable weight and after adjusting for age and BMI, the relative risk for diabetes mellitus increased 2-fold in women who had a weight gain of 5.0 to 7.9 kg and increased by 3-fold in those who gained 8.0 to 10.9 kg.<sup>9,10</sup>

**TABLE 36-2: RISKS OF CARDIOVASCULAR AND METABOLIC DISORDERS  
WITH OBESITY<sup>10</sup>**

Life expectancy	<ul style="list-style-type: none"> <li>• 30% increase in mortality rate for each 5-unit increase in BMI</li> <li>• In patients with BMI &gt;40, life expectancy is reduced by 8 years</li> </ul>
Hypertension	<ul style="list-style-type: none"> <li>• 5-fold increased risk of hypertension in obese individuals</li> <li>• 85% of hypertensive patients have a BMI &gt;25</li> </ul>
Cardiovascular disease	<ul style="list-style-type: none"> <li>• 9% increase in cardiovascular mortality rate with each unit increase in BMI</li> </ul>
Type 2 diabetes	<ul style="list-style-type: none"> <li>• Men with BMI <math>\geq 35</math> have 42-fold increase in risk of diabetes compared to men with BMI &lt;23; this risk is about 100-fold higher in women with BMI &gt;35</li> <li>• 74% lifetime risk of type 2 diabetes if BMI &gt;35</li> </ul>
Obstructive sleep apnea (OSA)	<ul style="list-style-type: none"> <li>• Severe OSA (apnea-hypopnea index <math>\geq 15</math>) affects 11% of normal weight men, but this rate increases to 21% in those who were overweight and 63% in those with obesity</li> </ul>
Cancers	<ul style="list-style-type: none"> <li>• Obesity has been estimated to cause 20% of all cancers</li> <li>• Obesity also increases rate of cancer-related mortality</li> </ul>
Hepatobiliary system	<ul style="list-style-type: none"> <li>• Risk of nonalcoholic fatty liver disease and cirrhosis is increased by 4- to 5-fold</li> <li>• Gallstone risk increases by about 2.5-fold</li> </ul>

---

## Metabolic Syndrome

The observation that central obesity, with or without excess total body weight, and associated hypertension, hyperlipidemia, and insulin resistance can increase risk of CVD and diabetes suggested the existence of a “metabolic syndrome.” This syndrome has also been known as syndrome X

or obesity dyslipidemia syndrome. Several differing definitions have been used for this condition, as summarized in [Table 36-3](#).<sup>11</sup>

**TABLE 36-3: VARIOUS DEFINITIONS OF METABOLIC SYNDROME**

	NCEP ATPIII	IDF	WHO	EGIR	AACE
Required		Ethnic-specific waist circumference cut points (Table 36-4)	Insulin resistance in top 25 percent; glucose $\geq 6.1$ mmol/L (110 mg/dL); 2-hour glucose $\geq 7.8$ mmol/L (140 mg/dL)	Insulin resistance or fasting hyperinsulinemia in top 25%	High risk of insulin resistance or BMI $\geq 25$ kg/m <sup>2</sup> or waist $\geq 102$ cm (men) or $\geq 88$ cm (women)
<b>Number of additional abnormalities</b>	$\geq 3$ of:	and $\geq 2$ of:	and $\geq 2$ of:	and $\geq 2$ of:	and $\geq 2$ of:
Glucose	$\geq 5.6$ mmol/L (100 mg/dL) or drug treatment for elevated blood glucose	$\geq 5.6$ mmol/L (100 mg/dL) or diagnosed diabetes		6.1-6.9 mmol/L (110-125 mg/dL)	$\geq 6.1$ mmol/L (110 mg/dL); $\geq 2$ -hour glucose 7.8 mmol/L (140 mg/dL)
High-density lipoprotein cholesterol (HDL-C)	$< 1.0$ mmol/L (40 mg/dL) (men); $< 1.3$ mmol/L (50 mg/dL) (women) or drug treatment for low HDL-C	$< 1.0$ mmol/L (40 mg/dL) (men); $< 1.3$ mmol/L (50 mg/dL) (women) or drug treatment for low HDL-C	$< 0.9$ mmol/L (35 mg/dL) (men); $< 1.0$ mmol/L (40 mg/dL) (women)	$< 1.0$ mmol/L (40 mg/dL)	$< 1.0$ mmol/L (40 mg/dL) (men); $< 1.3$ mmol/L (50 mg/dL) (women)
Triglycerides	$\geq 1.7$ mmol/L (150 mg/dL) or drug treatment for elevated triglycerides	$\geq 1.7$ mmol/L (150 mg/dL) or drug treatment for high triglycerides	$\geq 1.7$ mmol/L (150 mg/dL)	$\geq 2.0$ mmol/L (180 mg/dL) or drug treatment for dyslipidemia	$\geq 1.7$ mmol/L (150 mg/dL)
Obesity	Waist $\geq 102$ cm (men) or $\geq 88$ cm (women)		Waist/hip ratio $> 0.9$ (men) or $> 0.85$ (women) or BMI $\geq 30$ kg/m <sup>2</sup>	Waist $\geq 94$ cm (men) or $\geq 80$ cm (women)	
Hypertension	$\geq 130/85$ mm Hg or drug treatment for hypertension	$\geq 130/85$ mm Hg or drug treatment for hypertension	$\geq 140/90$ mm Hg	$\geq 140/90$ mm Hg or drug treatment for hypertension	$\geq 130/85$ mm Hg

Abbreviations: AACE, American Association of Clinical Endocrinologists; EGIR, European Group for the Study of Insulin Resistance; IDF, International Diabetes Federation; NCEP ATPIII, National Cholesterol Education Program Adult Treatment Panel III; WHO, World Health Organization.

The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) definition of metabolic syndrome is the most widely used, whereas the International Diabetes Federation (IDF) defines it as increased waist circumference, with ethnic-specific waist circumference cut points ([Table 36-4](#)).

**TABLE 36-4: ETHNIC-SPECIFIC WAIST CIRCUMFERENCE VALUES FOR THE INTERNATIONAL DIABETES FEDERATION DEFINITION OF METABOLIC SYNDROME**

Ethnicity	Male (cm)	Female (cm)
Europids	≥94	≥80
South Asians	≥90	≥80
Chinese	≥90	≥80
Japanese	≥90	≥80

The estimates on the prevalence of metabolic syndrome can thus vary based on definition used and population studied. For example, using the NHANES 1999 to 2002 data, approximately 35% of the population met the NCEP ATP III definition of metabolic syndrome, but this increased to 39% using the IDF definition. The prevalence of the syndrome increases with increasing BMI. Whereas 5% of normal-weight individuals have metabolic syndrome, the risk increases to 60% for those with BMI >30.<sup>12</sup>

Despite the extensive literature on metabolic syndrome, many have raised questions about the use of this term and whether it captures a unique pathology, as implied by calling it a “syndrome,” and whether it confers CVD risk beyond its individual components. These questions have raised uncertainty and debate about the value of this diagnosis. Regardless of whether it is a unique syndrome or just a collection of several known risk factors associated with excessive visceral fat, we now know that the driver of the underlying pathology is the chronic inflammatory state associated with excess accumulation of adipose tissue in liver, muscle, and adipose tissue stores. Although adipose tissue was originally thought to be a relatively quiescent accumulation of stored calories, it is now known that adipose tissue is metabolically active and can be the source of many adipocyte-derived peptides (eg, leptin, adiponectin, resistin) and cytokines (eg, tumor necrosis factor- $\alpha$ , interleukin-6), collectively referred to as adipokines. The actions of these agents lead to a state of chronic inflammation, which in turn interferes with many physiologic cellular processes (eg, insulin signaling), and cause vascular endothelial dysfunction and vascular inflammation, leading to the development of atherosclerotic CVD.

The cornerstone of treatment for patients diagnosed with obesity and metabolic syndrome has been risk reduction in the form of weight loss, increased exercise, and treatment of associated diabetes, hypertension, and hyperlipidemia.

Although modest weight loss (5%-10% excess weight) can lead to reductions in the risk of these chronic diseases, achieving durable weight loss is challenging, especially as the degree of obesity increases. Current approaches to weight loss are covered in the following sections.

## APPROACHES TO WEIGHT LOSS

### Diet and Lifestyle

Regarded as the cornerstone of weight management, the essential element of all diets is a reduction in caloric intake. The usual goal is to restrict caloric intake to 1200 to 1500 calories for women and 1500 to 1800 calories for men. Although multiple diets have been promoted, there is little evidence that one is superior to the other. In a study of 811 patients assigned to 4 diets with differing carbohydrate, protein, and fat compositions, the weight loss at 2 years was similar between the groups, as were satiety, hunger, and satisfaction with the diet.<sup>13</sup> Importantly, the weight loss with dieting alone is modest. In fact, in studies in which the dieting was not supervised or supported, the weight loss was often insignificant (1-2 kg). With increased intensity of support and follow-up (either in person or virtual), weight loss can be improved, with approximately one-third of patients achieving a meaningful 5% reduction in total body weight during the study period. The absolute average weight loss, however, remains modest at 4 to 5 kg and is often not sustained once the follow-up and support are removed.<sup>14</sup>

Exercise and increased activity are another important component of lifestyle modification that is recommended. General recommendations are to increase daily activity to >10,000 steps per day and perform >150 minutes of aerobic physical activity per week.<sup>15</sup> However, the data on the additional impact of exercise on weight loss are surprisingly modest, with a meta-analysis comparing diet alone to diet and exercise program, showing that pooled weight loss was only 1.14 kg greater for the diet-plus-exercise group than the diet-only group.<sup>16</sup> This highlights the importance of dieting and reducing caloric intake. However, the addition of exercise brings about related health benefits and can play an important role in weight loss maintenance, when dietary adherence may be less strict.

## Weight Loss Medications

For those with need and desire to lose a greater percentage of their weight, there is an increasing list of available medications, with 4 US Food and Drug Administration (FDA)-approved weight loss medications entering the market over the past 5 years. Prescribing these medications requires detailed knowledge of the medication and mode of action, as well as the potential side effects and interactions with other medications that patients may be taking. Bariatric surgeons are becoming increasingly familiar with prescribing these medications, allowing them to offer their patients a more diverse and tailored weight management option. Pharmacotherapy can be initiated in patients with BMI >30 or BMI >27 with related comorbidities and is being increasingly used in patients with inadequate weight loss or weight regain after bariatric surgery. These medications can help increase compliance with low-calorie diets by suppressing hunger and increasing satiety.

Table 36-5 provides a summary of current FDA-approved agents.<sup>15,17</sup> Usual practice is to try a medication for 3 months and, if significant weight loss is not seen, discontinue and try an alternative.

**TABLE 36-5: FDA-APPROVED DRUGS FOR WEIGHT MANAGEMENT**

Generic Drug Name (Trade Name)	FDA Approval	Mode of Action	TBWL%	Side Effects
Phentermine	1959	Adrenergic agonist that stimulates sympathetic nervous system, thus increasing basal metabolic rate and reducing appetite	5%-6%	Dizziness, dry mouth, irritability, difficulty sleeping
Orlistat (Xenical or Alli)	1999	Inhibits pancreatic and gastric lipase, causing fat malabsorption	5%-10%	Diarrhea, fecal incontinence, flatulence
Lorcaserin (Belviq)	2012	Serotonin receptor agonist that reduces food intake by selectively activating POMC neurons in the hypothalamus	5%-7%	Headache, hallucination, heart valve damage
Phentermine-topiramate (Qsymia)	2012	Norepinephrine/dopamine reuptake inhibitor and $\gamma$ -aminobutyric acid (GABA) receptor agonist	7%-10%	Headache, paresthesia, dry mouth, cleft palate
Bupropion SR-naltrexone SR (Contrave)	2014	Bupropion: dopamine/norepinephrine reuptake inhibitors; naltrexone: opioid receptor antagonist	5%-6%	Headache, insomnia, constipation, tremor
Liraglutide (Saxenda)	2014	Glucagon-like peptide-1 receptor agonist that works by reducing appetite, increasing satiety, and delaying gastric emptying	7%-9%	Diarrhea, nausea, pancreatitis

Abbreviation: TBWL%, total body weight loss percentage.

Phentermine was introduced in 1959 and became part of the drug combination “fen-phen” that was ultimately withdrawn from the market in

1997 due to the heart valve disease caused by the fenfluramine component of the formulation. Phentermine is approved for short-term use (3 months), with most weight loss being observed in the first few weeks.

Orlistat was the only FDA-approved weight loss medication until 2012, but its gastrointestinal side effects limited tolerability in many patients. However, in patients with obesity and baseline constipation, it can be an attractive option.<sup>18</sup>

Lorcaserin, at the recommended dose, is a selective 5-HT<sub>2c</sub> receptor agonist that is thought to reduce food intake and increase satiety by selectively activating these receptors on anorexigenic proopiomelanocortin (POMC) neurons in the hypothalamus. Activation of other serotonin receptors, specially 5-HT<sub>2a</sub> and 5-HT<sub>2B</sub>, can lead to the side effects associated with the drug, including hallucinations and possible heart valve disease.<sup>19</sup>

Phentermine-topiramate is another combination drug containing phentermine. The other ingredient, topiramate, was originally approved for migraine and epilepsy but was also noted to reduce food intake.<sup>20</sup>

Bupropion slow release (SR)-naltrexone SR is another combination drug containing 2 agents that have been on the market for many years but for different indications: bupropion for depression and naltrexone for opiate dependency and alcohol addiction. The drugs work in a synergistic fashion to release hypothalamic release of  $\alpha$ -melanocyte-stimulating hormone, a potent anorectic neuropeptide.<sup>21</sup>

Liraglutide was approved in 2010 for the treatment of type 2 diabetes but was also found to cause weight loss in a dose-dependent manner. This led to the approval of the drug at a higher dose of 3.0 mg for management of obesity. The drug is administered as a daily subcutaneous injection, starting at a low dose with weekly dose escalation.<sup>22</sup>

## **Endoluminal Therapies and Alternative Devices**

To address the need of many in whom diet, lifestyle modifications, and/or medications have been unsuccessful in achieving meaningful weight loss, gastrointestinal innovators have developed many endoscopic devices with the goal of achieving greater weight loss while avoiding the uneasiness of surgery.

**Table 36-6** provides an overview of the FDA-approved endoluminal devices.<sup>15</sup> Intra-gastric balloons, the most commonly used devices, have a long history that dates back to the Garren-Edwards bubble, which was approved by the FDA in 1985 but subsequently withdrawn from the market in 1988 due to increasing rates of complications. Over the subsequent years, balloon designs have evolved with improved safety and efficacy. There are currently 3 different FDA-approved intra-gastric balloons for patients with BMI of 30 to 40; duration of use is 6 months, after which they need to be removed. The Orbera and ReShape balloons are endoscopically placed and removed, whereas the Obalon system, which consists of 3 smaller balloons placed at 2-week intervals using fluoroscopy, only requires an endoscopy for removal. Main side effects are gastrointestinal related and include nausea, vomiting, abdominal pain, reflux, and burping. Serious adverse events related to the balloon have also been reported. Balloons, especially those not removed on time, can rupture with balloon migration and possible bowel obstruction.<sup>23,24</sup> With increasing utilization of the balloons, cases of spontaneous overdistention and acute pancreatitis have also been reported, and an FDA warning was recently issued. Regaining of lost weight is a common problem in patients after balloon removal, although some studies have suggested that with continued diet and exercise, some weight loss can be maintained for up to 5 years after removal.<sup>25</sup>

 **TABLE 36-6: FDA-APPROVED ENDOLUMINAL DEVICES FOR MANAGEMENT OF OBESITY**

Device Name	FDA Approval	Mode of Action	TBWL%	Comments
Orbera intra-gastric balloon	2015	Space-occupying devices that produce early satiety and delay gastric emptying	7%-15%	Approved for 6-month use in those with BMI of 30-40
ReShape dual intra-gastric balloon	2015			
Obalon intra-gastric balloon	2016			
Aspire Assist	2016	Aspirate ingested food intake and modify eating habits	10%-15%	Approved for BMI of 35-55
Endoscopic sleeve gastroplasty	NA	Reducing gastric volume	15%-20%	A commercially approved endoscopic suturing platform is used to perform the endoscopic suturing

Abbreviations: NA, not applicable; TBWL%, total body weight loss percentage.

The Aspire Assist device consists of a gastrostomy tube (A-tube) attached to a port, which is used to aspirate gastric contents 20 to 30 minutes after

eating a meal. The device is approved for patients with BMIs up to 55 and can be used long-term.<sup>26</sup> Some believe the device may have a role as a bridge to a more definitive weight loss intervention, by helping patients with high BMI achieve significant preoperative weight loss. Main side effects include abdominal pain, nausea and vomiting, tube blockage, granulation and irritation at the tube site, and risk of gastrocutaneous fistula after tube removal.

Endoscopic sleeve gastropasty is an endoscopic procedure in which a sleeve-like gastric conduit is created, similar to a sleeve gastrectomy. A series of endoscopic full-thickness sutures are placed endoscopically using a commercially available suturing device (Overstitch; Apollo Endosurgery) to create a narrowed gastric conduit with reduced gastric volume. Several serious adverse events have been reported with this procedure, including perigastric collections requiring interventional radiology drainage and self-limited splenic hemorrhage.<sup>15</sup>

Another FDA-approved obesity device is the VBLOC system. Unlike the procedures summarized in [Table 36-6](#), this device is placed laparoscopically under general anesthesia as an outpatient surgical procedure. The system consists of a subcutaneously placed neuromodulator, connected via 2 electrodes placed laparoscopically around the anterior and posterior vagal trunks. Several studies have shown an 8% to 10% total body weight loss with this procedure, which was superior to controls.<sup>27</sup> The device received FDA approval in 2015 for patients with a BMI of 35 to 45 with at least 1 other obesity-related condition, such as type 2 diabetes. The serious adverse event rate with the device is low and reported at <5%, with 1 case of gastric perforation at the time of device removal.

Although medications and described devices may adequately address the needs of patients with stage I obesity, for those with more significant obesity, bariatric surgery has become the standard of care. The next chapter of this book will provide a detailed review of the technical aspects of various surgical techniques available. All procedures lead to durable and meaningful weight loss, which leads to significant improvements in many comorbidities. [Table 36-7](#) summarizes treatment recommendations based on patients' BMI as proposed by the American Heart Association/American College of Cardiology/The Obesity Society Obesity Guideline and supported by the American Gastroenterological Association's Practice Guide on Obesity and

<sup>a</sup>Such as cardiovascular disease risk factor (diabetes, prediabetes, hypertension, dyslipidemia, increased waist circumference) or other obesity-related conditions.

<sup>b</sup>Including diabetes, hypertension, or sleep apnea.

Despite such guidelines highlighting the role of surgery in weight management, only 1% to 2% of patients who qualify for weight loss surgery proceed with the operations. The reasons behind this low rate are unclear and likely multifactorial. Insurance barriers, access to appropriate surgical expertise, and provider and patient bias toward obesity management and surgery play a role. Another important factor is that the invasiveness of surgery, permanent change to gastrointestinal anatomy, and risk of weight regain and surgical complications dampen the enthusiasm of many to proceed with surgery. This will continue to be the driving engine behind further innovation and development in gastrointestinal-based interventions for treatment of obesity.

# **SURGICAL TREATMENT OF MORBID OBESITY AND TYPE 2 DIABETES**

*Bruce D. Schirmer*

## **INTRODUCTION**

The surgical treatment of obesity originated with the concept that a surgical intervention to alter digestive anatomy and physiology could benefit patients with a metabolic related disease. At the University of Minnesota in the 1950s, surgeons performed an operation to bypass the distal small bowel to limit absorption of lipids in a patient with severe hyperlipidemia.<sup>1</sup> Over 60 years later, the field of metabolic and bariatric surgery has evolved to provide increasingly safe and effective surgical treatment options for patients who suffer the consequences of severe metabolic disease, such as type 2 diabetes mellitus. As these treatments have evolved, there has been a concurrent improved understanding of the physiology underlying the diseases being targeted. This has often been a result of the observations of treatment effects of surgical procedures. Increased insight and knowledge have also arisen as a result of trying to better understand how these interventions can be optimally

used for disease treatment. The comorbid metabolic diseases that arise secondary to morbid obesity are generally much better understood than the actual disease of obesity itself. Consequently, surgical treatment has to date focused more on the improvements and resolution of those diseases rather than the disease of obesity. The major manifestation of the disease of obesity, weight itself, certainly has been the focus of bariatric surgery. However, the underlying genetic, physiologic, and metabolic factors that contribute to create the obesity disease state are still not well understood. Hence, surgical therapy has focused on weight as the parameter for treating the disease, while underlying causes are still not directly targeted. Indeed, as investigation continues as to the etiologies of the disease of obesity, surgical therapy may have a more limited role in the future. However, at this time it remains the single most effective treatment for reversing the disease, both in terms of the obvious problem of weight itself as well as the comorbid medical problems that accompany the disease in varying frequency from individual to individual.

The metamorphosis of the surgical patient who has had a successful bariatric operation and has changed from an individual literally burdened by diseases of—and related to—obesity is a dramatic and rewarding phenomenon. Metamorphosis is a truly accurate word to describe this therapeutic change. The massive improvement in quality of life, in physical, mental, and social areas, causes most patients who experience this process to be almost reborn in the true sense of the word. They are relieved of physical pain, social stigmatism, lifestyle limitations, low self-esteem, and a variety of other negative consequences of the obesity state with its concurrent problems. Often the simple fear of imminent death from obesity-related diseases, and the relief that treatment has allowed them to have a chance to live longer is a powerful aspect of treatment success.

The metamorphosis of the surgical patient who has undergone an operative procedure with successful weight loss and resolution or improvement of comorbid medical problems is joyful and dramatic. However, the patient who, after having achieved this success, then relapses into the obesity state through regain of weight and return of metabolic diseases, is equally tragic. To date surgery has been unsuccessful in optimally treating the latter patient, who represents perhaps 20% to 40% of patients who undergo surgical therapy for morbid obesity, depending on the procedure and nature of the diseases. Current surgical therapy is highly

effective in treating the results of the disease of obesity: excess weight and the medical problems that result. This will be well illustrated in the text to follow. However, the reader is reminded that current surgical therapy is also not designed to eliminate the disease of obesity itself, a disease that is still poorly understood in terms of its etiology.

## **BRIEF HISTORY OF BARIATRIC SURGERY**

Bariatric surgery emanated from the need to control a severe metabolic problem. In 1954 in Minneapolis, Drs. Kremen and Linner performed the first jejunio-ileal bypass in a human to control hyperlipidemia. This case and a number of others were reported in the first series in the literature in 1963 by Payne.<sup>1</sup> The operation proved effective for treating that problem but caused a variety of malabsorptive and nutritional issues that proved to be unacceptable for all but the most severe cases of hyperlipidemia. Now, six decades later, the field of bariatric surgery is once more turning to the metabolic benefits of operative procedures as the main focus of further research and development of the field. Thus the appropriate appellation for the field is now metabolic and bariatric surgery.

Few bariatric operations were done in the 1960s. When Mason and Ito first described the gastric bypass in 1969, the first and longest-lasting bariatric procedure was launched.<sup>2</sup> After modification by Griffen to drain the gastric pouch using a Roux limb<sup>3</sup> (Fig. 37-1), the procedure became alternatively the most or second most popular metabolic and bariatric operation from then until now. The history of bariatric surgery is one largely of those operations that have come and gone during the past five decades, while the Roux-en-Y gastric bypass (RYGB) has remained in use and provided effective results.

**FIGURE 37-1** Roux-en-Y gastric bypass as described by Griffen, modified from Mason.

In the 1970s, the jejunoileal bypass was initially popular, then abandoned due to its occasional production of progressive and lethal hepatic failure.<sup>4</sup> The damage to the reputation of the field of bariatric surgery from the backlash to the poor results of the jejunoileal bypass was felt for the next 25 years. Restrictive-only operations were thereafter viewed as much safer and more appropriate. While the gastric bypass did have a mild element of malabsorption, it was primarily a restrictive operation. Stomach stapling of various configurations was next performed, with all of them proving

ineffective at maintaining adequate restriction for the long term if simple staple lines with gaps or gastric to gastric anastomoses were employed. In the 1980s, the vertical banded gastroplasty (VBG) (Fig. 37-2) was introduced, also by Mason, for the purposes of providing an operation with a durable anatomic configuration that was solely restrictive.<sup>5</sup> The operation had a decade of success before it became apparent that patient adaptation to the restriction, which was to adopt a new diet of high-calorie liquids, usually defeated the operation in the long term.<sup>6</sup> Stenosis of the outflow caused further need to revise the operation, to the point where most have now probably been converted to gastric bypass or other procedures.

**FIGURE 37-2** Vertical banded gastroplasty.

Bariatric surgeons began to perform primarily malabsorptive operations in relatively small numbers once the initial success by Scopinaro and colleagues was demonstrated for the biliopancreatic diversion (BPD)<sup>7</sup> (Fig. 37-3). Later, to avoid the high rate of marginal ulcer seen after BPD, both Marceau and Hess performed the duodenal switch (DS) (Fig. 37-4), which modified the

gastric portion of the operation and used a duodenoileal anastomosis.<sup>8,9</sup>

**FIGURE 37-3** Biliopancreatic diversion.

**FIGURE 37-4** Duodenal switch.

The advent of performing bariatric surgery laparoscopically evolved in the decade from 1994 to 2004, during which time Wittgrove's initial success<sup>10</sup> doing a laparoscopic gastric bypass was reproduced by others including Schauer<sup>11</sup> and Nguyen.<sup>12</sup> Gastric bypass was the procedure of choice at the time, and the one that U.S. surgeons learned to do initially laparoscopically. In 2003, the FDA approved the use of the laparoscopic adjustable gastric band (AGB) (Fig. 37-5), which had risen rapidly in popularity in Europe and

Australia since its first performance by Belachew in 1993.<sup>13</sup> The lap band was technically easy for surgeons to place, and it enjoyed considerable popularity in the United States for the next 5 to 6 years. However, by that time it became clear the long-term results of the band were not what had been expected, and many patients began demanding to have them removed and revised to other procedures. By 2015, the lap band represented only about 5% of bariatric procedures performed in the United States, and for 2014 the published figure is 7.4%.<sup>14</sup>

**FIGURE 37-5** Adjustable gastric banding.

Concurrent with the fall of the lap band was the rise of the sleeve gastrectomy (SG) (Fig. 37-6). It was originally performed as the gastric portion of the DS operation. When the DS was performed laparoscopically, the initial experience by Gagner showed a higher than expected morbidity and mortality.<sup>15</sup> The operation was then divided into two stages, with the laparoscopic gastric portion of the operation being initially done, after which,

with weight loss, the malabsorptive portion of the operation was added. However, many patients had such good success after just the gastric portion, they would not agree to any further surgery.<sup>16</sup> Their success then stimulated surgeons to perform the SG as a primary procedure. It has now become the most popular procedure done both in the United States and internationally.

**FIGURE 37-6** Sleeve gastrectomy.

The history of bariatric surgery has been intertwined with the history of metabolic surgery. The two have now become relatively synonymous, but it has only been in the past 15 years that there has been significant attention devoted to studying the metabolic effects of bariatric operations. Pories and others had reported the astonishingly fast reversal of type 2 diabetes after gastric bypass many years earlier,<sup>17</sup> but few others had focused on the changes that the operation caused in glucose metabolism until this century. Mechanisms of alterations of glucose metabolism, changes in systemic cytokine production, the variances and effects of the gut flora on metabolism, influences of circulating gastrointestinal hormones and other vasoactive peptides, and the role of neural input to satiety, food intake, and absorption have all been and are being studied currently, yielding a growing body of scientific knowledge to explain the clinical efficacy previously seen but not fully understood that is produced by bariatric operations. Adding to such knowledge in the future can only serve to improve the effectiveness of combatting obesity and its associated significant metabolic and systemic illnesses that serve as the leading cause for the now observed reversal of life expectancy from progressively longer to stable or possibly shorter for the next generation.<sup>18</sup>

## THE DISEASE OF OBESITY

The disease of obesity is complex, multifactorial, and cannot be adequately addressed in full detail in this chapter. However, there do seem to be some essential components that are important to the abnormal gain of weight by individuals who suffer from severe obesity. These include

1. An occasional or steady alteration in satiety such that large quantities of food may be ingested in a single sitting
2. Some genetic component to the disease, as yet still not well understood
3. A likely environmental component to the disease, based on eating habits, lifestyle, and activity and exercise levels of individuals
4. New evidence that gut flora may be important in influencing amounts of food absorbed between normal-weight and obese individuals

Obesity is currently classified into several categories. [Table 37-1](#) gives the

current Western definition of the classes of obesity, based on body mass index (BMI) (weight in kg/height in meters squared). Asian countries employ a slightly different classification, with class 1 obesity beginning with a BMI of 27. Severe obesity is associated with numerous comorbid medical problems. They are listed in [Table 37-2](#). The major medical reason for performing metabolic and bariatric surgery is to improve these medical problems. While they are quite clear-cut, and the improvements of them have been well documented in the literature, they are not always the major reason for having surgery from the patient’s point of view. Often the patients are quite concerned with these problems, but they also may suffer from other less medically significant but just as altering lifestyle problems including ability to ambulate without difficulty, ability to bend and reach objects, to dress easily, to buy clothes off the rack, to be able to comfortably fit into seats for air travel, to drive a car comfortably, and to be able to play and interact with children and grandchildren. Loss of positive self-feelings, loss of sexual function and ability, and limited physical abilities to perform activities of daily living or activities required by a job all may play major roles in the patient seeking surgical help for the problem of severe obesity. Resolution of these issues is less well recorded in the literature, but well reflected in the very high patient satisfaction ratings for the results of their metabolic and bariatric operations, even when those operations do not meet the “standard” definitions of success we as surgeons have defined, such as loss of over 50% of excess weight and improvement in medical problems.

**TABLE 37-1: WEIGHT CLASSES BASED ON BMI**

<b>Class</b>	<b>BMI</b>
Normal weight	22-27
Overweight	27-30
Class 1 obesity	30-35
Class 2 obesity	35-40
Class 3 obesity	40-50
Class 4 obesity	>50

**TABLE 37-2: COMORBID MEDICAL PROBLEMS ASSOCIATED WITH SEVERE OBESITY**

## **Cardiovascular**

Hypertension  
Cardiomyopathy  
Increased coronary artery disease  
Ventricular hypertrophy and arrhythmias  
Right-sided heart failure  
Pulmonary hypertension  
Cor pulmonale  
Increased incidence of VTE  
Venous stasis disease

## **Pulmonary**

Obstructive sleep apnea  
Asthma

## **Gastrointestinal**

Gastroesophageal reflux disease  
Cholelithiasis  
Fatty liver disease

## **Metabolic**

Type 2 diabetes mellitus  
    Diabetic nephropathy  
    Diabetic retinopathy  
    Diabetic peripheral neuropathy  
Hyperlipidemia  
Hypercholesterolemia  
Accelerated peripheral vascular disease

## **Musculoskeletal**

Degenerative joint disease  
Osteoarthritis  
Chronic back pain  
Abdominal wall hernias

## **Neoplastic**

Increased incidence of the following neoplasms:

Breast  
Uterus  
Colon  
Pancreas  
Prostate

---

Psychosocial issues may also be very prevalent in the background of some patients who develop severe obesity. There is a known higher incidence of being physically, emotionally, or sexually abused as a child.<sup>19</sup> The use of food as a means to combat anxiety, depression, or other adverse emotions may certainly complicate the disease process. Addressing such problems as a comprehensive treatment plan is important for optimal success for many patients. Addictive behavior to a pathologic extent is often felt to be a contraindication to surgery, and addressing such issues preoperatively to determine if the addictive behavior is severe enough to warrant disqualification from surgery is also very important.<sup>20</sup>

## **NONOPERATIVE THERAPY**

The patient who seeks help surgically to combat weight problems and has not tried conservative therapy of dieting, exercise, behavior modification, or other such programs is a true rarity. It is safe to say that virtually all if not all of patients who undergo surgical therapy have tried to diet on their own or under medically supervised plans. Short-term success of loss of 5% to 10% of body weight is not uncommon for such patients, but regain of weight is almost universal and progressive weight gain with advancing age, further pregnancies, or other life crises is the usual history given by patients. The percentage of patients who are successful in losing more than 10% of body weight through diet and exercise programs and keeping it off for years is estimated to be in the 3% range.

## **PATIENT SELECTION**

Selection of patients then, for surgery, is based on the criteria given in [Table 37-3](#). These criteria were established at the time of the last National Institutes of Health (NIH) Consensus conference on surgical treatment of obesity. Most experts agree that the criteria are outdated and need revision. In particular, there is now good evidence in the literature that for stage 1 obesity, surgical intervention can have significant benefits for the treatment of associated medical problems, particularly type 2 diabetes.<sup>21,22</sup>

**TABLE 37-3: INDICATIONS FOR PERFORMING METABOLIC SURGERY**

1. BMI  $\geq 40$  kg/m<sup>2</sup>
2. BMI  $\geq 35$  kg/m<sup>2</sup> and a comorbid medical problem associated with obesity such as type 2 diabetes, hypertension, obstructive sleep apnea, etc.
3. Failed diet attempt
4. Psychologically stable for surgery
5. No significant active addiction problem
6. Motivated and capable of understanding lifestyle changes

The actual criteria from that NIH conference also included the need to follow patients long-term. While all attempts to do so have been exercised by many practices, including our own, a very high follow-up rate is difficult to achieve long-term due to a variety of problems, including but not limited to loss of insurance coverage for follow-up visits, geographic relocation, and simple lack of motivation to take a day off work to be seen when one is doing well and follow-up is already well established with the primary care physician. We recently were able to document the fact that our approximately 20% to 25% follow-up rate for patients based on voluntary return to clinic annually was an excellent representative sample of the outcomes of the whole group. When the group of patients who had been seen in follow-up regularly for over ten years after gastric bypass was compared to those patients who had not been seen recently but were re-contacted through a special study, there was no difference in the outcomes for the group that had been followed closely versus the one that had been lost to follow-up.<sup>23</sup> We feel these data debunk the popular criticism raised in the past of many publications reporting results after metabolic and bariatric surgery which did not have a high follow-up percentage of patients. It is likely the patient sample being seen is representative of the group, based on our experience.

Controversial criteria for inclusion of patients for metabolic and bariatric surgery include age, weight (upper limits), and sometimes individual surgeon requirements for adherence to preoperative diets and cessation of any addictive habits. Relative to age, the younger range of patients can be variable. Large series of adolescent patients have been reported after undergoing metabolic and bariatric surgery, with good success.<sup>24</sup> Most

bariatric surgeons who are not pediatric surgeons, however, do not include many patients under the age of 18 in their practice, but there is no hard and fast rule on this. Similarly, some bariatric surgeons have an upper age limit for performing various operations. Others assess patients on an individual basis for likelihood of being able to physiologically tolerate and recover well from surgery. While many series of older patients have been reported with successful outcomes in the literature, careful scrutiny of larger collected databases reveals the invariable increased incidence of postoperative mortality and slight increases in morbidity for the population over age 65.<sup>25</sup>

Some surgeons impose a mandatory preoperative diet to achieve a small amount of weight loss for their patients. A few have published a demonstrated benefit for doing so, largely to eliminate the potential for a fatty liver and its technical interference with surgery.<sup>26</sup> However, insurance companies have almost uniformly now adopted a policy of requiring patients to complete a medically supervised diet. This can be as long as 12 months. The benefit of such preoperative diets has clearly been shown to be negative in the literature, and such onerous requirements often serve only to delay the ability of patients in need of the benefits of surgical therapy to receive them. The American Society for Metabolic and Bariatric Surgery (ASMBS) has recently published a review of this topic with strong recommendations against this practice.<sup>27</sup>

Many practices and institutions have upper limits of weight at which they will no longer offer metabolic and bariatric surgery. We also have such a limit, though it is high (600 lbs). At very high weights, the ability to safely perform surgery and to diagnose and treat potential postoperative problems becomes prohibitive if the size of the patient precludes postoperative imaging studies, safe transfer and ambulation, and adequate facilities to meet the patient's needs.

## **CENTERS OF EXCELLENCE**

Most centers that now perform bariatric surgery participate in the Centers of Excellence program under the supervision of the American College of Surgeons (ACS) working together with the ASMBS. The merger of the two systems of accreditation for bariatric surgery centers happened about 6 years ago, and the current Metabolic and Bariatric Surgery Accreditation and

Quality Improvement Program (MBSAQIP) certifies most medical centers in the country that perform metabolic and bariatric surgery. This centers of excellence concept has been instrumental in improving the overall quality of surgical care rendered to patients undergoing metabolic surgery. Standards for professional training, surgical outcomes, patient education and follow-up, use of a multidiscipline team approach, equipment and supplies in both the inpatient and outpatient settings, and reporting of data all are important components to the accreditation formula, which has produced demonstrably better outcomes in centers of excellence versus centers that have not been a part of such a system.<sup>28</sup>

The benefit of a multidiscipline team in rendering the best possible care for patients is generally espoused by those with experience in the field. The MBSAQIP recognizes the need for such an approach. [Table 37-4](#) gives a list of the essential and the desirable professionals that are best incorporated into the multidiscipline approach to metabolic and bariatric surgery.

**TABLE 37-4: PROFESSIONAL MEMBERS OF THE MULTI-DISCIPLINE TEAM  
CARING FOR THE PATIENT UNDERGOING METABOLIC AND BARIATRIC  
SURGERY**

**Essential**

Surgeon

Program coordinator

## PREOPERATIVE EVALUATION AND PREPARATION

Once a patient has decided they wish to undergo metabolic and bariatric surgery, the single biggest hurdle they face in the United States today is obtaining insurance approval for this procedure. Despite many articles in the literature documenting the long-term financial savings in health care costs for patients who undergo metabolic surgery versus those who do not,<sup>29-31</sup> the current climate of insurance support for these procedures is one of near hostility. Other than an innate bias against obesity and the concern that a loosening of criteria would bring a wave of patients to receive the benefits of appropriate surgery, there seem no other logical explanations other than the fact that the average duration of an insurance policy may only be about as long as the time it takes for the benefits of surgery to be seen long-term in terms of financial savings. Thus if an insurance company is concerned only about that quarter or yearly expenses, they could conceivably take a position that the short-term cost savings are not adequate to support metabolic surgery. However, if all the insurance industry were to adopt the policy of supporting these procedures, then the well-documented savings in costs to patients over a 3-year or longer period would be realized. In the state of Virginia, for example, there is actually a law that states any insurance company that offers comprehensive health insurance must offer treatment for severe obesity, including a surgical option. What the insurance companies have done, however, is make such coverage contingent upon a special rider to the policy that charges an exorbitant amount (for example, \$5000 extra per patient per year) for this coverage. Small employers cannot afford these major increases in premiums. Small employers in Virginia have also recently been denied the ability to obtain bariatric coverage for any price if their number of employees is very low. Thus the only patients who are currently able to obtain insurance approval in Virginia at this time are largely employed by the state, large corporations, or have federal insurance (Medicare and Medicaid). These riders have effectively eliminated access to health care for many deserving patients in the state of Virginia. The story is repeated in many versions across the country. Obesity remains the last unlegislated bias in our society.

If a patient is fortunate enough to potentially receive insurance approval

for metabolic and bariatric surgery, the other issues that need to be decided early on are:

1. Appropriateness for surgery as judged by the multidiscipline team
2. The most appropriate procedure for the patient and agreeable to her/him
3. Identifying and optimally preoperatively treating associated comorbid medical problems

Sufficient preoperative visits to determine the answers to all three of the above issues are needed. For our practice, our initial visit encompasses multidiscipline evaluation, extensive teaching, and identification of medical problems. The most appropriate operation is also chosen. A period of time in which insurance company requirements are then fulfilled, insurance approval is obtained, and medical issues are optimally treated then follows. Finally, another clinic visit in which review of the operative procedure, reinforcement of perioperative expected outcomes, review of expected measures to speed safe surgery and recovery, and the early phases of postoperative diet and exercise plans are again reviewed. The operative consent is discussed in great detail. A date for surgery is chosen.

## **Choice of Operation**

Patient preference does play a role in choice of operation. If a patient simply will not undergo an operation, that is the end of that discussion. I would prefer to offer a patient some surgical therapy that will treat his or her severe obesity and its medical problems to a great extent, even if it is not the most optimal operation for a patient, than perform nothing. A few exceptions exist of course to this general statement. Some guidelines we use in helping to select operative procedures are as follows:

1. RYGB results in better treatment of preoperative gastroesophageal reflux disease (GERD) and severe, especially insulin-dependent type 2 diabetes.
2. Patients who are smoking are not candidates for RYGB (complications of marginal ulcers).
3. The laparoscopic AGB has a very limited applicability for likely success.
4. Patients with extensive bowel surgery are likely best served with an SG.

Currently, SG has replaced gastric bypass as the most commonly performed procedure in the United States and in the world (Table 37-5) This popularity is likely due to its efficacy to date, and the fact it is a technically easier procedure for the average laparoscopic surgeon to perform. Patients are also demanding it because of the often-verbalized perception that it is “less invasive.” While it does avoid any change in the route of the alimentary tract, sending 70% of the stomach to the pathologist is not exactly less invasive. It does also have the benefit of having less long-term complications, especially avoiding the problems of bowel obstruction and marginal ulcers seen after gastric bypass. For many patients, the SG is very appropriate. We tend to recommend gastric bypass for patients with significant GERD, significant type 2 diabetes, and who have a BMI over 60. Some surgeons would argue the patient with a BMI over 60 should undergo a malabsorptive operation, and that is valid based on the outcomes data.<sup>32</sup> However, I have chosen not to perform malabsorptive procedures since our patient population often comes from a long distance and keeping close follow-up is very difficult. Close follow-up is uniformly felt to be a requirement for performing malabsorptive procedures such as the duodenal switch.

**TABLE 37-5: PERCENTAGES OF METABOLIC AND BARIATRIC OPERATIONS DONE IN THE UNITED STATES 2011-2016**

Reproduced with permission from English WJ, DeMaria EJ, Brethauer SA, et al: American Society for Metabolic and Bariatric Surgery estimation of metabolic and bariatric procedures performed in the United States in 2016, *Surg Obes Relat Dis* 2018 Mar;14(3):259-263.

## Evaluating Medical Problems

Once the operation has been chosen, the patient must be evaluated and treated for associated comorbid medical problems. The medical problems most often not identified prior to our evaluation have included obstructive sleep apnea, hyperlipidemia, and gallstones. However, the entire list of problems given in

Table 37-2 should be assessed for existence, and tested for if they may be present. Appropriate preoperative treatment is indicated. Baseline metabolic deficiencies that are common in the patient population considering metabolic surgery include iron deficiency anemia, vitamin D deficiency, and hyperglycemia from unrecognized early diabetes. Common preoperative screening tests we employ include an upper endoscopy for anyone with symptoms of GERD. Detection of Barrett esophagus, though infrequent, is essential preoperatively. The incidence of lesions that may alter the surgical treatment to some extent has been approximately 5% based on our historical data.<sup>33</sup> A sleep study is ordered for patients with high assessment scores for sleep apnea. An ultrasound of the gallbladder is routinely performed for all patients with a gallbladder. Other pertinent positives in the history and physical include risk factors for increased incidence of venous thromboembolism (VTE), including previous history of VTE, pulmonary hypertension, and venous stasis ulcers.

During this evaluation, conditions that might merit simultaneous second surgical procedures may be identified. The two most common are gallstones and abdominal wall hernias. We have recommended that patients who have gallstones undergo a simultaneous laparoscopic cholecystectomy. Our results in performing this procedure associated with gastric bypass have been published and show an extremely low (less than 1%) incidence of complications from the cholecystectomy as well as no increased length of stay or morbidity.<sup>34</sup> For patients who do not have gallstones, we advocate a 6-month course of ursodiol at 300 mg bid to decrease the incidence of postoperative gallstones to approximately 4% (data obtained after gastric bypass).<sup>35</sup>

Abdominal wall hernias are not infrequent in this patient population. The most common primary one is umbilical hernia. If an umbilical hernia is large enough to potentially have a loop of bowel incarcerated in it postoperatively, it should be repaired. Studies carried out on the question of whether to repair abdominal wall hernia defects at the time of gastric bypass or defer repair until later have shown a significantly high incidence of incarcerated hernias needing emergency surgery when the hernia was not repaired at the time of the gastric bypass.<sup>36</sup> Now, even the use of mesh to repair abdominal wall defects after SG has been shown to be safe, based on negative intraoperative peritoneal fluid cultures during one study.<sup>37</sup> For the extremely large hernia

where there is significant bowel involvement in the hernia sac, performance of an open procedure to repair the hernia and do the metabolic operation simultaneously seems the best choice. In this patient population, the incidence of postoperative infections is less well documented, so primary repair and closure if possible is still recommended until further data are available.

The most commonly unplanned procedure performed during metabolic and bariatric surgery is a liver biopsy. Some institutions perform them routinely or nearly routinely, so that the procedure is not unplanned. However, most practices, ours included, will perform a laparoscopic liver biopsy based on the gross appearance of the liver. Any excessive fattiness, and certainly any evidence of scarring are indications for a biopsy. Biopsy results showing any degree of fibrosis should have follow-up with a hepatologist.

## **Patient Education**

The major components of preoperative preparation are optimal treatment of medical problems, patient education, and adherence to planned preoperative protocols as indicated. We have discussed the treatment of existing medical problems above. The importance of preoperative education and teaching is paramount. Patients who are educated and know what to expect will be much more at ease with the events before and after surgery. They will be prepared to follow instructions and recommendations more closely, with better outcomes. Realistic expectations of time in the hospital, pain and its treatment, expected recovery time, and other postoperative issues should all be well discussed before surgery.

## **Preoperative Protocols/ERAS**

Preoperative protocols differ from institution to institution. Many institutions now have adopted the early recovery after surgery (ERAS) type guidelines for many procedures, including metabolic surgery.<sup>38</sup> The truth is, metabolic surgery, by doing virtually all procedures laparoscopically, emphasizing early ambulation as a prophylaxis against VTE, and avoiding nasogastric tubes and introducing liquids soon after surgery, had already achieved many of the

main components of the ERAS protocol. Improvements in pain control and volumes of intravenous fluids given during surgery by our anesthesiology colleagues have been definite benefits of an ERAS program. The ability of patients to take liquids until 2 hours prior to surgery has also been a benefit for our patients, who otherwise were often a bit dehydrated at the start of surgery since their daily liquid requirement is increased due to increased body habitus.

Other than ERAS protocols, some practices have incorporated preoperative diets of the short-term low-carbohydrate variety for their patients. We have not used this approach, and have had few reasons to consider doing it. Enforcement and the penalties for noncompliance seem to be more difficult issues for us than the benefits. Such benefits of a preoperative diet have been reported by some surgeons in surgeon-supervised diets, but the overall improvements in outcomes have been modest and not enough to recommend that this practice be uniformly adopted.<sup>27</sup>

VTE prophylaxis is important, yet there is no one agreed-upon formula. Based on the clinical practices of members of the ASMBS,<sup>39</sup> most patients receive sequential compression foot or leg devices to wear during surgery and while hospitalized postoperatively. Most patients also receive chemoprophylaxis using either regular or low molecular weight heparin. Most surgeons begin this just prior to surgery, with subcutaneous prophylactic doses based on weight. The duration of chemoprophylaxis is controversial. High-risk patients should get a longer course, but whether that is 1 week or up to 4 weeks or longer is still unclear. Despite the importance of this topic, and the fact that pulmonary embolism remains the leading cause of death after metabolic and bariatric surgery, there is still not widespread agreement on the type of heparin, its timing and duration that is optimal for prophylaxis.<sup>39</sup>

Preoperative antibiotics given intravenously within 1 hour prior to starting surgery and redosed until the procedure is completed (and in some institutions up to 24 hours later) has been proven effective in decreasing surgical skin site infections.

## **Postoperative Protocols and Follow-Up**

Postoperative protocols have evolved over the years to now embrace

relatively early discharge from the hospital. Sleeve gastrectomy patients being discharged on the first day after surgery, and gastric bypass patients being discharged either then or the second day after surgery are well published and accepted as safe practice. Early ambulation, early feeding, and minimizing opioid narcotic use with substitution of other non-narcotic pain medications are now hallmarks of most postoperative protocols after metabolic surgery.

Long-term postoperative follow-up has always been advocated to determine the outcomes of the intervention of metabolic and bariatric operations. As noted above, we now have evidence that a substantial sampling, without complete follow-up, of patients probably gives an excellent approximation of the true outcomes of long-term results. Metabolic side effects and consequences exist for all the operations, though the malabsorptive procedures have much greater potential metabolic derangements long-term.

## **Nutritional Issues Following Surgery**

Completely restrictive operations that do not alter the alimentary tract, such as the laparoscopic AGB, have the only consequence of decreasing total nutrient intake. A multivitamin is all that is recommended for postoperative prophylaxis. For the SG, where the stomach is decreased in volume, adding a reliably absorbed source of vitamin B<sub>12</sub> is indicated due to the role of the stomach in its normal absorption. Patients who undergo gastric bypass are at risk for malabsorption of iron and calcium, both preferentially absorbed in the duodenum and proximal jejunum. Diversion of the stomach from the food stream also decreases B<sub>12</sub> absorption. Supplements for these two minerals and vitamin B<sub>12</sub> are indicated as well as a multivitamin to protect against low folate levels or other vitamins not as well absorbed after gastric bypass. Malabsorptive operations, such as the duodenal switch, can produce protein calorie malnutrition as the most severe consequence. Parenteral nutrition may be needed to correct malnutrition, and the reoperative rate to address long term consequences is approximately 7%.<sup>40</sup> Periodic replacement of fat-soluble vitamins via a parenteral route in addition to all the supplements recommended for gastric bypass is standard for patients after a duodenal switch. For all patients who have metabolic surgery, annual or more frequent

follow-up by a physician (primary care or surgeon) is indicated long-term to help monitor and prevent any of the above vitamin and mineral deficiencies.

## **THE OPERATIVE PROCEDURES**

In 2017, there are now two main operative procedures done as metabolic and bariatric operations: SG and RYGB. There are two procedures uncommonly done: laparoscopic AGB and DS. There is also an emerging, not yet considered standard procedure gaining popularity that may well become a standard procedure in the near future: single anastomosis gastric bypass (SAGB). Finally, there are nonsurgical weight loss options now available for patients with class 1 obesity such as intragastric balloons, endoscopic sleeve gastropasty, and others, which are described below as well. Operative procedures that have only historic interest, such as vertical banded gastropasty or biliopancreatic diversion are not described, as they are now rarely performed. A special section on revisional operations is also included. In addition, no longer is any extensive description given to open operative procedures, as they have now all been well eclipsed by their laparoscopic counterparts and have relevance only in a historic sense or in operative procedures where previous surgical scarring (such as in revisional surgery) make an open approach necessary. In general, few variations from the laparoscopic approach in terms of the operative steps are needed when converting from laparoscopic to open surgery. Thus all operative descriptions to follow assume a laparoscopic approach is used. The operative descriptions below are how I perform these operations. Most can have significant variability in the steps and techniques and still accomplish the same operation, and this is certainly acknowledged.

### **Sleeve Gastrectomy**

#### **TECHNIQUE**

Port placement involves a 12-mm camera port approximately 15 cm down from the xyphoid and just to the left of the midline, two ports for the surgeon in the right upper quadrant, with the lower of the two being a 15-mm port and the upper a 5 mm port. The operation is best conducted if the skilled first assistant has two 5-mm ports in the left upper quadrant for assisting. (Fig. 37-

7). We also favor always using a 10-mm 45-degree telescope for our procedures.

**FIGURE 37-7** Port positions for lap sleeve gastrectomy.

The liver is retracted with a Nathanson retractor, placed in the left xyphoid region to retract the left lobe of the liver. The pylorus is identified. The harmonic scalpel is used to divide the attachments to the greater curvature of

the stomach beginning 4 cm proximal to the pylorus and ending at the left crus of the diaphragm (Fig. 37-8). Care must be taken to avoid splenic injury in dividing the short gastric vessels. Any posterior gastric adhesions should also be divided so that the stomach is mobilized on the lesser curvature blood supply and the prepyloric vessels.

**FIGURE 37-8** Dividing the attachments of the greater curvature.

The sleeve is now created. Using an intragastric dilator or tube is helpful to gauge sleeve luminal size. It has been shown that a 40 Fr dilator is optimal size for the lumen. Anything smaller must not be directly touching the stapler as it is closed, or too narrow a lumen may result. The area where narrowing is most common and is most concerning is the incisura. Staple height is gauged by stomach thickness, with higher staple height loads being used on the antrum and shorter ones on the fundus. Controversy exists as to whether to use buttress material while stapling. Large pooled data show a slight difference in favor of less bleeding if such buttressing is used, but the differences are not appreciable in common practice. Leaks are no different whether buttressing is used or not. Some surgeons reinforce their staple lines with oversewing, and some suture only areas of obvious bleeding or concern.

I personally use an Ewald tube (34 Fr) and place the stapler close but not directly adjacent to it while it is positioned along the lesser curvature (Fig.

37-9). Once the sleeve is created, the tube serves as a good mechanism for injecting methylene blue dye forcefully into the stomach to confirm security of the staple line. The resected stomach is removed through the 15-mm port site, enlarging it slightly as needed. We close all port sites 10 mm or larger with interrupted suture or sutures of 0 Vicryl placed laparoscopically with a Berci suture passer.

**FIGURE 37-9** Stapling the stomach to create the sleeve.

## OUTCOMES

SG has been shown to produce an excess weight loss at 8 years of 67% in one series.<sup>41</sup> It improves medical conditions quite well, as shown in data from the ACS Bariatric Surgery Center Network (BSCN) initial report on the first 900 plus such procedures recorded in that database<sup>42</sup> (Table 37-6). The one medical problem that is not well treated by SG is GERD. Patients who have GERD have been shown to do less well on the whole than those who do not. GERD is reported as variably improved after SG. In the ACS database, it was improved in 50% of patients versus 70% after RYGB.<sup>42</sup> In other series GERD was reported to arise anew in from 8% to 47% of patients previously asymptomatic after SG.<sup>43,44</sup> Preoperative and intraoperative search for the presence of a sliding hiatal hernia, and its subsequent repair at the time of SG

can improve these results. Barrett esophagus is considered a contraindication for SG by many surgeons.

**TABLE 37-6: DATA ON IMPROVEMENT IN COMORBID MEDICAL CONDITIONS FROM ACS BSCN CENTERS BY OPERATIVE PROCEDURE**

Percentage Improved or Resolved			
	LAGB	LSG	LRYGB
Diabetes	44	55	83
Hypertension	44	68	79
Sleep apnea	38	62	66
Hyperlipidemia	33	35	66
GERD	64	50	70

Data from Hutter MM, Schirmer BD, Jones DB, et al: First report from the American College of Surgeons – Bariatric Surgery Center Network. Laparoscopic sleeve gastrectomy has morbidity and effectiveness positioned between the band and the bypass, *Ann Surg* 2011 Sep;254(3):410-420.

Thirty-day mortality for SG has been at approximately 0.1% to 0.25% nationally and internationally in large series.<sup>42,45</sup> Early severe postoperative complications have been in the 4% to 5% range, including leak rate of approximately 2.4%, bleeding rate of also approximately 1%, and stenosis rate of approximately 2.1% that needed reintervention.<sup>46</sup> Overall postoperative complication rates are given as approximately 9% for SG.<sup>42</sup> We have observed an approximately 6% incidence of excessive nausea unexplained by any anatomic finding postoperatively. These patients have a syndrome similar to morning sickness, and anti-emetics, intermittent intravenous fluids, and supportive encouragement allow them to weather the usually 1- to 2-month duration of symptoms. Fortunately, the long-term complication rates for this operation, as witnessed in our own practice, are limited to weight regain and a few rare cases of late stenosis and exacerbation of GERD.

## TREATING COMPLICATIONS

Early recognition is always important in treating complications. Isolated tachycardia or dyspnea can be the only early sign of a staple line leak. Waiting until the patient is febrile, has peritonitis and hypotension, leukocytosis on labs, and a radiograph showing a leak before instituting treatment puts the patient at risk for mortality. A high index of suspicion must be present when dealing with suspected leaks. The clinical picture, not just a radiographic study, should determine reoperation. Leaks most commonly occur in the proximal staple line, as a result of high pressure generated by stenosis distally in the sleeve. The combination of stenosis and leak presents two issues that must be resolved before the patient can be functional. Late leaks (over 7 days after surgery) do occasionally present after SG, whereas they are almost unknown that late after RYGB. Many leaks will present after the patient has been discharged, so this must be considered. The optimal treatment for a leak may vary based on its size and severity. A small leak demonstrated on gastrograffin swallow might on rare occasions be adequately treated with endoscopic suturing and stenting and IV antibiotics. A percutaneous drain may also be needed. Most commonly, however, reoperation involves attempting to close the leak if feasible with sutures, placing multiple drains, and creating a jejunostomy tube for enteral feeding access. Leaks after SG can be notoriously difficult to resolve. They tend to not heal quickly, and may become chronic. If so, endoscopic stenting early after surgery may help if the anatomy of the leak area is favorable to a stent. Long-term leaks (of multiple months' duration) may require operative conversion to a RYGB at the site of the leak.

Postoperative bleeding is most commonly from the staple line, and bleeding goes largely into the peritoneal cavity. A drop in hemoglobin or hematocrit postoperatively must be followed up to be certain there is no ongoing bleeding. Transfusion and operative therapy are added based on the severity of the bleeding. Operative therapy with suturing of the bleeding is much preferred to radiologic or endoscopic intervention in the immediate postoperative period unless the bleeding is manifested as hematemesis, in which case upper endoscopy is the procedure of choice.

Stenosis is often slightly slower to manifest itself. It may be present acutely after surgery or present within the first 2 months. Confirmation of stenosis by gastrograffin swallow can be followed by endoscopy, which may at times be therapeutic if the stenosis is largely from the stomach twisting and creating a stenotic area at the twist. Retwisting, however, will require

operative intervention to secure the stomach in an untwisted configuration. Most often there is stenosis at the incisura, where the stomach makes its turn. Dilating this endoscopically using pneumatic dilation or fluoroscopically may produce satisfactory results in about half of cases. Stenting further increases the success to an estimated 90% by some reports. Persistent stenosis may require conversion to a RYGB above the site of the stenosis in 10% to 45% of cases.<sup>47,48</sup>

## **Roux-en-Y Gastric Bypass**

### **TECHNIQUE**

The RYGB is performed in a variety of ways. The essential elements of the operation are to:

1. Create a small proximal gastric pouch based on the lesser curvature
2. Create a Roux limb of 75 cm to over 150 cm and create an enteroenterostomy at that length to the biliopancreatic limb
3. Anastomose the proximal end of the Roux limb to the proximal gastric pouch

Variations of the operation include the route of the Roux limb (retrogastric retrocolic to antegastric antecolic and all variations), the length of the Roux limb, and the means of creating the gastrojejunostomy (linear stapling, circular stapling, and hand suturing). Closure of mesenteric defects is done by most but not all surgeons. Testing the gastrojejunostomy for leaks is done by most but not all surgeons.

My personal technique is as follows:

Ports are placed in a similar location for SG (see [Fig. 37-7](#)), but the camera port is placed a few cm lower, and the surgeon's right-hand and the assistant's right-hand ports are 12-mm ports to accommodate the stapler. The omentum is elevated, and the ligament of Treitz identified with certainty. The proximal jejunum is divided 40 to 50 cm distal to the ligament of Treitz with a linear stapler ([Fig. 37-10](#)). The mesentery at that site is then further divided toward its base to maximally mobilize the Roux limb. Division is stopped short of encountering the base of the mesentery with its large vessels. The proximal end of the Roux limb has a small Penrose drain sutured to it for

identification and manipulation. The desired length of the Roux limb is then measured out, placing the proximal Roux limb into the left upper quadrant as this measurement occurs. The location on the jejunum for the enteroenterostomy is lined up adjacent to the proximal jejunum, with both lengths of bowel lined up in an isoperistaltic fashion so the mesentery is flat adjacent to each other (avoid twisting the distal jejunum so that it is antiperistaltic). The enteroenterostomy is created using a double fire staple technique with the linear stapler (Fig. 37-11). The stapler defect is sutured closed. The mesenteric defect is then sutured closed.

**FIGURE 37-10** Dividing the jejunum to create the Roux limb of RYGB.

A

B

**FIGURE 37-11** Creating the enteroenterostomy.

The transverse colon mesentery is exposed in the area of the ligament of Treitz. A defect is made in the mesentery a few cm to the patient's left and just above the ligament. This placement usually allows for creation of a defect in the mesentery that avoids major vessels and allows a large enough opening to be created to see the posterior stomach. The stomach is grasped and pulled into the opening, after which the Penrose drain and the proximal 2 inches of the Roux limb are placed into the retrogastric space (Fig. 37-12). Care must be taken to be certain that the Roux limb mesentery is not twisted.

**FIGURE 37-12** Placing the proximal Roux limb behind the stomach in a retrocolic retrogastric position.

The Nathanson liver retractor is placed in the left xyphoid area and the left lobe of the liver retracted. The harmonic scalpel is used to make an opening adjacent to the lesser curvature of the stomach, just above the incisura. For especially large patients, this opening should be made more distally, at the incisura, to insure enough length of the proximal gastric pouch to reach the Roux limb without tension. A green load of the linear stapler is used to partially divide the stomach from the lesser curvature side (Fig. 37-13). The surgeon must be certain all tubes are removed from the stomach before firing. Then an Ewald tube is placed into the gastric lumen by the anesthesiologist, and lined up along the lesser curvature of the stomach. It is used as a guide against which are placed subsequent loads of the linear stapler to divide the proximal stomach and finish creating the proximal gastric pouch (Fig. 37-14). Once that pouch is created, the Penrose drain is located in the retrogastric region and used to bring the Roux limb up such that the staple line is facing directly toward the camera. The proximal Roux limb is then sutured to the distal gastric pouch so the two are side by side. Then a gastrojejunostomy is created using a blue load of the linear stapler, fired to its full length (Fig. 37-15). The stapler defect is sutured closed, reinforced with a second suture line,

and tested for integrity by forcefully injecting methylene blue into the anastomotic area via the Ewald tube (which was withdrawn several inches at the time of stapling of the gastrojejunostomy and subsequently repositioned at the anastomosis). Sutures are placed in the transverse colon mesentery and between the Roux limb and biliopancreatic limb to close mesenteric defects (Fig. 37-16).

**FIGURE 37-13** Dividing the stomach partially from the lesser curvature to begin creating the proximal gastric pouch.

**FIGURE 37-14** Completing division of the stomach to create the proximal gastric pouch.

**FIGURE 37-15** Creating the gastrojejunostomy (linear stapled technique).

**FIGURE 37-16** Closing the mesenteric defects for retrocolic retrogastric RYGB.

## OUTCOMES

The RYGB has been shown to produce, in general, approximately 65% to 75% excess weight loss at 1 year. We have shown the 10-year weight curve stabilizes at approximately 50% of excess weight loss.<sup>49</sup> Weight regain tends to be not uniform: many patients maintain all their weight loss, while about 30% experience considerable weight regain. Resolution of comorbid medical problems remains true even after 10 years, as shown in [Table 37-7](#).<sup>49</sup> RYGB has been especially effective in treating insulin-dependent type 2 diabetes.<sup>50</sup> It also is far superior to SG in treating GERD.<sup>51</sup> We have shown it is also an effective operation for patients with a BMI over 60.<sup>52</sup>

**TABLE 37-7: DATA ON RESOLUTION OF COMORBID MEDICAL PROBLEMS  
10 YEARS AFTER GASTRIC BYPASS FROM OUR UVA SERIES**

Comorbid Condition	Preoperative Prevalence	10-Year Prevalence	P Value
Gastroesophageal reflux disease	0.384	0.286	0.0005
Cardiac comorbidity	0.252	0.156	<0.0001
Degenerative joint disease	0.610	0.320	<0.0001
Diabetes mellitus	0.413	0.176	<0.0001
Obstructive sleep apnea	0.358	0.162	<0.0001
Hypertension	0.592	0.471	<0.0001
Pulmonary comorbidity	0.275	0.130	<0.0001
Psychiatric comorbidity	0.389	0.286	0.0003

Mortality for laparoscopic RYGB published from the ACS database shows a 0.15% 30-day mortality.<sup>42</sup> Other databases confirm this extraordinarily low number, with the Bariatric Outcomes Longitudinal Database figure being 0.12%.<sup>53</sup> It is especially gratifying to see these results since only a little more than a decade earlier, data were published from the decade previous to that showing a 2% mortality in patients with federal insurance after RYGB.<sup>54</sup> Many of those patients, however, had their operations performed open before the age of laparoscopy. Nevertheless, a documented greater than tenfold decrease in mortality for an operation in a 15- to 20-year period is most remarkable, and is probably not duplicated in the surgical literature for another procedure.

Complication rates for laparoscopic RYGB from the ACS BSCN database showed a 14% 30-day postoperative complication rate, with a reoperative rate of 5%.<sup>42</sup> Leaks after RYGB have been consistently in the 1% range.<sup>55</sup> Bleeding is in the 1% range as well.<sup>56</sup> VTE is reported in just under 1% of cases, and pulmonary embolism remains a leading cause of death.<sup>53</sup> Longer term complication rates after RYGB include a marginal ulcer rate reported as widely varying between 2% to 12%, which may reflect the degree of aggressiveness and classification of the reporting authors or the surgical techniques used.<sup>57</sup> Small bowel obstruction is generally given as about 5% now, since the majority of surgeons have adopted closing mesenteric defects. Still, about half of those obstructions are from herniation through mesenteric defects and can represent potential for significant bowel ischemia if not treated promptly.<sup>58</sup>

## TREATING COMPLICATIONS

As with SG, leaks after RYGB are notorious for often presenting with fairly subtle clinical findings, such as isolated tachycardia or dyspnea. A high index

of suspicion for the postop patient that “just does not look right” should include leak as the primary diagnosis. The leak may not be manifested on a gastrograffin swallow, especially if it is from the distal gastric staple line or distal anastomosis.<sup>59</sup> A low threshold for reoperation should exist. Operative intervention includes identifying and closing the leak if feasible, placing multiple drains, and for all proximal gastric leaks, placement of a distal gastric feeding tube for enteral nutrition. Enteroenterostomy leaks require repair if feasible, drains, and a more distal jejunostomy tube.

Bleeding after RYGB manifests itself in two ways. Early hematemesis requires return to the operating room and general anesthesia with endoscopic treatment of the bleeding, which is invariably at the anastomosis of the gastrojejunostomy. A fall in hematocrit with or without melena is treated with transfusion and surgery or radiologic intervention if bleeding does not stop after modest transfusion or becomes hemodynamically significant. Radiologic imaging can be very helpful in determining the bleeding site, and may also be therapeutic. If embolized, the bowel usually should be operatively visualized for viability within the next 24 hours.

Acute upper abdominal pain and bloating within a few days after RYGB is a potential life-threatening problem. If there is an obstruction at the enteroenterostomy (alternatively postop hematoma and bleeding could be a cause as could distal bowel obstruction from a port site or abdominal wall hernia) then the distal stomach and its secretions, as well as bile and pancreatic juice, are all trapped in the obstructed lumen, potentially resulting in the rupture of the distal stomach staple line (Fig. 37-17). Such an event is often fatal. Awareness of this problem for any patient with acute pain and pressure in the left upper quadrant within the first few days after RYGB is essential to its timely diagnosis and successful treatment. In general, any vomiting soon after a RYGB is a concern for great worry and the burden of proof is on the surgeon to confirm there is no obstruction.

**FIGURE 37-17** CT showing obstruction of the enteroenterostomy and dilation of distal gastric pouch after RYGB.

Later postoperative bowel obstruction can also be life-threatening if it involves the bowel incarcerating in a mesenteric defect. Many patients have lost a significant length of small bowel in this situation, where recognition and treatment of the problem was too late to prevent bowel gangrene.<sup>60</sup> Once again, the rule of thumb for patients after RYGB is that all bowel obstructions are to be treated operatively unless there is convincing evidence this is a partial bowel obstruction only from adhesions. The operative treatment of a bowel obstruction from a mesenteric defect is to identify the terminal ileum and work retrograde up the ileum to the enteroenterostomy so that there is definitive identification of all parts of the bowel (distal, Roux limb, biliopancreatic limb).

Marginal ulcers can be a very burdensome problem for those patients susceptible to them. The etiology of marginal ulcers is unknown. The hallmark of a marginal ulcer is persistent epigastric pain not responsive to food. Vomiting may occur if the ulcer is acute or chronic, with stenosis of the

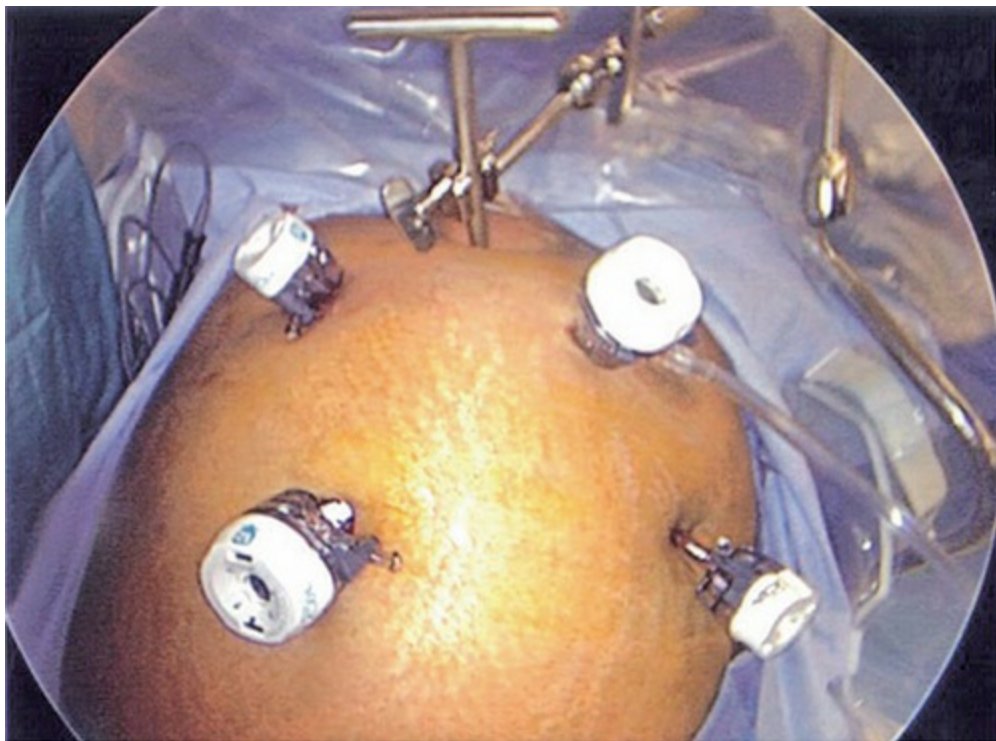

gastrojejunostomy. Endoscopy is the best procedure to both diagnose and potentially treat the problem. Endoscopic dilation may be helpful in alleviating obstructive symptoms until the ulcer heals. Most ulcers will heal given appropriate medical therapy.<sup>61</sup> Patients who are smokers have a much lower chance of the ulcer healing while they still smoke. An untreated persistent marginal ulcer can perforate and create a surgical emergency. It can also fistulize into the lower stomach, creating a channel for persistent acid washing back on the ulcer and precluding healing in most situations. Such a gastrogastic fistula usually needs operative treatment. Revision of the anastomosis is needed as well as separation from the distal stomach (and wedge resection). Multiple recurrent ulcers or a gastrogastic fistula in a patient who is a persistent smoker is a situation where takedown of the Roux limb and creation of a gastrogastrostomy may be indicated.

Nutritional consequences of RYGB are not uncommon. Due to the poor absorption of iron, patients will need iron supplementation. An iron form that does not require an acid environment for breakdown and absorption (ie, not ferrous sulfate) is indicated as oral supplementation. The incidence of iron transfusion parenterally in patients after RYGB is appreciable: 8.5% needing transfusion and 58% being anemic in one recent study.<sup>62</sup> Vitamin B<sub>12</sub> and calcium, though also not as well absorbed, usually are still adequately absorbed to prevent severe complications from their deficiency. Although the operation has been performed for nearly 50 years, it is still not certain to what degree the potential malabsorption of calcium in patients undergoing gastric bypass produces a major clinical risk for osteoporosis and bone disease. Some literature has documented the increased potential for this, but in practice the number of patients who present with severe osteoporosis after gastric bypass is small. Supplementation of calcium, however, is generally recommended to prevent this problem.<sup>63</sup> Vitamin D is often deficient in the general population, and whether there is a significantly increased incidence of its deficiency in patients who have undergone gastric bypass is not clear or proven. However, when one monitors the vitamin levels of patients who undergo gastric bypass for abnormalities, vitamin D deficiency will be a prevalent problem and require supplementation in a significant percentage of patients, reported in one study in a northern climate as being 64%.<sup>64</sup>

## **Laparoscopic Adjustable Gastric Banding**

## TECHNIQUE

Port placement for the laparoscopic adjustable gastric banding (lap band) procedure varies from surgeon to surgeon but most often includes placement of a 12-mm port approximately 15 cm below the xyphoid for the camera, and adding a 15-mm port in the lower part of the right upper quadrant and a 5-mm port in the midportion of the right upper quadrant. The assistant then uses either one or two 5-mm ports in the left upper quadrant. A liver retractor is needed. We place a Nathanson retractor in the left epigastric region, similarly to both SG and gastric bypass (Fig. 37-18).

**FIGURE 37-18** Port placement for laparoscopic adjustable gastric banding (AGB).

The gastrohepatic ligament is opened in its avascular portion in the area of the upper stomach. This allows visualization of the base of the right crus. The tissue along the base of the right crus is incised and a tunnel developed along the surface of the crura, exiting at the angle of His (Fig. 37-19). A grasper passed through this tunnel then grasps the tubing end of the lap band appliance, pulling it through the tunnel such that the buckle end of the appliance is left anteriorly while the remainder of the lap band and tubing has

been pulled through and around the proximal stomach (Fig. 37-20). The tubing is inserted into the buckle, and the buckle secures the lap band closed. The buckle is positioned along the lesser curvature of the very proximal stomach, about 1 to 1.5 cm below the level of the esophagogastric junction. The fundus of the stomach is then imbricated up over the band in all areas anteriorly except the buckle, with two or three sutures used to imbricate the fundus loosely over the band (Fig. 37-21). The tubing is then brought out through the abdominal wall, with this wound serving as the location of the port, which is connected to the tubing at that site and sutured to the abdominal wall fascia to secure it in place. One type of port had metal claws that secured the port to the fascia. Our preference for port location is in the epigastric region, which allows better palpation and therefore access for postoperative adjustments.

**FIGURE 37-19** Creating the tunnel for the lap band against the crura.

**FIGURE 37-20** Pulling the lap band appliance through the tunnel prior to securing the buckle closed.

**FIGURE 37-21** Imbricating the fundus up over the band to secure it in

place.

Adjustment of the lap band is key to its success. Incremental additions of saline are added to the system through the port via a percutaneous technique. A Huber type needle is necessary to safely access the system. Once the patient's band has been tightened to the appropriate level, follow-up is less frequently needed from the surgeon, while follow-up with the nutritionist is usually still appropriate on a regular basis.

## **OUTCOMES**

The lap band enjoyed singular success worldwide for about 15 years, from its introduction in 2004 to its high watermark in terms of popularity in the United States in 2009. Since then, it has rapidly fallen out of favor, with more and more surgeons not performing it or performing it on a very limited basis. This is due to the relatively high incidence of poor weight loss long-term in patients who had a lap band placed. Initial weight loss is usually the case with the procedure, but often it is not long-lasting. Regain of weight, though often not rapid, may occur slowly. Also, patients who experienced slippage or prolapse of the band usually had to have all the fluid removed from the system. If the prolapse resolved with that maneuver, additional visits to refill the system slowly back to a restrictive level were needed. Weight regain often occurred if these were not done promptly. Should such scenarios become repeated, the patient would usually become discouraged and asked to have the band removed. Loss of insurance coverage for follow-up visits or any complications of the band also led some patients to seek band removal. In many cases they also then wished to have an alternate procedure done at the time of band removal. Revisional surgery has dramatically increased in the past decade, in large part due to lap band patients having their procedure converted to another one, such as a SG or a gastric bypass.

Initially, the lap band had a good weight loss profile for a medium-term follow-up, with groups reporting an approximately 50% excess weight loss after 2 years, maintained at close to that level for several years. The weight loss curves of lap band patients and gastric bypass patients looked, in some studies, to be on a pattern of representing similar weight loss after about 5 years.<sup>65</sup> However, more problems began to occur with more regularity long-term. Port problems, prolapse, and other issues caused an appreciable

incidence of reoperation.<sup>66</sup> Many patients who had changes in employers in the United States and had a lap band, lost their insurance coverage for subsequent adjustments and therefore stopped the careful follow-up and support and counseling sessions that were shown to be important in the success of the lap band.

Recent studies have shown that the removal of lap bands has occurred in as many as half the patients in some practices in the United States.<sup>66</sup> The incidence of performance of lap band has dropped to under 5% of metabolic and bariatric operations by most recent estimates.<sup>67</sup> In our current practice, the procedure is offered on a limited basis to individuals who have a BMI not much above 40, need to lose only about 75 pounds for health reasons, and are established as being physically active and used to exercising. In such situations, the lap band can be very effective. While it can be effective in other patient demographic groups, the percentage of success is less in our experience.

When patients are adherent to diet and exercise plans and the band is successful, they experience the same resolution of medical problems as with other operations. The lap band was the first procedure to be shown to be effective in treating type 2 diabetes in patients with class 1 obesity.<sup>68</sup> Improvement in hypertension, sleep apnea, hyperlipidemia, and other medical problems is well documented after performance of a lap band procedure.<sup>69,70</sup>

## **TREATING COMPLICATIONS**

Prolapse, or slippage, is the most frequent severe complication that results from the lap band procedure. This occurs when the stomach below the band is pushed up into the center of the band, or conversely the band slips down the stomach such that herniation of a portion of the stomach up through the center of the band occurs. Both descriptors essentially lead to the same problem: too much stomach through the center of the band and situated above it. If the prolapse is severe, the stomach herniated through the band can become so tight that edema cuts off blood flow to the prolapsed stomach and gangrenous changes may result. This situation is life-threatening, and patients present in severe pain and then extremis. Mild cases of prolapse present with more insidious symptoms of increasing obstruction or new-onset GERD. Such symptoms should alert the surgeon to the potential of prolapse. Mild cases of prolapse are easily treated by removing all the fluid within the

system, decompressing the band, and allowing the prolapsed stomach to spontaneously reduce. Patients clinically report immediate relief of symptoms, and can tolerate liquids. If there is any question as to whether prolapse has resolved, an upper GI series is indicated. A plain film of the abdomen may be diagnostic for prolapse as well, with the angle of the lap band changing from a 7 o'clock to a 1 o'clock orientation (just tilted right of vertical) to instead a flat horizontal orientation caused by the prolapse (Fig. 37-22). Failure to reduce the prolapse with removal of all the fluid from the system is an indication for emergent reoperation to revise the band and reposition it (or remove it if the patient requests). Removal is indicated when gastric resection for gangrene has occurred.

**FIGURE 37-22** Prolapse of lap band can cause orientation of the band to shift toward a horizontal position.

Port malposition is an unfortunately not uncommon problem. The port, if not properly secured to the fascia, may turn and become oriented sideward or even flip over completely in the subcutaneous space. Proper securing to the anterior fascia of the abdominal wall is the best prevention of this problem. Reoperation may be the only option if percutaneous access ability is lost by

port malposition.

Chronic overfilling of the band system and resulting near-complete gastric outlet obstruction may have the benefit of producing more weight loss but has the negative side effect of causing chronic esophageal dilation above the obstruction point. Left untreated, this can lead to deterioration in esophageal motor function.

Erosion of the lap band may occur as well. In our experience, the few cases we observed were within the first week or two after surgery. Signs and symptoms of a perforated viscus are present. The diagnosis is confirmed by radiographic studies. More chronic erosion of the band may occur as well, but also in low numbers of less than 2% of cases.<sup>71</sup> Port infection, epigastric pain, and upper GI bleeding are all ways in which a chronic erosion may occur. Endoscopic removal of a well-eroded band may be feasible. More commonly, operative removal is needed.

## Duodenal Switch

### TECHNIQUE

Port position for laparoscopic DS usually involves two ports in the right upper quadrant, two in the left upper to mid abdomen, and a port near the umbilicus. Additional ports may be added as needed for either of the anastomoses. The operation begins with the creation of a SG. The performance of this is identical to that described above for that procedure. Once the SG has been created, the first part of the duodenum is gently dissected on its inferior border. An area about 2 to 3 cm distal to the pylorus is chosen, and a tunnel is made under the duodenum at that location. The duodenum is then divided with a linear stapler.

The terminal ileum is identified, and an approximately 200 cm length of terminal ileum measured. At that point, the ileum is divided with a stapler, and the distal end of the bowel is brought up to the divided proximal end of the duodenum. There an end-to-side anastomosis is created, usually by suturing, but stapling is also described. The final step of the operation is to create an enteroenterostomy between the distal remaining end of the ileum and a position along the terminal ileum usually 100 to 150 cm proximal to the ileocecal valve. The mesenteric defect at the intestinal anastomosis is closed. The resulting anatomy is shown in [Figure 37-4](#).

## **OUTCOMES**

The DS produces the best long-term weight loss of any of the currently recognized conventional metabolic and bariatric procedures. Series have consistently shown 1- to 5-year weight loss of over 66% to 73% of excess body weight.<sup>72</sup> It also appears to have the lowest incidence of failure due to weight regain.<sup>73</sup>

Resolution of comorbidities is excellent with the DS. It is the most effective procedure for eliminating hyperlipidemias of any etiology, as well as being as good as or better than gastric bypass for reversing type 2 diabetes and fatty liver disease.<sup>74</sup> It is also effective against sleep apnea, hypertension, and most other comorbidities associated with obesity. Less has been published on the effectiveness against these latter diseases than has been for gastric bypass, but it is generally felt the improvements would be comparable if not superior. GERD, however, is not treated as well as with gastric bypass, and the DS produces the exact same effectiveness against it as does the SG. Of course this is not surprising given the gastric anatomy of the two operations is identical.

The DS is championed by its advocates as being the optimal metabolic procedure to treat the disease of obesity, as it allows normal gastric emptying via the pylorus, is immune to marginal ulcers, and provides the same effectiveness in terms of reversing the insulin resistance and improving carbohydrate metabolism as that seen after gastric bypass.<sup>75</sup> Since its malabsorptive component serves to limit weight regain, the DS is often considered as the treatment of choice for anyone who has failed a SG or gastric bypass.

## **TREATING COMPLICATIONS**

DS has the potential to have many of the same complications that are seen after RYGB or SG. Gastric staple line leaks, stenosis of the gastric lumen, and bleeding from the staple line are seen in a similar complication rate as SG. Anastomotic leak from the duodenoileostomy or the ileoileostomy may occur in approximately 1% to 3% and 1%, respectively. Stenosis of either anastomosis early after the procedure can present with abdominal pain, distention, and if allowed to progress, blowout of a proximal staple line from obstruction. Signs of distention, pain, vomiting, or any obstructive symptoms

early are cause for immediate determination that no such potentially lethal obstruction exists. The treatment is operative if any doubt exists as to such a condition being present, just as with RYGB.

Late bowel obstruction may occur from an internal hernia. A high index of suspicion must exist to make an early diagnosis. Obstructive symptoms after DS warrant investigation including CT with oral contrast to determine if an obstruction is present. Evidence suggesting a hernia mandates operative intervention to avoid potential bowel necrosis from incarceration through a mesenteric defect.

The other major types of postoperative complications that arise after DS are related to malabsorption and nutrition. Mechanical issues from frequent bowel movements postoperatively can include development of hemorrhoids or perianal excoriation from diarrhea. The treatment is local and alterations in diet to include gut-slowing medications, fiber, and local care. These complications will slow eating if overeating is the etiology. The DS causes malabsorption of a variety of nutrients. Vitamin B<sub>12</sub> will be poorly absorbed from the combination of decreased gastric intrinsic factor and decreased terminal ileal absorption of this vitamin. All fat-soluble vitamins will similarly be poorly absorbed due to the decreased exposure to the terminal ileum. Iron and calcium will be very poorly absorbed due to diversion of the food from the duodenum and proximal jejunum, their primary sites for absorption. Thus for DS patients, daily supplementation of iron, calcium, and B complex vitamins orally is standard treatment. In addition, parenteral administration of B<sub>12</sub>, fat-soluble vitamins, and at times also iron is also indicated. Nutritional complications seen after DS or other malabsorptive operations are listed in [Table 37-8](#). The relative incidence of such complications in the literature has varied, but just abnormal laboratory values of fat-soluble vitamins after DS was over 60% in some reports.<sup>76</sup>

**TABLE 37-8: NUTRITIONAL COMPLICATIONS SEEN AFTER MALABSORPTIVE OPERATIONS INCLUDING DUODENAL SWITCH**

Protein-calorie malnutrition  
Electrolyte abnormalities (especially magnesium)  
Fat soluble vitamin deficiencies  
Iron deficiency  
Calcium malabsorption leading to secondary hyperparathyroidism  
and bone loss  
Vitamin D deficiency  
Vitamin B<sub>12</sub> deficiency  
Folate deficiency  
Thiamin deficiency (after any procedure causing vomiting)  
Less common documented by may occur:  
Copper deficiency  
Zinc deficiency

---

Of the minerals that may be inadequately absorbed in patients with malabsorptive anatomy, magnesium is the leading candidate to produce symptomatic malabsorption. Patients may need intravenous magnesium supplementation on a regular basis, but otherwise do not need other parenteral replacement in as frequent a fashion.

Gallstones are almost inevitable after DS if the patient has not had a cholecystectomy. Decreased absorption of bile salts occurs after DS, leading to a decreased bile salt pool and hence a much increased risk of forming gallstones. It is recommended that prophylactic cholecystectomy be considered by many experts who are experienced in performing DS. If cholecystectomy is not done at the index operation, the potential for gallstone formation and its presenting symptoms must be considered when DS patients present with epigastric or right upper quadrant pain years after surgery.

The most concerning nutritional complication that occurs after DS and other metabolic malabsorptive procedures is protein-calorie malnutrition. Hypoalbuminemia after a DS is a concern. The typical symptoms of inadequate protein intake including edema, hair loss, muscle wasting, and even ascites can result. If left untreated, the progressive malnutrition that follows leads to an immunocompromised state and often death from infectious problems as in any malnourished patient. When hypoalbuminemia and symptoms of protein-calorie malnutrition arise after DS, the initial treatment is total parenteral nutrition to correct the problem. If the problem returns or persists, operative revision of the DS to lengthen the “common

channel” of bowel in which the bile and food mix together is needed. No exact formula is known, but most surgeons when faced with this situation will err on the side of providing a significantly longer common channel. The estimated incidence of reoperation for protein-calorie malnutrition varies from 3% to 7% in large reported series of DS.<sup>40,77</sup>

## Single Anastomosis Gastric Bypass

Although it has not been officially adopted by the ASMBS as a conventional operation for metabolic and bariatric surgery, the SAGB is developing popularity in other countries and is gaining further converts in the United States. This operation was first introduced by Rutledge and labeled the “mini gastric bypass.”<sup>78</sup> Published results showed excellent postoperative weight loss and a complication rate lower than or comparable to the best series of RYGB. However, local reports of a higher incidence of severe bile reflux esophagitis in this patient population than was reported in the literature caused the community of bariatric surgeons to be skeptical of the procedure.<sup>79</sup> It has subsequently taken many years and multiple further publications in the literature<sup>80-82</sup> to be more accepted internationally and now being considered for adoption in the United States. Since such adoption may occur in the near future, it was felt that at least a brief overview of the procedure is indicated here.

### OPERATIVE TECHNIQUE

The operation is set up similarly to RYGB. Ports are comparably placed. The operation begins with creation of a proximal gastric pouch much as one would during RYGB. However, the pouch must be started at the incisura to provide an adequately long gastric pouch to limit the potential for bile reflux back to the esophagus. The pouch is made using a dilator or tube as a guide, keeping it narrow as with RYGB, and totally separating it from the distal stomach.

Once the pouch is made, the ligament of Treitz is identified and then a point is chosen from usually 150 cm to 200 cm distal to the ligament of Treitz for creation of the gastrojejunostomy. The anastomosis is normally sutured but can be stapled.

## OUTCOMES

Multiple studies have been published in the literature regarding the outcomes after SAGB. Prospective studies initially comparing it to RYGB showed comparable outcomes for weight loss or improved weight loss,<sup>80</sup> with comparable rates of postoperative complications. Subsequent series have continued to confirm that the efficacy of the operation in terms of weight loss and treatment of comorbid medical problems is very comparable to RYGB.<sup>81-83</sup>

## TREATING COMPLICATIONS

The most concerning immediate complications for SAGB are similar to those of RYGB. Anastomotic leak presents in a similar fashion, and requires operative intervention in most cases. Endoscopic intervention for small controlled leaks may be considered. Adequate drainage, a stable patient, and favorable anatomy for stent placement and security are all needed, as they are with any situation where a gastrointestinal leak is being treated by stenting. Usually operative intervention to drain the leak, re-suture it if the tissue permits, and creation of a reliable enteral feeding access distally (distal jejunostomy feeding tube) are all indicated.

Stenosis of the gastrojejunostomy, which may occur soon after surgery or in a more delayed course, can be initially treated with endoscopic dilation. Reoperation may be needed for persistent stenosis refractory to dilating. The occurrence of a marginal ulcer leading to stenosis decreases the likelihood that dilation alone will correct the stenosis.

Malabsorption of iron, calcium, and B<sub>12</sub> are all as concerning after SAGB as they are after RYGB, and must be supplemented and monitored long-term postoperatively.

## Revisional Procedures

Revision of all of the major procedures listed above is well documented in the literature. Some procedures are more commonly revised than others. The indications for revision are largely grouped into two types: either as a result of a complication of the operation requiring revision, or as a result of poor efficacy of the operation and either poor weight loss or weight regain. The

former group of problems has largely been discussed in the sections regarding treatment of complications of these procedures. This section deals with the revision of procedures for poor efficacy or weight regain.

In general, this author takes a relatively stern approach to revisional surgery. Based on years of experience, my general philosophy of offering revisional surgery is as follows: If the patient has had a bad or ineffective operation, then a revision is indicated. If the patient has had overall poor weight loss or weight regain after a soundly performed operation, and the reason for weight regain is noncompliance with recommended diet and exercise plans, then revisional surgery is not offered. It should be pointed out that many of my colleagues do not ascribe to this philosophy, and feel revisional surgery should be offered to most patients who fail an operation and have indications based on current weight and medical problems for a metabolic and bariatric operation.

Understanding that these conflicting philosophies exist, the following is a summary of techniques and outcomes of revisional surgery as currently documented in the literature.

## **REVISION OF LAP AGB**

The most commonly revised operation at this time is the AGB. Many patients have had the operation revised and had the band and port either entirely removed or removed and a second metabolic and bariatric operation performed. One recent report suggested approximately 20% of patients who had a lap band in New York have had the band removed.<sup>84</sup> There is some controversy as to whether removal of the band is best done as an initial procedure, with revisional surgery done as a second procedure. Data from France showed a higher leak rate when a single-stage rather than two-stage approach was used.<sup>85</sup> However, another large series from Germany showed no increase in leak rate for a two-stage approach of conversion of lap band to gastric bypass.<sup>86</sup> The German study emphasized, however, that complications for revision of a lap band to a lap gastric bypass were twice that seen for the initial creation of a gastric bypass.

In general, it has usually been shown that there is a higher complication rate for revisional surgery than is present for an initial index procedure to which the patient is being converted. This is not surprising given the fact that the presence of scar tissue makes reoperation always more challenging and

difficult than surgery on virgin tissue. One recent report from the National Surgical Quality Improvement Program (NSQIP) database showed that the conversion of a lap band to a SG had only more minor complications but no increase in major complications versus the index procedure.<sup>87</sup> These were one-stage conversion operations. Other series have shown a higher incidence of complications for conversion of a lap band to a SG than the initial performance of a lap band, as has a large series reported from the National Inpatient Sample.<sup>88</sup>

The Altieri study suggested that more patients had conversion of their lap band to a gastric bypass than to a sleeve gastrectomy. The data have also shown that conversion of a lap band to RYGB is associated with better postoperative weight loss than conversion to a SG.<sup>89</sup> Twelve- to 24-month followup of excess weight loss for SG was 22%, whereas it was 58% for RYGB. Interestingly, conversion to DS after failed lap band was associated with lower EWL at 1 year than RYGB but higher at 2 years (78.4% EWL).

Conversion of SG to RYGB has been generally done mainly for problems of GERD and stenosis. However, some patients who have failed to lose adequate weight after SG have been converted successfully to RYGB. Conversion of SG to DS is also a relatively commonly employed option for those patients who fail SG from a weight loss perspective and who are felt by a surgeon to warrant conversion to an operation that adds malabsorption to the already present restriction of the gastric sleeve.

Revision of RYGB has been a controversial topic for many years. With its long track record, it is well established that approximately 20% to 35% of patients undergoing RYGB will regain a substantial amount of weight. Our 10-year review of patients undergoing RYGB showed the %EWL for the group at 1 year of just over 70% to a 10-year value of 52%.<sup>48</sup> The weight loss was maldistributed between a smaller fraction of patients regaining a significant amount of weight versus the majority of patients regaining little weight. Given that as many as one-third of patients may regain enough weight to qualify for metabolic and bariatric surgery, the options used by surgeons in the past have included relatively low invasive procedures such as endoscopic suturing of the gastrojejunostomy or adding a band around the gastric pouch, and more extensive revisions including long limb gastric bypass, in which the Roux limb is made significantly longer and the biliopancreatic limb anastomosed to it much more distal and closer to the

ileocecal valve, and conversion to a DS type procedure. The latter two procedures produce significant designed malabsorption. Excess weight loss from a combination of both restriction and malabsorption has been reported in this setting, and is a small but potential danger for any such patient.<sup>90</sup> Careful follow-up is needed after all such operations.

To date, most revisional endoscopic procedures to narrow the gastrojejunostomy after RYGB have been associated with modest amounts of weight loss. Sclerotherapy has been tried using a variety of methods, and has been generally abandoned for poor long-term results. Endoscopic suturing has been performed for over a decade. Initial reports of modest success with a few patients have not been followed up with long-term results showing efficacy.<sup>91,92</sup> A relatively recent report showed 15% to 20% of EWL in the first 6 months in an 11-center trial using a suction type suturing device (transoral outlet reduction [TORe] procedure). This actual amount of weight though averaged only 4.5 kg.<sup>93</sup> This device is no longer on the market due to lack of efficacy. An endoscopic device to narrow gastric pouch size, the StomaPhyX device, has been withdrawn from the market after results showing 10 kg weight loss at 1 year.<sup>94</sup> Improved suturing devices are now available for such procedures, and long-term data after their use for anastomotic narrowing is pending.

Adding a band to the pouch of a RYGB has been advocated by some surgeons as part of the primary procedure. Data from one such series showed a 7% improvement in EWL at 1 year;<sup>95</sup> however the actual comparison between banded and non-banded RYGB patients weight loss was not statistically significant. Prevention of weight regain or weight loss after adding a band to a failed RYGB have been reported,<sup>96</sup> but to date this option has not gained much popularity in terms of a revisional operation.

In general, measures that are advocated prior to and after any major revisional metabolic and bariatric surgery include the following:

1. A thorough evaluation of the causes for the patient to regain weight or not lose the expected weight, and therapies to address those causes in addition to surgical reintervention
2. A detailed outline of the current alimentary tract anatomy including upper GI, CT if indicated, and upper endoscopy to evaluate the current anatomy after the patient's previous surgery

3. A copy of old medical records about the index operation and its details
4. Incorporation of a multidiscipline team approach to the care of the patient, even more so than at the index operation
5. Thorough and complete follow-up, especially if the revisional operation creates an element of malabsorption

## Endoscopic Procedures

Endoscopic procedures to address weight loss have recently gained considerable popularity relative to their use a decade ago. Most of these procedures are still not considered conventional treatment for morbid obesity. However, some are approved for use in class 1 and class 2 obesity. A brief summary of these procedures and their reported results to date is given here.

### INTRAGASTRIC BALLOONS

In 1985, the Garren Edwards intragastric balloon was approved for use in the United States and was placed in a large number of patients in its first few years of availability.<sup>97</sup> However, after 3 years the lack of overall efficacy, weight gain after balloon removal, and an increasing incidence of complications from the balloon caused a reassessment of the device,<sup>98</sup> leading soon thereafter to its withdrawal from the market. The FDA would not approve a gastric balloon again until 2015. In the interim, the BioEnterics IntraGastric Balloon (BIB) was used in many other countries, with overall results being a 13.2% total body weight loss (TBWL) at 6 months and a 7.5% early removal rate, 18.3% GERD rate, 2% ulcer rate, 1.4% migration rate, 0.3% obstruction rate, 0.1 perforation rate, and a 0.08% death rate.<sup>99</sup>

In 2015, two intragastric balloons were approved for use in the United States. The Orbera single balloon system and the ReShape dual balloon system both had comparable weight loss in their initial FDA trials, with 7.4%<sup>100</sup> and 7.6%<sup>101</sup> of TBWL, respectively. Both had a high incidence of initial nausea, vomiting, and abdominal pain, and an early removal rate of 7.5% to 9%.

A third balloon, the Obalon balloon, was approved for use in 2017. This balloon can be placed by swallowing a capsule that can then be inflated. Multiple balloons, up to three, can be inserted as part of the therapy.

Endoscopic removal is needed, however. Weight loss is comparable to the other balloons by reports to date.<sup>102</sup>

The major limitation to the intragastric balloon as currently available is the lack of sustained long-term weight loss. One of the few studies that have followed patients for 5 years has shown excess body weight loss of 42% at 6 months and only 13% at 5 years.<sup>103</sup> Other relative limitations to the appeal of the intragastric balloon include the severe initial symptoms of nausea, vomiting, and abdominal pain, the need for endoscopy to remove or introduce and remove the balloons, and the relatively expensive cost of about \$8000 to \$12,000 at various centers, which is not usually reimbursed by most insurance carriers.

Other space-occupying intragastric devices are being tested for efficacy. None are FDA approved yet. They include devices that partially obstruct the pylorus (transpyloric shuttle),<sup>104</sup> the esophagogastric junction (full sense),<sup>105</sup> or release hydrophilic particles within the stomach to absorb water and swell to occupy space (Gelesis 100).<sup>106</sup> One device, an endoscopically placed long plastic tube secured at the pylorus and designed to prevent contact of food with the duodenum and proximal jejunum, was initially somewhat successful in improving the manifestations of type 2 diabetes.<sup>107</sup> However, it has been withdrawn from the market due to an increased rate of intrahepatic abscess.

Another FDS-approved device available for patients with class 1 and 2 obesity is a 30 Fr percutaneous endoscopic gastrostomy (PEG) tube that can be hooked to a suction device after meals to empty much of the ingested gastric contents. Initial reports showed a wide variability in weight loss by patients who had the AspireAssist device placed, with an average of 37.2 +/- 27.5% of excess weight loss at 1 year.<sup>108</sup>

In this author's estimation, the most important endoscopic procedure currently being performed is the endoscopic sleeve gastropasty (ESG). Relying on the improved suturing capacity of the OverStitch device, intragastric sutures are placed to limit the lumen of the distal and mid stomach to create anatomy quite similar to the SG. The fundus is not sutured, however, due to its thin walls and the potential for injury from sutures placed through the gastric wall in this location. The procedure has mainly been performed for patients with class 1 and class 2 obesity. One recent study showed the procedure produced a durable weight loss for 242 patients at three institutions. The 6-month TBWL of 16.8 +/- 6.4% increased to 19.8 +

11.6% at 18 months follow-up.<sup>109</sup> This procedure has not yet been approved for reimbursement by most insurance carriers, and as such is still a cash procedure for patients.

## **Special Topics Related to Metabolic and Bariatric Surgery**

### **CHOLELITHIASIS**

The presence of gallstones at the time of a metabolic and bariatric index operation has usually been addressed by simultaneous cholecystectomy along with the bariatric operation. While some reports have shown an increased length of stay for performance of cholecystectomy with RYGB,<sup>110</sup> we have shown that adding cholecystectomy to RYGB is safe, confers a less than 1% complication rate, and does not alter length of hospitalization.<sup>34</sup> We thus advocate a preoperative or intraoperative ultrasound to screen for the presence of gallstones. Difficult biliary anatomy or exposure of the gallbladder can be an indication to abort the additional elective procedure in favor of a time when, with weight loss, such exposure may be improved. However, we have encountered this situation very rarely.

For the patient who has no gallstones, we currently recommend no prophylactic cholecystectomy and instead that the patient take oral ursodiol, 300 mg bid for 6 months, which has been shown to decrease the incidence of gallstone formation after RYGB to 4%.<sup>35</sup> Surgeons who perform DS are much more likely to include cholecystectomy as part of the index operation, given the high incidence of gallstone formation after this procedure.

### **PREOPERATIVE UPPER ENDOSCOPY**

The performance of screening upper endoscopy prior to metabolic surgery is still controversial. Many series have been published in the literature that describe a high incidence of some pathology found when routine upper endoscopy is performed prior to metabolic surgery.<sup>111,112</sup> A recent meta-analysis found that surgical therapy was altered in a total of 7.6% of cases based on preoperative endoscopic findings.<sup>113</sup> The conditions most likely to alter the surgical approach include Barrett esophagus, severe esophagitis or

gastritis, adenomatous polyps of the stomach, or a large hiatal hernia. Upper endoscopy is probably more routinely indicated prior to RYGB, where the gastric and duodenal anatomy will no longer be endoscopically accessible postoperatively. Screening prior to any procedure is generally felt indicated for GERD or a history of GERD-related complications. While routine upper endoscopy probably is the optimal choice for determining any pathology preoperatively, current insurance plans often will not reimburse this procedure unless indications such as GERD are present.

## **PREGNANCY**

The data over the years continue to support the fact that metabolic and bariatric surgery procedures are generally very safe in terms of imparting little risk to a woman who becomes pregnant after she has acclimated to the procedure. We advocate our patients use birth control for the first year after surgery, since irregularities in menstrual cycles are the norm, and since conception soon after a procedure such as RYGB can be stressful for the mother, who will often have to be carefully monitored for adequate fluid and nutritional intake, especially during the first trimester. However, there are few reports of any significant morbidity to the fetus in a pregnancy after metabolic and bariatric surgery.

## **METABOLIC SURGERY: MORE THAN JUST WEIGHT LOSS**

The emphasis of reports on metabolic and bariatric surgical procedures during the 20th century was clearly on the parameter of weight loss. This defined an operation's efficacy and success. However, the resolution of comorbid medical problems associated with obesity was certainly documented in many reports of bariatric surgery during that period. The mechanism of improvement of comorbid medical problems was felt to lie largely in the fact that the inciting reason for the problem, obesity, had now been corrected. While this is certainly true to a great extent, the actual mechanisms of why obesity accelerated and increased the presence of some of these medical conditions were and to some extent probably remain poorly understood. The observation that weight loss led to resolution of many of the

comorbid medical problems that existed for severely obese patients seemed to place the logical etiology for the medical problem in the obese state itself.

However, certain observations strained the logic that weight loss alone was responsible for the resolution of comorbid medical problems. The strongest example of this was the fact that patients with type 2 diabetes often resolved their disease after only a few weeks of weight loss. Insulin requirements would disappear within weeks, whereas weight loss was at that time still relatively minor compared to the eventual accumulation of lost weight that would follow in subsequent months. The explanation for this remained unclear. However, its observation was quite clearly documented by Pories<sup>114</sup> and Sugerman,<sup>115</sup> among others.

In the past 20 years, there has been a significant acceleration in the amount of research done to explore this observed phenomenon. Below is a summary of the evolution of that process as well as the currently best accepted theories for how RYGB is so effective in the treatment of type 2 diabetes in severely obese patients.

Recent studies have suggested that there is much more involved in the process of weight loss and maintenance of weight loss after metabolic and bariatric surgery than just simple caloric restriction. Weight loss-independent factors that contribute to the success of bariatric operations have now been shown to include changes in the luminal composition of the gut, changes in postprandial gut hormone secretions, and alterations in energy expenditure seen after bariatric surgery.<sup>116</sup>

The argument against simple mechanical limitation of intake as being the cause of success of bariatric surgery lies in several important observations. For gastric bypass, the size of the gastric pouch and the diameter of the anastomotic opening between the stomach pouch and the Roux limb should correlate strongly with successful weight loss after surgery. However, except for the general concept that too large a gastric pouch will lead to less success after surgery, there is no strict correlation between pouch volume and weight loss success.<sup>117</sup> Nor is there one between anastomotic size and weight loss. Finally, sleeve gastrectomy, though having a significantly larger amount of gastric lumen available for food, produces weight loss that is nearly comparable to that of gastric bypass. In addition, the “malabsorptive” component of gastric bypass, diverting food beyond the duodenum and proximal jejunum, appears to account for little additional weight loss when

comparing gastric bypass to sleeve gastrectomy.

Simple caloric restriction, in the absence of any surgical changes to the gastrointestinal tract, will produce increased hunger. Anyone who has gone on a diet can attest to that. However, after both SG and gastric bypass, patients report an absolute lack of appetite. In some patients, there is almost an aversion to food. While the same aversion process will occur in a patient with a proximal obstruction of the gastrointestinal tract, after bariatric surgery, where no true obstruction exists, this lack of appetite is profound and can last many months, sometimes the better part of a year. In most individuals, appetite does eventually return. The process whereby this occurs within the CNS and the gut may hold the secret to satiety, probably the factor that is most aberrant in the disease state of morbid obesity.

Processes that have been implicated as being important in altering the metabolic process in terms of overall caloric intake as well as specific improvement in glucose disposal and insulin sensitivity include an alteration in the secretion of certain gastrointestinal hormones following bariatric surgery. The best studied of these metabolic changes for a specific disease to date involves the alterations in metabolism causing the rapid reversal of diabetes seen after gastric bypass.

It was observed decades ago that type 2 diabetes resolved much more quickly after RYGB than after other operations which eventually produced equal weight loss. Bypassing the duodenum was felt to be the key element in that rapid reversal. This spawned a generation of research about the enteric relationship to glucose metabolism. Rubino<sup>118</sup> showed convincingly in a seminal paper that the creation of a gastric bypass in an obese rat species eliminated the diabetes present. The diabetes returned when the operation was reversed. Further work on the role of the proximal gut in influencing glucose metabolism led to the hypothesis of the pivotal role of glucagon-like peptide 1 (GLP-1) in affecting insulin sensitivity.<sup>119</sup> This was largely accepted for the past decade, but new studies in mice without GLP-1 receptors show gastric bypass remains as effective in altering glucose metabolism.<sup>120</sup> Sleeve gastrectomy has also been shown to be effective, though not as effective as gastric bypass, in reversing type 2 diabetes in morbidly obese patients. Enhanced GLP-1 secretion after SG would not be on the basis of duodenal diversion of food contents.<sup>121</sup> Thus, although much evidence implied an important role for GLP-1 in affecting the rapid reversal of diabetes after

gastric bypass, its incretin effect is probably not the only factor at work in the overall process.

Other gastrointestinal hormones have been implicated in the improvement in carbohydrate metabolism after bariatric surgery. Glucose-dependent insulinotropic peptide (GIP), also found more densely in the proximal gut, has been implicated in improved glucose metabolism,<sup>122</sup> but a clear physiologic role has not been established. Peptide YY, found in the ileum, and known as the “ileal brake” has been hypothesized to produce improved weight loss after gastric bypass and sleeve gastrectomy. PYY release is stimulated by undigested food contents in the mid to distal small bowel. It has a metabolite that has been shown to be a very powerful appetite suppressant through interaction with the hypothalamus in animal models.<sup>123</sup> Its upregulation in mice is associated with improved glucose metabolism.<sup>124</sup> This may best explain its contributory role to the success of RYGB and SG in improving weight loss and glucose metabolism.

Other less well known and less extensively studied hormones may also add some component to the incretin effect seen after oral glucose administration after RYGB. These include oxyntomodulin, which appears to act on the GLP-1 receptor and produces weight loss when injected in obese humans,<sup>125</sup> and gustducin, which acts to stimulate GLP-1 secretion as well.<sup>126</sup>

Insulin sensitivity improves after RYGB due to increased release of insulin in response to the rapid emptying of glucose into the intestine in the absence of any pyloric regulation of gastric emptying. Sleeve gastrectomy has also been shown to have more rapid gastric emptying as well after a period of adaptation, and the same insulin surge has been documented. As animals lose weight, it has also been clearly shown that there is a weight-loss related increase in insulin sensitivity as time passes after surgery. This increased sensitivity likely has two components, one a more rapid one unrelated to weight loss and another related to weight loss. Studies performed using a glucose clamp technique, which allow differentiation of sensitivity to hepatic versus peripheral insulin, have shown that the initial improvement in glucose metabolism after RYGB is that of increased tissue sensitivity to hepatic insulin release.<sup>127</sup> Skeletal muscle increased insulin sensitivity only occurs after some weight loss, thereby being a later component of the overall insulin sensitivity.<sup>128</sup> Another component of the improved glucose

metabolism after RYGB and probably SG also is the increase in pancreatic beta cell mass following these operations.<sup>129</sup> Current hypotheses suggest that the increased secretion of GLP-1 and GIP are largely responsible for these increases in beta cell mass, which in turn increases the insulin response to a glucose challenge.

The microbiota of an individual is defined as the composition of all the bacteria found within the gut lumen of that individual. The human microbiota and its corresponding genetic component, the microbiome, is only now beginning to be studied and appreciated for its impact on health and disease of the individual. Changes in the microbiota following bariatric surgery have been well documented. These include a decrease in Firmicutes species and an increase in Bacterioides species<sup>130</sup> as well as an increase in Proteobacteria.<sup>131</sup> Alterations in the gut flora are felt to be important contributors to metabolism and energy expenditure, as evidenced by the fact that fecal transplants from obese humans or obese mice into germ-free mice showed weight loss compared to germ-free mice receiving fecal transplants from non-obese humans or mice.<sup>132,133</sup> The mechanisms for such action of the microbiota on the host energy metabolism and weight loss are as yet undefined.

The microbiota do control the composition of circulating bile acids. This may be a mechanisms by which these changes may be affected. It is known that alterations in the microbiota will produce alterations in the type and amount of circulating bile salts in the enterophepatic circulation. Bile salts and their interactions on hepatic lipid absorption and glucose disposal may be important regulators of metabolism and weight after bariatric surgery. It has been shown that bariatric surgery alters bile acid composition, and that diversion of bile surgically into the distal intestine in rats produces weight loss and improved glucose metabolism without any alteration of the stomach or proximal GI tract.<sup>134</sup>

Taurine conjugated bile acids are increased after bariatric surgery, both for sleeve and bypass operations.<sup>135</sup> In animal models after sleeve gastrectomy, increased amounts of circulating bile acids were found to correlate best with weight loss postoperatively, as well as with improvements in hepatic steatosis. Sleeve gastrectomy improved hepatic steatosis better than simple low calorie restriction weight loss, showing the likely enhanced effects of SG on hepatic fat metabolisms likely affected by alterations in the bile salt pool.<sup>136</sup> Further studies on the effects of alterations in bile salt pool

composition and action on metabolism are ongoing, with the goal of determining the mechanism of how alterations in bile salts in turn affect glucose and fat metabolism. The alterations in the bile salt pool appear to be related to alterations in the microbiota as a secondary effect of bariatric surgery. This is a rapidly expanding area of current research and likely will yield important further data to help explain the gross changes in body weight seen in animal models when gut flora is altered.

## SUMMARY

The disease of morbid obesity is finally recognized as a disease entity in itself. It usually has accompanying diseases that present with increasing frequency as the duration of the obese state continues. For the person with morbid obesity, surgery currently represents the only successful treatment for both the disease of obesity and its related co-morbidities. To date, the field of bariatric surgery is about 65 years old. The frequency of performance of bariatric operations increased dramatically at the turn of the century, corresponding to the availability of laparoscopic approaches to operations. Dramatic improvements in the safety and efficacy of bariatric operations during the past 15 years have resulted in the fact that currently bariatric surgical procedures are among the safest of abdominal operations performed, rivaling appendectomy and elective cholecystectomy for low mortality rates. During that same time frame, there has been increased recognition of the metabolic improvements to patients as a result of bariatric operations, confirming the concept that these operations are not only bariatric but metabolic in effect. Increased study of the mechanisms that promote and preserve the metabolic and bariatric effects of these procedures has also occurred during this time frame, leading to improvements in our understanding of some of these mechanisms and discovery of other as yet barely investigated mechanisms which appear to play important roles as well. It is safe to say that in future years, this research will lead to better optimization of interventional procedures that are metabolically beneficial to patients suffering from the diseases of obesity and its comorbid associated medical diseases. Similarly, based on the increased frequency of newer less invasive procedures and endoscopic approaches to procedures, it is also likely that the procedures of the future will be less invasive and more effective in reversing these disease processes. It is certainly hoped that this occurs, for to

date the acceptance of metabolic and bariatric surgery remains low by the general population, and its embrace by the medical community is still incomplete. Obesity continues to increase as a health problem, and a costly one. Innate biases against obesity remain within the perception of the public and even within health care providers. We have not yet reached the crucial tipping point of appeal and efficacy of interventions being popular enough so that they are used in significantly higher frequency to promote improvements in the metabolic process of obesity such that this disease and its related associated diseases become health care issues of decreasing importance. That remains the goal of metabolic and bariatric surgeons and bariatric medical physicians and researchers for the immediate future.

## **INTESTINE AND COLON**

# SMALL BOWEL OBSTRUCTION

*Kristina L. Go • Janeen R. Jordan • George A. Sarosi, Jr. • Kevin E. Behrns*

Bowel obstruction vexed medical practitioners as long ago as 350 BC, and it continues to do so today.<sup>1</sup> The management of patients with bowel obstruction is challenging because decision-making is complicated in many patient care scenarios. First, the diagnosis of bowel obstruction may be difficult in a patient who recently underwent surgery. That is, does this lack of gastrointestinal function represent an ileus or a true bowel obstruction? Second, the timing of surgical intervention may not be obvious. When is an operation appropriate in a patient who underwent recent surgery? Finally, what is the appropriate operation in patients who have had multiple, chronic intestinal obstructions? All of these scenarios represent high-risk decisions, and thus management of bowel obstruction requires critical analysis and decision-making. The goal of this review is to provide a contemporary summary of the epidemiology, diagnosis, and management of bowel obstruction in a broad context of impaired gastrointestinal function.

## DEFINITION

Bowel obstruction is defined by the lack of aborad transit of intestinal contents, regardless of etiology. Bowel obstruction may involve only the small intestine (small bowel obstruction), the large intestine (large bowel obstruction), or both via systemic alterations in metabolism, electrolyte balance, or neuroregulatory mechanisms (generalized ileus). Traditionally, the surgeon's perspective of a bowel obstruction represents a mechanical obstruction that is due to physical stenosis or occlusion of the intestinal lumen. In the broader context, however, ineffective motility, without any physical obstruction, causes a functional obstruction or ileus of the intestine. Furthermore, intestinal obstruction can be classified based on duration of presence (acute vs chronic obstruction), extent (partial vs complete), type of obstruction (simple vs closed-loop), and risk of bowel compromise (incarcerated vs strangulated).

Bowel obstruction continues to be one of the most common intra-abdominal problems faced by general surgeons. In a 2010 global burden of disease study, bowel obstruction and ileus were responsible for 2.1 deaths, 54 years of life lost, and 54 disability-adjusted life-years per 100,000 population, respectively, second only to peptic ulcer disease for all abdominal conditions for each of these parameters.<sup>2</sup> Independent of the underlying etiology, bowel obstruction remains a major cause of morbidity and mortality. Early recognition and aggressive treatment are crucial in preventing irreversible ischemia and transmural necrosis, thereby decreasing mortality and long-term morbidity. Despite multiple recent advances in diagnostic imaging and marked advances in our treatment armamentarium, intestinal obstruction will remain a significant surgical problem given the lack of treatment options to manage adhesions, hernias, and malignancies.

## **Mechanical Bowel Obstruction**

*Mechanical bowel obstruction* is defined as a physical narrowing or occlusion of the intestinal lumen. This blockage may be intrinsic or extrinsic to the wall of the intestine or secondary to luminal obstruction arising from intraluminal contents (eg, an intraluminal gallstone or other foreign body) (Table 38-1). Partial obstruction implies that the intestinal lumen is narrowed, and some intestinal content can transit distally. In the presence of a complete obstruction, the lumen is obliterated, and no intestinal content can pass beyond the point of obstruction. The risk of strangulation, that is, vascular

compromise of the intestine, increases markedly in the presence of a complete obstruction, especially when caused by an extraluminal etiology such as a hernia defect or an adhesive band compressing the small bowel mesentery. Accordingly, complete obstruction can be categorized further as simple, closed-loop, and strangulated obstruction. A simple obstruction has no associated vascular compromise, and the intestine can be decompressed proximally. Closed-loop obstruction occurs when both ends of the involved intestinal segment are obstructed (eg, volvulus or compressive adhesive bands), and results in increased intraluminal pressure secondary to increased intestinal secretion and accumulation of fluid in the involved intestinal segment. Closed-loop obstruction carries a substantial risk of vascular compromise and irreversible intestinal ischemia of the involved bowel, and thus requires emergent operative attention. Finally, strangulation occurs when the blood supply to the affected intestinal segment is compromised, leading to focal or segmental transmural necrosis. The affected segment may involve only a portion of the bowel wall compressed by a tight adhesive band or an entire intestinal segment as occurs with a strangulated hernia or a closed loop. If viability of the bowel is maintained after relief of the obstruction, strangulation can be reversed (reversible strangulation obstruction). In contrast, irreversible strangulation occurs if the vascular compromise has caused irreversible transmural necrosis whether or not the strangulation is relieved. All irreversible strangulated obstructions start as reversible strangulated obstructions, and thus early diagnosis is paramount to rescuing compromised intestine.

#### TABLE 38-1: MECHANICAL BOWEL OBSTRUCTION

## Lesions Extrinsic to the Intestinal Wall

### **Adhesions**

Postoperative

Congenital

Postinflammatory

### **Hernia**

External abdominal wall  
(congenital or acquired)

Internal

Incisional

### **Congenital**

Annular pancreas

Malrotation (rotational  
abnormality)

Omphalomesenteric duct  
remnant

### **Neoplastic**

Carcinomatosis

Extraintestinal neoplasm

### **Inflammatory**

Intra-abdominal abscess

“Starch” peritonitis

### **Miscellaneous**

Volvulus

Gossypiboma

Superior mesenteric artery  
syndrome

## Lesions Intrinsic to the Intestinal Wall

### **Congenital**

Intestinal atresia

Meckel’s diverticulum

Duplications/cysts

### **Inflammatory**

Crohn’s disease

Eosinophilic granuloma

### **Infections**

Tuberculosis

Actinomycosis

Complicated diverticulitis

Appendicitis

### **Neoplastic**

Primary neoplasms

Metastatic neoplasms

### **Miscellaneous**

Intussusception

Endometriosis

Radiation enteropathy/stricture

Intramural hematoma

Ischemic stricture

### **Intraluminal/obstructor obstruction**

Gallstone

Enterolith

Phytobezoar

Parasite infestation

Swallowed foreign body

(magnets, illicit drug mules,  
sharp objects that perforate the  
bowel, etc)

## Functional Bowel Obstruction or Ileus

Functional obstruction or ileus occurs when the bowel, small or large, fails to propel content distally in the absence of a mechanical obstruction. The pathophysiology of ileus involves electrolyte disturbances, impaired neuroregulatory innervation, imbalanced hormonal input, and other less common causes (Table 38-2). The most common form of functional bowel obstruction is postoperative ileus, because it is present to some extent after nearly all intra-abdominal operative procedures. Various types of extra-abdominal medical and surgical conditions may also cause a transient functional ileus. Besides these more frequent forms of functional bowel obstruction caused by a response to local or systemic stimuli, there is a group of rare, chronic, progressive, gastrointestinal (GI) “pseudo-obstructions.” These rare forms of functional obstruction are related either to hereditary or acquired visceral myopathies, visceral neuropathies, or a poorly understood disruption of myoneural coordination of organized contractile activity.

**TABLE 38-2: FUNCTIONAL BOWEL OBSTRUCTION, ILEUS, AND PSEUDO-OBSTRUCTION**

## Intra-Abdominal Causes

### Intraperitoneal problems

Peritonitis (chemical infections)

Intra-abdominal abscess

Contained anastomotic leak

Postoperative (physiologic)

Chemical:

Gastric juice

Bile

Blood

Autoimmune:

Serositis

Myositis

Vasculitis

Neuropathy

Intestinal ischemia:

Arterial or venous

Sickle cell disease

### Retroperitoneal problems

Urolithiasis

Pyelonephritis

Metastasis

Pancreatitis

Retroperitoneal trauma/  
hematoma

## Extra-Abdominal Causes

### Thoracic problems

Myocardial infarction

Severe congestive heart failure

Pneumonia

Thoracic trauma

### Metabolic abnormalities

Electrolyte imbalance

Sepsis

Lead poisoning

Porphyria

Hyperglycemia/ketoacidosis

Hypothyroidism

Hypoparathyroidism

Uremia

### Medicines

Opiates

Anticholinergics

Alpha-adrenergic agonists

Antihistamines

Psychotropic drugs

Catecholamines

### Miscellaneous

Acute spinal cord injury

Pelvic fracture

Head trauma

Chemotherapy

Radiation therapy

Hip arthroplasty

Renal transplantation

Acute megacolon (ulcerative  
colitis, *Clostridium difficile*  
infection)

Postoperative ileus represents the most common cause of delayed hospital discharge after abdominal operations. The duration of postoperative ileus may correlate with the degree of surgical trauma or the type of operation, and might even be considered a “physiologic” response. A prolonged “pathophysiologic” postoperative ileus may develop in patients operated on for radiation enteropathy, chronic obstruction, or severe peritonitis. Recovery from ileus after manipulation and local trauma differs among anatomic segments of the gastrointestinal tract. Generally, the small bowel recovers effective motor function within hours after an abdominal operation and, in fact, transient focal intestinal peristalsis is often visualized during an abdominal operation. In contrast, the stomach regains motor function 24 to 48 hours after an operation leading to delayed gastric emptying. The colon exhibits the slowest recovery response and may take 3 to 5 days to recover effective propulsive activity postoperatively.<sup>2</sup> Differentiation of postoperative ileus from early postoperative mechanical bowel obstruction is important, because these anomalies are caused by different pathophysiologic mechanisms.<sup>3</sup> In ileus, there is a prolonged inhibition of coordinated bowel activity that can take days or even weeks to resolve, depending on the etiology. The process of impaired postoperative peristaltic activity and coordinated aborad propulsion may be improved by the administration of alvimopan, a peripherally acting  $\mu$ -opioid receptor antagonist, which has been shown to decrease the incidence of ileus and shorten hospital length of stay.<sup>3</sup>

## **Early Postoperative (Mechanical) Bowel Obstruction**

*Early postoperative bowel obstruction* is defined as bowel obstruction occurring within the first 6 weeks postoperatively. This type of intestinal obstruction represents a distinct clinical entity with a unique pathophysiology, and it should be differentiated from both the classic mechanical bowel obstruction as well as from postoperative ileus. The formation of acute adhesions is the responsible cause in over 90% of early postoperative bowel obstructions necessitating surgical management. Other causes include internal herniation, fascial herniation especially after laparoscopic surgery, intra-abdominal abscess, intramural intestinal hematoma, and anastomotic edema or leak. The differential diagnosis is

difficult as it may not be easy or possible to differentiate early postoperative mechanical obstruction from postoperative ileus. Nausea, vomiting, abdominal distention, and obstipation are themselves relatively common findings in the early postoperative period and are alone not distinguishing features of mechanical obstruction. Because the initial symptoms of early postoperative mechanical obstruction tend to be vague, patients are often considered to have ordinary postoperative ileus. Pain secondary to the recent incision, and masked by the use of narcotic analgesics, makes the physical examination often unreliable as well. Interpretation of imaging studies may be difficult, because early postoperative bowel obstruction and ileus can present with similar findings on plain abdominal radiographs. Computed tomography (CT) and contrast studies can help differentiate patients who can be treated conservatively from those who may need operative intervention, especially those with either a focal site of obstruction or the presence of dilated proximal and decompressed distal small bowel; the latter defines a mechanical etiology.<sup>4</sup>

## EPIDEMIOLOGY

In recent decades, the overall incidence of small bowel obstruction has been stable over time as noted by a study that examined the incidence from 1988 to 2007 when it ranged from 579 to 654 diagnoses for bowel obstruction per 100,000 population.<sup>5</sup> The etiology of obstruction has not changed during the study period as adhesions remained the most common etiology.<sup>5</sup> The etiology and frequency of obstruction, however, was altered markedly throughout the 20th century when repair of hernias became commonplace, and thus the etiology of bowel obstruction related to incarceration in a hernia defect decreased and was replaced by adhesive obstruction as the most common cause of bowel obstruction. In the underdeveloped world, however, bowel obstruction still manifests with a clinical picture resembling that found in the early 20th century in Western societies, with incarcerated hernias leading the list in frequency. The wider application of minimally invasive surgical procedures with fewer adhesions may decrease the frequency of bowel obstruction secondary to postoperative adhesions,<sup>6</sup> particularly in cholecystectomies and hysterectomies. However, a review by Barmparas and colleagues<sup>7</sup> concluded that while laparoscopic colectomies lowered incidence

of adhesions, this did not correlate to a lower incidence of adhesive small bowel obstruction. Nonetheless, access to improved surgical care in lower middle-income countries will change the etiology of bowel obstruction and improve care.<sup>8</sup>

Obstetric, gynecologic, and other pelvic surgical procedures represent important etiologies for the development of postoperative adhesions.<sup>9</sup> Therefore, it is not surprising that a slightly greater frequency of bowel obstruction is observed in women.

About 80% to 90% of bowel obstructions occur in the small intestine; the other 10% to 20% occur in the colon. Colorectal cancer is responsible for 60% to 70% of all large bowel obstructions, while diverticulitis and volvulus account for the majority of the remaining 30%. In contrast, small bowel obstruction is most commonly attributed to adhesions, abdominal wall hernias, or neoplasms in most advanced Western societies.

Resources expended and costs incurred in the treatment of intestinal obstruction represent a substantive burden on the national health care system of any country. Surprisingly few contemporary data exist regarding the burden of costs for bowel obstruction over a large population regardless of etiology. Most studies are small, with less than 200 patients, and examine only one etiology of obstruction in a defined population. One dated study, however, estimated that adhesive bowel obstruction accounted for over 1 million days of inpatient care and \$1.33 billion in health care expenditures in the United States in 1994.<sup>9</sup> Indeed, it has been estimated that 1% of all hospitalizations, 3% of emergency surgical admissions to general hospitals, and 4% of major celiotomies (about 250,000) are undertaken because of bowel obstruction or procedures necessitating adhesiolysis.<sup>9</sup> Another study showed that between 12% and 17% of patients who have undergone a total colectomy are admitted for small bowel obstruction within 2 years of their index operation, while approximately 3% will require an operation to treat an established small bowel obstruction.

Bowel obstruction results in substantial overall mortality and morbidity. Depending on the clinical setting and the presence of related or unrelated comorbidities, mortality rates range from up to 3% for simple obstructions to as great as 30% when there is vascular compromise or perforation of the obstructed bowel. Further, bowel obstruction is frequently a recurrent problem, adding to the overall morbidity of an operation or even repetitive

successful nonoperative management. Recurrence rates vary according to method of management (conservative or operative). Intestinal obstruction recurs in about 12% of patients after a successful primary conservative treatment and in 8% to 32% of patients after operative management for adhesive bowel obstruction. Another study showed that while operatively treated patients had a decreased frequency of recurrence and a greater time interval to recurrence, they also had a greater hospital stay than patients treated conservatively. Also, there was no significant difference in incidence, type of treatment, or type of prior operative procedure among patients presenting with early or late small bowel obstruction. In this study, none of the analyzed variables were predictive of success of a particular treatment.<sup>10</sup>

## **PATHOPHYSIOLOGY**

Mechanical bowel obstruction results in numerous alterations of the normal intestinal physiology, including motility and absorption. The pathophysiology of bowel obstruction remains incompletely understood despite numerous investigations both clinically and experimentally. Bowel distension, decreased absorption, intraluminal hypersecretion, and alterations in motility are found universally, but the mechanisms mediating these relatively dramatic pathophysiologic derangements remain unclear. In addition, bowel obstruction is accompanied by considerable disruption of mechanisms of neural and hormonal control, the type and quantity of endogenous bacterial flora, and the innate immunity of the gut.

The older, classic literature addressing the pathophysiology of bowel obstruction considered a decrease in blood flow as the sentinel event leading to most of the observed pathophysiologic changes. More recent experimental work, however, suggests that an increase in blood flow in association with an intense intramural inflammatory reaction and subsequent mucosal production of reactive oxygen species mediate many of the pathophysiologic changes observed in the early phase of bowel obstruction.<sup>11</sup>

### **Distension, Absorption, and Secretion**

Bowel distension is a characteristic, fundamental, and constant pathophysiologic response to mechanical bowel obstruction. Accumulation of

swallowed air is responsible for much of the small bowel distention in the early phases of obstruction. As would be expected, intraluminal gas consists of approximately 75% nitrogen in the obstructed bowel. Fermentation of sugars, production of carbon dioxide by interaction of gastric acid and bicarbonates from pancreatic and biliary secretions, and diffusion of oxygen and carbon dioxide from the blood are other sources of gas in early obstruction. Dilation and inflammation of the bowel wall cause accumulation of activated neutrophils and stimulation of resident macrophages within the muscular layer of the bowel wall, impairing secretory and motor processes by release of reactive proteolytic enzymes, cytokines, and other locally active substances. Local release of nitric oxide, a potent inhibitor of smooth muscle tone and contractility by the inflammatory response, aggravates intestinal dilation through inhibition of contractile activity. Notably, a correlation between the amount and activity of nitric oxide synthase, the enzyme responsible for nitric oxide synthesis, and the severity of intestinal dilation observed exists. Furthermore, experimental data demonstrate a relationship between distention and the intramural production of reactive oxygen metabolites. In addition to disrupting gut motility, these metabolites also modulate permeability of the vasculature and the gut mucosa.

Along with the intraluminal accumulation of gas, the bowel also has a secondary decrease in net absorption resulting in the addition of water and electrolytes into the lumen during the first 12 hours of small bowel obstruction. By 24 hours, intraluminal water and electrolytes accumulate more rapidly because of a further decrease in absorptive flux; this decrease in net absorptive flux occurs via stimulation of a concomitant increase in net intestinal secretion (secretory flux). These changes are caused by increased permeability due to secondary mucosal injury resulting in intraluminal leakage of plasma, electrolytes, and extracellular fluid. Whether associated neural or systemic humoral/hormonal mechanisms aggravate this upregulation of unidirectional secretory flux also remains likely but poorly investigated or explained.

This net secretion of fluid into the lumen of the obstructed bowel is exacerbated further by the accumulation of intraluminal bacteria-derived toxins, bile acids, prostaglandins, vasoactive intestinal polypeptide, and mucosa-derived oxygen-free radicals. With a more chronic obstruction, bacterial proliferation occurs in the lumen, further disrupting absorption, secretion, and mucosal integrity. The decrease in the absorptive capacity and

increase in secretion lead to important fluid losses (enterosecretion) that may result in profound dehydration. Although the intestinal wall distal to the obstruction maintains relatively normal function, the inability of luminal content to reach the unobstructed small bowel and colonic absorptive surface is an important component of overall dehydration.

## **Intestinal Motility**

In an attempt to propel intraluminal contents past the obstruction, intestinal contractile activity increases in the early phase of bowel obstruction, probably in large part related to the intestinal distention. Later in the course of the bowel obstruction, however, contractile activity decreases likely secondary to a relative hypoxia of the intestinal wall and enhanced intramural inflammation. Although the exact mechanisms have not been described adequately, these responses may be similar to the changes found early after an abdominal operation, again related to inflammation of the intestinal wall.<sup>12,13</sup> Some investigators<sup>14</sup> have suggested that the alterations in intestinal motility are secondary to a disruption of the normal autonomic parasympathetic (vagal) and sympathetic splanchnic innervation, while others relate these changes more to a local effect of inflammation of the intestinal wall.

Splanchnic innervation has been the focus of extensive research, and especially so in the pathogenesis of paralytic ileus. Chemical sympathectomy has been successful in ameliorating ileus in several experimental models. Other pharmacologic approaches have focused on blocking the neural inhibitory mechanisms affecting enteric neuromuscular coordination via sympatholytics and cholinergic agonists.<sup>15,16</sup> Still other experimental approaches have been designed to prevent or inhibit the inflammatory response that accompanies the “physiologic” response to celiotomy or the abnormal inflammatory response accompanying generalized ileus. More recent investigative attention has been directed to impaired intestinal motility in the face of opioid administration postoperatively.<sup>17</sup> The  $\mu$ -receptor antagonist alvimopan appears to inhibit opioid-induced intestinal impairment and enhance motility.

## **Circulatory Changes**

Bowel wall ischemia may occur through several mechanisms such as extrinsic compression of the mesenteric arcades by adhesions or an axial twist of the mesentery in a hernia defect. Alternatively, progressive distention in the presence of a closed-loop bowel obstruction without mesenteric axial torsion can cause vascular compromise or strangulation. Rarely, extensive mesenteric venous thrombosis leads to compromised arterial inflow and ischemia. During an obstruction, the large bowel obstruction is especially susceptible to vascular compromise and subsequent colonic distention because watershed areas of colonic perfusion represent end organ blood supply. Colonic ischemia is further exacerbated by bacterial proliferation and generation of luminal gas.

Progressive distention of the bowel lumen with a concomitant increase in intraluminal pressure results in increased transmural pressure on capillary blood flow within the bowel wall. The possibility of intestinal wall ischemia presents a real concern in a closed-loop small bowel obstruction, especially in large bowel obstruction when the ileocecal valve is competent and the distended colon cannot decompress retrograde into the small bowel. The resultant increase in intraluminal pressure may compromise blood flow by exceeding venous pressure. This scenario occurs most commonly in the ascending colon where the luminal diameter and resulting wall tension are the greatest. This pathophysiology increases the urgency of treatment response for large bowel obstruction since vascular compromise may occur quickly. This type of bowel wall ischemia may lead to further disruption of intestinal absorption, a relative increase in net secretion, an unregulated increase in mucosal permeability, and intramural production of reactive oxygen species by activated resident and recruited leukocytes. These reactive oxygen species cause peroxidation of the lipid components of the cellular membrane, release of cytokines and other inflammatory mediators, and permit systemic toxicity. With strangulation of the blood supply, blood loss is exacerbated by infarcted bowel, which, together with the preexistent fluid loss, leads to more hemodynamic instability.

## **Microbiology and Bacterial Translocation**

The resident and transient flora of the upper small intestine consists mainly of gram-positive, facultative, anaerobic organisms in small concentrations, usually less than  $10^6$  colonies/mL. The bacterial count increases distally to

about  $10^8$  colonies/mL in the distal ileum. In addition to this increase in number of bacteria, a change of flora to primarily coliform and anaerobic organisms is apparent. In the presence of obstruction, however, a rapid proliferation of bacteria occurs proximal to the point of obstruction, consisting predominantly of fecal-type organisms. The proliferation of this fecal flora, proportional to the duration of obstruction, reaches a plateau of  $10^9$  to  $10^{10}$  colonies/mL after 12 to 48 hours of an established obstruction. The bowel distal to the obstruction tends to maintain its usual bacterial flora until the onset of a generalized inflammatory-provoked ileus, resulting only then in bacterial proliferation distal to the point of obstruction. Bacterial toxins play an important role in the mucosal response to bowel obstruction. Experiments in germ-free dogs with mechanical bowel obstruction have shown that net intraluminal accumulation of fluid and electrolytes does not occur, and net absorption continues.

Experiments, primarily in rodents, have shown that bacterial translocation occurs secondary to impairment of the barrier function of the intestinal mucosa if bowel obstruction persists. The disruption of the mucosal barrier begins early after the onset of bowel obstruction. The cellular response to obstruction is multifactorial. In the enterocyte, the endoplasmic reticulum dilates as early as 4 hours after onset of bowel obstruction. Mitochondrial swelling, focal epithelial necrosis, intracellular ballooning, and degenerative changes in the nucleus of epithelial cells (apoptosis) have been demonstrated as early as 6 to 12 hours after the onset of obstruction in this experimental model.<sup>18</sup> The mucosal defense is compromised further by a decrease in perfusion of the intestinal wall. The loss of mucosal integrity allows luminal bacteria to both translocate as well as to invade the submucosa and enter the systemic circulation via the portal venous and lymphatic systems. Several bacterial substances can be retrieved from peritoneal fluid and lymphatic channels even in the absence of perforation. In the rodent model, bacteria can be cultured from the spleen, liver, and mesenteric lymph nodes, indicating a marked increase in bacterial translocation. Concomitant with bacterial translocation, lymph fluid contains numerous bacterial proteins and lipoproteins that further disrupt normal gut function.

The demonstration of bacterial translocation in these elegant studies with rodent models led to the erroneous assumption of the existence of a similar bacterial translocation in humans. Reproducible documentation of true bacterial translocation in man is notably lacking, and existence of a true

bacterial translocation seems unlikely. Several studies have unsuccessfully tried to document the presence of bacteria in intra-abdominal lymph nodes, spleen, liver, and even lymphatics. In contrast, more recent work has shown that lipopolysaccharide and other inflammatory vasoregulatory mediators, but not bacteria, can be recovered from the mesenteric lymphatics. The eventual drainage of these inflammatory substances into the systemic circulation may lead both to the systemic manifestations of sepsis and further disruption of the mucosal barrier function.

The change in the intraluminal bacteriology in simple intestinal obstruction is important clinically, because it markedly increases the risk of infectious complications, especially if an intestinal resection is required or if an inadvertent enterotomy occurs with intraperitoneal contaminated or highly inoculated, bacterial-laden enteric contents. In contrast, with irreversible strangulation obstruction, a myriad of local and systemic alterations, such as systemic entry of bacterial products, activation of immunocompetent cells, release of cytokines, and increased formation of reactive oxygen intermediate, can promote the systemic inflammatory response syndrome and progress to multiple organ dysfunction with all its consequences.

## ETIOLOGY

### Adhesions

*Adhesions* are inflammatory-derived, fibrous attachments of connective tissue that adhere to organ surfaces. Adhesions may be congenital or acquired through postinflammatory and/or postoperative processes. Congenital or inflammatory adhesions are less frequent causes of bowel obstruction than postoperative adhesions, except in certain circumstances such as rotational disorders (malrotation) or a persistent urachus. The leading cause of small bowel obstruction in Western societies is postoperative adhesions, which are responsible for 40% to 80% of bowel obstructions in hospitalized patients. This wide variation in incidence of adhesive obstruction varies with referral patterns, community practice settings, racial cultures, and regional preferences.

Adhesion formation is nearly universal after celiotomy and starts within hours of an intra-abdominal operation, since the inflammatory phase is the

first requirement for adhesion development.<sup>19</sup> While the exact pathogenesis of adhesion formation remains incompletely understood, experts agree that adhesion formation is a surface event associated with peritoneal injury. This inciting trauma triggers a local inflammatory response leading to activation of the complement and coagulation cascades along with exudation of fibrinogen-rich fluid; the full establishment of this fibrinous inflammatory response is present 5 to 7 days after the trauma of a celiotomy.<sup>20</sup> Recent findings have identified the presence of sensory nerve fibers in human peritoneal adhesions, suggesting that these structures may be capable of conducting pain or other neural responses.<sup>21</sup>

Peritoneal healing (mesothelialization) appears to differ from the response in skin, where re-epithelialization occurs from the periphery inward. In the peritoneum, operative or traumatic defects are reperitonealized by implantation of mesothelial cells in multiple areas of the defect. This mesothelialization takes place quite rapidly, and resurfacing is often complete by 2 to 5 days after the injury, depending on local conditions.<sup>22</sup>

Normal peritoneal healing, however, is a complex, interrelated, programmed inflammatory process. The initial response involves infiltration of the wound area with polymorphonuclear leukocytes and lymphocytes. During the ensuing 24 to 36 hours, circulating and local macrophages are recruited by various chemokines. By 48 hours, a fibrin scaffold overlying the defect has been established, covered by macrophages and a few mesothelial cells. These mesothelial cells then coalesce to fully cover the defect over the next 2 to 5 days. Fibroblasts and other mesenchymal cells populate the underlying fibrin scaffold and begin to lay down a basement membrane. By 8 to 10 days, a single layer of mesothelial cells resting on a continuous basement membrane has been established, and the underlying reactive matrix and inflammatory cells regress. This process describes the simple resurfacing of an uncomplicated peritoneal defect.

In comparison to the previously described physiologic process of normal peritoneal healing, adhesion formation is a pathologic process. Studies suggest that adhesions form in response to the initial fibrin gel matrix in response to the local, inflammatory microenvironment. This fibrin gel matrix consists of numerous types of cells, including the initial leukocytes, but also other humorally active cells such as platelets, mast cells, and erythrocytes, in conjunction with surgical debris, nonviable tissue, foreign bodies, and

possibly bacteria. The resultant spectrum of fibro-inflammatory changes between physiologic mesothelial healing versus pathologic adhesion formation varies not only among individuals but is dependent also on many other conditions, such as inflammation, infection, devitalized tissue, and foreign bodies.

If the fibrin gel allows apposition of adjacent surfaces, a band or bridge may form (ie, an adhesion). This process of adhesion formation is dynamic, consisting predominantly of macrophages early, but by 2 to 4 days, larger strands of fibrin begin to appear along with fibroblasts. By 5 days, distinct bundles of collagen are apparent, and the fibroblasts begin to form a syncytium within the matrix. These cells predominate thereafter, and eventually the fibrin matrix and cellular elements are replaced by a vascularized, granulation-type tissue containing macrophages, fibroblasts, giant cells, and a rich vascular supply. Eventually, the surface of the adhesions are covered by a mesothelial layer, but only after formation of the underlying fibrous scar leading to surface opposition and transperitoneal fibroinflammatory bands of varying severity and extent.

An important factor in the spectrum of adhesion formation that contributes to the risk of future adhesive bowel obstruction is the type of surgical procedure performed. Operations involving structures in the inframesocolic compartment and those in the pelvic region such as colonic, rectal, and gynecologic procedures impart the highest risk. Open procedures, use of gloves containing starch granules, gallstone spillage during cholecystectomy, and separate peritoneal closure were also correlated with adhesive SBO in a review article.<sup>10</sup> Adhesive bowel obstruction may occur at any time postoperatively after a celiotomy, with reports ranging as early as within the first postoperative month to more than eight decades after the index operation. A study by Menzies and Ellis<sup>23</sup> found that about 20% of adhesive bowel obstructions occur within 30 days after the initial celiotomy, about 20% occur between 1 and 12 months postoperatively, another 20% tend to occur between 1 and 5 years postoperatively, with the remainder (~40%) occurring after 5 years. A Norwegian study of patients requiring an operation for adhesive bowel obstruction found that most episodes of recurrent bowel obstruction occurred within 5 years after the previous episode, but the risk of bowel obstruction persisted for more than 20 years after a prior episode, reaching an incidence as great as 29% at 25 years.<sup>24</sup> Therefore, a common predisposition to adhesive obstruction is the presence of a prior episode of

adhesive obstruction. Numerous surgical attempts to decrease or prevent the development of postoperative adhesions have been reported and are discussed subsequently. The literature on pharmacologic prophylaxis against postoperative adhesion formation is extensive and riddled with numerous false claims of benefit. Suffice it to say that no reliable or truly effective pharmacologic agent has been developed to augment mesothelialization and prevent adhesion formation. Several proprietary barrier products of variable efficacy have been developed and will be discussed.

## **Hernia**

Hernias are the second most common cause of bowel obstruction in most reported series. Inguinal hernias and hernias acquired postoperatively most frequently lead to intestinal obstruction, but congenital abdominal wall or internal hernias may on occasion cause a bowel obstruction by incarcerating intestinal contents. Hernias as an etiology are more common in males than in females, primarily because of the predominance of inguinal hernias in men. In contrast, incarcerated femoral or obturator hernias are more common in women.

Approximately 5% of external hernias will require emergency operation if they are not repaired electively. These hernias are usually incisional hernias, umbilical hernias, and indirect inguinal or femoral hernias. Inguinal hernias rarely incarcerate, which has changed their management from repair of all inguinal hernias to a watchful waiting approach in the asymptomatic or minimally symptomatic patient.<sup>25</sup> The presence of acute incarceration should prompt emergent operative management, because 10% to 15% of incarcerated hernias contain necrotic bowel at exploration (Figs 38-1 and 38-2). Chronically incarcerated hernias can develop strangulation, but most chronically incarcerated hernias can be managed electively.

**FIGURE 38-1** Gangrenous bowel from an irreversible, strangulated, incarcerated inguinal hernia.

**FIGURE 38-2** Umbilical hernia. Operative en bloc resection of hernia sac, umbilical skin, and irreversible strangulation obstruction.

## **Internal Hernia after Laparoscopic Gastric Bypass**

Minimally invasive surgery has brought new etiologies of intestinal obstruction. The reported incidence of internal hernia after laparoscopic

intestinal surgery, and especially after Roux-en-Y gastric bypass (RYGB), is 0.2% to 3%, a significantly increased incidence compared with the open approach.<sup>26,27</sup> Factors contributing to the increased risk of internal hernia after a laparoscopic approach include lack of adhesion formation, increased small bowel mobility, marked weight loss–induced increased mesenteric openings, and failure to close all mesenteric defects appropriately. There are two or three mesenteric defects created during laparoscopic RYGB, depending on whether the retrocolic or antecolic technique is used<sup>28</sup> (Fig. 38-3). Petersen’s defect or space is the best-known site of herniation and can arise with either an antecolic or retrocolic position of the alimentary limb.<sup>29</sup> It is named after Petersen, who in 1900 described two cases of internal herniation posterior to a loop gastrojejunostomy.<sup>30</sup> Internal hernias are often difficult to diagnose; indeed, patients with internal hernias present often with nonspecific or intermittent symptoms (periumbilical pain, nausea, vomiting, anorexia, abdominal distention). Spontaneous reduction in the hernia can occur, and CT, upper GI contrast series, and plain abdominal films may be nondiagnostic.<sup>28</sup> Symptoms of intermittent bowel obstruction after laparoscopic gastric bypass should raise suspicion for the presence of an internal hernia, especially after weight loss. The best measure to prevent these hernias is the meticulous closure of the created mesenteric defects, and suspicion of an internal hernia may itself be appropriate justification for operative exploration, especially via a diagnostic laparoscopy.

**FIGURE 38-3** Internal hernia defects after Roux-en-Y gastric bypass (RYGB). **A.** Retrocolic RYGB; **B.** Antecolic RYGB. R, Roux limb; ST, stomach. Mesenteric defect at enteroenterostomy (*solid arrows*), transverse mesocolic defect (*open arrow*), and Peterson's hernia posterior to Roux limb mesentery (*dashed arrows*).

## Trocar Site Hernia

The reported incidence of trocar site herniation is 0.2% to 3%; the true long-term incidence, however, might even be greater.<sup>31</sup> Trocar site hernias are observed rarely with 5-mm trocars but more frequently with the use of 10-mm, 12-mm, or bigger trocars and especially with the “cutting” or bladed trocars. Closure of the fascial defect and the use of noncutting, radial expanding trocars are recommended to decrease the risk for formation of trocar site hernias.<sup>31–33</sup> Trocar site hernias can lead to small bowel obstruction early or late after a minimal access, intra-abdominal procedure.

Following a laparoscopic procedure, patient complaints of pain in the region of a trocar site, nausea, or vomiting should lead to investigation for a bowel obstruction. In these cases, the bowel obstruction may be partial or complete. Commonly, the antimesenteric portion of the bowel wall will be incarcerated in the small fascial defect, resulting in a partial obstruction. These hernias are dangerous, because they may result in strangulation and necrosis in the absence of intestinal obstruction. Reduction of necrotic bowel during hernia repair can result in missed perforation and peritonitis. Although trocar-associated hernias are rare, with the widespread use of laparoscopy, they have become a well-known complication.

## **Malignant Bowel Obstruction**

Primary intra-abdominal neoplasms are a common cause of both large and small bowel obstruction. Colorectal, gastric, small bowel, and ovarian neoplasms are the most frequent causes of malignant bowel obstruction, either from the primary lesion (colon and small bowel neoplasms) or from peritoneal metastases (ovarian, colonic, and gastric neoplasms). In many of these patients, bowel obstruction is associated with a high rate of recurrence and morbidity, and may often be a terminal event.

Metastatic cancer can also cause bowel obstruction, usually small bowel obstruction. The most common form of obstructing metastatic lesion is peritoneal carcinomatosis related to one of the aforementioned primary, intra-abdominal malignancies, but localized hematogenous metastases to the wall of the small intestine from melanoma and carcinoma of the breast, kidney, or lung can also cause intraperitoneal metastases that can obstruct the bowel (Fig. 38-4).

**FIGURE 38-4** Renal cell carcinoma metastatic to small intestine.

## **Crohn's Disease**

Crohn's disease is a chronic, transmural, inflammatory ailment of the gastrointestinal tract that may affect any part of the alimentary tract from the mouth to the anus. Despite often intense involvement of the bowel wall, Crohn's disease is responsible for fewer than 5% of cases of small bowel obstruction. When true mechanical obstruction is present, the cause is usually secondary to the inflammatory process or to chronic stricture formation.

Other granulomatous diseases causing obstruction, such as tuberculosis and actinomycosis, are much less common in Western countries, but in the developing world where acquired immune deficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infection are endemic, intra-abdominal tuberculosis must be entertained in the diagnosis of intestinal obstruction.

## **Intussusception**

Intussusception is a relatively frequent cause of bowel obstruction in infancy, but it accounts for only 2% of bowel obstruction in the adult population.<sup>34</sup>

The median age of presentation in adults with intussusception is the sixth to seventh decade. The etiology of intussusception differs greatly between adult

and pediatric patients. In the vast majority of adult intussusceptions, there is a demonstrable inflammatory lesion or a neoplasm that serves as the lead point of the intussusception; however, up to 20% of adult cases are idiopathic.<sup>35</sup> Neoplasms causing intussusception in adults are malignant in almost 50% of patients. Although rare in the Western Hemisphere, intussusception is one of the most common causes of bowel obstruction in central Africa, for reasons not yet fully explained.

## Volvulus

Volvulus represents an axial twist of the bowel and its mesentery. This entity is an infrequent cause of small or large bowel obstruction in the Western Hemisphere (Figs 38-5 and 38-6). Volvulus is encountered more frequently in the geriatric population, in individuals with a long history of constipation, or in institutionalized, neurologically impaired, or psychiatric patients. Colonic volvulus comprises about 1% to 4% of all bowel obstructions and about 10% to 15% of all large bowel obstructions. The volvulated segment must be mobile to allow the degree of freedom necessary to permit an axial twist of the mesentery. The affected segment has either an especially long, narrow mesentery (eg, malrotation or cecal volvulus) and/or a lack of bowel wall fixation (floppy cecum syndrome).

**FIGURE 38-5** Sigmoid volvulus. **A.** Supine abdominal radiograph showing

the dilated, volvulated segment of redundant sigmoid colon pointing toward the right upper quadrant; *arrows* show the space between the sigmoid and hepatic and splenic flexures. **B.** Contrast enema in sigmoid volvulus showing cutoff at distal site of volvulated sigmoid having a “bird-beak” appearance.

**FIGURE 38-6** Cecal volvulus. Dilated volvulated cecum pointing to left upper quadrant. *Arrows* indicate the cecal tip.

Overall, sigmoid volvulus accounts for 75% of all patients with volvulus. In contrast, cecal volvulus is responsible for the majority of the remaining 25% of bowel volvulus incidences in the United States and is the most common cause of large bowel obstruction in pregnancy. The “cecal bascule” is a unique, though less common, form of cecal volvulus that occurs when the true anatomic cecum (ie, the part of the ascending colon that lies caudal to the

entrance of the ileocecal valve) folds anteriorly over onto the ascending colon, obstructing the lumen. This form of cecal volvulus may be intermittent and recurrent, and is especially difficult to diagnose.

Primary volvulus of the small intestine is extremely rare in the United States but is quite prevalent in central Africa, India, and the Middle East. Speculation about etiology has been related to abrupt dietary changes that occur during the religious holiday when the people celebrating Ramadan fast during the day and then consume a large meal after dark. Some investigators, however, maintain that this racial group has an exceedingly long, floppy small bowel mesentery that permits generous mobility of the small bowel.

## **Other Causes**

Numerous other causes of bowel obstruction exist, but these are so uncommon that we list them in [Table 38-1](#) for completeness but will not discuss them further other than to highlight two unique causes—radiation changes and radiation enteropathy—with images ([Figs 38-7](#) and [38-8](#)).

**FIGURE 38-7** Radiation changes in distal colon/rectum (*arrows*).

**FIGURE 38-8** Radiation enteropathy. Note the narrowed segments of ileum with much thickened bowel walls (separation between adjacent loops).

## **DIAGNOSIS**

The diagnosis of bowel obstruction is highly suspected clinically based on careful history-taking and physical examination, and it may be confirmed by imaging, such as abdominal radiography or CT. The etiology of the obstruction can often be determined by astute history-taking complemented with physical examination and imaging studies.

## **History and Physical Examination**

The classic clinical picture of a patient suffering from bowel obstruction includes intermittent crampy abdominal pain, distention, acute obstipation, nausea, and vomiting. Abdominal pain and then distention usually precede the appearance of nausea and vomiting by several hours. The more proximal the obstruction, the earlier and more prominent are the symptoms of nausea and vomiting, while distension is usually less prominent. Conversely, the more distal the obstruction, the more prominent the abdominal distention. Vomiting is relatively uncommon in colonic obstruction until its later stages. The abrupt onset of symptoms makes an acute obstructive cause more likely and may herald the presence of a closed-loop obstruction.

The location and character of pain may be helpful in differentiating mechanical bowel obstruction from ileus. Ileus tends to have a more diffuse and mild pain, often without waves of colic, while mechanical bowel obstruction usually presents as severe, truly colicky pain. Recurrent paroxysms occurring in short (10-30 seconds) crescendo-decrescendo episodes is often associated with mechanical small bowel obstruction, while in mechanical large bowel obstruction episodes are usually spaced farther apart and tend to last longer (1-2 minutes). Pain is usually described as visceral and poorly localized. Classically, the presence of constant or localized pain has been regarded as a sign of strangulation. Several studies, however, have shown that these findings are neither sensitive nor specific for the detection of strangulation.

Obtaining a complete medical history is of paramount importance to make the diagnosis and determine the etiology. The fundamentals of history-taking, including the type and location of pain, the temporal association of symptoms, associated symptoms, and aggravating and alleviating factors, are all important components in obtaining a thorough history. The past medical history may also be critical in both making the diagnosis and establishing the cause of bowel obstruction. It is especially important to inquire about previous episodes of bowel obstruction, recent and distant abdominal operations, current medications, a history of chronic constipation, recent changes in the caliber of stools, and a history of cancer including its stage at presentation and related treatments (operative therapy, chemotherapy, or radiation therapy). Other causes of chronic intestinal obstruction such as Crohn's disease or other intra-abdominal inflammatory processes should be discussed.

A thorough physical examination is mandatory and should include

assessment of vital signs and hydration status as part of the initial resuscitation. Tachycardia, hypotension, and oliguria are signs of advanced dehydration that mandate aggressive resuscitation. Fever may be associated with an infectious cause or with strangulation. Thereafter, the exam should proceed with abdominal inspection, auscultation, percussion, and palpation. It is important to look closely for potential hernia defects and previous surgical incisions, including inguinal incisions for previous herniorrhaphies. Differential diagnosis should also include the possibility of internal hernias or those “external” hernias not necessarily associated with an obvious bulge, such as obturator, femoral, or intramural Spigelian hernias.

Auscultation can determine the presence, frequency, and quality of the “obstructed” bowel sounds. Bowel obstruction may have the metallic tinkling sounds of “water dripping into a large hollow container,” indicative of dilated bowel with an air–fluid interface. Functional obstruction (ileus) may present with an absence of bowel sounds. Mechanical bowel obstruction presents with an increase in the frequency of bowel sounds, but more specifically the high-pitched “rushes” and “groans” followed by the metallic tinkling sounds. In both mechanical and functional bowel obstruction, a succussion splash may be heard in the presence of a dilated stomach or markedly dilated small bowel filled with an air–fluid interface. The presence of a succussion splash is not normal in a patient who has not eaten or ingested liquids in the previous 1 to 2 hours and should be regarded as an important, abnormal, and often underappreciated sign of bowel obstruction.

Abdominal palpation should reveal the presence of peritoneal signs, such as rebound, localized tenderness, and involuntary guarding that herald vascular compromise or perforation. The presence of these findings is suggestive of the need for an emergent operation. Abdominal masses should be sought and noted. A meticulous search for hernia defects, especially inguinal and femoral hernias, is essential, because they can easily be overlooked. Rectal examination is required to rule out fecal impaction or locate a low-lying rectal cancer as a cause of obstruction.

## **Laboratory**

Laboratory tests are essential in patients with bowel obstruction because they may aid in the diagnosis, and more importantly, any underlying metabolic defects should be corrected prior to operative therapy. While no laboratory

test is sensitive and specific enough to diagnose mesenteric ischemia reliably, a spectrum of laboratory tests may be helpful in determining the condition of the patient and should guide resuscitation. A complete blood cell count and differential, electrolyte panel, blood urea nitrogen, creatinine, and urinalysis should be obtained to evaluate fluid and electrolyte imbalance and to assess the possibility of sepsis. Arterial blood pH, serum lactate concentrations, and amylase and lactic dehydrogenase activity may be useful tests in the evaluation of bowel obstruction, especially when trying to exclude the presence of strangulation or underlying bowel necrosis. An increase in serum lactate concentrations should raise the suspicion of intestinal ischemia; however, it is often a late finding.<sup>36,37</sup> D-dimer was proposed as an early marker of acute mesenteric ischemia, but it appears to be insensitive.<sup>38,39</sup> Intestinal fatty acid-binding protein (I-FABP) is a highly sensitive marker for extensive mesenteric infarction; however, it does not appear to be sensitive enough to detect more limited intestinal ischemia in strangulated bowel.<sup>40,41</sup> Some authors have suggested that serum concentrations of phosphate and isoforms of creatine phosphokinase (isoform B),<sup>42,43</sup> plasma level of ischemia-modified albumin,<sup>44</sup> gut luminal tyrosine concentrations,<sup>45</sup> and  $\alpha$ -glutathione S transferase ( $\alpha$ -GST)<sup>46</sup> may identify the presence of intestinal cell necrosis. However, the specificity and especially the sensitivity are not accurate enough to base a management decision solely on these parameters.

## **Radiologic Findings**

The management of small bowel obstruction remains heavily reliant on excellent clinical acumen and appropriate imaging. The clinician is faced with answering the critical questions, “is this complete obstruction,” and “is the intestine ischemic?” The literature is replete with clinical studies examining the prognostic value of various forms of imaging in terms of predicting the need for operative management or the presence of intestinal ischemia.<sup>47</sup> Most of these series have investigated the role of CT, and we will highlight these findings.

### **FLAT AND UPRIGHT ABDOMINAL RADIOGRAPHS**

Plain radiographs, including a chest x-ray and flat and upright films of the

abdomen, remain a valuable initial imaging modality in patients with clinical small bowel obstruction. An initial chest x-ray may reveal extra-abdominal processes such as pneumonia that could be associated with an ileus rather than bowel obstruction. In addition, the presence of free air from a perforated viscus may indicate a diagnosis other than small bowel obstruction or a serious complication of small bowel obstruction requiring emergent treatment.

Flat and upright films of the abdomen in patients with a small bowel obstruction characteristically have multiple air–fluid levels in dilated loops of bowel and a paucity of gas in the distal (decompressed) small bowel and colon (Fig. 38-9). The location of the obstruction in the proximal or distal small intestine, however, greatly influences the findings on the plain abdominal films. A very proximal small bowel obstruction may be associated with films that demonstrate few, if any, air–fluid levels, with a relatively small gastric air–fluid level resulting from a fluid-filled stomach. Conversely, a distal small bowel obstruction will likely have multiple air–fluid levels with dilated loops of small bowel stacked on one another (Figs 38-10 and 38-11). Similarly, the pattern of bowel gas may assist in determining whether the obstruction represents a small or large bowel process. On a plain abdominal film, the small bowel lies centrally, and intestinal markings from the valvulae conniventes or plicae circularis encompass the entire diameter of the bowel, whereas the large bowel lies at the periphery of the abdomen, and haustral markings only partially cross the bowel. Furthermore, the appearance of the bowel gas may also give a clue as to the duration of the obstruction. So-called “fecalization” of the small bowel content, whereby the luminal content shows less of an air–fluid level and more of an appearance of semisolid content with pockets of gas, suggests a more chronic obstruction and may be helpful in supporting the need for operative intervention, not because of worry of strangulation but rather a chronic, established, non-resolving process.

**FIGURE 38-9** Supine abdominal radiograph showing an incomplete small intestinal obstruction. Note the dilated loops of small bowel.

A

B

**FIGURE 38-10** Complete small bowel obstruction. **A.** Supine abdominal radiograph shows multiple loops of dilated small bowel with colonic gas. **B.** Upright radiograph shows multiple air–fluid levels in the small intestine (*arrows*).

**FIGURE 38-11** Small bowel obstruction with fluid-filled loops of small bowel in left lower quadrant (*arrows*).

Rarely, a plain film of the abdomen will contain a pathognomonic sign of intestinal obstruction from gallstone ileus (a misnomer because it is a true mechanical obstruction), as is the case with pneumobilia in a patient with gallstones and no history of biliary instrumentation. Importantly, plain films of the abdomen are notoriously poor indicators of bowel involved with vascular compromise unless the devastating signs of portal venous gas and intestinal pneumatosis are evident. Closed-loop bowel obstructions are also difficult to diagnose on plain x-rays, because the involved bowel with a

proximal and distal occlusion may be fluid-filled and lack any gas. Thus, additional imaging procedures should be obtained in patients with any suspicion of compromised bowel.

## **CONTRAST STUDIES**

Though contrast studies using either dilute barium or hyperosmotic, water-soluble contrast of the small and large bowel have been an integral component of the diagnostic evaluation, enthusiasm for these studies has waned substantially. The radiologic literature and various guidelines developed by the radiologic community support strongly the use of contrast-enhanced CT as the diagnostic imaging modality of choice.<sup>48</sup> Nonetheless, in specific clinical situations, such as in a patient with an obstructing sigmoid or rectal tumor, a radiograph with rectally administered contrast may provide diagnostic information that is timely, economical, and clinically important (Fig. 38-12). On occasion, a small bowel follow-through series may be helpful in distinguishing between mucosal inflammation and extraluminal compromise from adhesions as the etiology of bowel obstruction in a patient with Crohn's disease. This diagnostic information may alter the therapeutic approach, but generally small bowel followthrough studies have little if any advantage over CT.

**FIGURE 38-12** Barium enema showing complete large bowel obstruction in the ascending colon.

When contrast agents are utilized, the risks of each agent must be considered carefully. The primary side effects of barium include inspissation in the obstructed large bowel. Also, barium results in severe intraperitoneal infection/barium peritonitis when extravasated in the face of small intestinal perforation. Gastrografin, if aspirated, can cause a severe pneumonitis; moreover, this contrast agent becomes diluted rapidly with an established

small bowel obstruction, and thereby yields little information in a distal small bowel obstruction. Finally, most surgeons agree that contrast studies are contraindicated in patients with a clear diagnosis of complete bowel obstruction and when strangulation or perforation is suspected.

## **COMPUTED TOMOGRAPHY**

In many centers, computed tomography (CT) has become the primary diagnostic imaging modality for the diagnosis of suspected intestinal obstruction, and in fact in some institutions it has replaced plain radiographs as the initial imaging test. The increased use of CT reflects the preference of clinicians for the additional diagnostic information garnered from this examination. CT not only provides information about the presence or absence of a luminal obstruction, but it can also define both the site of obstruction and the existence of extraluminal processes, a small bowel transition point, associated inflammation, fluid collections, masses, abdominal wall or internal hernias, and free intraperitoneal fluid. Further, CT can expedite the diagnosis of strangulation obstruction if findings including mesenteric edema, free peritoneal fluid, intestinal wall thickness, and the absence of fecalization of the small bowel content are present.<sup>47</sup>

Early detection of bowel ischemia is paramount to successful surgical management of obstruction. Several studies have reported a diagnostic accuracy of greater than 90% with the use of CT in intestinal obstruction.<sup>49-51</sup> Other work has attempted to identify radiographic characteristics that accurately detect ischemia. The presence of two or more beak signs, a whirl sign, a C- or U-shaped appearance of the bowel loop, and a high degree of obstruction were associated with nonsurgical treatment failure.<sup>52</sup> Among studies utilizing IV contrast, reduced bowel wall enhancement had a 95% specificity in determining ischemia, and absence of mesenteric fluid had an 89% sensitivity in ruling out strangulation.<sup>53</sup> O'Daly and colleagues found the association of peritoneal fluid with small bowel obstruction to be a strong predictor for the need for operative treatment.<sup>54</sup> In settings where iodinated contrast is contraindicated, the finding of increased bowel-wall attenuation on unenhanced images is concerning for bowel ischemia, with a 100% specificity and 56% sensitivity.<sup>55</sup>

Further reports evaluating the capability of CT to predict ischemia or strangulation have produced contradictory results. In a systematic review,

Mallo et al. found that the sensitivity, specificity, positive predictive value, and negative predictive value of CT for predicting ischemia were 83%, 92%, 79%, and 93%, respectively.<sup>56</sup> Conversely, Sheedy et al. noted that with CT, sensitivity was 15% and specificity 94% for identifying bowel ischemia prospectively in patients with small bowel obstruction.<sup>57</sup> A recent study by Zielinski et al. suggested that CT findings of free peritoneal fluid, thickened bowel, and mesenteric edema, combined with vomiting, were predictive of the need for eventual operative management, but though relatively sensitive for ischemia, CT was not very specific.<sup>47</sup>

Some studies suggest that a CT scoring system may accurately predict the need for operative intervention. Jones et al. found that a scoring system with the criteria of a dilated small bowel, identification of a transition point, ascites, complete obstruction, partial obstruction, evidence of a closed-loop obstruction, and/or free air predicted the need for operative treatment in 75% of patients.<sup>58</sup> It is important to remember that CT is better at identifying rather than excluding the presence of ischemia.

Although the increased use of CT in patients with bowel obstruction has provided greater diagnostic information, caution must be exercised in the use of this modality in distinguishing mechanical small bowel obstruction versus ileus. In one study, up to 20% of patients with a CT diagnosis of ileus required operative intervention eventually.<sup>59</sup> Overall, the current preference for the use of CT is associated with an increased likelihood of operative intervention and decreased mortality; however, whether these associations are causal or coincidental remains unknown.<sup>60</sup>

## **ULTRASONOGRAPHY**

Ultrasonography (US) is used infrequently in the diagnosis of intestinal obstruction. Features concerning for strangulated bowel include akinetic bowel loops, hyperechoic and thickened mesentery, and presence of peritoneal fluid.<sup>61</sup> Even though the reported specificity is 82%, sensitivity is 95%, and overall accuracy is 81%, this modality is highly operator-dependent, and the results are unlikely to be reproduced consistently in many institutions. US has been reported to be useful for the early recognition of strangulation obstruction in several Japanese and European studies<sup>62,63</sup>; however, in the absence of an experienced ultrasonographer, the reliability of

US remains questionable. Furthermore, US is difficult to perform in obese patients, and extensive bowel gas may obscure the pattern of intestinal obstruction.

## **MAGNETIC RESONANCE ENTEROGRAPHY**

Magnetic resonance enterography (MRE) has not been utilized as frequently as CT, because performance of this examination is more time consuming and requires substantial expertise in interpretation. In addition, in general practice MRE does not have a greater diagnostic accuracy than CT. In contrast, in centers that use MRE frequently, diagnostic accuracy exceeding 90% is achievable.<sup>64,65</sup> MRE may have an advantage of distinguishing benign from malignant bowel strictures in patients with suspected malignant bowel obstruction.<sup>66</sup>

## **VIDEO CAPSULE ENDOSCOPY**

Video capsule endoscopy (VCE) may be a valuable diagnostic tool in patients with subacute or chronic intestinal obstruction where other imaging techniques have not revealed an etiology. VCE is particularly helpful in patients with obstruction related to a stricture caused by inflammation or malignancy.<sup>67</sup> Overall, VCE may provide a diagnosis in nearly 40% of previously undiagnosed patients.<sup>68</sup> A major concern with the use of VCE, however, is retention or impaction of the capsule either at a stricture or in any area of severe kinking related to adhesions in a patient who otherwise may have resolution of the obstruction without an operation. The incidence of this circumstance appears infrequent, but impaction may require celiotomy.

## **Detection of Ischemia**

Identification of strangulation obstruction caused by ischemia of the intestine is a critical diagnosis, because the mortality associated with strangulated bowel obstruction is 9% to 40% compared to less than 5% in nonstrangulated intestinal obstruction.<sup>69</sup> Unfortunately, clinical and imaging parameters claimed to permit early detection and operative intervention remain unreliable, and in fact do not lead to early diagnosis. As mentioned previously, studies examining the efficacy of CT for diagnosis of

strangulation obstruction have yielded mixed results in the determination of intestinal ischemia. Jancelewicz et al. found that decreased bowel wall enhancement on CT, leukocytosis, and peritoneal signs were the only independent predictors of strangulated obstruction on a multiple logistic regression analysis.<sup>69</sup> Historically, acidosis, increased serum amylase activity, and increased serum lactate concentrations were also claimed to be indicators of strangulation. While abnormalities of these parameters may prove to be sensitive markers of strangulation, they generally lack specificity and do not offer useful positive or negative predictive value. Abdominal US and pulsed-Doppler US have been reported to be useful in identifying patients with strangulation. Ogata and associates reported that an akinetic, dilated loop of bowel observed on real-time US had a high sensitivity (90%) and specificity (93%) for the recognition of strangulation; the positive predictive value was 73%. The presence of free peritoneal fluid seen on US was also sensitive for strangulation.<sup>70</sup> Given the conflicting evidence, the importance of integrating physical exam, imaging, and other clinical parameters (eg, worsening acidosis) when assessing a patient with bowel obstruction cannot be overemphasized.

## MANAGEMENT

The initial management of patients with small bowel obstruction should focus on aggressive fluid resuscitation and nasogastric decompression of the stomach to prevent further accumulation of intestinal fluid and air. In addition, nasogastric decompression decreases the potential for aspiration and relieves vomiting. These therapies should be instituted in all patients, whether they are treated operatively or undergo a trial of nonoperative management. Blood should be analyzed for serum electrolyte concentrations, complete blood count, lactate concentration, typed and screened for potential transfusion, and when necessary, arterial blood gases should be analyzed as well.

The most important initial step in management is crystalloid fluid resuscitation that aims to replete fluid losses. Patients with small bowel obstruction often present with profound volume depletion and may require several liters of isotonic crystalloid solutions, such as normal saline (0.9% NaCl) or lactated Ringer solution with additional potassium as urine output is

restored. Resuscitation should be guided by urine output, provided the patient is hemodynamically stable and has normal renal function. Patients who are hemodynamically unstable or have impaired cardiac, pulmonary, or renal function may require monitoring of central venous pressure to better evaluate their volume status. Colloid solutions, such as 5% albumin or hetastarch, have little or no role in the resuscitation of patients with a small bowel obstruction. Proper fluid resuscitation includes correction of metabolic or electrolyte imbalances, which may be severe. Specifically, in patients who have experienced prolonged vomiting, potassium and chloride should be measured to diagnose hypokalemic, hypochloremic alkalosis and replacement therapy started after resuscitation with normal saline. Though potassium replacement is a critical component of therapy, replenishment of this electrolyte should begin only after renal function has been established by good urine output. Volume resuscitation, electrolyte replacement, and establishment of adequate urine output are critical before operative therapy is undertaken. Broad-spectrum antibiotics should be given to patients within an hour of the incision as prophylaxis against surgical site infection, but otherwise, antibiotics have no defined role postoperatively or in patients managed nonoperatively.

Most surgeons believe that nasogastric decompression is important to prevent further intestinal distention from swallowed air and to limit a broad transit of gastric contents. In addition, nasogastric decompression helps to prevent aspiration during vomiting and on induction of general anesthesia. Symptomatically, gastric decompression helps relieve abdominal distension and can improve respiratory function in patients with respiratory compromise.

Historically, long intestinal tubes placed distal to the pylorus were used to relieve small intestinal distention under the assumption that intestinal decompression may be therapeutic if related to adhesions, because the decompressed bowel may detort and thereby relieve the mechanical obstruction (Fig. 38-13). Success rates of up to 90% have been reported in some series of patients treated with a long nasointestinal tube.<sup>71</sup> In contrast, however, most prospective and retrospective studies have failed to demonstrate the superiority of nasointestinal versus nasogastric intubation,<sup>71,72</sup> making the added expense of fluoroscopic or endoscopic placement of a nasointestinal tube unwarranted. Use of these long intestinal tubes has fallen out of favor, and they are of historic interest only in the

preoperative treatment of small bowel obstruction.

**FIGURE 38-13** Abdominal radiograph showing distal passage of a long nasointestinal decompression tube into the small bowel distal to the ligament of Treitz.

## Nonoperative Management

Nonoperative management of intestinal obstruction should be considered only in patients with uncomplicated intestinal obstruction in the absence of peritonitis, a progressive leukocytosis, or impaired bowel wall perfusion on imaging. When indicated, this approach is reported to be successful in 62% to 85% of patients.<sup>73-76</sup> The rate of success of nonoperative management is influenced by patient selection, type of bowel obstruction (complete vs partial), etiology (eg, adhesions, hernia, or neoplasm), and the surgeon's threshold for conversion to operative management. Patients successfully managed nonoperatively require fewer hospital days<sup>73,74</sup> and avoid the morbidity or convalescence necessitated by an operation. Few studies have compared the long-term outcomes of patients with a small bowel obstruction treated nonoperatively versus operatively. One such study with over 4 years of follow-up reported by Landercasper and colleagues<sup>77</sup> found a recurrence rate of 29% in patients managed operatively versus a recurrence rate of 53% for patients managed nonoperatively. Even though the recurrence rates may be greater with nonoperative management, the authors point out that about half of the patients managed nonoperatively never developed a recurrent small bowel obstruction.

A study by Rocha et al.<sup>78</sup> used the radiologist definition of "high-grade" obstruction and reported that in these patients, comparing those treated conservatively versus those treated by operation, the conservatively treated patients had a significantly greater readmission rate at 5 years (24% vs 9%) than those treated operatively. Use of this radiologic finding may potentially extend the "indication" when criteria are met for high grade but not complete obstruction.

When patients with a small bowel obstruction are initially managed nonoperatively, vigilant attention must be paid to volume resuscitation, electrolyte homeostasis, and nasogastric decompression. Patients managed nonoperatively require the same aggressive resuscitation and replacement of daily losses with an appropriate crystalloid solution and electrolyte replacement as patients who are managed operatively. Fluid replacement should take into consideration the volume and electrolyte loss in the output of the nasogastric tube, urinary output, and insensible losses. Electrolytes should be monitored frequently and corrected as necessary. Delayed correction of

potassium and magnesium concentrations may lead to delayed return of bowel function and misdiagnosis of obstruction versus ileus.

Adequate proximal decompression is important to allow the bowel an opportunity to decompress. This concept is accomplished by maintaining a functioning nasogastric tube. If the patient becomes progressively more distended or develops vomiting, tube placement should be evaluated and tube function confirmed by bedside evaluation. Standard nasogastric tubes should be inserted, such that the second of four marks is evident at the tip of the nares. The first mark is 40 cm from the tip of the tube—that is, the normal distance from the nares to the esophagogastric junction. Thus, if all four marks are outside the nares, the tube most likely is not in the stomach. Likewise, if no marks are visible, the tube is coiled within the stomach or is in the duodenum. On occasion, an abdominal radiograph is necessary to confirm placement. If the tube is noted on a radiograph to be out of position, it should be repositioned and imaged again for proper placement. On evaluation, the tube should be connected to the suction apparatus, sumping properly (if the tube has a sump port), and should be checked for patency by flushing and aspirating water through the suction lumen. Oral intake should be nil in the presence of a nasogastric tube. In addition, the tube should never be “clamped” for prolonged periods of time, because by traversing the esophagogastric junction, the tube will lead to an incompetent lower esophagogastric sphincter and potential aspiration. Connection of the tube to a drainage bag for a brief trial is an appropriate alternative to clamping and may be used as a test to determine patient readiness for nasogastric tube removal.

Absolute contraindications to nonoperative management include suspected ischemia, large bowel obstruction, closed-loop obstruction, acutely incarcerated or strangulated hernia, and perforation. In an attempt to define which patients with an uncomplicated small bowel obstruction can be successfully treated nonoperatively, Chen and colleagues<sup>79</sup> used an orally administered, water-soluble contrast agent (Urografin) to study 116 patients with small bowel obstruction. The presence of contrast material within the colonic lumen within 8 hours of oral administration had an accuracy of 93% for predicting which patients would benefit from nonoperative therapy. In their study, only 19% of patients with a small bowel transit time of more than 8 hours had resolution of their obstruction with nonoperative treatment. One of the criteria for conversion to operative treatment was the failure of contrast

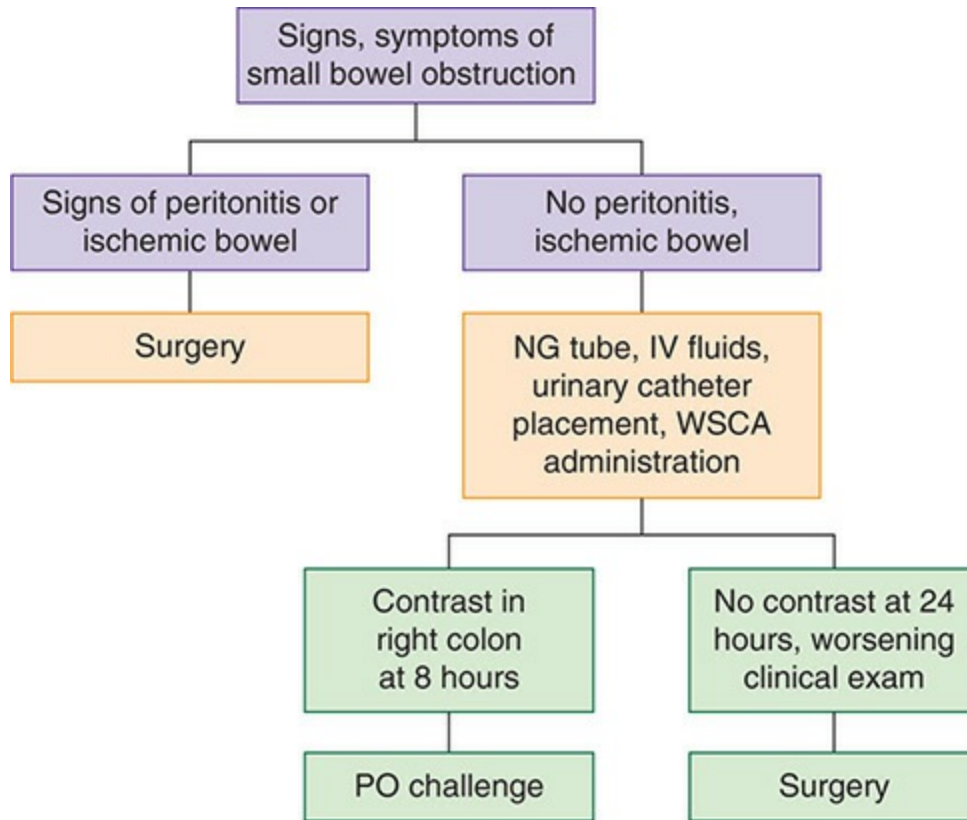

to reach the colon within 8 hours. Therefore, the 81% failure rate in patients in whom contrast never reached the colon within 8 hours after administration may be artificially high based on study design.

A relative contraindication to nonoperative management is complete small bowel obstruction—that is, dilated small intestine with no air in the bowel distally. In a prospective study by Fleshner and associates,<sup>74</sup> all patients with an uncomplicated small bowel obstruction underwent an initial trial of nonoperative management. They were able to manage 45% of patients successfully with a complete obstruction (by their definition), while 66% of patients with a partial obstruction were successfully managed nonoperatively, all with no mortality. These investigators, however, did not describe the incidence of intestinal ischemia at operation based on the presence or absence of complete versus partial obstruction. Another study by Fevang and colleagues<sup>73</sup> reported a 42% success rate in managing patients with a complete small bowel obstruction nonoperatively. When they compared complete and partial obstructions managed nonoperatively, there was a greater rate of bowel strangulation (10% vs 4%) and need for resection (14% vs 8%) in the group with complete obstruction at the time of operation for treatment failure. This group noted a mortality of 6% in patients with a complete obstruction initially managed nonoperatively versus 0% mortality for patients with a partial obstruction initially managed nonoperatively. Other groups have also noted a greater rate of ischemic bowel coupled with a lesser success rate in those patients with a complete obstruction managed nonoperatively.<sup>72,78</sup> These studies and the unreliability of clinical acumen to recognize strangulation obstruction accurately have led many surgeons to favor early operation for all patients with a complete small bowel obstruction,<sup>76</sup> leading to the often-quoted phrase “The sun should never rise or set on a (complete) small bowel obstruction.”

To better delineate partial and complete obstruction, studies have adopted a protocol-driven approach to utilize water-soluble contrast agents (WSCA) in nonoperative management. Among the protocols described in the literature, patients presenting with signs and symptoms of small bowel obstruction were assessed clinically and on CT imaging. Those demonstrating features concerning for ischemia underwent operative exploration immediately following appropriate resuscitation. The remaining patients receiving nonoperative treatment underwent gastric decompression, fluid resuscitation, urinary catheter placement, and WSCA administration.

Following WSCA, abdominal plain films were taken at 8 hours<sup>80,81</sup> after WSCA or 1, 2, 4, and 8 hours<sup>82</sup> after administration, depending on the study. Patients passed WSCA challenge if contrast reached the right colon by times ranging from 8 hours<sup>80,81</sup> to 24 hours<sup>82</sup> after WSCA. Patients who developed worsening signs and symptoms consistent with peritonitis underwent exploratory laparotomy. Among the patients who failed WSCA challenge but did not have a worsening exam, time from WSCA administration to operative management varied from 24 hours<sup>82</sup> to 4 to 5 days.<sup>80</sup>

Success rates using WSCA protocols have ranged from 57%<sup>82</sup> to 90.5%.<sup>83</sup> Based on a recent meta-analysis of 14 prospective trials, presence of contrast in the colon predicted resolution of obstruction with 96% sensitivity, 98% specificity, 99% positive predictive value, and 90% negative predictive value. The authors supported use of WSCA as both a diagnostic and therapeutic tool and demonstrated a decreased need for surgery and decreased hospital length of stay,<sup>52</sup> although results from individual studies remain mixed regarding length of stay and frequency of laparotomy. These studies support use of WSCA protocols in adhesive small bowel obstruction and suggest that protocols decrease use of non-therapeutic laparotomies while diminishing delays in surgical care when indicated (Fig. 38-14).

**FIGURE 38-14** Protocol using water-soluble contrast agents in nonoperative management of small bowel obstruction.

If nonoperative management is attempted in a patient with complete obstruction, the decision should be made with the understanding that there is a definite risk of overlooking an underlying strangulation obstruction,<sup>84</sup> and thus there should be a low threshold for operative intervention in patients with complete obstruction.

## When to Convert to Operative Management

Prompt operative intervention is mandatory in patients who develop signs and symptoms suggestive of a strangulation obstruction. These parameters include fever, tachycardia, leukocytosis, localized tenderness, continuous abdominal pain, and peritonitis. The presence of any three of these signs has an 82% predictive value for strangulation obstruction.<sup>84</sup> Similarly, the presence of any four of the above signs has a near 100% predictive value for strangulation obstruction. Obviously, patients who develop free air, signs of a closed-loop obstruction on abdominal radiograph, or gross peritonitis require

emergent operative exploration. If CT demonstrates evidence of ischemia, such as pneumatosis intestinalis, bowel wall thickening, portal venous gas, generalized ascites, or nonenhancement of the bowel wall, operative intervention should be strongly considered.<sup>76</sup>

The timing of conversion to operative management in a patient with a small bowel obstruction who is not improving with nonoperative management is more controversial. Some surgeons advocate operative intervention in any patient who fails to show improvement within 48 hours of initiating therapy.<sup>72,75</sup> Others advocate a more liberal use of nonoperative therapy, citing a mean time to successful resolution of up to 4.6 days.<sup>74</sup> The authors believe that nonoperative management can be continued greater than 48 hours with the understanding that delaying inevitable operative treatment will result in a greater overall hospital stay and increased costs, and may place the patient at increased risk for perioperative morbidity. As mentioned earlier, implementation of a protocol-driven approach with use of water-soluble contrast agents may be of diagnostic benefit in this setting, though further studies are needed to identify the optimal time to pursue operative care. It is important for the surgeon to remember that nonoperative management always carries a calculated risk of overlooking an underlying strangulation obstruction.<sup>85</sup>

## Operative Management

Once the decision has been made to pursue operative management, steps should be taken to prevent peri- and postoperative complications. Preoperative preparation includes assessing the medical fitness of the patient, and as time allows, taking steps to optimize the patient's medical status. Special consideration should be given to ensure that the patient has been resuscitated adequately by establishing adequate urine output, appropriate antibiotics have been administered, and any electrolyte abnormalities have been addressed. Consideration should be given to the administration of  $\beta$ -blockers to patients with cardiovascular comorbidities and especially to those who were on  $\beta$ -blockers prior to admission.<sup>85</sup> A nasogastric tube should already be in place to decrease the risk of aspiration during the induction of anesthesia; nevertheless, a rapid-sequence anesthetic induction will be necessary to protect the airway during intubation, even in the presence of a

nasogastric tube.

Several decisions must be made with regard to operative planning to provide the safest approach that will afford the best outcome for each individual patient. The choice of operative approach and incision is important to allow the surgeon adequate exposure and visibility. A laparoscopic approach should be considered in some patients.<sup>86</sup> When an obstruction develops in the early postoperative period, the original incision should be reopened provided extensive adhesions were not present originally. Safe entrance into the peritoneal cavity may be best achieved by approaching this from the extremes of the previous incision rather than going directly through the mid-portion of the incision. In patients without a history of prior abdominal operation or those who are remote from their original operation, a midline celiotomy affords the best exposure to all four quadrants of the abdomen. For example, patients with upper oblique, transverse, or subcostal type incisions may have pelvic adhesions that are difficult to address from the upper abdomen, especially through a high transverse incision.

Once within the abdominal cavity, the first step is to identify the site and cause of obstruction. If the point of obstruction is not obvious, decompressed bowel distal to the obstruction can be identified and followed proximally to the point of obstruction. Care should be taken when handling the obstructed bowel at or near the point of obstruction when acutely obstructed, especially if it is fixed at an apparent site of obstruction or if it is ischemic. This region is at high risk for strangulation and infarction, making it more likely to rupture with spillage of bacteria-laden enteric contents into the abdomen. The dilated bowel proximal to the offending obstruction is often thin-walled and at increased risk for perforation if the obstruction is acute. After the offending obstruction has been corrected, a thorough exploration of all four quadrants should always be undertaken to ensure that all intestinal injuries are repaired, nonviable segments are resected, and a second site of obstruction or fixation is not overlooked. This concept is especially true for volvulated segments of small bowel where two points of fixation are often present. Occasionally, obstructing bands traversing a sizeable part of the peritoneum can affect more than one loop of bowel. When a small bowel resection is necessary, intestinal continuity of the small bowel can be accomplished generally with a primary anastomosis unless there is generalized peritonitis and the edges of the remnant bowel are of questionable viability. When an intestinal anastomosis is performed, the surgeon must assess the discrepancy in bowel diameter and

wall thickness between the obstructed proximal bowel and decompressed distal bowel when choosing anastomotic techniques. The surgeon may consider a side-to-side or end-to-side anastomosis in situations where massive dilation of the proximal bowel makes an end-to-end anastomosis difficult technically. In addition, a stapled anastomosis may be less safe in cases where a large discrepancy in bowel wall thickness exists or when there is bowel wall edema, because uniform approximation of the tissue for a given staple height may not be possible.

Abdominal closure may be difficult to achieve when the small bowel is massively dilated. In these cases, intraoperative intestinal decompression will facilitate closure. Techniques described for intraoperative decompression include manual retrograde decompression into the stomach (with careful handling of the obstructed bowel), intraoperative passage of a long nasointestinal tube and, rarely, performance of a controlled enterotomy with passage of a decompressing tube. The latter technique is strongly discouraged except under very select circumstances, such as tremendous intestinal distention preventing abdominal closure or distention threatening bowel viability. Manual retrograde decompression of luminal contents around the ligament of Treitz, through the pylorus, and into the stomach allows for aspiration through the nasogastric tube by the anesthetist.<sup>87</sup> This maneuver is the safest and quickest technique because it allows closure of the abdominal wall while avoiding an enterotomy and excessive manipulation of the bowel. When decompressing the bowel, the inflamed and distended bowel must be handled gently, because experimental studies have demonstrated an increased rate of bacteremia after extensive manipulation of obstructed bowel.<sup>88</sup> In addition, the anesthesia team should be alerted to the maneuver to be certain that their nasogastric tube is functioning well. Although intraoperative decompression has not been shown to decrease the rate of postoperative complications or the speed of return of bowel function, it certainly does make abdominal closure easier, faster, and safer.

Nonviable bowel needs to be identified and resected. Resection should be undertaken with caution, especially in patients with a limited length of bowel from a previous resection or those with large sections of ischemia. Adjuncts for determining bowel viability include the use of Doppler US and intravenous fluorescein. These tests are relatively subjective, should be used with caution, and are only adjuncts to sound clinical judgment. In patients who would otherwise be left with less than two-thirds of their original bowel

length after resection of all bowel of questionable ischemia, consideration may be given to resecting all the grossly necrotic or obviously nonviable bowel but preserving bowel of questionable viability and performing an end ostomy or a second-look procedure 12 to 24 hours later, particularly if the viability of the ends to be anastomosed is in question.

## **BYPASS VERSUS RESECTION**

In patients with an incurable malignant small bowel obstruction, if the offending obstruction is unable to be released or it is deemed unsafe to attempt to dissect out the site of obstruction, intestinal bypass can be performed. Bypass relieves the obstruction while reestablishing intestinal continuity and preventing a closed-loop obstruction; however, the advisability of a bypass procedure should be considered. For instance, in the presence of carcinomatosis, a bypass may prove fastest and safest, because patient survival will be short. In contrast, patients with certain chronic inflammatory diseases will remain at risk for ongoing problems (eg, Crohn's disease or tuberculosis) related to the inflammation in any "bypassed" segment, and therefore such patients may be served better by resection than simple bypass.

The surgeon should at least consider an initial laparoscopic, minimal access approach in patients with uncomplicated small bowel obstruction. Laparoscopy is known to cause fewer adhesions than open laparotomy<sup>89</sup> and in that regard may be superior to laparotomy for the treatment of adhesive small bowel obstruction. Several studies have shown laparoscopy to be a safe and effective means of access for the operative treatment of small bowel obstruction.<sup>86,90-92</sup> When successful, a laparoscopic approach decreases both the duration of hospital stay<sup>86,90-92</sup> and the complication rate.<sup>90,92</sup> Patients successfully treated laparoscopically appear to have more rapid return of bowel function.<sup>90,92</sup> These reports show a large benefit to laparoscopic treatment for small bowel obstruction, but need to be interpreted carefully. Many series compare patients treated laparoscopically to those who failed initial laparoscopic treatment. Those patients unable to be treated laparoscopically likely had more extensive adhesions or complicated pathology possibly requiring resection. Operative intervention in these patients would be more involved and complex whether done open or laparoscopically. One would expect these patients to have greater hospital

stays, greater complication rates, and slower return of bowel function independent of the method of abdominal access. In addition, the skill and confidence level of the surgeon should weigh in the decision to approach the obstruction laparoscopically. First, if the surgeon lacks skill in using moderately advanced laparoscopic techniques, an open operation may be a better choice. Similarly, if the patient is known to have a frozen abdomen or has either a severely distended, tense abdomen with markedly distended bowel or multiple dense adhesions at the time of insertion of the laparoscope, conversion to an open procedure is wise. Initial access for creating the pneumoperitoneum in a patient with a small bowel obstruction is achieved best by a fully open approach under total visual control, but limited data support this concept.

## **RECURRENT SMALL BOWEL OBSTRUCTION**

Although the results of individual studies vary, between 4% and 34% of patients will experience recurrent small bowel obstruction regardless of management modality.<sup>9,74,76,77,79,92</sup> This wide range of recurrence rates likely results from variations in both the duration and quality of follow-up between studies as well as the etiology of the original bowel obstruction. Recurrent obstruction is more common in patients with multiple adhesions, matted adhesions, previous admissions for small bowel obstruction, and previous pelvic, colonic, and rectal surgery.<sup>9,77</sup>

In the past, numerous attempts have been made by surgeons to control the formation of adhesions in an effort to prevent future mechanical obstruction. A simple technique to prevent adherence of the bowel to the undersurface of the fascial incision is to interpose the omentum between the bowel and the incision. Theoretically, when adhesions from the posterior surface of the anterior abdominal wall form after omental interposition, they will involve the omentum and not the underlying bowel. Other more intricate techniques, such as the Noble plication and the Childs–Phillips transmesenteric plication, have been described in the more distant past. These procedures involve the suturing adjacent loops of small bowel into an orderly pattern in an attempt to plicate the bowel permanently in a position that will not allow mechanical obstruction. Although initial reports were encouraging, the Noble and Childs–Phillips procedures have multiple complications and are of historic interest only. The problems associated with plication procedures have included

prolonged operative times and high rates of enterocutaneous and enteroenteric fistula, abdominal abscess, and wound infection; moreover, the rate of recurrent obstruction is as great as 19%, bringing into question their efficacy. Attempts to “plicate” the bowel with a long intestinal tube, so-called intraluminal plication, have not proved effective.

In some patients, complete or adequate adhesiolysis is not possible or may risk vascular injury to a substantial segment of bowel because of the acute inflammatory nature or tenacity of the adhesions. This situation is especially common when celiotomy is deemed necessary or performed too soon after a previous intra-abdominal procedure (see the following section on early postoperative small bowel obstruction). This situation is especially common when the previous operation involved an extensive adhesiolysis. In such situations, it may be important to control any bowel injuries present, end any further dissection, and conclude the operation to prevent further bowel injury and its potential sequelae. This “conservative” approach may allow the acute inflammatory process to resolve or regress (often 3-6 months); should the obstruction not resolve by 6 months, the plan should be to reoperate at a time when the adhesions have matured, allowing a more controllable and much safer adhesiolysis. In some situations, the mature decision might be to provide proximal diversion with a proximal enterostomy if the obstruction has no chance for resolution (eg, due to malignancy or radiation) or if a more distal bowel repair is tenuous, or to place a tube gastrostomy for diversion and patient comfort. Pursuing a futile attempt to complete the adhesiolysis puts the patient at risk for serious bowel injury or devascularization injury necessitating resection of otherwise normal bowel with the risk of enterocutaneous fistula or subsequent short bowel syndrome.

## **ADHESION PREVENTION**

Over the last 100 years, multiple approaches have been employed in an attempt to prevent the formation of unwanted postoperative adhesions. These attempts include, among others, the use of cow cecum, shark peritoneum, sea snake venom, and fish bladder, as well as multiple fluids, mechanical barriers, and gels.<sup>93</sup> The concept of separating injured surfaces mechanically to prevent adhesions is attractive. The formation of fibrin bridges (and thus adhesions) may be preventable by separating injured surfaces in the postoperative interval during the critical period of healing and

mesothelialization by application of an absorbable biofilm. Estimates of the minimum amount of time necessary for an impermeable or semipermeable barrier to prevent adhesion formation appear to be about 36 hours. Some authors have placed a Silastic sheet between two injured peritoneal surfaces and when left in place for 36 hours, no adhesions formed between these surfaces thereafter.<sup>22</sup> Others have postulated that separating the surfaces at risk for the first 5 to 7 days until full mesothelialization occurs would seem to be most effective; however, the barrier should not incite its own inflammatory response and should not decrease fibrinolytic activity or suppress access to oxygen. The ideal product, therefore, should be bioabsorbable, last only 5 to 7 days, be easy to apply, be interposed between all injured surfaces, and not itself incite an inflammatory reaction.

The most effective method to date has been the application of a sheet of bioresorbable hyaluronate membrane. This approach has been shown to decrease the formation of adhesions at the site of application.<sup>93,94</sup> Multiple reviews have supported that use of this product decreased adhesion formation.<sup>95-98</sup> Whether hyaluronate application resulted in decreased incidence of reoperation for adhesive small bowel obstruction remains unclear. Reviews by Kumar and Zeng showed no association between hyaluronate use and incidence of postoperative bowel obstruction nor did hyaluronate decrease the need for operative intervention for intestinal obstruction.<sup>96,97</sup> Furthermore, if the membrane is wrapped around an intestinal anastomosis, the leak rate is increased. In a study evaluating long-term follow-up of barrier use, van der Wal and colleagues report no decrease in frequency of bowel obstruction, and barrier use failed to improve quality of life as determined on patient survey.<sup>99</sup>

Initial concerns that were raised over the safety of hyaluronate barriers appear unfounded, with the exception of iron cross-lined hyaluronate that was withdrawn from the market. A prospective, randomized, controlled trial showed that hyaluronate barriers did not increase the risk of intra-abdominal abscess or pulmonary embolism<sup>95</sup>; however, in a post-hoc subgroup analysis of 289 patients in whom the hyaluronate membrane was wrapped around a fresh anastomosis, the rates of leak, fistula formation, peritonitis, abscess, and sepsis were increased. Based on these studies and assumptions, the use of hyaluronate membranes in elective abdominal surgery does decrease the amount of postoperative adhesions at the site of application but does not

decrease the incidence of intestinal obstruction or the need for future reoperation for obstruction. Use of these products requires careful consideration, because they are expensive and their clinical benefit appears to be relatively low.

Other materials or substances are being developed that may someday move to the forefront of adhesion prevention. These include gel and liquid preparations such as hyaluronic acid and carboxymethylcellulose, hydrogel, fibrin sealant, and protein polymers. Other adhesion barriers include oxidized regenerated cellulose (ORC). ORC has been well studied and does help prevent adhesion formation, but its use requires a blood-free field that at times is not practical to achieve. The use of ORC, like hyaluronate membranes, has not been shown to decrease the incidence of subsequent adhesive small bowel obstruction.<sup>101</sup> Strategies including use of postoperative hyperbaric oxygen, peritoneal cell transplantation, and use of fetal-liver mesothelial cells have been described in animal models but have yet to be applied in a clinical setting.<sup>102,103</sup>

## **EARLY POSTOPERATIVE SMALL BOWEL OBSTRUCTION**

Early postoperative small bowel obstruction, herein defined as within 6 weeks of the original operation, is a relatively uncommon problem but remains a real dilemma encountered in every practice performing abdominal operations.

It is often difficult, if not impossible, to distinguish early obstruction from postoperative ileus, but fortunately the management is usually quite similar. Patients with suspected early mechanical small bowel obstruction should be managed initially by nasogastric decompression, fluid resuscitation, and correction of any electrolyte abnormalities. After a thorough physical examination and the decision that emergent intervention is not indicated, a search for the cause of obstruction should be undertaken. CT can be helpful in determining the etiology of an obstruction but is notoriously unreliable at differentiating ileus versus partial obstruction. Obstructions caused by extrinsic bowel compression amenable to percutaneous correction, including fluid collections, abscesses, and hematomas, may be diagnosed and treated by percutaneous drainage. CT may be able to detect those causes of obstruction that will likely require operative intervention, such as internal hernia, fascial

dehiscence, and uncontrolled anastomotic leak. Early CT may be warranted in patients who had a laparoscopic operation and have signs of early obstruction, because a port site hernia may be evident and would require prompt operation.

Generally, two categories of patients with early postoperative small bowel obstruction have been recognized.<sup>76</sup> The first category includes those in whom the obstruction becomes evident within 10 days of an abdominal operation. Conservative management is advised usually as long as signs and symptoms of ischemia and strangulation obstruction are not present and other remediable causes have been excluded. Patients within this time frame are not at a substantially increased risk of bowel-related complications after celiotomy, provided there are no internal hernias and, if the original operation was done laparoscopically, that port site hernias can be excluded. It is important to rule out correctable causes of extrinsic compression and reverse any electrolyte abnormalities, especially if ileus is also suspected. Strangulation obstruction, albeit rare, can occur in this group of patients, and thus a high index of suspicion must always be maintained. The etiology of a strangulation obstruction in this group is almost never related to adhesions but rather to some surgical misadventure, such as internal hernia, an overlooked segment of ischemia at the original celiotomy, bowel entrapped in the fascial closure, or an unsuspected abdominal wall hernia.

The second category of patients is those presenting between 10 days and 6 weeks after operation.<sup>76</sup> Conservative management is advised whenever possible for patients in this category as well. The risk of iatrogenic bowel complications during and after reoperation so early after celiotomy increases dramatically in this group secondary to the dense adhesions often present during this period after abdominal operation. The time period from 7 to 10 days up until 6 to 12 weeks postoperatively represents the window when the greatest inflammatory reaction is present intraperitoneally. The developing adhesions are highly vascular and friable. If the patient had no or very minimal adhesions at the time of celiotomy, reoperation is warranted; however, in a small, unpredictable group of patients without any previous adhesions, and reliably so in those with dense adhesions that had required substantial adhesiolysis at the time of original celiotomy, an acute inflammatory reaction involving the peritoneal surfaces may agglutinate adjacent loops of bowel, often involving the omentum and mesenteric surfaces.

Operations performed during this period have a much greater rate of iatrogenic injury and subsequent fistula formation. Those patients not responding to conservative management during this period are best placed on parenteral nutrition until the obstruction resolves or they are more than 6 to 12 weeks out from their last celiotomy. At this time, the decision to reoperate is made based on several considerations. First, if the patient had relatively few adhesions at the time of celiotomy, reexploration at 6 weeks to 3 months postoperatively may be warranted. In contrast, in those patients who required an extensive adhesiolysis at the time of original celiotomy, many experienced surgeons wait for a full 6 months prior to reoperation for several reasons: (1) by 6 months, the adhesions are reliably less vascular and more mature; (2) reoperation prior to 3 months may reveal a frozen abdomen in which the obstruction may be unable to be dissected free safely; and (3) the obstruction may resolve as the adhesions mature.

## **BOWEL OBSTRUCTION AFTER ROUX-EN-Y GASTRICBYPASS SURGERY**

As with all other operations and maybe more so in the current era of laparoscopic Roux-en-Y gastric bypass (RYGB), bowel obstruction is a worrisome complication after bariatric surgery for morbid obesity. Estimates of the rate of bowel obstruction after RYGB vary within a reported range of 0.3% to greater than 9% depending on the technique used to perform the operation. The rate of bowel obstruction appears to be less after open RYGB, but there are no large prospective studies comparing laparoscopic to open procedures at this time. In a large, collected review of more than 9500 patients undergoing laparoscopic RYGB, the rate of bowel obstruction was 3.6%.<sup>104</sup> Although some controversy exists, most authors suggest that the rate of bowel obstruction is less with use of an antecolic versus a retrocolic orientation of the Roux limb for the gastric bypass.<sup>104-107</sup> Bowel obstruction after RYGB can occur secondary to a variety of etiologies; however, the four most common etiologies, in decreasing order of frequency, are internal hernia, adhesive obstruction, stenosis at the jejunojejunostomy, and incisional hernia.

The diagnosis of bowel obstruction after laparoscopic RYGB is more difficult than after other surgical procedures secondary to the altered gastrointestinal anatomy created by the procedure and the often less typical

response of the patient with morbid obesity. After RYGB, the symptoms of bowel obstruction can be vague, and because the most common etiology is internal hernia, the symptoms are often intermittent. Abdominal pain is the most common symptom present in 82% of patients in one large series, and importantly, nausea and vomiting were seen in fewer than 50% of patients in this series. All three symptoms were present in only 28% of patients.<sup>106</sup> Unfortunately, imaging studies also have a lesser sensitivity for bowel obstruction in patients after RYGB, with reported sensitivities of 51%, 57%, and 33% for CT, UGI contrast study, and plain abdominal radiography, respectively.<sup>106</sup> When patients with unexpected gastrointestinal symptoms after RYGB are assessed, a high index of suspicion for bowel obstruction is warranted. Given the frequency of internal hernia as a cause of postoperative bowel obstruction and the low sensitivity of radiologic evaluation for bowel obstruction in patients after RYGB, a low threshold for laparoscopic exploration is warranted in patients with suspected bowel obstruction.

Internal hernia is the most common cause of bowel obstruction after RYGB. Anatomically, there are three different types of internal hernias seen after RYGB. All three types of internal hernias are transmesenteric defects created during the formation of the Roux limb and are illustrated in [Fig. 38-3](#). The so-called Peterson hernia occurs in the infracolic compartment through the potential space between the mesentery of the Roux limb, the transverse mesocolon, and the retroperitoneum, and can be seen with either an antecolic or retrocolic Roux limb. Herniation through the mesenteric defect created by the jejunojejunostomy is the second site of internal hernia observed after RYGB and can occur with both antecolic and retrocolic gastric bypass. Herniation through the mesenteric defect in the transverse mesocolon created by passage of the retrocolic Roux limb is the third type of internal hernia observed in RYGB and is only seen in retrocolic gastric bypass; this type of internal hernia was the most common type before the importance of meticulous closure of this defect was appreciated. Most authors believe that bowel obstruction after RYGB is substantially more common after laparoscopic retrocolic bypass, with reported rates of 3.2% to 5.1% after retrocolic and 0.3% to 1.7% after antecolic bypass reported in the largest series.<sup>104,107</sup> Meticulous closure of all potential hernia spaces with nonabsorbable suture at the time of RYGB is the best way to prevent internal hernia; however, care must be taken when closing the mesocolic defect, because obstruction at the mesocolic window from tight scar formation has

also been reported as a cause of bowel obstruction after RYGB.<sup>108</sup> When operating on a patient with internal hernia after RYGB, careful closure of the hernia defect with nonabsorbable suture after reduction in the hernia is the treatment of choice.

## **RADIATION ENTEROPATHY**

The management of radiation enteropathy is often difficult and frustrating. The clinical presentation can be quite diverse with recurrent intermittent small bowel obstruction, a true, chronic, persistent partial small bowel obstruction, or chronic diarrhea/malabsorption. Operative management is often extremely challenging secondary to the dense adhesions and chronic inflammatory reaction present after radiation. These patients also tend to develop recurrent areas of enteropathy consistent with progression of disease in bowel that appeared normal previously, because this ischemic disease is an ongoing and progressive chronic process. The need for operative correction with a resection and anastomosis has been reported to have a mortality rate as high as 21% in some series.<sup>100</sup> Patients with radiation enteropathy also have a high rate of anastomotic leak and fistula formation after operation because of the compromised vascular supply to the bowel. These effects are magnified in patients with atherosclerosis, hyperlipidemia, or type 2 diabetes. For these reasons, a cautious, conservative approach to the patient with radiation enteropathy is warranted whenever possible.

When operative management is necessary, the surgeon must decide between resection, bypass of the affected segment, or adhesiolysis. As noted earlier, resection has been reported to have a high mortality rate, with a 36% incidence of leak after primary anastomosis.<sup>94</sup> In the same study, bypass of the affected segment had a 10% mortality and 6% leak rate. Surgeons advocating aggressive resection back to healthy bowel, however, have reported leak rates between 0% and 8% when confounding conditions (abscess, fistula, necrosis, or recurrent cancer) were absent; such an aggressive approach may require an extensive resection but often involves resection of nonfunctional bowel anyway. In their retrospective analysis, Li et al. identified American Society of Anesthesiologists (ASA) class of III to IV, intraoperative transfusion, preoperative anemia, thrombocytopenia, and presence of radiation uropathy as independent risk factors to Clavien–Dindo grade III to IV morbidity when ileal or ileocecal resection was undertaken.<sup>109</sup>

Given the complexities in managing radiation enteropathy, implementation of a scoring system may help direct care and improve outcomes. Short bowel syndrome is always a concern, especially because the involved bowel is usually the distal ileum.

Most surgeons approach the treatment of radiation enteropathy cautiously. In those patients with recurrent cancer and radiation enteropathy, treatment should consist of palliative bypass of the diseased segment with creation of an anastomosis in visibly normal tissue. If the obstructive process is localized, wide resection back to healthy, non-irradiated tissue (if possible) with primary anastomosis is acceptable, provided adequate absorptive area is preserved. Usually this involves anastomosis from small bowel to the ascending colon, because the terminal ileum has usually been within the radiation field. While ideally a complete resection of the entire involved small bowel is optimal, the surgeon must consider the extent of the resection necessary as well as the anatomic segment involved. Because the distal ileum is commonly involved, major resection back to reliably normal, non-irradiated small bowel may require a total or subtotal ileal resection that carries its own nutritional complications. Thus, the surgeon is faced with a decision concerning preservation of mildly involved but functional ileum versus complete resection. In contrast, if the bowel is severely involved and nonfunctional, resection, despite its side effects, may be the best option. When the affected area contains dense adhesions or is stuck deep within the pelvis, bypass may be a better choice to avoid the very real concern of potential iatrogenic injury to the bowel, bladder, pelvic organs, and ureters; however, if there is a localized abscess or associated septic process, bypass is not a good option because the ischemic inflammatory process will continue. Attempts at complete lysis of adhesions alone without resection are controversial due to the risk of traumatizing the intestine with potential fistula formation. For the patient with advanced disease who presents years after irradiation, adhesiolysis may not be a good option, especially if the bowel is matted and agglutinated. In contrast, in the case of isolated adhesive bands and the patient being early (<2 years) after irradiation, lysis alone may be warranted; much of the decision needs to be based on the quality of the involved bowel and the site of obstruction. If the bowel is thickened, nonpliable, and strictured, resection or bypass is best.

## **CARCINOMATOSIS AND MALIGNANT OBSTRUCTION**

Bowel obstruction in the setting of carcinomatosis often represents the terminal phase of the malignant disease. Operative management is entirely palliative and needs to be applied selectively. In the case of limited life expectancy and malignant cachexia or ascites, nonoperative palliative measures are advised because operative intervention would be unnecessary and associated with a poor quality of life due to the convalescence required after a non-curative celiotomy. However, some patients with a good performance status may have a long life expectancy, and in this case, operative bypass with the idea of permitting renewed oral intake may be indicated. Patients and their families should be counseled that the relief of their obstruction will not affect disease progression but may improve quality of life. In addition, the surgeon should keep in mind that up to one-third of bowel obstructions presenting in the setting of carcinomatosis are due to adhesions and not to malignant obstruction.<sup>75</sup> Therefore, a short trial of conservative therapy with rehydration and nasogastric decompression is usually advisable, although many patients with carcinomatosis will fail this intervention. In addition, depending on the location and extent of the malignant disease involving the gastrointestinal tract, a palliative endoscopic stent placement may relieve the obstruction (Fig. 38-15).

**FIGURE 38-15** **A.** Obstructing rectal cancer (*arrows*). **B.** Intraluminal self-expanding metal stent restores luminal patency. (Reproduced with permission from Hünnerbein M, Krause M, Moesta KT, et al: Palliation of malignant rectal obstruction with self-

expanding metal stents, *Surgery* 2005;Jan;137(1):42–47.)

An initial minimal access, laparoscopic approach should at least be entertained in patients with a malignant obstruction, provided the access to the peritoneal cavity is safe. The least invasive approach is best for these patients, and if palliation, such as a bypass or gastrostomy tube, can be achieved laparoscopically, the patient would benefit substantially with decreased pain, possibly a shorter convalescence, and decreased duration of hospital stay, all of which are important considerations in the palliative care of patients with a limited life expectancy.

At exploration, multiple scenarios may be encountered. Some patients will have an isolated area of adhesions and require only adhesiolysis. Others will have a solitary metastasis causing either an intra- or extraluminal obstruction that can be corrected with a limited resection or bypass. If multiple areas of adhesions are present or the affected area is adherent to the abdominal wall or intra-abdominal structures in the patients with incurable malignant obstruction, bypass of the involved segment will provide symptom relief and the fewest opportunities for complication. One should consider placement of a tube gastrostomy if there is any question of the success of the operation, if impending obstruction seems imminent, or if relief of the obstruction is not possible. In the event of recurrent obstruction, a tube gastrostomy can be used to decompress the stomach and avoid the discomfort associated with a nasogastric tube. The decision to place a palliative, decompressive, tube gastrostomy is more difficult in the presence of ascites. In this situation, a better option would be a tube pharyngostomy.<sup>110</sup> In addition, if histologic diagnosis of the neoplasm had been obtained previously, a repeat biopsy should be entertained to ensure that the neoplasm has histologic characteristics consistent with the original biopsy.

# TUMORS OF THE SMALL INTESTINE

*Michael M. Reader • Barbara Lee Bass*

Primary tumors of the small intestine, both benign and malignant, are rare. With the potential to arise from virtually every cell type within the small intestine—the epithelium, neural tissues, and lymphatic and mesenchymal cells—the small bowel may also be the site for metastases from other primary tumors. The variety and uncommon nature of these tumors make generalizations regarding their management difficult. In this chapter, we will review the epidemiology and clinical diagnostic and management strategies for benign and malignant neoplasms of the small bowel.

## EPIDEMIOLOGY

Although the small bowel accounts for 75% of the length and 90% of the mucosal surface area of the gastrointestinal tract, less than 2% to 5% of gastrointestinal malignancies arise in this organ. Most of these tumors are clinically silent. Autopsy series have identified incidental small bowel tumors in 0.2% to 0.3% of hospital deaths—a rate 15 times the operative incidence of small bowel resections for tumors.<sup>1,2</sup> Over the past few decades, the overall incidence of small bowel tumors has increased, likely due to

enhanced detection with new diagnostic modalities. Although the incidence of adenocarcinoma has remained stable, there has been an almost 4-fold increase in the incidence of small intestinal neuroendocrine tumors (SI-NETs), which are now the most common primary tumor of the small bowel.<sup>1,2</sup>

Given the rare nature of these tumors, most published reports are collections of relatively small series of tumors accrued over a period of many years. Interestingly, these reports differ regarding the type of small bowel tumor, the distribution of tumors, and until the advent of molecular diagnostic criteria for gastrointestinal stromal tumors (GISTs), the classification of tumors of stromal origin. Nonetheless, in most series, adenocarcinomas (30%-50%), GISTs (15%), SI-NETs (carcinoid tumors; 20%-30%), and lymphomas (15%) compose the most common malignant tumors.<sup>2,3</sup> Small bowel tumors are more prevalent in older patients, with over 65% of patients with small bowel adenocarcinoma being age 60 or older.<sup>3</sup> The proportion of small bowel tumors that are benign varies from 14% to 52% in different series, a disparity explained by the failure to detect these typically asymptomatic benign lesions.

There are no satisfactory explanations for the observed variation in prevalence of small bowel tumors around the world. Neuroendocrine tumors (NETs) are uncommon in Asian series, whereas GISTs compose a higher proportion of reported series in the East.<sup>4,5</sup> Men are slightly more likely to develop small bowel neoplasms than women, with a male preponderance reported for both benign and malignant tumors.

## **PATHOGENESIS**

Given the length of the small bowel and its large mucosal surface, it is intriguing that it is such an uncommon site for malignancy. Unlike the adenoma-carcinoma sequence seen in the colon, a clear molecular progression sequence has not been defined in the small bowel other than the known polyposis syndromes. Only periampullary adenomas are known to be premalignant lesions with the potential to progress to adenocarcinomas. Adenomatous polyps arising elsewhere in the small bowel presumably have similar potential for malignant transformation, although the molecular traits of this transformation remain unknown. Such progression has not been

definitively documented at other sites in the small bowel. The only small bowel primary tumor with a known genetic pathogenesis is the GIST, which is linked to deleterious mutations of the *KIT* and *PDGFRA* genes.

Based on theories of luminal injury defined in the colonic mucosa, several hypotheses are proposed regarding the pathogenesis of epithelial-derived small bowel tumors. Unlike the colon with its high bacterial luminal content, the lumen of the healthy small bowel is relatively sparsely colonized with a commensal microbiome; bacterial metabolites implicated in the genetic alterations of colon carcinogenesis are absent. Transit through the small bowel is rapid—30 minutes to 2 hours—so exposure to potential toxins and metabolites is much more limited. The alkaline, mucus-rich succus entericus of the small bowel may have protective capacity and less noxious potential than the more solid contents of the colon. Enterocytes of the brush border epithelium express the enzyme benzopyrene hydroxylase, possibly protecting against mucosal damage by detoxifying the carcinogen benzopyrene. And lastly, high levels of luminal IgA and greater distribution of lymphoid tissue in the small intestinal epithelium and submucosa may provide an additional protective mechanism via an immune surveillance mechanism.

Bile acids and their metabolites have been implicated in the pathogenesis of small bowel adenocarcinoma. Postcholecystectomy patients may be at greater risk for the development of small bowel malignancy. In one study of patients with small intestinal malignancy, 12% had a history of cholecystectomy, and of those with duodenal adenocarcinoma, 25% had prior cholecystectomy. However, a causative relationship between cholecystectomy and small intestinal adenocarcinoma has not been identified.

## HIGH-RISK POPULATIONS

Several heritable and inflammatory gastrointestinal conditions are associated with an increased risk for development of small bowel tumors.

### **Familial Adenomatous Polyposis**

Patients with familial adenomatous polyposis (FAP) carry a lifetime risk approaching 100% for the development of adenomatous polyps of the duodenum, and these lesions may progress to adenocarcinoma. FAP patients

have an approximately 300-fold increased risk for development of adenocarcinoma of the duodenum over the normal population,<sup>3</sup> and this is the leading cause of cancer death in patients with FAP previously treated by colectomy. These patients require regular screening esophagogastroduodenoscopy and endoscopic or surgical excision of enlarging adenomas.

## **Crohn's Disease**

Patients with active jejunoileitis of Crohn's disease have a 100-fold increased incidence of adenocarcinoma. Active disease in the terminal ileum is the most frequent site of malignancy.<sup>6</sup> Abdominal complaints and symptoms consistent with their primary condition may delay evaluation and diagnosis, leading to detection of tumors at advanced stages. The prognosis for patients with adenocarcinoma arising in Crohn's disease is poor.<sup>7</sup> For patients undergoing bowel-preserving procedures such as stricturoplasty, a biopsy of the site of past or active disease is advised to rule out dysplasia or in situ carcinoma. Such findings, while rare, would warrant resection rather than bowel-preserving approaches.

## **Celiac Disease**

Celiac disease is associated with increased risk of lymphoma, which develops in up to 14% of patients.<sup>8</sup> A gluten-free diet has been postulated to decrease this risk, although this has not been substantiated.<sup>9</sup>

## **Posttransplantation Lymphoproliferative Disorder**

Patients on chronic immunosuppression therapy are at particular risk for small bowel malignancies, especially lymphomas and sarcomas. Transplant recipients on immunosuppression have a 45- to 100-fold increase in non-Hodgkin lymphoma (NHL), a condition termed posttransplantation lymphoproliferative disorder (PTLD).<sup>10</sup> The incidence of PTLT ranges from 1% to 20% of solid organ transplants and is usually of B-cell origin, with Epstein-Barr virus (EBV) being the most important risk factor. PTLT accounts for 30% of all malignancies in cyclosporine-treated patients, but

accounts for only 12% of malignancies in patients without cyclosporine in their regimen. PTLD tends to develop rapidly, with 47% of cases occurring within the first 6 months after transplantation and 62% of cases occurring within 12 months of transplantation, although risk continues for as long as immunosuppressive therapy is ongoing. Greater degrees of immunosuppression carry greater risk for development of PTLD. As transplant patients continue to live longer, it is anticipated that the incidence of PTLD will increase.<sup>11</sup>

## **Miscellaneous Conditions Associated With Small Bowel Neoplasms**

Patients with Peutz-Jeghers syndrome develop benign hamartomas throughout the intestinal tract. Surveillance is indicated, as these lesions are at risk of malignant transformation into adenocarcinoma.<sup>12</sup> Patients with von Recklinghausen disease may develop neurofibromas in the gastrointestinal tract that can undergo malignant transformation. HIV infection is also associated with the development of lymphoma in up to 30% of patients. Most are extranodal, and the gastrointestinal tract is the involved site in 10% to 25% of cases. More than 90% of patients present with stage IV disease, and median survival is 6 months.

## **CLINICAL PRESENTATION**

Patients with small bowel tumors present with nonspecific gastrointestinal and constitutional complaints. In hindsight, the gradual development of symptoms is usually evident. The most common symptoms include vague abdominal discomfort and cramps, gradual weight loss, anemia, nausea, and vomiting. These nonspecific complaints, coupled with the fact that most patients are older and often on medications that may also elicit these complaints, result in a high rate of misdiagnosis and delay in diagnosis. In most series, the average duration of symptoms prior to diagnosis ranges from weeks to many months. Initial diagnostic evaluation to exclude more common conditions that can cause such signs and symptoms, including evaluation of the gastroduodenum, colon, and biliary tract, is completed, but when negative, further evaluation of the small bowel may be delayed or

deferred.

Benign lesions rarely cause abdominal pain or obstruction; rather, their presence is often heralded by acute gastrointestinal hemorrhage. Benign neoplasms may grow to a large size prior to detection and may simply be discovered incidentally on a radiologic exam or at laparotomy.

## DIAGNOSIS

The diagnosis of small bowel tumors is hampered by a number of factors. In addition to the fact that these are rare tumors that produce nonspecific gastrointestinal complaints, the ability to fully image and observe the small intestine is challenging. With the introduction of capsule endoscopy and wider availability of small bowel enteroscopy, which allows for luminal visualization of the entire small bowel mucosal surface, accurate preoperative diagnosis is more common prior to surgery.<sup>13</sup>

History and physical exam are nonspecific. Abdominal mass, heme-positive stool, or signs of intestinal obstruction are usually absent. Laboratory data may demonstrate iron deficiency anemia in a minority of patients.

Plain abdominal films are an appropriate initial diagnostic test, although they are rarely helpful unless the patient presents with obstructive symptoms.

## Imaging

After ruling out more common conditions that elicit similar gastrointestinal and abdominal complaints with endoscopic evaluation of the gastroduodenum and colon, computed tomography (CT) of the abdomen is the appropriate initial imaging test. CT may reveal bulky tumors (Fig. 39-1C) or subtler findings suggestive of small bowel tumors, such as thickening of the small bowel wall. Thickening of the bowel wall to greater than 1.5 cm or the detection of discrete mesenteric lymph nodes or masses greater than 1.5 cm in diameter is highly suggestive of malignancy. If obstructing lesions are present, CT scan may reveal a transition zone demarcating dilated proximal bowel from decompressed distal bowel.

A

C

D

**FIGURE 39-1** Imaging of small bowel tumors. **A.** Magnetic resonance imaging showing intraluminal filling defect in the duodenum in a patient with occult gastrointestinal blood loss anemia. The lesion proved to be a neuroendocrine tumor (carcinoid). **B.** Octreotide scan of the same patient showing a focus of enhanced radioactivity corresponding to the duodenal filling defect. **C.** Sarcoma of the jejunum. Bulky mass with near luminal obstruction in a patient presenting with signs of small bowel obstruction. **D.** GIST tumor as lead point for intussusception in the jejunum. Patient presented with intermittent abdominal pain and obstruction.

Tumors of the distal small bowel may cause jejunoileal or ileocolic intussusception ([Fig. 39-1D](#)). During intussusception, the small bowel tumor serves as the lead point to pull the small bowel into the distal small bowel or colonic lumen; the mass lesion precludes spontaneous reduction. CT findings

of ileocolic or jejunoileal intussusception include the presence of concentric rings with a donut appearance involving the bowel. A luminal mass may be seen on CT or magnetic resonance (MR) contrast studies (Fig. 39-1A). This sign is nearly pathognomonic for small bowel tumor. In adults, radiographic attempts to reduce an intussusception should not be attempted. Rather, prompt surgical exploration and resection of the nonreduced intussuscepted bowel segment with mesenteric resection should be completed without intraoperative attempts at reduction.

Although a number of SI-NETs are metabolically active and express hormones, somatostatin scintigraphy (octreotide scanning) is of minor value in most cases to detect a primary SI-NET, although occasionally such a study is diagnostic (Fig. 39-1B). Positron emission tomography (PET) scanning also has limited utility in providing a discriminate diagnosis, as there is significant overlap between benign and malignant conditions. More recently, PET-DOTATATE scans have been introduced for identification and staging of these tumors, and this modality was recently approved by Medicare. Although diagnostic methods continue to improve, many patients with small bowel neoplasms still have initial presentation as a surgical emergency, and more than half of patients with malignant disease have metastatic spread at the time of operation.

Luminal contrast radiographic studies may be used if abdominal CT imaging fails to reveal evidence of a small bowel tumor, usually an upper gastrointestinal contrast series with small bowel follow-through. A small bowel follow-through study will show an abnormality in 53% to 83% of cases, although direct evidence of a tumor is detected in only 30% to 44% of cases.

Although enteroclysis (a dynamic contrast technique using a slurry of barium and methylcellulose infused into the small bowel via a nasoduodenal tube to uniformly distend the small bowel lumen) was formerly used to study the mucosal surface of the small bowel lumen, this procedure has been largely replaced by video capsule endoscopy (VCE) and CT/MR enterography.

CT and MR enterography use negative contrast agents given orally prior to the scan to enhance imaging of the bowel wall and luminal contents. Unlike enteroclysis, these procedures do not require nasoduodenal intubation. Although luminal distention is inferior to that of enteroclysis, the ease and tolerability of the procedures have made these modalities the diagnostic

studies of choice for challenging cases. The choice of CT or MR enterography is a matter of local preference as neither modality has been shown to be superior to the other in diagnostic yield.<sup>14</sup>

## **Small Bowel Endoscopy**

VCE is now widely used in the diagnosis of small bowel tumors in patients with otherwise negative diagnostic studies. The device is an ingestible 11 × 26 mm capsule, swallowed by the patient, that contains a miniature video camera, light source, battery, and transmitter that sends images (up to 50,000 overall) to a recording device worn by the patient. Currently, the device does not have the capacity for biopsies or for precise localization of lesions, although relative position can be discerned. The device can be very useful in identifying lesions within the lumen of the small bowel. The major complication of VCE is capsule retention, which is reported in 5% of cases, although the rate of requirement for surgical retrieval is less than 1%.<sup>15</sup>

Direct luminal examination of the small bowel is best accomplished with double-balloon enteroscopy (DBE). Using an enteroscope, overtube, and balloon-pump system, a series of push-and-pull maneuvers are used to intubate more of the bowel either antegrade or retrograde. Although, procedures are longer with DBE, some studies have shown advantages in depth intubated and increased findings requiring treatment.<sup>16</sup>

With widespread availability and utilization of VCE and DBE, the detection of small bowel tumors has increased. An advantage of DBE is the ability to obtain biopsy tissue for diagnosis and to place localizing tattoos to guide subsequent surgical resection.

Intraoperative enteroscopy, coupling surgically facilitated intubation of the small bowel with direct extraluminal observation during surgery, allows a more complete evaluation of the small bowel. It is of value in detection of occult bleeding from the small bowel but is rarely used for the diagnosis of small bowel tumors, because most can usually be readily identified by careful palpation or visualization of the bowel once operation is pursued.<sup>13,16</sup>

## **BENIGN TUMORS OF THE SMALL INTESTINE**

Although they account for 30% to 50% of primary neoplasms of the small

bowel, benign tumors are poorly characterized. Half of patients with benign tumors are symptom free, and most will be diagnosed at the time of presentation with a surgical emergency such as obstruction, gastrointestinal hemorrhage, or perforation. Gastrointestinal bleeding is the most common presenting complication, presumably a consequence of spontaneous necrosis when the benign lesion outgrows the available blood supply.<sup>5</sup>

Once these lesions are diagnosed, surgical segmental intestinal resection is appropriate. Although local excision via endoscopic mucosal resection or operative enterotomy with submucosal excision is feasible, it is generally not possible to grossly differentiate between benign and malignant lesions. Hence, transmural resection is preferred for indeterminate lesions. Open and laparoscopic approaches have been described.

## **Brunner Gland Adenomas**

Brunner gland adenomas are rare tumors of the proximal duodenum.<sup>17</sup> Originating in the Brunner glands of the duodenal submucosa that secrete alkaline bicarbonate-rich fluid and mucus, the pathogenesis of glandular hyperplasia and subsequent adenoma formation from this cell population remains unknown. Although Brunner gland adenomas have not been described to transform into carcinomas, endoscopic mucosal resection is advised to prevent complications including acute and chronic bleeding.

## **Adenomas**

As in the colon, small bowel adenomas are histologically classified as tubular, tubulovillous, or villous. Most common in the periampullary region, they can develop throughout the small bowel mucosa. Increased size correlates with malignant potential, and excision is advised when diagnosis is established, often as an incidental finding. Adenomas larger than 2 cm in diameter should be considered worrisome for malignancy. Large, periampullary duodenal adenomas may present with obstructive jaundice. In these cases, ultrasound will reveal evidence of biliary obstruction, prompting upper endoscopy with endoscopic retrograde biliary and pancreatic duct evaluation (endoscopic retrograde cholangiopancreatography), which will reveal the presence of the ampullary lesion. Without these physical signs to

direct the workup, duodenal adenomas are detected during evaluation of gastrointestinal blood loss or other abdominal complaints, with either contrast upper gastrointestinal series or esophagogastroduodenoscopy (EGD), which are equally sensitive in most series. Adenomas usually appear as intraluminal filling defects and may be pedunculated. CT scan may differentiate adenoma from carcinoma, as carcinomas are often associated with bowel wall thickening. Endoscopic ultrasound is most useful in the evaluation of duodenal adenomas to evaluate depth and to determine if mucosal excision or surgical resection is more appropriate. Transduodenal local excision for small lesions is appropriate, whereas lesions >3 cm in size have a high rate of associated malignancy and are most appropriately treated with either pancreas-sparing duodenectomy or pancreaticoduodenectomy for larger lesions or periampullary tumors in suitable operative candidates.<sup>18</sup> Surgical series of resected ampullary adenoma report in situ or frank adenocarcinoma in 34% to 40% of patients. Local recurrence is common for periampullary adenomas treated with excision only; recurrence rate was 40% at 10 years, 25% of which were malignant, in a retrospective series from the Mayo Clinic. For patients treated with excision only, annual surveillance with endoscopy is appropriate.<sup>19</sup>

## **Lipomas**

Lipomas of the gastrointestinal tract are typically identified as incidental findings on abdominal imaging. They rarely cause symptoms, although as polypoid, compressible intraluminal lesions, they may serve as lead points for intussusception. Lipomas are circumscribed lesions arising in the bowel wall appearing as fat density on CT imaging. Small tumors under 2 cm require no intervention, whereas larger lesions or growing lesions should be resected to rule out malignant liposarcoma.

## **Hamartomas**

The hamartoma is the characteristic lesion of Peutz-Jeghers syndrome, an autosomal dominant condition characterized by multiple gastrointestinal hamartomas and mucocutaneous pigmentation. The tumors are widely distributed throughout the bowel in affected individuals and, in rare cases, are

associated with intussusception, bleeding, or obstruction. While malignant transformation has been described, this is a rare event. Given the broad distribution of the tumors, prophylactic excision is not feasible and surgical intervention is appropriate only to treat complications caused by the tumors.<sup>12</sup>

## Hemangiomas

Hemangiomas are rare congenital lesions of the small bowel. They appear to grow slowly and may become symptomatic in midlife, when acute or chronic bleeding may develop. Arising from the submucosal vascular plexuses, hemangiomas are usually solitary and not at risk for malignant transformation. Hemangiomas associated with bleeding should be locally excised or resected with a limited small bowel resection. Endoscopic sclerotherapy or angiographic embolization has also been reported as a treatment option depending on the size and position of the tumor.

## Leiomyomas

Leiomyomas are rare benign tumors arising from the smooth muscle and stromal cells of the small intestine. Comprised of benign-appearing smooth muscle and stromal cells, they are distinguished from GISTs by molecular features, notably the absence of *cKit* mutations. These benign lesions are typically clinically silent. Often growing as extraluminal pedunculated lesions, they may present with mucosal ulceration, particularly in tumors originating in the duodenum; gastrointestinal hemorrhage; and bleeding. Symptomatic lesions warrant surgical resection (Fig. 39-2C).

A

D

**FIGURE 39-2** Gross appearance of tumors of the small intestine. **A.** Primary adenocarcinoma of the ileum demonstrating circumferential, extensively ulcerated, irregular mass on the mucosal surface with transmural tumor invasion showing thickening and retraction of the bowel wall. Diagnosis was established by CT with CT enterography. **B.** Renal cell carcinoma metastatic to the jejunum. This hemorrhagic focal lesion presented with occult gastrointestinal bleeding. Diagnosis was established by video capsule endoscopy. **C.** Leiomyoma of the second portion of the duodenum. This pedunculated extraluminal lesion presented in a patient with abdominal pain. A Whipple resection was performed anticipating GIST tumor. Final pathology revealed benign leiomyoma. **D.** GIST tumor of the ileum. Patient presented with intussusception diagnosed by CT. Surgical resection of nonreduced bowel performed.

# MALIGNANT NEOPLASMS

The small bowel can give rise to a number of different primary tumors and is also a site for metastasis from tumors of other origins. Primary malignancies include adenocarcinoma, GIST, carcinoid, lymphoma, and leiomyosarcoma, with rare reports of other lesions including liposarcoma, myxoliposarcoma, and lymphangiosarcoma. Metastatic tumors may come from any other cancer, but the most common metastatic lesions are from melanoma and lymphomas.

Malignant tumors are much more likely to elicit symptoms than benign tumors, including abdominal pain, weight loss, anorexia, and acute or chronic blood loss. As a group, patients with malignant small bowel tumors present at advanced stages and have a poor prognosis.

Up to 30% of patients with small bowel malignancy develop a second primary tumor in another organ. For patients with SI-NET (carcinoid) tumors, the incidence of second primaries is 50%. The second primary cancer may arise in any organ, but the most frequent second primary sites are the colorectum and breast.<sup>20,21</sup>

## Adenocarcinoma

### EPIDEMIOLOGY

Adenocarcinoma accounts for about 35% of small bowel tumors, making it the most common primary malignancy.<sup>7</sup> The frequency of small bowel tumors decreases along the length of the small bowel, with 80% located in the duodenum and proximal jejunum. Men are slightly more likely to develop adenocarcinoma than women. Risk factors for development of adenocarcinoma include polyposis syndromes, Crohn's disease, and celiac disease.

### CLINICAL PRESENTATION

Clinical presentation is dictated by the size and position of the tumor. Large tumors form the classic circumferential annular "apple core" constriction, leading to obstruction with symptoms of anorexia, vomiting, and crampy pain. Periampullary lesions may cause biliary obstruction with secondary jaundice. Absent advanced or strategically placed lesions with obstruction,

the only complaint may be vague, persistent abdominal pain.

## **DIAGNOSIS**

For patients with advanced lesions, plain abdominal films may show gastric distention or proximal small bowel obstruction. For the jaundiced patient, ultrasound or abdominal CT or MR cholangiopancreatography (MRCP) may demonstrate the duodenal mass and site of biliary obstruction. Upper gastrointestinal contrast studies and EGD have equal diagnostic rates of 85% to 90%, but EGD allows diagnostic tissue biopsy. CT reveals approximately 50% of small bowel adenocarcinomas, and the appearance is that of a heterogeneous infiltrating mass. Despite diagnostic strategies, preoperative diagnosis of cancers beyond the duodenum is achieved in only 20% to 50% of cases.

## **MANAGEMENT**

Surgical resection offers the only potential cure ([Fig. 39-2A](#)). Many patients have intra-abdominal metastases at initial surgery, with R0 resection (ie, no gross or microscopic disease left) achieved in only 50% to 65% of cases. Pancreaticoduodenectomy is appropriate for proximal duodenal tumors. In the third and fourth portions of the duodenum and in the mesenteric small bowel, a segmental resection with lymphadenectomy should be performed. Palliative procedures to relieve obstruction or control hemorrhage should be completed at the time of exploration for patients with metastatic disease. Endoscopic expandable stents may be the best strategy to palliate proximal gastrointestinal obstruction from recurrent or metastatic disease. Gastrojejunal bypass or gastrostomy tubes may be of palliative value for decompression or nutritional support in patients with carcinomatosis or unresectable disease.

## **STAGING AND PROGNOSIS**

The American Joint Committee on Cancer staging system applies to small bowel adenocarcinoma.<sup>22</sup> The tumor (T) classification describes depth of invasion, with T1 and T2 lesions within the bowel wall and T3 and T4 lesions penetrating the bowel wall. The node (N) classification is defined by the

presence or absence of lymph node metastases, and distant metastases are classified by M. Most patients present with stage III (lymph node involvement) or stage IV disease (distant metastases), which carry a poor prognosis.

The most significant prognostic factor is lymph node metastases, with poor survival linked to node-positive disease. Likely due to limited reported experience, the primary tumor features, including the degree of differentiation, do not appear to impact survival. Positive margins, extramural venous spread, positive lymph nodes, and a history of Crohn's disease are associated with poor prognosis.<sup>6</sup>

Adjuvant therapies including chemotherapy and/or radiation therapy have not demonstrated efficacy, although clinical trials are ongoing.<sup>20</sup> The rare nature of this tumor, with advanced-stage presentation, precludes development of clinical trials.

## **Non-Hodgkin Lymphoma**

The gastrointestinal tract is the most common extranodal site for development of NHL, comprising approximately 20% of all cases of NHL. Most gastrointestinal lymphomas arise in the stomach (60%), followed by the small bowel (30%), and then the colon. Small bowel lymphomas are distributed in the jejunum and ileum, reflecting the distribution of lymphoid tissue in the bowel. Diagnostic criteria for primary gastrointestinal NHL include the absence of superficial adenopathy on physical examination, absence of mediastinal adenopathy by chest imaging, normal peripheral blood cell counts, and absence of splenic or hepatic involvement. At surgery, disease must be restricted to the primary tumor with mesenteric lymph node involvement.<sup>23</sup>

The majority of cases of primary intestinal NHL are B-cell type with T-cell lymphoma composing only 10–25%. Low-grade lymphomas derived from mucosal-associated lymphoid tissue (MALT) typically arise in the stomach in association with *Helicobacter pylori* infection. These tumors may regress with treatment of this infection.<sup>24,25</sup> T-cell lymphomas tend to have a worse prognosis than B-cell tumors.

## **CLINICAL PRESENTATION**

The majority of patients present with nonspecific abdominal complaints. Malabsorption, obstruction, or palpable mass may be present. Although rare, small intestinal lymphomas may present with perforation.

## DIAGNOSIS

Lymphomas may grow to large size before clinical symptoms present. Most small bowel lymphomas will be demonstrable on CT scan as a mass, bowel wall thickening, displacement of adjacent organs, or luminal obstruction. Multiple lesions are present in 10% to 25% of patients. Tissue diagnosis requires biopsy of the submucosal lesion by endoscopy or CT-guided biopsy.

## STAGING AND PROGNOSIS

Staging is based on site involvement as outlined in [Table 39-1](#). Like tumors elsewhere in the small intestine, most patients present with stage III or IV disease. Fewer than 30% of patients have surgically resectable tumors, and prognosis is poor.<sup>22</sup>

**TABLE 39-1: STAGING FOR LYMPHOMA**

- Stage I Involvement of a single lymph node region; or localized involvement of a single extralymphatic organ or site in the absence of any lymph node involvement
- Stage II Involvement of 2 or more lymph node regions on the same side of the diaphragm; or localized involvement of a single extralymphatic organ or site in association with regional lymph node involvement, with or without involvement of other lymph node regions on the same side of the diaphragm
- Stage III Involvement of lymph node regions on both sides of the diaphragm, which also may be accompanied by extralymphatic extension in association with adjacent lymph node involvement, or by involvement of the spleen, or both
- Stage IV Diffuse or disseminated involvement of 1 or more extralymphatic organs, with or without associated lymph node involvement; or isolated extralymphatic organ involvement in the absence of adjacent regional lymph node involvement, but in conjunction with disease in distant site(s); any involvement of the liver or bone marrow, or nodular involvement of the lungs
- 

Data from American Joint Commission on Cancer. *Cancer Staging Handbook*, 6th ed. New York, NY: Springer; 2002.

## **TREATMENT**

With no randomized series and small series at single institutions, the optimal treatment of gastrointestinal NHL remains controversial. Most agree that surgical resection of isolated small bowel lymphoma for local control and prevention of perforation and bleeding are the cornerstones of treatment. For more extensive gastrointestinal lymphoma, there is no evidence-based consensus on optimal management, although a variety of chemotherapeutic regimens have been used.<sup>23,24</sup>

## **SMALL INTESTINAL NEUROENDOCRINE**

## TUMORS

SI-NETs, previously known as carcinoid tumors,<sup>26</sup> arise from the enterochromaffin cells at the base of the crypts of Lieberkühn. This redesignation was initiated based on the recognition that these tumors share cellular origin and synthetic capability of NETs originating throughout the mucosal surfaces of the body. Enterochromaffin cells are capable of amine precursor uptake and decarboxylation (APUD), and tumors derived from these can secrete vasoactive peptides responsible for the carcinoid syndrome. Eighty percent of NETs arise in the gastrointestinal tract, 10% in the bronchus or lung, and others in rare sites including the ovaries, testicles, pancreas, and kidneys. The appendix is the most common site in the gastrointestinal tract for primary NET, followed by the small bowel where these tumors are noted as SI-NETs (Table 39-1). Thirty percent of SI-NETs arise in the jejunum or ileum and have the most aggressive clinical features.

SI-NETs represent 5% to 35% of small bowel neoplasms; the mean age of presentation is 60 years with a slight male preponderance. Autopsy rates reveal that the incidence of occult tumors is approximately 2000 times that of the annual clinical incidence rate, indicating that the overwhelming majority never develop clinical findings.<sup>24,27</sup>

## CLINICAL PRESENTATION AND DIAGNOSIS

Most SI-NETs grow slowly and have insidious clinical manifestations; in hindsight, symptoms may be present for 2 to 20 years before diagnosis. Carcinoid syndrome secondary to metastatic disease is the presenting sign in 40% of patients. Rarely, intestinal necrosis secondary to desmoplastic occlusion of the mesenteric vessels may develop, leading to initial presentation as a surgical emergency.

The most common presenting symptom for patients with SI-NET is abdominal pain. The polypoid lesion serves as a lead point for intussusception characterized by intermittent symptoms and signs of obstruction. Abdominal films often demonstrate a distal small bowel obstruction, and the CT findings of intussusception are distinctive, demonstrating a multilayer ringed structure in the ileocolic region (Fig. 39-3).

**FIGURE 39-3** Concentric rings in the soft tissue mass in the right lower quadrant reveal an ileocolic intussusception. An ileal carcinoid tumor was the lead point.

Appendiceal NETs are typically solitary lesions. However, for carcinoids arising in other areas of the gut, multiple tumors are observed in 3% to 40% of patients.<sup>28</sup> In addition, 30% to 50% of SI-NETs are associated with second primary malignancies, most frequently of the breast and colon. SI-NETs have the capacity to elicit a marked desmoplastic reaction in the mesentery of the small bowel. The fibrotic reaction can cause sclerosis of mesenteric vessels, leading to kinking of the bowel or intestinal ischemia and necrosis. The fibrosis affects not only peritumoral tissues but also distant tissues in the heart and lungs and is attributed to the humoral products of the tumors, although the specific factors are unknown.<sup>29,30</sup>

## **STAGING AND PROGNOSIS**

Appendiceal NET, even at a small size, may cause appendicitis due to

luminal compression; hence, early diagnosis of appendiceal carcinoid is common. In contrast, SI-NETs exhibit a more aggressive phenotype and are frequently associated with lymph node spread and hepatic metastasis at initial presentation. Tumor size is proportional to the risk for metastatic spread. For SI-NETs smaller than 1 cm, there is a 20% to 30% incidence of nodal and hepatic spread. Tumors 1 to 2 cm in size have nodal spread in 60% to 80% of cases and hepatic disease in 20% of cases. The rates of nodal and hepatic metastasis for tumors larger than 2 cm is >80% and 40% to 50%, respectively.<sup>27</sup> Only very small SI-NETs (ie, <1 cm) can be treated with local excision. All others should be treated with segmental bowel and mesenteric resection.<sup>31</sup>

## **CARCINOID SYNDROME**

Carcinoid syndrome refers to vasomotor, gastrointestinal, and cardiac manifestations induced by systemic circulation of peptides produced by carcinoid tumors. The APUD cells of carcinoid tumors can produce vasoactive products including serotonin, histamine, kallikrein, bradykinin, and prostaglandins, although the specific mediator or mediators of the syndrome remain unknown. Carcinoid syndrome is confirmed by finding elevated 24-hour 5-hydroxyindoleacetic acid (5-HIAA) urinary excretion, the primary stable metabolite of serotonin. In addition to 24-hour urinary 5-HIAA, disease burden may also be assessed by plasma chromogranin A levels; other biomarkers including pancreastatin have been described.<sup>32</sup>

Attacks are characterized by intense flushing and tachycardia. Watery diarrhea, at times explosive and associated with cramping, may occur in some patients. Attacks may be spontaneous or precipitated by stress, alcohol, a large meal, or sexual intercourse. Flushing, a 5- to 10-minute sensation of heat associated with facial and truncal erythema, is the most common finding and affects approximately 80% of patients. Diarrhea occurs in most patients and is likely related to serotonin release, as serotonin antagonists can effectively treat this symptom. Abdominal cramps and malabsorption may occur. Cardiac manifestations are present in 60% to 70% of patients with advanced disease, due to tricuspid and pulmonary valve endocardial fibrosis, possibly secondary to high levels of 5-HIAA. As the disease progresses, the fibrotic plaque stiffens, leading eventually to right heart failure.

Carcinoid syndrome is due to metastatic tumor in either the liver or

retroperitoneum. Monoamine oxidase in the liver metabolizes serotonin to metabolites without vasomotor activity, one of the major effector hormones. Carcinoid syndrome occurs when metabolically active tumor is present in a site without portal drainage, such as a bronchial carcinoid or retroperitoneal tumor, or when hepatic metastatic tumor burden exceeds the capacity of hepatic monoamine oxidase to metabolize serotonin. Patients with gastrointestinal NETs that drain into the portal circulation must have metastatic disease prior to the development of the syndrome.

Management of patients with carcinoid syndrome due to metastatic hepatic tumor burden is optimized by utilization of surgical, image-guided interventional procedures and medical therapies. Given the relatively slow growth of NETs, including metastatic disease, surgical debulking of extensive hepatic disease or formal hepatic resection for resectable metastases can improve symptoms and prolong life. Five- and 10-year survival for patients with residual abdominal tumor and hepatic metastases exceeds 60%. While in general the initial surgery for resection of NET burden, including hepatic metastases, should attempt to debulk as much tumor as possible, the procedure must be planned to avoid catastrophic injuries, such as those to the superior mesenteric vessels, that could lead to short-gut syndrome.<sup>33</sup> Hepatic artery embolization or radiofrequency ablation may be more appropriate for widespread hepatic metastases and can give marked symptomatic relief and durable tumor control.<sup>34</sup>

Medical therapy is based on somatostatin analogues (octreotide), including short- and long-acting peptides for relief of carcinoid syndrome symptoms. NETs express somatostatin receptors, and the somatostatin analogues inhibit vasoactive peptide release from carcinoid tumors. Palliation of symptoms is effective in 90% of patients with octreotide. Some studies have demonstrated a tumor static or tumor reduction effect after the administration of somatostatin, although these latter findings have not been consistently reproduced. Efficacy of treatment can be documented by following excretion of tumor markers.

Chemotherapeutic agents for the treatment of metastatic carcinoid tumor include doxorubicin, fluorouracil, dacarbazine, and interferon- $\alpha$ , with response rates of approximately 20%. Combination protocols most often use streptozotocin and fluorouracil. Newer regimens include everolimus.

Preliminary reports on the use of targeted radiotherapeutics have been presented. Somatostatin analogues bind to somatostatin receptors on

carcinoid tumors with high affinity. After binding, the ligand-receptor complex is internalized. This internalization has led to the development of “smart bombs,” which are radiolabeled somatostatin analogues that theoretically deliver radiation specifically to carcinoid cells. <sup>111</sup>Indium-labeled pentetreotide demonstrated an enhanced tumor regression response compared to unlabeled analogue in one study.<sup>35</sup> However, these labeled moieties have not proven as effective as surgical resection or ablative procedures and therefore should be considered secondary options.

## **Gastrointestinal Stromal Tumors**

Although GISTs are the most common nonepithelial mesenchymal tumors of the small bowel, they are rare tumors of the gastrointestinal tract, representing only 0.2% of all gastrointestinal tumors. Approximately 30% to 35% of GIST arise in the small bowel, with 50% to 60% gastric and 5% colon and rectal in origin.<sup>36</sup> Men and women are equally at risk, and peak incidence occurs in patients age 50 to 70 years. Rarely, tumors can arise in patient younger than 20 years of age, usually in the setting of familial syndromes such as Carney triad, familial GIST syndrome, and neurofibromatosis type 1. GIST tumors arise from the interstitial cells of Cajal, the pacemaker cells of the GI tract intercalated between the intramural neurons and the smooth muscle cells. The molecular diagnostic feature of GIST is the presence of activating c-kit mutations, a transmembrane receptor tyrosine kinase involved in the regulation of cellular proliferation, apoptosis, and differentiation. More than 90% of GISTs express kit (CD117) mutations, a molecular marker that distinguishes them from histologically similar mesenchymal tumors of the small bowel including leiomyomas, leiomyosarcoma, schwannomas, and others.<sup>37</sup> Retrospective molecular analysis of mesenchymal tumors has led to reclassification of up to 70% of small bowel tumors as GISTs that had previously been classified as a variety of mesenchymal tumors.<sup>36,38</sup>

GISTs are characterized by indolent clinical symptoms including vague abdominal pain, weight loss, and occult gastrointestinal bleeding. Of all small bowel tumors, GISTs often grow to a large size before surgical presentation. They tend to grow insidiously as extraluminal masses from their submucosal origin in a noninvasive manner, characteristically pushing adjacent organs

away from the expanding mass. Gastrointestinal hemorrhage may develop in patients with necrotic GIST in communication with the bowel lumen.

Given the propensity of GISTs to grow to a large size prior to diagnosis, CT scan is most likely to be the initial positive test. A characteristic finding is the presence of a large space-occupying mass, often with evidence of central necrosis and compression of adjacent organs and calcifications.

Regardless of size, all GISTs should be considered to be malignant.<sup>36</sup> Malignant potential is determined by 2 major criteria: tumor size and mitotic rate. Biologically aggressive tumors are large tumors with a high mitotic index, whereas tumors with benign features are small and exhibit a low mitotic index. Thus, tumors are classified ranging from very low to high risk for malignant potential, a classification that has prognostic significance (Table 40-2).

## TREATMENT

Surgery is the primary therapeutic option, with the goal being complete resection. At operation, wide local excision of the primary tumor to achieve gross negative margins with incontinuity resection of adherent organs is appropriate to attain curative resection (Fig. 39-2D). Lymph node metastasis is rare, negating the need for wide mesenteric resection. Laparoscopic resection has been shown to be safe and oncologically sound.<sup>36</sup>

**TABLE 39-2: PROGNOSTIC FEATURES OF SMALL BOWEL  
GASTROINTESTINAL STROMAL TUMORS**

Tumor Features		Risk of Progression
Mitotic Index	Size (cm)	Small Bowel
<5 per 50 high-power fields (HPF)	≤2	Very low
	>2 and ≤5	Low
	>5 and ≤10	Moderate
	>10	High
≥5 per 50 HPF	≤2	Moderate
	>2 and ≤5	High
	>5 and ≤10	High
	>10	High

## MOLECULAR THERAPEUTICS AND GIST

Given the central role of activating mutations in the tyrosine kinases KIT and, more recently, platelet-derived growth factor receptor alpha (PDGFRA) in the pathogenesis of GIST,<sup>37</sup> this tumor has served as a prototype for molecular therapeutic drug development. Activation of KIT leads to phosphorylation of a receptor substrate protein, initiating an intracellular phosphorylation cascade leading to nuclear activation of transcription events, resulting in cell proliferation and survival. The discovery of a drug that inactivates KIT with a safe therapeutic margin has revolutionized the treatment of metastatic GIST. Imatinib mesylate is a small molecule that occupies the adenosine triphosphate binding pocket of the KIT kinase domain, blocking phosphorylation of the receptor and intracellular signaling. This binding arrests cellular proliferation and survival signaling.

Clinical use of imatinib is now routine in the management of GIST. This oral agent is well tolerated and highly effective for patients with metastatic GIST. While complete regression of tumor is rare, partial regression of disease and arrest of progression of disease can be achieved for durable intervals with continuous treatment in up to 80% of patients. Efficacy of treatment can be predicted and followed using fluorodeoxyglucose-PET scanning; these highly biologically active tumors will become metabolically silent with imatinib therapy in patients with responsive tumors. Emergence of

resistant clones within tumors has been recognized with prolonged use of imatinib. Some patients show a partial response or lack of disease progression with dose escalation of imatinib. However, newer receptor tyrosine kinase inhibitors, including sunitinib malate and regorafenib, have demonstrated efficacy for patients with tumor recurrence and resistance to imatinib with increased progression-free and overall survival.<sup>39,40</sup>

Neoadjuvant use of imatinib has been shown to result in a 70% response rate, yet based on current available evidence, it is still unclear whether preoperative therapy for GIST results in a clinically significant effect, leading to increased resectability or enhanced long-term survival.<sup>41</sup> The efficacy of imatinib in the adjuvant setting has been evaluated in the American College of Surgeons Oncology Group Z9001 trial, which found improved disease-free survival for patients with tumors greater than 3 cm who received imatinib.

## **Metastatic Lesions to the Small Bowel**

Although metastases to the small bowel are rare as a group, they are more common than primary small bowel neoplasms.

Metastatic spread can occur by direct invasion, hematogenous spread, or intraperitoneal seeding. Colon and pancreatic cancers are the most common primary sites for direct invasion. Hematogenous metastases spread most frequently from lung and breast carcinoma or melanoma. Peritoneal seeding may arise from any intra-abdominal malignancy including gastric, hepatic, ovarian, appendiceal, and colonic primary tumors.<sup>42</sup>

CT scan may identify metastatic lesions or reveal sites of partial or complete luminal obstruction. Metastases can be identified as bowel wall thickening or mesenteric masses. For small lesions, CT scan may be negative, whereas small bowel follow-through studies may reveal an irregular luminal filling defect. Carcinomatosis is frequently not specifically identifiable on imaging studies, although PET-CT is useful for identification of small bowel metastases in some tumor types.

Optimal palliative management is based on clinical criteria. Segmental intestinal resection (Fig. 39-2B) or bypass to relieve hemorrhage, obstruction, or pain is indicated except in late terminal stages of disease. Although cases of prolonged survival after intestinal resection of solitary metastases have been reported, progression of metastatic disease is more common.

Management of patients with carcinomatosis, regardless of tumor origin, remains challenging. Endoscopic luminal stents for obstructing duodenal lesions may offer short-term palliation, whereas intestinal bypasses and decompressive gastrostomy tubes are indicated for patients with advanced or more distal disease to enhance palliative care.

# CARCINOID TUMORS AND CARCINOID SYNDROME

*Teresa S. Kim • Liliana G. Bordeianou • Richard A. Hodin*

## INTRODUCTION

The term “karzinoide” was first used in 1907 by pathologist Siegfried Oberndorfer to describe small intestinal tumors that resembled carcinomas on histology, but behaved less aggressively clinically.<sup>1</sup> In the current literature, carcinoids refer to well-differentiated, low-to-intermediate-grade neuroendocrine tumors (NETs) of the bronchopulmonary and gastrointestinal (GI) tracts.<sup>2</sup> By definition, NETs are epithelial neoplasms with both neural and endocrine differentiation, which arise from many different cell types of the neuroendocrine system.<sup>2</sup> Carcinoids represent a diverse subset of NETs, which exhibit slow growth but variable clinical presentation, growth pattern, and prognosis, depending on anatomic site and cell of origin.<sup>2-4</sup> This chapter describes the clinical behavior of GI carcinoids, as well as their diagnosis and management by anatomic site. It concludes with a brief description of metastatic carcinoid and carcinoid syndrome, a rare but potentially life-threatening presentation.

## EPIDEMIOLOGY

GI carcinoids account for 0.5% of all newly diagnosed cancers and 71% of all NETs.<sup>5</sup> Several large population studies have been conducted to document the incidence of GI carcinoids, their distribution across anatomic sites, and trends in incidence and outcomes over time, based on data from the national U.S. Surveillance, Epidemiology, and End Results (SEER) registry.<sup>5-7</sup> In one series of 11,427 patients with NETs reported to SEER between 1973 and 1997, the average age at diagnosis was 61 years, and cases were distributed evenly across gender.<sup>6</sup> The majority of NETs arose in the GI tract (55%), followed by the bronchopulmonary tract (30%), pancreas (2%), and other rare sites including, in decreasing order, gynecologic, biliary, head and neck, and genitourinary systems.<sup>6</sup> Among GI carcinoids, the small intestine was the most common site (45%, predominantly ileum), followed by rectum (20%), appendix (17%), colon (11%), then stomach (7%) (Fig. 40-1).<sup>6</sup> Notably, pancreatic NETs were considered separately from GI carcinoids in this study. A more recent SEER-based series of 25,531 patients with histologically confirmed GI carcinoid tumors demonstrated similar findings, with 38% of cases arising in the small intestine, 34% in the rectum, 16% in the colon, and 11% in the stomach.<sup>5</sup> Appendiceal tumors were not considered separately in this latter analysis.

**FIGURE 40-1** Small intestine is the most common site of GI carcinoid. Based on 6145 cases of GI carcinoid reported to the U.S. SEER registry. (Data from Maggard MA, O'Connell JB, Ko CY: Updated population-based review of carcinoid tumors, *Ann Surg* 2004 Jul;240(1):117-122.)

The incidence of NETs has increased over the past 4 decades, with one study showing an increase of approximately 0.85 to 3.84 per 100,000 between 1973 and 1997.<sup>6</sup> A more recent series estimates the annual incidence of GI carcinoid tumors to be 5 per 100,000,<sup>7</sup> with the largest increases noted in localized tumors and those of the small intestine, rectum, and stomach.<sup>5</sup> More widespread use of axial imaging and endoscopy may partially explain this increase in diagnosis and incidence.

## CLINICAL PRESENTATION

GI carcinoids generally present in one of three ways: (1) incidentally on endoscopy or axial imaging, as with many gastric and rectal tumors, or within a surgical specimen, as with an appendiceal carcinoid following appendectomy for appendicitis; (2) with locoregional symptoms, such as abdominal pain, bowel obstruction, bleeding, or bowel ischemia, due to local

tumor growth or regional nodal invasion with surrounding mesenteric fibrotic reaction; or (3) with carcinoid syndrome, ie, chronic flushing, diarrhea, and, if advanced, heart failure, most often in the setting of midgut carcinoid metastatic to the liver.<sup>8–10</sup> The locoregional symptoms vary by primary tumor location. Intestinal obstruction and bleeding are most common with small intestinal carcinoids, rectal bleeding and pain tend to occur with rectal carcinoids, weight loss and abdominal pain are more frequently seen with colonic carcinoids, vomiting occurs with gastric carcinoids, and jaundice and upper GI bleeding are most often associated with duodenal and periampullary carcinoids.<sup>4</sup>

About half of all cases present with localized disease, while another quarter each present with regional or distant metastases.<sup>5,6</sup> Notably, patients with carcinoid tumors also have a higher incidence of additional primary cancers compared with the general population. Approximately 25% of patients harbor second malignancies of the small intestine, stomach, or extra-intestinal sites such as the thyroid and kidney.<sup>5</sup>

## GENERAL TUMOR LOCALIZATION AND STAGING

Nonspecific symptoms often necessitate further laboratory and radiologic evaluation to localize the tumor and confirm the diagnosis of carcinoid. Two commonly used biochemical tests are serum chromogranin A (CgA) level and 24-hour urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA).

CgA is a glycoprotein involved in intracellular vesicular transport. It is synthesized and secreted along with other peptide hormones by many types of non-neoplastic and neoplastic neuroendocrine cells.<sup>3,8</sup> The serum CgA level is elevated in about 90% of GI carcinoids, both functional and nonfunctional, and correlates with tumor burden.<sup>3,11</sup> It can be falsely elevated in many settings, however, including proton pump inhibitor therapy, pancreatic and small cell lung cancer, chronic renal insufficiency, and atrophic gastritis.<sup>3,8</sup> Therefore, it is a sensitive but nonspecific marker of GI carcinoid. As a consequence, it is less useful for screening or initial diagnosis and more suited for assessing treatment response or disease progression. Of note, CgA staining on immunohistochemical analysis is an important marker

used in the histologic diagnosis of NETs.<sup>11</sup>

Urinary 5-HIAA is a less sensitive but more specific test for carcinoid. A degradation product of serotonin (5-hydroxytryptamine [5-HT]), 5-HIAA is one of the most commonly secreted hormones from GI carcinoid tumors.<sup>11</sup> At the molecular level, tryptophan is taken up by neuroendocrine cells, hydroxylated to 5-HT, decarboxylated to serotonin, then stored in granules and ultimately secreted into the bloodstream, after which it is metabolized to 5-HIAA and excreted in the urine.<sup>8</sup> As a diagnostic test, 24-hour urinary excretion of 5-HIAA is most accurate for detecting midgut carcinoids metastatic to the liver and/or associated with carcinoid syndrome, with an estimated 70% sensitivity and 90% specificity.<sup>11</sup> Sensitivity is lower in the absence of carcinoid syndrome, in the setting of low-volume tumor burden, or for foregut and hindgut carcinoids, which rarely produce serotonin.<sup>3,11</sup> Specificity is limited by false positive elevations of urinary 5-HIAA, eg, in the setting of a tryptophan-rich diet.<sup>8,9</sup> Overall, the laboratory evaluation plays a limited role in the initial diagnosis of GI carcinoid, warranting further investigation.

Endoscopy and axial imaging are essential to tumor localization and staging. Endoscopy permits tissue sampling and gross visualization of primary carcinoids arising in the stomach, duodenum, terminal ileum, colon, and rectum. Multidetector computed tomography (CT) of the abdomen and pelvis, with arterial and venous phase intravenous (IV) contrast enhancement, can sometimes detect primary GI carcinoid tumors, which appear as solid hyperattenuating intraluminal masses on multidetector CT.<sup>10</sup>

CT is much more useful in delineating regional and distant metastases. For midgut carcinoids metastatic to regional lymph nodes, CT clearly depicts the characteristic mesenteric desmoplastic reaction, which manifests as an irregular, spiculated soft tissue mass infiltrating the mesenteric fat, often with associated calcifications, tethering, or kinking of adjacent bowel loops, and in some cases encasement of branches of the superior mesenteric vessels.<sup>10</sup> CT is also able to detect hypervascular liver metastases with approximately 80% sensitivity and 90% specificity.<sup>9</sup>

Magnetic resonance imaging (MRI) is useful for equivocal liver lesions. Carcinoid metastases generally demonstrate a T2-intense signal and rapid arterial enhancement with washout of contrast on later venous phase images.<sup>10</sup> In the setting of metastatic disease or carcinoid syndrome with an

occult primary, additional nuclear imaging with somatostatin receptor scintigraphy (eg, Octreoscan) may add useful information. Somatostatin receptor scintigraphy utilizes tumor cell–specific somatostatin receptor expression and a radiolabeled somatostatin analog (eg, 111-indium pentetreotide) to localize tumor, with variable sensitivity, which is reported to be about 2% to 23% and 80% to 90% for primary and metastatic carcinoids, respectively.<sup>4,12</sup>

Tissue diagnosis is ultimately confirmed following biopsy or surgical resection. The characteristic histologic findings include the organization of neoplastic cells into nesting, trabecular, or gyriform patterns, the presence of intracellular secretory granules, and positive immunostaining for neuroendocrine markers, such as CgA, synaptophysin, and neuron-specific enolase.<sup>2,4,13</sup> Additionally, NETs are classified according to two cellular features: (1) degree of cellular differentiation, ie, similarity to their non-neoplastic neuroendocrine cell counterparts and (2) grade, ie, proliferative rate, as measured by the number of mitotic figures per 10 high-power microscopic fields, or immunostaining with the cellular proliferation marker Ki-67.<sup>2</sup> As previously mentioned, carcinoids are defined as well-differentiated, low-to-intermediate-grade NETs, which harbor lower malignant potential compared with poorly differentiated, high-grade neuroendocrine carcinoma (NEC).<sup>2</sup>

Several staging systems have been proposed by the American Joint Committee on Cancer (AJCC), World Health Organization (WHO), and European Neuroendocrine Tumor Society (ENETS). Although these systems vary slightly in tumor classification, they generally conform to the tumor-node-metastasis (TNM) paradigm that distinguishes localized disease from regional nodal or distant metastasis.<sup>2</sup> Details and implications for management and prognosis are discussed by anatomic site below. Treatment guidelines are also summarized in [Table 40-1](#). Ultimately, for any carcinoid tumor, the goal is to determine the site and extent of disease, to resect all tumor (R0 resection) if possible, and to palliate symptoms related to locoregional tumor growth and carcinoid syndrome.

**TABLE 40-1: MANAGEMENT OF GI CARCINOIDS DEPENDS ON TUMOR SITE, SIZE, AND STAGE**

Anatomic Site	Size (and Related Tumor Criteria)	Treatment
Stomach	Type I or II <1-2 cm	Endoscopic resection (consider antrectomy for numerous progressing Type I tumors; first treat hypergastrinemia source for Type II tumors)
	>2 cm (or muscularis propria invasion, poor differentiation, positive endoscopic resection margin, suspected nodal metastasis)	Partial or total gastrectomy and lymphadenectomy
	Type III Any size	Partial or total gastrectomy and lymphadenectomy (with preoperative staging evaluation for metastases)
Duodenum	<1 cm	Endoscopic resection
	>1 cm (or suspected nodal metastasis)	Transduodenal excision, segmental resection, or pancreaticoduodenectomy
Small intestine	Any size, resectable (based on mesenteric vascular involvement)	Small bowel resection and high mesenteric lymphadenectomy (with preoperative staging evaluation for metastases, and intraoperative evaluation for synchronous tumors)
Appendix	<1 cm	Appendectomy
	1-2 cm	Appendectomy (versus right hemicolectomy)
	>2 cm (or mesoappendix/base invasion, positive margin, high grade, goblet cell histology)	Right hemicolectomy and mesenteric lymphadenectomy
Colon	<2 cm	Endoscopic resection
	>2 cm	Segmental colectomy and high mesenteric lymphadenectomy with total mesocolic excision (with preoperative staging evaluation for metastases)
Rectum	<1 cm	Endoscopic resection
	1-2 cm (or incomplete endoscopic resection)	Local transanal excision (consider advanced technique, eg, TEM, for proximal or small, high-risk lesions)
	>2 cm (or muscularis propria invasion, high grade, incomplete local excision, suspected nodal metastasis)	Low anterior or abdominoperineal resection and total mesorectal excision (with preoperative EUS or MRI to stage tumor and regional nodes, and CT to evaluate for metastases)
Metastatic Disease	Carcinoid syndrome	Somatostatin analog therapy (octreotide), for symptom control; consider palliative resection
	Midgut carcinoid with metastases	Octreotide long-acting release, consider surgical resection for prolonged disease control

Abbreviations: CT, computed tomography; EUS, endoscopic ultrasound; MRI, magnetic resonance imaging; TEM, transanal endoscopic microsurgery.

## MANAGEMENT AND PROGNOSIS BY ANATOMIC SITE

### Gastric Carcinoid

Gastric carcinoids, of which there are three different types, generally arise from a subset of neuroendocrine cells called enterochromaffin-like (ECL) cells, which arise in the gastric fundus and body. Under normal conditions, these cells secrete histamine and stimulate neighboring parietal cells to produce acid in response to gastrin.<sup>14</sup> Consequently, gastric carcinoids usually are not associated with serotonin secretion or carcinoid

syndrome.<sup>14,15</sup> From a pathophysiologic standpoint, chronic gastrin stimulation leads to ECL cell hyperplasia and subsequent neoplasia.<sup>15</sup> Importantly, the clinical behavior and management vary significantly among the three types of gastric carcinoids, as detailed below.

Type 1 gastric carcinoids are the most common form, comprising 70% to 80% of cases.<sup>13,16</sup> These tumors arise from ECL cells in the setting of chronic atrophic gastritis, achlorhydria, and secondary gastric endocrine (G-cell) hyperplasia with hypergastrinemia.<sup>16</sup> They often occur in middle-aged women and generally present as multiple nonfunctional, small subcentimeter multicentric polyps in the gastric fundus and body.<sup>15,16</sup> Workup, as for all gastric carcinoids, includes upper endoscopy, gastric pH, and serum gastrin measurements.<sup>16</sup> Laboratory evaluation also may reveal low hematocrit, iron, and vitamin B<sub>12</sub> levels in the setting of associated pernicious anemia.<sup>16</sup> Most type 1 gastric carcinoids are confined to the submucosa and metastasize in fewer than 10% of cases.<sup>13,15,16</sup> Given the indolent behavior of this subclass, endoscopic resection via snare polypectomy or endoscopic mucosal resection (EMR) is recommended for all type 1 gastric carcinoids smaller than 1 to 2 cm. Surgical resection is reserved for the rare lesion that is greater than 2 cm, or lesions associated with other high-risk features, such as invasion into the muscularis propria as determined by endoscopic ultrasound, poorly differentiated histology, positive endoscopic resection margin, or nodal or distant metastases.<sup>16</sup> Notably, type 1 tumors tend to recur at a median duration of 24 months following resection, with a 3% risk of progression to NEC.<sup>16</sup> The most recent ENETS guidelines published in 2016 recommend serial endoscopic surveillance every 24 months for newly presenting tumors, and every 12 months for recurrent disease.<sup>16</sup> Interestingly, for multiple progressive type 1 tumors, antrectomy to reduce gastrin production represents an alternative but somewhat controversial management option.<sup>13,15</sup>

Type 2 gastric carcinoids, the rarest form, comprise only 5% to 10% of cases, and similarly derive from ECL cells in the setting of hypergastrinemia.<sup>4,13,16</sup> Unlike type 1 tumors, however, type 2 gastric carcinoids are associated with *primary* hypergastrinemia, ie, Zollinger–Ellison syndrome, which is caused by a gastrinoma that is nearly always associated with multiple endocrine neoplasia type 1 (MEN-1) syndrome.<sup>16</sup> Type 2 gastric tumors also tend to present as multiple small polyps 1 to 2 cm

in diameter that are distributed throughout the gastric fundus.<sup>4,13,16</sup> Approximately 10% to 30% of patients develop nodal or liver metastases.<sup>4,13,16</sup> Management is targeted toward localizing and removing the source of the hypergastrinemia first, either surgically or medically, followed by surgical resection of the localized type 2 gastric carcinoids.<sup>13,16</sup>

Type 3 gastric carcinoids comprise 15% to 25% of cases and display pronounced aggressive clinical behavior. This form generally presents sporadically as a large solitary mass greater than 2 cm in diameter. The masses are associated with a higher incidence of local invasion through the gastric wall, higher proliferative rate on histology, and higher rate of associated nodal or distant metastases in 50% to 100% of cases.<sup>4,13,16</sup> Patients are more often male and may present with atypical carcinoid symptoms, such as pruritus and flushing due to histamine production.<sup>16</sup> The workup should include endoscopic ultrasound to assess the depth of tumor invasion, abdominopelvic CT, and sometimes somatostatin receptor scintigraphy to evaluate for metastatic disease. Management with radical gastrectomy and lymphadenectomy parallels the treatment of gastric adenocarcinoma.<sup>13,16</sup>

Prognosis varies dramatically across the three gastric carcinoid types: 5-year survival is estimated to be 95% for type 1 patients, 60% to 75% for type 2, and only 25% to 50% for type 3 patients.<sup>4</sup> Outcome also depends on extent of disease, with reduced 5-year survival rates of 73%, 65%, and 25% for local, regional, and distant disease, respectively.<sup>7</sup>

## Duodenal Carcinoid

Duodenal carcinoids are rare. They comprise only 2% to 3% of GI carcinoids.<sup>16,17</sup> Unlike other small intestinal carcinoids that arise from the serotonin-producing enterochromaffin cells, sometimes in association with carcinoid syndrome, the duodenal carcinoids generally derive from either gastrin-producing G cells (gastrinoma, 50%-60% of cases) or somatostatin-producing D cells (somatostatinoma, 20%-40% of cases), and the majority of these tumors are not associated with any functional clinical syndrome.<sup>16,17</sup> The duodenal carcinoids instead present with local symptoms such as abdominal pain, GI bleeding, or jaundice.<sup>17</sup> The majority of these tumors originate in the proximal duodenum, ie, the first or second portions or periampullary region.<sup>17</sup> Duodenal gastrinomas arise either sporadically or in

the context of MEN-1, in which case multiple tumors are common.<sup>16</sup> Somatostatinomas are often associated with the hereditary syndrome neurofibromatosis type 1 (von Recklinghausen disease) and more frequently involve the ampulla.<sup>16</sup> On presentation, duodenal carcinoids are generally small, less than 2 cm in diameter, with distant metastases in fewer than 10% of cases, but with nodal involvement in up to 40% to 60% of cases.<sup>7,16</sup> The recommended treatment for small ( $\leq 1$  cm) duodenal carcinoids is endoscopic resection.<sup>16</sup> For tumors located in the periampullary region that are larger than 1 to 2 cm, or associated with nodal metastases, surgical resection with either local resection and lymphadenectomy or radical resection via pancreaticoduodenectomy should be performed, although the extent of surgical resection remains controversial.<sup>16,18</sup> Prognosis varies by disease extent, with 5-year survival decreasing from 68% for localized disease to 55% and 46% for regional and distant metastases, respectively.<sup>7</sup>

## Small Intestinal Carcinoid

The small intestine is the most common site for GI carcinoids. Carcinoids are in fact one of the most common histologic subtypes of small intestinal neoplasms, comprising about 37% of cases, comparable to adenocarcinoma.<sup>19</sup> Small intestinal carcinoids most often arise in the ileum (45%-50%), followed by the duodenum (18%), and rarely the jejunum (6%).<sup>6,19</sup> As noted earlier, midgut carcinoids arise from a different cell type and behave differently from their foregut counterparts. Jejunoileal carcinoids derive from serotonin-secreting enterochromaffin cells and are most often associated with carcinoid syndrome, ie, flushing, diarrhea, and carcinoid heart disease.<sup>20</sup> Primary small intestinal carcinoids are notoriously slow-growing, manifest with nonspecific symptoms such as cramping and bloating, and are often diagnosed late in the disease process, with nodal and distant metastases in 40% and 30% of patients, respectively.<sup>7,21</sup> Additionally, 20% to 40% of small intestinal carcinoids are multicentric.<sup>4,20</sup> Primary tumors are difficult to localize either radiographically or endoscopically. CT often depicts nodal involvement, with the characteristic desmoplastic mesenteric reaction (Fig. 40-2A) or distant liver metastases.<sup>4</sup> Primary tumor localization therefore requires additional imaging with somatostatin receptor scintigraphy, which is reported to have increased sensitivity for small intestinal tumors

compared with other anatomic sites, and potentially other less-studied modalities such as video capsule endoscopy and double-balloon enteroscopy.<sup>20</sup>

A

B

C

**FIGURE 40-2** Small intestinal carcinoid characteristically spreads to the mesentery and is associated with a desmoplastic response, seen on CT as a spiculated mesenteric mass (*arrow*) tethering adjacent bowel loops (**A**). The recommended treatment for localized small intestinal carcinoid is radical small bowel resection with high mesenteric lymphadenectomy (**B**), sometimes requiring skeletonization of the mesenteric vessels to remove nodal disease (**C**). (Used with permission from Yi-Zarn Wang, MD, Baylor University Medical Center, Dallas, TX and Eugene Woltering, MD, Louisiana State University Health Sciences Center, New Orleans, LA.)

Surgical resection is the only potential cure for small intestinal carcinoid. Resectability should be determined in the multidisciplinary setting with multimodal evaluation as above. All patients with resectable disease, ie, without prohibitive mesenteric root fibrosis, superior mesenteric artery involvement, or diffuse metastases, should undergo oncologic small intestinal resection with regional lymphadenectomy.<sup>20,21</sup> Surgical exploration should include thorough evaluation of the entirety of the small bowel for multicentric tumors, adequate high mesenteric lymph node resection, and care to preserve as much mesenteric vasculature and bowel length as possible (Fig. 40-2B, C).<sup>20,21</sup> Prophylactic cholecystectomy has previously been recommended owing to the increased incidence of cholelithiasis in patients treated with somatostatin analogs, but prospective studies supporting this practice are lacking, and the decision is therefore deferred to the individual clinical setting and surgeon.<sup>20,21</sup> In patients with preoperatively diagnosed carcinoid syndrome, perioperative treatment with octreotide, a somatostatin analog, is essential to preventing carcinoid crisis, a potentially life-threatening constellation of signs including hemodynamic instability, flushing, bronchospasm, and, when severe, vasomotor collapse.<sup>21</sup> In nonresectable patients, palliative resection in the setting of impending or symptomatic bowel obstruction should also be considered in the appropriate clinical context.<sup>20</sup>

Prognosis varies with disease extent, with 5-year survival rates estimated to be 65%, 71%, and 54% for local, regional, and distant disease, respectively.<sup>7</sup> Radical small bowel resection with lymphadenectomy was associated with improved overall survival in a retrospective review of 603 patients with small intestinal carcinoid or carcinoid syndrome in a single-institution study.<sup>22</sup> Additional independent predictors of worse survival,

based on several SEER-based studies, include male gender, age greater than 55 years, African American race, tumor size greater than 1.0 cm, and involved margins.<sup>19,23</sup> Unfortunately, no effective adjuvant therapies are currently available.<sup>21</sup> Relatively indolent tumor growth warrants less frequent but long duration of surveillance, with an initial evaluation at 3 to 6 months postoperatively, followed by serial evaluation with history, physical exam, laboratory serum CgA and urinary 5-HIAA studies, and axial imaging with multiphasic CT or MRI at 6- to 12-month intervals.<sup>20,21</sup>

## Appendiceal Carcinoid

The appendix was previously thought to be the most common site of GI carcinoid but is now estimated to comprise only about 16% of cases,<sup>6</sup> with decreasing incidence over the past four decades.<sup>5,6</sup> Nevertheless, carcinoid represents the most common type of appendiceal neoplasm and is discovered, often incidentally, in about 0.5% of all appendectomy specimens.<sup>20,24</sup> Average age at diagnosis is 40 to 50 years, younger than other sites of carcinoid, and tumors are usually small, less than 1 cm in diameter, and localized to the tip of the appendix (Fig. 40-3).<sup>7,20</sup> Appearance on CT ranges from occult to findings suggestive of acute appendicitis, ie, diffuse thickening and adjacent fat stranding.<sup>4</sup>

**FIGURE 40-3** The majority of appendiceal carcinoids present as incidental findings on surgical pathology following appendectomy and often are small and localized to the tip of the appendix.

Tumor size correlates with malignant potential. In one SEER-based study of 89 patients with appendiceal carcinoid, nodal metastases were rare in patients with tumors 1 cm or smaller (15%), but increasingly more frequent with intermediate size tumors greater than 1 cm and less than 2 cm (47%) and large tumors greater than 2 cm (86%).<sup>25</sup> Appendectomy is therefore considered adequate treatment for most appendiceal carcinoids less than or equal to 1 cm.<sup>20,21</sup> There is little evidence to support oncologic right hemicolectomy for larger tumors,<sup>26</sup> but generally accepted indications in the literature include tumor size greater than 2 cm, invasion into the mesoappendix or base of the appendix, positive margin, high grade histology, or the more aggressive goblet cell histology, ie, mixed adeno-neuroendocrine carcinoma.<sup>20,24</sup> For intermediate-sized tumors 1 to 2 cm, some groups recommend axial imaging to evaluate for nodal or distant metastases or right hemicolectomy, but data demonstrating impact on survival are lacking.<sup>20,27</sup>

Overall prognosis for appendiceal carcinoid is excellent, with 5-year survival just under 100%.<sup>20</sup> As for other sites of GI carcinoid, survival varies with disease stage, with 5-year survival rates estimated to be 88% and 78% for localized and regional disease, respectively, but only 25% for the rare patient with distant metastases.<sup>7</sup>

## Colonic Carcinoid

Colonic carcinoids comprise about 11% of all GI carcinoid tumors, with 62% arising in the sigmoid or rectosigmoid junction, 21% in the ascending, 9% in the transverse, and 9% in the descending colon.<sup>6</sup> While proximal colonic tumors resemble small intestinal carcinoids in regard to cell of origin (enterochromaffin cells) and serotonin production, distal colonic tumors of the hindgut more often produce glucagon-like peptide and pancreas polypeptide (PP/PYY) and are generally not associated with carcinoid syndrome.<sup>28</sup> The clinical behavior of colonic carcinoids resembles that of small intestinal tumors in that patients most often present late, with over 50% harboring nodal or distant metastases at the time of diagnosis.<sup>7</sup> Initial workup

should therefore include staging evaluation with IV contrast-enhanced CT of the chest, abdomen, and pelvis, plus additional metastatic evaluation with liver MRI and/or somatostatin receptor scintigraphy in the setting of clinical suspicion or equivocal CT.<sup>28</sup> Tumors smaller than 2 cm may be excised endoscopically. However, most carcinoid tumors of the colon are larger than 2 cm, and in the absence of diffuse disease, require oncologic resection with segmental colectomy and mesenteric lymphadenectomy according to the principles of total mesocolic excision, similar to management of colonic adenocarcinoma.<sup>28,29</sup> This includes full mobilization of the colon along fascial planes to expose the unfragmented mesentery at its take-off from the superior mesenteric artery (SMA). On the right, a Kocher maneuver may be necessary to achieve a high central vascular ligation of the mesentery. An extended right hemicolectomy with high ligation of the entire middle colic artery may be needed when the tumor is close to the take-off of the right branch of the middle colic artery. On the left, flush ligation of the internal mesenteric artery (IMA) on the aorta as well as high ligation of the internal mesenteric vein (IMV) may be needed, although this maneuver should not be performed unless there is a high index of suspicion for metastatic lymph nodes, as this can lead to sexual dysfunction and urological disorders.

Colonic carcinoids carry a worse prognosis than other anatomic sites, due in part to their late presentation and more aggressive biology.<sup>30</sup> Five-year survival rates are worse (85%, 46%, and 14% for localized, regional, and distant disease, respectively) compared with the small intestine carcinoids.<sup>7</sup> Thus, careful surgical technique at the index operation is critically important. Although laparoscopic case reports describing high-quality total mesocolic excisions with high central vascular ligation have been touted, we encourage early conversion to open surgery if and when the colonic mesentery is foreshortened and/or heavily involved with metastatic nodules.

## Rectal Carcinoid

Carcinoids that arise in the rectum account for 20% of all GI carcinoids, rendering the rectum the second most common site of disease behind small intestine.<sup>6</sup> Similar to distal colonic tumors, rectal carcinoids are rarely associated with serotonin production or carcinoid syndrome.<sup>30</sup> They often are discovered incidentally on lower endoscopy. The prevalence of these tumors

has increased over the past 4 decades, and they nearly always present as small tumors localized to the submucosa (Fig. 40-4A, B).<sup>7,30,31</sup>

**FIGURE 40-4** Most rectal carcinoids are diagnosed incidentally by the appearance of a small submucosal mass on lower endoscopy (A). Endorectal ultrasound confirms submucosal tumor localization (B). (C) Local transanal excision is indicated for intermediate-sized lesions 1 to 2 cm, as well as small lesions (<1 cm) that have incomplete endoscopic excision or high-risk pathologic features. Such lesions can be excised using advanced transanal surgical techniques, such as transanal endoscopic microsurgery (TEM), transendoscopic operation (TEO), or transanal minimally invasive surgery (TAMIS). Transanal excision proceeds with cauterization of a margin 1 cm around the lesion or residual scar (i-ii), full thickness dissection to the mesorectal fat (iii), removal of the specimen en bloc without fragmentation

(iv), and watertight closure (v).

Given their low risk (<3%-5%) of metastasis,<sup>7,28</sup> rectal carcinoids smaller than 1 cm can be excised endoscopically via polypectomy or with an advanced endoscopic technique such as EMR.<sup>28,30</sup> This statement is made with some reservation, however, since the adequacy and appropriateness of endoscopic resection depends on the following criteria: the tumor must be removed en bloc and without fragmentation, and the disease must not invade the muscularis propria or have high mitotic activity.<sup>28</sup> Thirty percent of tumors resected endoscopically with close margins will have residual disease on a follow-up of local excision, highlighting the importance of transanal scar reexcision and full-thickness resection of the surrounding rectal wall with a 1-cm margin.<sup>32</sup>

Local excision can also be offered to patients presenting with intermediate-size tumors measuring 1 to 2 cm in maximal diameter. Such excisions can be performed using standard transanal instruments when tumors are distal and easy to reach, or advanced transanal endoscopic microsurgery (TEM) for lesions located more proximally in the rectum (Fig. 40-4C).<sup>32</sup> Given the current technical advances in transanal minimally invasive surgery, including TEM, transanal endoscopic operation (TEO), and transanal minimally invasive surgery (TAMIS), radical resection with total mesorectal excision for intermediate-size rectal carcinoids is rarely justified.

For the uncommon large (>2 cm) rectal carcinoid, or for tumors with high-risk features such as muscularis propria invasion, high grade classification, or incomplete resection on local excision, further evaluation should proceed with pelvic MRI or endorectal ultrasound to better assess tumor size, depth, and nodal involvement. In addition, staging CT of the chest, abdomen, and pelvis can be performed to better evaluate for distant metastases, most notably to liver.<sup>28</sup> In the absence of unresectable metastatic disease, these rectal tumors should be managed with either a low anterior or abdominoperineal resection with concurrent total mesorectal excision.<sup>28,30</sup> Tumors in the proximal rectum can be treated with a tumor-specific total mesorectal excision, provided the surgeon is able to achieve a generous distal margin of at least 5 cm of intact mesorectum measured externally, not endoscopically, below the tumor edge.

Overall prognosis is favorable for the majority of rectal carcinoid patients,

with 5-year survival rates estimated to be 90%, 62%, and 24% for localized, regional, and distant disease, respectively.<sup>7</sup>

## Metastatic Carcinoid and Carcinoid Syndrome

Carcinoid syndrome most often occurs in patients who have small intestinal carcinoid metastatic to the liver. The syndrome consists of a constellation of vasomotor, GI, and cardiac symptoms thought to be mediated by peptides secreted by tumor cells into the systemic circulation, eg, serotonin, histamine, kallikrein, bradykinin, and prostaglandins.<sup>21</sup> The symptoms include flushing, diarrhea, wheezing in the setting of acute carcinoid crisis, and progressive right heart failure due to right-sided valvular fibrosis in severe cases.<sup>21</sup> Although the precise pathophysiology remains to be elucidated, carcinoid symptoms are generally attributed to elevated levels of tumor-derived hormones in the systemic circulation, ie, in the setting of large-volume metastatic burden in the liver or retroperitoneal metastasis.<sup>21</sup> Diagnosis is dependent on clinical findings. Supportive laboratory evaluation includes elevated 24-hour urinary 5-HIAA secretion as discussed above. Imaging studies to detect and follow metastatic disease include IV contrast-enhanced CT or MRI, and in certain settings, somatostatin receptor scintigraphy.<sup>33</sup>

The management options for metastatic carcinoid remain limited. Somatostatin analog therapy and surgical debulking can alleviate symptoms<sup>21,34</sup> and potentially aid with disease control, although data supporting the latter statement are primarily based on retrospective case series. Prospective randomized studies evaluating the effect of surgical metastasectomy on survival are lacking. Nevertheless, several large case series of patients with resected or ablated liver metastases from GI NET primaries, predominantly small intestinal carcinoids, demonstrate improved survival compared with historical controls, with 5-year survival rates up to 74%, and median survival up to 10 years, compared with 30% to 40% 5-year survival and 2- to 4-year median survival historically reported for patients with untreated hepatic metastases.<sup>35,36</sup> In this series, however, the 5-year recurrence rate was greater than 80% to 90%, reiterating the current goal of surgical metastasectomy, which is disease control rather than cure.<sup>35,36</sup>

The role of systemic therapy has been clarified in the PROMID trial, a published randomized controlled study of 85 patients with metastatic, well-

differentiated midgut carcinoid, randomized to either placebo or octreotide long-acting release (LAR). This trial demonstrated prolonged time to tumor progression (6 vs 14 months, respectively) with systemic therapy, with the greatest effect noted in patients with low tumor burden in the liver and resected primary tumor.<sup>37</sup> No difference in overall survival was detected, but the results warrant additional investigation with higher patient numbers. No other effective medical therapies exist for metastatic carcinoid. The response rate to traditional cytotoxic chemotherapy, eg, 5-fluorouracil and streptozocin, is 20% to 30% at best.<sup>28</sup> Novel agents under investigation include targeted inhibitors of the vascular endothelial growth factor (VEGF) and mammalian target of rapamycin (mTOR) signaling pathways,<sup>21</sup> and radiolabeled somatostatin analogs for targeted radiotherapy,<sup>28,30</sup> but the clinical efficacy of these newer agents remains to be proved.

## GENERAL OUTCOMES

The overall prognosis for patients with GI carcinoid is excellent, with 5-, 10-, and 20-year disease-specific survival rates of 91%, 86%, and 77%, respectively.<sup>5</sup> However, tumor size greater than 1 to 2 cm correlates with nodal spread, and overall survival varies significantly by disease stage (ie, nodal or distant metastases) and site of origin.<sup>6</sup> Survival is notably worse with more widespread disease. Five-year disease-specific survival rates decline from 98% to 89% to 59%, respectively, for localized, regional, and distant disease.<sup>5</sup> According to several large SEER-based studies, additional independent predictors of survival include site other than the small intestine, well-differentiated histology, female gender, Caucasian versus African American race, younger age, diagnosis in the most recent decade, and small primary tumor size.<sup>5,7</sup>

## CONCLUSIONS

GI carcinoid tumors generally behave in a more indolent fashion compared with adenocarcinoma counterparts. Nevertheless, they represent a diverse spectrum of disease with varying malignant potential. For primary, localized disease, surgery remains the only potential cure. The goals of evaluation and management should be to localize and determine extent of disease, resect all

disease if feasible, and palliate symptoms related to locoregional tumor growth or systemic hormone-related symptoms, ie, carcinoid syndrome, with surgical resection or medical therapy—namely, somatostatin analog treatment. Medical therapies for unresectable, metastatic carcinoid remain limited and warrant further investigation.

## HISTORY

Although appendicitis is now well recognized as a leading cause of surgically treated abdominal pain, Galen and other early anatomists overlooked the vermiform appendix for centuries.<sup>1</sup> The Renaissance artist, Leonardo da Vinci, became the first to document the existence of the appendix in sketches circa 1500. Subsequently, anatomists da Carpi<sup>2</sup> and Vesalius<sup>3</sup> formally described the appendix in the mid-1500s. Soon thereafter, in 1554, Fernel described the first recorded case of disease of this organ: a 7-year-old girl with diarrhea was administered treatment with a large quince fruit, which obstructed the appendiceal lumen after it was ingested.<sup>4</sup> She developed severe abdominal pain and died. Autopsy showed the quince fruit obstructing the appendiceal lumen, with resultant appendiceal necrosis and perforation, thereby resulting in the first description, postmortem, of what would later be known as “appendicitis.”

It was not until several centuries later that appendicitis was first diagnosed before autopsy and treated. Amyand is credited with performing the first

appendectomy in 1736, when he operated on a child with an inguinal hernia that had been complicated by the development of an enterocutaneous fistula.<sup>5</sup> On exploration of the hernia sac, he discovered the appendix, which had been perforated by a pin, resulting in an appendicocutaneous fistula. As a result of his original description, an inguinal hernia sac containing the appendix carries Amyand's eponym.<sup>6</sup> Nearly 150 years passed before Lawson Tait in London performed the first successful transabdominal appendectomy for a gangrenous appendix in 1880.<sup>7</sup> Less than a decade later, in 1886, Reginald Fitz of Harvard Medical School described the natural history of the inflamed appendix and coined the term "appendicitis."<sup>8</sup> In 1889, Charles McBurney of the Columbia College of Physicians and Surgeons in New York presented his series of cases of surgically treated appendicitis and, in doing so, described the anatomic landmark that now bears his name. McBurney's point is the location of maximal tenderness "very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus."<sup>9</sup> In the 1890s, Sir Frederick Treves of London Hospital advocated conservative management of acute appendicitis followed by appendectomy after the infection had subsided<sup>10</sup>; unfortunately, his youngest daughter developed perforated appendicitis and died from such treatment. The first laparoscopic appendectomy was performed by Kurt Semm in 1980.<sup>11</sup> Refinement of the minimally invasive approach is the most recent of numerous advances in the diagnosis and treatment of appendicitis. Nonetheless, acute appendicitis continues to challenge surgeons to this day.

## ANATOMY

Embryologically, the appendix and cecum develop as outpouchings of the caudal limb of the midgut loop in the sixth week of human development. By the fifth month, the appendix elongates into its vermiform shape. Containing all layers of the colonic wall, the appendix is, by definition, a true diverticulum. At birth, the appendix is located at the tip of the cecum. Because of unequal elongation of the lateral wall of the cecum, the adult appendix originates from the posteromedial wall of the cecum, caudal to the ileocecal valve. The adult appendix averages 9 cm in length,<sup>1</sup> with its outside diameter ranging from 3 to 8 mm and its lumen ranging from 1 to 3 mm. The

base of the appendix is consistently found by tracing the teniae coli of the colon to their confluence at the base of the cecum. The appendiceal tip, however, can vary significantly in location (Fig. 41-1). Although usually located in the right lower quadrant (RLQ) or pelvis, the tip can occasionally reside in the left lower quadrant or right upper quadrant (RUQ).

**FIGURE 41-1** Anatomic variation in the position of the appendix. (1) Preileal; (2) postileal; (3) promontoric; (4) pelvic; (5) subcecal; (6) paracolic or prececal.

The arterial supply of the appendix comes from the appendicular branch of

the ileocolic artery, which originates posterior to the terminal ileum, enters the mesoappendix near the base of the appendix, and runs its course through to the tip of the appendix (Fig. 41-2). Lymphatic drainage flows to lymph nodes along the ileocolic artery.

**FIGURE 41-2** The appendix and its arterial supply.

## **ACUTE APPENDICITIS**

## Epidemiology

The incidence of acute appendicitis ranges from 8.6 to 11 cases per 10,000 person-years.<sup>12,13</sup> The disease is slightly more common in males, although perforated cases have no gender predilection. In a lifetime, 8.6% of males and 6.7% of females can be expected to develop acute appendicitis. Young age is a risk factor; nearly 70% of patients are younger than 30 years of age when diagnosed with acute appendicitis. The highest incidence of appendicitis in males is in the 10- to 14-year-old age group (27.6 cases per 10,000 person-years), while the highest female incidence is in the 15- to 19-year-old age group (20.5 cases per 10,000 person-years). Overall, perforation occurs in 19% of cases of acute appendicitis. Perforated appendicitis has a bimodal distribution, with a predilection for patients at extremes of age. The ratio of perforated to nonperforated appendicitis is significantly higher among patients younger than 5 and older than 65 years, compared to those between 5 and 65 years of age. Although acute appendicitis is relatively uncommon in people older than 65 years, the elderly have perforated disease up to 50% of the time.<sup>12</sup>

## Etiology and Pathophysiology

The physiologic function of the appendix remains unknown, although some postulate it to be a microbial reservoir.<sup>14</sup> Equally, the pathophysiology of the appendix in appendicitis is incompletely understood. Wangensteen and Dennis<sup>15</sup> extensively studied the role of obstruction in appendicitis in the 1930s. Based on anatomic studies, he postulated that mucosal folds and a sphincter-like orientation of muscle fibers at the appendiceal orifice make the appendix susceptible to obstruction. As such, the pathophysiology of appendicitis is commonly believed to adhere to the following sequence of events: (1) Closed-loop obstruction caused by a fecalith (or other nidus, such as a calculus or neoplasm) leads to swelling of the mucosal and submucosal lymphoid tissue at the base of the appendix; (2) intraluminal pressure increases as the appendiceal mucosa secretes fluid against the fixed obstruction; (3) appendiceal wall pressure exceeds capillary pressure and causes mucosal ischemia; and (4) luminal bacterial overgrowth and translocation of bacteria across the appendiceal wall further result in

inflammation, edema, ischemia, and ultimately necrosis. If the appendix is not removed, perforation may ensue.

Although appendiceal obstruction is widely accepted as the primary cause of appendicitis, some evidence suggests that this may be only one of several possible mechanisms. First, some patients with a fecalith have a histologically normal appendix and, furthermore, the majority of patients with appendicitis show no evidence for a fecalith.<sup>16</sup> Arnbjörnsson and Bengmark<sup>17</sup> intraoperatively inspected the appendices of patients with suspected appendicitis. The intraluminal pressure of each appendix was measured prior to removal and found to be elevated in only 8 of 27 patients with nonperforated appendicitis. The authors did not observe signs of obstruction in the remaining patients with nonperforated appendicitis or those with a normal appendix. Taken together, these studies imply that obstruction is just one of the possible etiologies of acute appendicitis. Further mechanisms have yet to be completely elaborated.

Regardless of the role of obstruction as the inciting factor for appendicitis, it is a tenet of general surgery that, if left untreated, appendiceal inflammation will progress to necrosis and, ultimately, to perforation. In one study of the natural history of appendicitis, patients undergoing appendectomy for suspected appendicitis were queried about their duration of symptoms.<sup>18</sup> Patients found to have nonperforated appendicitis reported an average duration of 22 hours of symptoms prior to presentation to the hospital, while those with perforated appendicitis reported an average of 57 hours. Similarly, in a study of over 1000 patients who underwent appendectomy for acute appendicitis, Ditillo and colleagues<sup>19</sup> assessed the relationship between duration of symptoms and rate of perforation. Compared to the 6% perforation rate among those with less than 12 hours of symptoms, patients with 48 to 71 hours of symptoms had a 33% perforation rate and patients with greater than 71 hours of symptoms had a 39% perforation rate.<sup>19</sup>

However, the time course of this progression varies between patients. Among cases of perforated appendicitis, as many as 20% present within 24 hours of the onset of symptoms.<sup>19</sup> Although concern for perforation should be elevated when evaluating a patient with more than 24-hour duration of symptoms, the clinician must remember that perforation can also develop more rapidly. Importantly, this does not mean that surgeons are obliged to hastily proceed to an operation when appendicitis is suspected in order to

minimize the likelihood of perforation in exchange for a higher rate of misdiagnosis. Rather, Temple and colleagues<sup>18</sup> demonstrated that patients with perforated appendicitis proceeded to surgery more rapidly than those with nonperforated appendicitis (6.5 vs 9 hours), but perforated patients had significantly longer prehospital symptoms (57 vs 22 hours). That is, longer duration of prehospital delay is the major contributor to perforation rather than delayed in-hospital diagnosis.<sup>20,21</sup>

Some epidemiologic work highlights unsolved aspects of the mechanism of progression from nonperforated to perforated appendicitis. A study of US discharges in the National Hospital Discharge Survey notes that, although the incidence of nonperforated appendicitis has continued to decrease over time, the incidence of perforated appendicitis has slowly increased, despite the increasing and nearly pervasive availability of cross-sectional imaging and minimally invasive surgery.<sup>22</sup> The authors suggest that this divergence in trends may indicate an underlying difference in pathophysiology between perforated and nonperforated appendicitis, rather than simply a difference in duration of disease.

## Diagnosis

### PRESENTATION

Although acute appendicitis is the most common surgically correctable cause of abdominal pain, its diagnosis remains challenging in many instances. Presenting signs and symptoms are variable and often initially subtle. Arriving at the correct diagnosis is essential, however, as a delay in diagnosis may allow progression to increasingly complex disease with concomitantly elevated morbidity and mortality. Conversely, incorrectly diagnosing appendicitis, although not catastrophic, subjects the patient to a potentially unnecessary operation.

The classic presentation of acute appendicitis begins with cramping, intermittent abdominal pain, thought to be due to obstruction of the appendiceal lumen, as nociceptors supplying the visceral peritoneum are stimulated by stretch. Classically, in 12 to 24 hours, the pain migrates to the RLQ as transmural inflammation of the appendix leads to inflammation of the peritoneal lining of the right lower abdomen. The character of the pain also changes from dull and colicky to sharp and constant. Movement or

Valsalva maneuver often worsens this pain, so that the patient typically desires to lie still; some patients describe pain with every bump in the car or ambulance ride to the hospital.

The prototypical patient with appendicitis initially endorses pain that is periumbilical or diffuse and difficult to localize. The onset of pain is typically followed shortly thereafter with nausea. Vomiting may or may not be present. If nausea and vomiting precede the pain, the astute clinician should consider another diagnosis, such as gastroenteritis. Upon detailed questioning, patients who have appendicitis commonly report anorexia, and appendicitis is unlikely in those with a normal appetite. Patients may report low-grade fever, while higher temperatures and shaking chills might again alert the surgeon to consider other diagnoses, including appendiceal perforation or nonappendiceal sources of abdominal pain.

## **PHYSICAL EXAMINATION**

On inspection, patients with acute appendicitis appear mildly ill, feel warm to the touch, and have a slightly elevated pulse. They often lie still to avoid the irritation to the parietal peritoneum caused by movement. The surgeon should systematically examine the entire abdomen, starting in the left upper quadrant away from the patient's described pain. Maximal tenderness is typically in the RLQ, at or near McBurney's point, located one-third of the way from the anterior superior iliac spine to the umbilicus. This tenderness is often associated with localized muscle rigidity and signs of peritoneal inflammation, including rebound, shake, or tap tenderness. RLQ tenderness is one of the most specific of all signs of acute appendicitis.<sup>23</sup> Its presence should always prompt diagnostic consideration of appendicitis, even in the absence of other signs and symptoms. Because of the various anatomic locations of the appendix, however, it is possible for the tenderness to be in the right flank, RUQ, suprapubic region, or left lower quadrant. Patients with a retrocecal or pelvic appendix may lack abdominal tenderness to palpation. In such cases, digital rectal examination can potentially be helpful to elicit right-sided pelvic tenderness. However, in general, digital rectal exam is an inaccurate assessment tool for diagnosing appendicitis.<sup>24</sup>

Multiple physical exam signs contribute uniquely to the diagnosis of acute appendicitis. The Rovsing sign, or pain in the RLQ that occurs with release of applied pressure to the left lower quadrant, results from focal peritoneal

inflammation in the RLQ. Psoas sign, or pain with right hip flexion, can be seen with a retrocecal appendix due to inflammation adjacent to the iliopsoas muscle group. The obturator sign, or pain with internal rotation of the flexed right thigh, indicates inflammation adjacent to the obturator internus muscle in the pelvis.

However, many patients with acute appendicitis do not endorse the aforementioned typical history and physical examination. In practice, the surgeon is frequently reminded that the classic presentation of acute appendicitis is not universally present. For instance, the initial vague colicky pain may be overlooked or forgotten. When the pain becomes constant, it may localize to quadrants of the abdomen other than the RLQ due to alteration in appendiceal anatomy, as with late pregnancy or underlying malrotation. Among patients with a retrocecal appendix, the pain may not localize until generalized peritonitis from perforation occurs. Increased urinary or bowel frequency may occur due to appendiceal inflammation irritating the adjacent bladder or rectum. Because appendicitis is so common, a high index of suspicion for appendicitis is warranted in nearly all patients with abdominal pain. At the same time, because the differential diagnosis of appendicitis is extensive, patients should be queried about certain symptoms that may suggest an alternative diagnosis. Surgeons must also remember that a previous appendectomy does not definitively exclude the diagnosis of appendicitis, as “stump appendicitis” (appendicitis in the remaining appendiceal stump after appendectomy), although rare, has been described.<sup>25</sup>

## **SYMPTOMS AND SIGNS OF PERFORATED APPENDICITIS**

When acute appendicitis has progressed to appendiceal perforation, other symptoms may be present. Patients will often endorse 2 or more days of abdominal pain. The pain usually localizes to the RLQ if the perforation has been walled off by surrounding intra-abdominal structures including the omentum, but it may be diffuse if generalized peritonitis ensues. The pain may become so severe that patients do not remember the antecedent colicky pain. A history of poor oral intake and dehydration may also be present.

In cases of perforated appendicitis, patients can look gravely ill. Patients with perforation often have rigors and high fevers. On physical examination, patients may appear flushed with dry mucous membranes. If a systemic

inflammatory response ensues, tachycardia and blood pressure depression will eventually occur in the absence of treatment. If the perforation has been walled off by surrounding structures to create an abscess or phlegmon, a mass may be palpable in the RLQ. Finally, if free intraperitoneal rupture has occurred, the patient can demonstrate signs of generalized peritonitis with diffuse rebound tenderness.

While most patients with perforated appendicitis present with symptoms related to the inflamed appendix itself or to a localized intraperitoneal abscess from perforation, other more rare presentations may occur. These are most likely to occur in the very young and very old, who may be unable to describe their symptoms and often present late in the course of their disease. On occasion, patients will present with bilious vomiting and obstipation due to a small bowel obstruction resulting from appendiceal perforation. Infectious complications can occur as well. A retroperitoneal abscess can form due to perforation of a retrocecal appendix. Alternatively, a hepatic abscess can form due to hematogenous seeding through the portal venous system. An intraperitoneal abscess may fistulize to the skin, resulting in an colocutaneous fistula. Finally, pylephlebitis (septic portal vein thrombosis) presents with high fevers and jaundice and can be confused with cholangitis; it is a rare dreaded complication of acute appendicitis and carries a high mortality.<sup>26</sup>

## **LABORATORY STUDIES**

Laboratory studies contribute to the diagnosis of appendicitis, but no single test is definitive. A white blood cell (WBC) count is perhaps the most useful laboratory test. Typically, the WBC is slightly elevated in nonperforated appendicitis but may be quite elevated in the presence of perforation. The clinician must remember, however, that the WBC can be normal in patients with acute appendicitis, particularly in early cases. Although a late diagnostic sign, serial WBC measurements commonly demonstrate a rising value over time among patients with appendicitis.<sup>27</sup> Urinalysis is performed to evaluate other potential causes for abdominal pain, specifically urinary tract infection and ureterolithiasis. Significant hematuria with colicky abdominal pain and the inability to find a comfortable resting position suggest the alternative diagnosis of ureterolithiasis. A urinary tract infection, on the other hand, is not uncommon in patients with appendicitis. It is not uncommon for the

urinalysis in a patient with appendicitis to show some degree of pyuria or hematuria due to inflammation of the ureter by the adjacent appendix. As such, its presence does not exclude the diagnosis of acute appendicitis, but it should be identified and treated.

In certain clinical situations, other laboratory tests are indicated. Measurement of serum liver enzymes and amylase can be helpful in diagnosing liver, gallbladder, or pancreatic disease for patients endorsing midabdominal or RUQ pain. Among women of childbearing age, the urine  $\beta$ -human chorionic gonadotropin should be checked to alert the clinician to the possibility of ectopic or concurrent pregnancy. Ectopic pregnancy is another cause of RLQ pain that demands emergent diagnosis and treatment. Concurrent pregnancy should be identified before a patient with suspected appendicitis is subjected to ionizing radiation from imaging studies or to general anesthesia.

## DIAGNOSTIC SCORES

Diagnostic scoring systems have been developed in attempts to improve the diagnostic accuracy of acute appendicitis.<sup>28</sup> The most prominent of those scores, developed by Alvarado,<sup>28</sup> was based on a retrospective analysis of 305 patients with abdominal pain suspicious for appendicitis (Table 41-1). This scoring system assigns points for symptoms (migration of pain, anorexia or urine acetone, and nausea/emesis), physical signs (RLQ tenderness to palpation, rebound tenderness, and pyrexia), and laboratory values (leukocytosis and a left shift). One prospective study reported that an Alvarado score  $\geq 7$  in male patients or  $\geq 9$  in female patients was equivalent to computed tomography (CT) imaging consistent with acute appendicitis.<sup>29</sup> Although these scores can help guide clinical thinking, they do not markedly improve diagnostic accuracy.<sup>30</sup> With the recent improvement in imaging studies, these scores have become increasingly marginalized.

TABLE 41-1: ALVARADO SCORING SYSTEM FOR ACUTE APPENDICITIS<sup>28</sup>

Diagnostic Criteria	Point Value
Symptom	
Migration of pain	1
Anorexia or urine acetone	1
Nausea/emesis	1
Sign	
RLQ tenderness to palpation	2
Rebound tenderness	1
Pyrexia $\geq 37.3^{\circ}\text{C}$	1
Laboratory values	
Leukocytosis	2
Left shift	1

Abbreviation: RLQ, right lower quadrant.

## IMAGING STUDIES

The potential imaging modalities currently used for the diagnosis of acute appendicitis include ultrasound (US), CT, and magnetic resonance imaging (MRI). Of historic note, prior to the widespread use of modern imaging techniques, an RLQ fecalith (or appendicolith) on abdominal plain film was considered pathognomonic for acute appendicitis. However, identification of a fecalith on abdominal plain film is not a specific or sensitive sign for acute appendicitis. Teicher and colleagues<sup>31</sup> reviewed the abdominal radiographs of 100 patients who underwent negative appendectomy and 100 patients who underwent appendectomy with pathologically proven appendicitis. Of those with appendicitis, 11% had an appendicolith on x-ray, compared to 3% of those without appendicitis. Similarly, an extensive review of appendectomy specimens at the Mayo Clinic<sup>16</sup> showed that fecaliths or appendiceal calculi were present in 9% of patients with nonperforated appendicitis and 21% of those with perforated appendicitis. Fecaliths were also present in 7% of patients with suspected appendicitis who had a pathologically normal appendix and in 2% of patients who had an appendectomy for other reasons. These data suggest that plain abdominal radiographs are neither helpful nor cost-effective and, as such, are not recommended for the diagnosis of acute appendicitis. Plain radiographs may be indicated for evaluation of possible

perforated viscus, especially in certain patient populations such as elderly patients with severe abdominal pain.

Abdominal ultrasonography is an important imaging modality for the diagnosis of acute appendicitis. A recent meta-analysis of 14 prospective studies showed US to have an overall sensitivity and specificity of 86% and 81%, respectively.<sup>32</sup> Findings that suggest appendicitis include thickening of the appendiceal wall, loss of wall compressibility, increased echogenicity of the surrounding fat signifying inflammation, and loculated pericecal fluid (Fig. 41-3). The advantages of US include its widespread availability and the avoidance of ionizing radiation and the side effects of intravenous contrast, such as renal toxicity and allergic reactions. In addition, US (both abdominal and transvaginal) is particularly useful in assessing obstetric and gynecologic causes of abdominal pain in women of childbearing age. US is highly operator-dependent, however, and it is frequently unable to visualize the normal appendix.<sup>33</sup> In the current epidemic of overweight and obesity in the United States, body habitus also limits the utility of US in the diagnosis of appendicitis, especially among patients with increasing body mass index (BMI).<sup>34</sup>

**FIGURE 41-3** Appendiceal ultrasound showing distended, noncompressible appendix measuring 1.7 cm in transverse dimension ( $>0.6$  cm is abnormal). (Used with permission from M. Stephen Ledbetter, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

CT is the most frequently used imaging modality for the evaluation of acute appendicitis. CT benefits from a high diagnostic accuracy for appendicitis<sup>32</sup> as well as visualization and diagnosis of many of the other causes of abdominal pain that can be confused with appendicitis. The radiographic findings of appendicitis on CT include a dilated ( $>6$  mm), thick-walled appendix that does not fill with enteric contrast or air, as well as surrounding fat stranding to suggest inflammation (Fig. 41-4).<sup>35</sup> In a meta-analysis of 12 prospective studies, CT demonstrated a sensitivity of 94% and a specificity of 95%.<sup>32</sup> Appendicitis is highly unlikely if enteric contrast fills

the lumen of the appendix and no surrounding inflammation is present. However, the clinician must remember that a CT performed early in the course of appendicitis might not show the typical radiographic findings.

**FIGURE 41-4** Computed tomography of acute appendicitis. The *arrow* points to an enlarged, fluid-filled appendix with wall hyperemia that does not fill with oral contrast. The paucity of intra-abdominal fat limits identification of fat stranding. (Used with permission from M. Stephen Ledbetter, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

While CT imaging may rule out alternative diagnoses or assist in operative planning, it is important to note that CT imaging only reduces the rate of negative appendectomy among certain patients. Wagner and colleagues<sup>36</sup> conducted a review of over 1400 patients who underwent appendectomy for suspected acute appendicitis. The authors discovered that preoperative CT was associated with a lower rate of negative appendectomy only for adult female patients, but not for adult male patients or children.<sup>36</sup>

A number of prospective studies have compared the accuracy of CT and US in imaging the appendix (Table 41-2).<sup>33,37,38</sup> Balthazar and colleagues<sup>37</sup> performed CT and US on 100 consecutive patients with suspected appendicitis. The sensitivity of CT was considerably higher (96% for CT vs 76% for US), whereas the specificity was comparable (89% for CT vs 91% for US), yielding a higher accuracy for CT (94% for CT vs 83% for US). CT

was also able to provide an alternative diagnosis in more patients and was better able to visualize an abscess or phlegmon (Fig. 41-5). Horton and colleagues<sup>38</sup> randomized patients with suspected appendicitis to either CT or US. Their findings echo those of Balthazar, with both CT and US having high specificity (100% for CT vs 90% for US), but CT demonstrating significantly higher sensitivity than US (97% for CT vs 76% for US). Yet another prospective study showed similar results, with CT having higher sensitivity (96% for CT vs 62% for US) and specificity (92% for CT vs 71% for US) than US<sup>33</sup> and better ability to visualize other intra-abdominal pathology in the absence of appendicitis.

**FIGURE 41-5** Computed tomography of perforated appendix. Note retrocecal abscess (*arrows*) with enhancing wall and periappendiceal fat stranding and adjacent cecal thickening (*arrowhead*). (Used with permission from M. Stephen Ledbetter, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

	US	86	81	NA

Abbreviations: CT, computed tomography; NA, not applicable; US, ultrasound.

Taken together, these studies suggest an algorithm for evaluation of patients with suspected acute appendicitis. Patients with a history, physical examination, and laboratory studies consistent with appendicitis should undergo appendectomy based on clinical judgment. In those with an evaluation suggestive but not convincing for appendicitis, further imaging is warranted. In women of childbearing age, this should begin with a pelvic US to evaluate for ovarian pathology. For other patients, transabdominal US should be considered initially with a subsequent abdominopelvic CT scan if the diagnosis remains questionable or an intra-abdominal abscess/phlegmon requires better evaluation. Rectal contrast CT is rarely needed but can be employed to better visualize the appendix.<sup>33,35</sup> Patients with a CT showing nonperforated appendicitis should undergo appendectomy. In many instances, patients with a normal CT do not require hospital admission. If symptoms persist, admission to the hospital for observation is warranted. Imaging modalities that avoid ionizing radiation may be preferentially used among children and pregnant patients, as discussed below.

## DIFFERENTIAL DIAGNOSIS

Because many of its signs and symptoms are nonspecific, the differential diagnosis of acute appendicitis is extensive and includes both abdominal and nonabdominal sources of pain (Table 41-3). However, some diagnoses are more likely than others in certain settings. Meckel diverticulitis causes similar symptoms with the possible addition of episodic painless hematochezia but is relatively uncommon.<sup>39</sup> Gastroenteritis is considerably

more common and should be expected when nausea and vomiting precede the abdominal pain or when diarrhea is a prominent symptom. Crohn's disease affecting the terminal ileum may resemble appendicitis in its initial presentation, but on further questioning, the patient may describe a subacute course, including fever, weight loss, and pain.

**TABLE 41-3: DIFFERENTIAL DIAGNOSIS OF ACUTE APPENDICITIS**

### **Gastrointestinal causes**

Cecal diverticulitis  
Sigmoid diverticulitis  
Meckel diverticulitis  
Epiploic appendicitis  
Mesenteric adenitis  
Omental torsion  
Crohn's disease  
Cecal carcinoma  
Appendiceal neoplasm  
Lymphoma  
Typhlitis  
Small bowel obstruction  
Perforated duodenal ulcer  
Internal hernia  
Intussusception  
Acute cholecystitis  
Hepatitis  
Pancreatitis

### **Infectious causes**

Infectious terminal ileitis (*Yersinia*, tuberculosis, or cytomegalovirus)  
Gastroenteritis  
Cytomegalovirus colitis

### **Genitourinary causes**

Pyelonephritis or perinephric abscess

Nephrolithiasis  
Hydronephrosis  
Urinary tract infection

**Nonabdominal causes**

Streptococcal pharyngitis  
Lower lobe pneumonia  
Rectus muscle hematoma

**In women**

Ovarian cyst (ruptured or not ruptured)  
Corpus luteal cyst (ruptured or not ruptured)  
Ovarian torsion  
Endometriosis  
Pelvic inflammatory disease  
Tubo-ovarian abscess

**In pregnancy**

Ectopic pregnancy  
Round ligament pain  
Chorioamnionitis  
Placental abruption  
Preterm labor

---

In middle-aged and older adults, other inflammatory conditions should be considered, including gastric or duodenal ulcer (with symptoms from fluid tracking into the right paracolic gutter), cholecystitis, and pancreatitis. In addition, the symptoms of cecal or sigmoid diverticulitis overlap with those of acute appendicitis. Cecal diverticula, like the appendix, are true diverticula containing all layers of the intestinal wall. Cecal diverticulitis, intuitively, is similar in pathogenesis and presentation to appendicitis. Because a redundant, floppy sigmoid colon can extend to the right side of the abdomen, patients with sigmoid diverticulitis can sometimes present with RLQ pain. Those patients typically describe a more rapid progression to localized tenderness, as well as a prodrome of alteration in bowel habits. Malignancies can present with acute RLQ pain due to perforation of a cecal carcinoma or appendicitis caused by tumor obstructing the appendiceal orifice. Such patients will also

often have guaiac-positive stools, anemia, and a history of weight loss.

In women of childbearing years, diagnosing the underlying cause of RLQ pain can be even more difficult. In addition to the causes of RLQ pain mentioned above, young women can also have pain from obstetric and gynecologic etiologies such as ruptured ovarian cyst or follicle, ovarian torsion, ectopic pregnancy, acute salpingitis, and tubo-ovarian abscess. A complete history including recent menstrual history, as well as pelvic examination, can be helpful in differentiating these causes of pain from acute appendicitis. Nonetheless, appendicitis can be difficult to diagnose in this patient population, and higher rates of misdiagnosis have been described in women of childbearing age.<sup>40</sup>

## SPECIAL CONSIDERATIONS

### Children

In the pediatric population, appendicitis most commonly afflicts children age 10 to 19 years, with an overall incidence of approximately 20 cases per 10,000 person-years.<sup>12</sup> By age 20, approximately 4% of children and adolescents will have undergone an appendectomy.<sup>41</sup> Among those younger than 20, infants age 0 to 4 have the lowest incidence of appendicitis (2 cases per 10,000 person-years), but up to two-thirds will present with perforation.<sup>42</sup> Perforation is disproportionately common because infants often present later in their disease course due to the difficulty inherent in obtaining an accurate history. The diagnosis is further complicated by diseases of childhood that can mimic appendicitis. For instance, mesenteric adenitis, or inflammation of the mesenteric lymph nodes, can present with fever and RLQ pain. Streptococcal pharyngitis and bacterial meningitis can also present with fever, nausea, and abdominal pain. These diagnoses and others including ovarian cysts, ovarian torsion, urinary tract infection, pelvic inflammatory disease, and complications of a Meckel diverticulum should be considered when evaluating children or adolescents for suspected appendicitis.

For the many children with an equivocal history, physical examination, and laboratory data, imaging with US is the preferred initial study.<sup>43</sup> US lacks ionizing radiation, does not require contrast or sedation, and is relatively

inexpensive. Unfortunately, however, ultrasonography is operator dependent. A meta-analysis by Doria and colleagues<sup>44</sup> of over 7000 patients documents a pooled sensitivity and specificity of 88% (95% confidence interval [CI], 86%-90%) and 94% (95% CI, 92%-95%), respectively, for the sonographic diagnosis of appendicitis. An important determinant in the diagnostic success of US is BMI of the child. The sensitivity of US has been reported to be 76% for children with a BMI below 25, but as low as 37% for children with a BMI of greater than 25. US had 82% sensitivity for appendicitis in one study in which the patient population had a mean BMI of 17.<sup>45-47</sup>

When US results are indeterminate, cross-sectional imaging with MRI or CT can help identify intra-abdominal pathology. MRI warrants consideration as the preferred second-line imaging test among children with suspected appendicitis, provided that the modality and its interpretation are institutionally available, the child is clinically stable, and the child is of old enough age to tolerate lying still for a relatively lengthy study. MRI lacks ionizing radiation and has at least equivalent sensitivity and specificity to CT. In a single-institution study of 510 MRIs, Kulaylat and colleagues<sup>48</sup> reported both a sensitivity and specificity of 97% for the diagnosis of acute appendicitis. The median imaging duration was 11 minutes. In comparison, CT has the benefits of nearly universal availability, ease of interpretation, and rapid examination. ++However, ionizing radiation from CT in childhood theoretically causes a small increase in the lifetime risk of certain cancers.<sup>49</sup> Based on estimated radiation exposure from a CT scan, studies have hypothesized that a 1-year-old and 15-year-old would theoretically develop a 0.18% and 0.11% lifetime risk, respectively, of fatal radiation-induced malignancy following a CT scan.<sup>45</sup> A recent study by Pearce and colleagues<sup>50</sup> studied the long-term outcomes of patients under age 22 who underwent CT examination between 1985 and 2002. The authors reported one excess occurrence of leukemia and one excess occurrence of a brain tumor per 10,000 head CTs. Despite this association between ionizing radiation and malignancy, the retrospective nature of the available research and the small magnitude of the absolute risk of malignancy (given the low overall rate) should be emphasized. Therefore, clinicians should consider the risks and benefits of MRI and CT, and efforts should be directed toward reducing radiation dose when imaging children.<sup>51</sup>

There is substantial variability in usage of imaging modalities. For

example, in a study by Rice-Townsend and colleagues of data from the Pediatric Health Information System database, hospital utilization of preoperative imaging with CT or US ranged from 21% to 73%.<sup>52</sup> In efforts to systematically reduce such variation, Rangel and colleagues proposed an algorithm to diminish the utilization of CT imaging for children with suspected appendicitis. Incorporating laboratory tests and US findings, the rate of CT utilization was substantially decreased, from 21% to 4%, with an unchanged rate of negative appendectomy.<sup>53</sup>

## Elderly

Although appendicitis is more common in younger age groups, it is an important cause of abdominal pain in the elderly. Perhaps because of a diminished inflammatory response, the elderly can present with less impressive symptoms and physical signs, longer duration of symptoms, and decreased leukocytosis compared to younger patients.<sup>54</sup> Perforation is thus more common, occurring in as many as 50% of patients older than 65.<sup>12</sup> These patients may have cardiac, pulmonary, renal, and other comorbidities, resulting in considerable potential morbidity and mortality from perforation. In one series, the mortality from perforated appendicitis in patients older than 80 was 21%.<sup>55</sup> These factors argue that RLQ pain in elderly patients must be efficiently investigated. Because of the multiple other possible causes of abdominal pain in this patient population (including malignancy, diverticulitis, and perforated peptic ulcer disease), prompt CT scan should be considered when the diagnosis is in question.

## Pregnancy

The diagnosis of acute appendicitis in the pregnant patient can be particularly challenging, as nausea, anorexia, and abdominal pain may be symptoms of appendicitis, abnormal pregnancy, and normal pregnancy. The differential diagnosis of appendicitis includes not only the conditions possible in nonpregnant women but also certain conditions specific to pregnancy: ectopic pregnancy, chorioamnionitis, preterm labor, placental abruption, and round ligament pain. In addition, the gravid uterus can displace the abdominal viscera, shifting the location of the appendix cephalad from the RLQ.

Appendicitis affects 1 in every 1400 pregnant women.<sup>56</sup> It can occur in any trimester, with perhaps a slight increase in frequency during the second trimester.<sup>57</sup> Perforation is most common in the third trimester, potentially resulting from a longer duration from the onset of symptoms to operation.<sup>57</sup>

In the first and early second trimesters, the presentation of appendicitis is similar to that seen in nonpregnant women. In the third trimester, women may not present with RLQ pain due to cephalad displacement of the appendix by the gravid uterus. Baer and colleagues performed barium enemas on normal pregnant women and found the appendix to migrate superiorly toward the RUQ in later stages of pregnancy.<sup>58</sup> Their findings suggest that appendicitis may present with RUQ or flank pain in late pregnancy. Two retrospective studies note that symptoms do not always reflect this cephalad displacement, however. Even in the third trimester, pain and tenderness are more common in the right lower quadrant than the RUQ.<sup>56</sup>

Several studies highlight the difficulty of clinically diagnosing a pregnant patient with appendicitis. Brown and colleagues<sup>59</sup> reviewed case-control studies that defined the relationship between preoperative presentation and the postoperative diagnosis of appendicitis in pregnant patients. Although patients presented with RUQ pain, RLQ pain, and fevers, only nausea, vomiting, and peritonitis were found to significantly correlate with the diagnosis of appendicitis. Furthermore, laboratory values are altered in the setting of pregnancy, and leukocytosis (including with a neutrophilic predominance) can be a normal finding.<sup>60</sup>

Given the challenge of clinically diagnosing appendicitis in pregnancy, imaging is critical. US is accurate in pregnancy<sup>61</sup> and is a useful radiologic study because it has no known adverse fetal effects.<sup>62</sup> However, nonvisualization of the appendix is a frequent problem, especially in increasingly advanced gestations.<sup>63</sup> In the setting of an US equivocal for appendicitis, MRI is an excellent modality. Like US, to date, no adverse effects of MRI on the developing fetus have been reported.<sup>64</sup>

In a retrospective, multicenter study of 709 pregnant women with abdominal pain who underwent MRI for the evaluation of acute appendicitis, 66 (9%) had MRI findings consistent with appendicitis. The authors report sensitivity and specificity rates of 97% and 99%, respectively.<sup>65</sup> Gadolinium should be avoided due to potential for teratogenicity. If MRI is unavailable or will cause an extreme delay in management, CT imaging of pregnant patients

with suspected appendicitis can and should be performed. The risk of radiation should be weighed against the risk of spontaneous abortion from an unnecessary laparotomy or from undiagnosed appendicitis progressing to perforation. Although ionizing radiation has risks to the fetus, the radiation from a typical abdominopelvic CT is below the threshold of 5 rad (50 mGy) at which teratogenic effects are seen.<sup>66</sup> Furthermore, CT imaging protocols can be modified to reduce the amount of fetal radiation, without impacting diagnostic value.<sup>67</sup>

The pregnant patient should proceed directly to appendectomy if appendicitis is suspected. A normal appendix is not an uncommon finding, as negative appendectomy has been reported in approximately one-third of cases due to the difficulty of diagnosis in this population.<sup>56</sup> Negative appendectomy should not be considered an error in management, because the risk to the fetus varies directly with the severity and progression of appendicitis. In a large California inpatient database, the fetal loss rate after negative appendectomy was 4%.<sup>56,68</sup> However, fetal mortality was 2% to 5% in cases of nonperforated appendicitis and 6% to 35% in cases of perforated appendicitis.<sup>59</sup> These data warrant an expedited approach to appendectomy that favors operation.

As laparoscopic appendectomy has become increasingly popular, the technique has been adapted to appendectomy in pregnancy.<sup>69</sup> Pregnancy can increase the complexity of the procedure, as the gravid uterus can make laparoscopic visualization difficult, particularly if the appendix is located in the pelvis. In addition, carbon dioxide insufflation of the abdomen results in fetal hypercarbia and decreased placental blood flow, the effects of which have not been completely studied.<sup>70</sup> A meta-analysis including 11 studies from 1990 to 2011 with 3415 patients estimated a 91% higher relative risk of fetal loss in the laparoscopic group compared with the open appendectomy group.<sup>71</sup> However, a more recent retrospective review from 2009 directly comparing laparoscopic to open appendectomy in 42 pregnant women found no intra- or postoperative complications in either group and 1 fetal loss in both groups.<sup>72</sup> Given the large time frame and retrospective nature of included studies in the aforementioned meta-analysis, the conclusions drawn from this synthesis are limited. Caution should be exercised when selecting surgical approach to appendectomy during pregnancy. Furthermore, certain risk-minimizing measures should be taken, such as limiting the degree of

pneumoperitoneum. After uncomplicated appendectomy, there do not appear to be any lasting effects on child development. Choi and colleagues prospectively studied pregnant women who underwent appendectomy.<sup>73</sup> Of 29 patients who delivered without complication (1 fetal death occurred due to extreme prematurity) and completed a detailed study survey of developmental milestones, none indicated developmental delay for their child, with a mean follow-up time of nearly 4 years.

## **Immunocompromise**

The immunocompromised state alters the normal response to acute infection and wound healing. Appendicitis must be considered among those with abdominal pain who have undergone organ transplantation, are receiving chemotherapy, have a hematologic malignancy, or have decreased CD4 cell counts due to infection with the human immunodeficiency virus (HIV). The differential diagnosis of abdominal pain in the immunosuppressed population is broad and includes hepatitis, pancreatitis (from medications or cytomegalovirus infection), acalculous cholecystitis, intra-abdominal opportunistic infections (cytomegalovirus colitis or mycobacterial ileitis), secondary malignancies (lymphoma or Kaposi sarcoma), graft-versus-host disease, and typhlitis. This broad differential diagnosis often results in delay in diagnosis and late presentation to surgical evaluation, at which time perforation may be more likely.<sup>74</sup>

Appendicitis in patients with HIV and acquired immunodeficiency syndrome (AIDS) presents unique challenges. Abdominal pain is not an uncommon symptom in these patients, making differentiation between surgical and nonsurgical causes difficult. Nonetheless, immunocompromised patients with appendicitis present with symptoms similar to those of the general population, including RLQ pain, nausea, and anorexia. Fever and WBC may not be helpful in this population given the underlying poor immune response. Therefore, imaging studies, particularly CT, have been supported by some authors.<sup>74</sup> There is no specific contraindication to operation in immunocompromised patients. Once diagnosed with appendicitis, appendectomy should be performed promptly.

## **TREATMENT**

## Nonoperative Management

Appendectomy was one of the first intra-abdominal operations performed, and appendicitis has since been a surgically treated disease. Historically, Treves was an advocate of early nonoperative management of acute appendicitis, even prior to the advent of antibiotics.<sup>10</sup> In the postantibiotic era, Coldrey<sup>75</sup> presented his retrospective series of 471 patients with appendicitis treated with antibiotics. This treatment failed in at least 57 patients, with 48 requiring appendectomy and 9 requiring drainage of an appendiceal abscess. Decades after this 1959 study, interest in nonoperative management (NOM) has reemerged, based on the results of several randomized controlled trials. NOM is currently a topic of controversy in the contemporary management of acute appendicitis.

Recent data suggest that NOM with intravenous antibiotics may present an alternative to appendectomy. This management strategy parallels the treatment of sigmoid diverticulitis and is based on work suggesting that nonperforated and perforated appendicitis are distinct diseases.<sup>22</sup> Potential benefits of NOM derive from the upfront avoidance of an invasive procedure, which must be weighed against the risk of immediate progression of disease as well as the long-term risk of recurrent appendicitis. Given the association between appendicolith and complicated appendicitis, patients with this imaging finding should not undergo NOM.<sup>76,77</sup> Similarly, these data on NOM do not necessarily apply to other high-risk patients, such as pregnant patients, the immunosuppressed, and the elderly. On the other hand, antibiotic treatment is a useful temporizing measure in environments with no surgical capabilities such as in space flight and submarine travel.<sup>78</sup> Of note, early data suggest feasibility of NOM among children with acute appendicitis. A recent prospective, nonrandomized cohort study was conducted of 102 children 7 to 17 years of age with suspected uncomplicated acute appendicitis who were offered the choice of NOM and appendectomy. Among children who underwent NOM, the 1-year rate of appendectomy (ie, 1-year failure rate of NOM) was 24%.<sup>79</sup> Potential benefits of NOM in the pediatric population were found to be fewer disability days and lower health care costs related to treatment of appendicitis at 1 year after diagnosis, despite longer initial length of hospital stay.<sup>79,80</sup>

There are several important issues to highlight when considering NOM.

First, laparoscopic (or open) appendectomy for uncomplicated acute appendicitis is a safe procedure, performed with very low levels of complication. Second, recurrence rates after NOM can be as high as 35%.<sup>81</sup> In the recent Appendicitis Acuta (APPAC) study (described below), the recurrence rate of 27% exceeded the predefined threshold of an unacceptably high rate of recurrent appendicitis.<sup>82</sup> In addition, imaging alone has a substantial false-negative rate for diagnosing perforated appendicitis.<sup>77</sup> For example, in a 2011 trial by Vons and colleagues,<sup>77</sup> 18% of patients who underwent appendectomy were unexpectedly found to have perforated appendicitis and peritonitis at the time of operation. Finally, NOM does not assess the presence of appendiceal neoplasm, which is discovered in as many as 1.5% of appendectomy specimens.<sup>82</sup>

An early randomized controlled trial, performed by Eriksson and associates,<sup>81</sup> first sought to evaluate the comparative effectiveness of NOM and appendectomy in 1995. The authors randomized 40 adults with presumed appendicitis to appendectomy or 10 days of intravenous and oral antibiotics. The results included a high rate of recurrent appendicitis after NOM. Eight (40%) of the 20 patients in the antibiotic group required appendectomy within 1 year: 1 patient for perforation within 12 hours of randomization and another 7 for recurrent appendicitis (1 of whom had perforation).

Since then, several other randomized controlled trials have addressed this same question. [Table 41-4](#) displays the characteristics of 6 important randomized trials comparing the effectiveness of appendectomy and NOM.<sup>81-86</sup> These data generally suggest fewer workdays lost with NOM and decreased duration and severity of abdominal pain. Initial cost may also be decreased with NOM, although long-term cost in the setting of recurrence and the need for close follow-up is challenging to define. In contradistinction, length of hospital stay tended to be lower with appendectomy. Neoplasm was detected after 0.5% to 1.5% of appendectomies. Recurrence rates after NOM ranged from 8% to 32%. This is consistent with a recent meta-analysis, in which the likelihood of failure was 23%.<sup>83</sup>

**TABLE 41-4: STUDIES COMPARING NONOPERATIVE AND OPERATIVE MANAGEMENT OF ACUTE APPENDICITIS**

Author and Year	No. (NOM, surgery)	Recurrence Rate (NOM only)	Cost	LOS	Duration of Abdominal Pain	Neoplasm (surgery only)	Workdays Lost
Salminen et al, <sup>82</sup> 2016	257, 273	27%	NR	Favors surgery	Favors NOM	1.5%	Favors NOM
Vons et al, <sup>77</sup> 2011	123, 120	32%	NR	Similar	Similar	NR	Similar
Turhan et al, <sup>84</sup> 2009	107, 183	8%	Favors NOM	Favors surgery	NR	NR	NR
Hansson et al, <sup>85</sup> 2009	202, 167	14%	Favors NOM	Similar	Favors NOM	1/167 and 1/202	Favors NOM
Styrud et al, <sup>86</sup> 2006	128, 124	15% (1-year)	NR	Similar	NR	0%	Similar
Eriksson and Granström, <sup>81</sup> 1995	20, 20	35%	NR	NR	Favors NOM	0%	NR

Abbreviations: LOS, length of hospital stay; NOM, nonoperative management; NR, not reported.

The most recent and largest to date randomized controlled trial was a noninferiority study by Salminen and colleagues.<sup>82</sup> The APPAC trial was performed in 6 Finnish hospitals between 2009 and 2012. The researchers evaluated the effectiveness of antibiotic therapy (intravenous ertapenem for 3 days followed by oral levofloxacin and metronidazole for 7 days) versus open appendectomy (laparoscopic appendectomy was performed only 5% of the time) as the primary treatment for uncomplicated acute appendicitis among nonpregnant patients age 18 to 60 years. Patients with evidence of fecaliths, perforation, abscess, or tumor on CT imaging were excluded. Among patients randomized to NOM, the primary end point was need for appendectomy and recurrent appendicitis during 1-year of follow-up. Based on existing literature, the threshold for noninferiority was set at 24%. There were 273 and 257 patients randomized to appendectomy and NOM, respectively.<sup>82</sup> Appendectomy was a successful management strategy 99.6% of the time. In the NOM cohort, 27.3% of patients required an appendectomy within the first year of follow-up, exceeding the a priori threshold for noninferiority. Those with recurrent appendicitis underwent appendectomy at a median of 102 days after initial treatment. The complication rate after appendectomy for recurrent appendicitis in the NOM cohort was relatively low at 7%, compared to a complication rate of 20% in the appendectomy cohort. While this difference was statistically significant, many complications were minor, including superficial surgical site infection and pain-related symptoms. Appendiceal neoplasms were intraoperatively discovered in 1.5% of patients in the appendectomy cohort.

In summary, currently available data show a moderately high rate of

recurrence of appendicitis with NOM and a small but important risk of malignancy. As such, for the majority of patients with uncomplicated acute appendicitis, laparoscopic (or open) appendectomy should be considered the gold standard treatment, while NOM may be offered on a case-by-case basis in certain circumstances.

## Preoperative Preparation

When the decision is made to perform an appendectomy for acute appendicitis, the patient should proceed to the operating room with little delay to minimize the chance of progression to perforation. While in-hospital progression to perforation is rare and most cases of appendiceal perforation occur prior to surgical evaluation, the operation should nevertheless be expedited.<sup>20,21</sup> Patients with appendicitis may be dehydrated from fever and poor oral intake. Intravenous fluids should be infused, and vital signs including urine output should be closely monitored. Markedly dehydrated patients may require a Foley catheter to ensure accurate urine output monitoring. Severe electrolyte abnormalities are uncommon with nonperforated appendicitis, as vomiting and fever have typically been present for 24 hours or less but may be significant in cases of perforation. Any electrolyte derangements should be corrected prior to the induction of general anesthesia.

Intravenous broad-spectrum antibiotics have been shown to significantly reduce the incidence of postoperative wound infection and intra-abdominal abscess, including after negative appendectomy.<sup>41</sup> Antibiotics should be administered at the time of diagnosis and re-dosed appropriately. The typical flora of the appendix resembles that of the colon and includes gram-negative aerobes (primarily *Escherichia coli*) and anaerobes (*Bacteroides* species). No standardized antibiotic regimen exists. Acceptable options include a second-generation cephalosporin or a combination of antibiotics directed at gram-negative bacteria and anaerobes, tailored to institutional antibiogram. In nonperforated appendicitis, a single preoperative dose of cefoxitin suffices.<sup>87</sup> In cases of perforation, an antibiotic course of at least 4 days after source control is obtained is advocated, in accordance with recent findings from the randomized controlled Study to Optimize Peritoneal Infection Therapy (STOP-IT).<sup>88</sup>

## Laparoscopic Versus Open Appendectomy

Open appendectomy (OA) has been the standard of care for the surgical management of acute appendicitis since Amyand performed the first appendectomy in 1736. Little changed in the surgical management of this disease until Semm developed the laparoscopic appendectomy (LA) in 1980. Over the ensuing decades, laparoscopy has increasingly taken hold as the preferred approach to appendectomy. In an analysis of the Nationwide Inpatient Sample, Masoomi and colleagues<sup>89</sup> documented an increase in the use of laparoscopy for appendectomy over the past decade, from 43% in 2004 to 75% in 2011.

Numerous randomized controlled trials have compared these 2 surgical approaches, sometimes with conflicting results.<sup>90,91</sup> Meta-analyses and systematic reviews have combined these studies to address the controversy (Table 41-5).<sup>92-94</sup> These meta-analyses have similar findings, which can be summarized as follows: (1) OA can be performed more quickly; (2) LA patients have less postoperative pain and reduced narcotic requirements; (3) there is a trend toward reduced length of stay with LA; (4) LA patients have fewer wound infections; (5) OA patients develop fewer intra-abdominal abscesses; (6) LA patients return to work more quickly; (7) operating room and hospital costs are decreased with OA; and (8) societal costs may be decreased with LA.<sup>92-94</sup> Based on the available data, one cannot definitively recommend either OA or LA over the other.

TABLE 41-5: LAPAROSCOPIC VERSUS OPEN APPENDECTOMY

## Favors Laparoscopy

## Favors Open

Diagnosis of other conditions

Decreased pain and lower  
narcotic requirement

Decreased number of overall  
surgical site infections

Decreased length of stay

More rapid return to usual  
activities

Decreased societal cost

Shorter operating room time

Decreased operating room costs

Decreased number of intra-  
abdominal abscesses

Decreased hospital costs

---

Data from McCall JL, Sharples K, Jadallah F. Systemic review of randomized controlled trials comparing laparoscopic with open appendectomy: a metaanalysis. *J Am Coll Surg.* 1998; 186:545–553 and Sauerland S, Lefering R, Neugebauer EA. Laparoscopic versus open surgery for suspected appendicitis. *Cochrane Database Syst Rev.* 2004;4:CD001546.

Laparoscopic appendectomy may be especially advisable for certain patient populations, including for women of childbearing age, obese patients, and the elderly. Among women of childbearing age, obstetric and gynecologic pathology may be clinically indistinguishable from appendicitis, and a normal appendix is found in more than 40% of patients with suspected appendicitis.<sup>95</sup> However, when a normal appendix was discovered, gynecologic pathology was found in 73% of women explored laparoscopically but only 17% of women who had an OA.<sup>96</sup> Among such patients with uncertain diagnosis, laparoscopy can thus be both diagnostic and therapeutic, avoiding a laparotomy if nonappendiceal pathology is found. Additionally, laparoscopy warrants consideration among obese patients, for whom open dissection is more technically challenging. In a National Surgical Quality Improvement Program (NSQIP) study of obese patients undergoing appendectomy, Mason and colleagues<sup>97</sup> reported a 57% reduction in morbidity with laparoscopy, compared to the open approach, after adjusting for preoperative risk factors. For the elderly, LA was found to confer lower mortality (0.4% vs 2.1%) for uncomplicated appendicitis and a less complicated postoperative course (shorter length of hospital stay and higher rate of discharge home) for perforated appendicitis.<sup>98</sup> Finally, among children, Esposito and colleagues<sup>99</sup> conducted a literature review, which

revealed a lower incidence of surgical site infection, lower analgesic use, and more rapid recovery with laparoscopic, compared to open, appendectomy. Operative time was longer with laparoscopy than laparotomy for complicated appendicitis, but not for uncomplicated appendicitis. Ultimately, the decision of surgical approach to appendectomy should depend on patient factors and surgeon comfort with the technique.

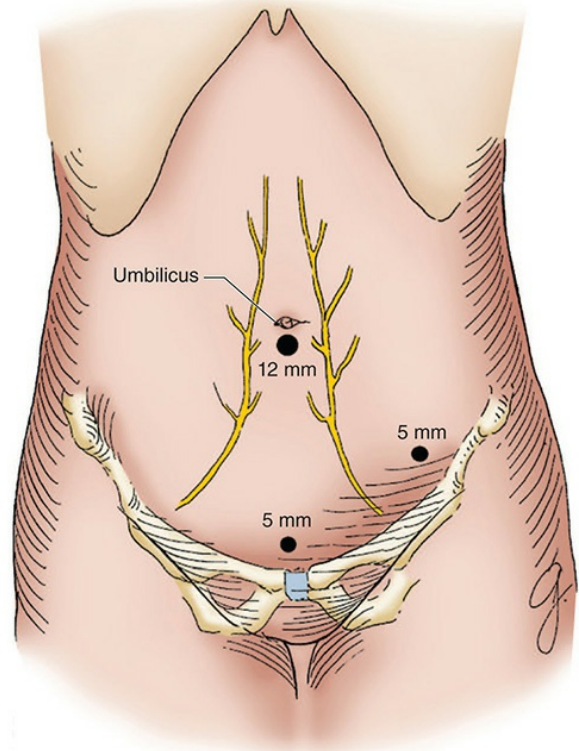

## Laparoscopic Appendectomy

Multiple port placements for LA exist. The authors use a three-port technique, with an umbilical port, a suprapubic port, and a left lower quadrant port (alternatively, an RLQ port could be used in the place of the latter). Although the third port can be placed in either the left lower quadrant or RLQ, we prefer the left lower quadrant. This follows the laparoscopic principle of triangulation, such that the port locations direct the camera and instruments toward the RLQ for optimal visualization of the appendix.

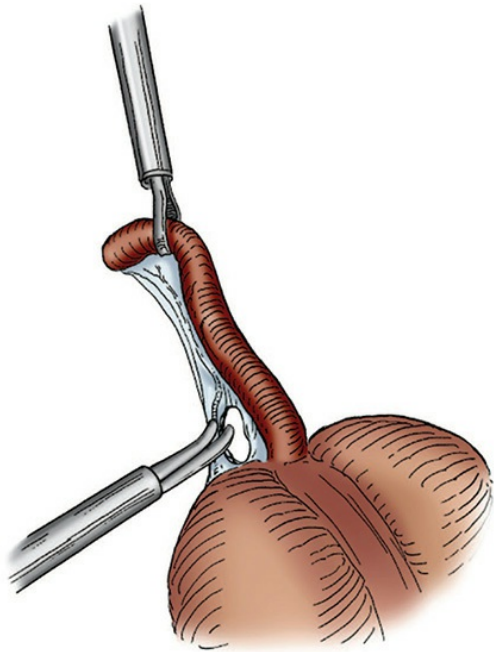

The patient is positioned supine on the operating room table with the left arm tucked to allow room for both the surgeon and assistant (Fig. 41-6). The video monitor is placed at the patient's right side and, once pneumoperitoneum is performed, the surgeon and assistant both stand on the patient's left. Prior to incision, a nasogastric tube and a Foley catheter can be placed to decompress the stomach and urinary bladder. A Foley catheter can be avoided if a reliable patient urinates immediately prior to entering the operating room. A 1- to 2-cm vertical or transverse incision is made just inferior to the umbilicus and carried down to the midline fascia. A 12-mm trocar is placed using either Hasson or Veress technique, depending on surgeon preference. After insufflation of the abdomen and inspection through the umbilical port, a 5-mm suprapubic port is placed in the midline, taking care to avoid injury to the bladder. Next, a 5-mm port is placed in the left lower quadrant. These port sites typically provide excellent cosmesis postoperatively due to their small size and peripheral location on the abdomen.

D

**FIGURE 41-6** Laparoscopic appendectomy technique. **A.** Patient positioning, **B.** Port placement, **C.** Creation of mesoappendix window, and **D.** Transection of the appendix.

A 5-mm, 30-degree laparoscope is inserted through the left lower quadrant trocar. Placing the laparoscope in the left lower quadrant allows triangulation of the appendix in the RLQ by instruments placed through the 2 midline trocars. The surgeon operates the 2 dissecting instruments and the assistant operates the laparoscope. The appendix is identified at the base of the cecum at the confluence of the teniae coli. Any adhesions to surrounding structures can be lysed with a combination of blunt and sharp dissection supplemented with electrocautery. If a retrocecal appendix is encountered, division of the

lateral peritoneal attachments of the cecum to the abdominal wall often improves visualization. Care must be taken to avoid injury to underlying retroperitoneal structures, specifically the right ureter and iliac vessels. The appendix or mesoappendix can be gently grasped with a Babcock clamp placed through the suprapubic port and retracted anteriorly. A dissecting forceps placed through the umbilical port creates a window in the mesoappendix at the appendiceal base. Caution should be taken not to injure the appendiceal artery during this maneuver, the risk of which can be reduced by dissecting close to the appendiceal base and out of the mesoappendix. The base of the appendix should be adequately dissected so that it can be divided without leaving a significant stump.<sup>25</sup> The appendix should be divided at the confluence of the appendix and cecum, or just onto the cecal wall, to avoid the possibility of stump appendicitis or mucocele (see Fig. 41-6).

The appendix can be removed in a retrograde fashion, first dividing the appendix, followed by division of the mesoappendix. A laparoscopic gastrointestinal anastomosis stapler is placed through the umbilical port and fired across the appendiceal base. After reloading, the stapler is again inserted through the umbilical port and placed across the mesoappendix, which is also divided with firing of the stapler. Alternatively, the appendix can be secured using an Endoloop<sup>100</sup> (Ethicon, Endo-Surgery, Cincinnati, OH) and the mesoappendix secured with Endoloop, clips or an electrocautery device. If desired, the appendix can be removed antegrade by first dividing the mesoappendix prior to directing attention to the base. The appendix should be placed in a retrieval bag and removed through the umbilical port site to minimize the risk of wound infection. The operative field is inspected for hemostasis and can be irrigated with saline, although irrigation is typically not necessary. Finally, the fascial defect at the umbilicus is closed with absorbable 0 suture, and all skin incisions are closed with fine subcuticular absorbable suture. For nonperforated appendicitis, no further antibiotics are required.

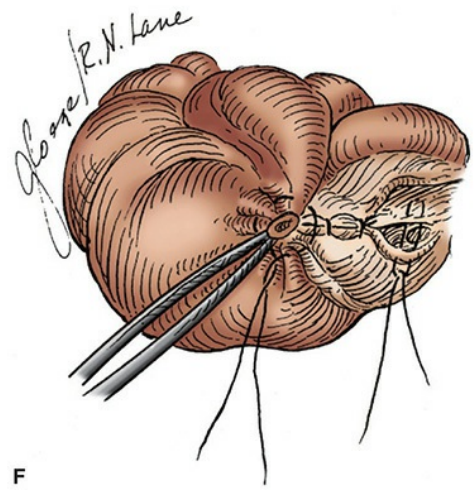

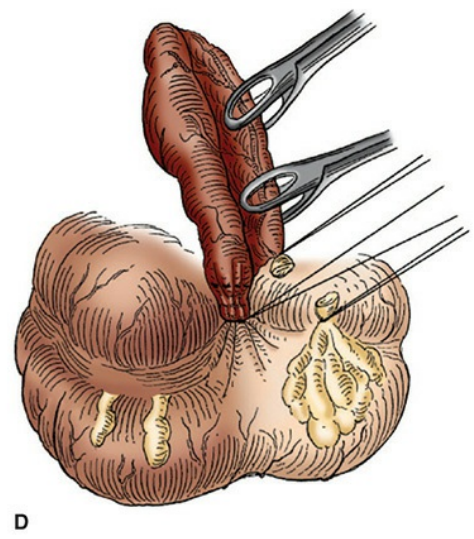

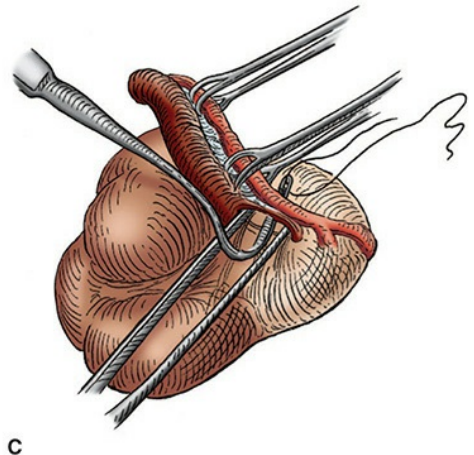

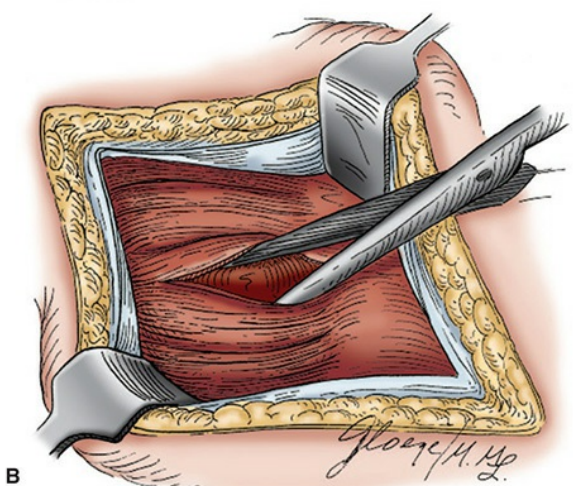

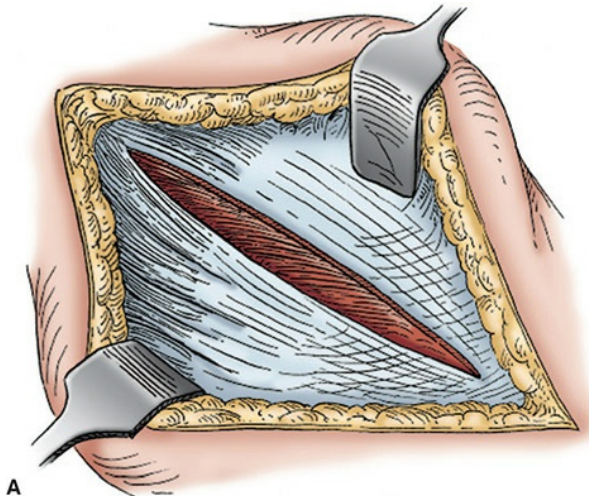

## Open Appendectomy

If OA is chosen, the surgeon must then decide on the location and type of incision. The patient should be reexamined after the induction of general anesthesia, which enables deep palpation of the abdomen. If a mass representing the inflamed appendix can be palpated, the incision can be

centered at that location. If no appendiceal mass is detected, the incision should be centered over McBurney's point, one-third of the distance from the anterior superior iliac spine to the umbilicus. A curvilinear McBurney's incision is made in a natural skin fold to avoid tension on the closure. It is important not to make the incision too medial or too lateral. An incision placed too medial opens onto the anterior rectus sheath, rather than the desired oblique muscles, while an incision placed too lateral may be lateral to the peritoneal cavity.

The operation proceeds as McBurney first described it in 1894.<sup>101</sup> The incision extends through the subcutaneous tissue, exposing the aponeurosis of the external oblique muscle, which is divided, either sharply or with electrosurgery, in the direction of its fibers (Fig. 41-7). A muscle-splitting technique is typically used, in which the external oblique, internal oblique, and transversus abdominis muscles are separated along the orientation of their muscle fibers. The peritoneum is thus exposed, grasped with forceps, and opened sharply along the orientation of the incision, taking care not to injure the underlying abdominal contents. Hemostat clamps can be placed on the peritoneum to facilitate its identification at the time of wound closure. Cloudy fluid may be encountered on entering the peritoneum. Although some advocate bacterial culture of the peritoneal fluid, studies show that this superfluous practice neither helps direct the antibiotic regimen<sup>102</sup> nor reduces infectious complications.<sup>103</sup>

**FIGURE 41-7** Open appendectomy technique.

With a correctly placed incision, the cecum will be visible at the base of the wound. The incision should be explored with a finger in an attempt to locate the appendix. If the appendix is palpable and free from surrounding structures, it can be delivered through the incision. Frequently, the appendix is palpable, but adherent to surrounding structures. Filmy adhesions can be divided using blunt dissection, but thicker adhesions should be divided under direct vision. The cecum can be partially delivered through the incision to provide better exposure of the appendix. If necessary to further improve exposure, the incision can be extended medially by partially dividing the rectus muscle or laterally by further dividing the oblique and transversus

abdominis muscles. If the nonpalpable appendix cannot be visualized, it can be located by following the teniae coli of the cecum to the cecal base, from which the appendix invariably originates. Once located, the appendix is delivered through the incision. Grasping the mesoappendix with a Babcock clamp can sometimes facilitate this maneuver.

The arterial supply to the appendix, which runs in the mesoappendix, is now clamped, ligated with 3-0 silk suture, and divided. This is usually performed in an antegrade fashion, from the appendiceal tip toward the base. As in the laparoscopic approach, adequate dissection is necessary to ensure that the entire appendix can be removed without leaving an excessively long appendiceal stump, thereby allowing the potential for stump appendicitis.

In excising the appendix, the surgeon must decide whether or not to invert the appendiceal stump. Traditionally, the appendix had been ligated and divided and its stump inverted with a purse-string suture for the theoretical purpose of avoiding bacterial contamination of the peritoneum and subsequent adhesion formation.<sup>104</sup> However, prospective studies show no advantage to appendiceal stump inversion.<sup>105</sup> In one such study, 735 appendectomy patients were randomly assigned to ligation plus inversion or simple ligation of the appendiceal stump. There was no difference between the 2 groups in the incidence of wound infection or adhesion formation, and operating time was shorter in the simple ligation group. Inversion may also have the deleterious effect of deforming the cecal wall, which could be misinterpreted as a cecal mass on future contrast radiographs.<sup>105</sup> Furthermore, the long-standing notion that stump inversion reduces postoperative adhesions was discredited by Street and colleagues.<sup>106</sup> In their analysis, postoperative adhesions requiring operation were significantly increased in the inversion group.

To divide the appendix, the surgeon can use either suture ligation or a gastrointestinal stapler. For ligation, 2 hemostat clamps are placed at the base of the appendix. The clamp closest to the cecum is removed, having crushed the appendix at that site. Two heavy, absorbable sutures such as 0 chromic gut are used to doubly ligate the appendix, and the appendix is subsequently divided proximal to the second clamp. The exposed mucosa of the appendiceal stump can be cauterized to minimize the theoretical risk of postoperative mucocele, although no data exist to support this. If appendiceal stump inversion is chosen, a seromuscular purse-string 3-0 silk suture is

placed in the cecum around the appendiceal base after ligation but prior to division of the appendix. The purse-string suture should be placed approximately 1 cm from the base of the appendix, as placing it too close to the appendix makes stump inversion difficult. After the appendix is divided, the purse-string suture is tightened and tied while the assistant uses forceps to invaginate the appendiceal stump. Alternatively, the appendix can be divided at its base using a TA-30 stapler. Again, the stump need not be inverted, but can be if desired, using interrupted Lembert sutures with 3-0 silk suture. No matter how the appendix is divided, the residual appendiceal stump should be no longer than 3 mm to minimize the possibility of stump appendicitis in the future.<sup>25</sup>

Occasionally, inflammation at the tip of the appendix makes antegrade removal of the appendix difficult. In such cases, the appendix can be removed in a retrograde fashion. In so doing, the appendix is divided at its base using one of the methods described previously. The mesoappendix is then divided between clamps, starting at the appendiceal base and progressing toward the tip (Fig. 41-8).

**FIGURE 41-8** Retrograde dissection of the appendix. The base of the appendix is secured with a pursestring suture, transected, and dissected off the cecum.

In certain cases, the appendiceal inflammation extends to the base of the appendix or beyond to the cecum. Division of the appendix through inflamed, infected tissue leaves the potential for leakage of cecal contents with a resultant abscess or fistula. Ensuring that the resection margin is grossly free of active inflammation minimizes this risk. If the base of the cecum is also inflamed but there is sufficient noninflamed cecum between the appendix and

the ileocecal valve, an appendectomy with partial cecectomy can be performed using a stapling device.<sup>107</sup> Care should be taken to avoid narrowing the cecum at the ileocecal valve. If the inflammation extends to the ileocecal junction, an ileocectomy with primary anastomosis may be necessary.

After the appendix is removed, hemostasis is achieved and the RLQ and pelvis are irrigated with warm saline. The peritoneum is closed with a continuous 0 absorbable suture. This layer provides no strength but helps to contain the abdominal contents during abdominal wall closure. The internal and external oblique muscles are then closed in succession using continuous 0 absorbable suture. To decrease postoperative narcotic requirements, the external oblique fascia can be infused with local anesthetic. Interrupted absorbable sutures are typically placed in Scarpa's fascia, and the skin can be closed with a subcuticular absorbable suture. With a preoperative dose of intravenous antibiotics and primary closure of the skin, fewer than 5% of patients with nonperforated appendicitis can be expected to develop a wound infection.<sup>108</sup>

## Postoperative Care

Postoperative care is similar after laparoscopic and open approaches. Patients with nonperforated appendicitis typically require a 24- to 48-hour hospital stay. Patients can be started on a clear liquid diet immediately, which can be advanced to their preoperative baseline diet as tolerated. No postoperative antibiotics are required for nonperforated appendicitis. Patients can be discharged when they tolerate a regular diet and pain is controlled on oral agents.

## PERFORATED APPENDICITIS

When appendicitis progresses to perforation, management depends on the nature of the perforation. If the perforation is contained, a solid or semisolid periappendiceal mass of inflammatory tissue can form, referred to as a *phlegmon*. In other cases, contained perforation may result in a pus-filled abscess cavity. Finally, free perforation can occur, causing intraperitoneal dissemination of purulent fluid and fecal material. In the case of free

perforation, the patient is typically quite ill and perhaps septic. Urgent laparotomy or laparoscopy, as described above, is necessary for appendectomy and irrigation and drainage of the peritoneal cavity. Sometimes patients with free perforation present with an acute abdomen and generalized peritonitis, and the decision to operate is made without a definitive diagnosis. Depending on the clinical stability of the patient, a diagnostic laparoscopy or exploratory laparotomy through a midline incision is performed. Once perforated appendicitis is confirmed, appendectomy again proceeds as described previously. Peritoneal drains are not necessary, as they do not reduce the incidence of wound infection or abscess after appendectomy for perforated appendicitis.<sup>109,110</sup> The final operative decision is whether or not to close the surgical site. Because of wound infection rates ranging from 30 to 50% with primary closure of grossly contaminated wounds, many advocate delayed primary or secondary closure.<sup>111</sup> However, a cost-utility analysis of contaminated appendectomy wounds showed primary closure to be the most cost-effective method of wound management.<sup>112</sup> Our technique of skin closure is interrupted permanent sutures or staples every 2 cm with loose wound packing in between. Removal of the packing in 48 hours often leaves an excellent cosmetic result with an acceptable incidence of wound infection. Patients continue to receive treatment with broad-spectrum antibiotics for at least 4 days after source control and should remain in the hospital until afebrile and tolerating a regular diet.<sup>88</sup>

If the patient does not have signs of generalized peritonitis but an abscess or phlegmon is suspected by history and physical exam, a CT scan can be particularly helpful to confirm the diagnosis. A solid, inflammatory mass in the RLQ without evidence of a fluid-filled abscess cavity suggests a phlegmon. In such instances, appendectomy can be difficult due to dense adhesions and inflammation. Ileocecectomy may be necessary if the inflammation extends to the wall of the cecum. Complications such as inadvertent enterotomy, postoperative abscess, or enterocutaneous fistula may ensue. Because of these potential complications, many support an initially nonoperative approach.<sup>113</sup> Such an approach is only advisable if the patient is not clinically ill. Nonoperative management includes intravenous antibiotics and fluids as well as bowel rest. Patients should be closely monitored in the hospital during this time. If fever, tenderness, and leukocytosis improve, diet can be slowly advanced, usually within 3 to 5 days. Patients are discharged home when clinical parameters have

normalized. Using this approach, many patients can be spared an appendectomy at the time of initial presentation.

If imaging studies demonstrate an abscess cavity, CT- or US-guided drainage can often be performed percutaneously or transrectally.<sup>113</sup> Studies suggest that this approach to appendiceal abscesses results in fewer complications and shorter overall length of stay.<sup>113</sup> Again, following drainage, the patient is closely monitored in the hospital and is placed on bowel rest with intravenous antibiotics and fluids. Advancement of diet and hospital discharge progress as clinically indicated.

## **INTERVAL APPENDECTOMY**

Treatment following initial nonoperative management of an appendiceal phlegmon or abscess is controversial. Some recommend interval appendectomy<sup>114</sup> (appendectomy performed approximately 6 weeks after inflammation has subsided), while others consider subsequent appendectomy unnecessary.<sup>115</sup> Factors to be considered when advising patients on interval appendectomy include a relatively low incidence of future appendicitis (8%-10% and often associated with an appendicolith) and a morbidity associated with an interval appendectomy of approximately 11%.<sup>115</sup> Importantly, malignancy was detected in 1.2% of cases, and colonoscopy is recommended after resolution of acute disease.<sup>115</sup> These factors must be weighed against the higher morbidity associated with an immediate appendectomy in the setting of acute recurrent appendicitis in the future (as high as 36% when appendicitis is associated with a phlegmon or abscess)<sup>115</sup> as well as the possibility of an ongoing appendiceal pathology, including inflammatory bowel disease and cancer.<sup>115</sup> Because it can now be performed laparoscopically on an outpatient basis and with low morbidity,<sup>116</sup> interval appendectomy should be considered for patients who were initially treated for perforated appendicitis with nonoperative management.

## **NORMAL APPENDIX**

Because of the difficulty in diagnosing appendicitis, it is not uncommon for a normal appendix to be found at appendectomy. Misdiagnosis can occur more

than 15% of the time, with considerably higher percentages in infants, the elderly, and young women.<sup>40</sup> Negative appendectomy must be avoided when possible, because of the risk of surgical complications and the cost associated with unnecessary surgery.<sup>117</sup> Nonetheless, in certain instances, a noninflamed appendix is found at laparotomy or laparoscopy. The surgeon must then decide whether or not to remove the appendix. For multiple reasons, it is generally advisable to remove the grossly normal appendix. First, if the pain recurs and the appendix has been removed, appendicitis will no longer be a possibility and can be removed from the differential diagnosis. If the patient suffers RLQ pain in the future and the appendix has not been removed, but the patient has a classic RLQ scar, a surgeon evaluating the patient may assume a history of appendectomy and erroneously disregard appendicitis as a possible diagnosis. As LA becomes more popular, this may even become true for patients with port site scars suggestive of appendectomy. Finally, there is strong evidence that a surgeon's gross assessment of the appendix can be inaccurate. In one study, 11 (26%) of 43 appendectomy specimens described as normal by the surgeon showed acute appendicitis on pathologic examination.<sup>118</sup> As a result, removal of a grossly normal appendix at the time of the operation for suspected appendicitis is recommended.

When a normal appendix is discovered at appendectomy, it is important to search for other possible causes of the patient's symptoms. The terminal ileum can be inspected for evidence of terminal ileitis, which could be from infectious causes (*Yersinia* or tuberculosis) or Crohn's disease. If Crohn's disease is discovered and the cecum is not inflamed, appendectomy should be performed without an increase in complication rate. In the setting of cecal inflammation, appendectomy should not be performed, and appropriate medical therapy for the treatment of newly diagnosed Crohn's disease should be initiated postoperatively. The ileum should also be evaluated for an inflamed or perforated Meckel diverticulum, which should be excised. In females, the ovaries, fallopian tubes, and uterus should be examined for pathology as well. Evaluation of the left adnexa can be difficult through an RLQ incision, highlighting the utility of laparoscopy for female patients.

## **CHRONIC APPENDICITIS**

Although rare, chronic appendicitis can explain persistent abdominal pain in

some patients. Patients do not present with the typical symptoms of acute appendicitis. Instead, they endorse weeks to years of RLQ pain and may have had multiple medical evaluations in the past. When queried, they may describe an initial episode with more classic symptoms of acute appendicitis, for which no treatment was delivered.<sup>119</sup> Diagnosis can be difficult, as laboratory and radiologic studies are typically normal. Because the diagnosis is often uncertain preoperatively, laparoscopy can be a useful tool to allow minimally invasive exploration of the abdomen.<sup>120</sup> Pathology evaluation revealing chronic inflammation confirms the diagnosis.

## **ASYMPTOMATIC APPENDICOLITH**

As CT imaging becomes more widely used, it is likely that an increasing number of asymptomatic appendicoliths will be discovered. As discussed previously, appendicoliths are not pathognomonic for appendicitis but should be considered in conjunction with the clinical presentation and other diagnostic studies. Lowe and colleagues<sup>121</sup> compared CT imaging of children with suspected appendicitis to children with abdominal trauma. Six (14%) of 44 patients with suspected appendicitis had an appendicolith but proved not to have appendicitis. In addition, 2 (3%) of the 74 trauma patients had an appendicolith on CT. These children were not followed to see if appendicitis developed later in life, but the considerable number of asymptomatic appendicoliths seen on adult abdominal radiographs suggests that many patients with an appendicolith will never develop appendicitis.<sup>16,31</sup> Based on this, appendectomy for asymptomatic appendicolith cannot be recommended.

## **NEOPLASMS OF THE APPENDIX**

Neoplasms of the appendix are rare, discovered in less than 1% of appendectomies. Signs and symptoms of appendicitis prompt appendectomy in up to 50% of patients with appendiceal neoplasms, and it is not uncommon for such patients to develop acute appendicitis.<sup>122</sup> Patients may also present with a palpable mass, intussusception, urologic symptoms, or an incidentally discovered mass on abdominal imaging or at laparotomy for another purpose. Typically, the diagnosis is not known until the time of operation or pathologic evaluation of the appendectomy specimen. However, preoperative

diagnosis may become more common as imaging techniques improve and become more widely used. Because of their common embryologic origin, the appendix and colon are susceptible to many of the same neoplastic growths. The most common appendiceal tumors include cystic neoplasms, neuroendocrine (carcinoid) tumors, adenocarcinoma, and metastases. Other tumors have been reported but are extremely rare, such as lymphoma, stromal tumors (leiomyoma and leiomyosarcoma), and Kaposi sarcoma.<sup>123</sup>

## Cystic Neoplasms and Pseudomyxoma Peritonei

Sometimes referred to as *mucocèles*, mucinous neoplasms of the appendix include a spectrum of benign and malignant diseases, including simple cyst, mucinous cystadenoma, mucinous cystadenocarcinoma, and pseudomyxoma peritonei. Mucocèle is not a true pathologic diagnosis and instead refers to the macroscopic appearance of an appendix distended with mucus. Any of the above conditions can grossly form a mucocèle, but the more specific diagnostic term is more precise.<sup>124</sup> The term low-grade appendiceal mucinous neoplasm (LAMN) can be used to refer to mucinous tumors with low-grade cytology, whereas tumors with high-grade cytology are classified as mucinous cystadenocarcinoma.<sup>125</sup> The pathway from mucinous cystadenoma to cystadenocarcinoma is postulated to be akin to that of progression from colonic polyps to adenocarcinoma. A simple cyst results from nonneoplastic occlusion of the appendiceal lumen, is usually less than 2 cm in diameter, and is often an incidental finding at appendectomy. In contrast, mucinous cystadenomas, benign tumors that represent the majority of “mucocèles,” can grow to 8 cm or larger (Fig. 41-9).<sup>126</sup> Patients typically remain asymptomatic due to slow-growing distension of the appendix and instead present incidentally with a mass on physical examination or abdominal imaging (Fig. 41-10). On plain radiograph or CT, wall calcification is characteristic.<sup>124</sup> Ten-year disease-free survival progresses from 100% in low-grade mucinous neoplasms confined to the appendix, to 88% in low-grade mucinous neoplasms with extra-appendiceal acellular mucin, to 9% in low-grade mucinous neoplasms with extra-appendiceal neoplastic epithelium, to 0% in appendiceal mucinous neoplasms with poor prognostic markers of invasion, complex architecture, or high-grade cytology.<sup>127</sup>

**FIGURE 41-9** A 14-cm mucinous cystadenoma of the appendix. The appendiceal tip is to the left, and the base is to the right. (Used with permission from Jacqueline M. Wilson, MD, PhD, Brigham and Women's Hospital, Boston, MA.)

**FIGURE 41-10** Computed tomography axial image at the level of the terminal ileum shows a fluid-filled mass (*arrowhead*) corresponding to the mucinous cystadenoma seen in [Figure 41-9](#). The more proximal appendix (*arrow*) is seen between the mass and cecum. (Used with permission from M. Stephen Ledbetter, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

Mucinous appendiceal masses should be surgically removed because of the potential for underlying malignancy.<sup>126</sup> In one study of 129 patients who underwent resection of appendiceal mucoceles, Stocchi and colleagues noted that tumor size was not statistically related to risk of malignancy.<sup>126</sup> For mucinous cystadenoma, appendectomy is sufficient if the lesion does not involve the appendiceal base. Occasionally, the mass will rupture prior to or at the time of removal, but this rupture is typically contained to the RLQ and is considered localized pseudomyxoma peritonei (see below). If the mass is benign, appendectomy and removal of any residual mucin are curative.<sup>126</sup> Mucinous cystadenocarcinoma represents the malignant form of cystic neoplasms of the appendix. In contrast to cystadenoma, patients are more likely to be symptomatic with abdominal pain, weight loss, an abdominal mass, or signs of acute appendicitis. Right hemicolectomy should be performed in the setting of any indication of malignancy in an appendiceal mass with the possibility of cure.<sup>126</sup> The laparoscopic approach is not generally recommended because of the possibility of malignancy and the risk of spillage of mucin-secreting cells throughout the abdomen. Because of an association with colon and rectal carcinoma, a screening colonoscopy is recommended postoperatively.<sup>126</sup>

It is not uncommon, however, for the malignant diagnosis to be unknown until the pathologic evaluation of the appendectomy specimen indicates incidental appendiceal mucinous cystadenocarcinoma. In such cases, reoperation with right hemicolectomy is recommended, as 5-year survival for mucinous cystadenocarcinoma is 75% after hemicolectomy and less than 50% after appendectomy alone.<sup>128</sup> Some referral centers advocate extensive initial resections including omentectomy, as well as repeated debulking procedures for recurrent disease.<sup>129</sup>

Pseudomyxoma peritonei is a condition in which tumor perforation has seeded the peritoneum with mucinous tumor cells. On physical exam, increasing abdominal girth may also be present, suggesting perforation and peritoneal dissemination of mucin-secreting cells characteristic of

pseudomyxoma peritonei. Diffuse pseudomyxoma peritonei is highly predictive of malignancy; in one series, 95% of patients with pseudomyxoma had an associated mucinous cystadenocarcinoma.<sup>126</sup> The recommended treatment consists of a minimum of a right hemicolectomy with debulking of any gross spread of disease and removal of all mucin. Recently, hyperthermic intraoperative chemotherapy (HIPEC) is increasingly being used. Chua and colleagues<sup>130</sup> report results from a large multicenter study of 2298 patients with pseudomyxoma peritonei from appendiceal origin who were treated with cytoreductive surgery and HIPEC. The authors document a median survival and progression-free survival of greater than 16 and 8 years, respectively. Outcomes were significantly worse for those with gross residual disease after debulking surgery. Data from a French multicenter study indicate that patients with pseudomyxoma peritonei should be referred to centers with experience in their treatment, as higher center volume was significantly associated with improved disease-free survival.<sup>130</sup> Long-term management involves debulking for symptomatic disease, with a high likelihood of repeated surgery.

## Adenocarcinoma

Primary adenocarcinoma of the appendix is classified into 3 types: mucinous (discussed previously), colonic, and signet-ring cell. The colonic type is least common, least likely to secrete mucin, and most likely to present with acute appendicitis due to obstruction of the appendiceal lumen.<sup>124</sup> Staging is distinguished from that of colonic adenocarcinoma in the American Joint Committee on Cancer staging manual.<sup>131</sup> The colonic type has a less favorable prognosis, with only 41% 5-year survival after treatment, compared to 71% for the mucinous type. The optimal treatment is right hemicolectomy, and reoperation should be recommended if the diagnosis is made on pathologic evaluation of an appendectomy specimen.<sup>128</sup> Signet-ring cell type confers the poorest prognosis. The effectiveness of adjuvant chemotherapy or radiotherapy on primary appendiceal adenocarcinoma is unknown. HIPEC may be considered for patients with disseminated appendiceal adenocarcinoma, with promising results from a series of 46 consecutive patients with median overall survival and disease-free survival of 56.4 months and 20.5 months, respectively.<sup>132</sup>

## Carcinoid Tumors

The most common neoplasm of the appendix, carcinoid tumors, compose more than 50% of all appendiceal tumors.<sup>122</sup> Among malignant tumors of the appendix, carcinoids are less aggressive and carry a much more favorable prognosis than adenocarcinomas, with 5-year survival approaching 90%.<sup>133</sup> Most appendiceal carcinoids are found incidentally at the time of appendectomy for appendicitis. However, perhaps because the majority of appendiceal carcinoids are located at the tip of the appendix, the carcinoid mass is the cause of appendicitis only 25% of the time.<sup>123</sup> Tumor size, extent of disease, and histology are the primary determinants of malignant potential. Approximately 75% of carcinoids are less than 1 cm in size and only 5% to 10% are over 2 cm. Lymph node invasion and distant metastases are rare except in tumors over 2 cm.<sup>134</sup> In a pooled summary of 517 patients, nodal metastasis were found in 0%, 7.5%, and 33% of patients with tumors  $\leq 1$  cm, 1.1 to 1.9 cm, and  $\geq 2$  cm, respectively.<sup>135</sup>

Goblet cell carcinomas were previously categorized as a subtype of carcinoid but have characteristics of both carcinoid and adenocarcinoma.<sup>136</sup> Goblet carcinoma behaves more aggressively than classic carcinoid but still has a better prognosis than adenocarcinoma.<sup>133</sup> Reflecting this in a study of 2812 patients with appendiceal neuroendocrine tumors in the National Cancer Database, Hsu and colleagues reported a 5-year overall survival rate of 86% for malignant carcinoid tumor, 78% for goblet cell carcinoid, and 56% for composite goblet cell carcinoid-adenocarcinoma.<sup>137</sup>

Treatment of appendiceal carcinoid is dictated primarily by tumor size. Regardless of the operation, it is important to visually inspect and palpate the bowel to investigate the possibility of multifocal disease. Simple appendectomy is sufficient for tumors less than 1 cm in diameter because of the low likelihood of lymph node involvement. Among patients with tumors of 1 to 2 cm in diameter, right hemicolectomy is reserved for patients with positive margins or deep mesoappendiceal invasion, higher proliferation rate (grade 2), or angioinvasion.<sup>138</sup> For masses larger than 2 cm, right hemicolectomy is recommended. Because of a concern for increased metastatic potential, some authors also advocate right hemicolectomy regardless of tumor size in the setting of young patients; carcinoids at the appendiceal base; and/or histopathologic evidence of lymphatic invasion,

lymph node involvement, spread to the mesoappendix, tumor-positive resection margins, or cellular pleomorphism with a high mitotic index.<sup>139</sup>

## **SMALL BOWEL DIVERTICULA**

Small bowel diverticula can be characterized according to their anatomic location (duodenal, jejunoileal, and distal ileal diverticula) or the type of diverticula (false or true diverticula). Small bowel diverticula are typically false diverticula, which by definition do not contain all the layers of the bowel wall and involve herniated mucosa and submucosa. They occur at points of weakness, where blood vessels enter the mesenteric border of the small bowel. In contradistinction, intraluminal diverticula occur from congenital abnormalities. Finally, a distal ileal (Meckel) diverticulum is a true diverticulum containing all of the layers of the small bowel. It is a congenital anomaly resulting from the failure of the vitelline duct to obliterate and is located along the antimesenteric border of the distal ileum. Although the presence of small bowel diverticula is not uncommon, most are asymptomatic and thus never appreciated. Fewer than 4% of small bowel diverticula cause symptoms, including inflammation, hemorrhage, obstruction, perforation, and malabsorption.

### **Duodenal Diverticula**

Duodenal diverticula (DD) account for approximately 45% of small bowel diverticula and have a reported incidence on radiologic and autopsy studies of 5% to 22%.<sup>140</sup> They are rarely multiple (12%), and the vast majority (88%) are located in the medial wall of the second portion of the duodenum.<sup>141</sup> When the diverticulum is located adjacent to the ampulla of Vater, as is often the case, it is known as a perivaterian or periampullary diverticulum. DD typically occur in patients age 50 to 65 years and are often asymptomatic at presentation. Less than 5% of patients with DD present with symptoms, including nausea, vomiting, RUQ abdominal pain, fevers, chills, and bleeding. These presentations are often noted in case reports and result from one of many potential complications, including inflammation, obstruction of the duodenum or biliary-pancreatic duct, fistula formation in the bile duct, bezoar formation inside the diverticulum, and perforation. Although it is the

most unusual complication, DD perforation is the most serious and can carry a mortality of up to 20%. Perforation usually results from acute inflammation but may also result from enterolithiasis, ulceration, increased intraluminal pressure (eg, during endoscopy), abdominal trauma, gallstones, or ischemia. Perforation usually occurs posteriorly and thus can result in a retroperitoneal abscess and sepsis. Anterior perforation can also occur, resulting in intraperitoneal spillage or communication with surrounding structures. Of resultant fistulae, including to the pancreas, colon, and gallbladder, the most catastrophic is duodenal perforation into the aorta.

The nonspecific nature of the presenting symptoms and their commonality with other gastrointestinal diseases such as pancreatitis, cholecystitis, cholangitis, and peptic ulcer disease highlight the fact that the diagnosis of a complicated DD is often one of exclusion (unless one of the aforementioned unique presentations occurs). Radiologic studies including plain abdominal films and US may be helpful to exclude other etiologies but are not definitive. CT imaging and upper endoscopy are the modalities of choice for evaluation. In the case of an inflamed diverticulum, CT may demonstrate a thickened duodenal wall and surrounding fat inflammation. If perforation has occurred, an extraluminal collection of air and fluid (predominantly retroperitoneal) may be identified. In addition, the administration of oral contrast with a CT scan or an upper gastrointestinal swallow study may define the extent of a leak in the case of a perforation. However, it is rare to identify a DD on CT scan, and additional studies may be required. Side-viewing endoscopy and endoscopic retrograde cholangiopancreatography (ERCP) are valuable in correctly diagnosing the presence of a DD as well as potentially treating some of the associated complications. Successful endoscopic management of hemorrhage, duodenal obstruction, pancreatobiliary obstruction resulting in pancreatitis or cholangitis, and retroperitoneal abscess drainage associated with a DD have been reported.<sup>142</sup>

The management of DD depends on the presence or absence of symptoms and the clinical stability of the patient. Given the precarious typical location of a DD near the ampulla of Vater and the concomitant morbidity associated with resection, asymptomatic DD discovered on imaging or endoscopy for other reasons should be observed. Symptomatic DD can be managed endoscopically, nonoperatively, or with surgical exploration and resection or bypass. If inflammation with or without perforation is present, nonoperative management, including nasogastric decompression, antibiotics, serial

examinations, and radiologic-guided drainage if an abscess is present, has been reported. This approach can be considered in patients with mild symptoms who are clinically stable or when CT confirms a contained leak.<sup>140-142</sup> If the patient is not a candidate for nonoperative management because of hemodynamic instability, generalized peritonitis, or persistent severe symptoms, the choice of surgical intervention depends on such factors as the location of the diverticulum and other intraoperative findings. In the setting of minimal inflammation and favorable diverticular anatomy, a simple closure of the perforated diverticulum or diverticulectomy with single- or double-layer duodenal closure after Kocherization of the duodenum is the treatment of choice. After repair, appropriate drainage tubes should be placed and the greater omentum can be used to reinforce the repair. It is imperative to avoid damaging the pancreatic and distal common bile ducts during the repair, so cannulation of the ampulla of Vater (either retrograde or antegrade through the cystic duct with subsequent cholecystectomy) can be performed to help visualize the ampulla prior to dissecting the diverticulum. At times, diverticular anatomy is unfavorable with significant inflammation at the site of the diverticulum, the diverticulum buried in the pancreatic head, or the papilla located deep in the diverticulum. In such cases, a diversion should be performed by either a distal gastrectomy with a Billroth II reconstruction or a Roux-en-Y gastrojejunostomy. Again, appropriate drainage tubes are typically placed to decompress the affected areas. In addition to diversion and diverticulectomy, segmental duodenal resection for a perforated DD has also been reported for the rare case of a DD located in segment III or IV of the duodenum. A pancreaticoduodenectomy may also be necessary if the DD lies in close proximity to the common bile and pancreatic ducts and the inflammation is thought to be too severe for safe diversion or drainage.<sup>140,142</sup> If symptoms derive from obstruction of the pancreaticobiliary system, causing cholangitis or pancreatitis, resection of the duodenum may not be required. In such cases, treatment may consist of diversion of bile flow with a Roux-en-Y choledochojejunostomy and duodenojejunostomy.<sup>142</sup>

## **Jejunoileal Diverticula**

The least common of the small bowel diverticula, jejunoileal diverticula (JID) have a rare prevalence of 0.002% to 5% based on postmortem and enteroclysis studies. The risk of diagnosis increases with age and peaks in the

sixth and seventh decades of life. JID are acquired pseudodiverticula believed to result from a jejunoileal dyskinesia causing increased intraluminal pressures and ultimately herniation of the mucosa and submucosa through the weakest site of the muscularis propria of the bowel wall (ie, the mesenteric border where paired blood vessels enter the bowel wall). They can be single (33%) or multiple (66%) and located in the jejunum (55%-80%), ileum (15%-38%), or both (5%-7%).<sup>143</sup> Interestingly, patients with JID also frequently have other coexisting gastrointestinal diverticula, including those found in the colon (20%-70%), duodenum (10%-40%), esophagus, and stomach (2%), highlighting a potential common etiology.<sup>144</sup>

Most patients with JID are asymptomatic (up to 70%). When symptomatic, the diagnosis of a JID is often challenging because patients often present with vague abdominal symptoms. There is no gold standard imaging technique used to diagnose a JID. Upper gastrointestinal studies with small bowel follow-through as well as traditional enteroclysis and CT enteroclysis studies are beneficial. CT, tagged red blood cell scan, or angiogram may demonstrate findings consistent with a complication of a JID such as inflammation, perforation, or bleeding. Capsule endoscopy and double-balloon endoscopy are useful in diagnosing small bowel disorders and may be of benefit in identifying JID in a nonacute setting.<sup>144</sup> Ultimately, JID are often identified on exploratory laparotomy or laparoscopy for other indications or for the evaluation of chronic or acute symptoms.<sup>144</sup>

Asymptomatic, incidentally discovered JID need not be resected. When symptomatic, patients with JID can be divided into those with acute or chronic symptoms. Forty to 60% of patients with a known diagnosis of JID present with chronic symptoms. These symptoms are often nonspecific and include nausea, vomiting, postprandial bloating, recurrent abdominal pain, cramping, weight loss, fatigue, and failure to thrive. Because of the vague nature of the presenting symptoms, these patients often go undiagnosed or misdiagnosed for several months (average 22 months) prior to being correctly diagnosed.<sup>143</sup> The underlying pathophysiology of the chronic symptoms is believed to be related to either intestinal dyskinesia or bacterial overgrowth from blind loop syndrome due to stasis in the diverticular lumen. When bacterial overgrowth and a blind loop syndrome are present, the patient may develop malabsorption, steatorrhea, and megaloblastic anemia resulting from vitamin B<sub>12</sub> deficiency. Frequently, chronic symptoms from JID can be

successfully managed medically. Medical management consists of a low-residue diet, antispasmodics, antacids, analgesics, and vitamin B<sub>12</sub> supplementation. Bacterial overgrowth and blind loop syndrome can be initially managed with antibiotics. In the rare case in which medical management fails, patients may require resection of the segment of bowel containing the diverticulum with subsequent primary anastomosis.

Approximately 10% to 19% of patients with JID present with acute, often emergent, symptoms resulting from a complication of the diverticulum, including gastrointestinal hemorrhage, diverticulitis, obstruction, fistula formation, and perforation. The presentation and management of a patient with an acute complication of a JID depend on the complication. Inflammation resulting in diverticulitis occurs in 2.3% to 6.4% of patients with JID and can present as mild abdominal pain or diffuse peritonitis associated with free perforation.<sup>143</sup> If perforation occurs in the setting of full-thickness necrosis, it can be associated with a mortality of up to 40%.<sup>143</sup> Traumatic and foreign body perforations of JID have also been described. If the perforation is contained within the mesentery, nonoperative management with bowel rest and antibiotics with or without percutaneous drainage can be attempted. Similarly, in a clinically well patient, asymptomatic pneumoperitoneum in the setting of a known JID is not an absolute indication for surgery and this scenario may be managed nonoperatively.<sup>143</sup> Lack of clinical improvement after a period of nonoperative management, however, mandates resection of the affected segment of bowel with a primary anastomosis. Similarly, patients presenting with more significant findings of fever, elevated WBC, peritonitis, and septic physiology require immediate laparotomy with resection of the affected segment of bowel.<sup>143</sup>

Of patients with JID, 2% to 4.6% present with obstruction related to adhesions, intussusception, volvulus, and extrinsic compression from a fluid-filled diverticulum or, rarely, from an enterolith formed in the diverticulum causing obstruction at the diverticulum or at the ileocecal valve. Obstruction believed to be secondary to adhesions can initially be managed conservatively. However, if nonoperative management fails, lysis of adhesions and segmental bowel resection of the JID with a primary anastomosis are required. Similarly, surgical resection is indicated for the management of obstruction resulting from intussusception, volvulus, or extrinsic compression.<sup>144</sup> Enterolith ileus associated with a JID is best

managed by an initial attempt at manual lysis of the stone without an enterotomy. If not possible, the stone can be retrieved, advanced into the colon, and/or mechanically fractured through an enterotomy performed in a nonedematous segment of bowel.<sup>145</sup> If 1 or multiple diverticula appear inflamed or scarred, segmental resection of the involved bowel with a primary anastomosis is mandated. However, many patients often have multiple diverticula over a long stretch of bowel, and thus, if no evidence of inflammation or scarring is present, avoiding resection is indicated.<sup>143</sup> Approximately 3% to 8% of patients with JID present with bleeding complications. Hemorrhage from a JID can be slow and chronic in nature or acute and massive presenting with hemorrhagic shock. Upper and lower endoscopies are often negative, and the diagnosis is made with angiographic and radioactive red blood cell studies. Although successful intervention with angiographic embolization has been documented, segmental bowel resection is frequently the required treatment.<sup>143,146</sup>

## Meckel Diverticula

Meckel diverticula are the most common congenital malformations of the gastrointestinal tract, occurring in 1% to 3% of the population.<sup>147</sup> A Meckel diverticulum is a true diverticulum containing all 3 layers of the intestinal wall. The structure results from the failure of the obliteration of the vitelline (omphalomesenteric) duct, which normally occurs during the fifth to seventh weeks of fetal life. Blood supply derives from the vitelline artery, a branch of the superior mesenteric artery. It is typically located on the antimesenteric border of the small bowel within 100 cm of the ileocecal valve. Although Meckel diverticula are often lined with ileal mucosa, they may also contain ectopic gastric, duodenal, colonic, and endometrial mucosa as well as pancreatic tissue, carcinoid tissue, Brunner's glands, and hepatobiliary tissue.<sup>148</sup> Gastric mucosa, followed by pancreatic tissue, is the most commonly occurring heterotopic tissue.

Similar to other small bowel diverticula, the majority of Meckel diverticula are asymptomatic and discovered incidentally at the time of an operation for other indications. Recent reviews indicate that up to 84% of Meckel diverticula found at operation were asymptomatic. A symptomatic Meckel diverticulum can present in both the pediatric and adult population.

However, the frequency of presentation decreases with increasing age. There is a male predominance (3:1) of both symptomatic and asymptomatic Meckel diverticula in both pediatric and adult populations.<sup>147</sup>

Symptomatic presentation results from one of many potential complications, including bleeding, obstruction, diverticulitis, perforation, intussusception, ulceration, and, rarely, the presence of malignancy within the Meckel diverticulum. In the adult population, the most common presentations are bleeding (38%), obstruction (34%), and diverticulitis (28%). In the pediatric population the most common presentations are obstruction (40%), bleeding (31%), and diverticulitis (29%).<sup>147,148</sup> Obstruction may result from the Meckel diverticulum serving as a lead point for intussusception, a point of fixation for volvulus, or as a result of an adhesive band to the diverticulum. Bleeding in the setting of a Meckel diverticulum is believed to result from acid secretion from ectopic gastric mucosa, leading to ulceration of and subsequent bleeding from ileal mucosa. The typical presentation is episodic, painless gastrointestinal hemorrhage. The most common sites of ulceration are the base of the diverticulum at the juncture between ectopic gastric and ileal mucosa, followed by the mesenteric ileal mucosa. Among patients who develop malignancy in the Meckel diverticulum, carcinoid predominates. Finally, just as an Amyand hernia contains the appendix, a Littre hernia contains a Meckel diverticulum. The most common type of Littre hernia is inguinal in adults and umbilical in children.<sup>149</sup>

Preoperative diagnosis of a symptomatic Meckel diverticulum can be difficult. A technetium-99m pertechnetate scan is the most accurate noninvasive study used to interrogate the presence of a Meckel diverticulum. The tracer used in this study is specific for ectopic gastric mucosa, and thus false-positive results may occur when a duplication cyst containing gastric mucosa is present. A false-negative result occurs if the Meckel diverticulum does not contain ectopic gastric mucosa. During the study, a bladder catheter can be used to avoid accumulation of contrast media obscuring the area of interest. Despite these limitations, studies have found technetium-99m pertechnetate scans to be highly sensitive and specific in both the pediatric and adult populations.<sup>147</sup> In cases of a suspected bleeding Meckel diverticulum, angiography, and a tagged red blood cell scan may be of diagnostic value. If suspicion is high, other etiologies have been ruled out, and noninvasive diagnostic tools exhausted, exploratory laparoscopy may be used to diagnose and treat a complicated Meckel diverticulum.

Surgical resection is indicated for symptomatic Meckel diverticula. Options for resection include a diverticulectomy or a segmental bowel resection with a primary anastomosis. Indications for segmental bowel resection include damage to the normal ileal mucosa due to ulceration or bleeding as well as the presence of diverticulitis or palpable ectopic tissue at the diverticular-intestinal junction.<sup>148</sup> In other circumstances, a diverticulectomy can be performed if amputating the diverticulum at its base will not compromise the ileal lumen. If diverticulitis is present, the line of resection should be free of inflammation. Amputation should be performed in a transverse orientation and can use a surgical stapling device. The staple line can then be oversewn with interrupted 3-0 silk Lembert sutures. Alternatively, the diverticulum can be resected between bowel clamps and the defect sutured closed transversely in 2 layers, using a continuous inner layer of 3-0 Vicryl or chromic suture followed by an outer layer of 3-0 silk Lembert sutures. In either case, the surgeon should identify and ligate the artery perfusing the Meckel diverticulum.

For an asymptomatic Meckel diverticulum incidentally discovered on imaging study, we recommend nonoperative management. The potential benefit of an operation is outweighed by the high number needed to treat (n = 758) and the risk of complications with diverticulectomy or bowel resection.<sup>150</sup> For an asymptomatic Meckel diverticulum incidentally discovered during an operation, the appropriate action is slightly less clear and likely depends on patient selection. In a meta-analysis that includes nearly 3000 patients, Zani and colleagues<sup>150</sup> report that the postoperative complication rate was significantly higher among patients who underwent incidental diverticulectomy (5.3%) compared to those with the Meckel diverticulum left in situ (1.3%). Furthermore, of the 64 patients included in the systematic review who did not undergo resection of their asymptomatic Meckel diverticulum, none developed complications with long-term follow-up. Caution should be used when interpreting these data, which incorporate the findings of dated and retrospective studies.<sup>150</sup> The authors proceed to argue that appendicitis is 50-fold more likely to occur than symptomatology from a Meckel diverticulum.<sup>150</sup> While incidental appendectomy has become an obsolete practice, incidental diverticulectomy may have even less utility.

Despite this, the risk of developing symptoms was estimated to be as high as 6%, and selected asymptomatic patients may be at higher risk than others.

As such, some authors support incidental diverticulectomy for any patient who fulfills any of the following criteria: (1) younger than 50 years, (2) male sex, (3) diverticulum greater than 2 cm in length, and (4) ectopic or abnormal features within a diverticulum. These criteria are based on a review of 1476 patients who underwent incidental diverticulectomy at a single institution between 1950 and 2002.<sup>148</sup> Of those, 1238 patients were asymptomatic and 238 were symptomatic. The aforementioned criteria were significantly associated with symptomaticity in multivariable analysis. The decision to resect an asymptomatic Meckel diverticulum should be made on a case-by-case basis, based on these patient factors.

# SHORT BOWEL SYNDROME AND INTESTINAL TRANSPLANTATION

*Diego C. Reino • Douglas G. Farmer*

## INTRODUCTION

Intestinal failure (IF), including surgical short bowel syndrome (SBS), is a life-threatening condition that is associated with several major medical complications as well as limitations in quality of life. The evolution of treatment strategies for IF/SBS has seen significant changes in the past 30 years. Like several major advances in surgery, the discovery of anastomotic techniques by Alexis Carrel in the early 1900s paved the way for intestinal transplantation (ITx). As a parallel to surgical discoveries, the development and implementation of parenteral nutrition (PN) and hormonal analogs has allowed clinicians to support IF patients and bridge them toward the ultimate therapy of ITx. The purpose of this chapter is to provide an overview of the causes and medical management of IF/SBS, indications for and various

surgical techniques within ITx. The chapter reviews the landmark developments in surgical therapy techniques and provides an outline for the different technical variations within ITx.

## **BACKGROUND/HISTORY**

The evolution in the medical management of IF/SBS has relied heavily on the advent of PN. Prior to 1968, patients who suffered a massive infarction of their small intestine were often left unresected at the time of laparotomy due to the lack of intravenous nutritional support in the perioperative setting.<sup>1</sup> This often led to consecutive operations for resections of necrotic bowel and patients would ultimately succumb to sepsis and multiorgan failure. The first major breakthrough for PN was ushered in as an alternative therapy for the IF patient in 1968. Wilmore and colleagues were able to demonstrate that the infusion of a hypertonic nutrient solution through a dedicated central venous catheter (CVC) could deliver all of the necessary nutrients to sustain growth and development in an infant with intestinal atresia and IF/SBS.<sup>2</sup> This development was a major stepping stone that paved the way for the surgical developments that followed.

Richard Lillehei and Thomas Starzl established the early techniques of ITx in canine models in the 1950-1960s.<sup>3,4</sup> However, the first reports of ITx came in the mid-1980s when Williams, Starzl, and others documented the first successful isolated intestine, multivisceral, and liver-intestine transplants in humans.<sup>5-8</sup> Together, these landmark medical and surgical establishments set the groundwork for the modern era of ITx.

## **PATHOPHYSIOLOGY OF INTESTINAL FAILURE AND ADAPTATION**

The complex mechanisms and relationships of the neurohormonal, enteric nervous, and immune systems of the intestine are beyond the scope of this chapter. However, it must be noted that IF/SGS results from an inadequate delivery of micronutrients, fluid, and electrolytes via the gastrointestinal tract. In the IF/SBS patient, compensatory mechanisms of adaptation can be achieved in the remnant bowel in an attempt to restore the threshold for

nutrient delivery.<sup>9-11</sup> Clinically, the cornerstone of successful adaptation relies upon enterocyte mass. Likewise, patients with a greater length of functional bowel and the presence of an ileocecal valve (ICV) are likely to succeed at achieving an adapted state. The functional response of the remnant gut in the IF/SBS patient is primarily to modify sodium, water, and glucose absorption. Enterocyte hyperplasia contributes to increasing enterocyte mass; however, modifications in enterocyte-specific gene expression that leads to improved nutrient trafficking also adds a functional increase to the enterocyte mass, thus rendering an adapted state.<sup>9-11</sup> These molecular mechanisms have been the foundation that have led to the surgical concepts which focus on bowel lengthening procedures. The techniques such as the Bianchi and the serial transverse enteroplasty (STEP) procedures strive to increase overall enterocyte mass, and these are discussed in further detail later in this chapter.

## **INTESTINAL FAILURE: DEFINITIONS AND CLASSIFICATIONS**

Historically, “short bowel syndrome” was a blanket term that had been used for patients who suffered a catastrophic loss of bowel length that rendered them incapable of maintaining enteral nutrition. These patients were all managed with total parenteral nutrition (TPN), and thus there was no need to further stratify the definition or causes of IF. Advances in prenatal and neonatal intensive care along with more recent developments in medical therapies such as recombinant growth hormone, somatostatin, and glucagon-like peptide-2 (GLP-2) analogs have forced us to further classify the definition of IF. In 2006, a group of experts developed a consensus definition whereby “Intestinal failure results from obstruction, dysmotility, surgical resection, congenital defect, or disease-associated loss of absorption and is characterized by the inability to maintain protein-energy, fluid, electrolyte or micronutrient balance.”<sup>12</sup> With a well classified definition, we are now better able to evaluate the relative efficacy of these therapies and thus offer some patients the opportunity to regain nutritional autonomy free of PN or intravenous fluids.<sup>12</sup> Thus, it is important to recognize that while IF can occur as a result of surgical resection of the gut (“short bowel syndrome”) it can also result from conditions that disrupt gastrointestinal motility or enterocyte function. In these latter cases, the length of remnant intestine is irrelevant and

usually normal.

## **PEDIATRIC CAUSES OF INTESTINAL FAILURE**

The pathogenesis of IF in the pediatric population can be classified into (1) anatomic/surgical reductions of bowel (necrotizing enterocolitis, intestinal atresia, gastroschisis, and midgut volvulus), (2) neuromuscular diseases of the gut (intestinal aganglionosis or Hirschsprung disease), chronic intestinal pseudoobstruction, and (3) congenital diseases of the intestinal epithelium (microvillous atrophy, tufting enteropathy, intestinal epithelial dysplasia). In some cases, overlap can occur as in a pseudo-obstruction patient with multiple small bowel resections. The details of the complex medical management and maintenance of nutrition in this patient population is beyond the scope of this chapter. However, it must be noted that growth can be achieved on long-term PN, and the aim of appropriate medical management should be to prevent complications of PN such as catheter-related sepsis and vascular thrombosis. Moreover, a combined use of early enteral feeding with supplemental PN can help prevent intestinal failure –associated liver disease (IFALD) as the ultimate complication of PN use.

## **ADULT CAUSES OF INTESTINAL FAILURE**

IF within the adult population is largely attributable to massive resection of bowel following a catastrophic event suffered by the patient. Generally, it is the result of a surgical complication from a previous procedure.<sup>13</sup> However, adult causes of IF can be categorized into iatrogenic complications, ischemic complications, infiltrative disease processes, obstruction related, and functional problems (see [Table 42-1](#)).

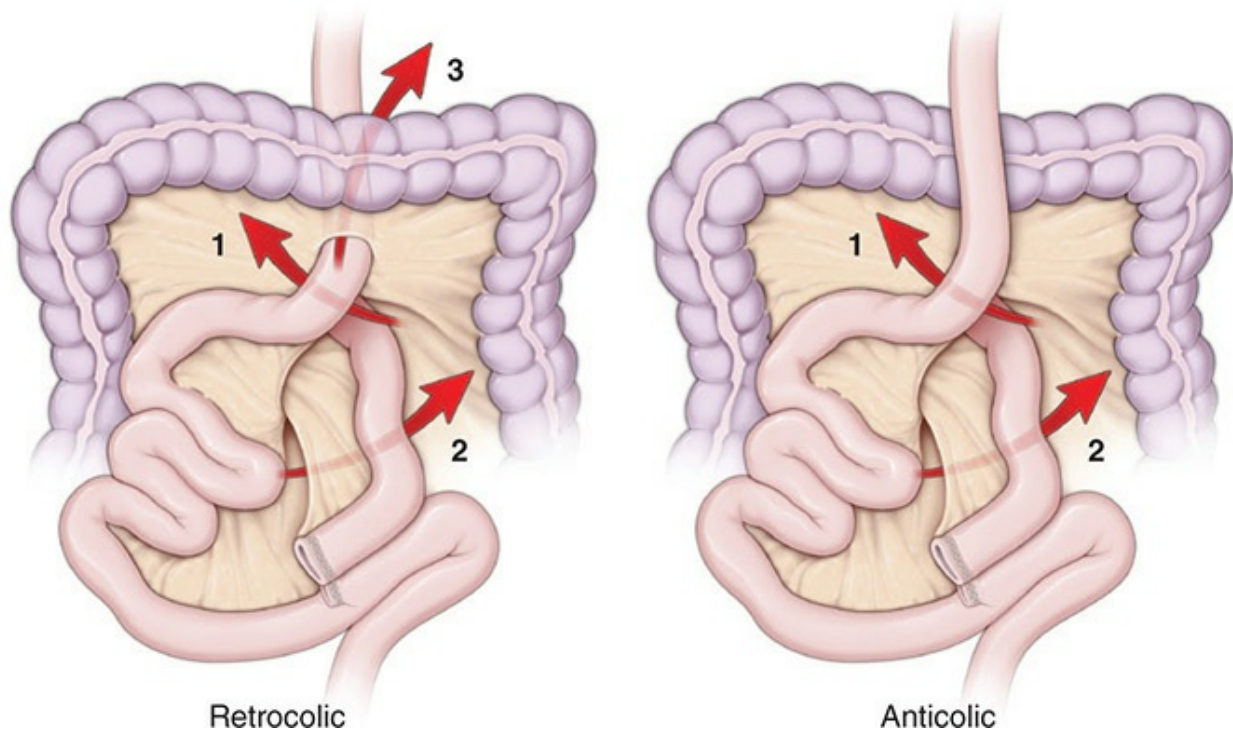

**TABLE 42.1: ETIOLOGIES OF INTESTINAL FAILURE**

Iatrogenic	Ischemic	Infiltrative	Obstructive	Functional
Blunt trauma	Arterial embolism	Desmoid tumors	Adhesive	Pseudoobstruction
Penetrating trauma	Venous occlusion	Carcinoid	Internal hernia	IBD
Operative misadventure	Low flow/shock	Amyloidosis	Radiation enteritis	Bacterial overgrowth
		Malignancy

When referring to iatrogenic complications, we will focus on how IF/SBS can occur as a result of bariatric surgery for example. These patients are at risk of developing postoperative adhesions, incisional hernias, mesenteric ischemia, and internal hernias that can occur after a mesenteric defect is created during Roux-en-Y gastric bypass (RYGB) surgery. Internal hernias can develop through this defect that result in an obstruction and ultimately infarction of significant segments of bowel. The incidence of internal hernias is approximately 5% in patients who have undergone RYGB.<sup>14</sup> The three main locations where internal hernias can develop are posterior to the roux limb mesentery known as the Petersen hernia, through the mesenteric defect created for the jejunojejunostomy, or through the transverse mesocolic defect created for a retrocolic roux limb (Fig. 42-1).<sup>15</sup> Although the incidence of internal hernias is low, the treatment of this complication is highly time-sensitive and if left unexplored, catastrophic loss of bowel can occur that renders the patient with SBS if they are even able to survive the initial insult.

**FIGURE 42-1** Three potential sites for internal herniation after Roux Y gastric bypass. (Reproduced with permission from Huang, CK. *Essentials and controversies in bariatric surgery*. London, UK: IntechOpen Limited; 2014.)

Ischemic events can be classified based on the distribution of blood supply to the bowel; namely, the celiac axis, the superior mesenteric artery (SMA), and the inferior mesenteric artery (IMA). The celiac trunk supplies blood to the liver, stomach, duodenum, and the foregut up to the proximal jejunum. The SMA takes over and perfuses the remainder of the small bowel and the colon up to the splenic flexure. Finally, the IMA supplies blood to the remainder of the colon and rectum. Ischemia to these segments of bowel can occur as a result of direct trauma from penetrating missile/stab injuries or blunt trauma, as described by Asensio in his multi-institutional, retrospective series.<sup>16</sup> In this review, the authors highlighted that although the incidence of these injuries is minimal, at approximately 1%, they are often lethal and the patients who survive are often left with a short segment of bowel. More commonly, embolic events from atrial fibrillation and severe atherosclerotic vascular disease results in perfusion defects, with the most devastating being to the SMA.<sup>17</sup> These patients can often present with the sine qua non of “pain out of proportion to physical exam”; however, the onset of symptoms can be insidious, and late intervention is often fatal. After diagnosis with helical CT

scan, angiographic or open embolectomy is often undertaken with the hopes of instituting thrombolytic therapy and reconstituting blood flow. The advantage of open procedures in this scenario is the ability to inspect the bowel and thus facilitate a second-look laparotomy if needed.

Mesenteric venous thrombosis is another type of vascular insult that can occur, although less commonly. The most common clinical scenario is that of a chronically ill or institutionalized patient who becomes progressively dehydrated, resulting in venous thrombosis. Without sufficient outflow, the bowel becomes progressively engorged, ultimately restricting arterial inflow resulting in ischemia. In previously healthy individuals, mesenteric venous thrombosis can often occur after routine laparoscopic surgery as a result of pressure effects from pneumoperitoneum. These clinical scenarios often coincide with an underlying hypercoagulable disorder such as Protein S or C deficiency that contributes to the mesenteric venous thrombosis.<sup>18</sup>

The infiltrative processes that lead to IF/SBS are from small bowel amyloidosis or desmoid, carcinoid, and other metastatic tumors that not only invade the bowel wall but can often infiltrate the vasculature at the mesenteric root, compromising long segments of bowel. Desmoid tumors are often associated with Gardner syndrome, and these tumors create a desmoplastic reaction with a subsequent area of dense fibrosis that cause local obstructions and enterocutaneous fistulae formation.<sup>19</sup> Carcinoid tumors (see [Chapter 40](#)) are similar to desmoids; however, they are also notorious for mesenteric involvement, with a dense desmoplastic reaction that results in much wider areas of bowel resection.<sup>19</sup> Finally, metastatic cancers that infiltrate the small bowel or retroperitoneum such as gynecologic tumors, colon cancers, and retroperitoneal sarcomas can all cause the same degree of local destruction as primary bowel tumors.

Functional causes of IF/SBS are largely due to pseudo-obstruction, Hirschsprung disease, or scleroderma, which were briefly mentioned in the “Pediatric Causes of Intestinal Failure” section. These are pure motility disorders that affect the transit and ultimate absorption of nutrients. The functional causes of IF/SBS are generally diagnosed at a young age, although they can progress into adolescence and even early adult years if patients can be maintained on effective PN.

Crohn’s disease is mainly classified as a mucosal etiology of IF/SBS (see [Chapter 46](#)). Although SBS is classically defined by having less than 200 cm

of bowel, Crohn's results in SBS due to the malabsorption that occurs at the mucosal surface, rendering patients with normal bowel length functionally with SBS. The severe forms of Crohn's disease result in IF/SBS through the development of fistulae, bowel perforations, and abscesses which frequently necessitate surgical resection and subsequent gradual shortening of bowel.<sup>20</sup> The cornerstone of treatment for Crohn's disease are the aminosalicylates, antibiotics, corticosteroids, and immunosuppressants such as Azathioprine and 6-mercaptopurine. However, newer therapies such as anti-TNF drugs (infliximab, adalimumab) are being used with the intention to reduce morbidity and the amount of bowel resections that are associated with moderate to severe Crohn's disease.<sup>21</sup> In an effort to ward off the need for ITx, bowel lengthening procedures such as the STEP procedure and stricturoplasty are often being employed in order to preserve bowel length in Crohn's patients.<sup>22,23</sup>

Intractable diarrhea of infancy comprises a spectrum of disorders that includes microvillous atrophy or microvillous inclusion disease, tufting enteropathy, and autoimmune enteropathy. The general features of these congenital enteropathies are that they affect the development of the intestinal mucosa that leads to intractable diarrhea during infancy and is not related to a bacterial or viral pathogen. The clinical features of these disorders are large volume diarrhea associated with electrolyte abnormalities and the ultimate need for PN. Although the clinical features are distinct, diagnosis is most commonly achieved with histopathological analysis.

## **ASSESSMENT OF SBS-ASSOCIATED INTESTINAL FAILURE**

Patients with SBS and IF/SBS often have very complex past medical histories and the approach to their care can be overwhelming. When evaluating these patients, it is of paramount importance to approach the evaluation in a consistent, systems-based manner. Langnas et al. best described the components of the history and physical evaluation as follows:

1. A thorough review and summary of the past medical record. This is extremely important and painstaking. Every effort should be made to review appropriate surgical and pathological documentation to confirm

- the preexisting diagnoses.
2. The cause of SBS, the anatomy and length of the intestine, including a detailed review of prior surgical procedures and any related complications. Upper GI small bowel series, barium enema, and endoscopic studies should be reviewed to determine the anatomy of the remnant bowel and anastomotic locations.
  3. The number of central lines and the reasons they were changed.
  4. Causal microorganisms for central line infections.
  5. Nutritional assessment including parenteral and enteral intake, daily caloric requirements, and macro- and micronutrient components of PN.
  6. Laboratory evaluation including serum electrolytes, liver function tests, glomerular filtration rate (GFR), albumin/prealbumin, prothrombin time, vitamin B<sub>12</sub>, fat-soluble vitamins, serum citrulline, and stool calprotectin levels.
  7. Detailed vaccination status.
  8. Complete physical exam with focus on hydration status, nutritional status (height, weight, basal metabolic index), type of central line, and inspection for signs of nutritional deficiencies and complications from PN such as dermatitis or signs of chronic liver disease.<sup>24</sup>

## PARENTERAL NUTRITION IN THE INTESTINAL FAILURE PATIENT

Prognostic factors for adaptation include length of remnant bowel, location (ileum>jejunum), presence of ICV, absence of stoma, presence of colon in continuity, absence of liver disease, age of patient, time since onset, and the absence of an underlying GI disease/disorder. Of the aforementioned factors, the length and function of a patient's remnant bowel are the main parameters that determine the need for PN dependence. In all cases of IF/SBS, it is critical to first assess the ability to maintain at least partial enteral nutrition, as it has been shown that partial feeding via the enteral route is associated with a better prognosis than a nonfunctioning gut.<sup>25</sup> Thus, exclusive use of PN should be avoided because this population of patients has the highest incidence of vascular, infectious, and metabolic complications including IFALD.<sup>26-30</sup> To that end, a thorough assessment to determine the ability to

establish intestinal/colonic continuity and to surgically correct any forms of obstruction in order to restore intestinal continuity should be carried out prior to initiating PN.

The typical PN formula contains macronutrients (in the form of hypertonic dextrose up to 70%), lipids, amino acids, vitamins, minerals, electrolytes, and fluid. Conceptually, the dextrose is included as a source of carbohydrate delivery, protein as crystalline amino acids, lipids provide essential fatty acids, and sterile water helps meet the patient's fluid requirements.<sup>1</sup> It should also be noted that all of the components of PN including electrolytes, vitamins, and trace elements play a collaborative role in nutritional efficiency, and along with energy, in maintaining a positive nitrogen balance. Thus, when instituting a home PN plan, it is important to ensure that the patient and caregivers are properly trained and capable of executing the plan at home.

## COMPLICATIONS OF PARENTERAL NUTRITION

Problems related to PN can be broken down into three categories: catheter-related, metabolic, and organ dysfunction.<sup>31</sup> Catheter-related problems are the most demanding components of caring for IF/SBS patients; however, it must be recognized that these catheters and maintenance of vascular access are literally the lifelines for these patients. Ideally, CVCs should be tunneled and placed in the superior vena cava (SVC) with the tip outside of the heart borderline on the post-procedure chest x-ray. These catheters should ideally be reserved for PN only and should be single lumen, although patients who are chronically requiring other intravenous solutions such as IV antibiotics or frequent replacement fluids may benefit from a dual-lumen catheter.

CVC thrombosis and occlusion are the most common complications associated with the use of these catheters, having been reported in up to 60% of patients.<sup>31</sup> However, CVC-related infections carry a very high morbidity and if not recognized early can be fatal. The single most common organism that is being isolated in patients receiving home PN is coagulase-negative *Staphylococcus* (CONS), accounting for up to 60% of home PN bacteremias. This is followed by *Enterococcus*, *S. aureus*, and *Candida* sp. Gram-negative bacteria account for 14% to 25% of infections.<sup>32-34</sup> It is important to

recognize that the management of CVC infections in this patient population is different from most patients. Typically, a suspected CVC infection mandates removal of the catheter, particularly in the inpatient setting. In IF/SBS patients, however, a trial of broad-spectrum antibiotics while leaving the suspected catheter in situ is important in order to preserve as many future access sites as possible. If 48 hours of antibiotics has not demonstrated clinical improvement or if the patient is clinically worsening during the trial period, then removal of the tunneled catheter is warranted. If the suspected organism causing the sepsis is a fungus, earlier removal is recommended.

Metabolic complications generally are related to fluid/electrolyte disturbances and macro- or micronutrient delivery problems. The complexities of management of hyper- and hypoglycemia are beyond the scope of this chapter. However, it is critical to acknowledge that IF/SBS patients often have high-output ostomies or enterocutaneous fistulae, both of which require higher additional water and electrolyte replacements and vigilant attention to the patient's hydration status. It is known that these patients live in a chronically dehydrated state, and this contributes to a silent renal insufficiency that is not always readily apparent. Blood urea nitrogen (BUN) and creatinine are not reliable indicators of renal function in these patients, as they are often sarcopenic, and these variables will often underestimate the degree of renal impairment. Ament and others at UCLA have previously demonstrated that children with IF who were on TPN had a reduction in yearly GFR that was inversely correlated with chromium concentration in TPN as well as the duration of TPN use.<sup>35</sup> Thus, we have made it our practice to follow the GFR closely for these patients in the outpatient setting, and our intestinal transplant evaluation process includes a nuclear medicine GFR study to accurately determine the patient's renal function.

Organ dysfunction is the final stage of PN-related complications. In addition to the renal insufficiency discussed above, other organ systems that can be injured with PN include the skeletal system (osteomalacia, osteopenia, osteoporosis), intestine (bacterial overgrowth, increased permeability, and bacterial translocation), neurologic (memory disturbance), gallbladder (sludge/cholelithiasis/dyskinesia) and liver (steatosis, cholestasis, fibrosis, cirrhosis, and portal hypertension).

IFALD is a well-recognized complication of PN for both children and adults. It is commonly identified by the presence of jaundice, although that

represents an advanced stage of liver disease. More conventional practice has focused on using liver function tests at 1.5 times the upper limit of the reference range, for at least 2 weeks, and in the absence of another cause to define the presence of IFALD.<sup>35,36</sup> Given the large variation in defining IFALD, incidence estimates are often difficult to obtain. It has been consistently reported, however, that approximately 50% of children on PN for 4 to 12 weeks have cholestasis, but in adults there is a much wider variation in frequency of IFALD, with around 30% to 50% having a mild disturbance of liver function tests and between 2% and 30% becoming cholestatic after a median of 6 months of PN.<sup>26,37-40</sup> Nonetheless, it is important to recognize that a large proportion of patients on PN will suffer from some form of liver injury, and the early signs of IFALD must be recognized and treated with adjustment of PN formulas that reduce total calories and increase the carbohydrate:lipid ratios. If allowed to progress, decompensated IFALD can occur very rapidly, and this accounts for the high mortality rate of patients awaiting combined liver and intestine transplants.

## **EMERGING PHARMACOLOGIC OPTIONS FOR INTESTINAL FAILURE**

The period of adaptation following the onset of SBS-associated intestinal failure is believed to last approximately 24 months. The process of adaptation occurs through both structural (villous cell hyperplasia, increased crypt depth, and intestinal dilatation) and functional (increased mucosal enzyme activity and reduction of intestinal transit) mechanisms leading to a gradual increase in absorptive capacity. Nutritional (eg, glutamine) and non-nutritional (eg, growth factors) substances have been implicated in promoting this adaptive response. In the last decade, most intestinal failure research has been focused on exploring the potential of these substances as supportive intestinal failure treatment. However, clinical trials so far have not demonstrated reproducible or meaningful clinical benefits with the use of glutamine or growth hormone.<sup>41</sup>

GLP-2 is a 33-amino acid peptide that has shown great promise in helping intestinal failure patients achieve PN independence. Human and animal studies have revealed that dietary fiber and short-chain fatty acids, carbohydrates, and fats are potent stimulators of GLP-2 secretion.<sup>41</sup> GLP-2

exerts a wide variety of effects on the gastrointestinal tract and is a key mediator of intestinal adaptation. In animal studies, GLP-2 treatment induces mucosal growth in the small and large intestine through an increase in crypt cell proliferation and a reduction of villous cell apoptosis. This increase in mucosal mass is accompanied by enhanced functional absorptive capacity. Recent multicenter, placebo-controlled studies of GLP-2 in SBS patients demonstrated meaningful reduction of up to 20% less PN use in patients who received GLP-2.<sup>42</sup> Future studies using GLP-2 in combination with other growth hormones could potentially pave the path toward PN independence for many intestinal failure patients.

## **AUTOLOGOUS LENGTHENING TECHNIQUES OF THE GI TRACT**

The basic principles behind surgical adaptation are to recruit and optimize the surface area of unused intestine in order to improve intestinal function and achieve enteral nutrition. First and foremost, fistulae and ostomies must be closed and bowel obstructions must be surgically relieved. Once this has been achieved, bowel tapering and lengthening procedures can be performed. Prior to embarking on these often-treacherous surgical explorations, it must be deemed that the patient has a reasonable chance to achieve independence from PN and that the remaining bowel length and function will not be better served by transplantation. Several surgical options exist, such as reversed segments, colonic interposition, and nipple valve construction. These techniques have not been widely used or commonly successful. We will primarily focus on the more commonly used non-transplant surgical options including the Bianchi procedure (longitudinal lengthening) and the STEP procedures.

### **Bianchi Procedure**

The Bianchi procedure was first described in 1980 in a pig model.<sup>43</sup> It was then applied to humans, and several published reports became available in the 1990s depicting their results. In brief, the technical conduct of the procedure intends to achieve longitudinal length by dividing the small bowel at either end of a dilated loop. The plane between both leaves of the mesentery is then

developed so as to maintain the blood supply to both of the stapled ends of bowel. A GI stapling device is then passed between both leaves of mesentery and applied to the single, dilated loop of bowel. Once the stapler is fired, the single loop of bowel then becomes two parallel loops of normal caliber bowel, each with its own mesentery. The two new loops of bowel are then sewed to each other in an antegrade, end-to-end fashion forming a “lazy S” configuration (see Fig. 42-2).<sup>44</sup> Several published series of Bianchi longitudinal lengthening procedures have been published and many of the authors were able to reproducibly double the lengths of bowel in their series of patients. With the increased length, patients were able to achieve improved intestinal motility and prolonged transit times. Although most series of patients were small, Weber and others were able to demonstrate complete parenteral independence in many patients along with improved carbohydrate and fat absorption.<sup>45-47</sup> Although the early results of this procedure were promising, it largely has become of historical value due to complexity of the procedure, the difficulty in predicting which patients would become enterally independent, and the advent of intestinal transplantation.

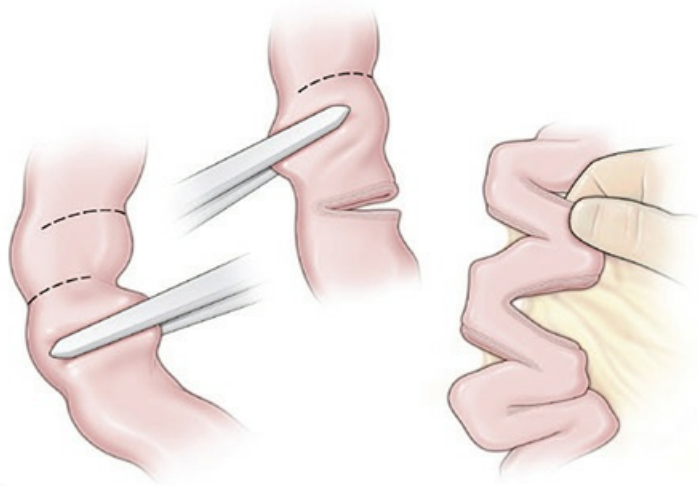

**FIGURE 42-2** Longitudinal intestinal lengthening. (A) The small bowel is divided at either end of a dilated loop. The mesentery is dissected to create a

plane along the axis of the intestine between branches of mesenteric blood vessels. **(B)** The mesentery has two leaves. Arterial and venous branches of mesenteric vessels alternate from one leaf of the mesentery to the other. **(C)** A gastrointestinal stapling device can be passed between the leaves of the mesentery. **(D)** When the stapler is fired, the single loop of dilated intestine is divided into two parallel loops. **(E)** The parallel loops can then be turned in a “lazy S” fashion to approximate the distal end of one loop to the proximal end of the second loop. In this way, the parallel loops are anastomosed end-to-end to reestablish continuity and double the length of the small bowel. In addition, the lengthened segment is then reanastomosed to the normal small bowel or colon proximally and distally (not shown).

## Serial Transverse Enteroplasty

In 2003, Kim and others introduced a novel technique for bowel lengthening.<sup>48</sup> Once again, the general concept was to introduce overall surface area in order to increase mucosal contact with nutrients. With the STEP procedure, however, this was achieved by narrowing the luminal diameter that would result in increased bowel distances between areas of undivided bowel, thus leading to increased transit times. In brief, the dilated segment of small bowel is narrowed by alternate firings of the GI stapling device from the mesenteric and antimesenteric borders of the bowel. This would result in luminal diameters between 1 cm and 2.5 cm and a resultant increase in bowel length (see [Fig. 42-3A-C](#)).<sup>48</sup> In 2013, Kim and others published their results from the STEP registry data which included 111 patients in 50 centers worldwide. They were able to demonstrate that 47% of patients who were on PN pre-STEP were able to achieve complete enteral nutrition after their STEP procedure.<sup>49</sup> The overall mortality in this study was 11%, but it likely reflected the high acuity of the patients who were undergoing surgery as the two main risk factors for death on multivariate analysis were higher direct bilirubin and shorter bowel length.<sup>49</sup> Intestinal lengthening procedures have a clear role in patients with intestinal failure. The basic premise is that patient selection is of paramount importance because patients who are jaundiced should likely be considered for transplantation, and lengthening procedures are likely contraindicated.

## INTESTINAL TRANSPLANTATION

ITx marks the final available therapy for patients with IF/SGS who in general have failed PN therapy. The indications are:

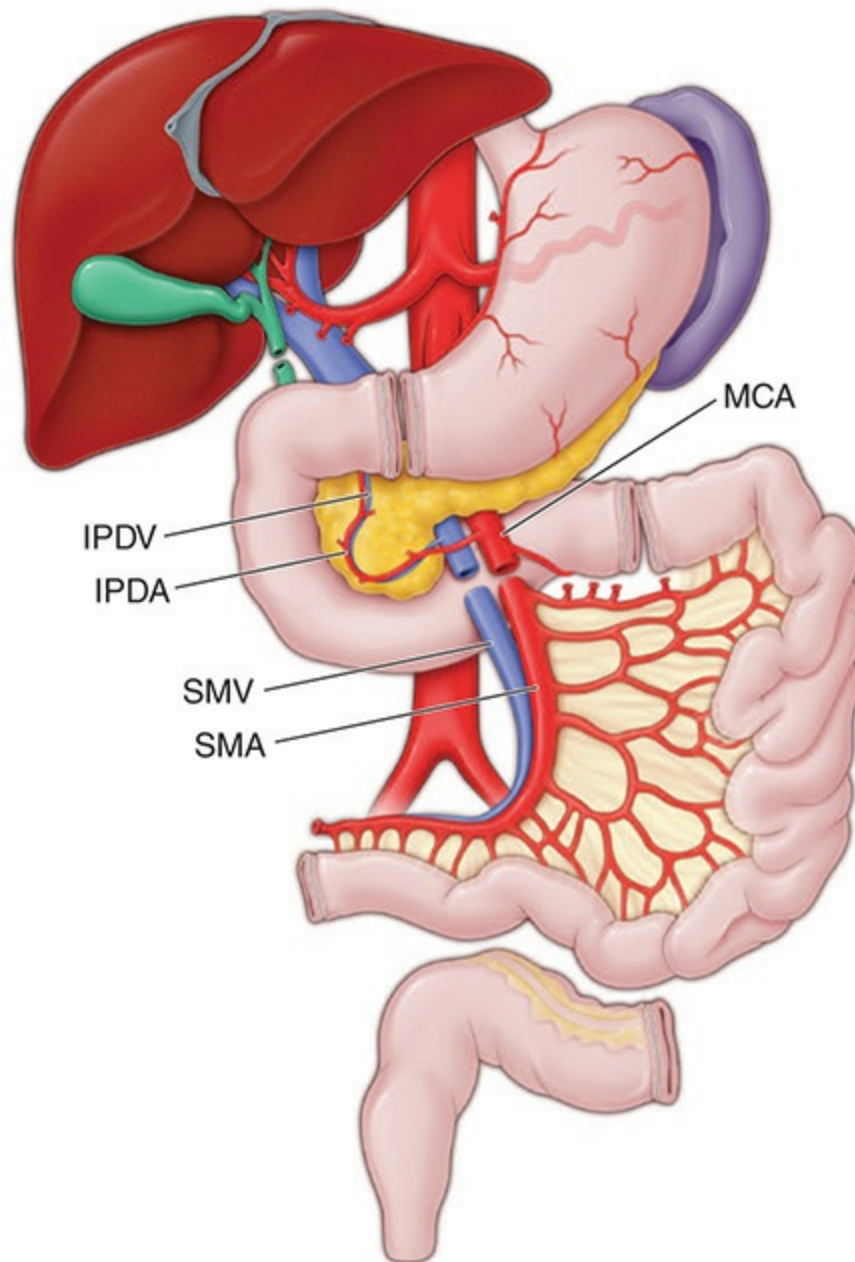

1. Patients with permanent/irreversible IF/SBS with one or more life-threatening PN-related complications such as loss of central venous access, recurrent catheter-related bloodstream infections, and/or IFALD.
2. Patients with a poor prognosis for enteral adaptation, such as those with complete loss of midgut, should also be considered early in their onset of IF/SGS for ITx.
3. Patients with poor quality of life, uncontrollable fluid and electrolyte disorders, and chronic abdominal pain while on PN should be considered.
4. Patients with low-grade unresectable malignancies such as gastrointestinal stromal tumors (GISTs) or desmoids may benefit. Likewise, patients with polyposis syndromes may benefit from subtotal enterectomy and transplantation.
5. Lastly, patients with pan portosplenomesenteric venous thrombosis not amendable to shunting or isolated liver transplantation should be considered. Once patients have been deemed candidates for ITx, a complete multidisciplinary evaluation at a transplant center is carried out to determine eligibility. Specifications for this process vary from center to center and have been outlined in "Assessment of SBS-Associated Intestinal Failure". Once accepted for transplantation, the patients are listed for the intestinal type of allograft deemed necessary. In general, diseased organs are replaced while functional ones should be retained.

## Donor Selection

In general, cadaveric donors of intestinal grafts are often young, healthy individuals who have suffered a catastrophic brain trauma or anoxic brain injury. These donors are a highly selected subset of patients mainly because of the sensitivity of the intestine to ischemic injury. Thus, many of the events surrounding brain death (down time, length of cardiac arrest/cardiopulmonary resuscitation) and peri-donation management (vasopressor requirements) of the donor will often exclude these patients as donors for intestinal grafts.

## Donor/Graft Techniques

The donor operation for multiorgan procurements is employed when the team is planning to procure multivisceral grafts. Within the abdominal compartment, preparation for rapid aortic cross-clamp is performed by first cannulating the inferior mesenteric vein for infusion of portal cooling flush both prior to aortic cross-clamp and after cross-clamping/exsanguination has occurred. The infrarenal aorta is encircled and cannulated and the supraceliac aorta is also encircled in preparation for placement of a vascular clamp just prior to exsanguination and cooling with University of Wisconsin solution (ViaSpan<sup>®</sup>, Barr Laboratories). After these steps and in coordination with the chest teams, the liver, pancreas, and small intestine can be procured either separately or in combination, depending on the recipient's needs (see [Fig. 42-4](#)).<sup>50</sup>

**FIGURE 42-4** Diagram demonstrating the graft options resulting from a multiorgan procurement. Divisions at duodenum and jejunum indicate potential levels of transection, both vascular and gastrointestinal. Thus, all organs can be procured either separately or in any combination.

## Intestinal Type of Grafts

In general, there is little consensus on the terminology regarding allograft type. This chapter utilizes the intestinal graft types as described by the

program at UCLA.<sup>51</sup> The graft types are (1) isolated intestinal allograft, (2) liver-intestine allograft, (3) multivisceral allograft, and (4) modified multivisceral allograft. Of note, accessory organs can be easily added to most of the graft types. Accessory organs are the stomach, colon, and kidney. These are discussed separately.

## ISOLATED INTESTINE GRAFTS

Isolated intestine (I-ITx) grafts contain all or part of the donor jejunioileum. The jejunum is stapled past the ligament of Treitz, and the small mesenteric vessels connecting the proximal mesentery are ligated. In this scenario, the SMA and SMV are used as the vascular pedicles at the root of the mesentery in the recipient operation. If the pancreas is not being procured, the SMA can be lengthened to include a cuff of aorta and the SMV can go up as far as the portal vein (PV) (see Fig. 42-5a).<sup>50</sup> This graft type is indicated for patients with IF/SBS only who have normal foregut and liver function.

**FIGURE 42-5** (A) Demonstrates a jejunioileal graft procured with its vascular pedicle consisting of the SMA and SMV. (B) Demonstrates a liver-intestine (L-ITx) graft procured using the traditional technique; the entire liver and jejunioileal segment is present. The vascular inflow is shown off a cuff of donor aorta. (C) Demonstrates multivisceral (MVTx) allograft. ([A,C]: Reproduced with permission from Moon JI, Tzakis AG: Intestinal and multivisceral transplantation, *Yonsei Med J* 2004 Dec 31;45(6):1101-1106.)

## **LIVER-INTESTINE GRAFTS**

The original description of this technique was by Grant et al.,<sup>8</sup> where this graft included an en bloc liver and intestine only, while the donor pancreas was removed. Today, the most commonly used method for procurement of the liver-intestine (L-ITx) graft is the “Omaha technique.”<sup>52,53</sup> With this technique, the liver is mobilized using standard techniques. The duodenum is stapled off distal to the pylorus, the pancreas is left wholly intact for biliary drainage, and the entire jejunioileum is mobilized and controlled. At completion, the L-ITx graft consists of liver, duodenum, pancreas, spleen, and jejunioileum with the vascular pedicles of a common aorta/celiac/SMA trunk and an intact donor PV and bile duct (see Fig. 42-5b).<sup>52</sup> Liver-inclusive grafts are used in the clinical scenarios where patients have experienced liver failure, as in IFALD coupled with IF/SBS.

## **MULTIVISCERAL GRAFTS**

The multivisceral (MVTx) graft is very similar to the L-ITx graft described above. The stomach is most commonly included in this allograft type. During the procurement operation, rather than dividing at the level of the pylorus, the esophagus is transected above the GE junction. At completion, the organ complex consists of liver, duodenum, pancreas, spleen, and jejunioileum with or without the stomach. Vascular inflow is the same as described above for the L-ITx graft (see Fig. 42-5c).<sup>52</sup> This allograft is used in patients with disease of both the foregut and midgut who also have irreversible IFALD.

## **MODIFIED MULTIVISCERAL GRAFTS**

Modified multivisceral MMVTx grafts are basically the same as the MVT except that the liver is not included in the complex. This allograft is used in patients with disease of both the foregut and midgut but where native liver function is preserved or salvageable.

## **Accessory Organs**

As noted above, the stomach can be added onto the MVT or MMVTx allografts largely in patients who have motility disorders involving the

stomach. Of note, due the fact that a vagotomy is performed in the donor, a pyloroplasty is required in this scenario. Alternatively, the stomach transplant can be omitted and thus a partial or subtotal gastrectomy is performed with the use of a Roux-en-Y gastrojejunostomy for final GI reconstruction.

Colon-inclusive transplantation was initially deemed to be higher risk with worse outcomes.<sup>54</sup> However, subsequent experiences demonstrated that colon inclusion can be accomplished without a higher rate of sepsis or graft loss.<sup>55</sup> In the donor, rather than transect the intestine at the terminal ileum, the line of transection can occur in the mid-transverse colon (beyond middle colic vessels) or more distal. Inclusion of the colon is indicated for patients without significant remnant native colon, as it has been shown to improve fluid management post transplant.

Concomitant kidney transplantation can also occur in patients with poor chronic renal function deemed candidates for such a transplant. The kidney allograft can be included en bloc with the visceral organs. We most commonly keep the right kidney intact, with the renal artery included in the aortic cuff and the renal vein included in the inferior vena cava (IVC). In this manner, only ureteral reimplantation is required in the recipient.

## Recipient Operation

The recipient operation can vary considerably between patients; thus, we briefly touch upon the major components of the recipient operation. As we have noted throughout this chapter, *vascular access* is of paramount importance with these patients. Preoperative mapping with a magnetic resonance venogram (MRV) is usually performed during the initial evaluation, and this is often necessary to help guide the anesthesiologist during CVC placement. Central access above the diaphragm is usually necessary both because of substantial blood loss encountered during the organectomy in a hostile abdomen and also because large-bore peripheral IV access is generally not possible in these patients.

*Exposure* is the key to any operation. In a hostile abdomen, achieving exposure is often treacherous, and an adequate incision followed by extensive adhesiolysis is generally necessary before organectomy can proceed. For liver-inclusive grafts, a bilateral subcostal and vertical incision is necessary with extension of the midline incision to below the umbilicus. For patients

who are not receiving the liver as part of their grafts, a midline laparotomy incision is sufficient. With these incisions, optimal exposure to achieve venous outflow into the portomesenteric circulation and also to restore gastrointestinal continuity can be established.

Recipient *organectomy* is variable depending upon the organ(s) being transplanted. In general, the I-ITx recipient undergoes mobilization of the remnant jejunioileum. This is resected while leaving behind a suitable length of jejunum to perform jejunojejunostomy between donor and recipient jejunum as well as distal colon to perform jejunocolostomy between donor jejunum and recipient colon. *Vascular inflow and outflow* was discussed for each type of grafts above. However, it should be mentioned that during the recipient operation liberal use of aortic conduits should be used. Generally, donor iliac or donor aorta can be used to create a conduit at the recipient infrarenal aorta that will be then be sewn to the allograft during implantation. When en bloc organs are procured, the suprahepatic IVC of the donor graft serves as the venous outflow. *Biliary reconstruction* requirements are variable depending on the graft used. In liver-inclusive grafts procured using the Omaha technique or as MVTx grafts, biliary anastomosis is not needed. This is followed by *restoration of intestinal continuity*. Again, the grafts being used as detailed previously will dictate the targets for intestinal anastomosis. Of importance, however, is the critical step of creating intestinal continuity along with an ileostomy to allow for allograft surveillance with biopsies in the perioperative period. *Enteral feeding tube* placement is the next surgical step, and this can be in the form of a Stamm gastrostomy in patients who do not receive a stomach, or as a jejunostomy tube into the transplanted intestine. Finally, *abdominal wall closure* is often complex, since these patients have had multiple previous operations and primary fascial closure is often difficult to achieve. In order to provide a tension-free closure, the liberal use of prosthetic materials as a temporary closure device while abdominal wall and bowel edema subsides is often the best strategy. A second-look laparotomy can then be performed and a definitive closure can be performed at that time either primarily or with permanent mesh (see [Fig. 42-6](#)).<sup>50</sup>

**FIGURE 42-6** Diagrams demonstrating an isolated intestinal graft after implantation (**A**), and liver-intestinal graft with inclusion of the whole pancreas (**B**) and a multivisceral graft (**C**). The vascular anastomoses are indicated. Abbreviations: SMV, superior mesenteric vein; PV, portal vein; SMA, superior mesenteric artery; IVC, inferior vena cava.

## COMPLICATIONS OF INTESTINAL TRANSPLANTATION

Surgical complications after ITx can be broken down into postoperative-, endoscopic-, or vascular access–related. The postoperative complications have evolved over time. Biliary complications are no longer a major problem given that we no longer perform a complete hilar dissection as was originally described by Grant et al.<sup>8</sup> Thus, this has left us mainly with intestinal perforation, mechanical obstructions, anastomotic leaks, intra-abdominal abscesses, chylous ascites, ostomy-related complications, and vascular complications.<sup>50</sup> These complications are all life-threatening in an immunosuppressed patient, and a low threshold for reexploration should be maintained as the clinical presentation can often be insidious.

Endoscopic complications are not uncommon in the intestinal transplant patient. These patients are regularly monitored for rejection in the postoperative period and they are thus at risk for bleeding, hematoma causing obstruction of the bowel lumen, perforation, and stomal disruption.<sup>24</sup> In a

recent review of 1770 endoscopic procedures in intestinal transplant recipients, the rate of procedural complications, including but not limited to bleeding and perforation, was 1.8%.<sup>56</sup> Similarly, vascular complications often persist in the post-transplant period. This often presents a challenge since most patients who have a functional graft have not completely weaned off of PN in the postoperative period. Some groups have reported up to a 15% incidence of patients experiencing thrombosis of their central veins that have required balloon angioplasty to maintain access following transplantation.<sup>57</sup>

Medical complications after ITx are largely related to infectious and immunosuppression-related issues. Recipients of intestinal transplants are at major risk for infections because the transplanted organ represents a reservoir of pathogens. In the immediate perioperative period, the source of infection is often from catheter-related bacteremia, anastomotic dehiscence, or intra-abdominal fluid collections. In long-term patients, urinary tract infections, pneumonia, and catheter infections predominate as the causes for infections. However, it should be noted that patients with marginal graft function often are subject to bacterial translocation with resultant bacteremia. Thus, prevention of bacterial overgrowth with scheduled administration of oral antibiotics can often be useful to prevent recurrence of bacteremia.

Immunosuppression-related complications are vast in number and beyond the scope of this chapter. However, it is important to recognize that there is a broad spectrum of complications that occur as a result of over- or under-immunosuppression.<sup>58</sup> On the one hand, acute rejection is almost invariable for most intestinal transplant recipients, especially in young patients or those who are noncompliant with their immunosuppression regimen. At the opposite end of the spectrum, infectious complications and post-transplant lymphoproliferative disorder (PTLD) can occur in patients who are over-immunosuppressed or have received induction agents at the time of transplant such as antithymocyte globulin (ATG) or lymphocyte-depleting agents. Given the presence of lymphoid-rich tissue in intestinal grafts, graft-versus-host disease (GVHD) can occur in up to 5% of patients and is clinically marked by diarrhea, ulceration of oral mucosa, and skin rash.<sup>24</sup> It is this balancing act of over- versus under-immunosuppression that calls for very close monitoring, even when patients are remote from their operations, as these complications can arise over the entire course of a transplant recipient's life.

## SUMMARY AND FUTURE DIRECTIONS

ITx has evolved since the initial attempts in the 1960s. Our knowledge of immunology, experience with surgical techniques, and perioperative care has improved substantially and this has afforded a 1-year graft survival of approximately 80%.<sup>54</sup> The field of ITx depends on the contributions from a multidisciplinary team and strong support from an intestinal rehabilitation program that can bridge IF/SBS patients toward transplant. Aggressive rehabilitation programs that focus on minimizing complications from PN, re-establishing GI continuity, maximizing enterocyte mass via STEP procedures, and optimizing macro- and micronutrient delivery all contribute to successful patient outcomes. Future directions that will focus on tolerance induction, prevention of PTLD, and tissue engineering will help pave the path for intestinal transplantation and hopefully minimize the morbidity associated with immunosuppression.

# **DIVERTICULAR DISEASE AND COLONIC VOLVULUS**

*Timothy Eglinton • Frank A. Frizelle*

Diverticular disease and colonic volvulus are common benign colonic conditions that can cause patients significant symptoms, impair of quality of life, and on occasion lead to fatal outcomes without treatment. Management at times can be challenging as decisions for surgical intervention must be carefully balanced against the patient's relative procedural risks and comorbidities, which also can be significant. In this chapter, we discuss the current understanding of these 2 pathologies.

## **DIVERTICULAR DISEASE**

Colonic diverticula are the most common structural abnormality of the bowel and constitute the fifth most costly gastrointestinal disorder in Western society.<sup>1,2</sup> An acquired condition, diverticula usually affect the sigmoid colon in Western societies, but they are also found on the right colon in countries with diets rich in fiber, especially in Asia. The prevalence of clinically apparent diverticular disease has increased over the past century,<sup>3</sup> which probably reflects both an increase in detection and an aging population. Until 30 years ago, the proportion of patients requiring surgery or dying from

diverticular disease was decreasing<sup>4</sup>; however, over the past 20 years, the rates of hospital admission and surgical intervention have increased, while inpatient and population mortality rates from diverticular disease have remained unchanged.<sup>5</sup>

Colonic diverticulum is an acquired condition with increased prevalence with increasing age. It affects fewer than 10% of people in their fifth decade of life, increasing to around 50% to 66% in their ninth decade.<sup>6</sup> Most patients with diverticulosis do not require surgery; however, complications of diverticular disease may require surgery. Such surgery can be challenging, and good outcomes rely on timely and appropriate intervention.

The terms used include diverticulum (diverticula—plural); diverticulosis, which indicates asymptomatic diverticula; diverticulitis (simple or complicated), or diverticula with inflammation; and diverticular disease, which is diverticula with or without inflammation.

## History

Diverticular disease was initially described by Littré in 1700 as saccular outpouchings of the colon.<sup>7</sup> Cruveilhier is credited with the first clear and detailed description of the pathogenesis of diverticulitis and complicated diverticular disease.<sup>8</sup> In 1899, Graser introduced the term “peridiverticulitis” and suggested that diverticula were caused by herniation of colonic mucosa through areas of penetration of the vasa recta. This is now well established as the pathogenesis of colonic diverticulosis.<sup>9</sup> In contrast, the mechanism for diverticulitis was not identified until 1904 by Edwin Beer.<sup>10</sup> This seminal work on the pathophysiology of diverticular disease reviews the medical literature on diverticular disease at the turn of the 19th century. Beer summarized the use of cadaveric and animal experiments to identify diverticula associated with colonic wall blood vessels and ascribes the cause of diverticulitis to hard fecal matter lodged within the diverticulum.<sup>11</sup> He described the ensuing pathologic processes of mucosal ulceration, acute inflammation, abscess formation, colonic perforation, and fistulation. Beer also describes the process of cicatricial contraction caused by marked “connective tissue growth.” Beer also succinctly summarizes 18 case reports into 6 clinical scenarios, including diverticula that produce stenosis of the sigmoid or upper rectum, diverticula that lead to perforation into the

peritoneum, diverticula that lead to abscesses or localized peritonitis in the left iliac fossa, diverticula that lead to perforation into the urinary bladder, diverticula that are densely adherent to the bladder, and diverticula and carcinoma. He proposed that impacted fecal matter at the neck of the diverticulum caused inflammation and subsequent abscess and fistula formation.

Moynihan<sup>12</sup> reported a case of peridiverticulitis in 1907 and underlined the difficulties in distinguishing diverticular disease from malignancy. Telling and Gruner's classic paper describing complex diverticular disease was not published until 1917.<sup>13</sup> At this time, the prevalence and pathophysiology of diverticular disease were well recognized, as were the complications, including acute diverticulitis, abscess, fistula, perforation, and obstruction.

The development of radiologic imaging of the large intestine was important in establishing a diagnosis and documenting the extent of diverticular disease.<sup>14</sup> In 1914, De Quervain and Case were the first to demonstrate colonic diverticula with x-rays.<sup>15,16</sup>

## **Etiology**

Diverticular disease is a disease of Western populations. A number of studies have shown an increase in incidence over the past 30 years.<sup>3,5</sup> Migrant studies likewise confirm an increase in incidence when populations move to a Western country. There is a widely held view that fiber content of food is important and that the high intraluminal pressure associated with low-fiber diets precipitated by colonic compartmentalization causes an unsustainable increase in tension within the bowel wall. This is compounded by the hyperelastosis and altered collagen structure seen in the colon due to aging.<sup>17,18</sup> Both mechanisms ultimately lead to a loss of bowel wall integrity and the formation of diverticula. Exercise and a reduction in the intraluminal pressure associated with a high-fiber diet may be protective.<sup>19</sup>

High intraluminal pressures are generated because of colonic motility. Colonic motility is complex and not easily studied. The most common motor patterns are tonic segmenting and rhythmic contraction. Tonic segmentation creates stationary narrow rings that appear as haustral markings. Their purpose is to slow the fecal stream and to permit water absorption and

electrolyte exchange. Infrequent propulsive peristaltic contractions move fecal matter in a caudal direction; these occur around 6 times a day.<sup>20</sup>

The alteration in pressure caused by these movements has been implicated in the pathogenesis of colonic diverticulosis. Several groups have studied colonic motility with intraluminal manometry in humans and animals. Most studies agree that there is increased phasic pressure activity, but this relates more to the presence of symptoms rather than diverticula. The results, however, are heterogeneous, principally because of methodologic differences, in particular relating to bowel preparation and pressure sensors.<sup>21</sup> It may therefore be unreasonable to draw firm conclusions from these investigations.<sup>22</sup>

More generalized alterations in colonic motility have been implicated in the pathogenesis of colonic diverticular disease. In vitro and in vivo studies, however, are conflicting. Some demonstrate an absence of slow-wave activity (favoring nonpropagating contractile activity), and some demonstrate unimpaired or increased slow-wave activity.<sup>23,24</sup> Others have demonstrated an increase in fast-wave activity, which persists after resectional surgery.<sup>25</sup> The exact relevance of these myoelectric changes remains uncertain.

Diverticulosis is a Western disease that has a striking geographic distribution. The disease is rare in rural Africa and Asia with the highest prevalence seen in the United States, Europe, and Australia.<sup>26</sup> Within a single country, the disease incidence can vary depending on ethnicity.<sup>27</sup> Urbanization can also increase diverticular disease incidence, possibly attributable to a dietary change.<sup>28,29</sup> The incidence of complicated diverticular disease also seems to be increasing.<sup>30</sup>

Diverticular disease in Asian patients is often right-sided with manifestations early in life and is often multiple. The reasons for this variation are unknown; however, it has been suggested that both diet and elastin/collagen differences may play a role.<sup>31</sup>

## **Morphologic Features**

Colonic diverticula are false diverticula most commonly found in the sigmoid colon (95%). The sigmoid colon is the exclusive site in about 50%, and the entire colon is involved in just 5%. The muscular colonic wall is composed of both longitudinal and circular layers. The circular layer of the muscularis

propria forms a continuous sheet of muscle throughout the large bowel. The longitudinal layer forms 3 discrete condensations called taeniae; 1 of these is adjacent to the mesentery while the other 2 are antimesenteric. The taeniae coalesce to form an enveloping muscular layer in the rectum. Much of the colonic wall is therefore devoid of longitudinal muscle, and it is in these areas that diverticula form. Herniations of muscularis mucosa occur between the taeniae along the arteries (vasa recta) that penetrate the muscle wall en route to the submucosa and mucosa (Figs 43-1 and 43-2).

**FIGURE 43-1** Relationship of diverticulum and vasa recta.

Lab no. Date Path.

**FIGURE 43-2** Cross section through the sigmoid colon containing diverticula (*arrows*).

Many studies have demonstrated a change in the histologic structure of the muscularis propria in diverticular disease. In a classic study, Whiteway and Morson<sup>17</sup> found the muscle cells to be normal with no evidence of hyperplasia or hypertrophy, but both layers were thickened. They demonstrated excessive amounts of elastin in the taeniae but not in the circular muscle.<sup>17</sup> Repeated intermittent distension of the colon can result in increased synthesis of connective tissue components.<sup>32</sup> It may be that the Western diet with its lower fecal load only intermittently distends the bowel wall and encourages elastin deposition.

The importance of collagen and elastin types in the colonic wall is increasingly being recognized. Elastin deposition, termed “elastosis,” explains the contracted and thickened appearance of the diverticulum-affected colon. The taeniae shorten, and because of fascial linkage between the longitudinal and circular muscles, the colonic wall looks like a concertina. Thickened circular muscle folds project into the lumen, causing a decrease in caliber. The mesocolon is also foreshortened, possibly as a result of chronic inflammation. Other studies have suggested that the type of collagen may be

important.<sup>33</sup> One study has shown that in the bowel sections of patients with diverticulitis, there were decreased levels of mature collagen type I and increased levels of collagen type III with a resulting lower collagen I:III ratio. The expression of matrix metalloproteinase 1 was reduced significantly in the diverticulitis group.<sup>33</sup> These findings support the theory of structural changes in the colonic wall as one of the predisposing pathogenic factors for the development of diverticula (Fig. 43-3A and 43-3B).<sup>33</sup> In those with certain connective tissue diseases, such as Marfan and Ehlers-Danlos syndromes, diverticular disease is a common association.

**A**

**B**

**FIGURE 43-3** **A.** Sigmoid colon with diverticula. **B.** Mucosal view of colonic diverticula.

Diverticulitis always starts with a microperforation, leading to peridiverticulitis. This is instigated by either a rise in intraluminal pressure and/or erosion by inspissated feces. Nonresolution of this initial injury leads to complications of diverticulitis.

## Presentation

Given the high incidence of diverticulosis, it is surprising that clinical manifestations are relatively infrequent. Many patients are unaware that they have colonic diverticula until they develop acute symptoms or when diverticulosis is found incidentally during colonic investigations. Typically an acute attack of diverticulitis begins with lower abdominal pain that then localizes to the left iliac fossa. An inflamed sigmoid colon can lie against the dome of the bladder or the cecum, mimicking a urinary tract infection or appendicitis. Fever, tachycardia, and a leukocytosis accompany the acute attack. The inflammatory response starts at the site of a blocked diverticulum, and bacterial proliferation eventually leads to abscess formation. Minor episodes may be self-limiting, but an abscess can develop and then rupture into the abdomen causing a purulent peritonitis. More rarely, feculent peritonitis occurs when a diverticulum ruptures freely into the peritoneum.<sup>34-41</sup>

Physical examination will often reveal peritonitis localized to the left iliac fossa or suprapubic area; a palpable mass is not uncommon.

The differential diagnosis includes appendicitis, segmental ischemic colitis, colorectal cancer, inflammatory bowel disease, gastroenteritis, and irritable bowel disease.

In the absence of complications, patients with acute diverticulitis are best managed conservatively with antibiotics. Generalized rigidity suggests purulent or fecal peritonitis, and early surgery is required in this situation. Once fluid and electrolyte resuscitation has begun, an emergency laparotomy or laparoscopy with an appropriate colonic resection should be performed.

Often, diverticular disease presents in a more indolent manner with nagging left iliac fossa pain, abdominal distension, and a change in bowel habit. In the course of investigations to exclude colon cancer, diverticular disease may be discovered by computed tomography (CT) colonography, or colonoscopy (Figs 43-4, 43-5A, and 5B). In the majority of these patients,

education about the natural history of the disease with advice on dietary modification and supplementary written information will suffice. A very limited number of patients who continue to have symptoms despite long periods of medical management may benefit from surgery in the absence of other specific complications of the disease; however, determining the contribution of symptoms from diverticular disease and associated conditions such as irritable bowel syndrome can be difficult. These patients often have persisting symptoms following surgery.

**FIGURE 43-5** CT axial view of sigmoid diverticula.

## COMPLICATIONS

**Free Perforation.** Feculent peritonitis is usually associated with toxemia and signs of generalized peritonitis. These patients will require an immediate laparotomy, resection, and diversion. Mortality rates for emergency operations have remained unchanged at 12% to 36% for the past 20 years and are most often affected by the patient's underlying fitness for surgery.

**Fistula.** An inflamed segment of sigmoid colon can adhere to a number of intra-abdominal structures or to the abdominal wall. A fistula may arise spontaneously as a result of the inflammatory condition itself or as a result of surgical intervention. It is more common in males, in those with previous abdominal surgery, and in immunocompromised patients. Diverticular fistulas can drain either internally or externally. Often, these fistulas are single tracts, but in about 8% of patients, they are multiple. Rare sites of fistulous involvement include the ureters, other colonic segments, and stomach.

**Colocutaneous.** Occasionally, a paracolic diverticular abscess will discharge spontaneously through the abdominal wall, causing a colocutaneous fistula. More often, a fistula will result from incision and drainage of a pointing paracolic abscess or from a drain placed under radiologic control. A fistula can arise from a leaking colonic anastomosis in patients who have undergone resection for diverticular disease.

**Colovesical.** This is the most common fistula, accounting for about two-thirds of diverticular fistulae. It is more common in men because in women the uterus is interposed between the bladder and the colon. A relatively mobile sigmoid colon becomes adherent to the dome of the bladder and a communication develops. Patients present with recurrent urinary sepsis, urgency, frequency, and pneumaturia. Fecaluria is uncommon. Cystoscopy sometimes identifies an area of inflamed transitional epithelium but is more useful to exclude bladder cancer. A double-contrast enema or CT colonography provides a useful map of the anatomy and in some cases can confirm the presence of a fistula. Caution should be exercised when using barium in an acute situation to avoid peritoneal contamination.

**Coloenteric.** Small bowel can become adherent to an inflamed diverticulum-affected colon. Fistulas form when an abscess discharges through the small bowel wall. This may be asymptomatic.

**Colovaginal.** This is a particularly debilitating fistula. The patient may pass flatus and feces through the vagina and suffer recurrent vaginal infections. Colovaginal fistulas usually only occur if a previous hysterectomy has been performed. Barium studies of both the bowel and the vagina or pelvic magnetic resonance imaging (MRI) usually can confirm the diagnosis. They are also helpful to exclude colonic malignancy as a cause; however, an examination of the vagina may also be required to exclude the rare possibility of a gynecologic malignancy.

Single-stage operative resection with primary anastomosis and repair of the contiguous organ can be performed in most circumstances.<sup>42</sup> Interposition of the pediculated greater omentum between the anastomosis and the site of the fistula is a useful adjunct in preventing recurrent fistula formation.

**Bleeding.** Severe hemorrhage from diverticular disease is rare (5%).<sup>43,44</sup> However, distinguishing diverticular bleeding from other causes can be a diagnostic challenge, particularly because diverticular disease is so prevalent.<sup>45,46</sup> In elderly patients, angiodysplasia is the most common colonic cause of rectal bleeding. Taken together, bleeding from angiodysplasia and diverticula account for 90% of cases of severe lower intestinal hemorrhage. In diverticular bleeding, the penetrating vasa recta that has led to the development of the diverticulum is easily eroded as it is only separated from the bowel lumen and its contents by a thin layer of mucosa. On histology, there is thinning of the media and thickening of the intima of the vasa recta with rupture of the vessel usually at the dome of the diverticulum. There usually is no inflammation associated with the bleeding diverticulum.<sup>47,48</sup>

Diverticular hemorrhage presents with abrupt passage of large-volume bright or dark red blood per rectum and may be associated with lower abdominal pain probably related to colonic distension. Most diverticular bleeding occurs from left-sided diverticula except in patients of Asian ethnic origin, in whom it is more common to find the bleeding occurring on the right side.<sup>31</sup> Diverticular bleeding is more common in those on nonsteroidal anti-inflammatory drugs (NSAIDs). Colonoscopy in situations of large-volume bleeding is considered futile if not dangerous. CT angiography is now considered the most useful diagnostic test as it more readily localizes the site of bleeding should the bleeding rate exceed 0.5 mL/min. Formal mesenteric angiography to embolize the segmental vessel is then undertaken with good bleeding control and low associated complications (Fig. 43-6).<sup>49,50</sup> Failing

this, other techniques to control or localize the bleeding site include vasopressin injection or methylene blue. A more sensitive test for colonic bleeding is a radiolabeled red blood cell scan or technetium-99m–labeled sulfur colloid (>0.1 mL/min), but accuracy in localizing the bleeding site is not as good.<sup>51</sup> Colonoscopy can be used before a laparotomy or as an adjunct with the abdomen open if all else fails in a patient who continues to bleed. It is useful in an attempt to localize and control the bleeding or to minimize the amount of colonic resection. It is also important to note that in these situations a preoperative gastroscopy is mandatory to exclude an upper gastrointestinal tract source of bleeding. Most diverticular hemorrhage ceases spontaneously (70%-80%), with rebleeding rates of 22% to 38%.<sup>44,45,52</sup> High-dose barium impaction therapy has been suggested to reduce the risk of rebleeding, and a recent randomized controlled trial with medium-term follow-up supported its efficacy.<sup>53</sup> CT colonography or colonoscopy in patients who have stopped bleeding is useful to exclude malignancy, particularly in those with smaller volume bleeding, with associated suspicious symptoms, or with a significant personal or family history of cancer.

**FIGURE 43-6** Formal angiography demonstrating “contrast blush”—active bleeding from sigmoid colon.

**Obstruction.** Obstruction due to diverticular disease accounts for 10% to 20% of large bowel obstructions (LBOs) in Western society. Diverticular disease causes colonic obstruction through either luminal stenosis as a result of wall edema on top of the already thick-walled, fibrotic colon or extrinsic compression from an abscess (Fig. 43-7). Often the obstruction is incomplete. Small bowel obstruction can occur if a loop of small bowel becomes adherent to the inflamed sigmoid colon. The diagnosis is usually apparent from the patient’s history. Radiologic confirmation either by contrast enema or by CT with oral and rectal contrast should be obtained. Caution is wise in those with questionable underlying active diverticulitis particularly if complicated by localized perforation. Direct visualization and histologic exclusion of malignancy are mandatory but at times difficult.

**FIGURE 43-7** CT scan of active diverticulitis with occlusion of colonic lumen secondary to inflammation (*arrow*). Differential diagnosis is a sigmoid colon malignancy.

Management of colonic obstruction in this setting depends on the mode of presentation and the medical fitness of the patient. An insidious onset is characterized by pain, increasing constipation, and the passage of ribbon-like stools. The majority of patients, however, will present acutely with a classic LBO. The surgical options include a Hartmann resection and resection with primary anastomosis or rarely with a diverting loop ostomy. In patients deemed unfit for surgery, the endoscopic or fluoroscopic deployment of a colon stent is a useful alternative procedure with a high clinical success rate.<sup>54</sup>

**Abscess.** Abscess formation is the most common complication of acute diverticulitis. It occurs when the center of the inflammatory mass or phlegmon becomes necrotic. The patient presents with worsening abdominal pain, undulating fever, leukocytosis, and raised inflammatory markers. A mass is often palpable in the left iliac fossa or suprapubic region. It may also be felt transvaginally or transrectally. The most common site for a diverticular abscess is in the sigmoid mesocolon, although a variety of unusual presentations have been described.<sup>55</sup> A significant number of abscesses are detected radiologically on CT or ultrasound scanning. Most small (<5 cm) pericolic abscesses can be treated medically with bowel rest and antibiotics.<sup>56</sup> CT or ultrasound-guided drainage is indicated for larger or unresolving abscesses via a percutaneous approach when accessible (Fig. 43-8).<sup>41,57-59</sup> Alternatively, these abscesses may also be drained transanally or transvaginally depending on their location. This is successful in up to 90% and will allow subsequent observational management or a single-stage resection.<sup>59-62</sup> Factors that limit success with this management include abscesses that involve enteric fistulae or multilocular collections especially those containing solid feces. More recently, laparoscopic drainage has been taken up with enthusiasm by several groups with some promising results.<sup>63-66</sup>

**FIGURE 43-8** Sigmoid diverticulitis complicated by a paracolic abscess (with a percutaneous drainage tube in situ).

**Giant Colonic Diverticulum.** Giant colonic diverticulum (GCD) was first described in 1946 by Bonvin and Bonte<sup>67</sup> in the French literature. The first radiologic description was by Hughes and Greene in the American literature in 1953.<sup>68</sup> Various names have been used to describe GCD, including solitary air cyst, giant air cyst, giant gas cyst, encysted pneumatocele, colonic pneumocyst, and giant diverticulum. The variety of names highlights the fact that there has been no clear definition or a single accepted name for these poorly defined lesions that present as large gas-filled cysts attached to the colon (diverticulum). GCD are rare clinical entities with just over 100 cases reported. The age at presentation is comparable to that of patients with conventional diverticular disease. Abdominal pain is the most common symptom, affecting 70% of patients, while 10% are asymptomatic. The most

common physical finding is an abdominal mass, affecting 60% of patients, while 4% have normal physical examinations. Plain abdominal radiology is usually diagnostic of GCD, but CT is often obtained to fully identify the anatomy. Treatment is recommended early, preferably soon after presentation, because of the high complication rate. Surgical treatment may either require a diverticulectomy or segmental resection, and the outcome is usually good.<sup>69</sup>

**Cancer.** There is little evidence to support an association between diverticular disease and colorectal cancer; however, a recent population-based, case– control study from Sweden identified a causal association between sigmoid diverticulitis and a long-term increased risk of left-sided colon cancer.<sup>42</sup>

## Investigations

The spiral CT scan has changed the investigation of acute diverticular disease with sensitivities of 90% to 95%. Although it is debatable whether CT alters disease management in minor diverticular disease, it is invaluable in excluding other causes of abdominal pain and documenting the extent of extraluminal disease. In circumstances in which access to CT is limited, a water-soluble contrast enema study may show mucosal thickening, edema, irregularity, and occasional extravasation of contrast (Fig. 43-9). Sensitivity of a contrast enema study is high.<sup>70</sup> Any free perforation is usually contained in an abscess cavity. Contrast enemas are particularly useful for demonstrating the presence and course of an enteric fistula. Barium should be avoided in the emergency setting, as the consequences of barium-induced peritonitis are catastrophic.

**FIGURE 43-9** Localized perforation with contrast extravasation into abscess cavity as demonstrated on double-contrast study.

The real advantage that CT scanning affords, in addition to confirmation of the diagnosis, is to direct the treatment of complicated diverticular disease.<sup>71-73</sup> Radiologically guided drainage of diverticular abscesses is a useful adjunct to medical management, and can, if successful, avoid the requirement for emergency surgery (see Fig. 43-8).

The role of ultrasound scanning in patients suspected of having diverticular disease has been confined to the treatment and follow-up of diverticular abscess. It is highly operator-dependent, but it can be used to insert drains and to measure the response of the abscess to drainage.

It was traditional practice following resolution of the first episode of diverticulitis to assess the colon for extent of disease and to exclude colorectal malignancy. This can be undertaken with colonoscopy, CT colonography, or barium enema. Care must be taken to wait for full resolution of the attack as an inflamed colon is easy to perforate; also, at times colonoscopy may be very difficult or impossible due to inflammatory adhesions. Colonoscopy generally underestimates the extent of the disease. Recent evidence has challenged the need for routine colonoscopy following an attack of uncomplicated diverticulitis diagnosed by a good-quality CT of

the abdomen. The yield of colorectal cancer in this setting is equivalent to or lower than that in asymptomatic individuals undergoing screening colonoscopy.<sup>74</sup> Examination of the colon remains mandatory after complicated diverticulitis, after a clinical diagnosis of only diverticulitis, or in the presence of any other symptoms suggestive of colorectal cancer or another alternative diagnosis.

Other tests available that may be useful in assessing fistulous disease include MRI scans, cystoscopy, fistulogram, vaginogram, or vaginoscopy.

## Classification of Diverticulitis

The Modified Hinchey classification is a useful grading system for diverticulitis.<sup>34,75-77</sup>

More recently, various modifications of the Hinchey classification have been proposed to further subclassify these stages, and these are amalgamated in [Table 43-1](#). Stage 0 is clinical, mild diverticulitis without imaging information. Stage I has been subdivided into stage Ia, which is pericolic inflammation, and stage Ib, which is diverticulitis associated with pericolic abscess. Stage IIa is distant abscess amenable to percutaneous drainage. Stage IIb is complex abscess with or without fistula. Stages III and IV are the same as for the original Hinchey staging.

**TABLE 43-1: CLASSIFICATION OF DIVERTICULITIS**

## Stage 0    Clinical mild diverticulitis without imaging

---

Stage Ia	Pericolic inflammation
Stage Ib	Diverticulitis with associated pericolic abscess
Stage IIa	Diverticulitis associated with distant abscess (retroperitoneal or pelvic) amenable to percutaneous drainage
Stage IIb	Diverticulitis associated with distant abscess (retroperitoneal or pelvic) that is complex and/or associated with a fistula
Stage III	Diverticulitis associated with purulent peritonitis
Stage IV	Diverticulitis associated with fecal peritonitis

---

## Management

### ACUTE UNCOMPLICATED DIVERTICULITIS

The majority of patients with acute uncomplicated diverticulitis are managed conservatively with intravenous antibiotics, and 95% improve without requiring acute surgery.<sup>78</sup> The antibiotic should target gram-negative rods and anaerobes, especially *Bacteroides* species. A combination of metronidazole and ciprofloxacin or a broad-spectrum antibiotic such as meropenem or amoxicillin and clavulanate (Augmentin) is most commonly used.<sup>79</sup> There is, however, quite a variation in the treatment regimen used among clinicians, and there is no specific regimen that has been shown to be superior.<sup>80</sup> A recent randomized trial called into question the need for antibiotics at all in acute diverticulitis, finding no difference in resolution rates or progression to complications in patients treated with or without antibiotics.<sup>81</sup> Despite this, antibiotics will remain the standard treatment in most centers until further evidence becomes available.

The decision to operate should be made at a senior level, as the actual number of patients who require resectional surgery for diverticular disease is small.<sup>82</sup> The increasing use of interventional radiology and laparoscopic surgery has impacted on how diverticular disease is currently managed. This is coupled with a trend to not perform any resectional surgery but, when necessary, to do so with a primary anastomosis in patients presenting with

acute uncomplicated diverticulitis.

## ACUTE COMPLICATED DIVERTICULITIS

Operative indications include free perforation with peritonitis, abscesses not able to be managed conservatively, fistula, and obstruction. The operative rate for complicated diverticulitis overall in the past has been between 19% and 55%.<sup>83-88</sup> Complicated diverticulitis has been shown by some to be associated with high rates of recurrent complications and high rates of mortality.<sup>39,89</sup> The mortality in some reports approaches 40%, especially in immunocompromised patients,<sup>39,90-92</sup> and similarly, in those with an American Society of Anesthesiologists score of  $\geq 3$ , there is a mortality rate of up to 28%.<sup>35-37,39,85,89,90,93-96</sup>

When either an abscess or a diverticulum ruptures into the peritoneal cavity, widespread bacterial contamination ensues with resultant generalized peritonitis. Surgery is principally directed at controlling peritoneal sepsis and should be tailored to each situation. A conservative approach can be taken with elderly and medically unfit patients who are unlikely to survive surgical intervention. The combined use of appropriate antibiotic therapy and regular review is surprisingly successful in this cohort, even in the presence of a pneumoperitoneum.

In patients who are fit for surgery, a period of vigorous resuscitation and antibiotic therapy is still warranted. Even in the face of advanced peritoneal signs, a number of patients will respond to these measures and avoid the requirement for surgery, and others who come to surgery will be in a better condition to withstand the physiologic trauma of surgery. Serial clinical observation is of greatest benefit when pursuing this course. If there is no initial improvement in 8 hours or sustained improvement over 24 hours, then the patient should be recommended to have surgery.

The operative approach is dictated by the findings and condition of the patient. The most common approach is resection of the affected segment of bowel, usually the sigmoid colon, with or without anastomosis. Historically, 3-stage procedures were performed with a defunctioning stoma, followed by resection of the sigmoid, and finally closure of the stoma at a third procedure. This approach was abandoned with a recognition that resection of the affected colon is associated with a lower morbidity and up to 3 times less mortality compared with nonresection procedures.<sup>90,97</sup> This focused the aims

of surgery on removal of the source of sepsis and toileting of the abdominal cavity.

The development of laparoscopic surgery once again challenged the necessity of resection with the introduction of laparoscopic lavage and drainage for complicated diverticulitis. The first prospective report of this approach in 2008 documented good results in Hinchey stage III disease.<sup>98</sup> The technique involves laparoscopic lavage with drain placement with or without closure of the perforation. This avoids emergency resectional surgery and its associated morbidity and mortality, as well as that from stoma formation and reversal.<sup>99</sup> The promising results from early series led to a number of randomized trials performed predominantly in Europe.<sup>100-102</sup> Emerging results from these trials have been mixed but generally do not lend strong support to the use of laparoscopic lavage. Two studies suggested increased complication rates in the laparoscopic lavage group compared with the resection group.<sup>100,101</sup> In contrast, a third study did demonstrate reduced requirement for reoperation in the laparoscopic lavage group.<sup>102</sup> All the trials excluded Hinchey stage IV peritonitis from laparoscopic lavage so there is no doubt this severe disease still mandates resection. The data from trials of Hinchey stage III disease will continue to mature, but in the interim, it appears the previously held principle of surgical resection of the diseased segment should be upheld in the majority of patients with perforated diverticulitis requiring emergency surgery.

The amount of resected tissue depends on the extent of the diverticular disease. At the time of the initial acute surgery, the inflamed bowel needs to be resected. The extent of this resection depends on whether a primary anastomosis is being undertaken or a Hartmann procedure is being performed. When bowel continuity is restored after a Hartmann procedure, total sigmoid colectomy plus removing all of the diverticula bearing colon and a rectal anastomosis has been shown to reduce the risk of recurrence by some<sup>103,104</sup> but not others.<sup>105</sup>

The decision of whether to undertake an anastomosis in the acute setting is dependent on a number of criteria: the frailty of the patient, the degree of contamination and sepsis, the preparedness of the bowel, and the experience of the surgeon. The Hartmann procedure entails resection of the sigmoid colon with formation of end colostomy and is the safest option when conditions do not favor primary anastomosis. Hartmann resections are not

without their own complications. Up to 50% of patients will never have their stoma closed, particularly the elderly.<sup>39,83,106,107</sup> There is also definite morbidity (up to 16%) and mortality (up to 4%) related to restoration of continuity.<sup>36,94,106-109</sup> Occasionally, there are complications related to rectal stump dehiscence.<sup>110</sup>

Primary anastomosis can be performed in the emergency setting but only if conditions are wholly favorable.<sup>111,112</sup> Performing anastomoses in the presence of gross purulent or fecal contamination is controversial and should only be performed by experienced hands. The requirement for bowel preparation for left-sided anastomosis is equally controversial, but recent studies have cast doubt on the need for this, albeit in the elective setting.<sup>113</sup> Presacral drainage is often used at the end of the operation but without evidence of its effectiveness.<sup>114</sup>

## **ELECTIVE SURGERY**

Surgery should be reserved for patients who are medically fit with several proven attacks of acute diverticulitis or who have ongoing sequelae from complicated diverticular disease. In recent years, the role of surgery has been reassessed,<sup>115-118</sup> and as a result, a more conservative approach has evolved, based on a better understanding of the natural history of diverticular disease, including that most patients will not get further episodes of acute diverticulitis and a significant minority of patients, whose principal symptom is chronic pain, will continue to be symptomatic after resection.<sup>119</sup>

Elective resection has generally been offered to patients who have suffered 2 attacks of acute diverticulitis in a short period of time, but recommendations have ranged from 1 to 4 episodes.<sup>56,83,89</sup> The argument has been that this will prevent recurrent diverticulitis as well as its associated complications.<sup>79,84,93,120-129</sup> This is based on historical data that suggest recurrences of up to 67%, with higher morbidity (up to 60%) and mortality associated with recurrent diverticulitis particularly after two episodes.<sup>35,37,56,83,85-87,128,130-138</sup> It was also previously demonstrated that patients older than 50 years respond less well to conservative treatment following successive attacks of diverticulitis; a response rate of only about 6% was reported for the third recurrence.<sup>136</sup> In another series, rerecurrence was estimated at 2% per year with the first recurrence being the most

significant predictor of this.<sup>86</sup> Most often, any recurrence that occurs does so in the first 6 months after the initial attack, and recent data would suggest that it is in fact failure of resolution of the inflammation from the first episode rather than a true recurrence. Some have argued that there is a reduction in the recurrence rate of diverticulitis from 12.5% to 6%,<sup>103,139</sup> with good long-term results following surgery.<sup>127,140</sup>

There is increasing evidence that conservative management is adequate in most patients following both complicated and uncomplicated attacks of diverticulitis in this situation. A large population-based study recently showed very few patients going on to have surgery after initial conservative treatment of diverticulitis.<sup>78</sup> Another group showed that successful conservatively treated complicated disease, in particular abscesses, is not associated with further recurrence or complicated recurrences.<sup>86</sup> A recent study followed 502 patients, 337 with uncomplicated diverticulitis and 165 with complicated diverticulitis, for a median of 101 months. Of the 320 patients with uncomplicated diverticulitis managed conservatively, 60 (18.8%) had one episode of recurrence, whereas 15 (4.7 %) had 2 or more episodes. After an initial attack of uncomplicated diverticulitis, only 5.0 % developed complicated disease. Complicated disease recurred in 24% of patients, compared with a recurrence rate of 23.4% in those with uncomplicated diverticulitis ( $P = .622$ ). When recurrence occurred, it usually did so within 12 months of the initial episode.<sup>141</sup>

Recent evidence suggests that less than a quarter of patients having emergency surgery for acute diverticulitis have a previous history, and often complications arise during the first attack of diverticulitis, rather than during subsequent episodes.<sup>90,131,142</sup> Such episodes were associated with a more benign course and responded well to nonoperative management.<sup>134,143</sup> Two groups have shown that the less severe and more readily conservatively managed complications of pericolic abscess occur in recurrent cases rather than free perforation.<sup>39,144</sup> Following elective resection, up to 25% will continue to have symptoms suggesting a coexistent pathology such as irritable bowel.<sup>6,119</sup> Up to 16% will develop recurrent diverticulitis, with a small percentage requiring further surgery.<sup>103-105,145-147</sup> Furthermore, prophylactic colectomy has a mortality risk of up to 4%, and a diverting stoma is used in up to 14%, necessitating a further operation to reverse.<sup>39</sup>

Risk-reducing measures in elective surgery include weight control, routine

administration of prophylactic preoperative antibiotics, and preoperative optimization of the respiratory status of the patient with chronic pulmonary disease. Attempts have been made to stratify the management of diverticular disease by pathologic and radiologic means.<sup>148,149</sup> In one study, patients characterized as having a mild attack of diverticulitis had a 14% risk of having a recurrent episode, whereas severe forms had a risk of 39%. Ultimately, the wide spectrum of disease encountered makes dogmatic statements about intervention unreliable, and sound clinical judgment is still required to decide when to intervene.

Indications for operative intervention are different in 2 patient subgroups: those younger than 50 years and the immunocompromised. Data on young patients with diverticular disease are mainly retrospective. The prevalence of colonic diverticula has been estimated at between 6% and 9% in the general population age 40 years or younger, with a male preponderance (62%-100%).<sup>123,150-152</sup> Patients in this group are thought to have a more virulent course with more complicated recurrences, and an aggressive policy of surgical resection has been proposed,<sup>123,129,130,143,152-157</sup> particularly in obese males.<sup>123,158,159</sup> Others more recently have challenged this opinion, arguing that there is no difference between the young and old population.<sup>160</sup> There were very few free perforations with recurrent attacks and certainly no increased mortality in this age group.<sup>78,87,132,151,157,161-164</sup> Whether the higher propensity for a complicated course in this age group is a true association or the presentation has been altered because of delayed diagnosis remains debatable.<sup>147,165-167</sup> Between 29% and 55% of younger patients will be readmitted to the hospital with acute diverticulitis following their initial presentation, with the majority (up to 88%) of these subsequently undergoing elective or emergency surgery.<sup>82,143,152-154,168</sup> A number of these patients were diagnosed at operation for another surgical condition, most often with appendicitis, and were thus often unnecessarily operated on.<sup>78,163,164</sup> It is unclear whether there is an advantage to operating after the initial acute attack of diverticulitis in this age group, especially if it is uncomplicated.

It is uncertain whether patients who are chronically immunosuppressed are more at risk of developing diverticular disease. It is thought that patients who have long-term uremia have a higher incidence of diverticulosis, possibly due to chronic constipation and generalized tissue weakness. Patients with polycystic kidney disease have a very high incidence of colonic diverticular

disease.<sup>169</sup> Several groups have reported that immunocompromised patients with acute diverticulitis have a more complicated course compared to nonimmunosuppressed patients.<sup>170-172</sup> Patients who are recipients of renal transplants have a high mortality rate from acute complicated diverticular disease. In some centers, routine colonic screening of patients awaiting renal allografts is performed.<sup>173</sup>

There is limited evidence that the cessation of smoking and stopping NSAIDs will reduce the rate of recurrent attacks of diverticulitis. There is some evidence that the long-term administration of a poorly absorbed antibiotic will have such an effect.<sup>174-178</sup> Mesalazine has been trialed both for treatment of acute attacks and prevention of recurrence, but there is insufficient evidence to support its use.<sup>179</sup>

## **ELECTIVE LAPAROSCOPIC SURGERY**

Laparoscopic colectomy has been practiced routinely for over 2 decades. Numerous randomized trials demonstrate laparoscopic surgery in colon cancer is oncologically equivalent to the open approach with better cosmesis, less analgesic usage, and shorter hospital stays.<sup>180-182</sup> There is lower quality evidence for laparoscopic colectomy in diverticular disease, but results from specialized centers suggest good results.<sup>183,184</sup> Some groups have included complicated cases, including abscesses and fistulas.<sup>185-188</sup> Published studies comparing laparoscopic and open resection of left-sided colonic diverticular disease have demonstrated benefits in terms of shorter hospital stay and convalescence despite a longer operating time.<sup>189,190</sup> Major complications and the length of the colon resection are generally the same when compared with the traditional open approaches.<sup>185-187</sup> Conversions to open depend on factors such as the clinician's surgical experience and the complexity of the diverticular complications involved.<sup>191</sup>

Caution should be exercised because the laparoscopic approach in diverticular disease can be more technically challenging than operating on malignant disease because of the recurrent inflammation and fibrosis. Significant experience in laparoscopic surgery and appropriate patient selection are required to maintain the benefits of the laparoscopic approach with acceptably low morbidity rates.

Furthermore, publication bias is likely to promote laparoscopic resection

as being more favorable, and the true morbidity, cost, and conversion rates may differ from figures published in the medical literature. In over 1100 patients reported over the past 5 years, the postoperative complication rates range from 7.3% to 21%. Conversion rates range between 4% and 14%, operating time ranges from 141 to 300 minutes, and return of bowel activity takes between 2 and 2.9 days.<sup>185-187,189</sup> A recent analysis of the cost of laparoscopic surgery compared with open surgery demonstrated that the total cost of the laparoscopic approach was significantly less (US\$3458 vs US\$4321;  $P < .05$ ).<sup>189</sup> These economic factors will have ramifications for surgical treatment in the future.

## Summary

The prevalence of diverticular disease has increased and is continuing to do so in Western countries. The management of diverticular disease is becoming an increasing financial burden to health systems with limited resources. There is little evidence that a change in lifestyle measures can reduce the prevalence of diverticular disease. Fortunately, colonic diverticula are usually asymptomatic.

The acute management of diverticulitis is usually conservative with antibiotics and bowel rest, with few patients needing emergency operations. Abscesses can be adequately treated with percutaneous drainage. When an operation is required, the quality of the surgery appears to be more important than whether the operation is undertaken open or laparoscopically. In the acute setting, the affected segment of colon should be resected. The place of elective resection is uncertain. The wide spectrum of disease encountered makes dogmatic statements about intervention unreliable, and sound clinical judgment is still required to decide when to intervene. Further prospective trials investigating recurrence rates, and in particular risk factors for recurrence, as well as the role of prophylactic surgery in the various subgroups are required.

## COLONIC VOLVULUS

A colonic volvulus occurs when a segment of colon twists around its mesentery giving rise to a partial or complete bowel obstruction. This

condition is not just confined to humans with dogs and horses both suffering from this disease.

## Epidemiology

Colonic volvulus occurs frequently in developing countries such as Africa and South America, accounting for at least 50% of causes of LBO, but in developed nations, it is third after cancer and diverticular disease, at about 10%.<sup>192,193</sup>

In developed countries, sigmoid and cecal volvulus are the 2 most common forms of colonic volvulus, with the former increasing in incidence with age, especially in those older than 60 years. In sigmoid volvulus, there is a higher incidence in males due to their dolichomesocolic anatomy (sigmoid mesocolon is longer than wide) compared to females.<sup>192-194</sup> In cecal volvulus, there is a younger age of presentation, usually around 40 years of age and particularly in women. Overall, the ratio of sigmoid to cecal volvulus is about 4:1. The other sites, including the descending colon, flexures, and transverse colon, are rarely involved. In developing countries, the peak incidence is in males in the 40- to 60-year age group, who account for up to 90% of cases.<sup>193</sup>

## Etiology

A redundant colon that is mobile on a long mesentery is a prerequisite that predisposes to colonic volvulus. Redundancy of the colon is due to colonic dysmotility, excessive fiber intake, or a genetic predisposition. Adynamic ileus and distal obstruction are also predisposing factors. In cecal volvulus, up to 50% will have a history of prior abdominal surgery. Volvulus in Western society is often seen in institutionalized, bed-bound elderly patients with an acquired megacolon. Mobility of the sigmoid colon is obvious with a long and narrow mesentery. In the right colon, poor fixation is often related to partial or complete malrotation of the bowel, and in the splenic flexure, volvulus occurs when there is congenital lack of fixation of the splenicocolic, gastrocolic, and phrenocolic ligaments.<sup>192,193</sup>

## Morphologic Features

In colonic volvulus, there is axial twisting of the bowel loops around the vascular axis, leading to a closed-loop obstruction with bowel ischemia and potential gangrene. If neglected, perforation of this bowel loop may occur. In cecal volvulus, there is usually a counterclockwise axial twisting of the cecum, ascending colon, and terminal ileum around the mesenteric pedicle. Cecal bascule is a variant of the true cecal volvulus with the difference being an absence of the axial twist; rather, the redundant cecum folds back transversely and upward over the ascending colon. True cecal volvulus is about 9 times more common than cecal bascule. Bowel ischemia or infarction in this group can occur but is unusual.<sup>195</sup> Ileosigmoid knotting occurs when the ileum gets caught up in the sigmoid volvulus and an ischemic process ensues in both the twisted bowel loops.

## Presentation

Colonic volvulus commonly presents with bowel obstruction, vomiting, obstipation, abdominal pain, and distension. About half of patients will have symptoms suggestive of a previous attack. Clinical examination usually reveals a massively distended abdomen that is asymmetrical and tympanic. The rectum is invariably empty. Signs of peritonitis often indicate underlying complications of perforation or gangrene.

## Complications

Perforation of the twisted segment of bowel (closed-loop obstruction) or bowel ischemia and infarction may occur. Secondary renal failure or multiorgan failure could arise because of third-space loss or loss from vomiting. Alternatively, this may be due to reperfusion injury after the volvulus is untwisted. Abdominal compartment syndrome is a rare complication.

## Investigations

A plain supine abdominal x-ray is usually sufficient in the diagnosis of

sigmoid and cecal volvulus (Figs 43-10 and 43-11). Up to 40% cases of cecal volvulus are in fact misdiagnosed as sigmoid volvulus. In cecal volvulus, the dilated colon assumes the shape of a large coffee bean (“tear drop” or “comma” appearance) with 1 fluid level and the point directed toward the left upper quadrant (see Fig. 43-11). There is often a lack of gas in the distal colon, and up to half of patients will have dilated small bowel as well. In sigmoid volvulus, the shape is that of a “bent inner tube” with its point aimed at the right upper quadrant (see Fig. 43-10). Other features include “2 air to 1 fluid level” and a “pair of scales,” whereby the fluid levels are at different horizontal levels. Dilated proximal large bowel and small bowel may be evident. Rarely, even when present, is there free air under the hemidiaphragms due to the overwhelming amounts of colonic luminal gas that is present in the background. To confirm the diagnosis, a gastrografin (diatrizoate meglumine) or barium enema study may be performed to look for the “bird beak” sign that indicates the site of twisting of the colon. This, however, is becoming obsolete as CT scan is now readily available and commonly used to differentiate causes of abdominal pain. The “bird beak,” whirl, or coffee bean signs are the most diagnostic features of volvulus on CT scan (Figs 43-12 through 43-14).<sup>196</sup> CT scans can also be used to help exclude other diagnoses, including causes of distal bowel obstruction that may be associated with the volvulus, as well as help determine if the volvulus is complicated by ischemia or perforation.<sup>193</sup> Alternatively, a rigid or flexible sigmoidoscopy or colonoscopy can be performed. This has a higher rate of therapeutic success than an enema study, in particular for the sigmoid volvulus.

**FIGURE 43-14** Cecal volvulus on coronal CT scan section with the beaking effect (*arrow*).

## Management

In Western countries, the mortality associated with colonic volvulus is high, at about 20% overall and even higher when there is concomitant gangrenous colon. This is primarily due to the high comorbidities of this particular group of patients.<sup>194</sup>

Management of colonic volvulus should include a combination of careful resuscitation, urgent diagnosis, and decompression as soon as feasible. Of note, reperfusion syndrome is a real phenomenon following de-torsion of an ischemic or gangrenous bowel segment. Potential serious bacterial/toxin translocation and multiorgan failure are consequences that the treating

clinician must constantly keep in check.<sup>197,198</sup>

Colonic volvulus especially involving the sigmoid colon may be decompressed by rigid sigmoidoscopy or colonoscopy. The latter has been shown to be more effective at decompression and carries a lower risk of complications. The twisting point is often found high above the anal verge with decompression manifesting as a sudden rush of flatus and liquid feces via the anus or sigmoidoscope. The mucosa of the obstructed loop and the site of twisting should be inspected to evaluate the level of bowel ischemia. If no immediate surgery is required, a rectal tube should be placed to prevent further recurrences of the volvulus to allow the continuing decompression of the obstructed colon. For recurrent sigmoid volvulus in a patient who may withstand surgery, a sigmoid colectomy with or without anastomosis, once the bowel is adequately decompressed, is warranted. In the absence of perforation, there is no difference in outcome between a primary anastomosis and Hartmann procedure for gangrenous disease.<sup>199</sup> The mortality of this is only slightly higher at 5.5% (primary resection and anastomosis) versus 4.2% (Hartmann).<sup>200</sup> The recurrence rate after resection is almost zero.<sup>201</sup>

Laparotomy and de-torsion with or without colopexy is a poorer alternative with similar morbidity but higher recurrence of up to 40%.<sup>202</sup> Similarly, there is a high recurrence rate for mesosigmoidoplasty.<sup>200</sup> Surgery undertaken in these emergency situations had mortalities of 40% compared to 5.9% for elective operations.<sup>195</sup> In patients who are medically at too high risk for an anesthetic, removing the rectal tube 48 hours later to allow the obstructed colon to deflate and then observing for 24 hours for recurrence before discharge is an option. Alternatively, colonoscopic-assisted placement of 2 colostomy tubes (percutaneous endoscopic colostomy) to fix the offending bowel loop to the anterior abdominal wall has recently been described in a series of 19 patients with good success and low morbidity. Only one patient had a recurrence requiring another tube colostomy to be inserted because of recurrence. Another patient died from tube dislodgement and peritonitis.<sup>203</sup> Laparoscopic colopexy, extraperitonealization of the sigmoid colon, and laparoscopic colectomies have more recently been widely used.<sup>204-206</sup> It should be noted that the redundant bowel can make laparoscopic retraction troublesome, and the redundancy in the bowel can facilitate colectomy through a relatively small incision without the need for laparoscopic assistance. A medial to lateral approach for laparoscopic-

assisted resection has been found to be advantageous.<sup>205</sup>

Cecal volvulus is more difficult to rectify using colonoscopy, primarily because of an inability to reach the obstructed right colon. There is also a higher risk of perforation.<sup>207</sup> Consequently, surgery is often required. If feasible, an ileocolic resection with or without anastomosis is performed. This has the lowest recurrence rate but a high morbidity at about 30% and a mortality of up to 20%.<sup>207,208</sup> Alternatively, cecopexy may be performed but is associated with a recurrence rate of approximately 20%. A tube cecostomy fixation (Fig. 43-15) has been advocated by some, claiming a low recurrence rate of about 2% and low morbidity, but others have shown that it has a morbidity of about 52% and mortality of 22%.<sup>207,209</sup>

**FIGURE 43-15** Cecal volvulus untwisted through lateral oblique incision and insertion of cecostomy tube (Foley catheter).

## Conclusion

Colonic volvulus most commonly occurs in the sigmoid and is the third most common cause of bowel obstruction. It is readily seen on plain abdominal x-ray and CT scan. Sigmoid volvulus can often be nonoperatively

decompressed before a decision is made for definitive resection that rarely leads to recurrence. Cecal volvulus often requires an operation to fix it. Delayed management of volvulus may result in perforation, leading to high rates of complications and mortality, especially in this elderly age group.

# COLONIC VOLVULUS

*Christina M. Papageorge • Eugene F. Foley*

## DEFINITION/INTRODUCTION

Colonic volvulus refers to the twisting of the colon around its mesenteric axis. Although an uncommon cause of large bowel obstruction in the United States, it is a potentially life-threatening condition that necessitates expedient surgical evaluation and treatment. The twisting of the colon results in a closed-loop obstruction, occlusion of the mesenteric vessels, and subsequent ischemia of the affected segment of bowel. Volvulus can affect any part of the bowel, and is classified based on the segment of colon involved. Given its redundancy and relatively long, narrowly-based mesentery, the sigmoid colon is the most common site of colonic volvulus, followed in frequency by the cecum. Other much rarer forms of colonic volvulus include cecal bascule, transverse colonic volvulus, ileosigmoid knotting, and splenic flexure volvulus. Sigmoid volvulus accounts for up to 80% of all colonic volvuli, while the cecum appears to be involved in approximately 20% of cases.<sup>1,2</sup>

## EPIDEMIOLOGY

In the United States, it is estimated that colonic volvulus accounts for less

than 5% of all large bowel obstructions (LBOs), making it the third most common cause of LBO after cancer and diverticular disease in adult patients.<sup>1-4</sup> Interestingly, dramatic international geographic variation in the incidence of this disease process has been observed. In some countries, including Pakistan, India, and Brazil, sigmoid volvulus alone has been reported to account for 20% to 30% of all intestinal obstructions and is implicated in over 54% of obstructions in Ethiopia.<sup>1</sup> It has long been known that colonic volvulus has a much higher incidence in parts of Africa, the Middle East, and South America. It has been postulated that this variability is related to the very-high-fiber diets common in these regions leading to colonic redundancy, as well as Chagas disease–related megacolon in South America.<sup>1</sup>

Not only is there geographic variability in the incidence of colonic volvulus, but also in the demographics of the populations most commonly affected. In the United States and other Western developed nations, the stereotypical demographic of the patient presenting with sigmoid volvulus is an elderly, chronically ill, institutionalized patient with a history of chronic constipation. In addition, there seems to be an association with neuropsychiatric disorders such as Parkinson disease and dementia. However, these comorbidities do not necessarily correlate with volvulus in areas where colonic volvulus is a more endemic phenomenon.<sup>2</sup>

While sigmoid volvulus occurs in similar proportions of men and women, with perhaps a slight male bias, cecal volvulus has a clear female predominance. Cecal volvulus also tends to affect younger patients, with a mean age of diagnosis around the fourth or fifth decade of life. [Table 44-1](#) highlights some of the key differences between sigmoid and cecal volvulus.

**TABLE 44-1: KEY DIFFERENCES BETWEEN SIGMOID AND CECAL VOLVULUS<sup>a</sup>**

	Sigmoid Volvulus	Cecal Volvulus
<b>Incidence</b>	60%-80% of colonic volvuli	~20% of colonic volvuli
<b>Demographics</b>	Older, chronically ill, institutionalized; slight male predominance	Younger (40s-50s), female
<b>Etiology/risk factors</b>	Chronic constipation Hirschprung disease Chagas disease	Congenital non-fixation of cecum
<b>Presentation</b>	Marked abdominal distention, consistent with LBO	Often less distention; consistent with distal SBO
<b>Imaging findings</b>	“Coffee bean” or “bent inner tube” sign on KUB; cleft oriented toward LLQ	“Kidney bean” sign; cleft oriented toward RLQ
<b>Success with endoscopic detorsion</b>	Frequent	Rare to never
<b>Definitive management</b>	Sigmoidectomy	Right hemicolectomy

<sup>a</sup>While both involve twisting of a segment of the colon, these types of volvuli differ in important ways, suggesting that they may best be conceptualized as distinct disease processes.

## ETIOLOGY/PATHOPHYSIOLOGY

The pathophysiology of colonic volvulus is quite straightforward: the colon twists at least 180 degrees, resulting in closed-loop obstruction and occlusion of the vascular supply. Particularly in the case of sigmoid volvulus, the underlying mechanism of this twisting involves the presence of a large, floppy, redundant colon in combination with a long, narrow mesenteric base. This set of conditions, more common in elderly, infirm patients with constipation, accounts for the predominant involvement of the sigmoid colon. The relatively narrow mesentery provides a pivot point around which the heavy, mobile colon can rotate. In some cases, the colon may detorse spontaneously, and indeed, some patients report a history of similar symptoms at the time of presentation. However, the volvulus becomes problematic as it results in obstruction of the bowel lumen as well as occlusion of the arterial and venous blood supply, with a subsequent natural history of bowel gangrene, necrosis, and perforation.

Multiple underlying etiologies for this process have been proposed, all of which share the resulting pathogenesis of an enlarged, redundant colon that is prone to twisting. Chronic constipation and laxative use are likely the most common causes of sigmoid volvulus in the United States. However, a redundant colon can also contribute to the problem of constipation, making it difficult to ascertain the directionality of the causal relationship between these two processes. In other geographic areas, a high-fiber diet has been implicated, or possibly even genetic variation in colon and mesenteric length. In South America, Chagas disease is commonly an underlying cause of megacolon and subsequent volvulus. Hirschsprung disease is similarly associated with both a dilated colon and colonic volvulus.

In contrast to sigmoid volvulus, in which the chronic colonic elongation that predisposes to twisting is generally conceptualized as an acquired condition, the pathogenesis of cecal volvulus may in fact be more congenital in nature.<sup>5</sup> While the same underlying situation of a floppy colon is necessary for cecal volvulus, this is more commonly seen in the setting of either prior mobilization of the right colon or congenital non-fixation of the cecum. This notion is further suggested by the differences in patient demographics that have been observed between cecal and sigmoid volvulus. As noted earlier, cecal volvulus patients tend to be much younger, more often female, and of thinner body habitus. These characteristics as well as intraoperative findings suggest that incomplete congenital fixation of the cecum plays a primary role in the pathogenesis of cecal volvuli.<sup>2</sup> Therefore, cecal and sigmoid volvulus should be thought of as distinct disease processes, affecting different patient populations and having different underlying etiologies.

## DIAGNOSIS

Colonic volvulus can present as a partial or complete large bowel obstruction. Nonspecific signs and symptoms of acute bowel obstruction include nausea, vomiting, abdominal pain, distention, and constipation or obstipation. Sigmoid volvulus is often associated with significant abdominal distention, given the distal location of the obstruction, and obstipation. Cecal volvulus, in contrast, may present with less impressive distention and signs and symptoms consistent with distal small bowel obstruction. If the volvulus has progressed to gangrene and perforation of the involved colon, the patient may present with diffuse abdominal pain and tenderness consistent with peritonitis. Fever and leukocytosis are ominous signs suggestive of ongoing or impending bowel compromise.

The differential diagnosis for colonic volvulus includes other causes of mechanical and non-mechanical bowel obstruction, such as obstructing colon cancer, diverticular disease, and Ogilvie syndrome. These may be differentiated on the basis of acuity, associated signs and symptoms, and imaging. The patient may report a history of intermittent obstructive symptoms or chronic constipation, especially in the case of sigmoid volvulus.

The diagnosis of volvulus can often be made with plain radiographs alone. The classic “bent inner tube” or “coffee bean” sign on an anteroposterior

abdominal radiograph is diagnostic of sigmoid volvulus in up to 80% of cases.<sup>6</sup> With this finding, the “coffee bean” arises from the pelvis, and the cleft is classically oriented toward the left lower quadrant, pointing in the direction of the sigmoid colon (Fig. 44-1). Additional findings suggestive of closed loop obstruction include air–fluid levels on supine or decubitus images and absence or paucity of gas in the rectum, which can be particularly helpful in differentiating this diagnosis from pseudo-obstruction.<sup>6</sup> The diagnosis of sigmoid volvulus can be confirmed with a contrast enema demonstrating a bird’s beak appearance (Fig. 44-2). While this imaging study may also be therapeutic in some cases, resulting in colonic detorsion, contrast enema should be avoided if there is concern for perforation or bowel compromise.

**FIGURE 44-1** “Coffee bean sign” of sigmoid volvulus. The convexity is located in the right upper quadrant, and the cleft points toward the left lower quadrant, where the sigmoid colon originates.

**FIGURE 44-2** Contrast enema in the setting of sigmoid volvulus demonstrating bird’s beak appearance. The tapered appearance, or “bird’s beak,” of the contrast correlates with the twisted segment of colon.

The classic plain film finding of cecal volvulus is that of the “kidney bean,” in which the air-filled cecum is located in the left upper quadrant and the cleft points toward the right lower quadrant (Fig. 44-3). However, cecal volvulus can sometimes be more difficult to definitively diagnose with plain films alone,<sup>7</sup> and therefore cross-sectional imaging can be useful. Markedly dilated cecum consistent with obstruction in association with mesenteric swirling is highly suggestive of volvulus.<sup>8,9</sup> While sigmoid volvulus is associated with diffuse colonic dilation, given its distal location, the distal colon should be decompressed in the setting of cecal volvulus, and the small bowel may even not exhibit significant dilatation in the setting of a competent ileocecal valve.

**FIGURE 44-3** “Kidney bean sign” of cecal volvulus. The convexity is located in the left upper quadrant, and the cleft points toward the right lower quadrant, where the cecum originates.

## MANAGEMENT

The first consideration in the management of volvulus of any variety is resuscitation and correction of electrolyte abnormalities. The primary goals of surgical treatment for volvulus are to achieve emergent detorsion of the colon in order to restore blood supply and alleviate obstruction; to remove any gangrenous, necrotic, or perforated segments of bowel; and to reduce the risk of recurrent volvulus. In general, prompt treatment is necessary to avoid progression to necrosis and perforation. However, optimal operative timing and initial approach are dependent on patient condition and presentation.

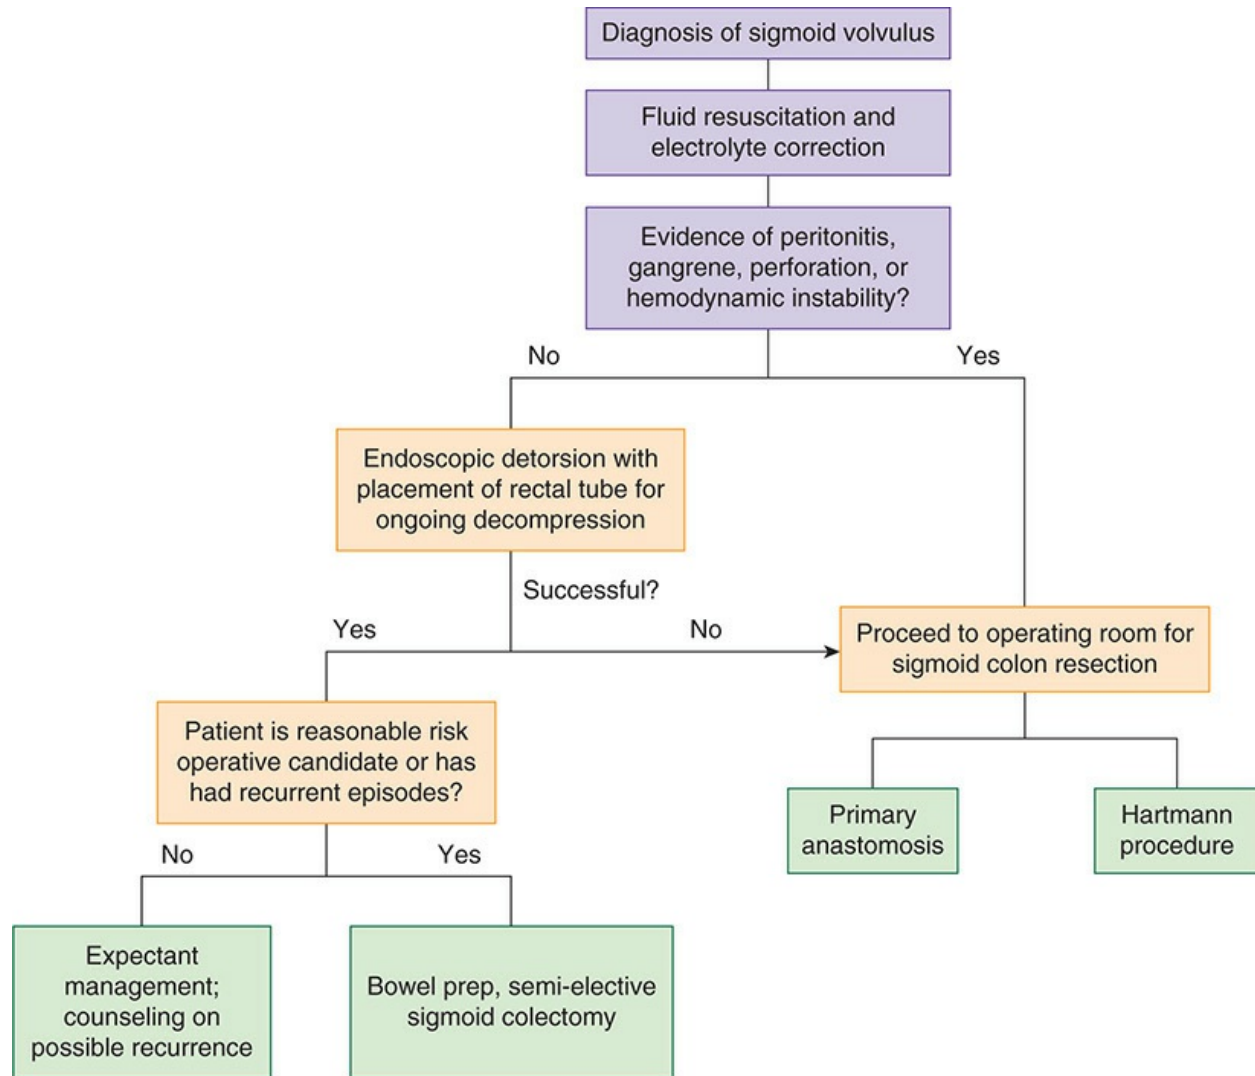

## Sigmoid Volvulus

In the absence of existing or threatened perforation, sigmoid volvulus can be managed initially with attempts at endoscopic detorsion. This procedure may be performed using either a colonoscope, sigmoidoscope, or most commonly, a rigid proctoscope. In the event of successful detorsion, which is accomplished in the majority of cases, placement of a rectal tube may facilitate ongoing decompression.<sup>3</sup> Historically, reported risk of recurrent volvulus following endoscopic detorsion ranges from 23% to 71%,<sup>10-13</sup> and therefore non-urgent or elective sigmoid colectomy is recommended after completion of resuscitation and bowel preparation.<sup>3,13</sup> While sigmoidectomy is recommended for most of these patients, it is not mandatory, and should be considered in the context of the individual patient's comorbidities, functional status, and life expectancy. In the elderly, poor surgical risk patient, prophylactic sigmoidectomy is often difficult for families and surgeons to strongly endorse after just the first bout of volvulus, and therefore it is more commonly performed only after recurrent episodes.

If, on the other hand, the patient exhibits signs concerning for gangrene, perforation, or peritonitis at the time of presentation, emergent surgical intervention is indicated, without an attempt at endoscopic decompression. In the absence of clear perforation, findings on endoscopic evaluation that suggest bowel compromise and warrant surgical exploration include mucosal necrosis, ulceration, or presence of dark blood. Depending on the degree of intraperitoneal contamination and the patient's overall condition, surgical options include a Hartmann procedure versus sigmoid colectomy with primary anastomosis. The ability to perform a primary anastomosis is dependent on the quality of the proximal bowel as well as patient clinical condition in the operating room. While resection with primary anastomosis has clearly been demonstrated to be safe and effective in the semi-elective or elective treatment of sigmoid volvulus, the most commonly performed procedure in patients requiring emergent operation is a Hartmann procedure.<sup>14,15</sup>

An alternative option to either endoscopic detorsion or sigmoid colon resection is operative detorsion with or without fixation of the colon. This approach should be utilized only when endoscopic decompression is not an option or fails to achieve detorsion, and when all bowel is viable. Fixation without resection, or sigmoidopexy, is typically reserved for patients deemed to be poor candidates for partial colectomy, and historically has been very

rarely used in patients with sigmoid volvulus.<sup>4</sup> Figure 44-4 provides a basic algorithm outlining the typical approach and important considerations in the management of a patient with sigmoid volvulus.

**FIGURE 44-4** Basic algorithm for the management of a patient with sigmoid volvulus.

## Cecal Volvulus

Unlike sigmoid volvulus, cecal volvulus can rarely be treated effectively endoscopically, and vascular compromise tends to occur earlier in the course of this disease. Because of these factors, early surgical intervention is usually indicated in patients with cecal volvulus. There are several operative options

in the acute treatment of cecal volvulus, including resection and primary anastomosis, resection with diversion, cecopexy, and cecostomy tube placement. Detorsion of the cecum with cecopexy is associated with recurrence rates up to 40%.<sup>16</sup> Catheter tube cecostomy has been described for the treatment of cecal volvulus to achieve decompression, diversion, and cecal fixation.<sup>17</sup> It has been advocated by some as a means to treat cecal volvulus while simultaneously avoiding resection of unprepped bowel. However, others have reported concerning complications with this technique, including cecal necrosis, intraperitoneal leakage, fistula, and recurrence rates up to 14%.<sup>16</sup> Because of these limitations of non-resective operations in the treatment of cecal volvulus, and because these patients tend to be younger and healthier than their sigmoid volvuli counterparts, right colectomy has become the preferred surgical treatment for most patients with cecal volvulus. In addition, once the volvulized cecum is removed, there is often healthy-appearing terminal ileum and transverse colon with which a satisfactory primary anastomosis can be safely created. Thus, the preferred surgical treatment for acute cecal volvulus in most patients is a resection with primary anastomosis. Resection with ileostomy diversion may be indicated in a sicker patient or under the circumstances of significant intraabdominal sepsis. Cecostomy or cecopexy may be considered a last resort in the treatment of unstable patients otherwise unable to tolerate laparotomy and resection and in the absence of gangrene or necrosis.

Given the relative rarity of colonic volvulus, there has been a paucity of literature to guide the development of clear evidence-based practice guidelines.<sup>18</sup> Halabi et al. recently performed a large retrospective review of administrative data in order to describe management trends of colonic volvulus in the United States from 2002 to 2010.<sup>4</sup> This study, which used the National Inpatient Sample database, reported a nonoperative approach (enema or endoscopic decompression) used to manage 17% of cases. The majority of patients managed operatively underwent a resection (89% of surgical cases), while a minority underwent either detorsion without fixation (4.2%), fixation such as cecopexy or sigmoidopexy (3.3%), or enterostomy procedure such as cecostomy or sigmoidostomy (3.3%). Laparoscopy was used in less than 4% of patients overall undergoing surgery for colonic volvulus, but was found to increase in usage over the more recent years. The potential advantages of laparoscopy over a laparotomy for the treatment of volvulus are underwhelming. Because the pathophysiology of volvulus

requires a long colonic mesentery, most volvuli can be delivered and resected through a very small laparotomy incision, which is ultimately comparable in size to the extraction site incision required if performed laparoscopically. Furthermore, the long, redundant, acutely obstructed colon makes laparoscopic exploration technically quite difficult. For these reasons, authors have abandoned the laparoscopic approach in most cases of volvulus and believe the significant majority will continue to be done via a small laparotomy.

## PROGNOSIS

The prognosis in patients suffering from colonic volvulus is clearly related to the severity of illness at the time of presentation. A recent large retrospective study of national administrative data in the United States sought to identify risk factors of mortality in patients undergoing surgery for sigmoid or cecal volvulus.<sup>4</sup> This group reported an overall mortality of 9.4% and 6.7% in patients undergoing resection for sigmoid and cecal volvulus, respectively. The strongest predictors for mortality in those with sigmoid volvulus were presence of peritonitis, gangrene, or necrosis, stoma use, and coagulopathy. In patients presenting with cecal volvulus, coagulopathy, age >60 years, and metastatic cancer best predicted mortality following resection. Notably, in both groups, anastomotic complications occurred in over 15% of patients.

In a similar study using the California Inpatient Database, Kasten et al. reported a 21% mortality over 3 years in patients requiring total colectomy for the treatment of their volvulus.<sup>18</sup> In contrast, patients treated with detorsion and fixation, but no bowel resection, had the lowest morbidity and mortality but were found to have a re-intervention rate of over 25% within an approximately 2-year follow up period.<sup>18</sup> The significant mortality and morbidity associated with colonic volvulus is likely a reflection of both the severity of the disease process as well as the baseline comorbidity and poor functional status of patients that tend to be affected.

## OTHER FORMS OF VOLVULUS

Cecal bascule is a variant of cecal volvulus in which the cecum folds anteriorly and superiorly on top of itself toward the fixed ascending colon,

creating an organoaxial rotation, rather than a true mesenteroaxial volvulus. This process occurs less frequently than true cecal volvulus,<sup>7</sup> and is thought to be associated with less vascular compromise.<sup>19</sup> In addition, cecal bascule may be more likely to spontaneously reduce, resulting in intermittent symptoms of cecal obstruction. Nonetheless, if unrecognized and persistent, cecal bascule can progress to ischemia, necrosis, perforation, and sepsis.<sup>7,20</sup> Therefore, it is generally recommended to proceed with resective therapy for patients with acute, persistent cecal bascule, or those felt to have symptoms referable to intermittent, recurring cecal bascule.

Volvulus of the transverse colon has been described, but it occurs very infrequently. This process appears to be most similar to that of sigmoid volvulus, with chronic constipation acting as one of the major risk factors. Radiographically, it most closely resembles sigmoid volvulus, but can be differentiated by the more proximal site of obstruction demonstrated on contrast enema. As in the treatment of sigmoid volvulus, detorsion may be attempted in the appropriate setting via an endoscopic approach; however, there is a lower success rate, and the patient often ultimately requires surgical intervention.

Even less common than transverse colon volvulus is volvulus of the splenic flexure, which has been described in the literature as scattered case reports.<sup>21</sup> Like sigmoid volvulus, chronic constipation is a common complaint among patients developing splenic flexure volvulus.<sup>21</sup> The underlying pathophysiology of this condition appears to involve non-fixation of the splenic flexure, which may occur in the setting of prior mobilization of the splenic flexure or adhesion formation from prior abdominal surgery. Alternatively, it has been described in association with a congenital abnormality of the gastrocolic, splenocolic, or phrenocolic ligaments or lateral peritoneal attachments. Management of this problem is guided by the same principles used for sigmoid volvulus. Devitalized colon must be resected emergently, and partial colectomy should be considered to prevent recurrence.

Finally, a type of volvulus termed the ileal-sigmoid knot is a relatively well-described entity in regions where colonic volvulus is more common.<sup>22,23</sup> Also known as “compound volvulus” or “double volvulus,” this condition is a variant of sigmoid volvulus. As its name implies, ileal-sigmoid knotting occurs when the ileum wraps around the base of the sigmoid colon, resulting

in two closed-loop obstructions. It occurs predominantly in men and has a mean age of diagnosis around 40 years. This form of volvulus is associated with more profound and early malperfusion of the bowel. Importantly, endoscopic detorsion is often futile in the setting of ileosigmoid knotting, and therefore it is crucial to differentiate this process from isolated sigmoid volvulus.<sup>22</sup> Emergent laparotomy should not be delayed. It is recommended that sigmoid resection be performed regardless of bowel viability, and that the decision to resect the involved portion of ileum be guided primarily by evidence of gangrene.

## SPECIAL POPULATIONS

There are several unique populations of patients worth noting in relation to colonic volvulus. Sigmoid volvulus is reportedly one of the most common, albeit still rare, causes of large bowel obstruction in pregnant women.<sup>1,24–26</sup> It is hypothesized that the gravid uterus displaces the sigmoid colon out of the pelvis and thereby predisposes it to twisting at its point of mesenteric fixation.<sup>27,28</sup> This complication of pregnancy occurs most frequently in multiparous women, and during the third trimester.<sup>25</sup> It can be diagnosed using MRI in non-emergent settings in order to avoid ionizing radiation exposure to the fetus.<sup>27</sup> If possible, endoscopic detorsion is favored over operative treatment in these patients. Regardless, rates of maternal and fetal mortality associated with the diagnosis of sigmoid volvulus are reportedly as high as 14% and 28%, respectively.<sup>26</sup>

Although rare, colonic volvulus has also been reported in children. It seems to occur most commonly in males and has an association with Hirschsprung disease. Indeed, nearly 20% of children presenting with sigmoid volvulus are found to have comorbid Hirschsprung disease, which likely increases one's risk of volvulus due to chronic constipation and bowel distention.<sup>29</sup> Mortality is significant in this population, with reported rates ranging from 11% to 22%.<sup>29,30</sup>

## CONCLUSIONS

Colonic volvulus is a rare but potentially life-threatening cause of large

bowel obstruction. It most commonly involves either the sigmoid colon or the cecum, and results in obstruction and strangulation, which can progress to gangrene and perforation. Sigmoid volvulus occurs in the setting of a large redundant colon in combination with a long, narrow mesentery, which is often the result of longstanding chronic constipation, while cecal volvulus is associated with congenital non-fixation of the cecum. Sigmoid volvulus can often be managed initially with endoscopic detorsion, followed semi-electively by sigmoid resection, while the management of cecal volvulus almost universally requires early cecal resection.

# CROHN'S DISEASE

*Heather Yeo • Alessandro Fichera • Roger D. Hurst • Fabrizio Michelassi*

*Crohn's disease* is a chronic inflammatory condition of the gastrointestinal (GI) tract that can give rise to strictures, inflammatory masses, fistulas, abscesses, hemorrhage, and cancer. This disease commonly affects the small bowel, colon, rectum, or anus. Less commonly, it can also involve the stomach, esophagus, and mouth. Often, the disease will simultaneously affect multiple areas of the GI tract.

The etiology of Crohn's disease is not known and there is no curative treatment. Current medical and surgical treatment is effective at controlling the disease, but even with optimal treatment, recurrences and relapses are frequent. The combined approach of optimal medical treatment with timely and strategic surgical intervention offers the most effective management to patients affected by Crohn's disease. Care of patients with Crohn's disease, however, can be particularly challenging, as it has a myriad of manifestations and potential complications. Additionally, its course and response to therapy can be difficult to predict. To add to the overall complexity, there are many therapeutic options that must be tailored to each individual patient and to each site of involvement to achieve optimal outcomes.

## HISTORY

Crohn's disease became recognized as a specific pathologic entity in 1932 when Crohn and colleagues first identified regional enteritis as a unique clinical entity.<sup>1</sup> In retrospect, case descriptions of what appeared to be Crohn's disease date back to at least 1612, when Fabry reported on the death of a boy experiencing severe abdominal pain.<sup>2</sup> Autopsy revealed a contracted ulcerated cecum and ileum with complete bowel obstruction. In 1761, Morgagni described a case of an inflamed ileum with perforation and thickened mesentery in a young man with a history of diarrhea and fever.<sup>3,4</sup>

It is unclear how common Crohn's disease might have been before 1932, as it is likely that cases of this disease occurring in an era of limited abdominal surgery may have been mistaken for other processes such as tumor or intestinal tuberculosis. In 1913, Sir Dalziel of Glasgow, Scotland, reported in the *British Medical Journal* on 13 patients and provided what is now recognized as a classic clinical and pathologic description of Crohn's disease.<sup>5</sup> Although not often cited, Dalziel's description predates the one by Crohn and colleagues, and some have argued that the disease should be known by the eponym "Dalziel-Crohn disease."

After the report by Crohn and colleagues, increased awareness of the disease led to a marked increase in reported cases in the 1930s through the 1950s. The general public's awareness of the disease increased when, in 1956, one of the most famous figures of the 20th century, President Dwight Eisenhower, was diagnosed with Crohn's disease of his terminal ileum. That same year, President Eisenhower underwent intestinal bypass surgery with the small intestine proximal to the area of disease anastomosed to the transverse colon.<sup>6</sup> Following this operation, he remained relatively free of symptoms for the remainder of his life.<sup>7</sup>

Early in the history of Crohn's disease, optimal surgical management remained disputed. Initially, many thought that the disease was one of both the bowel and the mesentery, and similar to malignancies, wide excision with radical dissection of the mesentery was believed to be the best way to provide for the optimal long-term outcome.<sup>8</sup> It was also appreciated that diversion of the fecal stream was effective at decreasing active inflammation and ameliorating symptoms. Frequently performed in the 1940s and 1950s, bypass operations are now only rarely undertaken for Crohn's disease, given

the risk of malignancy in the excluded segment.<sup>9-11</sup> Additionally, a greater understanding of the clinical course of Crohn's disease has led to more conservative resections, as it is appreciated that wide surgical margins of normal tissue and radical resection of the mesentery do not affect early recurrence of disease.

Despite the increased attention given to Crohn's disease of the small intestine, Crohn's colitis was not widely recognized as a form of Crohn's disease until 1960 when Lockhart-Mummery and Morson firmly established the pathologic criteria for distinguishing Crohn's disease from idiopathic ulcerative colitis.<sup>12</sup>

## EPIDEMIOLOGY

Since the original description of Crohn's disease in 1932, the number of reported cases has increased greatly. Today, it is estimated that the incidence of Crohn's disease in the United States is approximately 4 new cases per year for every 100,000 persons. Because this disease is chronic and patients live for many years with the ailment, the prevalence is much higher and is reported to be between 80 and 150 cases per 100,000 persons.<sup>13,14</sup> The incidence of Crohn's disease increased rapidly from 1930 to at least the 1980s, but more recently, the incidence of new cases now appears to have stabilized.

The United States, Canada, and Europe have the highest incidence of Crohn's disease. It is much less common in Asia, South America, and Japan. Crohn's disease is believed to be uncommon in Africa, but accurate data regarding the incidence of inflammatory bowel disease in this region of the world are lacking. The peak age of presentation for Crohn's disease is between 15 and 25 years old. As such, Crohn's disease typically affects young adults, yet the disease can occur at almost any age. It should be noted, however, that Crohn's disease is very rare in children younger than 6 years.<sup>15</sup>

In the United States, the incidence of Crohn's disease is highest among Caucasians, low among blacks, and lowest among Hispanics and Asians. It is 3 to 4 times more common among ethnic Jews than non-Jewish whites. It also appears to be slightly more common in women than in men, although a slight male predominance has been reported in some populations.<sup>16</sup>

Familial clusters of Crohn's disease are not uncommon, with a 6- to 10-

fold increase in the risk of this disease in first-degree relatives of those affected by this disease or its sister ailment, ulcerative colitis. Although familial aggregations are common, the distribution within families does not indicate a pattern of simple Mendelian inheritance.

## ETIOLOGY

The etiology of Crohn's disease is not known. Many possible causes have been the subject of both speculation and investigation.<sup>4</sup> Basic science research into the molecular biology of Crohn's disease has begun to give some better insight into the genetics of this condition, but much regarding its ultimate causes remains unclear.

It is known that Crohn's disease is an altered immune response that results in inflammation and destruction of intestinal tissues. It is not clear if this altered immune response is the result of a primary dysfunction in the gut-related immune system or whether an unknown pathologic trigger induces an otherwise normal immune system to overreact. Most believe that Crohn's disease occurs in individuals with a genetic predisposition and that development of the disease is dependent on exposure to environmental triggers that start the pathologic sequence that ultimately manifests as Crohn's disease.

To date, no specific primary defect in the systemic or mucosal immune system has been identified. Studies of intestinal transport mechanisms have demonstrated an increase in intestinal permeability in both Crohn's disease patients and their symptom-free first-degree relatives.<sup>17-21</sup> This has led some to speculate that Crohn's disease is the result of an altered mucosal barrier function that allows abnormal interactions to take place between the multitude of antigenic substrates normally found in the gut lumen and the immunocompetent tissue of the submucosa.

As indicated by the observed familial aggregations and variability of risks among differing ethnic and racial groups, a genetic predisposition is likely to have a major role in the etiology of Crohn's disease. The distribution of Crohn's disease within family aggregates is complex and defies classification with simple Mendelian transmission of disease. Genetic linkage studies have identified susceptibility to Crohn's disease to the *CARD15/NOD2* gene mapped to chromosome 16q12.<sup>22,23</sup> *CARD15* is a gene product related to

innate immunity, and it is preferentially expressed to Paneth's cells of the ileum.<sup>24,25</sup> While the *CARD15/NOD2* gene has been linked to susceptibility to Crohn's disease, the known mutations of *CARD15* are neither necessary nor sufficient to contract this disease. Hence, it appears that the genetic relationship of *CARD15/NOD2* to Crohn's disease is complex and still poorly understood.

The suspicion that infectious agents may play a role, either directly as a primary cause of Crohn's disease or indirectly as a trigger to stimulate a defective immune system, has generated much attention. This hypothesis has always found strength in the identification of noncaseating granulomas as the characteristic histopathologic lesion found in Crohn's specimens and in the isolation of *Mycobacterium paratuberculosis* from resected Crohn's disease specimens. This finding has been far from consistent, and even sensitive polymerase chain reaction studies have been unable to provide definitive evidence for the presence of *M paratuberculosis*-specific DNA in Crohn's disease-affected segments of the bowel. Other infectious agents have been studied and shown not to be causative agents for Crohn's disease. These include measles virus, non-pylori *Helicobacter* species, *Pseudomonas*, and *Listeria monocytogenes*.<sup>26</sup> To date, no single infectious agent has been consistently associated with Crohn's disease.

Although diet modification can ameliorate the symptoms of Crohn's disease, no dietary factor has been identified as its cause. Smoking, however, has been associated with the development of Crohn's disease, with smokers having a substantially higher risk for contracting this disease than nonsmokers.<sup>27-30</sup> Additionally, smoking is known to exacerbate existing Crohn's disease and can accelerate its recurrence after resection.<sup>31,32</sup> The component of cigarette smoke that is responsible for these deleterious effects on the clinical course of Crohn's disease is not known.

## PATHOLOGY

The earliest gross manifestations of Crohn's disease are the development of small mucosal ulcerations called aphthous ulcers.<sup>33</sup> Aphthous ulcers appear as red spots or focal mucosal depressions and typically occur directly over submucosal lymphoid aggregates. As the inflammation progresses, the ulcers enlarge and become stellate. The enlarging ulcerations then coalesce to form

longitudinal mucosal ulcerations. In Crohn's disease of the small bowel, these linear ulcerations almost always occur along the mesenteric aspect of the bowel lumen. Further progression leads to a serpiginous network of linear ulcerations that surround islands of edematous mucosa producing the classic "cobblestone" appearance. Mucosal ulcerations may penetrate through the submucosa to form intramural channels that can bore deeply into the bowel wall and create sinuses, abscesses, or fistulas.

The inflammation process progresses to extend through all layers of the bowel wall. The inflammation of Crohn's disease also involves the mesentery and regional lymph nodes such that the mesentery may become massively thickened. With early acute intestinal inflammation, the bowel wall is hyperemic and boggy. As the inflammation becomes chronic, fibrotic scarring develops and the bowel wall becomes thickened and leathery in texture.

Histopathologic examination of Crohn's disease typically demonstrates transmural inflammation characterized by multiple lymphoid aggregates in a thickened submucosa. Lymphoid aggregates may extend beyond the mucosa and can be found within the muscularis propria.<sup>33</sup> The presence of well-formed lymphoid aggregates in an edematous fibrotic submucosa is a classic histologic feature of the disease. Another sentinel microscopic feature of Crohn's disease is the presence of noncaseating granulomas. Noncaseating granulomas are a valuable diagnostic feature of Crohn's disease, but they are seen in only 50% of resected specimens and are rarely seen on endoscopic biopsies. Additionally, the presence of granulomas does not correlate with disease activity, as areas of active inflammation are no more likely to contain granulomas than areas of quiescent disease.<sup>34</sup>

## CLINICAL PRESENTATION

The clinical presentation and symptoms of Crohn's disease vary greatly depending on the segment of intestine involved<sup>35</sup> and the predominant features of the disease: stricturing, perforating, or inflammatory. While the next few paragraphs discuss the influence of disease patterns and locations, there are additional more complex classifications that are used to subcategorize disease. The most common of these are the Rome, Montreal, and Vienna classifications ([Table 45-1](#)). These classifications are used help to

guide clinical decisions and frame medical and surgical management.<sup>36,37</sup>

**TABLE 45-1: COMPARISON OF ROME, VIENNA, AND MONTREAL CLASSIFICATION SYSTEMS FOR CROHN'S DISEASE**

	Rome Classification	Vienna Classification	Montreal Classification
Age at diagnosis, years		A1 <40 A2 ≥40	A1 ≤16 A2 17-40 A3 >40
Disease location	Stomach/duodenum Jejunum Ileum Colon  Rectum Anal	L1 terminal ileal L2 colonic L3 ileocolonic L4 upper GI	L1 terminal ileal L2 colonic L3 ileocolonic L4 isolated upper GI modifier (added to L1-L3 when concomitant upper GI disease present)
Disease extent	Localized Diffuse		
Disease behavior	Inflammatory  Fistulizing Fibrostenotic	B1 nonstricturing, nonpenetrating B2 stricturing B3 penetrating	B1 nonstricturing, nonpenetrating B2 stricturing B3 (internal) penetrating p = perianal disease modifier (added to B1-B3 when concomitant perianal disease present)
Operative history	Primary Recurrent		

Reproduced with permission from Krishnaprasad K, Andrews JM, Lawrance IC, et al: Inter-observer agreement for Crohn's disease sub-phenotypes using the Montreal Classification: How good are we? A multi-centre Australasian study, *J Crohns Colitis* 2012 Apr;6(3):287-293.

## Patterns of Disease

Crohn's disease can be categorized into 3 general manifestations: stricturing disease, perforating disease, and inflammatory disease.<sup>38</sup> These 3 classes do not represent truly distinct forms of the disease; rather, they are terms that are used to describe the predominant gross manifestation of the disease.<sup>39</sup> It is typical for more than 1 pattern to occur in the same patient or even the same segment of intestine; even so, 1 pattern tends to predominate in most cases. It is generally the predominant pattern of disease that determines the clinical presentation and affects the therapeutic options.

## STRICTURING PATTERN

Chronic inflammation of Crohn's disease results in the development of fibrotic scar tissue that constricts the intestinal lumen with cicatricial

strictures, often referred to as “fibrostenotic lesions.” Patients with a stricturing pattern of this disease generally develop partial or complete intestinal obstruction, and hence their symptoms are primarily obstructive in nature. Being the result of submucosal deposition of connective tissue, fibrostenotic strictures are not reversible with medical therapy. Once fibrostenotic areas become symptomatic, significant improvement rarely occurs and surgical intervention is often required. While surgery is clearly the standard of care for these patients, there are data on successful treatment with endoscopic balloon dilation and stenting in selected patients with strictures refractory to medical therapy.<sup>40</sup>

## **PERFORATING PATTERN**

Perforating Crohn’s disease is characterized by the development of sinus tracts, fistulas, and abscesses. Penetrating sinus tracts develop from deep mucosal ulcerations. These sinus tracts penetrate through the muscularis propria and give rise to abscesses or to fistulas if they penetrate into surrounding structures. The term “perforating” disease can be misleading, as free perforation with spillage of intestinal contents into the abdominal cavity is not a common phenomenon with Crohn’s disease. Inflammatory response around the advancing sinus tract typically results in adhesion to surrounding structures. The sinus usually bores through the area of adhesion such that abscess formation or fistulization to other structures occurs much more often than free perforation into the abdominal cavity. Typically, perforating disease is accompanied by a degree of stricture formation, but the fistula or abscess generated by the perforating component of the disease dominates the clinical picture.

## **INFLAMMATORY PATTERN**

The inflammatory pattern of Crohn’s disease is characterized by mucosal ulceration and bowel wall thickening. The edema that results from inflammation can lead to an adynamic segment of intestine and luminal narrowing. This pattern often gives rise to obstructive symptoms in the small intestine and diarrhea in the colon. Of the 3 patterns of Crohn’s disease, the inflammatory pattern is much more likely to respond to medical therapy.

## Location of Disease

Crohn's disease is a panintestinal condition that may affect any area from the mouth to the anus. The most commonly affected location is the terminal ileum, and one-fifth of all patients have more than 1 intestinal segment affected simultaneously.

### **CROHN'S DISEASE OF THE FOREGUT**

Crohn's disease of the upper GI tract gives rise to symptoms of nausea, vomiting, dysphagia, or odynophagia.<sup>41</sup> Oral Crohn's disease usually manifests with aphthous ulcers in the hard palate that may cause discomfort, especially during mastication and deglutition. Esophageal Crohn's disease is uncommon, but it is believed to be more frequent in children than in adults.<sup>42</sup> Esophageal involvement in Crohn's disease may be asymptomatic or may give rise to dysphagia or odynophagia. Esophageal Crohn's disease is associated with Crohn's disease elsewhere within the GI tract, as disease isolated to the esophagus is extremely rare. Symptomatic Crohn's disease of the stomach and duodenum is more common than disease of the esophagus, yet both locations are the least frequently involved by Crohn's disease. The symptoms are usually related to the obstructive nature of the disease with delayed gastric emptying, a sense of postprandial gastric fullness, nausea, and vomiting.

### **CROHN'S DISEASE OF THE SMALL INTESTINE**

Abdominal pain is the predominant symptom of small bowel Crohn's disease, as it occurs in 90% of cases.<sup>35</sup> Abdominal pain may be the result of obstructive or septic complications. Pain related to partial obstruction is mostly postprandial and crampy in nature; pain from septic complications is typically steady and associated with fevers. Other common symptoms and findings include anorexia and weight loss. Weight loss is usually related to food avoidance, but in severe cases, it may be the result of malabsorption. With disease of the small intestine, patients may develop a palpable mass, usually located in the right lower quadrant, related to an abscess or phlegmon in perforating disease or a thickened loop of intestine in obstructive disease. Evidence of fistulization to the skin, urinary bladder, or vagina may also be

elicited with an accurate history and physical examination.

## **CROHN'S COLITIS**

Crohn's involvement of the colon typically results in diarrhea that may or may not be bloody. Acute flares of Crohn's colitis are often associated with fever and abdominal pain that is often exacerbated by bowel movements. Strictureing of the colon with more advanced disease can give rise to colonic obstruction. Like Crohn's disease of the small intestine, Crohn's colitis can give rise to abscess formation and fistulas. Toxic megacolon can occur with Crohn's disease, but this severe complication is rare and less frequently seen than in ulcerative colitis.<sup>43</sup>

## **PERINEAL CROHN'S DISEASE**

Crohn's disease frequently affects the anal crypts and gives rise to perianal fistulas, abscesses, and anal strictures. Perineal Crohn's disease is also associated with hypertrophic perianal skin tags, fissures, and perineal scarring. Approximately 40% of patients with Crohn's will develop perineal manifestations.<sup>44,45</sup> Anal Crohn's disease is almost always associated with Crohn's disease present elsewhere in the GI tract, although perianal disease can be the initial symptomatic manifestation of Crohn's disease.

## **EXTRAIESTINAL CROHN'S DISEASE**

In addition to the inflammation of the GI tract, a variety of extraintestinal manifestations can occur in Crohn's disease. These include ocular, dermatologic, hepatobiliary, and joint disorders.<sup>46,47</sup> Such extraintestinal manifestations occur in a minority of patients, but, when present, they produce symptoms that can be more severe than those of the primary intestinal disease. Ocular manifestations of Crohn's disease include uveitis and episcleritis.<sup>48</sup> Cutaneous manifestations of Crohn's disease include erythema nodosum and pyoderma gangrenosum. Joint disorders such as ankylosing spondylitis, sacroiliitis, and seronegative polyarteritis can occur. Patients with Crohn's disease are also at risk for the development of primary sclerosing cholangitis. However, the risk for primary sclerosing cholangitis is much less in Crohn's disease patients than in patients who suffer from

ulcerative colitis.

Peripheral polyarteritis, episcleritis, uveitis, and erythema nodosum typically correlate with the activity of intestinal Crohn's disease. These particular extraintestinal manifestations usually regress with complete surgical resection of the affected segment of intestine or with successful medical control of the intestinal inflammation. Pyoderma gangrenosum may also improve with treatment of primary intestinal disease, but available clinical data on this particular issue have not always been consistent. The clinical course of ankylosing spondylitis and primary sclerosing cholangitis tends to be independent of the level of disease activity within the intestine. Ankylosing spondylitis and primary sclerosing cholangitis do not improve with surgical resection of the Crohn's disease-affected bowel.

## DIAGNOSIS

The onset of Crohn's disease is often insidious, and many patients will experience some symptoms for months or even years before the diagnosis is made. The diagnosis of Crohn's disease is typically made by a thorough history and physical examination along with intestinal radiography, endoscopy, and pathologic confirmation. There is no specific laboratory test that is diagnostic for Crohn's disease, although serologic and inflammatory markers are typically elevated and correlate with disease activity (eg, calprotectin and C-reactive protein). Advanced imaging studies such as computed tomography (CT) scan or magnetic resonance imaging (MRI) can assess or detect some of the complications and manifestations of Crohn's disease<sup>49</sup> but do not replace endoscopic and pathologic confirmation.<sup>50</sup>

## History and Physical Examination

The symptoms of Crohn's disease are dependent on the location of the involved segment, the pattern and the severity of disease, and the associated complications. As noted previously, in most cases, the onset of disease is gradual, with the most common complaints being intermittent abdominal pain, bloating, diarrhea, nausea, vomiting, weight loss, and fever.<sup>51</sup> Patients may also have symptoms related to complications of the disease, including abdominal masses, pneumaturia, perianal pain and swelling, or skin rash. In

some cases, the onset of symptoms can be more sudden, with patients relating a history reminiscent of acute appendicitis. In these cases, pain in the right lower quadrant may have been present only for a few hours or days. However, a brief history of symptoms such as these is atypical.

In patients suspected of having Crohn's disease, a complete physical examination should include a thorough abdominal assessment and digital rectal exam. In cases of ileal Crohn's disease, tenderness is typically present in the right lower quadrant, and occasionally a palpable mass is present. The oral cavity should be examined for the presence of aphthous ulcers. The perianal area should be examined for the presence of fistulas, abscesses, or enlarged skin tags. A digital rectal examination should assess for the presence of anal strictures, fissures, and rectal mucosal ulcerations. The skin in the extremities should be examined for erythema nodosum and pyoderma gangrenosum.

## Imaging

### SMALL BOWEL RADIOGRAPHY

Upper intestinal contrast studies, either small bowel follow-through or enteroclysis, are the best means for assessing the small bowel for Crohn's disease.<sup>52-55</sup> The radiographic abnormalities of small bowel Crohn's disease are often distinctive<sup>56</sup> (Fig. 45-1). With early Crohn's disease, mucosal granulations with ulceration and nodularity can be identified. Thickening of the mucosal folds and edema of the bowel wall itself can be demonstrated as the disease progresses. With more advanced disease, cobble stoning becomes radiographically apparent. Small bowel contrast studies can also provide information regarding enlargement of the mesentery, as well as formation of an inflammatory mass or abscess. Such findings are demonstrated by a general mass effect separating and displacing contrast-filled loops of small intestine (see Fig. 45-1; Fig. 45-2). Small bowel contrast studies can demonstrate some of the complications of Crohn's disease, including high-grade strictures and fistulas. It is important to note, however, that small bowel radiography may not identify all such lesions. For instance, many enteric fistulas including ileosigmoid and ileovesical fistulas are not typically demonstrated on contrast radiography.<sup>57,58</sup> Thus, the absence of radiographic evidence for fistulization does not exclude this possibility. Additionally,

small bowel studies may not demonstrate all the areas of disease with significant strictures.<sup>59</sup> While small bowel radiographs may underestimate the extent of complicated Crohn's disease, small bowel studies performed by an experienced GI radiologist are very effective as a diagnostic tool for this disease. Besides their diagnostic utility, small bowel radiographs can also help in assessing the extent of the disease by identifying the location and length of involved and uninvolved intestine and by recognizing whether the disease is continuous or discontinuous with skip lesions separated by areas of normal intestine (Fig. 45-3). Experienced radiologists can also assess areas of luminal narrowing and determine if they are the result of acute inflammatory swelling or are the result of fibrostenotic scar tissue. Such a distinction provides valuable information regarding the value of medical therapy versus early surgical intervention, as inflammatory stenoses are likely to respond to medical therapy whereas fibrotic strictures are best treated with surgery.

## ENDOSCOPY

Upper and lower endoscopies allow for inspection of mucosal disease and provide an opportunity for a biopsy for histologic evaluation. Upper endoscopy is useful in the diagnosis of mucosal lesions of the esophagus, stomach, and duodenum; it also easily identifies strictures and grades their severity. Characteristic colonoscopic features of Crohn's disease include aphthous ulcers, longitudinal ulcerations, skip lesions often with rectal sparing, pseudopolyps, and strictures.<sup>53</sup> In many cases, the terminal ileum can be entered and evaluated.

## **CAPSULE ENDOSCOPY**

Capsule endoscopy is a new tool in the diagnosis and evaluation of Crohn's disease.<sup>60,61</sup> With this study, a small camera embedded within a capsule-size casing is swallowed, and images from the camera are transmitted to a small electronic receiver worn by the patient. Images from the capsule endoscopy can detect subtle mucosal lesions that may not be apparent on small bowel x-rays. Prior to the capsule endoscopy, patients with suspected Crohn's disease should undergo a small bowel contrast study to exclude stricture formation, as the capsule may fail to pass through areas of narrowing and result in intestinal obstruction. The value of capsule endoscopy in the diagnosis of Crohn's disease has been recently evaluated in a prospective study from the Mayo Clinic.<sup>62</sup> This study compared capsule endoscopy, CT enterography (CTE), ileocolonoscopy, and small bowel follow-through in the diagnosis of small bowel Crohn's disease in a prospective blinded trial and found that the sensitivity of capsule endoscopy was not significantly different from that of the other tests. A meta-analysis of capsule endoscopy studies comparing it to CTE suggested that the prevalence of abnormalities detected on capsule endoscopy was 38% higher than that of CTE.<sup>63</sup> However, this value was significantly higher than CTE only for the subgroup of patients with known Crohn's disease. The need for a preliminary small bowel contrast study to detect asymptomatic partial small bowel obstruction before the capsule endoscopy can be safely performed and the lack of a clear advantage over other imaging studies limit the utility of capsule endoscopy as a first-line test in Crohn's disease and perhaps reserves this study for those cases in which there is a substantial diagnostic uncertainty.

## **COMPUTED TOMOGRAPHY**

CT findings of uncomplicated Crohn's disease are nonspecific, and routine CT is not necessary for the diagnosis of Crohn's disease. CT, however, is very useful in identifying enteric involvement (>90%) and complications associated with Crohn's disease.<sup>64-66</sup> Specifically, CT can readily identify thickened and dilated intestinal loops, inflammatory masses, abscesses, and hydronephrosis resulting from retroperitoneal fibrosis and ureteral narrowing. CT scans may also raise suspicion for an enterovesical fistula as suggested by the presence of air within the urinary bladder. More recently, cross-sectional

imaging techniques have assumed an increasing role in the imaging of patients with Crohn's disease. Using ileoscopy and biopsy of the terminal ileum as reference to evaluate the performance characteristics of cross-sectional enterography,<sup>67</sup> CTE has been shown to have a higher sensitivity than barium small bowel follow-through.<sup>62</sup> These findings have convinced many to use CTE combined with ileocolonoscopy as a first-line test for the diagnosis and staging of Crohn's disease.<sup>62</sup> CTE exploits the high spatial resolution and speed of modern CT, using large volumes of neutral oral contrast agents to generate detailed images of the small bowel wall, lumen, and mesentery.<sup>68</sup> In addition, CTE has several potential advantages over barium studies in the identification of fistulizing disease. Unlike traditional fistulography, CTE does not suffer from superimposition of bowel loops and displays the mesentery, retroperitoneal, and abdominal wall musculature, typically involved by fistulas. Sinus tracts and abscesses can also be readily characterized by CTE.<sup>68</sup> Widespread access and rapid scan time make CT useful and convenient; however, recent concerns about radiation-induced cancer arising from medically related CT<sup>69</sup> have stimulated a reassessment of the role of CTE in young Crohn's disease patients<sup>70</sup> and have prompted many to encourage the use of magnetic resonance enterography (MRE).

## **MAGNETIC RESONANCE ENTEROGRAPHY**

MRE has similar advantages to CTE, such as the ability to evaluate the entire small bowel, detect transmural inflammation, grade the severity of inflammation, and detect extracolonic inflammation, without the requirement of ionizing radiation. In fact, in a recent study, MRE was shown to have almost identical sensitivities to CTE for detecting active small bowel inflammation, although image quality across the study cohort appeared to be better with CTE.<sup>71</sup> Improved soft tissue contrast with MRI provided by the combination of T2/T1 postcontrast and diffusion-weighted images has the potential to allow a better assessment of the relative inflammation versus fibrosis burden in stricturing Crohn's disease, although the utility of this characterization is still being studied.<sup>66</sup> MRI is also able to provide functional motility information, which may have a role in surgical planning. Although imaging modalities are evolving, currently, MRE appears to be a comparable alternative to CTE, in particular when radiation exposure is a concern, and

provide complementary information to ileocolonoscopy in the diagnosis of Crohn's disease.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for small bowel Crohn's disease includes irritable bowel syndrome, acute appendicitis, intestinal ischemia, pelvic inflammatory disease, endometriosis, and gynecologic malignancies. Other disorders that are within the differential diagnosis include radiation enteritis, *Yersinia* infections, intestinal injury from nonsteroidal anti-inflammatory agents, intestinal tuberculosis, and small bowel tumors.

Among the most important ailments to consider are small bowel malignancy and intestinal tuberculosis. In patients in whom small bowel malignancy is suspected, resection should be undertaken to make certain the diagnosis. The exclusion of intestinal tuberculosis can be difficult, as the inflammation and stricturing of the terminal ileum can occur in a manner that closely mimics Crohn's disease. The patient should be assessed for exposure to tuberculosis and screened for tuberculosis with a purified protein derivative skin test. Chest radiography should also be considered. Even when the diagnosis of Crohn's disease is certain, patients who coincidentally are found to also have latent tuberculosis should be treated in accordance with American Thoracic Society guidelines prior to the initiation of immunosuppressive therapy for management of their Crohn's disease.<sup>72</sup>

Intestinal injury from nonsteroidal anti-inflammatory drugs (NSAIDs) can result in focal enteritis with ulceration and stricture formation.<sup>73,74</sup> These manifestations can be very difficult to distinguish from Crohn's disease of the small bowel. This rare side effect from the commonly used NSAIDs often requires resection or biopsy to confirm the diagnosis.

For Crohn's disease of the colon, the differential diagnosis includes ulcerative colitis, infectious colitis, collagenous colitis, ischemic colitis, diverticular disease, Behçet disease, colonic neoplasm, solitary rectal ulcer syndrome, and NSAID colopathy.

The entity that is most difficult to distinguish from Crohn's colitis is ulcerative colitis. The diagnosis of ulcerative colitis cannot be made with absolute certainty, as it is possible for Crohn's disease of the colon to reproduce all the features of ulcerative colitis. It is only when features appear

that are unique to Crohn's disease that the diagnosis of Crohn's disease can be made. Such distinguishing features of Crohn's disease include small bowel involvement, perianal disease, skip lesions, transmural inflammation, fistulas, abscesses, and noncaseating granulomas. After a complete history and physical examination complemented by appropriate radiologic, endoscopic, and humoral studies, Crohn's disease and ulcerative colitis can be distinguished with a high degree of confidence in as many as 85% to 90% of cases, yet in the remaining 10% to 15% of cases, the differential diagnosis will remain indeterminate.

## **MEDICAL MANAGEMENT**

The goal of medical treatment of Crohn's disease is to provide long-lasting symptomatic relief while avoiding excessive morbidity. Crohn's disease cannot be cured by medical treatment, but it may afford long periods of disease control and avoidance of surgical intervention. Thus, it is important that the surgeon have an understanding of the basics of medical therapy for Crohn's disease. Selecting the optimal medical treatment for each individual requires experience and special expertise because of the variable course of the disease, the myriad of different clinical presentations and associated complications, and the desire to optimize medical treatment for each clinical situation. Multiple different medical therapies are used for the treatment of Crohn's disease and depend on the location and severity of the disease as well as goals of treatment (induction vs maintenance of remission).

### **5-Aminosalicylic Acid**

The aminosalicylates as a group of medications include sulfasalazine and 5-aminosalicylic acid (5-ASA) derivatives. The exact mechanism of action for these agents is not clear, but 5-ASA is thought to function through various pathways.<sup>75</sup> 5-ASA compounds inhibit leukotriene production by inhibition of 5-lipoxygenase activity. 5-ASA also inhibits the production of interleukin-1 and tumor necrosis factor (TNF). 5-ASA compounds are weak inhibitors of cyclooxygenase (COX) activity, and it is unlikely that they act through the inhibition of prostaglandin production. Aminosalicylates are effective in the treatment of mild to moderate Crohn's disease. 5-ASA given

in a controlled-release preparation is also effective as maintenance therapy to prevent recurrence after a flare of disease has been effectively managed either medically or surgically.<sup>76-79</sup>

Aminosalicylates come in a variety of preparations, each designed to deliver the drug in a topical fashion to the affected segments of intestine.<sup>80</sup> For instance, Asacol (mesalamine) is 5-ASA contained within a pH-dependent resin designed to release the drug in the terminal ileum and colon where the pH is typically greater than 7.0. Pentasa (mesalamine) is 5-ASA contained within ethylcellulose-coated microgranules designed to slowly release the active compound throughout the entire small bowel and colon. Colazal (balsalazide) is 5-ASA bound to an inert carrier by an AZO bond. This bond is broken by bacterial enzymes found within the colon, releasing the active 5-ASA compound to the colonic mucosa. The most common side effects are headache, fever, rash, and reversible infertility in men; a rarer complication is pancreatitis.

It is important to emphasize that mesalamine and its derivatives should not be confused with acetylsalicylic acid (aspirin) and other NSAIDs. Unlike 5-ASA compounds, classic NSAIDs are powerful inhibitors of COX-1 and COX-2. Many clinicians have had concerns that NSAIDs may exacerbate Crohn's disease.<sup>81-83</sup> Although the basis of these concerns has been challenged,<sup>84,85</sup> it is recommended that patients with Crohn's disease avoid NSAIDs and use alternative medications when appropriate.

## **Antibiotics (Ciprofloxacin/Metronidazole)**

Antibiotics have a well-established role in the management of septic complications of inflammatory bowel disease such as abscesses or wound infections. They may be used in the maintenance therapy of chronic perineal septic complications and in the treatment of bacterial overgrowth associated with chronic obstructive disease of the small bowel. Their benefit in primary treatment of Crohn's disease is not well established, although they are commonly used in clinical practice.<sup>86</sup>

## **Corticosteroids**

Corticosteroids are the most effective agents for controlling acute

exacerbations of Crohn's disease, but their use is limited due to the risk of serious side effects. The majority of patients with active small bowel Crohn's disease will experience clinical remission with a short course of oral prednisone given in a dose between 0.25 and 0.5 mg/kg/d.<sup>87</sup> For patients unable to take oral medications, methylprednisolone can be administered in the adult at doses of 40 to 60 mg given as a daily infusion.<sup>88</sup> Common side effects from corticosteroids include diabetes, osteoporosis, cataracts, osteonecrosis, myopathy, psychosis, opportunistic infections, and adrenal suppression. The risks for these side effects are related to both the dose and the duration of steroid therapy.

## **Immunomodulators (Azathioprine and 6-Mercaptopurine)**

Azathioprine and 6-mercaptopurine (6-MP) are immunosuppressive agents that inhibit cytotoxic T-cell and natural killer cell function. These agents have been shown to be effective in treating mild to moderate Crohn's disease.<sup>88,89</sup> Azathioprine given at 2.0 to 2.5 mg/kg/d or 6-MP in doses of 1.0 to 1.5 mg/kg/d will result in a 50% to 60% response rate in patients with active Crohn's disease.<sup>88,90</sup> Both 6-MP and azathioprine are also effective in maintaining remission following surgery or successful medical management.<sup>77</sup>

## **Biologic Therapies (Anti-TNF Therapies and Anti-Integrin Antibodies)**

Three anti-TNF therapies are approved for treatment of Crohn's disease in adults in the United States, and all have been shown to be effective for treatment of GI manifestations of Crohn's disease. Indirect evidence suggests that there are no significant differences in efficacy between these 3 anti-TNF therapies; however, no randomized controlled trials have directly compared them.<sup>91</sup>

Infliximab, the best studied, is a chimeric mouse-human monoclonal antibody to TNF. TNF is a proinflammatory cytokine that is believed to be important in the pathophysiology of Crohn's disease. Infliximab binds to both

free and membrane-bound TNF and prevents TNF from binding to its cell surface receptors.<sup>75</sup> Clinical trials have demonstrated an 80% response rate with a single dose of infliximab.<sup>92,93</sup> It is important to note that the doses and dosing intervals of infliximab must be individualized, but a typical regimen would include 5 mg/kg of infliximab given intravenously at weeks 0, 2, and 6, with a dose of 5 mg/kg every 8 weeks thereafter.

Because anti-TNF drugs are potent immunosuppressive agents, concerns have been raised about the risk for poor wound healing and postoperative septic complications. Current available data on the perioperative risks are somewhat conflicting. Early studies have suggested that preoperative anti-TNF drug use does not appear to increase the risk for postoperative complications following abdominal surgery for Crohn's disease.<sup>94-96</sup> More recently, however, a study from the Cleveland Clinic demonstrated an increased risk for infectious complications and intra-abdominal abscesses in Crohn's disease patients undergoing surgery who received infliximab.<sup>97</sup> This study also found that the presence of a diverting stoma significantly decreased the risk for septic complications in patients who had been treated with anti-TNF drugs.

Although experience with anti-integrin therapies is still slight, there are several promising drugs on the horizon. Natalizumab is an anti- $\alpha$ -4 integrin and blocks leukocyte migration to areas of inflammation. The effectiveness of natalizumab was confirmed in the Encore trial, in which 509 patients with moderate to severe active Crohn's disease were randomized (1:1) to receive natalizumab 300 mg versus placebo. An improved response was seen in 48% of the natalizumab-treated patients compared to 32% of the patients receiving placebo ( $P = .001$ ). Vedolizumab is a humanized anti- $\alpha$ 4- $\beta$ 7 integrin monoclonal antibody that may help in moderate to severe Crohn's disease<sup>98</sup> and was recently approved by the US Food and Drug Administration. Ustekinumab is a human IgG monoclonal antibody that blocks the activity of interleukin (IL)-12 and IL-23 and has shown benefit in patients resistant to TNF antagonists. Additional monoclonal antibodies are being investigated and show promise.

## Other Medical Therapies

Other agents that are used with varying success in the treatment of Crohn's

disease include methotrexate, cyclosporine, tacrolimus, and thalidomide. Each of these agents requires a complete and sophisticated knowledge of appropriate dosing, side effects, therapeutic efficacy, and toxicities, which is beyond the scope of this chapter. These medications are often used in conjunction with the more standard medications.

## **SURGICAL TREATMENT**

Similar to medical treatment, the goal of surgical treatment of Crohn's disease is to provide long-lasting symptomatic relief while avoiding excessive morbidity. Crohn's disease cannot be cured by surgical therapy, and thus surgery, like medical treatment, should be considered palliative. Complete extirpation of disease should not be the primary goal of surgery, as this does not produce cure and is frequently counterproductive. Rather, treatment of complications and palliation of symptoms while avoiding excessive loss of intestine should be the main aims of surgical treatment.

To avoid excessive loss of intestine, nonresectional techniques such as strictureplasty may be required. Additionally, optimal surgical therapy may require leaving behind segments of the intestinal tract affected by mild but asymptomatic disease with resection of only the areas of severe and symptomatic Crohn's disease. The best surgical strategy for each patient with Crohn's disease takes into account the indications for surgical treatment and the natural history of the disease, with its high risk for recurrence and the need for repeated surgeries.

## **Indications for Surgery**

### **FAILURE OF MEDICAL TREATMENT**

The failure to respond to medical treatment and the inability to tolerate effective therapy are the most common indications for surgical treatment of Crohn's disease.<sup>99</sup> Some patients may respond to the initial medical therapy only to rapidly relapse with tapering of the medical treatment. For example, some patients respond well to steroid therapy but become steroid dependent as tapering of the steroid dose results in recurrent symptoms. Because of the severe complications that are virtually inevitable with prolonged steroid treatment, surgery is warranted if the patient cannot be weaned from systemic

steroids within 3 to 6 months. The occurrence of complications related to the medical treatment or the progression of disease while on maximal medical treatment represent additional indications for surgical treatment.

## **INTESTINAL OBSTRUCTION**

Partial or complete intestinal obstruction is a common indication for operation for Crohn's disease.<sup>100</sup> The clinical presentation of chronic partial small bowel obstruction is much more typical than complete obstruction. Patients with chronic partial small bowel obstruction due to Crohn's disease may experience postprandial cramps, abdominal distension, borborygmi, and weight loss. To avoid symptoms, many patients will restrict their diets to soft foods or even liquids. If partial obstruction from Crohn's disease is primarily due to acute inflammation and bowel wall thickening, initial medical therapy is warranted. If, however, the obstructive symptoms are due to high-grade fibrostenotic lesions, medical treatment will not reverse these lesions and surgery is indicated.

When complete intestinal obstruction occurs, initial conservative treatment with nasogastric decompression and intravenous hydration is warranted.<sup>34,101</sup> Intravenous steroids are also administered. This allows for decompression of acutely distended and edematous bowel and, in most cases, for resolution of the complete obstruction. Resolution of the complete obstruction should not lead the physician to attempt treating the patient with continuing medical therapy. Patients with complete obstruction who respond well to initial conservative therapy are at high risk for persistent or recurrent symptoms of obstruction and are best managed with surgery once adequate decompression is achieved. The surgery can be performed under elective and safer conditions after appropriate bowel preparation.

## **FISTULAS**

Intestinal fistulas occur in one-third of Crohn's disease patients.<sup>57</sup> Intestinal fistulas, however, are the primary indication for surgery in only a minority of patients. Thus, the presence of an intestinal fistula is not in and of itself an indication for surgery.<sup>102,103</sup> In general, intestinal fistulas are the primary indication for surgical treatment if they connect with the genitourinary tract, if their drainage is cause for personal embarrassment and discomfort

(enterocutaneous and enterovaginal fistulas), or if they create a bypass of such magnitude as to cause intestinal malabsorption.

Fistulas between the ileum and the urinary bladder often result in recurrent urinary tract infections, including pyelonephritis. While it is not mandatory to operate on all cases of enterovesical fistulas, surgery is warranted to avoid deterioration of renal function with recurrent infections or if symptoms persist despite appropriate medical therapy.

Enterocutaneous fistulas and enterovaginal fistulas often cause physical discomfort and personal embarrassment. A trial of medical therapy may be elected for enterocutaneous and enterovaginal fistulas, but most such cases will require surgery.<sup>104,105</sup>

Occasionally, an enteroenteric fistula can result in significant symptoms. Fistulas that result in functional bypass of a major intestinal segment can result in malabsorption or diarrhea. These fistulas need to be addressed surgically.

## **ABSCESSES AND INFLAMMATORY MASSES**

Intra-abdominal abscesses and inflammatory masses occur less frequently than fistulas but are more often an indication for operative intervention.<sup>106</sup> Small abscesses seen on CT may warrant a trial of treatment with antibiotics, but almost all intra-abdominal abscesses will require drainage. In a vast majority of cases, Crohn's abscesses can be drained percutaneously with CT or ultrasound guidance.<sup>107-109</sup> The rare large intraloop abscesses may require open surgical drainage. Often, in such cases, the abscess can be completely extirpated with the resection of the diseased segment of intestine.

Crohn's abscesses usually originate from a severely diseased segment of bowel. A Crohn's abscess that has been drained percutaneously is very likely to recur or result in an enterocutaneous fistula, and surgical resection is often advised even after successful drainage.<sup>109</sup> Inflammatory masses indicate severe disease and often harbor an unrecognized abscess.<sup>106</sup> Thus, inflammatory masses that do not readily respond to antibiotic treatment should be considered for surgical treatment.

## **PERFORATION**

Free perforation is a rare complication of Crohn's disease, occurring in fewer

than 1% of cases.<sup>110</sup> When this complication occurs, it is an obvious indication for urgent operation. The diagnosis of free perforation is made by detecting a sudden change in the patient's symptoms along with the development of the physical findings of peritonitis or the identification of free intraperitoneal air as demonstrated on plain x-rays or CT scans. The use of immunosuppressants and glucocorticosteroids can blunt many of the physical findings of acute perforation; therefore, the index of suspicion for perforation must be higher in immunocompromised patients who complain of worsening symptoms or show early signs of sepsis. Most patients, however, will demonstrate classic signs of peritonitis with rebound, rigidity, guarding, and loss of bowel sounds.

## **HEMORRHAGE**

Hemorrhage is an uncommon complication from Crohn's disease. Massive GI hemorrhage is rare and occurs more frequently from Crohn's colitis than in small bowel Crohn's disease.<sup>111</sup> Hemorrhage from small bowel Crohn's disease tends to be indolent with episodic or chronic bleeding requiring intermittent transfusions, but it rarely requires emergent surgery. Localization of the site of bleeding is accomplished by angiography in the presence of brisk bleeding; otherwise, colonoscopy can be attempted preoperatively to localize a source of lower GI hemorrhage. Intraoperative localization can be aided by enteroscopy or colonoscopy.

When severe hemorrhage occurs in Crohn's disease, it is usually due to erosion of a single vessel by a deep ulcer or fissure. Recurrent bleeding in an area of small bowel disease is a common phenomenon, and it has been argued that even after control of hemorrhage from small bowel Crohn's disease with conservative management, elective resection of the areas of Crohn's disease should be undertaken to prevent recurrent bleeding.

Patients with Crohn's disease are also at risk for bleeding from peptic ulcer disease. This is particularly true for patients receiving corticosteroid therapy. For this reason, Crohn's disease patients who develop GI bleeding should undergo an upper endoscopy to rule out gastric or duodenal ulcers.

## **CANCER OR SUSPICION OF CANCER**

The presence of Crohn's disease increases the risk of adenocarcinoma of the

colon and small intestine.<sup>112</sup> The diagnosis of adenocarcinoma of the small bowel is difficult because symptoms and radiographic findings of small bowel malignancy can be similar to those of the underlying Crohn's disease. Male patients and patients with long-standing disease appear to be at increased risk for small bowel adenocarcinoma.<sup>112</sup> Defunctionalized segments of bowel also seem to be at particular risk for malignancy.<sup>113</sup> For this reason, bypass surgery should be avoided for Crohn's disease of the small intestine, and defunctionalized rectal stumps should either be restored to their function or excised.

Adenocarcinoma of the small intestine should be suspected in any patient with long-standing disease whose symptoms of obstruction progress after a lengthy quiescent period. Surveillance for colonic malignancies can be undertaken by colonoscopy with random mucosal biopsy. If dysplasia is encountered, resection of the areas of Crohn's disease should be considered.<sup>114,115</sup> Areas of stricture formation within the colon should be closely examined and biopsied. Strictures that are too narrow to allow passage of the colonoscope or cannot be adequately assessed colonoscopically should be resected or biopsied if a stricturoplasty is performed.

## **GROWTH RETARDATION**

Growth retardation occurs in a quarter of children affected by Crohn's disease. Although steroid treatment may delay growth in children, the major cause of growth retardation in Crohn's disease patients is the malnutrition associated with active intestinal disease.<sup>116,117</sup>

## **Preoperative Preparation and Evaluation**

A complete assessment of the GI tract is required prior to surgery. Full delineation of the extent of disease and associated complications is necessary to plan for the optimal surgical strategies.

Assessment of the small intestine can be performed with a small bowel follow-through, an enteroclysis study, MRE, or CTE. The colon and rectum are best evaluated by colonoscopy. Barium enema studies can also be used to evaluate for colonic disease, particularly in cases in which strictures do not

allow passage of the colonoscope. If the patient has had a previous resection of the ileocecal valve, a contrast enema can be a useful means of evaluating the ileocolonic anastomosis and the preanastomotic segment for recurrent disease. If an abscess, fistula, or inflammatory mass is suspected, a CT scan of the abdomen and pelvis with both oral and intravenous contrast should be obtained. CTE combined with ileocolonoscopy is used by many as a first-line test for the staging of Crohn's disease.<sup>62</sup> In patients in whom urgent surgery is required, a full evaluation of the GI tract prior to surgery may not be feasible. In these cases, evaluation of disease must be accomplished intraoperatively, and both the patient and the surgeon must be prepared for a wide variety of surgical possibilities.

As with preparation for any major operation, metabolic derangements must be treated prior to surgery. Fluid and electrolyte abnormalities must be corrected. Patients with profound anemia need to be transfused, and coagulopathies must be addressed. Patients with cardiovascular or pulmonary disease should have the condition stabilized and their functional capacity optimized prior to operation. Most patients with Crohn's disease will not require preoperative parenteral nutrition, as most suffer from only a minor degree of malnutrition. There are rare cases, however, in which the nutritional status of the patient has been so severely compromised that they benefit from several weeks of bowel rest, parenteral nutrition, and ongoing medical treatment before operation.

The absolute need for mechanical bowel preparation is controversial.<sup>118-120</sup> Traditionally, mechanical bowel preparations have been an unquestioned standard to lessen the risks of sepsis and to allow for a safe anastomosis. Recently, these advantages have been challenged.<sup>118,119</sup> Even so, it is common practice for patients undergoing intestinal resection for Crohn's disease to undergo a complete mechanical bowel preparation with either polyethylene glycol or sodium phosphate. Should the patient be unable to tolerate oral preparations, enemas can be used. Prophylactic broad-spectrum antibiotics are administered perioperatively,<sup>121</sup> and stress dose steroids must be given to patients suspected of hypothalamic-pituitary-adrenal suppression. If feasible, well-contained intra-abdominal abscesses should be drained percutaneously prior to surgery. If an abdominal stoma is contemplated, the optimal site for the stoma location should be marked preoperatively. In patients in whom preoperative CT scan suggests significant inflammation in

proximity to the ureters, preoperative ureteral stenting can be helpful.

Some have suggested that, to improve the safety of surgery for Crohn's disease, anti-inflammatory Crohn's medication should be either lowered or discontinued prior to elective surgery. Recent studies, however, have shown that preoperative use of steroids and antimetabolites does not appear to affect the perioperative morbidity, and hence, discontinuation of these medications is not likely to result in significant benefit. Methotrexate and infliximab, on the other hand, are 2 medications that may be worth discontinuing at least 2 weeks and 2 to 3 months, respectively, prior to surgery. Laboratory studies have shown decreased wound healing with methotrexate,<sup>122</sup> and clinical data to evaluate the safety of methotrexate in patients undergoing bowel resection with anastomosis are lacking. A recent study from the Cleveland Clinic has demonstrated an increased risk for infectious complications and intra-abdominal abscesses after recent treatment with infliximab.<sup>97</sup>

## Surgical Options

### INTESTINAL RESECTION

Intestinal resection with anastomosis or stoma formation is the most common surgical procedure performed for the treatment of Crohn's disease. Most cases of Crohn's disease require only limited resections that are generally well tolerated and do not place these patients at risk for short bowel syndrome. Cumulative clinical data including randomized studies have indicated that resection of Crohn's disease need only encompass the grossly apparent disease, as wider resections do not improve the outcome after surgery.<sup>97,123-126</sup> Microscopic resection margins that are grossly normal but demonstrate microscopic evidence for Crohn's activity do not result in early recurrence or other complications. Hence, intraoperative frozen section of the resection margins is not necessary.<sup>127</sup>

The extent of mesenteric dissection does not affect the long-term results either; hence, the mesentery can be divided at the most advantageous level. Division of the thickened mesentery of small bowel Crohn's disease can be the most challenging aspect of the procedure. Identification and isolation of individual mesenteric vessels are not feasible with a thickened Crohn's mesentery. Although many approaches to this problem have been described, a common technique is to apply overlapping clamps on either side of the

intended line of transection. The mesentery is then divided between the clamps, and the tissue contained within the clamps is suture-ligated (Fig. 45-4). In severe cases, a vascular clamp may be used at the root of the small bowel mesentery to obtain proximal control: mattress sutures may then need to be applied to the cut edge of the mesentery to control bleeding. The use of tissue welding devices can be useful for sealing vessels within the thickened mesentery. Even with these devices, mattress sutures in the mesentery are commonly needed for complete hemostasis. Despite the difficulty dealing with the thickened and often hyperemic mesentery, resection can be performed with a low risk for postoperative hemorrhage, and the risk for postoperative hemoperitoneum requiring reexploration has been reported to be less than 0.5%.<sup>99</sup>

**FIGURE 45-4** Technique for division of thickened Crohn's mesentery.

## ANASTOMOSIS

There is no overriding consensus regarding the optimal technique for intestinal anastomosis in Crohn's disease.<sup>76,128-132</sup> It is well established that recurrent Crohn's disease after resection of terminal ileal disease is most

likely to occur at the ileocolonic anastomosis or at the preanastomotic ileum. It has been proposed that large-caliber anastomoses require a longer period to stricture down to a critical diameter that becomes symptomatic. The argument is made that a longer side-to-side anastomosis may be beneficial over an end-to-end or end-to-side anastomosis.<sup>131</sup> To date, however, clinical data do not indicate a benefit for one particular intestinal configuration over another.<sup>130</sup> Intestinal anastomosis for Crohn's disease cases can be fashioned with a stapling device or may be hand-sutured. When performed under selective conditions, resection with primary anastomosis for Crohn's disease can be performed with a high degree of safety, and small bowel anastomotic dehiscence rates can be kept under 1%.<sup>99</sup> In the presence of sepsis, severe scarring, malnutrition, or recent use of methotrexate or infliximab, it may be wise to protect the anastomosis with a proximal loop stoma or to forego the anastomosis altogether and bring out an end stoma at the point of resection.

## **STOMA FORMATION**

Permanent stomas are required for the surgical treatment of Crohn's proctitis and occasionally required for the management of severe, unrelenting perianal disease. Temporary stomas are much more common and typically used as a means of protecting a distal anastomosis or when an anastomosis is not advisable.

If an ileostomy or colostomy is contemplated, selection of the optimal placement of the stoma should be determined preoperatively.<sup>133</sup> Proper stoma location is critical to achieve a satisfactory stoma. It is preferable to locate the ileostomy over the left or right rectus abdominis muscle on a flat area away from deep skin folds and bony prominences.<sup>134</sup> The surface of the abdomen must be evaluated in both the sitting and standing positions, as this will often demonstrate skin folds and creases not evident in the supine position. Attention must be paid to determining the level of the patient's belt line, and every effort is made to place the stoma below it. Once the optimal position of the stoma has been identified, it is marked in a manner that will remain visible at the time of surgery.

Complications related to intestinal stomas are common. They include peristomal hernia, prolapse, and stricture. Peristomal hernia is the most common ostomy-related complication. It can be anticipated that approximately 25% of patients with a permanent stoma will require surgical

revision of their ostomy to deal with 1 or more of these complications.<sup>135</sup>

## **BYPASS PROCEDURES**

Bypass procedures became popular in the 1940s and 1950s once physicians and surgeons realized that aggressive enterectomies did not reduce the incidence of recurrence and were fraught with the development of short gut syndrome. Initially conceived to bypass an area of stricture or obstruction, the use of bypass procedures was eventually extended to Crohn's disease complicated by septic complications. Increased experience with bypass procedures revealed that persistence of disease put patients at risk of persistent sepsis and eventually neoplastic transformation. Because of these complications, bypass procedures were supplanted by limited intestinal resection as the main surgical option in the late 1960s in all intestinal districts except the duodenum, where a simple side-to-side retrocolic gastrojejunostomy adequately relieves the obstructive symptoms. With increased experience and confidence in the performance of strictureplasty, duodenal disease is now more often managed using strictureplasties.

## **STRICTUREPLASTY**

Strictureplasty techniques have gained popularity as a safe and effective means of treating stricturing Crohn's disease of the small intestine without resorting to lengthy resections. Strictureplasties are best used when resection would otherwise result in loss of a lengthy segment of bowel and thus place the patient at risk for short bowel syndrome. This would include cases with long segments of stricturing disease and patients with multiple prior resections. They are also indicated when they offer a simpler alternative to resection, such as in short recurrent disease at a previous ileocolic or enteroenteric anastomosis.

It is generally accepted that the advantage conferred by a strictureplasty over a resection in the preservation of intestinal absorptive capacity is mainly due to the sparing of normal areas in between strictures that would be otherwise sacrificed. Although this is true, there is increased evidence that the acuity of the disease decreases at the site of the strictureplasty and the disease becomes quiescent and may have a lower rate of recurrence of disease.<sup>136</sup> Whether this correlates with a simultaneous restoration of absorptive function

has not yet been established.

The most commonly performed strictureplasty is the Heinecke-Mikulicz strictureplasty.<sup>137-139</sup> The Heinecke-Mikulicz is named after the pyloroplasty technique from which this procedure is derived. With the Heinecke-Mikulicz strictureplasty, a longitudinal incision is made along the antimesenteric border of the stricture (Fig. 45-5). This incision should extend for 1 to 2 cm into the normal elastic bowel on either side of the stricture. Once the enterotomy is made, the area of the stricture should be closely examined. If there is any concern that the stricture may harbor a malignancy, a biopsy with frozen section must be obtained. Complete hemostasis should be obtained with precise application of electrocautery. The longitudinal enterotomy of the Heinecke-Mikulicz strictureplasty is then closed in a transverse fashion. The closure can be accomplished with either single- or double-layered sutures. The Heinecke-Mikulicz stricture technique is appropriate for short-segment strictures of 2 to 5 cm in length.

**FIGURE 45-5** Heineke-Mikulicz strictureplasty.

The Finney strictureplasty, also named for the pyloroplasty technique from which this approach is derived, can be used for strictures up to 15 cm in length.<sup>137</sup> With the Finney strictureplasty technique, the strictured segment is folded onto itself in a U-shape<sup>140</sup> (Fig. 45-6). A row of seromuscular sutures is placed between the 2 arms of the U, and a longitudinal U-shaped enterotomy is then made paralleling the row of sutures. The mucosal surface is examined, and biopsies are taken as necessary. Homeostasis is obtained with electrocautery. Full-thickness sutures are then placed beginning at the posterior wall of the apex of the strictureplasty and then continued down to

approximate the proximal and distal ends of the enterotomy. This full-thickness suture line is then continued anteriorly to close the strictureplasty. To complete the procedure, a row of seromuscular Lembert sutures is placed anteriorly. In essence, the Finney is a short side-to-side functional anastomosis. A very long Finney strictureplasty may result in a functional bypass with a large lateral diverticulum. This diverticulum, in theory, could be at risk for bacterial overgrowth and the blind loop syndrome. Fortunately, this theoretical concern has not been observed in clinical practice.

**FIGURE 45-6** Finney strictureplasty.

The purpose of the strictureplasty is to preserve intestinal length that otherwise would be sacrificed with resection. Those cases with long segments of stricturing disease are the ones in which nonresectional methods should be aggressively pursued. To manage such cases, multiple strictureplasties are typically required. In general, however, repeated Heinecke-Mikulicz or Finney strictureplasties should be separated from each other by at least 5 cm. Otherwise, the result can be a bulky and relatively unyielding segment of intestine with considerable tension placed on each suture line.

Patients with multiple strictures grouped close together are best managed with a side-to-side isoperistaltic strictureplasty, also called *Michelassi strictureplasty*.<sup>141</sup> With this technique, the segment of stricturing disease is divided at its midpoint. The proximal and distal ends are then drawn onto

each other in a side-to-side fashion (Fig. 45-7). Division of some of the mesenteric vascular arcades facilitates the positioning of the 2 limbs over each other. The proximal and distal loops are then sutured together with a layer of interrupted seromuscular sutures. A longitudinal enterotomy is then made along both of the loops (Fig. 45-8). The intestinal ends are spatulated to provide a smoothly tailored fit to the ultimate closure of the strictureplasty. Again, this is the time to examine the mucosal surface of the intestine to detect potential areas of neoplastic transformation and control bleeding. The outer suture line is reinforced with an interior row of either interrupted or running full-thickness sutures. This inner suture line is continued anteriorly. The anterior closure is then reinforced with an outer layer of interrupted seromuscular sutures to complete the strictureplasty (Fig. 45-9).

**FIGURE 45-7** Isoperistaltic side-to-side strictureplasty. The segment of intestine affected by Crohn's strictures is divided, and the 2 limbs are drawn onto each other.

**FIGURE 45-8** Isoperistaltic side-to-side stricturoplasty. Longitudinal enterotomies are made along the antimesenteric borders of the 2 limbs.

**FIGURE 45-9** Isoperistaltic side-to-side stricturoplasty. The 2 limbs are anastomosed together in a lengthy side-to-side fashion.

Originally described in 1996, this procedure has been used with increasing frequency. The isoperistaltic side-to-side stricturoplasty is recognized as an effective means of treating extensive small bowel Crohn's disease and provides the best option for those cases that would otherwise require extensive intestinal resection with loss of significant length of small bowel.<sup>136,139,142,143</sup>

Unlike resection, diseased segments are retained with stricturoplasty, and suture lines are placed in Crohn's disease-affected tissue. This has been a cause of concern regarding the risk of intestinal suture line dehiscence, long-term recurrences, and risk for malignancy. The ongoing and now substantial clinical experience with these techniques has allayed these concerns.<sup>144</sup> In appropriately selected patients, perioperative morbidity from stricturoplasty appears to be similar to that of resection and primary anastomosis. Specifically, intestinal suture line dehiscence appears to be uncommon with any of the described stricturoplasty techniques.<sup>145,146</sup> The most common postoperative complication directly related to stricturoplasty is hemorrhage

from the strictureplasty site. This has been reported to occur in up to 9% of cases. Fortunately, the GI hemorrhage following strictureplasty is typically minor and can be managed conservatively with transfusions alone. Rarely, more persistent bleeding may require intra-arterial infusion of vasopressin, but the need for reoperation to control hemorrhage after strictureplasty is very rare. It is by now also well established that strictureplasty techniques provide excellent long-term symptomatic relief that is comparable to resections with anastomosis. Although there are no controlled studies directly comparing strictureplasty to resection, multiple reports of the observed symptomatic recurrence rates after strictureplasty compare well with published recurrence rates after resection and anastomosis.<sup>139,146,147</sup>

Epidemiologic studies have shown an increased risk for small bowel adenocarcinoma in Crohn's disease patients.<sup>114</sup> This risk is increased in patients with long-standing disease. It is not known if strictureplasty by virtue of its retention of diseased tissue increases this risk. At the time of the writing of this chapter, there have been only 2 reported cases of an adenocarcinoma developing at a site of previous small bowel strictureplasty, and thus, it is believed that the risk of malignancy after strictureplasty is low.<sup>148,149</sup>

## Laparoscopy

Over the past 2 decades, laparoscopy has been dramatically changing all aspects of GI surgery. Specifically in colon and rectal surgery, laparoscopy has been widely used in benign disease,<sup>150,151</sup> including inflammatory bowel disease, and more recently in colon cancer.<sup>152</sup> Several single-institution small reports suggest that not only is laparoscopic surgery for Crohn's disease feasible and safe but also it reduces length of hospitalization and recovery and allows for a smaller wound, with an overall reduction in morbidity.<sup>153-166</sup>

Most patients with Crohn's disease are well suited for laparoscopy. They are usually young, otherwise healthy, and interested in undergoing an operation that involves minimal scarring, because they face the risk of multiple major abdominal operations in their lifetime. On the other hand, Crohn's disease represents a difficult arena even for the experienced open colorectal surgeon. Many of the unique features of Crohn's disease, such as the intense inflammation and thickened mesentery, enteric fistula, inflammatory masses or abscesses, and multiplicity of areas of intestinal

involvement, have deterred many surgeons from even considering a laparoscopic approach.

Two prospective controlled studies have shown several advantages of the laparoscopic-assisted approach over the conventional approach.<sup>153,155</sup> Bemelman and colleagues<sup>155</sup> compared 48 open ileocolic resections with 30 laparoscopic-assisted resections. This study showed similarly low morbidity rates in both groups but a shorter hospital stay and improved cosmetic results in favor of the laparoscopic group.<sup>155</sup> Alabaz and associates<sup>153</sup> compared 48 open ileocolic resections with 26 laparoscopic-assisted resections. The patients in the laparoscopic group returned to work more quickly, had better cosmetic results, and were more likely to have improved postoperative quality of life.<sup>153</sup> A prospective randomized trial comparing open and laparoscopic-assisted resections in 60 patients undergoing elective ileocectomy for Crohn's disease not complicated by abscess formation or complex fistula showed a faster postoperative recovery of respiratory function (measured as recovery of 80% of forced respiratory volume and forced vital capacity), shorter abdominal incisions, and longer performance time in the laparoscopic-assisted group. These differences were all statistically significant. With limited follow-up, there was no difference in recurrence rate.<sup>160</sup> This study demonstrated that in experienced hands, morbidity from the laparoscopic approach compares favorably with that of a conventional open approach. Obviously these results need to be confirmed by larger series with longer follow-up.

The indications for laparoscopic surgery for Crohn's disease should not differ from conventional open surgery, as described previously. Contraindications to a laparoscopic approach include patients who are critically ill and unable to tolerate the pneumoperitoneum due to hypotension or hypercarbia, patients with extensive intra-abdominal sepsis (abscess, free perforation, or complex fistula), and difficulty in identifying the anatomy (previous surgery, obesity, or adhesions). The same variety of surgical procedures described previously can be performed laparoscopically.

After induction of general anesthesia, the patient is placed on the operating table supine or in the modified lithotomy position. Rectal irrigation with diluted iodine solution is performed, especially in patients with involvement of the rectum and sigmoid colon. An epidural catheter is usually inserted at the time of surgery. The sympathetic blockade achieved with epidural

administration of local anesthetics and opioids prevents bowel distension, hence facilitating exploration of the GI tract and handling of the bowel. Depending on the procedure planned, 4 or 5 trocars are used, with the camera placed at the level of the umbilicus.

Every operation for Crohn's disease, whether open or laparoscopic, should start with a complete examination of the entire GI tract starting from the ligament of Treitz. The patient is placed in the reverse Trendelenburg position and right lateral decubitus with the assistant standing on the patient's left side retracting the transverse colon into the upper quadrants and the surgeon at the right of the patient or in between the patient's legs, tracing the intestine from the ligament of Treitz all the way to the ileocolic pedicle. This maneuver is facilitated by progressively rotating the patient from the reverse Trendelenburg to a full Trendelenburg position and left lateral decubitus. In the presence of skip areas of involvement from Crohn's disease, these are marked intracorporeally with sutures in order to facilitate retrieval of the diseased segments when the specimen is exteriorized.

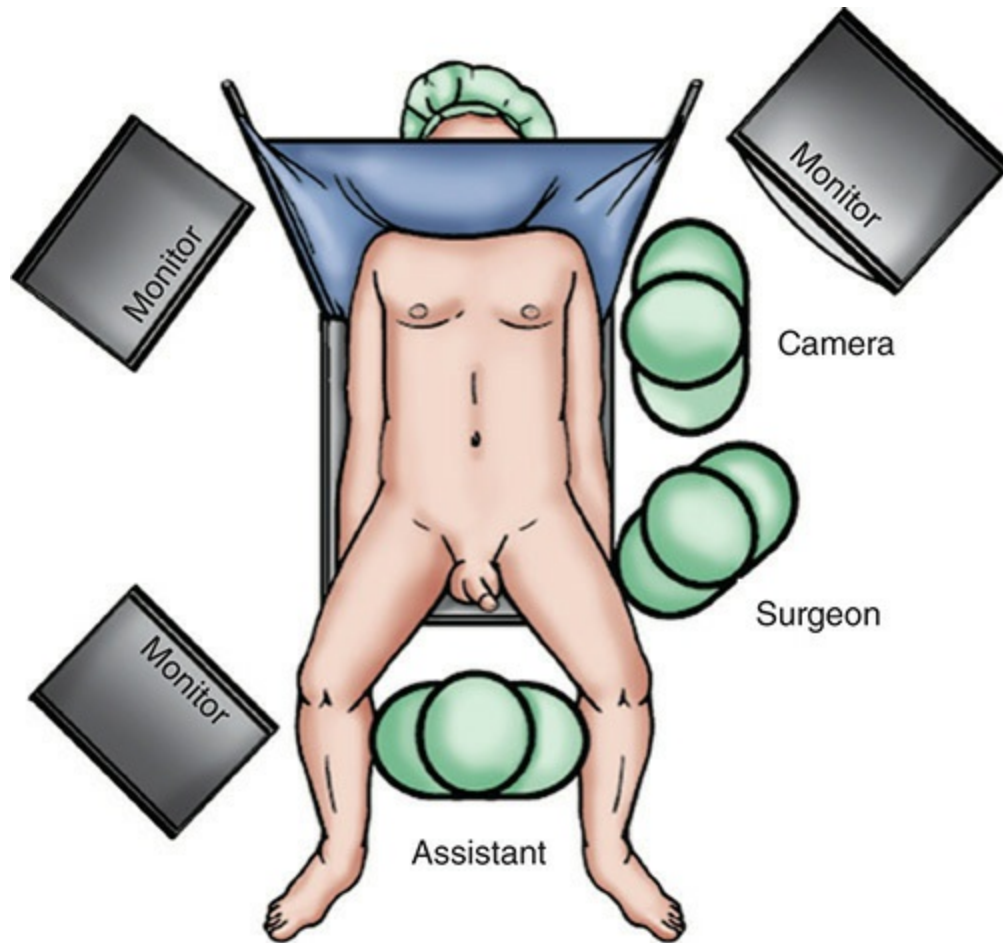

Laparoscopic-assisted ileocolic resection is the most commonly performed laparoscopic procedure for Crohn's disease. For laparoscopic ileocelectomy, a 4-trocar technique is used (Fig. 45-10). Trocars of 5 mm can be used exclusively, as a 5-mm, 30-degree camera offers the same resolution as larger ones and the vascular pedicles can be divided intracorporeally with 5-mm instruments. After the bowel has been evaluated in its entirety as previously described, the assistant, standing on the right of the patient or in between the patient's legs, places the ileocolic pedicle under tension with an intestinal grasper placed through the right lower quadrant trocar (Fig. 45-11). The surgeon on the patient's left side dissects and divides it (Fig. 45-12). Once this is accomplished, a medial-to-lateral submesenteric mobilization of the ascending colon all the way to the hepatic flexure is completed (Fig. 45-13). When the submesenteric mobilization is completed, the lateral colonic peritoneal reflection is divided all the way to the hepatic flexure (Fig. 45-14). The terminal ileum is completely mobilized by dividing the peritoneum at the level of the pelvic rim to allow a tension-free anastomosis through a small incision. It is often necessary to completely mobilize the hepatic flexure without dividing the right branch of the ileocolic vessels in order to facilitate exteriorization of the specimen (Fig. 45-15). It is imperative to make sure that the mobilization is adequate before evacuating the pneumoperitoneum and making an incision to avoid a difficult anastomosis through a small incision

or the need for a larger incision to exteriorize the specimen. Should this occur, a gel port can be applied through the abdominal incision to allow for creation of the pneumoperitoneum again and further intra-abdominal dissection.

**FIGURE 45-10** Port site locations for laparoscopic ileocecectomy.

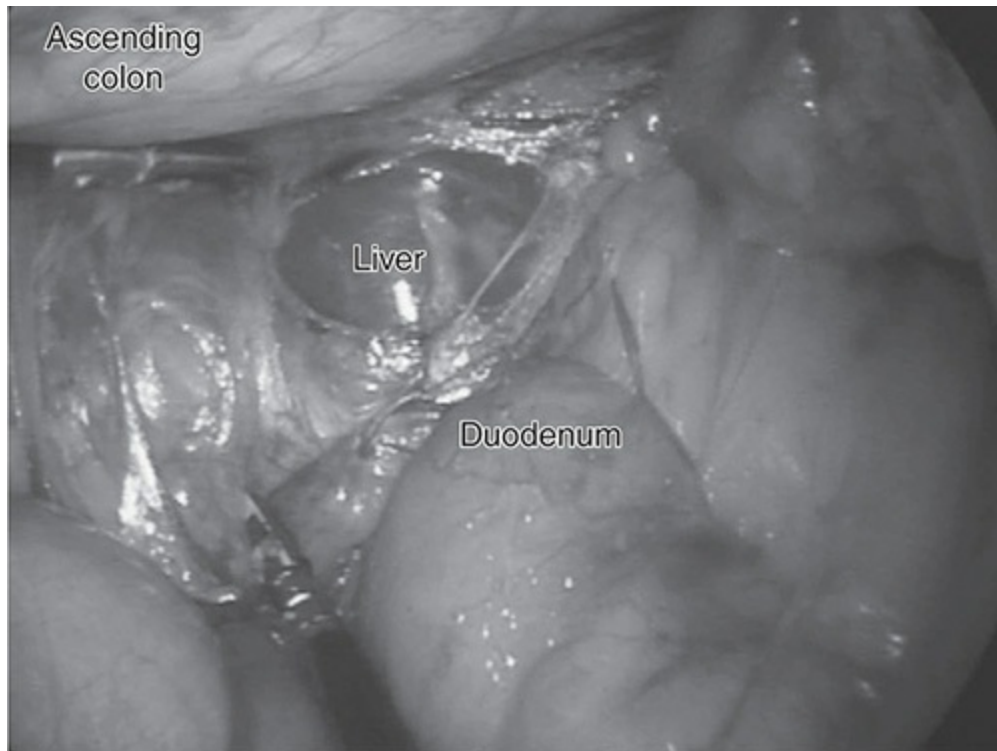

**FIGURE 45-11** Optimal position of the surgeons and assistants for laparoscopic ileocecectomy.

**FIGURE 45-15** Final mobilization of the hepatic flexure. (Reproduced with permission from the University of Chicago General Surgery Archives.)

Once the ileum, cecum, and ascending colon are fully mobilized, the instruments are removed. With the pneumoperitoneum still in place, the umbilical port site or the right lower quadrant port site is enlarged. The pneumoperitoneum is evacuated, and the specimen is exteriorized. The ileocolonic resection is then completed by dividing the remainder of the mesentery and the bowel extracorporeally. An anastomosis is then constructed in a standard fashion.

## **MANAGEMENT OF COMPLICATED CROHN'S DISEASE**

### **Crohn's Disease of the Duodenum**

Primary Crohn's disease of the duodenum almost always manifests with stricturing disease that can be managed by strictureplasty or with bypass procedures (Fig. 45-16). Fortunately, resection of the duodenum for Crohn's disease is almost never required.<sup>167-169</sup> Perforating Crohn's disease almost never affects the duodenum. When the duodenum is involved with Crohn's fistulas, it is always the result of disease within a distal segment (typically the terminal ileum or neoterminal ileum) that fistulizes into an otherwise normal duodenum.<sup>170</sup> Yet, Crohn's disease of the duodenum can offer a particularly challenging problem due to the retroperitoneal location of the organ and its intimate proximity to the pancreas.

**FIGURE 45-16** Upper GI study demonstrating Crohn's strictures of the duodenum. Contrast seen within the biliary ducts is due to deformity and incompetence of the ampullary sphincter secondary to the Crohn's disease. (Reproduced with permission from the University of Chicago General Surgery Archives.)

Strictureing disease of the duodenum is often focal, and many cases can be managed with a strictureplasty.<sup>171</sup> To safely accomplish a strictureplasty, the duodenum must be fully mobilized with a generous Kocher maneuver. Heinecke-Mikulicz strictureplasties can be safely performed in the first, second, and proximal third portion of the duodenum. Strictures of the last portion of the duodenum are better handled with a Finney strictureplasty constructed by creating an enteroenterostomy between the fourth portion of the duodenum and the first loop of the jejunum.

If the duodenal stricture is lengthy or the tissues around the stricture are

too rigid or unyielding, a strictureplasty should not be performed and an intestinal bypass procedure should be undertaken. The most common bypass procedure performed for duodenal Crohn's disease is a simple side-to-side retrocolic gastrojejunostomy.<sup>127</sup> This procedure effectively relieves the symptoms of duodenal obstruction related to Crohn's strictures but carries a high risk for stomal ulcerations. To lessen the likelihood of ulcerations forming at the anastomosis, it has been recommended that a vagotomy be performed along with the gastrojejunostomy.<sup>127</sup> Because of the concerns of vagotomy-related diarrhea, a highly selective vagotomy is preferred to a truncal vagotomy. If the stricturing Crohn's disease is limited to the third or fourth portions of the duodenum, a Roux-en-Y duodenojejunostomy to the proximal duodenum is preferred to a gastrojejunostomy.<sup>170</sup> The Roux-en-Y duodenojejunostomy has the advantage of bypassing strictures and eliminates the concern regarding acid-induced marginal ulceration and the need for vagotomy.

As noted previously, when the duodenum is involved with a Crohn's fistula, it is almost always the case that the diseased segment is located distal in the GI tract, and the duodenum itself is otherwise free of active Crohn's disease.<sup>170</sup> Most of these duodenal fistulas are small in caliber and asymptomatic, but larger fistulas may shunt the duodenal contents to the distal small bowel such that malabsorption and diarrhea result. In the majority of cases, duodenoenteric fistulas are identified with preoperative small bowel radiography; however, many are discovered only at the time of surgery.<sup>172</sup> With complex fistulizing disease involving an inflammatory mass, great care at the time of surgery should be undertaken to limit the size of the duodenal defect resulting from the resection of the fistula. Most duodenal fistulas are located away from the pancreaticoduodenal margin, and thus, these fistulas can be managed by resection of the primary Crohn's disease with primary closure of the duodenal defect. Larger fistulas or fistulas that are involved with a large degree of inflammation may result in a sizable duodenal defect. Such large defects may require closure with a Roux-en-Y duodenojejunostomy or with a jejunal serosal patch.<sup>172,173</sup> As noted previously, duodenal resections are almost never necessary for Crohn's disease, and they should be considered the surgical option of last resort.

## **Crohn's Disease of the Small Bowel**

## **COMPLETE INTESTINAL OBSTRUCTION**

Complete small intestinal obstruction resulting from Crohn's disease only rarely requires urgent surgical intervention, as the vascular supply to the intestinal loop is never compromised and almost all cases of complete or high-grade partial small bowel obstruction from Crohn's disease respond to conservative management. Such patients should be treated with nasogastric decompression, intravenous hydration, and steroid therapy.<sup>127</sup> This approach allows for resolution of the acute episode of obstruction in a vast majority of cases. Unfortunately, most patients whose Crohn's disease is severe enough to experience an episode of complete or high-grade partial obstruction are at high risk for recurrent episodes and persistent symptoms. For this reason, elective surgery should be considered once the episode of complete obstruction has resolved. The advantage of this approach is that surgery can be performed under safer conditions when the obstruction has resolved, the bowel is not distended or edematous, and an appropriate bowel preparation has been performed. If the obstruction fails to respond to appropriate conservative treatment, surgery is required. In these situations, the surgeon needs to have a high index of suspicion for small bowel cancer as the cause of the obstruction, as obstructions from cancers do not respond to bowel decompression and steroid treatment.

## **ILEOSIGMOID FISTULAS**

Ileosigmoid fistula is a common complication of perforating Crohn's disease of the terminal ileum. Typically, the inflamed terminal ileum adheres to the sigmoid colon that is otherwise normal and free of primary involvement of Crohn's disease. Most ileosigmoid fistulas are small and do not produce any symptoms. Asymptomatic ileosigmoid fistulas do not in and of themselves require operative management. On the other hand, large ileosigmoid fistulas can result in bypass of the intestinal contents from the terminal ileum to the distal colon and thus give rise to debilitating diarrhea (Fig. 45-17). Such symptomatic fistulas often fail to respond to medical therapy and should be managed surgically.

**FIGURE 45-17** Contrast enema demonstrating large ileosigmoid fistula. (Reproduced with permission from the University of Chicago General Surgery Archives.)

More than half of the ileosigmoid fistulas from Crohn's disease are not recognized prior to surgery.<sup>174</sup> For this reason, the surgeon should be prepared to deal with this complication in any case of Crohn's disease that involves the terminal ileum. Ileosigmoid fistulas can be managed by simple division of the fistulous adhesion and resection of the ileal disease. The defect in the sigmoid colon is then debrided, and simple closure is undertaken. In this manner, 75% of ileosigmoid fistulas can be managed.<sup>58,174</sup> The remainder requires resection of the sigmoid colon. Sigmoid colon resection is necessary when primary closure of the fistula is at risk for poor healing. This is the case either when the sigmoid is also involved in Crohn's disease, when the fistulous opening is particularly large, or when there is extensive fibrosis extending along the sigmoid colon. In addition, fistulous tracts that enter the sigmoid colon in proximity to the

mesentery can be difficult to close and often require resection and primary anastomosis.

## **ILEOVESICAL FISTULA**

Ileovesical fistulas occur in approximately 5% of Crohn's disease patients.<sup>99</sup> Hematuria and fecaluria are virtually diagnostic of ileovesical fistula, but these symptoms are absent in one-third of cases.<sup>175</sup> Small bowel x-rays, cystograms, and cystoscopy often do not detect the fistula. Air within the bladder, as noted on CT scan, is often the best indirect evidence for the presence of an enterovesical fistula. An ileovesical fistula is an indicator of complex fistulizing disease, as most ileovesical fistulas occur along with other enteric fistulas. For example, as many as 60% of patients with an ileovesical fistula will also have an ileosigmoid fistula.<sup>58</sup>

The necessity for surgery for ileovesical fistula is controversial. Many patients with ileovesical fistulas can be managed medically for extended periods of time without significant complications. Healing rates with medical treatment are not clearly defined, but they are probably low, and most patients with ileovesical fistulas will ultimately undergo surgery. Surgery is indicated when recurring urinary infections occur, particularly pyelonephritis, with concomitant potential for worsening of renal function.

Surgical treatment of ileovesical fistulas requires resection of the ileal disease with closure of the bladder defect. Most ileovesical fistulas involve the dome of the bladder, and thus debridement and primary closure can be accomplished without risk of injury to the trigone. Decompression of the bladder with an indwelling Foley catheter should be continued postoperatively until the bladder is confidently healed without leaks. A cystogram taken on postoperative day 5 is a convenient means for confirming the seal of the bladder repair and the safety of removing the Foley catheter.

## **ENTEROVAGINAL AND ENTEROCUTANEOUS FISTULAS**

These are rare fistulas caused by perforating small bowel disease draining through the vaginal stump in a female who has previously undergone a hysterectomy or through the abdominal wall, usually at the site of a previous scar. These fistulas often require surgical intervention because they cause

physical discomfort and personal embarrassment. Surgical treatment requires resection of the small bowel disease. The vaginal cuff does not need to be closed; the chronic infection along the abdominal wall fistulous tract requires debridement and wide drainage to allow healing by secondary intention.

## ABSCESS

Intra-abdominal abscesses that result from Crohn's disease tend to follow an indolent course with modest fever, abdominal pain, and leukocytosis. Rapidly progressive and overwhelming sepsis is not typical for the clinical course of Crohn's disease-related abscesses. In fact, in up to one-third of intra-abdominal Crohn's abscesses, preoperative clinical signs of localized infection are absent and the abscesses are discovered only at the time of operation. When an abscess is suspected or an abdominal mass is palpated, a CT scan should be obtained, as 50% of tender intra-abdominal masses will harbor an abscess collection within.<sup>106</sup> The CT scan can detect most chronic abscesses and can also delineate the size and location of the abscess as well as the relationship of the abscess to critical structures such as the ureters, duodenum, and the inferior vena cava (Fig. 45-18).

**FIGURE 45-18** CT scan of the pelvis demonstrating large Crohn's abscess. (Reproduced with permission from the University of Chicago General Surgery Archives.)

Most abscesses with Crohn's disease are in fact very small collections that are contained within the area of diseased intestine and its mesentery. In the case of small intraloop or intramesenteric abscesses, resection of the defective segment and its mesentery often extirpates the abscess such that drains are not necessary and primary anastomosis can be performed without risk.

Large abscesses related to Crohn's disease are best managed with CT-guided percutaneous drainage.<sup>108</sup> Percutaneous drainage is often very effective at controlling the sepsis and healing the abscess cavity.<sup>107</sup> With percutaneous drainage of a Crohn's disease abscess, an enterocutaneous fistula often occurs as the abscess typically connects to a deeply penetrating sinus emanating from a segment of Crohn's disease-affected intestine. Percutaneous drainage then completes the fistulous tract from the intestine through the sinus to the abscess cavity and out the drain. Such a fistula may spontaneously close or it may persist, and the intestine may continue to be a source of sepsis. With successful drainage of the abscess, the sepsis often clears well enough that it can be tempting to try to manage the disease without subsequent surgery. Published clinical data on the optimal approach to such patients are unfortunately lacking. Even so, in the absence of Crohn's symptoms, initial nonoperative management after successful percutaneous drainage can be undertaken in carefully selected patients.<sup>109</sup> On the other hand, if drainage through the fistula continues, surgical resection of the affected segment of intestine becomes necessary.

## **PERFORATION**

Free perforation is a surprisingly uncommon phenomenon because the chronic progressive inflammation of Crohn's disease normally leads to adhesions with adjacent structures. Most perforations from Crohn's disease occur in the ileum and are usually proximal to a stenotic lesion.<sup>110,127</sup> The diagnosis of free perforation is made by detecting a sudden change in the patient's symptoms along with the development of the physical findings of peritonitis or the identification of free intraperitoneal air as demonstrated on plain x-rays or CT scans. Free perforation is an absolute indication for emergent laparotomy with resection of the diseased segment and exteriorization of the proximal bowel as an end ileostomy. The distal bowel end can be exteriorized as a mucous fistula or closed as a defunctionalized

pouch, depending on the degree of peritoneal contamination. Creation of a primary anastomosis even with a proximal protecting loop ileostomy carries a high risk of anastomotic breakdown and should be avoided. Primary closure of the perforation should never be attempted, as sutures will not be able to approximate the edges of the perforated, edematous, and diseased bowel in a satisfactory and tension-free way and the presence of a distal intestinal stenosis or partial obstruction will cause an increase in the intraluminal pressure at the level of the local repair with subsequent dehiscence.

## **HEMORRHAGE**

Hemorrhage from small bowel Crohn's disease is managed by resection of the diseased portion of intestine. For patients with multiple skip areas of Crohn's disease, small bowel angiography may be attempted to localize the exact site of bleeding.<sup>111</sup> Localization with angiography may be unsuccessful if the bleeding is episodic or insufficiently brisk to be identified with angiography. In patients in whom small bowel hemorrhage stops spontaneously, the risk for rebleeding is high. Thus elective resection of active Crohn's disease after the first episode of hemorrhage should be considered.

## **Crohn's Disease of the Colon**

The optimal management of Crohn's disease of the colon is dependent on the distribution and the location of the disease (Fig. 45-19).

**FIGURE 45-19** Contrast enema demonstrating severe Crohn's colitis with multiple high-grade strictures. (Reproduced with permission from the University of Chicago General Surgery Archives.)

## **CECAL DISEASE**

Colonic disease limited to the cecum is almost always associated with terminal ileal disease. The terminal ileitis is the predominant component of the ileocecal disease. Terminal ileal disease with extension into the cecum behaves much like disease limited to the terminal ileum. For this pattern of disease, surgical resection should encompass the margins of gross disease with an anastomosis between the neoterminal ileum and the proximal ascending colon. Recurrence of disease at the anastomosis or at the preanastomotic ileum is common, but the risk for recurrent disease within the distal colon or the rectum is low. This pattern of disease does not imply a

predisposition to more extensive colonic disease.

## **RIGHT-SIDED COLITIS**

Disease involving the entire right colon can occur alone but more typically occurs along with disease of the terminal ileum. Extensive involvement of the right colon as a form of ileocolonic disease is less common than the ileocecal pattern. Surgical treatment involves a standard right hemicolectomy to encompass the gross limits of the disease. An anastomosis between the ileum and the transverse colon is then fashioned. With a standard right hemicolectomy, the anastomosis may rest in proximity to the duodenum. Recurrent disease at the preanastomotic ileum may thus secondarily involve the duodenum. This phenomenon can place the patient at risk for substantial morbidity should inflammatory encasement of the duodenum or fistulization into the duodenum occur. For this reason, it is advantageous to protect the duodenum by interposing omentum between the duodenum and the ileocolonic anastomosis.

## **EXTENSIVE COLITIS WITH RECTAL SPARING**

Extensive colitis with sparing of the rectum occurs in approximately 20% of individuals suffering from Crohn's colitis. In such cases, the rectum should be closely examined endoscopically, and, should the rectum be truly free of disease, a total abdominal colectomy with ileorectal anastomosis can be performed when fecal continence is adequate and the patient does not have extensive perineal septic complications. This procedure often results in good long-term function and enables many patients to avoid an ileostomy. Older patients or patients who have undergone an extensive small bowel resection may experience frequent and loose stools to the point that incontinence may develop after an ileorectal anastomosis. Additionally, recurrent disease within the rectum can result in significant deterioration of bowel function requiring further medical or even surgical intervention. Up to 50% of patients who undergo an ileorectal anastomosis for colonic Crohn's disease will ultimately require a proctectomy with permanent ileostomy because of poor bowel function with incontinence or recurrence of disease in the rectum.<sup>176</sup>

## **PROCTOCOLITIS**

Surgical management of extensive involvement of the colon and rectum requires total proctocolectomy with permanent ileostomy in almost all cases. In most instances, a total proctocolectomy can be performed in a single step. The presence of severe perianal disease, however, may require that the procedure be performed in 2 stages. At the first stage, the intra-abdominal colon and majority of the rectum are removed and a short rectal stump is created at the level of the levator muscles. At the same time, perineal abscesses are drained and fistulas are laid open. This first step removes the diseased colon and rectum without creating a perineal wound that may be difficult to heal in the presence of active perineal sepsis. Once the perineal sepsis is cleared and the perineum is healed, the short anorectal stump can be removed through a perineal approach. At the second stage, primary closure of the perineum can be accomplished without the high risk of persistent perineal wounds.

Restorative procedures such as an ileal pouch–anal anastomosis or continent ileostomy have traditionally not been offered to patients who have Crohn’s colitis because of the recurrent nature of the disease. Even so, some of these procedures have been performed in patients whose diagnosis of Crohn’s disease was not known or suspected at the time of surgery. Various reports indicate that recurrence of Crohn’s disease within the pouch is common and removal of the pouch is often necessary. On the other hand, patients who do not suffer from recurrent disease generally do well and typically experience good pouch function.

While it is commonly accepted that restorative proctocolectomy with J-pouch ileoanal anastomosis should not be undertaken for Crohn’s colitis, there is a specific pattern of Crohn’s disease that appears to be at low risk for problems with recurrence after an ileoanal anastomosis.<sup>177,178</sup> In cases in which Crohn’s disease is limited to the colon and rectum without any history of small bowel involvement and without any perineal manifestations, the risk for pouch failure after ileoanal anastomosis appears to be low, and such patients can be considered for the ileoanal procedure. This particular pattern of Crohn’s disease, however, is rare, as most patients with Crohn’s proctocolitis will have some degree of small bowel involvement or perineal manifestations and thus would not be considered candidates for the ileoanal procedure.

## PROCTITIS

Crohn's inflammation limited to the rectum is unusual. Surgical management of Crohn's proctitis mandates proctectomy with permanent stoma. The need for resection of the normal proximal colon is controversial.

Abdominoperineal resection with end sigmoid colostomy has been associated in some reports with a high risk for stomal complications and recurrent disease in the proximal intestine when compared to total proctocolectomy with end ileostomy. For these reasons, total proctocolectomy with ileostomy has been recommended for Crohn's disease limited to the rectum and distal colon. This more extensive resection may be of greater value in younger patients who have no history of small bowel Crohn's disease, as it appears that colorectal Crohn's disease without small bowel involvement is unlikely to result in recurrence within the small bowel once a proctocolectomy is performed.<sup>43</sup> If the patient has undergone a prior resection for small bowel Crohn's disease, they may be at risk for high output from the ileostomy and therefore may benefit from the preservation of colonic absorptive capacity. Preservation of the colonic absorptive capacity may be beneficial also in the elderly patient. Thus, these patients may be better managed with a proctectomy and end sigmoid colostomy.

Proctectomy for Crohn's disease does not require a wide excision of perirectal tissue. To avoid injury to pelvic sympathetic and parasympathetic nerves, the dissection should be undertaken close to the rectal wall. This is sometimes challenging in the presence of severe rectal mesenteric inflammatory reaction. In the absence of significant perianal disease, the perineal dissection is best carried out along the plane between the internal and external sphincters.<sup>179</sup> This intersphincteric dissection allows for a perineal closure that is associated with fewer complications and better healing than wider dissections that encompass the entire sphincter mechanism. In some patients, fistula from the perianal Crohn's disease can traverse the intersphincteric plane and a wider dissection is required in order to encompass the diseased tissue. In the presence of significant perianal disease, a staged approach, as described previously, can be used as an option. Occasionally, however, because of extensive rectal disease, closure of the rectal stump may be technically challenging or not feasible, forcing the surgeon to proceed with a proctectomy in the face of perianal sepsis. These dissections may need to be carried out widely, and extensive loss of perianal

skin and subcutaneous tissue may occur. The resultant defects are often too large for primary closure, and closure may require advanced tissue transfer techniques such as gluteal flaps, gracilis flaps, or myocutaneous rectus abdominis pedicle flaps. These closures may have to be staged as well in the presence of perineal sepsis. Large open perineal wounds may be managed temporarily or definitively with the assistance of the vacuum-assisted closure device. This device allows for rapid contracture of the wound and facilitates healing.

## **SEGMENTAL COLITIS**

The optimal management of segmental colitis is dependent primarily on the location of the disease and secondarily on the presence and severity of concurrent perineal complications, the degree of fecal continence, and the natural history of the disease in the residual colon. Segmental involvement of the right colon should be managed by simple right hemicolectomy with ileotransverse anastomosis. For segmental disease involving the transverse colon, an extended right hemicolectomy is generally preferred to a segmental transverse colectomy. Such an approach may have a lower risk of recurrence compared to a segmental resection of the transverse colon. In addition, the extended right hemicolectomy avoids a colocolonic anastomosis that is associated with a higher risk for anastomotic dehiscences and strictures.

For disease in the descending or sigmoid colon, the appropriate surgery is more controversial. Presence and severity of concurrent perineal complications, the degree of fecal continence, and the natural history of the disease in the residual colon all play a role in deciding on the approach for each individual patient. Studies have indicated that segmental colonic resection with colocolonic anastomosis or rarely colonic strictureplasty can be performed with overall good results.<sup>180,181</sup> However, such a strategy may be at risk for early disease recurrence within the colon.<sup>43</sup> Even if the risk for recurrence is higher with segmental resection, the benefits of preserving the absorptive capacity in appropriately selected cases may outweigh the higher risk of recurrence.

## **PERIANAL DISEASE**

The perianal manifestations of Crohn's disease include abscesses, fistulas,

fissures, anal stenosis, and hypertrophic skin tags.<sup>182,183</sup> Perianal Crohn's disease originates from inflammation within the anal crypts. This inflammation gives rise to sepsis and to fistulization (Fig. 45-20). Perianal Crohn's disease is common and occurs in one-third of the patients who suffer from intestinal Crohn's disease.<sup>45</sup> Perianal Crohn's disease is usually associated with active or quiescent disease elsewhere within the GI tract. It is controversial as to whether the activity of perianal Crohn's disease parallels that of the intestinal disease. There is also controversy over whether medical or surgical control of the intestinal disease can ameliorate the perianal manifestations. Unlike idiopathic perianal abscesses and fistula-in-ano that occur in patients without Crohn's disease, perianal Crohn's disease tends to be recurrent, complex, and sometimes progressive.

**FIGURE 45-20** Dynamic proctogram demonstrating Crohn's fistula-in-ano. (Reproduced with permission from the University of Chicago General Surgery Archives.)

Surgical incision and drainage are required to manage perianal abscesses (Fig. 45-21). Attempts at treating purulent collections with antibiotics alone are invariably unsuccessful. With surgical drainage of the abscess, the incision should be placed close to the anal margin. The cavity may be packed with ribbon gauze or drained with a 10- to 16-Fr mushroom catheter. If a fistula tract can be identified at the time of drainage of the suppuration, a loose seton may be placed to ensure adequate drainage.

**FIGURE 45-21** CT scan demonstrating a large perirectal abscess secondary to Crohn's disease. (Reproduced with permission from the University of Chicago General Surgery Archives.)

Uncomplicated submucosal or intersphincteric fistulas are best treated with an initial trial of either metronidazole or ciprofloxacin. These antibiotics are moderately effective in promoting healing of Crohn's fistulas and are associated with a low risk of complication.<sup>184,185</sup> If a low-lying submucosal or intersphincteric fistula fails to heal with antibiotic treatment, a surgical fistulotomy can be performed. These low-lying fistulas typically heal well after fistulotomy, and the risk of incontinence is low.

Surgical fistulotomies and cutting setons should not be used for suprasphincteric fistulas and should also be avoided for most transsphincteric

fistulas. For complex fistulas, the risk for surgical complications is higher, and more aggressive medical therapy is warranted before surgery is recommended. Medical treatment for extensive Crohn's fistulas includes the use of 6-MP, azathioprine, and cyclosporine. Probably the most effective agent at promoting healing of perianal fistulas related to Crohn's disease is infliximab. With infliximab treatment, healing of complex perianal fistulas is seen in 60% of cases.<sup>186,187</sup> Recurrence of the fistula after infliximab is discontinued, however, may be high. Additionally, persistent stasis or sepsis within the fistula tract can impede effective healing with medical treatment. To provide for adequate drainage throughout the fistula tract, many patients may benefit from placement of setons. The use of setons with infliximab therapy can improve the overall effectiveness of infliximab.<sup>188</sup> Typically the seton is placed prior to the initiation of infliximab therapy and then is removed after the second or third dose.

Fibrin glue has been used for the treatment of Crohn's disease-related fistulas, but reported experience is limited. Success rates with this approach are low, but given the low risk of complications, an attempt at fibrin glue may be worthwhile in selected cases.<sup>189,190</sup>

Closure of the internal opening of the fistula with a rectal advancement flap can be considered in cases of Crohn's disease.<sup>191</sup> With this approach, an incision is made at the dentate line, and a flap of mucosa and muscularis is undermined and advanced down over the internal opening of the fistula. The advancement flap is then sutured into position with absorbable sutures. Rectal advancement flaps for Crohn's disease have a low risk for anal incontinence but are associated with a high failure rate. Rectal advancement flaps are not appropriate in patients in whom the rectal mucosa is involved with Crohn's disease. In severe cases of perianal disease that do not respond to aggressive medical and surgical therapy, fecal diversion with a stoma may be necessary. Diversion of the fecal stream typically results in significant relief of local inflammation and can assist in the healing of perianal fistulas. Proctectomy is indicated when perianal disease is unrelenting or when damage to the sphincters results in debilitating incontinence.

## **POSTOPERATIVE RECURRENT DISEASE**

Crohn's disease carries a high risk for recurrence after surgery. The actual

incidence of recurrent disease depends on the defining parameters of recurrence. For example, histologic evidence for recurrence can be seen in many patients within days of surgical resection.<sup>192</sup> Endoscopic evidence for recurrent Crohn's disease can be seen in over 80% of patients within 3 years.<sup>193</sup> Most cases of histologic or endoscopically detected recurrences, however, do not go on to produce symptoms of Crohn's disease. For this reason, histologic or endoscopic evidence of recurrent disease may be used as an end point in investigative studies but is not typically used as a guide for clinical management.<sup>194</sup>

The development of symptoms related to recurrent Crohn's disease activity is the most commonly applied definition of disease recurrence, as it is the recurrence of symptoms that has the most relevance to the patient. The onset of symptoms of recurrent Crohn's disease is often insidious, and the severity of symptoms varies greatly. To create a reproducible standard for recurrence of Crohn's disease symptoms, the Crohn's Disease Activity Index (CDAI) can be applied as a means of measuring recurrent disease.<sup>195,196</sup> A CDAI of greater than 150 is generally accepted as defining clinical recurrence. Once symptoms suggestive of recurrent disease occur, it is still necessary to carry out radiologic and endoscopic tests to confirm that the symptoms are in fact related to Crohn's disease.

The clearest end point as a definition of recurrence is the need for reoperation. Dates of surgery are readily documented even in a retrospective fashion. While reoperation is the most precise definition of recurrence, even this standard does not allow for accurate and reproducible comparisons between series as some centers may submit patients to surgery earlier than other centers.

Reported crude and cumulative recurrence rates vary greatly. Symptomatic or clinical recurrence occurs in about 60% of patients at 5 years, and recurrences increase with time such that at 20 years clinical recurrence can occur in between 75% and 95% of cases.<sup>35,197,198</sup> Reports of surgical recurrence rates range from 10% to 30% at 5 years, 20% to 45% at 10 years, and 50% to 70% at 20 years.<sup>74,100,197-201</sup>

While many factors that may influence the risk of recurrence have been studied, the cumulative literature has validated very few as true risk factors. The data are conflicting for most of the proposed predictors of recurrent Crohn's disease. Much of the clinical data examining potential risk factors

are confounded by poorly defined end points and improper study design. There is, however, general consensus that cigarette smoking has a significant effect on the clinical course of Crohn's disease.<sup>30</sup> Smoking not only exacerbates existing Crohn's disease but also has been identified as a risk factor for the development of recurrent Crohn's.<sup>27,28,30</sup> What is so striking about the effect of cigarettes on Crohn's disease is that smoking has the opposite effect on what is thought to be a very similar disease, ulcerative colitis.<sup>29</sup> While smoking exacerbates Crohn's disease, it seems to lessen the activity of ulcerative colitis.

The mechanism by which smoking results in exacerbation of Crohn's disease is not known. Smoking is an independent risk factor for endoscopic, symptomatic, and surgical recurrence.<sup>31,32</sup> The risk from smoking appears to be dose-related, with heavy smokers being at higher risk. This effect is reversible, as smokers who quit smoking prior to surgery can lower their risk of recurrence to a level similar to that of nonsmokers. Because of the harmful effects on the clinical course of Crohn's disease combined with the many other clearly established health hazards caused by cigarette smoking, all patients with Crohn's disease should be strongly counseled to quit smoking.

There is concern that NSAIDs may exacerbate the activity of both ulcerative colitis and Crohn's disease.<sup>74,82</sup> Although there are no studies that have examined the specific issue of NSAIDs and the risks for postoperative recurrence of Crohn's disease, the currently available data certainly warrant some caution, and patients with Crohn's disease should be advised to avoid NSAIDs.

## **POSTOPERATIVE PREVENTION AND MAINTENANCE THERAPY**

### **Medical Prevention/Maintenance**

The risk for recurrent disease can be lessened with postoperative maintenance therapy. Traditionally the most common agents used for postoperative suppression of disease were controlled-release 5-ASA (Pentasa) and 6-MP.<sup>77-79</sup> Maintenance with 5-ASA is associated with few side effects, but up to 16 pills have to be taken daily. 6-MP is less expensive and is taken on a once-

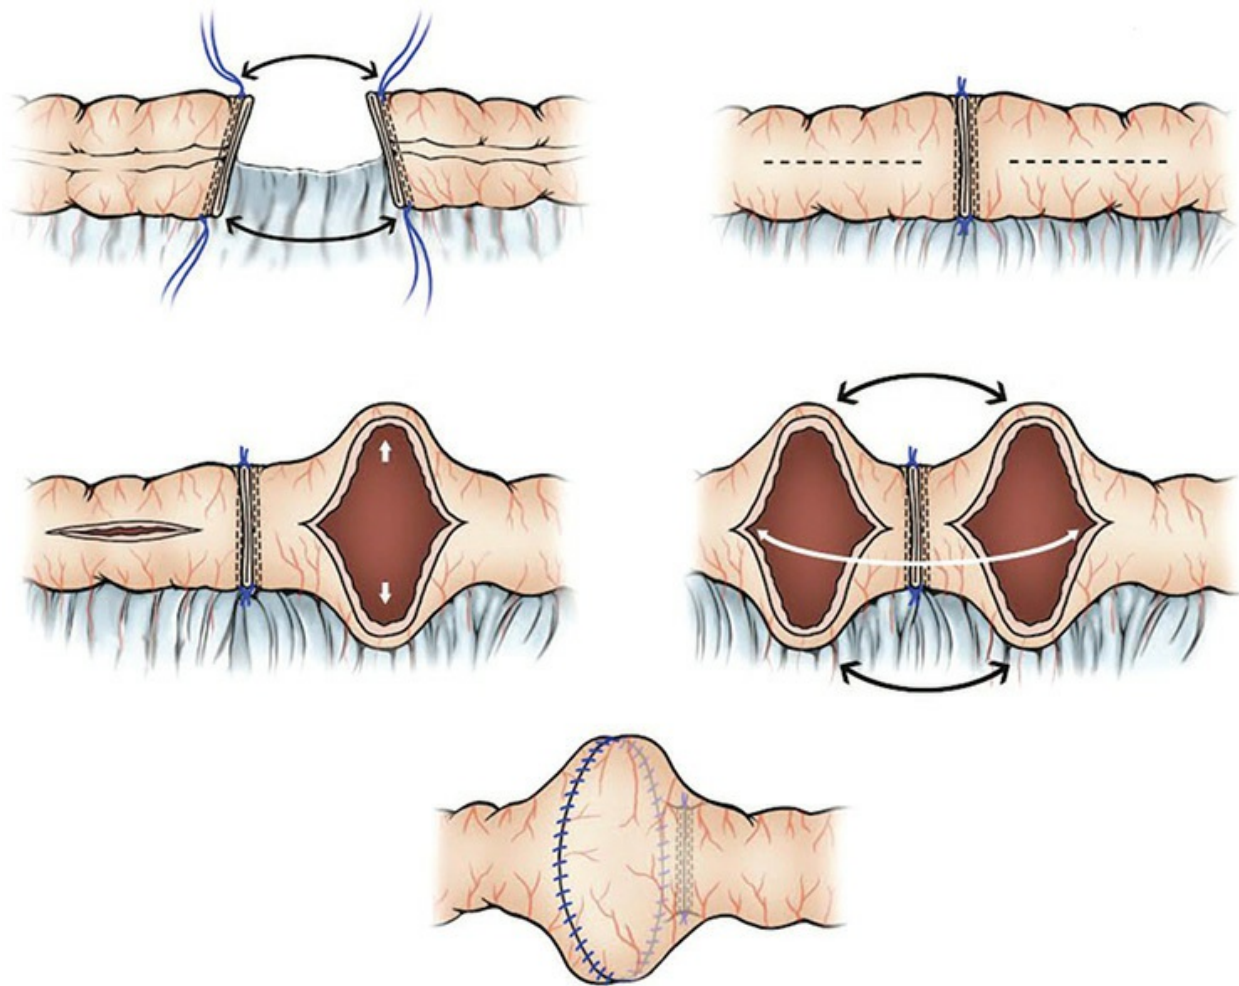

daily basis. Additionally, 6-MP may be more effective in diminishing the risk of recurrence.<sup>77</sup> 6-MP, however, is associated with potential bone marrow suppression, so that patients on 6-MP maintenance must be followed with periodic blood cell counts. The effect of these agents on the natural course of Crohn's disease is not dramatic, and many patients will go on to develop recurrence while on maintenance therapy. The largest benefit demonstrated with 6-MP in a multicenter trial showed a decrease of symptomatic recurrence from 77% with placebo to 50% with 6-MP.<sup>77</sup> Recently, anti-TNF agents have shown efficacy in the prevention of Crohn's disease after resection. Most studies of anti-TNF agents have focused on 1-year clinical and endoscopic outcomes. A more recent randomized controlled trial by Regueiro et al<sup>202</sup> followed patients for 5 years after their initial surgery and showed a decreased recurrence rate and longer time to recurrence in patients being treated with anti-TNF medications. The options for maintenance therapy should be considered for most patients with Crohn's after operative intervention, but the decision for such therapy must be individualized for each patient.<sup>203-205</sup>

## Surgical Prevention

Recurrent Crohn's disease is most likely to occur in proximity to the location of the previously resected intestinal segment, typically at the anastomosis and preanastomotic bowel.<sup>100</sup> This is particularly true for terminal ileal disease. Additionally, the length of small bowel involved with recurrent disease parallels the length of disease originally resected.<sup>206,207</sup> Short-segment disease tends to recur over a short segment of the preanastomotic bowel, and lengthy disease typically is followed by lengthy recurrence. In addition, stenotic disease tends to recur as stenotic disease, and perforating disease tends to recur as perforating disease.<sup>197</sup>

There are mixed data on the role of surgical technique and procedure type in minimizing postoperative recurrence. Guo et al<sup>208</sup> performed a meta-analysis in 2013 evaluating side-to-side anastomoses in comparison to hand-sewn end-to-end anastomoses for small bowel disease and were unable to demonstrate a reduction in postoperative recurrence with side-to-side anastomoses. The difference between a side-to-side or end-to-end anastomosis for an ileocolic resection was evaluated by Mcleod et al<sup>209</sup> in a

randomized controlled trial, and no difference was found between the 2 anastomotic types. Interestingly, however, Yamamoto et al<sup>210</sup> had previously demonstrated that in patients who underwent strictureplasty at a diseased segment there seemed to be a protective effect of the strictureplasty as these patients have lower recurrence than those undergoing segmental resection. More recently, Japanese surgeon Toru Kono has described a new antimesenteric functional end-to-end hand-sewn anastomosis (Kono-S) (Fig. 45-22). Initial results from this author have been very encouraging, showing lower rates of recurrence compared to historical controls (0% vs 15%;  $P = .0013$ ) at 5 years. A multicenter randomized trial is under way in the United States to evaluate the Kono-S anastomosis compared with a standard anastomosis.<sup>211</sup>

**FIGURE 45-22** Antimesenteric functional end-to-end hand-sewn (Kono-S) anastomosis.

The Kono-S anastomosis is performed by first identifying and mobilizing the segment of bowel to be resected. Control of the lumen of the bowel proximal and distal to the disease segment is obtained by firing a linear GIA stapler with 4.8 staples placed perpendicular to the mesentery. The intervening mesentery is divided very close to the bowel to preserve innervation and vascularization. The GI continuity is then reestablished with a side-to-side antimesenteric enteroenteric anastomosis. Specifically, the 2 stapled suture lines are brought together with interrupted 3-0 silk sutures to serve as a support structure for the anastomosis. A 7- to 8-cm enterotomy is then created, starting 0.7 cm proximal to the stapled suture line on the antimesenteric side of the afferent intestinal loop in a distal to proximal direction; a similar length enterotomy is then created on the antimesenteric portion of the efferent intestinal loop, starting at 0.7 cm from the stapled suture line in a proximal-to-distal direction. The anastomosis is then performed in a side-to-side transverse direction between the 2 enterotomies with an internal layer of running 3-0 Vicryl. The anastomosis is then reinforced with an outer layer of interrupted 3-0 silk Lembert stitches. While preliminary results of the Kono-S are encouraging, the debate over surgical and anastomotic technique in Crohn's is far from over, and more research is needed.

## CONCLUSIONS

Management of Crohn's disease is complex and requires a multidisciplinary team approach. Diagnosis involves a focus on patient clinical exam, supplemented by radiology and confirmed by pathology. Initial management is typically medical and has had several advances over the past few years. Surgical intervention is typically reserved for refractory disease or complications of the disease and should be managed by surgeons with significant clinical expertise in inflammatory bowel disease working closely with their GI colleagues. While significant progress has been made over the past 30 years and new medications are changing the course of treatment, much more work remains to be done, including understanding how these medications will shift surgical treatment and whether specific surgical techniques lower the risk of recurrent disease.

# ULCERATIVE COLITIS

*Christina W. Lee • Freddy Caldera • Tiffany Zens • Gregory D. Kennedy*

## INTRODUCTION

Ulcerative colitis (UC) is a chronic relapsing and remitting intestinal disorder plagued by diffuse and continuous mucosal inflammation involving the rectum, and extending proximally throughout the colon. As one of two well-known disease types grouped under the umbrella of inflammatory bowel diseases (IBDs), the inflammatory hallmark in UC is limited to the mucosa. The etiology of UC is not yet completely understood; however, research over the last several decades has led to a better understanding of cellular, immunological, and molecular mechanisms involved in its pathogenesis. Scientists continue to discover new and innovative approaches in the development of potential biomarkers, diagnostic tools, and treatment options for patients with this disease. In this chapter, the authors present a broad overview of disease epidemiology, presentation and diagnosis, and current options for medical management with a focus on the surgical approaches to treatment of UC.

## EPIDEMIOLOGY

Over 1.5 million Americans and 2.2 million Europeans are currently estimated to be afflicted with UC.<sup>1</sup> The incidence of UC in the United States and Northern Europe is 9 to 20 cases per 100,000 patients per year.<sup>2</sup> Its prevalence ranges from 156 to 291 cases per 100,000 people.<sup>2</sup> UC is less common in Eastern and Southern European countries, specifically among Asian, Hispanic, and African American populations. Ashkenazi Jews have demonstrated some of the highest frequencies of UC, estimated at 3 to 5 times higher than other ethnic groups.<sup>2</sup> No significant gender discrepancy has been documented. Disease onset is not targeted to a specific age group and may present at any time. However, the age of onset is bimodal in distribution, wherein the primary peak is typically 15 to 30 years and a second, smaller peak occurs in the sixth to seventh decade of life.

## PATHOPHYSIOLOGY

Although the exact pathophysiology of UC remains unknown, it is postulated to be the result of a combination of dysregulated interactions between the host's genetic predisposition, environmental triggers and exposures, and the intestinal microbiome, all of which undoubtedly interact with the innate and adaptive immune systems. The overarching hypotheses suggest that the above-mentioned factors function dependently on one another to establish and maintain intestinal homeostasis, which is altered upon dysregulation of any of the contributing players, presenting a platform upon which UC can develop.

Studies in molecular genetics have shed light onto the genetic contribution to the development of UC. Monozygotic twin studies have demonstrated concordance rates of 16% in UC.<sup>3</sup> In addition, 8% to 14% of patients with UC were found with a family history of IBD, and a first-degree family member with UC statistically increases a person's risk of development of IBD by approximately tenfold.<sup>3,4</sup> To date, genome-wide association studies have identified 163 loci linked to IBD.<sup>3</sup> Although disease-specific genes have not yet been identified, patients with UC are often found with mutations of epithelial barrier function, innate and adaptive immune responses, and response to oxidative stress.

Over the years, it has become clear that the environment plays a pivotal role in the onset and progression of UC. This was first evidenced by epidemiological studies demonstrating an increased incidence of disease from 5.3 to 10 per 100,000 people in second-generation Asian immigrants to the United Kingdom.<sup>5</sup> Many modifiable risk factors have been identified in the literature. Western diets high in saturated fats, refined sugars, meats, and milk products are linked to increased risk of developing UC. In contrast to Crohn's disease, smoking has been found to have a protective effect in UC. Smokers are less likely to develop UC and milder disease.<sup>3</sup> Breastfeeding has also shown protective effects against UC if continued for greater than 3 months.<sup>1</sup> Some evidence suggests that lifestyle factors such as high stress, poor sleep habits, and decreased exercise can be risk factors for development of UC. Finally, studies have demonstrated patients who have undergone an appendectomy are at decreased risk of developing UC, although the mechanism of this protective effect is not fully understood.

Alterations in the gut microbiome have been implicated in the development of UC, generating a greater emphasis in research to understand this complex interaction. To illustrate this, an infection with *Salmonella* or *Campylobacter* has been associated with an 8- to 10-fold increased risk of developing of UC the following year.<sup>6</sup> Likewise, use of certain medications, such as NSAIDs and antibiotics, which can alter the gut microflora, is linked to an increased risk of IBD development.<sup>7</sup>

## DIAGNOSIS

The diagnosis of UC is established through a combination of clinical presentation, laboratory tests, imaging, and endoscopic evaluation. A universal scoring or classification system has yet to be widely accepted. Several parameters have been described, such as disease severity (mild, moderate, severe, or fulminant), age of onset, and extent of disease (proctitis, proctosigmoiditis, left-sided, or pan-colitis). All other forms of colitis including infectious, ischemic, and radiation colitis should be excluded prior to diagnosis of UC in a patient.

Typically, patients will present with complaints of hematochezia, abdominal pain, diarrhea, pain with defecation, occult or gross rectal bleeding, and/or tenesmus. Symptoms gradually progress over the course of

several weeks to months. Eventually, the patient may develop systemic symptoms including low-grade temperatures, weight loss, and fatigue.

There are no disease-specific laboratory tests to diagnose UC. Nonspecific markers of inflammation are often measured, including elevated C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), iron-deficiency anemia (in the instance of chronic rectal bleeding), thrombocytosis, and hypoalbuminemia. In addition, fecal calprotectin (FC) or stool lactoferrin (SL) is more sensitive (88% for FC, 82% for SL) and specific (79% for FC, 79% for SL) markers of intestinal inflammation, although these biomarkers are also elevated in intestinal inflammation of any etiology.<sup>8</sup> Autoantibodies may be helpful in differentiating Crohn's disease from UC. Antineutrophil-cytoplasmic antibodies (ANCA), specifically perinuclear antibodies (pANCA), are found in approximately 60% to 70% of patients with UC, compared to 2% to 28% of patients with Crohn's.<sup>2</sup> In contrast, anti-*Saccharomyces cerevisiae* antibodies (ASCA) are found in 39% to 69% of Crohn's patients but only 5% to 15% of UC patients.<sup>2</sup> Other antibody testing including anti-goblet cell antibodies (GAB) can be used to differentiate UC patients from other forms of colitis.

Imaging serves as a useful adjunct to diagnosis since it may demonstrate direct evidence of colonic inflammation. Modalities such as computed tomography, ultrasound, MRI, and endoscopy (Figs 46-1, 46-2, and 46-3) can reveal acute mucosal wall thickening, fat stranding, and perforation. Leukocyte scintigraphy is an uncommon imaging technique used to quantify leukocytes in the intestinal wall. It is particularly useful in ascertaining the distribution (continuous vs discontinuous) of disease and response to treatment. However, endoscopy remains the gold standard for imaging in the diagnosis of UC.

**FIGURE 46-1** MRI. Yellow arrows point to segments of visualized colon which are narrowed, ahaustral, and foreshortened.

**FIGURE 46-2** CT. This is a representation of the classic lead pipe in both descending and ascending colon (*yellow arrows*). This effect is less appreciated on the right. The thick red arrow demonstrates post-inflammatory polyps, which are true reparative lesions as opposed to pseudopolyps.

A

B

**FIGURE 46-3** CT, Pancolitis. A. This cross-section clearly demonstrates pancolitis with a striated wall appearance from mucosal enhancement and

intramural edema (*yellow arrows*). **B.** This is a patient with an acute on chronic UC flare. The striated appearance is due to chronic submucosal fat deposition.

All patients with presumed UC should undergo both an esophagogastroduodenoscopy (EGD) and colonoscopy with sampling of the ileum, four colonic sites, and the rectum, with a minimum of two biopsies from each site.<sup>9</sup> Typically, the bowel of patients with UC demonstrates diffuse continuous mucosal inflammation, characterized by edema and widespread erythema with ulcerations and bleeding starting at the rectum with proximal extension ([Fig. 46-4](#)). In addition, there is often loss of vascularity, loss of haustral folds, mucosal erosions, mucosal friability, and evidence of mucopurulent exudates. Pseudopolyps are often observed in longstanding disease. Histologically, the mucosa is infiltrated with inflammatory cells; namely, mononuclear cells with plasmacytosis and lymphocytes, villous atrophy, goblet cell depletion, crypt cell branching and atrophy, Paneth cell metaplasia, and crypt cell abscesses.<sup>7</sup>

## MEDICAL MANAGEMENT

UC is a chronic medical condition that is not medically curable, but like other chronic health conditions it requires long-term therapy directed at controlling gastrointestinal inflammation. The two main goals of medical treatment for

UC are achieving clinical remission (the absence of symptoms), and once that is accomplished, maintaining remission (prevention of flare-ups). To achieve the goals of therapy, two treatment strategies are used: induction and maintenance therapy.

*Induction therapy* is defined as a treatment that induces a quick treatment response and achieves clinical remission. The initial choice of therapy depends upon the severity of disease and required rapidity of action. For example, a patient who feels well but has a high disease burden may be able to wait the necessary 3 or 4 months for immunomodulators to take effect, whereas a patient who is significantly symptomatic needs an effective agent with immediate action. *Maintenance therapy* is defined as a treatment that has been proven in clinical studies to prevent relapses and maintains patients in clinical remission. These medications have different onsets of action, and the choice of therapy depends on the severity of disease. Medications that are used as maintenance therapy are called corticosteroid-sparing therapy. Corticosteroids are not effective in the prevention of flare-ups and have many undesirable side effects so are not used as maintenance therapy.

Most patients will be managed with medical therapy and kept in clinical remission, as only 10% to 15% of patients will require surgical therapy.<sup>10</sup> Surgical management is reserved for patients with severe colitis with or without complications (eg, toxic megacolon), or those with chronic colitis unresponsive to maximal medical management. Prior to proceeding with surgical treatment, consultation with a gastroenterologist should be considered to evaluate that maximal medical therapy has been used and to exclude conditions that may exacerbate disease (eg, *Clostridium difficile* colitis). In the following sections we review the medical management for outpatient and hospitalized patients with UC.

## OUTPATIENT MEDICAL THERAPY

### Aminosalicylates

Aminosalicylates are commonly used to treat mild to moderate UC and can be administered orally or topically. Sulfasalazine consists of an antibacterial component, sulfapyridine, bonded by an azo-bond to a salicylate, 5-aminosalicylic acid (5-ASA [mesalamine]). Sulfasalazine is split by bacteria

into active components in the colon. The mesalamine portion is the active portion of the drug and acts by interruption of the lipoxygenase and cyclooxygenase pathways, decreased production of IL-1, IL-2, and tumor necrosis factor (TNF) in the colonic mucosa. 5-ASA has been found to be effective in inducing and maintaining clinical remission in mild to moderate UC and usually improves symptoms by 2 to 4 weeks. Agents with 5-ASA are generally well tolerated, unlike sulfasalazine, in which patients usually experience side effects from the sulfa component. Rarely, 5-ASA can cause a paradoxical reaction leading to worsening diarrhea and should be stopped.

## Thiopurines

Thiopurines (azathioprine and mercaptopurine) are immunomodulators that downregulate the activity of the immune system, and in turn decrease the gastrointestinal inflammatory response. Azathioprine and 6-mercaptopurine are inactive prodrugs that require enzymatic conversion to produce active metabolites. These are purine analogs that become incorporated into DNA and inhibit DNA synthesis. They interfere with nucleic acid metabolism and cell growth and exert cytotoxic effects on lymphoid cells. The main limitation of these medications is their slow onset of action, which can be from 2 to 6 months and therefore this is not an effective medication to induce remission. However, they are effective in maintaining clinical remission in moderate to severe UC. A meta-analysis showed that compared to placebo, only five patients needed to be treated to maintain remission.<sup>11</sup> Thiopurines are generally well tolerated, but side effects include reversible bone marrow suppression, increased liver function test, pancreatitis, and opportunistic infections.

## Biologics

Biologics are genetically engineered medications that interfere with the body's inflammatory response in IBD by targeting specific molecular players in the process such as TNF. Unlike corticosteroids, which tend to suppress the entire immune system and thereby have the potential to produce major systemic side effects, biologics offer a distinct advantage in IBD treatment because they act selectively, with a targeted mechanism of action.

## **TNF INHIBITORS**

Infliximab, adalimumab, and golimumab are effective in inducing and maintaining clinical remission in UC.<sup>12-15</sup> Infliximab is a chimeric anti-TNF inhibitor and is administered intravenously every 8 weeks after induction dosing. Adalimumab and golimumab are fully humanized anti-TNF inhibitors and are administered by subcutaneous injection every 2 weeks or monthly, respectively. These drugs work by binding to and preventing the activity of a specific protein in the body, tumor necrosis factor-alpha (TNF- $\alpha$ ). TNF- $\alpha$  is a cytokine, a specialized protein that promotes inflammation in the intestine and other organs and tissues. The agent binds to soluble and membrane-bound TNF- $\alpha$ , deactivating it and resulting in reduced inflammation. Use of thiopurines in combination with infliximab was found to be more efficacious in maintaining clinical remission compared to infliximab alone.<sup>16</sup> TNF inhibitors can exacerbate latent tuberculosis or hepatitis B, leading to disseminated tuberculosis or fulminant hepatitis B. Therefore, prior to initiating TNF inhibitors patients should be evaluated for these infections. Patients who are using TNF inhibitors also carry an increased risk for opportunistic infections, lymphoma, and non-melanoma skin cancer.

## **SELECTIVE ADHESION MOLECULE INHIBITORS**

Vedolizumab is the first selective adhesion molecule inhibitor, and was approved in May 2014. It is a humanized monoclonal antibody that inhibits adhesion molecule  $\alpha 4 \beta 7$ , which results in blocking leukocyte migration and therefore gut inflammation. It only targets gastrointestinal leukocyte migration and provides selective immunosuppression of the gastrointestinal tract and does not cause systemic immunosuppression like TNF inhibitors. The GEMINI trial found it to be effective in inducing and maintain remission in moderate to severe UC.<sup>17</sup> There do not appear any increased risks of adverse events or infections with vedolizumab.

## **Corticosteroids**

Corticosteroids are potent nonspecific mediators of the inflammatory response. They can be administered by mouth, intravenously, or by rectum. They are effective in induction therapy but are not effective in maintaining

remission. Corticosteroids decrease inflammation by inhibiting arachidonic acid and cytokine release, and by inhibiting chemotaxis and phagocytosis. Corticosteroids are associated with many significant side effects (eg, osteoporosis, diabetes, cataracts, infections) and should always be used in conjunction with corticosteroid sparing therapy.

## INPATIENT MANAGEMENT

Patients failing outpatient medical management should be admitted for intravenous corticosteroids, which are essential in the management of severe or fulminant UC; up to 70% of patients will respond to intravenous corticosteroids.<sup>18</sup> Patients admitted for acute management of UC should receive 400 mg of hydrocortisone per day or 60 mg of methylprednisolone in divided doses.<sup>19</sup> The medication should be administered in bolus injections, since they were no more effective than continuous infusion.

While awaiting a response to corticosteroids, a flexible sigmoidoscopy should be performed to confirm the degree of inflammation and exclude infections. *C. difficile* infections can increase risk for blood transfusion, surgery, and mortality in patients with UC.<sup>20</sup> Cytomegalovirus infection can be associated with steroid refractory UC and excluded with colonic biopsies. All patients should receive thromboprophylaxis with subcutaneous heparin or low molecular weight heparin, since patients are at increased risk for deep venous thromboembolism.<sup>21</sup> There is no evidence to suggest that empirical treatment with antibiotics in severe colitis is beneficial. Agents that could potentially precipitate the effects of toxic megacolon, such as anticholinergics, antidiarrheals, NSAIDs, and opiates, should be discontinued.

A response of corticosteroids should be seen by 3 to 5 days. If a response is not seen, rescue therapy with higher level medications or surgery should be strongly considered, as continuing steroids is unlikely to lead to a clinical benefit.<sup>22</sup> Infliximab and cyclosporine have both been shown to be effective rescue therapy; a recent clinical trial demonstrated both to have similar efficacy in inducing clinical remission and preventing colectomy.<sup>23</sup> Infliximab is more commonly used due to its better safety profile compared to cyclosporine, which can have serious adverse effects including nephrotoxicity, seizures, and infections. Infliximab in the inpatient setting

can have long-term benefits, with colectomy rates of 50% 3 years after treatment.<sup>24</sup>

## **SURGICAL MANAGEMENT**

Despite the improvements made in medical therapy, the only definitive cure for UC remains surgical resection of the colon and rectum. As mentioned, the majority of patients can be managed adequately with medical treatment; however, when emergencies are included, as many as 45% of patients have been reported to require operative treatment.<sup>25,26</sup> The overwhelming benefit is elimination of disease, countered by wide variability in function and re-establishing continence postoperatively. Despite these challenges, most patients report a high quality of life with satisfactory long-term functional outcomes.<sup>26</sup>

### **Indication for Surgical Intervention**

The overarching principle in surgical treatment is to eliminate disease and the risk of colorectal cancer. The main goals of operative intervention include achieving definitive cure by resection of the colon and rectum, reconstructing a route of elimination, and minimizing morbidity and improving quality of life. As with all procedures, risks and complications are true possibilities. Surgery should be considered a therapeutic alternative rather than a failure of medical therapy. Hence, discussions between the patient, gastroenterologist, and colorectal surgeon should be introduced early into the patient's treatment time course.

Given the wide variability in clinical manifestation, disease behavior largely directs the indications for surgical intervention. The first, and invariably the most straightforward, indication includes life-threatening complications such as toxic megacolon, perforation, and uncontrolled hemorrhage. The emergent nature of this approach is associated with higher morbidity and a greater number of subsequent operations.<sup>27,28</sup> A second category encompasses cancer-related indications such as proven high-grade dysplasia, multifocal low-grade dysplasia, strictures, or localized cancer. A diagnosis of cancer and dysplasia is an absolute indication for surgery (Fig. 46-5). Patients comprising the largest indication category include those with

chronic, continuous disease and developed unresponsiveness to medical therapy. These patients are largely steroid dependent, have developed adverse effects, and exhibit insufficient responses to other medical therapies.

**FIGURE 46-5** Barium enema. A patient with severe ulcerative colitis and a cancerous lesion in the ascending colon shown by a long apple-core segment

(*yellow arrow*). Note the smooth, ahaustral lead pipe appearance (*red arrow*) with backwash ileitis (*thin yellow arrow*).

There is no doubt that the degree of ineffectiveness of medical therapies will vary among patients. Therefore it is critical that conversations regarding when the expectation of medical therapies have not been met are introduced to the patient, along with the treatment offered by surgical intervention. Pending no emergencies, the decision to proceed with elective colectomy may be left to the well-informed patient.<sup>25</sup>

Historically, non-resectional strategies were the mainstay of surgical approaches, comprising segmental resections for limited disease scattered throughout the colon. The following section discusses the surgical options under acute and elective clinical scenarios, as the management of either is indicatively unique.

## MANAGEMENT OF ACUTE COLITIS

Severe acute colitis presents a potential surgical emergency. Under ideal circumstances, acute colitis may be initially treated with medical therapy and daily re-evaluation. The patient should be informed that colectomy is a very possible alternative in the instance that the colitis is refractory to medical treatment. Deterioration or failure of symptoms to resolve within the first 3 days triggers the need for urgent colectomy.<sup>26</sup> The absolute indications for surgery are toxic megacolon, perforation, and severe, unremitting colorectal bleeding ([Fig. 46-6](#)).<sup>27</sup>

**FIGURE 46-6** Abdominal plain radiograph, toxic megacolon. Grossly dilated transverse colon with “thumbprinting” due to mucosal edema.

If treatment is initiated via medical therapy, the colorectal surgeon must be consulted for early evaluation and daily assessment in the instance of any deterioration during IV steroid therapy or rescue treatment. Response to medical therapy may be objectively monitored by stool frequency, CRP levels, and abdominal imaging.<sup>27</sup> Colectomy is recommended by the

European Crohn's and Colitis Organization (ECCO) guidelines if there is no improvement by days 4 to 7 following initiation of medical therapy under acute circumstances, or if the patient has been taking 20 mg of prednisolone or more daily for over 6 weeks.<sup>10</sup>

The operation of choice in urgent and emergent situations is total abdominal colectomy (TAC) with end ileostomy, leaving the rectum in situ. This is commonly a staged procedure where the goal is to remove the diseased colon as quickly as possible without distorting anatomic planes. Hence the rectum is not resected until a subsequent procedure may be planned to allow the patient to recover from the initial insult and taper off immunosuppressive medications. Management of the rectal stump remains problematic and can be a source of postoperative complications if it opens up in the postoperative period. Some surgeons opt for high ligation of the rectum at the level of the promontory with transanal rectal drainage. The alternative includes creating a mucous fistula, where the clear advantage lies in the fact that no closed bowel is left within the abdomen. Traditionally, emergent operations are performed in an open approach; however, evidence from specialty centers has recently emerged suggesting laparoscopic subtotal colectomy is not only safe, but demonstrates improved short-term perioperative outcomes.<sup>29,30</sup> While clearly adding some benefit to patients in the acute setting, laparoscopy should be undertaken in this setting only by an expert laparoscopist. The colon is often enlarged and quite friable, increasing the technical difficulty of the operation. In addition, laparoscopy is contraindicated in patients who are septic or who have experienced a perforation.

## **Brief Operative Technique**

Following induction of general anesthesia with endotracheal intubation, the procedure is begun with the patient in standard Lloyd-Davis position. A urinary catheter is placed and a site demarcating the end ileostomy is made in either the right or left lower quadrant. In the standard open approach, a midline incision provides adequate access into the abdomen with the option of placing the stoma in either lower quadrant. Initial exploration of the abdominal cavity is performed. It is here that the surgeon takes note of tissue integrity and friability in addition to any evidence of disease to the terminal ileum, as this could be suggestive of Crohn's disease. This is particularly

important in the acute setting, or in a patient with an otherwise unknown diagnosis of UC. The colon is fully mobilized from its peritoneal attachments and both flexures are freed using a combination of cautery and energy devices. The mesentery is ligated and division of the mesenteric vessels is performed. The terminal ileum is then divided immediately proximal to the ileocecal valve. In the total abdominal colectomy, the colon is divided at the level of the mid to distal sigmoid with preservation of the inferior mesenteric artery and superior rectal arteries. In addition to preserving the presacral planes, it is critically important to preserve the ileocolic artery in order to allow for later pouch reconstruction. Preservation of the ileocolic artery prevents foreshortening of the mesentery, which allows the future pouch to easily reach to the anal canal.
