### **Notice**

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

# CONTENTS

*Contributors*  
*Preface*

## **INTRODUCTION**

### **1. Gastrointestinal Surgery: A Historical Perspective**

*David L. Nahrwold*

### **2. Preoperative and Postoperative Management**

*Zara Cooper / Edward Kelly*

### **3. Enhanced Recovery Programs for Gastrointestinal Surgery**

*Anthony J. Senagore*

### **4. Performance Measurement and Improvement in Surgery**

*Andrew M. Ibrahim / Justin B. Dimick*

### **5. Endoscopy and Endoscopic Intervention**

*Nabil Tariq / Jeff Van Eps / Brian J. Dunkin*

### **6. Fundamentals of Laparoscopic Surgery**

*Fernando Mier / John G. Hunter*

### **7. Minimally Invasive Approaches to Cancer**

*Jonathan C. King / Herbert J. Zeh, III*

### **8. Robotics in Gastrointestinal Surgery**

*Yanghee Woo / Yuman Fong*

## **9. Pediatric GI Surgery**

*Tina Thomas / Cabrini Sutherland / Ronald B. Hirschl*

## **ABDOMINAL WALL**

### **10. Incisions, Closures, and Management of the Abdominal Wound**

*Robert E. Roses / Jon B. Morris*

### **11. Inguinal Hernia**

*Natalie Liu / Jacob A. Greenberg / David C. Brooks*

### **12. Perspective on Inguinal Hernias**

*Parth K. Shah / Robert J. Fitzgibbons, Jr.*

### **13. Ventral and Abdominal Wall Hernias**

*Andrew Bates / Mark Talamini*

### **14. Perspectives on Laparoscopic Incisional Hernia Repair**

*Camille Blackledge / Mary T. Hawn*

### **15. Intestinal Stomas**

*Cindy Kin / Mark Lane Welton*

### **16. Abdominal Abscess and Enteric Fistulae**

*Joao B. Rezende Neto / Jory S. Simpson / Ori D. Rotstein*

### **17. Gastrointestinal Bleeding**

*Eric G. Sheu / Ali Tavakkoli*

### **18. Lesions of the Omentum, Mesentery, and Retroperitoneum**

*Tara A. Russell / Fritz C. Eilber*

### **19. Abdominal Trauma**

*L.D. Britt / Jessica Burgess*

## **20. Abdominal Vascular Emergencies**

*John J. Ricotta / Cameron M. Akbari*

## **ESOPHAGUS**

### **21. Esophageal Diverticula and Benign Tumors**

*Marco E. Allaix / Marco G. Patti*

### **22. Achalasia and Other Motility Disorders**

*Jeffrey A. Blatnik / Jeffrey L. Ponsky*

### **23. Gastroesophageal Reflux Disease, Hiatal Hernia, and Barrett Esophagus**

*Robert D. Bennett / David M. Straughan / Vic Velanovich*

### **24. Paraesophageal Hernia Repair**

*Jeffrey A. Blatnik / L. Michael Brunt*

### **25. Perspectives Regarding Benign Foregut Diseases and Their Surgeries**

*Lee L. Swanstrom / Silvana Perretta*

### **26. Cancer of the Esophagus**

*Daniel King Hung Tong / Simon Law*

### **27. Surgical Procedures to Resect and Replace the Esophagus**

*Jon O. Wee / Shelby J. Stewart / Raphael Bueno*

### **28. Perspective on Cancer of the Esophagus and Surgical Procedures to Resect and Replace the Esophagus**

*Joshua A. Boys / Tom R. DeMeester*

## **STOMACH AND DUODENUM**

### **29. Benign Gastric Disorders**

*Ian S. Soriano / Kristofell R. Dumon / Daniel T. Dempsey*

**30. Gastric Atony**

*Rian M. Hasson / Scott A. Shikora*

**31. Gastric Adenocarcinoma and Other Neoplasms**

*Waddah B. Al-Refaie / Young K. Hon / Jennifer F. Tseng*

**32. Perspective on Gastric Cancer**

*Hisashi Shinohara / Mitsuru Sasako*

**33. Gastrointestinal Stromal Tumors**

*Nicole J. Look Hong / Chandrajit P. Raut*

**34. Perspective on Gastrointestinal Stromal Tumors**

*Michael J. Cavnar / Ronald P. DeMatteo*

**35. Stomach and Duodenum: Operative Procedures**

*Joyce Wong / David I. Soybel / Michael J. Zinner*

**36. Morbid Obesity, Metabolic Syndrome, and Nonsurgical Weight Management**

*Ali Tavakkoli*

**37. Surgical Treatment of Morbid Obesity and Type 2 Diabetes**

*Bruce D. Schirmer*

**INTESTINE AND COLON**

**38. Small Bowel Obstruction**

*Kristina L. Go / Janeen R. Jordan / George A. Sarosi, Jr. / Kevin E. Behrns*

**39. Tumors of the Small Intestine**

*Michael M. Reader / Barbara Lee Bass*

**40. Carcinoid Tumors and Carcinoid Syndrome**

*Teresa S. Kim / Liliana G. Bordeianou / Richard A. Hodin*

**41. Appendix and Small Bowel Diverticula**

*Arin L. Madenci / William H. Peranteau / Douglas S. Smink*

**42. Short Bowel Syndrome and Intestinal Transplantation**

*Diego C. Reino / Douglas G. Farmer*

**43. Diverticular Disease and Colonic Volvulus**

*Timothy Eglinton / Frank A. Frizelle*

**44. Colonic Volvulus**

*Christina M. Papageorge / Eugene F. Foley*

**45. Crohn's Disease**

*Heather Yeo / Alessandro Fichera / Roger D. Hurst / Fabrizio Michelassi*

**46. Ulcerative Colitis**

*Christina W. Lee / Freddy Caldera / Tiffany Zens / Gregory D. Kennedy*

**47. Perspective on Inflammatory Bowel Disease**

*Patricia L. Roberts*

**48. Hereditary Colorectal Cancer and Polyposis Syndromes**

*Jennifer L. Irani / Elizabeth Breen / Joel Goldberg*

**49. Tumors of the Colon**

*Trevor M. Yeung / Neil J. Mortensen*

**50. Laparoscopic Colorectal Procedures**

*Dorin Colibaseanu / Heidi Nelson*

**51. Perspective on Colorectal Neoplasms**

*Martin R. Weiser*

**52. Benign Disorders of the Anorectum (Pelvic Floor, Fissures, Hemorrhoids, and Fistulas)**

*James W. Fleshman, Jr. / Anne Y. Lin*

**53. Constipation and Incontinence**

*Alexander T. Hawkins / Liliana G. Bordeianou*

**54. Cancer of the Rectum**

*Joel Goldberg / Ronald Bleday*

**55. Cancer of the Anus**

*Najjia N. Mahmoud*

**VII LIVER**

**56. Hepatic Abscess and Cystic Disease of the Liver**

*Nikolaos A. Chatzizacharias / Kathleen K. Christians / Henry A. Pitt*

**57. Benign Liver Neoplasms**

*Kevin C. Soares / Timothy M. Pawlik*

**58. Malignant Liver Neoplasms**

*Sameer H. Patel / Guillaume Passot / Jean-Nicolas Vauthey*

**59. Treatment of Hepatic Metastasis**

*Sean M. Ronnekleiv-Kelly / Sharon M. Weber*

**60. Perspective on Liver Resection**

*Jordan M. Cloyd / Timothy M. Pawlik*

**61. Portal Hypertension**

*Douglas W. Hanto / Sunil K. Geevarghese / Christopher Baron*

**VIII GALLBLADDER AND BILE DUCTS**

## **62. Cholelithiasis and Cholecystitis**

*Ezra N. Teitelbaum / Nathaniel J. Soper*

## **63. Choledocholithiasis and Cholangitis**

*Yu Liang / David W. McFadden / Brian D. Shames*

## **64. Choledochal Cyst and Benign Biliary Strictures**

*Purvi Y. Parikh / Keith D. Lillemoe*

## **65. Cancer of the Gallbladder and Bile Ducts**

*Jason S. Gold / Michael J. Zinner / Edward E. Whang*

## **66. Laparoscopic Biliary Procedures**

*Alexander Perez / Theodore N. Pappas*

## **67. Perspective on Biliary Chapters**

*Steven M. Strasberg*

## **68. Management of Acute Pancreatitis**

*Thomas E. Clancy*

## **69. Complications of Acute Pancreatitis**

*John A. Windsor / Benjamin P.T. Loveday / Sanjay Pandanaboyana*

## **70. Perspective on Management of Patients with Acute Pancreatitis**

*Stefan A.W. Bouwense / Hjalmar C. van Santvoort / Marc G.H. Besselink*

## **71. Chronic Pancreatitis**

*Marshall S. Baker / Jeffrey B. Matthews*

## **72. Cystic Neoplasms of the Pancreas**

*Michael J. Pucci / Charles J. Yeo*

## **73. Cancers of the Periapillary Region and Pancreas**

*Csaba Gajdos / Martin McCarter / Barish Edil / Alessandro Paniccia /  
Richard D. Schulick*

**74. Endocrine Tumors of the Pancreas**

*Mary E. Dillhoff / E. Christopher Ellison*

**75. Perspective on Pancreatic Neoplasms**

*Douglas B. Evans*

**76. Complications of Pancreatectomy**

*Mu Xu / O. Joe Hines*

**SPLEEN AND ADRENAL**

**77. The Spleen**

*Liane S. Feldman / Amani Munshi / Mohammed Al-Mahroos / Gerald M.  
Fried*

**78. Adrenal Anatomy and Physiology**

*David Harris / Daniel Ruan*

# PREFACE

For the editors, the production of the newest edition of *Maingot's Abdominal Operations* represents a labor of love. *Maingot's* has always filled a unique niche. This text has consistently offered a comprehensive discussion of surgical diseases of the abdomen with a focus on operative strategy and technique. The book has served as a needed reference to refresh our knowledge before a common operation or in preparation for a novel one. Our intended audience for this edition is the same as for the original publication; the book is meant for the surgical trainee as well as the practicing surgeon, and for the American surgeon as well as for our international colleagues. We continue to have a significant international audience and have made every effort to develop a product that is equally valuable to readers in India as well as Indiana. This is the fifth effort together for the senior editors, joined this time by a new editor (O.J.H.) with a fresh vision; it continues to be not only a pleasure but an honor and a privilege to have the opportunity to co-edit the 13th edition of this classic textbook.

Abdominal surgery has clearly evolved since Rodney Maingot's first edition of this text in 1940. Not only has our knowledge base increased substantially, but the procedures themselves have become both more complex and less invasive. The current subspecialization in abdominal surgery, a consequence of these changes, continues to challenge the need for a comprehensive text. Abdominal disease has been increasingly parceled between foregut, hepatobiliary, pancreatic, colorectal, endocrine, acute care, and vascular specialists. The editors continue to believe, however, that the basic principles of surgical care in each of the anatomic regions have more similarities than differences. Experience in any one of these organs can inform and strengthen the approach to each of the others. In fact, in community hospitals and rural settings both nationally and internationally, practices spanning multiple subspecialties remain the norm. Few would

question the need for the abdominal surgeon to be well versed in dealing with any unexpected disease that is encountered in the course of a planned procedure. For many of us, *Maingot's Abdominal Operations* has consistently helped to fill that need.

This textbook remains primarily disease focused, in addition to maintaining its organ/procedure format. The new edition of this textbook is a significant revision and, in many areas, a completely new book. We have continued to focus some chapters on technical operative procedures, whereas others elucidate new and continuing concepts in diagnosis and management of abdominal disease. The new edition is expanded compared with previous versions, and we have continued to present the opinions and knowledge of more than one expert. In areas where opinions and approaches differ, we have added even more "Perspective" commentaries by experts in the field who we expected might have distinct opinions about approaches and/or operative techniques. In response to recent developments, we have added chapters on quality metrics, enhanced recovery after surgery, and robotic surgery. We have attempted to maintain an international flavor and have included a cross-section of both seasoned senior contributors and new leaders in gastrointestinal surgery. We continue to provide a contemporary textbook on current diagnostic procedures and surgical techniques related to the management and care of patients with all types of surgical digestive disease.

An extensive artwork program was undertaken for this edition. Many line drawings have been recreated to reflect the contributors' preferred method for performing certain surgical procedures. Some of these drawings are new and give the book a more consistent look. In addition, this edition continues full-color text and color line art.

In the preface to the sixth edition, Rodney Maingot noted, "As all literature is personal, the contributors have been given a free hand with their individual sections. Certain latitude in style and expression is stimulating to the thoughtful reader." Similarly, we have tried to maintain consistency for the reader, but the authors have also been given a free hand in their chapter submissions.

We would like to thank the publisher, McGraw-Hill, and in particular Christie Naglieri and Andrew Moyer, for their unwavering support during the lengthy time of development of this project. Their guidance was invaluable to completing this project in a single comprehensive volume. Their suggestions and attention to detail made it possible to overcome the innumerable

problems that occur in publishing such a large textbook.

Finally, we want to acknowledge the expertise of each chapter and perspective contributor. Without their effort, this book would not have been possible. We acknowledge our editorial assistant, Linda Smith, who has survived the trials of this book; she has been invaluable, and we never would have been able to do it without her. Patrina Tucker and Heather Couture have also stepped up and made this project possible. We owe them a great debt of gratitude for helping with every step of the work. To all of those who have participated in the creation and publication of this text, we thank you very much.

# **INTRODUCTION**

# **GASTROINTESTINAL SURGERY: A HISTORICAL PERSPECTIVE**

*David L. Nahrwold*

## **INTRODUCTION**

Surgeons continue to have brilliant ideas and use amazing technology to bring safe and effective surgery to people all over the world, but it was not always so. The evolution of surgery to its present state has taken at least 200 years, and surgery is still evolving. Each of the many abdominal operations surgeons now performed has its own special history, from the idea that spawned it to the present state of its art. Abdominal operations were brought to fruition by innovative surgeons who carefully planned them and had the courage to perform them and the wisdom to modify and improve them.

Although the histories of all abdominal operations are interesting, a broader view of abdominal surgery puts those stories into perspective. The broader view is best obtained by asking: What enabled abdominal surgery to evolve to its present state? What were the barriers to the evolution of abdominal surgery? How were the barriers overcome, and who overcame

them? Although recognizing the individuals who developed and perfected individual operations is important, the perspective of this chapter is on how modern abdominal surgery came about and how it was enabled.

## **THE EARLY PROBLEMS**

Prior to the middle of the 19th century, few operations were done with the expectation that the patient would live and be cured of the disease for which it was performed. The fundamental barrier was the excruciating pain caused by opening the abdomen and manipulating its contents, even when tempered by the administration of alcohol or derivatives of opium such as laudanum and morphine. Patients often died from postoperative bleeding, dehydration, or malnutrition. But it was infection that was the bane of surgeons. Infections followed almost all operations. Wound infection and peritonitis were the killers of patients who had abdominal surgery. Without antibiotics or even standardized methods of dressing infected wounds, the consequences of infection were disastrous. Except in a few isolated instances, physicians knew that surgery was not a realistic therapeutic option until infection, hemorrhage, dehydration, and malnutrition could be alleviated or eliminated. Remarkable progress was made during the second half of the 19th century, enabling surgeons to bring hope to a large number of patients with diseases or conditions that swiftly became amenable to surgery.

## **ANESTHESIA**

The modernization of abdominal surgery was dependent on the patient's loss of sensation, anesthesia, during the procedure. The development of anesthesia eliminated the cruelty of surgery and enabled surgeons to incise, manipulate, and suture tissue in a disciplined manner without the urgency and disorder that surrounded operations in the conscious patient.

Dr. Crawford Long was the first to use ether for general anesthesia, in 1842, but he did not report it until 1849.<sup>1</sup> Meanwhile, in 1846, the Boston dentist William T.G. Morton demonstrated the use of ether as a general anesthetic in the amphitheater of the Massachusetts General Hospital in a patient with a tumor of the neck, which was removed by Dr. John Collins Warren, former Dean of the Harvard Medical School (1816-1819).<sup>2</sup>

## OVERCOMING INFECTION

Louis Pasteur conducted experiments between 1860 and 1864 showing that “pyogenic vibrio” caused puerperal fever and that fermentation of wine and milk did not proceed in the absence of living organisms. Heating milk and wine, now called pasteurization, killed the bacteria, but not the yeast, and made them safe to drink.<sup>3</sup>

Robert Koch, the German physician and microbiologist who in 1876 identified *Bacillus anthracis* as the cause of anthrax, learned how to grow bacteria on media and, in 1884, isolated *Vibrio cholerae*, the agent that causes cholera. In 1882, Koch identified the slow-growing *Mycobacterium tuberculosis* as the cause of tuberculosis. Between 1879 and 1889, he also isolated the organisms that caused typhoid fever, diphtheria, pneumonia, tetanus, meningitis, and gonorrhea. He found organisms in wound infections. Koch proved that the germs in the germ theory of disease were organisms that could be isolated and identified.<sup>4</sup>

The English physician Joseph Lister, professor of surgery at the University of Glasgow, soaked surgical dressings in carbolic acid (phenol) and applied them to the open leg wound of a boy who had suffered a compound fracture (Fig. 1-1). No infection ensued, and to his surprise, the bones healed solidly together. He published the results in a series of articles in *The Lancet* in 1867. He returned to the University of Edinburgh in 1869 and continued to develop methods of asepsis and antisepsis. Soon, surgeons performed operations under a mist of dilute carbolic acid that was sprayed in the operating room, instruments were dipped in carbolic acid before use, and the surgical wound was covered in dressings saturated with it.<sup>5</sup> This routine, with variations, became known as listerism, which Joseph Lister introduced to the United States during a visit in 1876.

**FIGURE 1-1** Joseph Lister. (Used with permission from Wellcome Images.)

Surgeons learned from listerism of the need to maintain sterile conditions at the operating table. Although the steam autoclave was invented in 1879, it was not used routinely for sterilization of instruments and supplies until early in the 20th century. Dr. William Halsted, who embraced listerism, introduced the use of surgical gloves at Johns Hopkins Hospital. However, the original use of the gloves made by the Goodyear Company was to protect the hands of the surgical team from the carbolic acid.<sup>6</sup>

Measures to control infection have been used routinely since the first half of the 20th century and affect hospital construction, all invasive procedures, interactions with patients, and behaviors in hospitals and other medical

facilities.

The medicinal use of sulfa drugs in the late 1930s, the discovery of penicillin in 1928 by Fleming, and its clinical use by Florey and his colleagues in the early 1940s began the successful search for many other antibiotics to combat infections by almost all known bacteria. During the second half of the 20th century and beyond, surgical infections have been ameliorated or cured by the large array of antibiotics that became available, although antibiotic-resistant bacteria from antibiotic overuse have recently become a problem. In recent decades, the evidence-based prophylactic use of antibiotics in abdominal surgery has almost eliminated surgical site infections.

## **THE SURGEON'S WORKPLACE**

Hospitals were built to provide clinical material for the faculties and students of the country's original medical schools. They included the Pennsylvania Hospital (1752), the New York Hospital (1771), and the Massachusetts General Hospital (1811), all of which became the workplaces of innovative physicians and surgeons who taught and conducted research (Fig. 1-2). However, most cities had no hospitals; instead, almshouses, poorhouses, and poor farms, living facilities for indigent people in the community were established by charitable organizations and wealthy individuals. Over time, many of them became hospitals for the sick and poor. Some physicians also established hospitals, often by converting a large home into a place for their sick patients. Many hospitals were dirty and poorly kept, and because some of the occupants had infectious diseases for which there were no cures, the other occupants also became infected and often died.

**FIGURE 1-2** The Pennsylvania Hospital. (Reproduced with permission from The Library of Congress.)

Because hospitals were known as dangerous places, middle- and upper-class families kept sick relatives at home. The typical horse-and-buggy doctor made rounds to the homes of his patients, and minor procedures, such as drainage of a carbuncle or suture of a wound, were performed in the home. Occasionally, a physician whose patient was in desperate straits would attempt an abdominal operation on the kitchen table, usually with disastrous results.

As medical diagnosis and treatment advanced, medical care in the home was no longer practical. Beginning in the latter half of the 19th century, religious organizations, civic groups, and municipalities began aggressive programs to build hospitals modeled after those in Europe, and by 1900, there were more than 4000 hospitals in the United States. However, the management, medical staffs, nursing, and other services of these hospitals varied from excellent to poor.

## **THE HOSPITAL STANDARDIZATION PROGRAM IMPROVES HOSPITALS**

Dr. Franklin H. Martin, a Chicago gynecologist, led the founding of the American College of Surgeons (ACS) in 1912 (Fig. 1-3). He and other leaders of the ACS were concerned about the marked variation in the quality of hospitals throughout the country and began a program to standardize hospitals in 1916 by establishing standards that hospitals were required to meet.<sup>7</sup> Surveyors visited the hospitals to determine their compliance and to offer help in meeting the standards. The ACS also held annual hospital standardization conferences to educate hospital personnel. The American Hospital Association, which initiated institutional memberships in 1918, also contributed to the modernization of hospital management.

**FIGURE 1-3** Dr. Franklin H. Martin, Founder of the American College of Surgeons. (Image courtesy of the Archives of the American College of Surgeons.)

Only 13% of the 692 hospitals surveyed in 1918 were approved by the ACS, but by 1939, 76% of the 3564 hospitals surveyed were approved.<sup>8</sup> Over the years, the standards proliferated, and in 1951, the ACS transferred the program to what is now The Joint Commission.

The Hospital Standardization Program and The Joint Commission were largely responsible for the current organization and functions of the modern hospital. The standards they set have saved many lives and made surgery safe.

## **NURSING AND HOSPITAL ADMINISTRATION**

Although hospitals proliferated early in the 20th century, few of them hired nurses to care for patients. Graduate nurses were hired by middle- and upper-class patients as “special nurses” to care for them in their homes or in the hospital during illnesses. To serve patients who could not afford special nurses, hospitals established schools of nursing in which the students were taught by a faculty of 1 or 2 graduate nurses and the medical staff of the hospital. Student nurses were assigned to wards to care for patients, often with very little supervision. Many of these schools closed during the Great Depression, and later, colleges and universities established degree programs, which now educate most of the country’s nurses. Prior to World War II, the supply of graduate nurses became sufficient for hospitals to hire nursing staffs to care for their patients. As the complexity of medical care escalated, nurses assumed many roles other than hospital care, and they continue to be indispensable to the healthcare system.

During the first half of the 20th century, when hospitals were simple organizations, hospital administrators learned from a mentor or on the job. By the middle of the century, hospitals had become departmentalized and complex, requiring expertise in finance, personnel management, construction, and many other fields of management. This led to the development of advanced degree programs in hospital administration, the first of which was established at the University of Chicago in 1934. Within a few decades, many universities had established such programs.

## **APPLYING THE BASIC SCIENCES**

Although the gross structure of the human body and its organs had been delineated by the middle of the 19th century, the functions of organs remained mysterious. Concurrent development of the basic sciences of pathology, microbiology, physiology, and chemistry during the second half of the 19th century led to an understanding of organ function and disease. During this period, Rudolph Virchow, using the ever-improving optics of the microscope, introduced histopathology to the medical sciences, and Friedrich von Recklinghausen described embolism, infarction, tissue degeneration, and many diseases and conditions such as uterine adenomyomata. Improved techniques for fixing, embedding, and staining tissue facilitated more accurate diagnoses in the early 20th century, and the process of preparing frozen sections of tissues, reported by Dr. Louis Wilson of the Mayo Clinic in 1905, enabled pathologists to accurately diagnose diseases during operations.<sup>9</sup>

New techniques enabled investigators to understand normal and abnormal gastrointestinal physiology. Between the 1890s and his death in 1936, the Russian physiologist Ivan Pavlov used Heidenhain pouches and gastric and esophageal fistulas in dogs to study salivary and gastric secretions as well as conditioned reflexes, work for which he received the Nobel Prize.<sup>10</sup> His experiments inspired many surgical investigators to use similar methods to study gastrointestinal hormonal physiology and motility during the 20th century. Their work, and the work of others, resulted in a comprehensive understanding of the biochemistry, physiology, and pharmacology of the hepatobiliary and digestive systems in health and disease.

Army surgeon Dr. William Beaumont performed the first human experiments in gastric physiology during the first half of the 19th century,<sup>11</sup> but it was not until Dr. Lester Dragstedt studied gastric secretion in ulcer patients that gastrointestinal physiology was applied to the development of surgical procedures to combat excessive acid secretion. He introduced vagotomy to reduce gastric acid secretion.<sup>12</sup> Upon finding that vagotomy inhibited gastric emptying, he and others added pyloroplasty or antrectomy.

Beginning with the administration of intravenous fluids to surgical patients by Dr. Rudolph Matas in 1924, many advances in biochemistry and physiology led to a greater understanding of body composition, nutrition, and fluid, electrolyte, and acid-base balance. The studies of Dr. Francis Moore and others culminated in his magisterial text, *Metabolic Care of the Surgical*

*Patient*, which taught surgeons how to deliver the highest level of pre- and postoperative care.<sup>13</sup> Drs. Jonathan Rhoads and Stanley Dudrick emphasized the importance of nutrition in surgical patients and demonstrated that intravenous alimentation could support normal growth and development of puppies and babies.<sup>14</sup>

The basic science of immunology matured during the 20th century, enabling the first kidney transplantation by Dr. Joseph Murray and his associates in 1954 and the first liver transplantation by Dr. Thomas Starzl in 1963.

## **BLOOD, TRAUMA, AND SHOCK**

After Karl Landsteiner identified the major blood groups A, B, and O in 1901, transfusion of blood and blood products became safer. Dr. George W. Crile, professor of surgery at Case-Western Reserve University, and Dr. William Halsted of The Johns Hopkins Hospital employed blood transfusions during surgical procedures. Reactions to transfusions were frequent until 1940, when the Rh system was discovered and taken into account in matching donor blood to patients. Dr. Bernard Fantus established the first hospital blood bank in the United States at Cook County Hospital in Chicago in 1937.<sup>15</sup>

Liquid and reconstituted dried plasma was used extensively for resuscitation from wounds during World War II. Lessons learned from the Korean conflict, the Vietnam War, and subsequent conflicts have been applied to the management of civilian trauma and burns, especially the techniques of resuscitation from shock, which were studied extensively by Dr. G Thomas Shires and his colleagues.<sup>16</sup> The wartime concepts of rapid evacuation for resuscitation and early transport to a major healthcare facility are embodied in the existing trauma system in the United States. The military experience has also informed the management of abdominal gunshot and knife wounds and blunt abdominal injuries in the civilian population.

## **THE SURGEON'S TOOLS**

More than 200 years have elapsed since Ephraim McDowell performed the first abdominal operation in the United States to remove a huge ovarian

tumor from a woman in Danville, Kentucky.<sup>17</sup> Subsequently, and especially during the latter half of the 19th century, operations were developed in Europe and the United States to deal with almost every abdominal disease or condition. The need to design and manufacture surgical instruments spawned an entirely new field, biomedical engineering, which became institutionalized in the late 1960s when universities began degree programs in biomedical engineering. The manufacture of surgical instruments and supplies is now vested in a huge industry that produces products ranging from silk sutures to robots.

Manufacture of most surgical instruments was routine by the beginning of the 20th century, including retractors, hemostats, scissors, forceps, and a variety of tools designed to grasp, hold, or manipulate abdominal organs and tissues. Improvements such as the disposable scalpel blade in the 1920s and disposable instruments in the 1970s have reduced labor costs of hospitals. The introduction of staplers for gastrointestinal side-to-side and end-to-end anastomoses by Russian investigators, brought to the United States and developed by Ravitch and Steichen<sup>18</sup> in the 1960s, was a major advance.

Hemostasis was facilitated by the development of a diathermy machine for electrosurgical cutting and cautery by William T. Bovie and introduced into clinical use by Harvey Cushing at the Peter Bent Brigham Hospital in 1920, eliminating the need to clamp and ligate small vessels. Since then, topical preparations, clips, electrical energy, and ultrasonic energy have been incorporated into various devices that have enabled minimally invasive surgery.

## **TECHNOLOGY DRIVES SURGERY**

Development of minimally invasive surgery was dependent on the visualization of organs in the abdominal cavity through a scope. In 1806, Phillip Bozzini made a major contribution by constructing a “lichtleiter,” a scope that incorporated mirrors to reflect light back to the eye. It was used primarily for gynecologic examinations (Fig. 1-4). The development of small bulbs illuminated by electric current enabled laparoscopy for diagnosis beginning in the first half of the 20th century, and flexible fiberoptic scopes for examining the interior of the gastrointestinal tract followed in the 1950s.

**FIGURE 1-4** Bozzini's lichtleiter. (Image courtesy of the Archives of the American College of Surgeons.)

Numerous advances in technology, many driven by the computer and the computer chip television camera, enabled laparoscopic surgery, which revolutionized abdominal surgery.

Laparoscopic surgery had its origin in obstetrics and gynecology, with the first laparoscopic organ removal, salpingectomy, performed by Tarasconi in 1975.<sup>19</sup> This was followed by laparoscopic cholecystectomy, first performed by Muhe in Germany in 1985, by Mouret in France in 1987, and Reddick in the United States in 1988.<sup>20</sup> Since then, every abdominal organ has been subjected to laparoscopic procedures.

The most recent technological development is the use of robots in surgery. After years of research and development by many organizations, the da Vinci surgery system was approved by the US Food and Drug Administration in 2000 for general laparoscopic surgery. The surgeon sits at a console where the interior of the abdomen is projected on a screen and uses a computer to control a robotic arm to which are attached various instruments. Newer versions, including a console for an assistant, have been used in general

surgery and the surgical specialties. The advantages and disadvantages of robotic surgery are still under evaluation as experience accumulates and the technology continues to improve.

## SUMMARY

Early abdominal surgery was enabled by the discovery of general anesthesia, means to control or eliminate infection, and the evolution of the hospital, where patients could be housed and surgeons could work in a supportive environment that included nurses and hospital administrators. Later, development of the basic sciences enabled the development of new operations and methods to deal with altered physiology and body chemistry caused by illness, trauma, and complex surgical procedures. Most recently, striking advances in technology have enabled the development of minimally invasive and robotic surgery.

# PREOPERATIVE AND POSTOPERATIVE MANAGEMENT

*Zara Cooper • Edward Kelly*

Surgeons of every specialty face increasingly complex surgical challenges. In addition, modern surgical treatment can be offered to more fragile patients, with successful outcomes. Mastery of the scientific fundamentals of perioperative management is required to achieve satisfactory results. The organ system–based approach presented here allows the surgeon to address the patient’s pre- and postoperative needs with a comprehensive surgical plan. This chapter will serve as a summary guide to best practices integral to conducting surgical procedures in the modern era.

## MANAGEMENT OF PAIN AND DELIRIUM

The most common neuropsychiatric complications following abdominal surgery are pain and delirium. Moreover, uncontrolled pain and delirium prevent the patient from contributing to vital aspects of his or her care, such as ambulation and respiratory toilet, and promote an unsafe environment that may lead to the unwanted dislodgment of drains and other supportive

devices, with potentially life-threatening consequences. Pain and delirium usually coexist in the postoperative setting, and each can contribute to the development of the other. Despite high reported rates of overall patient satisfaction, pain control is frequently inadequate in the perioperative setting,<sup>1</sup> with high rates of complications such as drowsiness from overtreatment and unacceptable levels of pain from undertreatment. Therefore, it is mandatory that the surgical plan for every patient include close monitoring of postoperative pain and delirium and regular assessment of the efficacy of pain control.

Pain management, like all surgical planning, begins in the preoperative assessment. In the modern era, a large proportion of surgical patients will require special attention with respect to pain control. Patients with preexisting pain syndromes, such as sciatica or interspinal disc disease, or patients with a history of opioid use may have a high tolerance for opioid analgesics. Every patient's history should include a thorough investigation for chronic pain syndrome, addiction (active or in recovery), and adverse reactions to opioid, nonsteroidal, or epidural analgesia. The pain control strategy may include consultation with a pain control anesthesiology specialist, but it is the responsibility of the operating surgeon to identify complicated patients and construct an effective pain control plan.

## **Opioid Analgesia**

Postoperative pain control using opioid medication has been in use for thousands of years. Hippocrates advocated the use of opium for pain control. The benefits of postoperative pain control are salutary and include improved mobility and respiratory function and earlier return to normal activities. The most effective strategy for pain control using opioid analgesia is patient-controlled analgesia (PCA), wherein the patient is instructed in the use of a preprogrammed intravenous pump that delivers measured doses of opioid (usually morphine or meperidine). In randomized trials, PCA has been shown to provide superior pain control and patient satisfaction compared to interval dosing,<sup>2</sup> but PCA has not been shown to improve rates of pulmonary and cardiac complications<sup>3</sup> or length of hospital stay,<sup>4</sup> and there is evidence that PCA may contribute to postoperative ileus.<sup>5</sup> In addition, PCA may be unsuitable for patients with a history of substance abuse, high opioid

tolerance, or those with atypical reactions to opioids.

## **Regional Analgesia**

Due to the limitations of PCA, pain control clinicians have turned to regional analgesia as an effective strategy for the management of postoperative pain. Postoperative epidural analgesia involves the insertion of a catheter into the epidural space of the lumbar or thoracic spine, enabling the delivery of local anesthetics or opioids directly to the nerve roots. The insertion procedure is generally safe, with complication rates of motor block and numbness between 0.5% and 7%,<sup>6</sup> and an epidural abscess rate of 0.5 per thousand.<sup>7</sup> Potential advantages of epidural analgesia include elimination of systemic opioids, and thus less respiratory depression, and improvement in pulmonary complications and perioperative ileus. There have been several large trials,<sup>8-10</sup> a meta-analysis,<sup>6</sup> and a systematic review<sup>11</sup> comparing PCA with epidural analgesia in the setting of abdominal surgery. These studies indicate that epidural analgesia provides more complete analgesia than PCA throughout the postoperative course. Furthermore, in randomized prospective series of abdominal procedures, epidural analgesia has been associated with decreased rates of pulmonary complications<sup>12,13</sup> and postoperative ileus.<sup>14,15</sup> Epidural analgesia requires a skilled anesthesia clinician to insert and monitor the catheter and adjust the dosage of neuraxial medication. Some clinicians may prefer correction of coagulopathy before inserting or removing the catheter, although the American Society of Anesthesiologists (ASA) has not issued official guidelines on this issue.

Peripheral nerve blocks are also effective in perioperative pain control and do not carry the same potential morbidities as the epidural approach. Using ultrasound guidance, a skilled practitioner can deliver a long-acting local anesthetic into the transversus abdominis plane (TAP) or in the rectus sheath to establish analgesia both intraoperatively and postoperatively. Randomized clinical data have confirmed the efficacy of regional blocks in controlling pain and reducing use of opioid analgesia.<sup>16,17</sup>

## **Analgesia with Nonsteroidal Anti-Inflammatory Drugs**

Oral nonsteroidal anti-inflammatory drugs (NSAIDs) have long been used for postoperative analgesia in the outpatient setting and, with the development of parenteral preparations, have come into use in the inpatient population. This class of medication has no respiratory side effects and is not associated with addiction potential, altered mental status, or ileus. In addition, these medications provide effective pain relief in the surgical population. However, use of NSAIDs has not been universally adopted in abdominal surgery due to concerns regarding the platelet dysfunction and erosive gastritis associated with heavy NSAID use. In prospective trials, NSAIDs were found to provide effective pain control without bleeding or gastritis symptoms following laparoscopic cholecystectomy,<sup>18</sup> abdominal hysterectomy,<sup>19</sup> and inguinal hernia repair.<sup>20,21</sup> NSAIDs have also been shown to improve pain control and decrease morphine dosage when used in combination following appendectomy.<sup>22</sup>

The sensation of pain is very subjective and personal. Accordingly, the surgeon must individualize the pain control plan to fit the needs of each patient. The pain control modalities discussed above can be used in any combination, and the surgeon should not hesitate to use all resources at his or her command to provide adequate relief of postoperative pain.

## **Postoperative Delirium**

Delirium, defined as acute cognitive dysfunction marked by fluctuating disorientation, sensory disturbance, and decreased attention, is an all too common complication of surgical procedures, with reported rates of 11% to 25%, with the highest rates reported in the elderly population.<sup>23,24</sup> The postoperative phase of abdominal surgery exposes patients, some of whom may be quite vulnerable to delirium, to a large number of factors that may precipitate or exacerbate delirium (Table 2-1). These factors can augment one another: postoperative pain can lead to decreased mobility, causing respiratory compromise, atelectasis, and hypoxemia. Escalating doses of narcotics to treat pain can cause respiratory depression and respiratory acidosis. Hypoxemia and delirium can cause agitation, prompting treatment with benzodiazepines, further worsening respiratory function and delirium. This vicious cycle can result in serious complications or death. Preoperative recognition of high-risk patients and meticulous monitoring of every patient's

mental status are the most effective ways to prevent postoperative delirium; treatment can be remarkably difficult once the cycle has begun.

**TABLE 2-1: CAUSES OF PERIOPERATIVE DELIRIUM**

Pain  
Narcotic analgesics  
Sleep deprivation  
Hypoxemia  
Hyperglycemia  
Acidosis  
Withdrawal (alcohol, narcotics, benzodiazepines)  
Anemia  
Dehydration  
Electrolyte imbalance (sodium, potassium, magnesium, calcium, phosphate)  
Fever  
Hypotension  
Infection (pneumonia, incision site infection, urinary tract infection)  
Medication (antiemetics, antihistamines, sedatives, anesthetics)  
Postoperative myocardial infarction

---

Patient factors that are associated with high risk of perioperative delirium include age greater than 70 years, preexisting cognitive impairment or prior episode of delirium, history of alcohol or narcotic abuse, and malnutrition.<sup>22,25</sup> Procedural factors associated with high delirium risk include operative time greater than 2 hours, prolonged use of restraints, presence of a urinary catheter, addition of more than 3 new medications, and reoperation.<sup>26</sup>

Once the patient's risk for postoperative delirium is identified, perioperative care should be planned carefully to decrease other controllable factors. Epidural analgesia has been associated with less delirium than PCA after abdominal surgery.<sup>26</sup> Sedation or "sleepers" should be used judiciously, if at all, with high-risk patients. If the patient requires sedation, neuroleptics such as haloperidol and the atypical neuroleptics such as olanzapine are

tolerated much better than benzodiazepines.<sup>27</sup> The patient's mental status, including orientation and attention, should be assessed with every visit and care should be taken to avoid anemia, electrolyte imbalances, dehydration, and other contributing factors.

Once the diagnosis of postoperative delirium is established, it is important to recognize that some of the causes of delirium are potentially life-threatening, and immediate action is necessary. Evaluation begins with a thorough history and physical examination at the bedside by the surgeon. The history should focus on precipitating events such as falls (possible traumatic brain injury), recent procedures, use of opioids and sedatives, changes in existing medications (eg, withholding of thyroid replacement or antidepressants), and consideration of alcohol withdrawal. The vital signs and fluid balance may suggest sepsis, hypovolemia, anemia, or dehydration. The exam should include brief but complete sensory and motor neurologic examinations to differentiate delirium from stroke. Pay attention to common sites of infection such as the surgical wound, the lungs, and intravenous catheters. Urinary retention may be present as a result of medication or infection. Deep venous thrombosis may be clinically evident as limb swelling. Postoperative myocardial infarction (MI) may often present as acute cardiogenic shock.

The history and physical examination should then direct the use of lab tests. Most useful are the electrolytes, blood glucose, and complete blood cell count. Pulse oximetry and arterial blood gases may disclose hypercapnia or hypoxemia. Chest x-ray may disclose atelectasis, pneumonia, acute pulmonary edema, or pneumothorax. Cultures may be indicated in the setting of fever or leukocytosis, but will not help immediately. Electrocardiogram (ECG) and cardiac troponin may be used to diagnose postoperative MI.

Resuscitative measures may be required if life-threatening causes of delirium are suspected. Airway control, supplemental oxygen, and fluid volume expansion should be considered in patients with unstable vital signs. The patient should not be sent out of the monitored environment for further tests, such as head computed tomography (CT), until the vital signs are stable and the agitation is controlled. Treatment of postoperative delirium depends on treatment of the underlying causes. Once the underlying cause has been treated, delirium may persist, especially in elderly or critically ill patients, who regain orientation and sleep cycles slowly. In these patients, it is important to provide orienting communication and mental stimulation during

the day and to promote sleep during the night. The simplest ways are the most effective: contact with family members and friends, use of hearing aids, engagement in activities of daily living, and regular mealtimes. Sleep can be promoted by keeping the room dark and quiet throughout the evening and preventing unnecessary interruptions. If nighttime sedation is required, atypical neuroleptics or low-dose serotonin reuptake inhibitors such as trazodone are better tolerated than benzodiazepines. If agitation persists, escalating doses of neuroleptics (or benzodiazepines in the setting of alcohol withdrawal) can be used to control behavior, but underlying organic causes of delirium must be investigated.

## CARDIAC EVALUATION

### Risk Assessment

It has been estimated that 1 million patients have a perioperative MI each year, and the contribution to medical costs is \$20 billion annually.<sup>28</sup> Thoracic, upper abdominal, neurologic, and major orthopedic procedures are associated with increased cardiac risk. Diabetes, prior MI, unstable angina, and decompensated congestive heart failure (CHF) are most predictive of perioperative cardiac morbidity and mortality, and patients with these conditions undergoing major surgery warrant further evaluation<sup>29</sup> (Table 2-2). Patient factors conferring intermediate risk include mild angina and chronic renal insufficiency with baseline creatinine  $\geq 2$  mg/dL.<sup>30</sup> It is worth noting that women were underrepresented in the studies on which the American College of Cardiology and the American Heart Association (ACC/AHA) guidelines are based.<sup>31</sup> A retrospective study in gynecologic patients found that hypertension and previous MI were major predictors of postoperative cardiac events, as opposed to the ACC/AHA guidelines, which indicate that they are minor and intermediate criteria, respectively.<sup>32</sup> Vascular surgical patients are at highest risk because of the prevalence of underlying coronary disease in this population.<sup>29,33</sup> Other high-risk procedural factors include emergency surgery, long operative time, and high fluid replacement volume. Intraperitoneal procedures, carotid endarterectomy, thoracic surgery, head and neck procedures, and orthopedic procedures carry an intermediate

risk and are associated with a 1% to 5% risk of a perioperative cardiac event.<sup>30</sup>

**TABLE 2-2: CLINICAL PREDICTORS OF INCREASED RISK FOR PERIOPERATIVE CARDIAC COMPLICATIONS**

### **Major**

Recent myocardial infarction (within 30 days)

Unstable or severe angina

Decompensated congestive heart failure

Significant arrhythmias (high-grade atrioventricular block, symptomatic ventricular arrhythmias with underlying heart disease, supraventricular arrhythmias with uncontrolled rate)

Severe valvular disease

### **Intermediate**

Mild angina

Any prior myocardial infarction by history or electrocardiogram

Compensated or prior congestive heart failure

Diabetes mellitus

Renal insufficiency

### **Minor**

Advanced age

Abnormal electrocardiogram

Rhythm other than sinus (eg, atrial fibrillation)

Poor functional capacity

History of stroke

Uncontrolled hypertension (eg, diastolic blood pressure >10 mm Hg)

---

Perioperative evaluation to identify patients at risk for cardiac complications is essential in minimizing morbidity and mortality. Workup should start with history, physical exam, and ECG to determine the existence of cardiac pathology. Screening with chest radiographs and ECG is required for men over 40 and women over 55. According to the ACC/AHA guidelines, initial preoperative cardiac risk can be assessed using a clinical calculator, the

Revised Cardiac Risk Index (RCRI).<sup>34</sup> This index includes history of ischemic heart disease, CHF, cerebrovascular disease, diabetes, chronic kidney disease, and planned high-risk procedure. Advanced or invasive testing is reserved for patients with 2 or more of these risk factors. Overall functional ability is the best clinical measure of cardiac fitness. Patients who can exercise without limitations can generally tolerate the stress of major surgery.<sup>35</sup> Limited exercise capacity may indicate poor cardiopulmonary reserve and the inability to withstand the stress of surgery. Poor functional status is the inability to perform activities such as driving, cooking, or walking less than 5 km/h.

Intraoperative risk factors include operative site, inappropriate use of vasopressors, and unintended hypotension. Intra-abdominal pressure exceeding 20 mm Hg during laparoscopy can decrease venous return from the lower extremities and thus contribute to decreased cardiac output,<sup>36</sup> and Trendelenburg positioning can result in increased pressure on the diaphragm from the abdominal viscera, subsequently reducing vital capacity. Intraoperative hypertension has not been isolated as a risk factor for cardiac morbidity, but it is often associated with wide fluctuations in pressure and has been more closely associated with cardiac morbidity than intraoperative hypotension. Preoperative anxiety can contribute to hypertension even in normotensive patients. Patients with a history of hypertension, even medically controlled hypertension, are more likely to be hypertensive preoperatively. Those with poorly controlled hypertension are at greater risk of developing intraoperative ischemia, arrhythmias, and blood pressure derangements, particularly at induction and intubation. Twenty-five percent of patients will exhibit hypertension during laryngoscopy. Patients with chronic hypertension may not necessarily benefit from lower blood pressure during the preoperative period because they may depend on higher pressures for cerebral perfusion. Those receiving antihypertensive medications should continue them up until the time of surgery. Patients taking  $\beta$ -blockers are at risk of withdrawal and rebound ischemia. Key findings on physical examination include retinal vascular changes and an S<sub>4</sub> gallop consistent with left ventricular hypertrophy. Chest radiography may show an enlarged heart, also suggesting left ventricular hypertrophy.

ECG should be obtained in patients with chest pain, diabetes, prior revascularization, prior hospitalization for cardiac causes, all men age 45 or

older, and all women age 55 or older with 2 or more risk factors. High- or intermediate-risk patients should also have a screening ECG. A lower-than-normal ejection fraction demonstrated on echocardiography is associated with the greatest perioperative cardiac risk and should be obtained in all patients with symptoms suggesting heart failure or valvular disease. Tricuspid regurgitation indicates pulmonary hypertension and is often associated with sleep apnea. The chest x-ray is used to screen for cardiomegaly and pulmonary congestion, which may signify ventricular impairment.

Exercise testing demonstrates a propensity for ischemia and arrhythmias under conditions that increase myocardial oxygen consumption. Numerous studies have shown that performance during exercise testing is predictive of perioperative mortality in noncardiac surgery. ST-segment changes during exercise including horizontal depression greater than 2 mm, changes with low workload, and persistent changes after 5 minutes of exercise are seen in severe multivessel disease. Other findings include dysrhythmias at a low heart rate, an inability to raise the heart rate to 70% of predicted, and sustained decrease in systolic pressure during exercise.

Unfortunately, many patients are unable to achieve adequate workload in standard exercise testing because of osteoarthritis, low back pain, and pulmonary disease. In this case, pharmacologic testing is indicated with a dobutamine echocardiogram. Dobutamine is a  $\beta$ -agonist that increases myocardial oxygen demand and reveals impaired oxygen delivery in those with coronary disease. Echocardiography concurrently visualizes wall motion abnormalities due to ischemia. Transesophageal echocardiography may be preferable to transthoracic echocardiography in obese patients because of their body habitus and has been shown to have high negative predictive value in this group.<sup>37</sup> Nuclear perfusion imaging with vasodilators such as adenosine or dipyridamole can identify coronary artery disease and demand ischemia. Heterogeneous perfusion after vasodilator administration demonstrates an inadequate response to stress. Wall motion abnormalities indicate ischemia, and an ejection fraction lower than 50% increases the risk of perioperative mortality. Angiography should only be performed if the patient may be a candidate for revascularization.

## **Coronary Disease**

Most perioperative MIs are caused by plaque rupture in lesions that do not

produce ischemia during preoperative testing.<sup>38</sup> This presents an obvious challenge for detecting patients at risk. Stress testing has a low positive predictive value in patients with no cardiac risk factors and has been associated with an unacceptably high rate of false-positive results.<sup>39</sup>

Preoperative optimization may include medical management, percutaneous coronary interventions (PCIs), or coronary artery bypass grafting (CABG).<sup>40</sup> The ACC/AHA guidelines<sup>29</sup> recommend revascularization for patients whose preoperative testing reveals severe disease that warrants intervention according to practice guidelines for coronary artery disease, independent of their perioperative status.

Patients warranting emergent CABG will be at greatest risk for that procedure. A recent study from the Veterans Administration hospitals recommends against revascularization in patients with stable cardiac symptoms.<sup>41</sup> Preoperative PCI does not decrease the risk of future MI or mortality in patients with stable coronary disease, and only targets stenotic lesions, rather than those most likely to rupture. One retrospective study found no reduction in morbidity or perioperative MI after percutaneous transluminal coronary angioplasty, and the authors proposed that surgery within 90 days of balloon angioplasty increased the risk of thrombosis.<sup>42</sup> However, PCI done more than 90 days before surgery did provide benefit when compared to those who had no intervention at all. Another retrospective study found that patients who have surgery within 2 weeks of stenting had a high incidence of perioperative MI, major bleeding, or death.<sup>43</sup> Although a retrospective review from the Coronary Artery Surgery Study registry showed a lower mortality rate in patients with coronary artery disease who were post-CABG than those without CABG (0.09% vs 2.4%), this benefit did not include the morbidity associated with CABG itself. Unfortunately, the benefit was overwhelmed by the 2.3% morbidity rate seen with CABG in this cohort.<sup>44</sup> Survival benefit of CABG over medical management is realized at 2 years or more after surgery,<sup>45</sup> so preoperative mortality may decrease overall short-term survival. Revascularization and bypass grafting should be restricted to patients who would benefit from the procedure independent of their need for noncardiac surgery. One of the disadvantages of PCI in the preoperative setting is the need for anticoagulation to prevent early stent occlusion. The use of platelet inhibitors to prevent stent occlusion must be included in the overall risk assessment, especially for surgery of the central

nervous system.

Catecholamine surges can cause tachycardia, which may alter the tensile strength of coronary plaques and incite plaque rupture.<sup>46,47</sup> Catecholamine surges can also increase blood pressure and contractility, contributing to platelet aggregation and thrombosis after plaque rupture and increasing the possibility of complete occlusion of the arterial lumen.<sup>48</sup> Perioperative  $\beta$ -blockade mitigates these effects and has been shown to reduce MI and mortality from MI by over 30% in vascular surgical patients with reversible ischemia.<sup>46</sup> Patients at highest risk still have a cardiac event rate of 10%, even with adequate perioperative  $\beta$ -blockade.<sup>29</sup>

In 1998, a landmark study<sup>49</sup> demonstrated a 55% reduction in mortality in noncardiac surgical patients with known coronary disease who were given atenolol perioperatively. This was followed by the DECREASE trial,<sup>50</sup> which showed a 10-fold reduction in perioperative MI and death compared to placebo. Thereafter, perioperative  $\beta$ -blockade was widely adopted as a quality measure. However, additional later investigations have shown that although perioperative  $\beta$ -blockers benefit patients with known ischemia, low-risk patients may in fact be harmed.<sup>51</sup> Tight rate control has been associated with increased risk of hypotension and bradycardia requiring intervention and stroke without any significant decrease in mortality.<sup>52-55</sup> Furthermore, critical analysis of the literature shows that studies have been inconsistent in the type of medication administered, the duration and timing of administration, and the target for heart rate control.<sup>56</sup> Consequently, results are difficult to interpret. Thus, prophylactic perioperative  $\beta$ -blockade should be restricted to patients with cardiac ischemia and has a limited role in patients with low or moderate risk of postoperative cardiac events.<sup>29</sup>

## **Congestive Heart Failure and Arrhythmia**

CHF is associated with coronary disease, valvular disease, ventricular dysfunction, and all types of cardiomyopathy. These are all independent risk factors that should be identified prior to surgery. Even compensated heart failure may be aggravated by fluid shifts associated with anesthesia and abdominal surgery and deserves serious consideration. Perioperative mortality increases with higher New York Heart Association class and preoperative pulmonary congestion. CHF should be treated to lower filling

pressures and improve cardiac output before elective surgery.  $\beta$ -Blockers, angiotensin-converting enzyme inhibitors, and diuretics can be employed to this end. The patient should be stable for 1 week before surgery.<sup>57</sup>

Arrhythmias and conduction abnormalities elicited in the history, on exam, or on ECG should prompt investigation into metabolic derangements, drug toxicities, or coronary disease. In the presence of symptoms or hemodynamic changes, the underlying condition should be reversed and then medication given to treat the arrhythmia. Indications for antiarrhythmic medication and cardiac pacemakers are the same as in the nonoperative setting. Nonsustained ventricular tachycardia and premature ventricular contractions have not been associated with increased perioperative risk and do not require further intervention.<sup>58,59</sup>

## Valvular Disease

Valvular disease should be considered in patients with symptoms of CHF, syncope, and a history of rheumatic heart disease. Aortic stenosis (AS) is a fixed obstruction to the left ventricular outflow tract, limiting cardiac reserve and an appropriate response to stress. History should elicit symptoms of dyspnea, angina, and syncope; examination may reveal a soft S<sub>2</sub>, a late-peaking murmur, or a right-sided crescendo–decrescendo murmur radiating to the carotids. AS is usually caused by progressive calcification or congenital bicuspid valve. Critical stenosis exists when the valve area is less than 0.7 cm<sup>2</sup> or transvalvular gradients are greater than 50 mm Hg and is associated with an inability to increase cardiac output with demand. If uncorrected, AS is associated with a 13% risk of perioperative death. Valve replacement is indicated prior to elective surgery in patients with symptomatic stenosis.<sup>29</sup> Myocardial ischemia may occur in the absence of significant coronary artery occlusion in the presence of aortic valve disease. Perioperative management should include optimizing the heart rate to between 60 and 90 beats per minute and avoiding atrial fibrillation if possible. Because of the outflow obstruction, stroke volume may be fixed and bradycardia will lower cardiac output. Similarly, hypotension is also poorly tolerated.

Aortic regurgitation (AR) is associated with backward flow into the left ventricle during diastole and reduced forward stroke volume. Bradycardia

facilitates regurgitation by increased diastolic time. Chronic AR causes massive left ventricular dilatation (cor bovinum) and hypertrophy, which is associated with decreased left ventricular function at later stages. AR is most often caused by rheumatic disease or congenital bicuspid valve. Medical treatment includes rate control and afterload reduction. Without valve replacement, survival is approximately 5 years once patients become symptomatic. This is an obvious consideration when planning any other surgical procedures.

Tricuspid regurgitation is usually caused by pulmonary hypertension secondary to severe left-sided failure. Other causes include endocarditis, carcinoid syndrome, and primary pulmonary hypertension. Hypovolemia, hypoxia, and acidosis can increase right ventricular afterload and should be avoided in the perioperative period.

Mitral stenosis is an inflow obstruction that prevents adequate left ventricular filling. The transvalvular pressure gradient depends on atrial kick, heart rate, and diastolic filling time. Tachycardia decreases filling time and contributes to pulmonary congestion. Mitral regurgitation is also associated with pulmonary hypertension with congestion, as the pathologic valve prevents forward flow, causing left atrial dilatation and subsequent atrial arrhythmias. History and physical exam should focus on signs of CHF such as orthopnea, pedal edema, dyspnea, reduced exercise tolerance, and auscultatory findings such as murmurs and an S<sub>3</sub> gallop. Neurologic deficits may signify embolic sequelae of valve disease. Perioperative rate control is essential for maintaining adequate cardiac output. ECG findings will reflect related arrhythmias and medications but will not be specific for valve disease. Laboratory studies should identify secondary hepatic dysfunction or pulmonary compromise. Left ventricular hypertrophy is an adaptive response, which may cause subsequent pulmonary hypertension and diastolic dysfunction.

Prosthetics in the mitral position pose the greatest risk for thromboembolism, and the risk increases with valve area and low flow. Mechanical valves pose a higher risk than tissue valves in patients with a history of valve replacement. Diuretics and afterload-reducing agents will enhance forward flow and minimize cardiopulmonary congestion. Patients with mitral valve prolapse (MVP) should receive antibiotics.

Mitral regurgitation may also impair left ventricular function and lead to pulmonary hypertension. Stroke volume is reduced by backward flow into the

atrium during systole. The left ventricle dilates to handle increasing end-systolic volume, eventually causing concentric hypertrophy and decreased contractility. The end result may be decreased ejection fraction and CHF. A decrease in systemic vascular resistance and increase in atrial contribution to the ejection fraction can both improve forward flow and reduce the amount of regurgitation. Echocardiography can clarify the degree of valvular impairment. Medical treatment centers on afterload reduction with vasodilators and diuretics. MVP is present in up to 15% of women and is usually associated with a midsystolic click and late systolic murmur on physical exam. Murmur is indicative of prolapse. Although MVP is associated with connective tissue disorders, it usually occurs in otherwise healthy, asymptomatic patients. Echocardiography is used to confirm the diagnosis and evaluate the degree of prolapse. Chronically, MVP may be associated with mitral regurgitation, emboli, and increased risk of endocarditis. Prolapse may be aggravated by decreased preload, which should be minimized in the perioperative period. Patients with MVP are at risk of ventricular arrhythmias with sympathetic stimulation and endocarditis, which can be addressed with pain control and antibiotic prophylaxis, respectively.

Individuals with underlying structural cardiac defects are at increased risk for developing endocarditis after invasive procedures. Surgical procedures involving mucosal surfaces or infected tissues may cause transient bacteremia that is usually short-lived. Certain procedures are associated with a greater risk of endocarditis and warrant prophylaxis (Table 2-3). Abnormal valves, endocardium, or endothelium can harbor the bloodborne bacteria for a longer period of time, and infection and inflammation can ensue. Although there are no randomized trials regarding endocarditis prophylaxis, the AHA recommends prophylaxis for those<sup>60</sup> at high and moderate risk for developing the condition. The highest-risk patients have prosthetic heart valves, cyanotic congenital heart disease, or a history of endocarditis (even without structural abnormality).<sup>61</sup> Conditions associated with moderate risk include congenital septal defects, patent ductus arteriosus, coarctation of the aorta, and bicuspid aortic valve. Hypertrophic cardiomyopathy and acquired valvular disease also fall into this category. MVP is a prevalent and often situational condition. Normal valves may prolapse in the event of tachycardia or hypovolemia and may reflect normal growth patterns in young people. Prolapse without leak or regurgitation seen on Doppler studies is not associated with risk greater than that of the general population, and no antibiotic prophylaxis is necessary.<sup>62,63</sup>

However, the jet caused by the prolapsed valve increases the risk of bacterial adherence and subsequent endocarditis. Leaky valves detected by physical exam or Doppler warrant consideration for prophylactic antibiotics.<sup>64</sup> Patients with significant regurgitation are more likely to be older and men, and other studies have shown that older men are more likely to develop endocarditis.<sup>64-66</sup> Some advocate prophylaxis for men older than 45 years with MVP even in the absence of audible regurgitation.<sup>66</sup> Prolapse secondary to myxomatous valve degeneration also warrants prophylactic antibiotics.<sup>67,68</sup>

**TABLE 2-3: AHA ENDOCARDITIS PROPHYLAXIS RECOMMENDATIONS**

### **Antibiotic Coverage Recommended**

Respiratory: tonsillectomy/adenoidectomy; bronchoscopy with biopsy; procedures involving respiratory mucosa

Gastrointestinal tract: any procedure in the setting of infected tissue in the gastrointestinal tract

Genitourinary tract: any procedure in the setting of established infection

### **Antibiotic Coverage Not Recommended**

Respiratory: endotracheal intubation; bronchoscopy without biopsy; tympanostomy

Gastrointestinal tract: transesophageal echocardiography; endoscopy without biopsy

In uninfected tissue: urethral catheterization; uterine dilation and curettage; therapeutic abortion; manipulation of intrauterine devices

Other: cardiac catheterization; pacemaker placement; circumcision; incision or biopsy on prepped skin

---

For patients at risk, the goal should be administration of antibiotics in time to attain adequate serum levels during and after the procedure. For most operations, a single intravenous dose given 1 hour prior to incision will achieve this goal. Antibiotics should generally not be continued for more than 6 to 8 hours after the procedure to minimize the chance of bacterial resistance. In the case of oral, upper respiratory, and esophageal procedures,  $\alpha$ -hemolytic *Streptococcus* is the most common cause of endocarditis, and

antibiotics should be targeted accordingly. Oral amoxicillin, parenteral ampicillin, and clindamycin for penicillin-allergic patients are suitable medications. Erythromycin is no longer recommended for penicillin-allergic patients because of gastrointestinal side effects and variable absorption.<sup>69</sup> Antibiotics given to those having genitourinary and nonesophageal gastrointestinal procedures should target enterococci.<sup>69</sup> While gram-negative bacteremia can occur, it rarely causes endocarditis. Parenteral ampicillin and gentamicin are recommended for highest-risk patients. Moderate-risk patients may receive amoxicillin or ampicillin. Vancomycin may be substituted in patients allergic to penicillin.

## PERIOPERATIVE MANAGEMENT OF ANTITHROMBOTIC MEDICATION

Estimates suggest that 250,000 patients receiving chronic anticoagulation require surgery in the United States each year. Operative bleeding risk must be balanced against thromboembolic risk for the patient off of anticoagulation and requires careful judgment. Factors that influence the risk of thromboembolism include the condition requiring chronic anticoagulation, the duration of the procedure, time expected off of anticoagulation, and the duration of perioperative immobility. Thromboembolic risk increases with the amount of time that the patient's anticoagulation is subtherapeutic.

Primary indications for chronic anticoagulation include arterial embolism associated with mechanical valves and atrial fibrillation and venous thromboembolism (VTE). Arterial events precipitate stroke, and valvular and atrial clot and systemic emboli are higher risk for morbidity and mortality than venous events. Patients at highest risk for perioperative embolism include those with mechanical prosthetic mitral valves, aortic caged-ball and tilted valves, rheumatic heart disease, or history of stroke or transient ischemic attacks (TIAs) in the past 3 months. The risk of thromboembolism without anticoagulation is higher than 10% per year in these high-risk patients.

Patients at moderate risk of thromboembolism without anticoagulation (4%-10% per year) have atrial fibrillation, a bileaflet valve, or history of stroke or TIA. The CHADS<sub>2</sub> score (CHF, hypertension, age, diabetes, and stroke) further stratifies embolic risk for patients with atrial fibrillation based

on comorbidities. One point is assigned for hypertension, diabetes, CHF, and age >75 years; 2 points are assigned for history of stroke or TIA. Patients with a cumulative score of 5 to 6 are highest risk; those with a score of 3 to 4 are moderate risk; and those with a score of 0 to 2 without history of stroke or TIA are low risk.

Chronic anticoagulation is indicated for VTE. Patients with VTE within 3 months of surgery and severe thrombophilia are at highest risk for perioperative events and should receive bridging anticoagulation with therapeutic doses of low-molecular-weight heparin (LMWH) or intravenous unfractionated heparin (UFH). Patients at moderate risk include those with a thromboembolic event 3 to 12 months before surgery and less severe thrombophilias. They can receive therapeutic or subtherapeutic doses of anticoagulation depending on the risk of bleeding associated with the procedure. Patients with a remote event are at lowest risk and do not require bridging anticoagulation. It is generally recommended to stop warfarin 5 days prior to surgery if a normal international normalized ratio (INR) is desired. Vitamin K may be administered in the days leading up to the event if the INR is not correcting quickly enough.

LMWH should be held 24 hours before surgery, and intravenous UFH should be held 4 hours before surgery. Oral anticoagulants may be started 12 to 24 hours postoperatively because they take at least 48 hours to affect coagulation. The timing of resuming intravenous and subcutaneous anticoagulants should be determined on a case-by-case basis.

Low-risk patients receiving clopidogrel or aspirin should have it held 5 to 10 days before surgery. Patients with coronary stents are chronically treated with clopidogrel and aspirin to mitigate the risk of stent thrombosis. Interruptions in therapy are associated with high risk of thrombosis and infarct. Patients with bare metal stents placed within 6 weeks of surgery or drug-eluting stents placed within 12 months of surgery should continue clopidogrel and aspirin in the perioperative period.

The perioperative antithrombotic guidelines<sup>70</sup> from the American College of Chest Physicians are summarized in [Table 2-4](#).

**TABLE 2-4: GUIDELINES FOR PERIOPERATIVE MANAGEMENT OF ANTITHROMBOTIC MEDICATIONS**

	Standard Anticoagulation	Antiplatelet Therapy	Should Warfarin or Antiplatelet Therapy Be Stopped Preoperatively?	Is Bridging Anticoagulation Indicated?	When Should Anticoagulant or Antithrombotic Be Restarted Postoperatively?
Low-risk atrial fibrillation	Warfarin goal INR 2.0	None	Yes, 5 days	No	When taking orals
Moderate-/high-risk atrial fibrillation	Warfarin goal INR 2.0	None	Yes, 5 days	No	When taking orals
Mechanical mitral valve	Warfarin goal INR 2.5-3.0	None	Yes, 5 days	Yes	Low bleeding risk: 24 hours High bleeding risk: 48-72 hours
Mechanical aortic valve	Warfarin goal INR 2.0	None	Yes, 5 days	Yes	Low bleeding risk: 24 hours High bleeding risk: 48-72 hours
Coronary stent	None	Clopidogrel Aspirin	Yes, 5-10 days No	No	Low bleeding risk: 24 hours High bleeding risk: 48-72 hours
Bare metal coronary stent within 6 weeks	None	Aspirin and clopidogrel	No	No	Low bleeding risk: 24 hours High bleeding risk: 48-72 hours
Drug-eluting stent within 12 months	None	Aspirin and clopidogrel	No	No	Low bleeding risk: 24 hours High bleeding risk: 48-72 hours
History of venous thromboembolism	Warfarin goal INR 2.0 for at least 3 months	No	Yes, 5-7 days	Low risk- no Moderate/ high risk- yes	

Low risk: venous thromboembolism (VTE) >12 months ago; CHADS<sub>2</sub> score 0-2 without prior stroke or transient ischemic attack (TIA).

Moderate risk: VTE in past 3-12 months, moderate thrombophilia, recurrent VTE, cancer; CHADS<sub>2</sub> score 3-4.

High risk: VTE in past 3 months, prior postoperative VTE, severe thrombophilia; CHADS<sub>2</sub> score 5-6, rheumatic heart disease, or stroke or TIA within 3 months.

Abbreviation: INR, international normalized ratio.

Data from Douketis JD, Spyropoulos AC, Spencer FA, et al: Perioperative management of antithrombotic therapy: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, *Chest* 2012 Feb;141(2 Suppl):e326S-e350S.

## PULMONARY EVALUATION

Pulmonary complications are common after surgery and can prolong hospital stays for 1 to 2 weeks.<sup>71</sup> Complications include atelectasis, pneumonia, exacerbations of chronic pulmonary disorders, and respiratory failure requiring mechanical ventilation. Smoking, underlying chronic obstructive pulmonary disease (COPD), and poor exercise tolerance are the greatest risk factors for postoperative pulmonary complications. Physicians should ask about a history of smoking, decreased exercise capacity, dyspnea, and chronic cough. Examination should note pursed lip breathing, clubbing, and chest wall anatomy that could impair pulmonary function. Pulmonary testing is unnecessary in patients without a clear history of smoking or pulmonary disease. The predictive value of screening spirometry is unclear, and no threshold value has been identified to guide surgical decision-making. Forced expiratory volume in 1 second less than 50% of predicted is indicative of exertional dyspnea and may herald the need for further testing. Preoperative chest x-ray abnormalities are associated with postoperative pulmonary complications,<sup>71</sup> but to this point, there are no recommendations for screening radiographs in patients without pulmonary disease. Any

preoperative chest x-ray must be examined for signs of hyperinflation consistent with COPD. While compensated hypercapnia has not been shown to be an independent predictor for postoperative ventilatory insufficiency in patients undergoing lung resection, preoperative arterial blood gas analysis provides useful baseline information for perioperative management of patients with chronic carbon dioxide retention. Transverse and upper abdominal incisions are associated with a higher rate of postoperative pulmonary complications than longitudinal midline incisions and lower abdominal incisions.<sup>72</sup> Surgery longer than 3 hours is also associated with higher risk.<sup>73</sup> General anesthesia is also associated with a higher risk of pulmonary complications than spinal, epidural, or regional anesthesia.<sup>74</sup>

Physiologic changes can be seen in the postoperative period, especially after thoracic and upper abdominal procedures. Vital capacity may decrease by 50% to 60%, and is accompanied by an increased respiratory rate to maintain tidal volumes. Normally, functional residual capacity usually exceeds the closing capacity of the alveoli so they remain open throughout the respiratory cycle. Prolonged effects of anesthetics and narcotics reduce functional reserve capacity postoperatively, causing alveolar collapse. These changes can last for weeks to months. A distended abdomen can impair diaphragmatic excursion; painful incisions around the diaphragm and other respiratory muscles contribute to splinting and inadequate pulmonary toilet. Narcotics can inhibit sighing and coughing reflexes, which normally prevent alveolar collapse during periods of sleep and recumbency. Analgesics must be titrated carefully to permit deep breathing and avoid impairing respiratory effort.

Inspired nonhumidified oxygen and halogenated anesthetics are cytotoxic and interfere with surfactant production and mucociliary clearance. Depressed respiratory reflexes, diaphragm dysfunction, and decreased functional reserve capacity all contribute to alveolar collapse and pooling of secretions. Aspiration risk is also increased. Excess secretions cause further alveolar collapse and create a milieu ripe for bacterial infection and pneumonia. Intubated patients should receive antacid prophylaxis and gastric drainage to minimize the risk of aspiration.

Multiple analyses have found that poor exercise tolerance is the greatest predictor of postoperative pulmonary impairment. The ASA risk classification is a gauge of general status and is highly predictive of both

cardiac and pulmonary complications.<sup>75,76</sup> Although advanced age is associated with increased incidence of chronic pulmonary disease and underlying impairment, it is not an independent risk factor for pulmonary complications.

Clearly, all smokers should be urged to stop before surgery. Even in the absence of coexisting pulmonary disease, smoking increases the risk of perioperative complications. Smoking confers a relative risk of 1.4 to 4.3, but a reduced risk of pulmonary complications has been shown in patients who stop smoking at least 8 weeks before cardiac surgery.<sup>77</sup> Even 48 hours of abstinence can improve mucociliary clearance, decrease carboxyhemoglobin levels to those of nonsmokers, and reduce the cardiovascular effects of nicotine. A nicotine patch may help some patients with postoperative nicotine withdrawal but may not be advisable in patients at risk for poor wound healing.

COPD confers a relative risk of 2.7 to 4.7 in various studies. Symptoms of bronchospasm and obstruction should be addressed before surgery, and elective procedures should be deferred in patients having an acute exacerbation. Preoperative treatment may include bronchodilators, antibiotics, steroids, and physical therapy to increase exercise capacity. Patients with active pulmonary infections should have surgery delayed if possible. Asthmatics should have peak flow equivalent to their personal best or 80% of predicted and should be medically optimized to achieve this goal. Pulse corticosteroids may be used without an increased risk of postoperative infection or other complication.<sup>78,79</sup>

Malnourished patients may not be able to meet the demands of the increased work of breathing, increasing their risk for respiratory failure. Obese patients have higher rates of oxygen consumption and carbon dioxide production, which increases their work of breathing. They may also exhibit restrictive physiology due to a large, stiff chest wall. A complete history should inquire about sleeping difficulty and snoring. Obesity increases the amount of soft tissue in the oropharynx, which can cause upper airway obstruction during sleep. Fifty-five percent of morbidly obese patients may have sleep-related breathing disorders such as obstructive sleep apnea and obesity-hypoventilation syndrome.<sup>80</sup> Symptoms include snoring and daytime sleepiness, and formal sleep studies are employed for definitive diagnosis. Sleep-disordered breathing is associated with hypoxia, hypercapnia, changes

in blood pressure, nocturnal angina, and increased cardiac morbidity and mortality including stroke and sudden death.<sup>81</sup> Arterial blood gas with partial arterial oxygen pressure less than 55 mm Hg or partial arterial carbon dioxide pressure greater than 47 mm Hg confirms the diagnosis. An increased incidence of pulmonary hypertension and right-sided heart failure is seen in patients with obesity hypoventilation syndrome, and these patients should have an echocardiogram before surgery. In severe cases, intraoperative monitoring with a pulmonary artery catheter may be prudent.

In the patient who is awake, postoperative care should include coughing and deep breathing exercises, and in nonambulatory patients, early mobilization should include turning every 2 hours. Early ambulation prevents atelectasis and pooling of secretions and increases the ventilatory drive. Upright position distributes blood flow and minimizes shunting. Preoperative medications should be resumed expeditiously. Incentive spirometry and pulmonary toilet are pulmonary expansion maneuvers, which reduce the relative risk of pulmonary complications by 50%.<sup>81</sup> Patients should receive preoperative education about these techniques. Inhaled ipratropium and  $\beta$ -agonists, used together, may prevent postoperative wheezing and bronchospasm and should be prescribed in patients at risk. Intermittent positive-pressure ventilation and nasal bilevel positive airway pressure may be enlisted for secondary prevention. Epidural analgesia is superior to parenteral narcotics in abdominal and thoracic procedures for preventing pulmonary complications.

## **GASTROINTESTINAL EVALUATION**

Stress ulceration has been a well-recognized complication of surgery and trauma since 1932, when Cushing reported gastric bleeding accompanying head injury. With later research in gastric physiology and shock, it has been recognized that the appearance of gastric erosion results from failure of the protective function of gastric mucosa and back diffusion of hydrogen ion, enabling gastric acid to injure the mucosa. Once the mucosa is injured, the defenses are further weakened, leading to further injury in a vicious cycle. The protective functions of the mucosa rely on the stomach's rich blood flow to maintain high oxygen saturation. The most critical factor in the development of erosive ulceration now appears to be mucosal ischemia. Once

the rich blood supply of the mucosa is compromised, the protective mechanisms are impaired, and gastric acid causes erosion, bleeding, and perforation.

In the late 1970s,<sup>82</sup> the incidence of gastric bleeding in critically ill patients was 15%. Recognition of the importance of organ perfusion has resulted in decreased rates of erosive stress gastritis. Factors often cited for this observation are improvement in resuscitation and monitoring technology, nutritional support, and effective agents for medical prophylaxis. The prophylactic medicines are targeted to reduce gastric acid secretion. Antacids have been shown to provide effective protection against erosive ulceration; however, there is increased risk of aspiration pneumonia. Antagonists of the histamine-2 (H<sub>2</sub>) receptors of the parietal cells impair gastric acid secretion and are effective prophylaxis for erosive ulceration.

With the emergence of proton pump inhibitor (PPI) medications, more effective control of gastric acid secretion was available, leading to widespread use of PPIs for stress ulcer prophylaxis. In high-risk, critically ill patients, PPIs have been shown to decrease the incidence of gastrointestinal bleeding as compared to H<sub>2</sub> blockers, but both carry increased risk of ventilator-associated pneumonia and pseudomembranous colitis.<sup>83</sup>

In the setting of elective operations when the patients are not critically ill, the incidence of stress ulceration is now very low, and routine use of ulcer prophylaxis medication has been questioned. In addition, the routine use of antisecretory medication, in particular in the elective setting, may lead to increased risk of pneumonia and pseudomembranous colitis.

## **Postoperative Ileus**

Ileus is a condition of generalized bowel dysmotility that frequently impairs feeding in the postoperative setting. Ileus typically occurs after abdominal surgery, even if the bowel itself is not altered. It has been shown that laparotomy alone, without intestinal manipulation, leads to impaired gastrointestinal motility. The small bowel is typically affected the least and can maintain organized peristaltic contractions throughout the perioperative period. The stomach usually regains a normal pattern of emptying in 24 hours, and the colon is last to regain motility, usually in 48 to 72 hours.

The exact mechanism that causes postoperative ileus is not known;

however, physiologic studies have demonstrated the significant contribution of both inhibitory neural reflexes and local mediators within the intestinal wall. Inhibitory neural reflexes have been shown to be present within the neural plexuses of the intestinal wall itself and in the reflex arcs traveling back and forth from the intestine to the spinal cord. These neural pathways may account for the development of ileus during laparotomy without bowel manipulation. In addition, inflammatory mediators such as nitric oxide are present in manipulated bowel and in peritonitis and may play a role in development of ileus.

Ileus can be recognized from clinical signs, such as abdominal distension, nausea, and the absence of bowel sounds and flatus, which should prompt the diagnosis. Abdominal x-ray imaging typically shows dilated loops of small bowel and colon. Bowel obstruction must also be considered with these clinical findings, however, and CT or other contrast imaging may be required to rule out obstruction.

Ileus can also appear following nonabdominal surgery and can result from effects of medications (most often narcotics), electrolyte abnormalities (especially hypokalemia), and a wide variety of other factors.

Occasionally, the patient sustains a prolonged period of postoperative ileus. This can be due to a large number of contributing factors, such as intra-abdominal infection, hematoma, effects of narcotics and other medications, electrolyte abnormalities, and pain. In addition, there can be prolonged dysmotility from certain bowel operations, such as intestinal bypass.

The role of laparoscopic surgery in prevention of ileus is controversial. In theory, with less handling of the bowel laparoscopically and with smaller incisions, there should be less stimulation of the local mediators and neural reflexes. Animal studies comparing open and laparoscopic colon surgery indicate earlier resumption of normal motility studies and bowel movements with the laparoscopic approach. Human trials have not been conclusive. Several series demonstrate earlier tolerance of postoperative feeding with the laparoscopic approach to colon resection; however, these have been criticized for selection bias, and such studies are impossible to conduct in a blinded fashion.

Early mobilization has long been held to be useful in prevention of postoperative ileus. While standing and walking in the early postoperative period have been proven to have major benefits in pulmonary function and prevention of pneumonia, mobilization has no demonstrable effect on

postoperative ileus.

In the expected course of uncomplicated abdominal surgery, the stomach is frequently drained by a nasogastric tube for the first 24 hours after surgery, and the patient is not allowed oral intake until there is evidence that colonic motility has returned, usually best evidenced by the passage of flatus. Earlier feeding and no gastric drainage after bowel surgery can be attempted for healthy patients undergoing elective abdominal surgery and has a high rate of success provided clinical symptoms of ileus are not present. In such patients, the use of effective preventive strategies is highly effective. These include maintenance of normal serum electrolytes, use of epidural analgesia, and avoidance of complications such as infection and bleeding. The routine use of nasogastric tubes for drainage in the postoperative period after abdominal surgery has come into question since the mid-1990s.

The most effective strategy for management of postoperative ileus following abdominal surgery has been the development of epidural analgesia. Randomized trials have shown that the use of nonnarcotic (local anesthetic–based) epidural analgesia at the thoracic level in the postoperative period results in a decreased period of postoperative ileus in elective abdominal surgery. Ileus reduction is not seen in lumbar-level epidural analgesia, suggesting that inhibitory reflex arcs involving the thoracic spinal cord may play a major role in postoperative ileus.

Narcotic analgesia, while effective for postoperative pain, has been shown to lengthen the duration of postoperative ileus, especially when used as a continuous infusion or as PCA. Patients report better control of postoperative pain with continuous infusion or PCA as compared to intermittent parenteral dosing. Many studies have been done comparing various types of opioid analgesics, in attempts to find a type that does not prolong ileus. There has been no clearly superior drug identified; all currently available opioids cause ileus. Opioid antagonists such as naloxone have been used in trials to decrease ileus in chronic narcotic use, and there is evidence that antagonists are effective in that setting; however, in postoperative ileus, the antagonists have not been shown to be clinically useful, again suggesting that other mechanisms are contributing to postoperative ileus.

## **Early Postoperative Bowel Obstruction**

Early postoperative bowel obstruction refers to mechanical bowel

obstruction, primarily involving the small bowel, which occurs in the first 30 days following abdominal surgery. The clinical picture may frequently be mistaken for ileus, and these conditions can overlap. The clinical presentation of early postoperative bowel obstruction is similar to that of bowel obstruction arising de novo: crampy abdominal pain, vomiting, abdominal distention, and obstipation. The incidence of early postoperative bowel obstruction has been variable in published series, due to difficulty in differentiating ileus from early postoperative bowel obstruction, but the reported range is from 0.7% to 9.5% of abdominal operations.

Retrospective large series show that about 90% of early postoperative bowel obstruction is caused by inflammatory adhesions. These occur as a result of injury to the surfaces of the bowel and peritoneum during surgical manipulation. The injury prompts the release of inflammatory mediators that lead to formation of fibrinous adhesions between the serosal and peritoneal surfaces. As the inflammatory mediators are cleared and the injury subsides, these adhesions eventually mature into fibrous, firm, bandlike structures. In the early postoperative period, the adhesions are in their inflammatory, fibrinous form and, as such, do not usually cause complete mechanical obstruction.

Internal hernia is the next most common cause of early postoperative bowel obstruction and can be diagnosed with a CT scan but may not be recognized until laparotomy. Internal hernia occurs when gaps or defects are left in the mesentery or omentum or blind gutters or sacs are left in place during abdominal surgery. The typical scenario is colon resection involving extensive resection of the mesentery for lymph node clearance. If the resulting gap in the mesentery is not securely closed, small bowel loops may go through the opening and not be able to slide back out. A blind gutter may be constructed inadvertently during the creation of a colostomy. When the colostomy is brought up to the anterior abdominal wall, there is a space between the colon and the lateral abdominal wall, which may also trap the mobile loops of small bowel. Defects in the closure of the fascia during open or laparoscopic surgery can cause obstruction from incarcerated early postoperative abdominal wall hernia. Fortunately, internal hernia is a rare occurrence in the early postoperative period; however, it must be suspected in cases in which bowel anastomoses or colostomies have been constructed. Unlike adhesive obstruction, internal hernia requires operative intervention due to the high potential for complete obstruction and strangulation of the

bowel.

Intussusception is a rare cause of early postoperative bowel obstruction in adults but occurs more frequently in children. Intussusception occurs when peristalsis carries a segment of the bowel (called the lead point) up inside the distal bowel like a rolled up stocking. The lead point is usually abnormal in some way and typically has some intraluminal mass, such as a tumor or the stump of an appendix after appendectomy. Other rare causes for early postoperative bowel obstruction include missed causes of primary obstruction at the index laparotomy, peritoneal carcinomatosis, obstructing hematoma, and ischemic stricture.

Management of early postoperative bowel obstruction depends on differentiation of adhesive bowel obstruction (the majority) from internal hernia and the other causes and from ileus. Clinicians generally rely on radiographic imaging to discern ileus from obstruction. For many years, plain x-ray of the abdomen was used: if the abdominal plain film showed air-distended loops of bowel and air-fluid levels on upright views, the diagnosis of obstruction was favored. However, plain radiographs can be misleading in the postoperative setting, and the overlap of ileus and obstruction can be confusing. Upper gastrointestinal contrast studies using a water-soluble agent have better accuracy, and abdominal CT using oral contrast has been shown to have 100% sensitivity and specificity in differentiating early postoperative bowel obstruction from postoperative ileus. However, unlike late adhesive bowel obstruction, contrast passage into the colon has not been shown to predict success for nonoperative management.

Once the diagnosis is made, management is tailored to the specific needs of the patient. Decompression via nasogastric tube is usually indicated, and ileus can be treated as discussed. Adhesive bowel obstruction warrants a period of expectant management and supportive care, as the majority of these problems will resolve spontaneously. Most surgical texts recommend that the waiting period can be extended to 14 days. If the early bowel obstruction lasts longer than 14 days, less than 10% resolve spontaneously, and exploratory laparotomy is indicated. The uncommon causes of early postoperative bowel obstruction, such as internal hernia, require more early surgical correction and should be suspected in the setting of complete obstipation, or when abdominal CT suggests internal hernia or complete bowel obstruction.

## Renal Evaluation

Patients without a clinical history suggesting renal disease have a low incidence of significant electrolyte disturbances on routine preoperative screening.<sup>84</sup> However, patients with renal or cardiac disease who are taking digitalis or diuretics or those with ongoing fluid losses (ie, diarrhea, vomiting, fistula, and bleeding) do have an increased risk of significant abnormalities and should have electrolytes measured and replaced preoperatively.

Preoperative urinalysis can be a useful screen for renal disease. Proteinuria marks intrinsic renal disease or CHF. Urinary glucose and ketones are suggestive of diabetes and starvation in the ketotic state, respectively. In the absence of recent genitourinary instrumentation, microscopic hematuria suggests calculi, vascular disease, or infection. A few leukocytes may be normal in female patients, but an increased number signifies infection. Epithelial cells are present in poorly collected specimens.

Patients with renal insufficiency or end-stage renal disease often have comorbidities that increase their overall risk in the perioperative period. Hypertension and diabetes correlate with increased risk of coronary artery disease and postoperative MI, impaired wound healing, wound infection, platelet dysfunction, and bleeding. Preoperative history should note the etiology of renal impairment, preoperative weight as a marker of volume status, and timing of last dialysis and the amount of fluid removed routinely. Evaluation should include a cardiac risk assessment. Physical exam should focus on signs of volume overload such as jugular venous distention and pulmonary crackles. In patients with clinically evident renal insufficiency, a full electrolyte panel (calcium, phosphorus, magnesium, sodium, and potassium) should be checked preoperatively, along with blood urea nitrogen and creatinine levels. Progressive renal failure is associated with catabolism and anorexia. Such patients need aggressive nutritional support during the perioperative periods to minimize the risk of infection and poor healing.

Dialysis-dependent patients should have dialysis within 24 hours before surgery and may benefit from monitoring of intravascular volume status during surgery. Blood samples obtained immediately after dialysis, before equilibration occurs, should only be used in comparison to predialysis values to determine the efficacy of dialysis.<sup>85</sup>

Postoperatively, patients with chronic renal insufficiency or end-stage renal disease will need to have surgical volume losses replaced, but care should be taken to avoid excess. Replacement fluids should not contain potassium, and early dialysis should be employed to address volume overload and electrolyte derangements. Patients with impaired creatinine clearance should have their medications adjusted accordingly. For example, meperidine should be avoided because its metabolites accumulate in renal impairment and can lead to seizures.

The choice of postoperative fluid therapy depends on the patient's comorbidities, the type of surgery, and conditions that affect the patient's fluid balance. There is no evidence that colloid is better than crystalloid in the postoperative period, and it is considerably more expensive.<sup>86</sup> Sepsis and bowel obstruction will require ongoing volume replacement rather than maintenance. Ringer's solution provides 6 times the intravascular volume as an equivalent amount of hypotonic solution. In patients with normal renal function, clinical signs such as urine output, heart rate, and blood pressure should guide fluid management. Once the stress response subsides, fluid retention subsides and fluid is mobilized from the periphery, and fluid supplementation is unnecessary. This fluid mobilization is evident by decreased peripheral edema and increased urine output. Diuretics given in the period of fluid sequestration may cause intravascular volume depletion and symptomatic hypovolemia.

Postoperative management includes close monitoring of urine output and electrolytes, daily weight, elimination of nephrotoxic medications, and adjustment of all medications that are cleared by the kidney. Hyperkalemia, hyperphosphatemia, and metabolic acidosis may be seen and should be addressed accordingly. Indications for renal replacement therapy include severe intravascular overload, symptomatic hyperkalemia, metabolic acidosis, and complicated uremia (pericarditis and encephalopathy) (Table 2-5).

**TABLE 2-5: OLIGURIA IN THE PERIOPERATIVE PATIENT**

	Prerenal	Intrarenal	Postrenal
Causes	Bleeding Hypovolemia Cardiac failure Dehydration	Drugs Contrast medium Sepsis Myoglobinuria	Obstruction
UOsm	>500 mOsm/L	Equal to plasma	Variable
$U_{Na}$	<20 mOsm/L	>50 mOsm/L	>50 mOsm/L
$Fe_{Na}$	<1%	>3%	Indeterminate

Abbreviations:  $Fe_{Na}$ , fractional excretion of sodium;  $U_{Na}$ , urinary sodium concentration; UOsm, urinary osmolality.

Postoperative renal failure increases perioperative mortality. Risk factors for postoperative renal failure include intraoperative hypotension, advanced age, CHF, aortic cross-clamping, administration of nephrotoxic drugs or radiocontrast, and preoperative elevation in renal insufficiency. Up to 10% of patients may experience acute renal failure after aortic cross-clamping. Postoperative renal failure rates are higher in hypovolemic patients, so preoperative dehydration should be avoided. Contrast nephropathy is a common cause of hospital-acquired renal failure and manifests as a 25% increase in serum creatinine within 48 hours of contrast administration.

Nephropathy is caused by ischemia and direct toxicity to the renal tubules. Diabetes and chronic renal insufficiency are the greatest risk factors for dye nephropathy. Early trials<sup>87</sup> indicated that patients receiving contrast have a lower incidence of contrast-induced nephropathy when treated with a sodium bicarbonate infusion or *N*-acetylcysteine. However, recent evidence from multicenter trials and meta-analyses shows no benefit in any pharmacologic intervention in reducing the incidence of radiocontrast nephropathy.<sup>88</sup>

Rising blood urea nitrogen and creatinine and postoperative oliguria (<500 mL/d) herald the onset of postoperative renal failure. Management is determined by the cause of renal insufficiency. Acute renal failure is classified into 3 categories: prerenal, intrarenal, and postrenal. Prerenal azotemia is common in the postoperative period. It is caused by decreased renal perfusion seen with hypotension and intravascular volume contraction. Intrarenal causes of oliguric renal failure include acute tubular necrosis (from aortic cross-clamping, shock, or renal ischemia), and less commonly, acute interstitial nephritis from nephrotoxic medication. Postrenal causes include

obstruction in the collecting system (from bilateral ureteral injury, Foley catheter occlusion, or urethral obstruction). Workup should include urinalysis, serum chemistries, and measurement of the fractional excretion of sodium. Rarely, invasive monitoring and cardiac echocardiogram may be employed to evaluate volume status. Renal and bladder ultrasound is indicated if obstruction is suspected.

Initial management of oliguria in adults includes placement of a bladder catheter and a challenge with isotonic fluids (500 mL of normal saline or Ringer's lactate). If a bladder catheter is already present, it should be checked to ensure that it is draining properly. A urinalysis should be obtained with special attention to specific gravity, casts, and evidence of infection. Hematocrit should be evaluated to exclude bleeding and blood pressure measured to rule out hypotension as causes. The fractional excretion of sodium can help determine the etiology of the renal failure (Table 2-5). Serum creatinine is used to follow the course of acute renal failure. Patients who have been adequately resuscitated or who are in CHF require evaluation to rule out cardiogenic shock. Urinary retention can be treated with a Foley catheter, and ureteral obstruction can be addressed with percutaneous nephrostomy.

Intravascular volume depletion adversely affects cardiac output, tissue perfusion, and oxygen delivery. Monitoring includes total body weight, urine output, vital signs, and mental status. However, body weight should not be used alone because total volume overload can be seen in the setting of intravascular volume depletion. Most cases of postoperative renal failure are associated with an episode of hemodynamic instability,<sup>47</sup> and perioperative hemodynamic optimization has been shown to decrease acute kidney injury and mortality.<sup>89</sup> Invasive monitoring to measure cardiac filling pressures may be utilized when clinical assessment is unreliable.

Fluid overload may be seen in patients with renal, hepatic, and cardiac disease and is associated with increased morbidity.<sup>90</sup> Critically ill patients may develop anasarca. It is difficult to determine volume status by observation alone, and invasive monitoring may be required.

Electrolyte abnormalities are common in the perioperative period. Serum sodium reflects intravascular volume status. Hyponatremia signifies excess free water in the intravascular space and is caused by excess antidiuretic hormone in the postoperative period. It occurs in the setting of normo-, hypo-

, or hypervolemia. It may be avoided by judicious use of isotonic fluids. Conversely, hyponatremia suggests a relative deficit of intravascular free water. Patients who are unable to drink or those with large insensible losses are most at risk. Treatment includes free water replacement.

Diuretics, malnutrition, and gastrointestinal losses may cause postoperative hypokalemia. Metabolic alkalosis shifts potassium into the intracellular compartment. Serum potassium levels less than 3 mEq/L warrant ECG monitoring and replacement in patients who are not anuric. Replacement in patients with renal insufficiency may be complex. Hyperkalemia is more commonly seen in renal patients. It may also be seen in myonecrosis, hemolysis, and acidosis. Cardiac arrhythmias are seen at levels above 6.5 mEq/L, and death is associated with levels greater than 8 mEq/L. These patients should have cardiac monitoring until their levels normalize. ECG will show widened QRS interval, peaked T waves, and absent P waves. Hyperkalemia should be treated with sodium bicarbonate to stimulate acidosis, as well as intravenous calcium and insulin with glucose to drive potassium into the intracellular compartment. Cation exchange resins can be administered orally or per rectum to bind ions in the gastrointestinal tract, but care should be taken for the patient who is post-gastrointestinal surgery or has underlying gastrointestinal problems. Dialysis can be employed if other measures fail.

## GLYCEMIC CONTROL

Hyperglycemia is a risk factor for postoperative infection and perioperative mortality. Intensive insulin therapy (IIT) has been associated with improved outcomes for intensive care unit (ICU) patients, and after cardiac surgery, in brain injury, and after acute MI. However, early enthusiasm for IIT has waned as more recent studies have shown that it is not as beneficial in medical patients as it is in surgical patients and has been associated with severe hypoglycemia.<sup>91</sup> More recently, a meta-analysis of 29 randomized trials of IIT in adult ICU patients showed no difference in mortality in patients receiving IIT versus conventional insulin therapy with goal blood sugar <200 mg/dL.<sup>92</sup> Although there does appear to be consensus that controlling glucose is a worthwhile therapeutic goal in surgical patients in particular, appropriate targets for control remain controversial. While

hyperglycemia is associated with increased infection and mortality,<sup>93</sup> IIT is associated with hypoglycemia and increased mortality. Results from an international, randomized controlled trial in ICU patients demonstrated a 2.6% increase in absolute risk of death in ICU patients with a blood glucose target of 81 to 108 mg/dL versus 180 mg/dL.<sup>94</sup> Others suggest that the variability in glucose level may affect morbidity and mortality more than blood glucose levels alone.<sup>95</sup> More investigation is needed to determine the optimal way to manage blood glucose levels in the postoperative patient.

Our current recommendation for glucose control in noncardiac surgery patients is to maintain blood glucose less than 180 mg/dL.

## HEMATOLOGIC EVALUATION

A complete preoperative evaluation should include assessment of hematologic disorders, which can increase the risk for postoperative bleeding or thromboembolism. Patients should be asked about a family history of bleeding disorders and personal history of bleeding problems, especially after procedures. Excessive bleeding after dental procedures and menorrhagia in women can alert the physician to undiagnosed hematologic disease. Risk factors for postoperative hemorrhage include known coagulopathy, trauma, hemorrhage, or potential factor deficiency.<sup>96</sup> Factor deficiencies can be seen with a history of liver disease, malabsorption, malnutrition, or chronic antibiotic use. Even high-risk patients have only a 1.7% risk of postoperative hemorrhage and a 0.21% risk of death related to postoperative hemorrhage.<sup>96,97</sup>

Routine tests may include a complete blood count, prothrombin time (PT), activated partial thromboplastin time (PTT), and INR, but are not required in the asymptomatic patient with no associated history. The complete blood count will reveal leukocytosis, anemia, and thrombocytopenia or thrombocytosis. A baseline hematocrit is useful for postoperative management when anemia is suspected. Platelet count also provides a useful baseline but does not provide information about platelet function. A bleeding time may be required to provide more information in select patients. However, bleeding time results are operator-dependent and highly variable, making it a poor screening tool for identifying high-risk patients.<sup>98,99</sup> An abnormal bleeding time is not associated with increased postoperative

bleeding,<sup>100</sup> nor has it proven useful in identifying patients taking NSAIDs or aspirin.<sup>98</sup> None of the aforementioned tests can be used to diagnose hereditary bleeding disorders. However, an elevated PTT may be seen in factor XI deficiency and should be obtained in patients at risk for this deficiency. Low-risk patients are very unlikely to have bleeding complications even if the PTT is abnormal<sup>99</sup> and have an increased risk of false-positive results that can lead to unnecessary testing. PTT is not a reliable predictor of postoperative bleeding<sup>101</sup> and should not be used to screen for bleeding abnormalities in patients without symptoms or risk factors.<sup>102,103</sup>

A platelet count of 20,000 or greater is usually adequate for normal clotting. Aspirin causes irreversible impairment of platelet aggregation and is commonly prescribed in patients at risk of cardiovascular and cerebrovascular disease. The clinical effect of aspirin lasts 10 days, and it is for this reason that patients are asked to stop taking aspirin 1 week before elective surgery. Desmopressin can be used to partially reverse platelet dysfunction caused by aspirin and uremia. Other NSAIDs cause reversible platelet dysfunction and should also be held before surgery. Glycoprotein IIb/IIIa inhibitors prevent platelet-fibrin binding and platelet aggregation and are used for 2 to 4 weeks after coronary angioplasty. Elective surgery should be avoided during these 2 to 4 weeks, as stopping treatment increases the risk of thrombosis. Patients who do not receive 4 weeks of antiplatelet therapy are at risk of stent thrombosis.<sup>104</sup>

Indications for red blood cell transfusion remain somewhat controversial and are often empirical in practice. Transfusing 1 unit of red blood cells or whole blood can increase the hematocrit by approximately 3% or hemoglobin by 1 g/dL. Multiple studies have demonstrated that overusing transfusion may adversely affect patient outcome and increase risk of infection. ASA guidelines<sup>105</sup> suggest that transfusion should be based on risks of inadequate oxygenation, rather than a threshold hemoglobin level. Generally, transfusion is rarely indicated when the hemoglobin level exceeds 10 g/dL but is almost always indicated when it is less than 6 g/dL, especially in the setting of acute anemia. Healthy individuals can usually tolerate up to 40% of blood loss without requiring blood cell transfusion, and blood products should not be used solely to expand volume or to improve wound healing. The decision to transfuse red cells or whole blood should be based on the patient's risk of

complications associated with impaired oxygen delivery, including hemodynamic indices, history of cardiopulmonary disease, rate of blood loss, and preexisting anemia.

Conditions associated with abnormal platelets and low platelet counts can be treated with platelet transfusions. The usual dose, 1 unit of platelet concentrate/10 kg body weight, can be expected to increase the platelet count by approximately 5000 to 10,000 in an average adult. In patients without increased risk of bleeding, prophylactic platelet administration is not indicated until counts fall below 20,000. Higher thresholds may be indicated for patients at increased risk of bleeding or with known platelet dysfunction or microvascular bleeding. Desmopressin can augment platelet function in uremia and incite release of von Willebrand factor (vWF) from the endothelium, which can improve platelet function. The decision to transfuse platelets should be based on the amount of bleeding expected, the ability to control bleeding, and the presence of platelet dysfunction or destruction.

Transfusion of fresh frozen plasma (FFP) is indicated to reverse warfarin before procedures or in the presence of active bleeding, for inherited or acquired coagulopathy that can be treated with FFP, and for massive transfusion of more than 1 whole blood volume. Microvascular bleeding can be seen if the PT/PTT is greater than 1.5 times normal, and FFP can be used to reverse bleeding in this setting. Warfarin reversal can be achieved with doses of 5 to 8 mL/kg, and 30% factor concentration can be achieved with 10 to 15 mL/kg. FFP should not be used to address volume depletion alone. Cryoprecipitate contains factors VIII, vWF, XIII, fibrinogen, and fibronectin, and can be used preventively in patients with these factor deficiencies and uremia.

Endothelial injury and venous stasis are the greatest risk factors for VTE. The patient with hereditary thrombophilia or a personal history of VTE, cancer, or recent surgery (within 4 weeks) has an increased risk of VTE.<sup>106</sup> Preventive measures include external pneumatic leg compression, early mobilization after surgery, and anticoagulation. Compression devices are contraindicated in patients with severe peripheral vascular disease, venous stasis, or risk of tissue necrosis. Inferior vena cava (IVC) filters are indicated in patients who cannot take anticoagulation or who have failed anticoagulation therapy. Patients with a history of VTE benefit from IVC filter placement in the short term, but IVC filter placement is accompanied by an increased incidence of deep venous thrombosis over the long term.<sup>107</sup>

Systemic anticoagulation is the preferred long-term option. LMWH and UFH are equally effective for prevention of pulmonary embolism in patients with deep venous thrombosis.<sup>107</sup> Recent VTE, atrial fibrillation, and mechanical heart valves are common indications for warfarin treatment.

Clinically, UFH activity is measured by PTT, and the therapeutic goal is usually 2.0 to 2.5 times normal. LMWH is a relatively stronger inhibitor of factor Xa and does not have the same effect on the PTT. The anticoagulant effect of LMWH is measured by factor Xa activity. Protamine can reverse the effects of heparin but may cause allergic reactions and induce hypercoagulability and should be used cautiously. FFP will not reverse heparin and can actually increase heparin activity because it contains antithrombin III. Direct thrombin inhibitors can also prolong the PTT. Direct thrombin inhibitors are not reversible with protamine and may require large amounts of FFP for reversal.

Heparin can be used for the prevention and treatment of VTE. Surgical patients over age 40 or those at increased risk for VTE should receive 5000 U subcutaneously every 8 to 12 hours, depending on their weight. High-risk patients with a history of VTE, cancer, or morbid obesity or those having orthopedic procedures should either receive subcutaneous heparin with a goal of high range of normal or LMWH. In the event of acute VTE, intravenous heparin should be started promptly with a therapeutic PTT goal of 1.5 to 2.0 times normal. Oral anticoagulation should be started within 24 hours and continued for 3 to 6 months.<sup>106</sup>

Heparin-induced thrombocytopenia (HIT) is a potentially lethal complication of heparin therapy. HIT is caused by an immunoglobulin G–mediated hypersensitivity reaction between the heparin moiety and platelet factor 4 (PF4). Patients with previous heparin exposure, such as orthopedic and cardiac surgical patients, are at greatest risk. The incidence of HIT is 0.5% to 5.0% in patients receiving UFH. HIT occurs with UFH or LMWH; the risk is highest with UFH.

Platelet counts usually drop 40% to 50% from baseline. Thrombosis can be venous or arterial, leading to deep vein thrombosis, extremity ischemia, and mesenteric ischemia of stroke. Digital ischemia and skin necrosis can also be seen. HIT remains a clinical syndrome that can be diagnosed by a decrease in platelet count <40% of baseline in 4 to 14 days of heparin administration once other causes of thrombocytopenia have been ruled out. The diagnosis can be supported by the enzyme-linked immunosorbent assay

for antiplatelet antibodies.

Because HIT can be life-threatening, heparin should be stopped as soon as HIT is suspected, and treatment with an alternative anticoagulant, such as the thrombin inhibitor bivalirudin, should be started immediately. Platelets should return to baseline after therapy is initiated. If thrombosis is present, patients should be anticoagulated for 6 months with warfarin. Warfarin should not be started until platelet counts have recovered.

Warfarin inhibits synthesis of vitamin K–dependent clotting factors (II, VII, IX, X, and proteins C and S). Poor diet, prolonged antibiotic use, and fat malabsorption can also cause vitamin K deficiency and cause abnormal coagulation. Liver disease can lead to multiple coagulation abnormalities including factor deficiencies, vitamin K deficiency, fibrinolysis, and elevated levels of fibrin degradation products. All patients with known or suspected liver disease should be tested for coagulopathy. Vitamin K can be administered subcutaneously or intravenously in deficient patients. The initiation of warfarin therapy is associated with a transient thrombotic state because plasma concentrations of protein C fall approximately 24 hours before concentrations of other clotting factors.

Heparin is the drug of choice for VTE during pregnancy because it does not cross the placenta. Adverse effects of heparin therapy may include hemorrhage, thrombocytopenia, and osteoporosis. HIT is an immune disorder seen in patients with prior exposure to heparin, which may cause thrombosis. Treatment includes cessation of heparin and utilization of alternative anticoagulants such as lepirudin, danaparoid, or argatroban. These should be given until platelet counts recover.

For patients on long-term anticoagulation therapy, the INR should be 1.5 or lower before elective surgery. After warfarin is discontinued, it takes about 4 days for an INR in the range of 2.0 to 3.0 to spontaneously reach 1.5, and about 3 days for the INR to reach 2.0 after it is restarted. If therapy is withheld preoperatively, most patients will have a window of 2 to 4 days when they are not anticoagulated and at risk for venous thrombosis. This risk is compounded by the increased risk of thromboembolism associated with surgery.<sup>108,109</sup> It has been estimated that surgery increases the risk of VTE by 100-fold in patients with recurrent disease.<sup>110</sup> Without anticoagulation, there is a 50% chance of recurrence within the 3 months after the first episode of venous thrombosis. Warfarin therapy reduces the risk to 10% after 1 month and 5% after 3 months. It is not advisable to interrupt anticoagulation within

1 month after an event of VTE, and if possible, surgery should be deferred until the patient has completed 3 months of therapy.<sup>110</sup> Chronic anticoagulation lowers the risk of thromboembolism in patients with atrial fibrillation and mechanical heart valves by 66% and 75%, respectively.<sup>110</sup>

Patients with prior embolic episodes are at increased risk for recurrence. Six percent of episodes of VTE and 20% of arterial thromboembolisms may be fatal,<sup>110</sup> and a significant percentage cause disability. Alternatively, the risk of death after postoperative hemorrhage is less than 1%,<sup>111</sup> so the judicious use of postoperative anticoagulation can be relatively protective. Preoperative heparinization is not required during the second and third months of warfarin treatment for deep vein thrombosis because the risk is sufficiently low. Such patients have increased VTE risk after surgery and should receive postoperative anticoagulation. Patients who are at risk for recurrent deep vein thrombosis and are within 2 weeks of the first episode or who cannot tolerate anticoagulation are candidates for an IVC filter.<sup>107</sup>

Elective surgery should be deferred for the first month after arterial embolism because of the high risk of recurrence during this period. If necessary, patients should receive perioperative heparin while oral anticoagulation is held. Patients on long-term anticoagulation to prevent arterial thromboembolism do not need perioperative heparin because the risk of bleeding outweighs the risk of arterial embolism during this period.

Heparin should be titrated to a goal PTT of 1.5 to 2.0 times normal and given as a continuous intravenous infusion. It should be stopped 6 hours prior to a procedure and can be restarted 12 hours after surgery if there was no evidence of bleeding at the end of the case. Heparin can be restarted without a bolus at the anticipated maintenance infusion rate.<sup>110,111</sup>

## INFECTIOUS COMPLICATIONS

Infectious complications can be most unwelcome and difficult to control after major abdominal surgery, yet they are surprisingly frequent despite all modern prophylactic measures. Reported surgical wound infection rates in elective operations vary from 2% for inguinal hernia repair,<sup>112</sup> to 26% for colectomy,<sup>113</sup> and is even higher for emergency surgery.<sup>114</sup> Surgical site infections (SSIs) increase overall mortality and morbidity and increase hospital length of stay and overall costs. Therefore, prevention and treatment

of infectious complications should be included in surgical decision-making for all abdominal procedures.

Prevention of SSIs begins with preoperative evaluation and identification of patients at high risk for SSI. Patient factors implicated in risk of SSI include age, diabetes mellitus, smoking, steroid use, malnutrition, obesity, active distant infection, prolonged hospital stay, and nasal colonization with *Staphylococcus aureus*.<sup>115-118</sup>

Standard basic surgical rules should be followed with every patient. These were codified as formal guidelines by the Centers for Disease Control and Prevention (CDC) and updated in 2017<sup>119</sup> and include recommendations for skin preparation with alcohol-based skin antiseptics, surgical barriers such as drapes and gowns, careful hand scrubbing, and appropriate selection of prophylactic antibiotics. Preoperative hair removal and antiseptic shower have not been shown to decrease SSI rates, and shaving and clipping of hair can increase SSIs. The CDC recommendations are summarized in [Table 2-6](#).

**TABLE 2-6: CDC CATEGORY 1 RECOMMENDATIONS FOR REDUCTION OF SURGICAL SITE INFECTIONS**

*These are strongly recommended based on best clinical evidence:*

Identify and treat distant infections prior to surgery

Do not remove hair routinely; if hair must be removed, use electric clippers immediately prior to surgery

Control hyperglycemia in the perioperative period

Cease tobacco smoking 30 days prior to surgery

Antiseptic shower the night prior to surgery

Antiseptic skin preparation

Surgery team should practice hand scrubs

Administer appropriate antimicrobial prophylaxis

Surgical barriers (gown, gloves, hat, mask)

Do not close contaminated skin incisions

---

Antibiotic prophylaxis may be indicated for patients at high risk or in contaminated surgical procedures, but antibiotics should not be used indiscriminately. Overuse of antibiotics is associated with emergence of

multidrug-resistant bacteria and increased rates of hospital-acquired infections. Selection of patients for antimicrobial prophylaxis requires stratification of patient risk factors, as discussed above, and procedure-specific risk factors. The degree of contamination in the surgical site has long been recognized as an independent risk factor for SSI,<sup>120</sup> leading to the wound classification system (Table 2-7) in use since 1983.

**TABLE 2-7: SURGICAL WOUND CLASSIFICATION**

**Class I. Clean**

Uninfected wounds without contamination

**Class II. Clean/Contaminated**

Uninfected wounds in procedures where the respiratory, gastrointestinal, or genitourinary tracts are entered in a controlled fashion without gross spillage

**Class III. Contaminated**

An operation with major breaks in sterile technique, gross spillage, or incisions into inflamed but not suppurating infections; fresh accidental wounds

**Class IV. Dirty/Infected**

Wounds with necrotic or devitalized infected tissue

---

Patients undergoing class I (clean) procedures have a very low infection rate and generally do not benefit from prophylactic antibiotics, unless there is some suspicion at the start of the procedure that some contamination may occur, such as unplanned enterotomy in a patient with many previous abdominal procedures. In addition, many surgeons prefer to use antibiotic prophylaxis in class I procedures when a prosthesis is implanted; examples include hernia repair and vascular bypass. In this setting, the risk of SSI is low, but the morbidity and mortality of an infected prosthesis are great, and prophylaxis may decrease the risk. To date, large prospective trials have not shown benefit of antibiotic prophylaxis in preventing prosthetic infections,<sup>121,122</sup> but smaller trials have suggested a decrease in site infection without change in implant infection rate.<sup>123,124</sup> Therefore, there is no strict

guideline for the use of systemic antibiotics for implant surgery, and the surgeon must tailor the use of antibiotics to the individual patient's risk.

Patients with class II (clean/contaminated) surgical wounds do benefit from systemic antibiotic prophylaxis. The most studied example of this class of wound is elective colon resection. Most current guidelines recommend systemic broad-spectrum antibiotic coverage using a second-generation cephalosporin plus metronidazole, if the parenteral route is used, and neomycin plus metronidazole or erythromycin base (both as nonabsorbable antibiotics), if the oral route is used.<sup>125</sup> Published evidence supports administration of antibiotics preoperatively in order to achieve maximum therapeutic levels at the time of incision and continuation of the antibiotic dosing schedule to maintain therapeutic levels during a long procedure. There is no documented study showing benefit to additional doses of antibiotics after the procedure is over and the skin is closed, and prolonged use of prophylactic antibiotics contributes to emergence of resistant bacteria.<sup>126,127</sup>

Patients with class III (contaminated) wounds are a mixed population. Some of these wounds are the result of inadvertent entry into a contaminated field, some result from traumatic injury, and some are planned operations for débridement of infected tissue. In the latter case, antibiotic therapy is indicated for specific therapy rather than prophylaxis. In the case of penetrating traumatic injury to the colon, there is strong evidence to support single-dose antibiotic prophylaxis at the time of laparotomy, similar to elective colon resection.<sup>128,129</sup> Surgical judgment must be individualized in these cases as to whether the risk of skin closure can be justified due to the high rate of wound infection despite antibiotic prophylaxis.

Patients with class IV (dirty) wounds are generally undergoing débridement of already infected and necrotic tissue and should be receiving antibiotic therapy targeted to the relevant organisms. Skin wound closure is generally not advised in these patients.

The wound classification system does not take into account patient risk factors or site-specific risk factors. Various physiologic scoring systems including the Acute Physiology Score and the Acute Physiology, Age, and Chronic Health Evaluation index have been used to predict perioperative infection risk with some success. In an effort to provide more accurate risk stratification, the CDC's National Nosocomial Infection Surveillance project has developed a risk index that accounts for patient risk factors, such as

malnutrition and chronic medical conditions, and operative factors, including duration and site of procedure.<sup>130</sup> Enlightened risk assessment of perioperative infections should be included in the discussion for informed surgical consent.

## NUTRITIONAL EVALUATION

The importance of proper nutritional assessment and management cannot be overstressed. In surgical patients, malnutrition increases risk for major morbidity,<sup>131,132</sup> including wound infection, sepsis, pneumonia, delayed wound healing, and anastomotic complications. Careful preoperative clinical assessment can identify patients at increased nutritional risk. The assessment should include a thorough history and physical exam with attention paid to usual weight, recent weight loss, changes in eating and bowel habits, changes in abdominal girth, loss of muscle bulk, and the presence of diseases that carry a risk of malnutrition such as COPD, diabetes mellitus, inflammatory bowel disease, and psychiatric conditions such as bulimia and anorexia nervosa. The history and physical exam should identify patients with nutritional risk; that risk can be stratified by calculation of the Nutritional Risk Index (NRI). The NRI is a simple calculation ( $15.19 \times \text{serum albumin [g/dL]} + 41.7 \times \text{present weight/usual weight}$ ) that has been shown in prospective studies to correlate with increased rates of mortality and complications from major abdominal surgery.<sup>133,134</sup> NRI less than 83 indicates a significantly increased rate of mortality and complications, especially wound dehiscence and infection. Severely malnourished patients have been shown to benefit from preoperative nutritional support.<sup>135,136</sup>

Malnutrition can be classified into protein deficiency (kwashiorkor), calorie deficiency (marasmus), or mixed protein-calorie deficiency. To complete the nutritional assessment and to guide nutritional support, it is useful to classify the patient's specific nutritional state (Table 2-8). Malnutrition states are much more common than is generally acknowledged, with 30% to 55% of hospital inpatients meeting criteria for one of these diagnoses.<sup>137</sup>

TABLE 2-8: ASSESSMENT OF NUTRITIONAL STATUS

**Protein Deficiency Criteria**

Albumin &lt;2.2 g/dL

Total lymphocyte count 800/ $\mu$ L or less

Weight maintained

Peripheral edema

Inadequate protein intake (&lt;50% of goal for 3 days or &lt;75% for 7 days)

Four criteria out of these five establish the diagnosis of protein deficiency

**Calorie Deficiency Criteria**

Weight loss: 5% over 1 month or 7.5% over 3 months or 10% over 6 months

Underweight: &lt;94% ideal body weight

Clinically measurable muscle wasting

Serum protein maintained

Inadequate calorie intake (50% for 3 days or &lt;75% for 7 days)

Three criteria out of these five establish diagnosis of calorie deficiency

**Mixed Protein-Calorie Malnutrition Criteria**

	Mild	Moderate	Severe
Weight loss	5%-9%	10%-15%	10%-15% over 6 months
Underweight	94%-85%	84%-70%	<70% ideal weight
Albumin	2.8-3.4 g/dL	2.1-2.7 g/dL	<2.1 g/dL
Total lymphocytes	1499-1200/ $\mu$ L	1199-800/ $\mu$ L	<800/ $\mu$ L
Transferrin	199-150 mg/dL	149-100 mg/dL	<100 mg/dL
			Muscle wasting
			Deficient intake (at least 3 days)

To establish the diagnoses of mild or moderate protein-calorie malnutrition, 2 of the 5 criteria shown must be met; to establish the diagnosis of severe protein-calorie malnutrition, 3 of the 7 criteria must be met.

Some interval of deficient nutritional intake is expected after an abdominal operation. In uncomplicated cases, this is usually the result of postoperative adynamic ileus and resolves promptly, in less than 7 days. Traditional surgical management includes provision of dextrose-containing intravenous fluids. The goal of this therapy is not to provide sufficient calories for complete nutritional support, but simply to provide enough carbohydrate to prevent breakdown of lean body mass. Certain organs, including the heart and brain, have an obligate requirement for carbohydrate as a primary energy source and do not store energy in the form of fat or glycogen. If intake is insufficient to meet this requirement, the body breaks down hepatic glycogen to provide glucose to the circulation, and ultimately the brain and heart. Once hepatic glycogen stores have been depleted (after about 1 day of no intake), lean muscle mass is converted to glucose via gluconeogenesis to produce carbohydrate. Provision of only 100 g of exogenous glucose per day is sufficient to prevent breakdown of lean muscle mass in otherwise healthy subjects.

In already malnourished patients or in patients who do not return to normal bowel function promptly, nutritional support is indicated. As in the preoperative setting, a thorough evaluation of the patient's nutritional status is necessary, as is the identification of the cause of bowel dysfunction. In the

postoperative setting, there are many potential causes of bowel dysfunction (Table 2-9), and nutritional support should be individualized for each patient's needs. Some patients may respond to enteral support, and some may require parenteral support. Whenever available, the enteral route is the preferred route of support, as it has been shown to cause less morbidity and mortality.<sup>138</sup>

**TABLE 2-9: POSTOPERATIVE CAUSES OF DEFICIENT NUTRITIONAL INTAKE**

Ileus  
Bowel obstruction  
Colitis (ischemic, infectious)  
Fistula  
Dysphagia  
Gastric dysmotility  
Intestinal insufficiency (short-gut syndrome)

---

Enteral nutritional support is effective in patients who have functional small bowel; examples include esophageal or gastric resection, patients with postoperative delirium or dysphagia, and patients who have gastroparesis. In the short term, if the dysfunction is expected to respond to treatment, nasogastric tubes can be used effectively to deliver full support. Patients who need long-term enteral support are best served with gastrostomy or jejunostomy tubes, which may be placed operatively or percutaneously. With good preoperative nutritional assessment and sound surgical judgment, these patients' needs for long-term postoperative support can often be anticipated, and long-term feeding access can be included in the operative plan. Enteral support may not be suitable for some patients; examples include early postoperative bowel obstruction, fistula, or intestinal insufficiency (short-gut syndrome). In such patients, parenteral support is indicated and should be initiated without delay, and futile attempts to use the enteral route should be avoided.

Irrespective of the route of support, every patient on nutritional support should have his or her nutritional needs assessed and provided. The

assessment begins with the calorie requirement. There are several formulas and nomograms that estimate basal energy expenditure, accounting for height, weight, age, sex, stress factors, and activity factors.<sup>139</sup> All of these methods are estimations and may underfeed or overfeed certain subgroups, especially the obese. The method in most common clinical use bases basal energy expenditure on adjusted body weight (ABW). Using this method, ABW is defined as the patient's ideal body weight plus the difference between actual body weight (BW) and the ideal body weight (IBW) divided by 2:

$$ABW = IBW + 0.5(BW - IBW)$$

The baseline caloric requirement for weight maintenance based on ABW is 25 kcal/kg/d. This target may be adjusted upward in patients with extreme metabolic demands, as is the case in burns or head injury.<sup>126</sup> Furthermore, the ABW can be used to establish the protein requirement. In unstressed normal subjects, the minimum daily protein requirement is 0.8 g protein/kg/d. In postoperative patients with healing wounds, this target is adjusted to 1.0-1.5 g/kg/d, and in severely ill patients to 2.0 g/kg/d. The highest requirements are seen in severe burn and bone marrow transplant patients.

Essential nutritional components must be provided, again irrespective of the route of support. These include water- and lipid-soluble vitamins, trace elements such as zinc and selenium, essential fatty acids such as linoleic and linolenic acids, and the 8 essential amino acids. These trace elements are provided in abundance in all enteral feeds and are part of the standard additives in parenteral formula.

Once nutritional support has been initiated, the patient's response to support must be followed closely, especially in parenteral support and in patients with preexisting metabolic conditions such as diabetes. Blood glucose should be monitored regularly during the first few days of support. Recent evidence has linked hyperglycemia in the postoperative setting, especially in critically ill patients, with increased risk of death and infection.<sup>140,141</sup> In addition, electrolyte abnormalities (especially those of potassium, magnesium, and phosphate) are often seen in the early period of nutritional support and should be corrected.

It is also important to follow the markers of nutrition repletion to ensure that the calories and protein provided (based on the initial estimate) are

sufficient and the patient is not mobilizing lean body mass due to inadequate support. Serum markers such as prealbumin, retinol-binding protein, and transferrin can be useful in this regard. They are serum proteins with short (2-7 days) turnover times that reflect the body's ability to synthesize new protein.<sup>139</sup> Unfortunately, the serum concentrations of these proteins are also affected by acute disease states and renal and hepatic failure and can be difficult to interpret in postoperative patients. Nitrogen balance can also be used to monitor nutritional support and reflects the ability to synthesize new protein. Nitrogen balance is calculated by subtracting nitrogen excretion from nitrogen intake. Nitrogen intake is calculated from the protein intake, where each gram of protein/6.25 = the number of grams of nitrogen. Nitrogen excretion has 2 components: urinary urea nitrogen (UUN) and insensible loss. UUN can be measured in a 24-hour urine collection; insensible loss is generally accepted to be 4 g/d, unless there is another source of loss, such as abdominal drainage of proteinaceous ascites, enterocutaneous fistula, or nephrotic syndrome. Thus, in most cases, nitrogen balance can be simplified to:

$$\text{Nitrogen balance} = \text{protein intake}/6.25 - 24\text{-hour UUN} - 4 \text{ g (insensible loss)}$$

A patient who takes in more nitrogen than he or she excretes in the urine and feces is in positive nitrogen balance and is synthesizing new protein. On the other hand, a patient who is excreting more nitrogen than he or she is receiving in nutritional support is in negative nitrogen balance and is therefore losing lean body mass, becoming more malnourished. These patients should be reevaluated for nutritional needs and for sources of nutritional depletion, such as uncontrolled diabetes mellitus, sepsis, and organ failure.

By itself, uncontrolled diabetes mellitus can be viewed as a perioperative nutritional complication, as it results in nutritional depletion, interferes with delivery of parenteral and enteral nutrition, and is associated with increased infectious morbidity.<sup>140</sup>

## **COMPREHENSIVE PERIOPERATIVE MANAGEMENT PATHWAYS**

Enhanced recovery after surgery (ERAS) pathways have been proposed<sup>141-143</sup> for the purpose of cost containment, standardization of care, and improvement of surgical outcomes. Initially advanced for elective procedures, especially partial colectomy, these pathways are increasingly being applied to diverse procedures in the elective and emergent setting.<sup>144</sup> The pathways are not universally standardized, but several international societies have published guidelines for the composition of ERAS pathways for elective colon resection based on best evidence-based practices.

For elective colon resection, the ERAS Society has developed a comprehensive, evidence-based bundle of guidelines that include specific recommendations for smoking cessation, preoperative carbohydrate loading (for nondiabetics), intravenous antibiotic prophylaxis, postoperative nausea and vomiting management, core body temperature management, fluid restriction, VTE prophylaxis, and others.<sup>145</sup> Adoption of an ERAS pathway has been associated with shortened length of hospital stay and improved outcomes in colorectal surgery in randomized prospective trials,<sup>146,147</sup> which has led to implementation of the ERAS approach in other procedures.<sup>148-150</sup> It should be noted that the concept of the pathway is that each pathway is specific to a given procedure and no universal ERAS pathway has been investigated.

# ENHANCED RECOVERY PROGRAMS FOR GASTROINTESTINAL SURGERY

*Anthony J. Senagore*

## INTRODUCTION

Enhanced recovery protocols (ERPs) were developed primarily for the care of the colorectal surgical patient during the late 1990s and demonstrated early success in the 2000s.<sup>1-7</sup> These efforts represented consensus from dietitians, nurses, surgeons, and anesthesiologists at the time and ultimately grew into codified components of care with excellent outcomes.<sup>8-11</sup> This work truly represents the culmination of the best science that has assessed the surgical stress response and mitigating therapies, principally from the work of Henrik Kehlet who deserves the title of “Father of Enhanced Recovery After Surgery.”<sup>8</sup> ERP implementation has evolved from a convoluted and often complex set of care plans to a true discipline for evidence-based care of the surgical patient. Although the early focus was on length of stay, the science

has evolved into an approach for improved patient-centric care that deserves the more proper title of “enhanced recovery protocols” (ERPs). The concepts related to preoperative cardiovascular and pulmonary risk assessment and risk modification are well defined by surgical and anesthesia textbooks and preoperative anesthesia clinic processes, and although they are clearly an essential part of a strong perioperative care plan, they are not typically considered ERP components of care. The majority of a gastrointestinal (GI) surgery–related ERP consists of a variety of shared components that will be addressed in a later section. These strategies are designed to recognize and optimize preoperative physiologic adverse factors, the perioperative stress response, narcotic-sparing analgesia, evidence-based reduction of “potentially preventable complications,” early and aggressive ambulation, and early return to enteral intake.<sup>3,8</sup> The optimal use of these strategies has consistently demonstrated a significant reduction in hospital stay and costs, while significantly improving patient safety. The potential components of care include preoperative assessment and education, nutritional repletion, improvement in perioperative glycemic management, anesthesia/analgesia, goal-directed fluid therapy, prevention of nausea and ileus, thromboembolic prophylaxis, minimally invasive techniques, temperature monitoring, early postoperative nutrition, and early mobilization.<sup>2</sup> The net result of a well-developed program with a high degree of institutional compliance has been a universal improvement in clinical outcomes, reduced length of stay, reduced cost, and most importantly, significantly improved physical recovery of the patient.<sup>5,9</sup> An interesting institutional journey is reflected in the work by Bakker et al,<sup>10</sup> who determined that the strongest predictors for a shorter duration of stay (5.7 days with high compliance vs 7.3 days with low compliance) were no nasogastric tube, early mobilization, early oral nutrition, early removal of epidural, early removal of catheter, and nonopioid oral analgesia. However, despite the institutional recognition of these fairly simple components of care and the benefits, the mean adherence rate was 73% in 2006 and 2007, 66% in 2008 and 2009, 63% in 2010 and 2011, and 82% in 2012 and 2013.<sup>10</sup> This implies that constant monitoring of both process and outcome is essential for durable success with ERPs.

Despite the almost 20-year recognition of the benefits of ERP, the current adoption rate of programs remains disappointingly low.<sup>9</sup> The low adoption rate is a function of a lack of understanding related to the relative impact of

various components of the plan, the perceived complexity of delivering the components, and most significantly, clinicians' unwillingness to change behavior in the face of incontrovertible evidence. The purpose of this chapter is (1) to define the mutually shared components across GI surgery ERPs and the rationale for these components; (2) to define procedure- and discipline-specific components of care; (3) to review the clinical and financial benefits in favor of ERPs; and (4) to review issues around adoption of ERPs at an institutional level. This chapter will review the shared components of GI surgery-related ERPs and the nuances related to esophageal, gastric, bariatric, liver/biliary, pancreatic, and colorectal surgery.

## SHARED COMPONENTS OF ERPS

The Enhanced Recovery After Surgery (ERAS) Society ([www.erassociety.org](http://www.erassociety.org)) has published multiple guidelines related to GI surgery, and the reader is referred to 2 major society websites focused on ERP that provide a variety of documents for open access to ERP plans (American Society of Enhanced Recovery at [aserhq.org](http://aserhq.org) and Society of American Gastrointestinal and Endoscopic Surgeons at [www.sages.org/smart-enhanced-recovery-program/](http://www.sages.org/smart-enhanced-recovery-program/)). The organizations provide analyses and quality rankings of the various data elements that can be interpreted by individual healthcare systems for relative benefits for local implementation. It is intriguing that despite the large database available to the ERAS Society, little has been published on actual outcomes, unlike the ubiquitous National Surgical Quality Improvement Program (NSQIP)-related publications. Once again, the attempt to assess the long lists of multiple components on these sites can be intimidating early in the process development of an organization that requires sometimes cumbersome change management strategies. It is well beyond the scope of this chapter to discuss the complex science of change management, but it is clear that a strategy of rapidly assessing current outcomes and implementing an aligned strategy can lead to rapid process improvement. This chapter will attempt to organize components of an ERP strategy into the following components of the episode of care to allow systems to assess the requisite integration of care required: preadmission; day of surgery; and intraoperative, postoperative, and discharge planning.

The major impediments to successful implementation are typically system

based and due to fragmented care delivery and debates over the validity of one or another element.<sup>10-15</sup> The experience by Nelson et al<sup>16</sup> and his colleagues<sup>17</sup> in Alberta, Canada, which provided regular outcomes data, may be an effective means to overcome resistance. Particularly in the United States, the lack of economic integration and therefore structural integration can increase the difficulties of change management. The lack of economic integration is also challenging because some components of the plan need to be administered before admission and, therefore, are not bundled into hospital payments, resulting in patient out-of-pocket costs that are not typically reimbursed. This is a significant stumbling block to the successful compliance with components such as immunonutrition and carbohydrate loading. Another important obstacle is the perceived need for complex risk adjustment models. In fact, US hospitals can access the important cost drivers of care using the readily available and routinely submitted administrative data. Alternatively, many hospitals participate in national programs, such as NSQIP or the Vizient programs, which provide easily accessible and robust data related to both outcomes and cost. It should be a relatively easy discussion to review high-impact negative outcomes and, in the true spirit of quality improvement, implement a plausible solution and in rapid sequence assess change in outcome.<sup>18-22</sup> An example of how difficult this approach can be is exemplified by the work of Harbaugh et al<sup>23</sup> assessing the only US Food and Drug Administration–approved prophylactic agent for reduction postoperative ileus (POI), which demonstrated that even across members of an advanced quality collaborative, adoption of a component with proven benefits is highly variable.

## **Preadmission**

### **ANEMIA**

Preoperative anemia occurs frequently in GI surgical patients as a result of chronic blood loss, nutritional deficiencies (typically iron), and the impact of neoadjuvant oncologic treatment. Conversely, outside of emergency surgery, which has a separate set of strategies for blood conservation and repletion, the preoperative period provides a sufficient time frame to address preexisting anemia.<sup>24-28</sup> Preoperative anemia and blood transfusions are associated with a higher incidence of postoperative infections, a longer

hospital stay, higher cost, and a worse overall outcome.<sup>29,30</sup> Iron deficiency anemia is by far the most frequent form of preoperative anemia, is particularly common among the elderly population, and is readily evaluated and treated in a time-compressed manner.<sup>31,32</sup> The opportunity for a system to include routine complete blood count and reflex to specific iron studies based on specific thresholds can lead to a cost-effective and efficient means of identifying at-risk patient populations.<sup>33,34</sup> Incorporation of this type of testing strategy can further lead to an integrated approach to effective treatment with iron infusions and a reduction in the need for perioperative transfusions.<sup>35,36</sup>

## **SARCOPENIA**

Sarcopenia is a common adverse risk factor for a variety of GI surgical procedures.<sup>37-41</sup> Once again, the ability to identify this risk factor is readily available as virtually all GI surgery patients are evaluated with abdominal computed tomography and the nomograms are well accepted. A typical algorithm is the use of a single slice at the level of the third lumbar vertebra (L3) or the measurement of total fat area (cm<sup>2</sup>), subcutaneous fat area (cm<sup>2</sup>), visceral fat area (cm<sup>2</sup>), and skeletal muscle area (cm<sup>2</sup>) using accepted Hounsfield unit (HU) thresholds (adipose tissue, -190 to -30; skeletal muscle, -29 to +150). These parameters are then normalized for patient stature and designated as total fat index (cm<sup>2</sup>/m<sup>2</sup>), subcutaneous fat index (cm<sup>2</sup>/m<sup>2</sup>), visceral fat index (cm<sup>2</sup>/m<sup>2</sup>), and skeletal muscle index (cm<sup>2</sup>/m<sup>2</sup>) in line with accepted methodology.<sup>42,43</sup> Sarcopenia is defined as a skeletal muscle index <43 cm<sup>2</sup>/m<sup>2</sup> for males and <41 cm<sup>2</sup>/m<sup>2</sup> for females using previously published cutoff values.<sup>44</sup> Unfortunately, despite the growing recognition of the frequency and significant impact of sarcopenia, there is surprisingly little information in the surgical literature regarding the appropriate method for repletion and/or the ability to reverse some percentage of the physiology in a time-compressed manner to influence surgical outcomes.

Current treatment strategies are designed to address nutritional supplementation of proteins, essential amino acids, and fatty acids, combined with focused resistance training and physical activity. Skeletal muscle possesses an inherent capacity for regeneration due to activation of resident

satellite cells and is regulated in part by host innate immune responses, especially the macrophage response.<sup>45</sup> In addition, muscle wasting in the surgical patient can also be associated with chronic inflammatory diseases and the related pathophysiologic impact of proinflammatory cytokines including interferon- $\gamma$ , interleukin (IL)-1, tumor necrosis factor- $\alpha$ , IL-6, IL-18, and IL-8.<sup>46</sup> This information is essential to understand the current gap in the ERP literature regarding the potential benefits of a specific regimen.<sup>47,48</sup> A number of meta-analyses regarding the assessment of immunonutrition have been published; however, virtually all of the data are from a period of time prior to adoption of ERPs, leading to conflicting outcomes when recent data are included.<sup>49-54</sup> This gap is highlighted by the meta-analysis performed by Hegazi et al,<sup>52</sup> which assessed 8 randomized controlled trials (RCTs) of preoperative immunonutrition versus standard enteral therapy and 9 RCTs of immunonutrition versus no supplements.<sup>52</sup> The authors found no advantage with immunonutrition over standard protein supplementation. Similarly, the comparison of 3 recent studies demonstrates the same conundrum regarding the benefits of supplement components within an ERP. Moya et al<sup>55</sup> randomized patients to receive either no supplement or immunonutrition and reported a reduction in surgical site infection (SSI) in the absence of a mechanical bowel preparation (MBP) or antibiotic bowel prep. Hübner et al<sup>56</sup> randomized patients undergoing elective major GI surgery to either immunonutrition or isocaloric isonitrogenous nutrition given for 5 days preoperatively within an ERAS pathway and demonstrated no improvement in outcomes. Finally, Thornblade et al<sup>57</sup> conducted a retrospective assessment of a quality database that assessed a population that received recommendations for usage of a preoperative supplement but provided no data on degree of compliance and suggested outcomes were better with the recommendation. These data are further complicated by recent data suggesting that glutamine, arginine (vs citrulline), and omega-3 fatty acids are associated with either increased risk or no benefit in many stressed patient populations.<sup>58-65</sup> The current data suggest that the commonly recommended supplements seeking to address benefits related to immunonutrition likely do not provide the mix of low carbohydrate, high leucine, and vitamin D components that appear optimal for sarcopenia.<sup>66-69</sup> Therefore, at this time, the data suggest that patients should be investigated for the presence of sarcopenia and that patients with sarcopenia will benefit from a supplement

versus no supplement. It remains unclear what the refinements in supplementation will be over time as well as what the relative benefits of immunonutrition are for nonsarcopenic and normally nourished patients.

## **CARBOHYDRATE LOADING**

At least 15% to 35% of patients undergoing major general, gynecologic, urologic, cardiothoracic, and orthopedic surgery will experience significant hyperglycemia in the immediate preoperative period, even if they are not diabetic. Postoperative hyperglycemia in nondiabetics is associated with at least a 2-fold increase in the risk of both surgical site infection (SSI) and mortality.<sup>70-74</sup> The risk of postoperative hyperglycemia is exacerbated by the commonly used and unnecessarily prolonged preoperative period of no oral intake (NPO), which creates a starvation-induced insulin resistance and gluconeogenesis response. Most ERPs recognize the risk associated with a prolonged NPO period and recommend the provision of a maltodextrin-containing beverage both the evening before and just 2 hours prior to surgery.<sup>75,76</sup> The concept of perioperative “carbohydrate loading” is frequently misunderstood, and practitioners may rely on sports drinks designed to support athletic-induced carbohydrate consumption from muscle activation and the associated dehydration. The administration of simple sugars (especially fructose) using fruit juices or sports drinks delivers an excessive glycemic index load, resulting in rapid and early glucose and insulin spikes followed by compensatory glucagon secretion, which does not improve insulin sensitivity. As a result, there are no published data assessing the impact of these products on “perioperative carbohydrate loading.”

Several studies using euglycemic clamp have demonstrated improved perioperative insulin sensitivity with administration of maltodextrin, as well as a reduction in postoperative gluconeogenesis, which together improve postoperative glucose metabolism for as long as 72 hours postoperatively.<sup>77-79</sup> However, the recent data from the PROCY trial suggest that the delivery of the recommended 3 doses of 40+ g of maltodextrin per dose does not sufficiently reduce the population rate of hyperglycemia (25% range) to decrease perioperative complications.<sup>80</sup> However, a strategy of administering 3 doses of 25 g provided similar benefits, with a perioperative hyperglycemia rate of 7%.<sup>81</sup>

The preoperative loading period also allows for the opportunity to support

a recently documented impact of surgical stress on the reduction of arginine bioavailability and an associated increase in asymmetric dimethyl arginine (ADMA), which is a natural inhibitor of arginine-associated nitric oxide function.<sup>82-84</sup> The net result is a lowering of the arginine/ADMA ratio in the early postoperative period, which is associated with increased SSI rates, cardiovascular complications, and acute kidney injury.<sup>85,86</sup> Both Ekeloef et al<sup>87</sup> and Ragina et al<sup>88</sup> recently demonstrated a significant reduction (20%-25%) of both arginine and endothelial function after colectomy. L-Citrulline has recently and consistently been demonstrated to safely and effectively restore systemic arginine levels and reduce ADMA in a variety of clinical scenarios. The major reason for reliance upon citrulline is that surgical stress increases the function of constitutively active hepatic arginase, which degrades a significant component of enterally administered arginine, rendering it inactive.<sup>89-91</sup> Conversely, virtually all enterally absorbed citrulline passes through the liver to subsequently be converted virtually completely to arginine in the kidney. The net result is that citrulline directly supports systemic access to arginine for use by all end organs and immune response cells (ie, macrophages and lymphocytes).<sup>92-94</sup> The higher degree of bioavailability of systemic arginine is also important because of its ultimate conversion to ornithine and then proline, which supports wound healing via collagen formation. Higher doses of arginine required to support similar systemic levels are limited by the GI side effects on small bowel secretion of fluid and electrolytes.<sup>92-94</sup> Therefore, the preoperative “loading” period may need to be further investigated to allow support of important aspects of both glycemic management and endothelial function.

## **BOWEL PREPARATION (COLON RESECTION ONLY)**

The classic article by Condon et al<sup>95</sup> assessed bowel preparation strategies in a 3-arm study comparing intravenous cephalothin alone versus oral neomycin and erythromycin alone versus both intravenous and oral regimens. This 3-arm trial showed superior outcome in the dual regimen; however, the intravenous medication was limited in bacterial coverage, which may have impacted the results. This issue was addressed by Coppa and Eng,<sup>96</sup> with 350 patients randomized to intravenous cefoxitin with or without oral neomycin and erythromycin. They found significant improvement as well with dual regimens for wound infection (11% vs 5%). As a result of that work and

other work, including the seminal work of Nichols and Condon, MBP including oral antibiotics supplemented with preoperative intravenous antibiotics has been a mainstay of colon surgery for decades.<sup>97-101</sup> MBP has been primarily associated with reductions in SSI, especially superficial wound infection, although more recently, it has been associated with a reduction in anastomotic leak.<sup>102,103</sup> However, in the ERP era, the utility of MBP has been questioned by 2 meta-analyses evaluating recent data.<sup>104,105</sup> The meta-analysis by Bucher et al<sup>105</sup> included 7 RCTs available in the literature and suggested a higher incidence of anastomotic dehiscence in patients receiving MBP (5.6%, 36/642 patients) versus no MBP (2.8%, 18/655 patients;  $P = .03$ ; odds ratio [OR], 1.85; 95% confidence interval [CI], 1.06-3.22). The rate of intra-abdominal infection (peritonitis or abscess) was similar in the MBP group (3.7%, 17/458 patients) compared with the no-MBP group (2.0%, 9/461 patients; OR, 1.69; 95% CI, 0.76-3.75;  $P = .18$ ).<sup>105</sup> The rate of wound infection was not significantly different in patients receiving MBP (7.5%, 48/642 patients) versus no MBP (5.5%, 36/655 patients; OR, 1.38; 95% CI, 0.89-2.15;  $P = .15$ ).<sup>105</sup> The meta-analysis is significantly impacted by 2 studies. The first is by Contant et al<sup>106</sup> that studied 1431 patients undergoing open colorectal resection randomized to intravenous antibiotics (aerobic and anaerobic coverage) with or without MBP. The data demonstrated a significant increase in the rate of intra-abdominal abscess (2.5% vs 0.3%); however, there was no significant difference in superficial wound infection (no MBP vs MBP, 14% vs 13.8%) or anastomotic leak (no MBP vs MBP, 5.4% vs 4.8%). The authors concluded that MBP can be safely avoided.<sup>106</sup> However, the increase in pelvic abscess rate and a fairly high superficial wound infection raise some concern over this recommendation and possibly the negative impact of no oral antibiotics. Jung et al<sup>107</sup> performed a similarly designed study of 1505 open colectomy patients and also concluded that there was no significant difference in wound infection (MBP vs no MBP, 7.8% vs 6.4%) or anastomotic leak (MBP vs no MBP, 2% vs 2.6%). A major pitfall of these combined data is the absence of the putative effective treatment that incorporates oral antibiotics with the MBP.

In recent years, many papers have reviewed large quality databases, and the consistent theme seems to be a significant reduction in both SSIs and anastomotic leaks.<sup>108-112</sup> The Michigan Surgical Quality Consortium

analyzed 2062 elective colectomies between January 2008 and June 2009; 49.6% of patients were administered MBP and 36.4% received MBP and oral antibiotics. Patients receiving oral antibiotics were less likely to have any SSI (4.5% vs 11.8%;  $P = .0001$ ), to have an organ space infection (1.8% vs 4.2%;  $P = .044$ ), and to have a superficial SSI (2.6% vs 7.6%;  $P = .001$ ).<sup>102</sup> Patients receiving bowel preparation with oral antibiotics were also less likely to have a prolonged ileus (3.9% vs 8.6%;  $P = .011$ ). Similarly, Kiran et al<sup>103</sup> reviewed the National Surgical Quality Improvement Program–targeted colectomy data initiated in 2012 to capture information on the use and type of bowel preparation and colorectal-specific complications. They found that in 8442 patients, MBP with antibiotics, but not without, was independently associated with reduced anastomotic leak (OR, 0.57; 95% CI, 0.35-0.94), SSI (OR, 0.40; 95% CI, 0.31-0.53), and POI (OR, 0.71; 95% CI, 0.56-0.90).<sup>103</sup> A recent meta-analysis and a review of the older prospective randomized trials came to the same conclusion based on high-quality studies.<sup>108,113</sup> Finally, Wick et al<sup>109</sup> described the incremental benefit of adding an MBP with oral antibiotics to their ERP with significant reductions in SSI. Therefore, despite the recommendations of the ERAS Society and in the absence of any convincing data from their data set or a well-powered study comparing no preparation to MBP with oral antibiotics, this author recommends the latter strategy as part of an effective ERP.

## **PREOPERATIVE EDUCATION**

The importance of providing consistent, precise, and easily understood information regarding the episode is key to developing an effective ERP.<sup>114-116</sup> It is beyond the scope of this chapter to define specifics because the goal of the educational program needs to be both patient centric and system specific. It goes without saying that in order to provide high-quality care and allow a pathway for the patient to be an effective member of the team it is essential that everyone agrees to the components of care. Patients are highly sensitive to variations in messaging, and failure in consistently messaging the processes and goals can render an ERP ineffective.

## **Day of Surgery**

## **SURGICAL CARE IMPROVEMENT PROJECT PROCESSES**

The Surgical Care Improvement Project (SCIP) program campaign began in August 2005 as a mandated national initiative with public reporting of compliance designed to primarily reduce the risk of SSI. There has been considerable debate on the relative benefits of various components, or even the degree of compliance on outcomes related to institutional adoption of the SCIP, and ultimately, the program was retired in December 2015. With respect to ERP, the important process measures that seem to be highly effective and that should be adhered to include selection of an appropriate parenteral antibiotic; administration of that antibiotic within 1 hour preoperatively; termination of the antibiotic prophylaxis within 24 hours of surgery; removal of the urinary catheter within 24 hours; and appropriate deep venous thrombosis prophylaxis.<sup>117-122</sup>

## **ILEUS PROPHYLAXIS**

POI had traditionally been perceived as an unavoidable outcome of major abdominal surgery, primarily due to poorly understood multifactorial pathophysiology.<sup>123</sup> Although POI is frequently blamed on factors out of the control of the surgeon, including neurogenic stimuli, release of inflammatory mediators, or requisite surgical manipulation, it has become clear that the majority of the cause is related to narcotic analgesics.<sup>123</sup> Surgery-related mediators also cause the release of endogenous opioid peptides that further exacerbate the effects of exogenous opioid analgesics (administered for analgesia) on the inhibition of bowel function.<sup>124-129</sup> POI occurs at a lower rate following minimally invasive surgical procedures due to a reduction in surgical trauma and postoperative pain but may still occur due to the effects of opioid analgesics.<sup>129,130</sup> Although not life-threatening, POI prolongs postoperative hospital stay and healthcare resource utilization and costs.<sup>130-133</sup> Therefore, without a reduction in POI, an ERP will be unsuccessful in safely reducing the hospital stay and potentially the readmission rate. Although a narcotic-sparing analgesic regimen (see later in this chapter) can minimize the risk of POI, the availability of alvimopan, a first-in-class oral  $\mu$ -opioid receptor antagonist, offers the only prophylactic treatment that reduces the rate of POI.<sup>134</sup> A pooled analysis of the phase III prospective,

randomized, and blinded alvimopan trials confirmed that a 12-mg dose provided optimal reduction in GI morbidity and return of GI function.<sup>135</sup> Subsequent to the prospective randomized trials, several large quality databases have been interrogated and confirmed the system-level benefits of a strategy of POI prophylaxis that incorporates alvimopan in the care plan.<sup>23,136-139</sup> Gum chewing has been advocated as another option to reduce the rate of POI; however, in a program employing early feeding strategies, the relative benefits of chewing gum remain unclear, but it is inexpensive and apparently safe.<sup>140,141</sup>

## **NAUSEA AND VOMITING PROPHYLAXIS**

Postoperative nausea and vomiting (PONV) are common and unpleasant side effects associated with anesthesia and surgery, with an incidence of approximately 30%.<sup>1</sup> High-risk patients may have a considerably higher incidence, especially females, nonsmokers, patients with a history of motion sickness or migraines, and patients exposed to narcotics or volatile anesthetics.<sup>142,143</sup> Current therapeutic options include a combination of antiemetics acting at different receptors.<sup>144</sup> The major receptor systems are involved in PONV including the cholinergic (muscarinic), dopaminergic (D<sub>2</sub>), and histaminergic systems. Ondansetron, granisetron, dolasetron, and tropisetron have shown efficacy for PONV prevention and are associated with a low incidence of side effects. Metoclopramide acts on both central dopamine and serotonin receptors and has both prokinetic and antiemetic effects but may be limited due to extrapyramidal side effects. Dexamethasone is an effective antiemetic, although its mechanism of action remains uncertain.<sup>144</sup> Based on current evidence, a multimodal approach to PONV should include the following strategy: (1) preoperative anxiolysis; (2) aggressive hydration (25 mL/kg) in outpatients unclear of impact in guided fluid management for major surgery; (3) oxygen; (4) prophylactic antiemetics (dexamethasone 10 mg at induction and ondansetron 1 mg at end of surgery); (5) total intravenous anesthesia with propofol, remifentanyl, and a nonsteroidal anti-inflammatory drug; and (6) avoidance of nitrous oxide.<sup>145,146</sup>

## **TRANSVERSUS ABDOMINIS PLANE BLOCK FOR**

## **ANALGESIA**

The initial description of the landmark technique for performing transversus abdominis plane (TAP) block advocated a single entry point, the triangle of Petit, to access a number of abdominal wall nerves, hence providing more widespread analgesia.<sup>147,148</sup> Ultrasound guidance was subsequently recommended to improve localization and deposition of the local anesthetic and was associated with a sensory block from T7 to L1.<sup>149</sup> Radiologic evidence suggests that 20 mL of dye in the TAP 20 to 240 minutes after injection migrated from the superior margin of the iliac crest to the level of the costal margin and posteriorly to the quadratus lumborum.<sup>149</sup> The “4-quadrant TAP block” is a further enhancement of analgesia and is beneficial due to analgesic impact to both the intercostal (upper TAP) plexi and the deep circumflex iliac artery plexi (lower TAP plexus).<sup>150,151</sup> Although data are pending from several ongoing trials, a 4-quadrant block appears to be a safe and inexpensive adjunct to an effective narcotic-sparing analgesia. This is supported by a variety of large data set analyses as well as a single-institution experience within an otherwise unchanged ERP.<sup>152-158</sup>

## **EPIDURAL ANESTHESIA AND ANALGESIA**

Epidural anesthesia as a component of ERP originated from the early work of Henrik Kehlet and his team, who investigated the potential benefits of reduction of the perioperative stress response.<sup>159,160</sup> Interestingly, unlike many of the subsequent analyses of ERP components by this team, it remained untested in randomized studies. As a result, it remains a component of recommendations of the ERAS Society (<http://erassociety.org/guidelines/list-of-guidelines/>). However, the growing understanding and adoption of various narcotic-sparing strategies have generally reduced the impact of epidural analgesia within an ERP. The majority of recent studies, especially in laparoscopic colorectal surgery, have identified limited adjunctive analgesia benefits.<sup>161-166</sup>

## **GUIDED FLUID MANAGEMENT**

The title of this section was purposely changed to “guided” rather than “goal-directed” to attempt to refine the direction the therapeutic management of

perioperative fluid appears to be heading. The current discussion includes *liberal versus restrictive* and *goal directed* as the 2 main approaches to particularly intraoperative fluid management. Conversely, the concept of “guided” offers a middle ground of fluid administration based on additional assessments identifying patients who may or may not be fluid responsive. The latter may benefit from a strategy of judicious pressor therapy for hypotension or inotropic support for impaired myocardial contractility.<sup>167,168</sup>

A report from the United Kingdom in 1999 identified that fluid imbalance led to serious postoperative morbidity and mortality and was associated with a high frequency of poor documentation of fluid balance.<sup>169,170</sup> That same report suggested that overhydration was a contributory cause of postoperative morbidity and mortality.<sup>169</sup> Both hypervolemia and hypovolemia impair cardiac function, pulmonary function, tissue oxygenation, wound healing, POI, renal function, and coagulation, which may all be affected by perioperative fluid administration.<sup>171</sup> Therefore, the true relationship between postoperative complications and volume loading is a U-shaped curve with the goal being lower on either arm of the U.<sup>172</sup>

The traditional approach to fluid therapy includes replacement of the fluid lost (by basal fluid requirements, perspiration through the surgical wound, loss to the third space and blood loss, and exudation through the surgical wound) and maintenance of physiologic functions (preloading of neuraxial blockade).<sup>173</sup> This approach has been associated with high volumes manifested by postoperative weight gain. Alternatively, restricted fluid therapy is based on a mL/kg/h strategy that seeks to achieve a zero balance.<sup>173</sup> The data have clearly demonstrated that a liberal versus restrictive fluid management is consistently associated with a greater incidence of major postoperative complications.<sup>174</sup> However, there is an often underappreciated complication rate associated with underresuscitation, primarily manifested by acute kidney injury.<sup>174</sup> Therefore, a recent critical analysis of the available studies reported that 3 of the trials showed improved outcome after restrictive fluid regimens; 2 trials showed no difference in the outcome.<sup>175</sup>

Goal-directed fluid management strategies have become popular and rely on one or another means of optimizing cardiac output; however, the data on relative benefits of supranormal cardiac output remain elusive.<sup>176</sup> Therefore, this approach is rapidly morphing into a concept of guided or individualized fluid administration, primarily based on an assessment of fluid

responsiveness.<sup>177</sup> The appropriate identification of fluid responsiveness under general anesthesia and mechanical ventilation requires a dynamic parameter of cardiac function. The current methodologies include indicators derived from pulse power analysis, pulse contour analysis, esophageal Doppler monitoring, and others.<sup>178-181</sup> Esophageal Doppler uses a thin plastic tube placed in the esophagus to calculate cardiac output based on the amount of blood that moves past the probe over a given time (stroke distance) and estimates the cross-sectional area of the aorta determined from nomograms.<sup>178</sup> Fluid responsiveness is then implied by changes in stroke volume. A typical strategy uses an increase in stroke volume of at least 10% by a fluid bolus of 3 mL/kg, as consistent with fluid responsive, and the boluses continue until that 10% increase is reached.<sup>178</sup> Alternatively, arterial pulse contour analysis measures the stroke volume on a beat-to-beat basis from an arterial pulse waveform, but the main drawback of this method is that it is an invasive procedure.<sup>181</sup> Respiratory variations in the arterial pulse pressure in patients on positive-pressure ventilation can inform clinicians about the status of a patient on the Frank-Starling relationship. High respiratory variations (>15%) mean that the patient is on the steep portion of the curve, and low respiratory variations (<10%) indicate that the patient is on the plateau (ie, not fluid responsive).<sup>182</sup> A similar strategy of boluses can be administered until the plateau is reached. The specific fluid remains controversial, with recommendations for colloid or balanced crystalloid as the predominant solutions.<sup>183-188</sup>

## **Postadmission**

### **NARCOTIC-SPARING ANALGESIA**

Effective analgesia with minimal side effects is one of the most important components of ERPs and, when fully adopted, results in high-quality and high-value surgical care. The same care plans can be adopted for a broad range of GI surgeries, but a transition in a conceptual approach to analgesia is required. We need to continue to separate ourselves from the concepts of the 1990s when regulatory agencies such as The Joint Commission identified pain as the “fifth vital sign” and the Centers for Medicare and Medicaid Services included satisfaction with analgesia as a quality reporting

measure.<sup>189</sup> The result was a tremendous increase in the use of narcotics, and unfortunately, a narcotic epidemic has occurred, with unintentional drug overdose now the second leading cause of accidental death.<sup>190</sup> Evolving acute pain management from the various forms of the World Health Organization “analgesic ladder” to the concepts of (1) TAP block/neuraxial block; (2) scheduled narcotic-sparing multimodal oral analgesia (nonsteroidal anti-inflammatory drugs [NSAIDs], acetaminophen, and gabalins); (3) oral narcotic for initial breakthrough pain; and (4) reservation of parenteral narcotics for severe residual pain.<sup>191</sup> The increasingly limited use of epidurals for the majority of ERP GI surgery indications has been mentioned earlier. In addition, the field of pharmacogenetics has yielded preliminary data regarding the ability to significantly reduce the amount of narcotics and treatment-related pain scores by using patient-centric optimally metabolized medications.<sup>192</sup>

As mentioned earlier, an oral, scheduled, multimodal analgesic plan is a key construct of ERP analgesia.<sup>193-196</sup> NSAIDs are potent analgesics (600 mg of ibuprofen is as efficacious as 15 mg of oxycodone hydrochloride) and act through inhibition of cyclooxygenase and prostaglandin synthesis.<sup>197</sup> The addition of NSAIDs (including nonselective and cyclooxygenase-2 inhibitors) has clearly and consistently been tied to superior analgesia and opioid-sparing effects.<sup>194,195</sup> NSAID administration has been associated with platelet dysfunction, GI tract irritation or bleeding, and renal dysfunction. A Cochrane review that examined 23 trials (comprising 1459 patients) noted that NSAIDs caused a clinically unimportant transient reduction in renal function in the early postoperative period in patients with normal preoperative renal function and should not be withheld from adults with normal preoperative renal function because of concerns about postoperative renal impairment.<sup>198</sup> Conversely, the perceived risk of NSAID-related increases in postoperative bleeding has been refuted by a significant amount of data.<sup>199-202</sup> There has been growing concern regarding NSAID-related anastomotic leak, which has been suggested in several reports. Some data suggest an association between NSAID use and an increase in anastomotic leakage; however, further studies are needed to determine the validity of this association.<sup>203-207</sup> There is some literature suggesting that variable systemic levels can occur in patients with mutations in the CYP2C8 or CYP2C9 genes, which can result in delayed metabolism and therefore supratherapeutic drug

levels.<sup>208-210</sup> Therefore, utilization of naproxen, which is one of the few NSAIDs (selective or nonselective) that is excreted unchanged in the urine and therefore not impacted by genetic variation, may offer a safer strategy.

Acetaminophen is available in both oral and parenteral forms and should also be provided in a scheduled fashion within an ERP. The recurring theme is improved analgesia, narcotic reduction, and reduced opioid side effects.<sup>202</sup> Although theoretically tied to hepatic toxicity, the risk is minimal when acetaminophen is administered in the usually recommended dosage range, which yields an additive analgesic benefit to concomitant NSAID use.

Gabapentinoids (gabapentin and pregabalin) are another synergistic component of the multimodal analgesic program. Gabapentin potentially acts to produce its pain-relieving effects by (1) inhibition of injury-induced spinal neuronal excitability, evoked hypersensitivity, and ongoing pain and (2) selective supraspinal modulation of affective qualities of pain, without alteration of reflexive behaviors.<sup>211</sup> Once again, robust meta-analyses indicate that a gabapentin or pregabalin administered preoperatively is associated with a decrease in postoperative pain and opioid consumption.<sup>212-214</sup> Gabapentinoids may be associated with adverse effects, including sedation, dizziness, and peripheral edema, and therefore, dose modification may be required during therapy, especially in the elderly.

Judicious use of narcotics may still be required for effective analgesia, and narcotics do not need to be withheld if used in the background of the narcotic-sparing regimen. There are robust data regarding potential benefits of intravenous narcotics administered via a patient-controlled delivery system versus epidural or other analgesic strategies, especially in conjunction with novel agents such as dexmedetomidine, which has shifted the focus back to an intravenous strategy.<sup>214-216</sup> The nuances of analgesic treatment by GI surgery discipline will be discussed in other chapters.

## **EARLY FEEDING**

Amazingly, early offering of food based on patient tolerance remains one of the more difficult components of ERP to implement as a result of persisting biases of much of the care team, including both nursing and surgery. In fact, the concept of early feeding safety was a product of the introduction of laparoscopic colectomy and existed prior to the actual introduction of ERP

programs.<sup>217</sup> Laparoscopy raised questions regarding the long-held dogma of NPO until return of bowel function. This concept was then appropriated by the ERP movement and is routinely recommended for ERP across all GI surgical procedures.<sup>218-220</sup> Optimal implementation occurs with implementation of the PONV and POI prevention strategies, as well as effective narcotic-sparing analgesic regimens. A common misconception is that intolerance of early feeding is not a cause of POI but rather the harbinger of the onset of POI.

## **EARLY AMBULATION**

Early ambulation after surgery is another easily understood but difficult to implement strategy within ERP, primarily related to the reliance upon nurses who have multiple other patient care obligations. In addition, there may be physical limitations of the nurse that may limit the ability to manage a larger, unsteady patient. The concept is not new, as evidenced by the work of Canavaro in 1946 who recognized the value of early postoperative ambulation.<sup>221</sup> Although the concept is advocated in virtually all published ERPs, the growing acceptance of mobility programs will likely be the component of care most likely to lead to successful implementation of the strategy.<sup>222</sup> Many institutions have implemented similar low-cost programs, relying on specially trained medical aides to assist patients to safely ambulate. Once again, effective narcotic-sparing analgesia that reduces the side effects of medications that can cause dizziness or unsteadiness are adjunctive to the process. In addition, early removal of urinary catheters and intravenous lines allows the patient to ambulate without being encumbered.

## **ERP SPECIFICS BY GI SURGICAL DISCIPLINE**

### **Esophagectomy**

The components of ERP for esophagectomy remain highly variable, but commonly accepted components seem to be epidural for postoperative analgesia, supplemental enteral nutrition, and active physiotherapist involvement to facilitate early postoperative mobilization. Conversely, there appears to be little consensus on the use of drains, use of nasogastric tubes,

time taken to commence oral intake, and use of postoperative oral contrast studies.<sup>223-225</sup> The confusion lies mainly with the fact that there is limited robust, high-grade evidence for many of the elements within ERP.<sup>224,225</sup> One facet that seems to be clear is that early enteral nutrition is superior to the use of total parenteral nutrition, with consistently lower septic complications associated with some form of enteral nutrition.<sup>226,227</sup> Various tube feedings (jejunostomy vs nasojejunal) have been assessed and offer effective means of feeding delivery with a low incidence but different set of tube-related complications. The timing of early oral intake after esophagectomy remains poorly evaluated, with some studies suggesting safety and a reduced length of stay, while others have suggested superior outcomes with prolonged use of tube-based enteral feeds.<sup>228-232</sup> Similarly, although not robust data, it appears that there is limited need for nasogastric decompression after esophagectomy, which improves patient comfort with increased risk of complications.<sup>233,234</sup> As a result of these data, it appears that virtually all of the components of ERP discussed earlier in the chapter apply to esophagectomy; however, experts in the field should focus on the optimal strategy for enteral nutrition and timing for resumption of oral intake.

## Gastrectomy

A recent systematic review and meta-analysis reviewed the highest quality data available for gastrectomy ERP, which consisted of 14 studies.<sup>235</sup> Although the authors identified highly disparate ERPs across the studies, most of the earlier mentioned processes of care were used. Once again, limited use of nasogastric tubes and early resumption of oral intake appear safe and feasible. They also identified that ERP was associated with reduced serum inflammatory response (C-reactive protein: standardized mean difference [SMD], 0.68 [95% CI, 1.16-0.19],  $P = .007$ ; interleukin-6: SMD, 0.62 [95% CI, 0.94-0.29],  $P < .001$ ), less weight loss (SMD, 0.79 [95% CI, 1.11-0.46],  $P < .001$ ), and lower cost (SMD, 1.02 [95% CI, 1.59-0.45],  $P < .001$ ), and no increase in postoperative morbidity (OR, 0.83 [95% CI, 0.65-1.06],  $P = .13$ ) or hospital readmission (OR, 1.67 [95% CI, 0.88-3.19],  $P = .12$ ).<sup>235</sup> Better identification of gastrectomy-specific differences in complications may allow better tailoring of a specific ERP.

## Hepatectomy

Hughes et al<sup>236</sup> performed a meta-analysis of studies assessing hepatectomy ERP and determined that basically all the elements associated with colectomy (with clear support for no bowel preparation) were safe and effective. Two areas of opportunity appear to be specific to hepatectomy: (1) optimal fluid management intraoperatively and (2) the necessity of epidural for analgesia. Clearly, using strategies to reduce intraoperative blood loss are important to reduce liver-specific surgical complications, especially reducing intraoperative central venous pressure and possibly acute normovolemic hemodilution.<sup>237-239</sup> Similarly, as is true in other GI surgical areas, the role of epidurals has been questioned and may actually impair recovery.<sup>240,241</sup>

## Pancreatectomy

Xiong et al<sup>242</sup> performed a meta-analysis of the available high-quality but limited data (14 studies) related to pancreatectomy. Discussions regarding the nuances of gland management, anastomotic technique, and drain management are beyond the scope of this chapter and not properly part of ERP. Again, the elements are variably implemented, but the majority of the process measures are useful in pancreatectomy. The benefits of implementation of an ERP include reduced length of stay (weighted mean difference,  $-4.17$  days; 95% CI,  $-5.72$  to  $-2.61$  days), reduced delayed gastric emptying (OR, 0.56; 95% CI, 0.44-0.71), reduced overall morbidity (OR, 0.63; 95% CI, 0.54-0.74), and reduced in-hospital costs compared with conventional perioperative care (all  $P < .001$ ).<sup>242</sup> Implementation of an ERP appears safe and will yield incremental improvement compared to standard care in pancreatectomy.

## THE BUSINESS CASE FOR ERPs

As the US healthcare system moves toward the concept of value-based purchasing, it is likely that some form of “bundled care” payment structure for GI surgery will be implemented and will demand a precise understanding of the cost and quality of care within a provider group. An example of the type of institutional-level economic data that are helpful is demonstrated by

the use of submitted billing information, as described by Asgeirsson et al.<sup>243</sup> These data identified the system-level “best case” economic outcome and defined clinical cost drivers for the most frequent variances to guide quality improvement. As an example, open colectomy was associated with higher cost compared with laparoscopic colectomy; however, the only team discussion was a frequent review to assure that use of minimally invasive techniques were used when indicated. Clearly, this “perfect outcome” is a combination of high-quality patient-centric outcomes, short length of stay, appropriate resource consumption, and reduction of complications and readmissions. This is often misconstrued as the mere presence of variation of care rather than a full discussion of patient-centric versus provider-centric outcomes, as well as necessary and unnecessary variations in care. This type of rigorous analysis demands a keen understanding of the evidence-based and cost-effective strategies that must be used by the team, not as a cookie cutter approach to care. The patient-centric approach often is confused with the need for risk adjustment, and although not every patient is set up for a similar outcome, the care plans for the primary disease and associated comorbidities can be anticipated and standardized. An example of this type of understanding is the concept of “diagnosis-related group migration,” which is defined as a patient admitted without any comorbidities who develops postadmission complications.<sup>244</sup> This is also a simple analytic approach for a US institution to implement because the data are reported for claim submission and represent either an honest assessment of current performance or an opportunity for improved documentation and coding. Although some process for assessing and communicating risk-adjusted outcomes is necessary for intra-institution and cross-institution cost and quality comparisons, there has been a failure to clearly articulate processes of care that are effective in delivering complication reduction and the remaining “acceptable” level of these occurrences using statistical process control or equivalent methodology.<sup>245,246</sup>

Fry et al<sup>247,248</sup> presented a system that was based on readily available administrative data that can accurately monetize the cost of a deliverable episode of care for a given provider. An equally precise and yet easy to calculate system is the Hospital Stay, Readmission, and Mortality Rates (HARM) score, which uses surrogate measures of length of stay, mortality, and readmissions.<sup>249,250</sup> Gramlich et al<sup>13</sup> provide one of the best descriptions of a system-wide implementation of ERP using the Province of Alberta,

Canada, journey. They described the many theories and potential mechanisms for change management and defined their use of the Quality Enhancement Research Initiative (QUERI) model and adoption of the Theoretical Domains Framework (TDF).<sup>251-254</sup> Readers are referred to the Gramlich article because it provides a good background for successful implementation. It will be intriguing, based on the earlier discussions on various elements of ERP, how the team revises their care plan based on new science. For example, it remains to be determined, given the recent data regarding the role of carbohydrate loading, the expected outcome (reduced hyperglycemia), and the failure of many of the commonly recommended strategies to be effective, whether their system will provide a platform for ongoing refinement and rapid process change.

Ultimately, the reader should be left with the conclusion although components of ERP may differ, it is easy to assess progress if a process is tied to an outcome and measured. In addition, it is clear that adoption of an ERP will routinely lead to some, often significant, improvements of clinical and financial outcomes. Therefore, the Nike tag line “Just do it” seems *apropos*. A recommended set of process measures and the associated outcome measures are provided in [Table 3-1](#).

 **TABLE 3-1: ENHANCED RECOVERY PROGRAM PROCESSES OF CARE AND ASSOCIATED OUTCOMES**

Process	Outcome Measure
Anemia evaluation	Blood utilization; surgical site infection; transfusion-associated complications
Patient education	Compliance with patient-performed care components; patient satisfaction
Assessment of nutrition/sarcopenia	Surgical site infection; respiratory failure/pneumonia; wound complications
Carbohydrate loading	Hyperglycemia rate (>140 mg/dL) in nondiabetics; surgical site infection; acute kidney injury
Bowel preparation (colectomy only)	Surgical site infection
Surgical care improvement program components	Surgical site infection; urinary tract infection
Ileus prophylaxis	Ileus rate; increased bed days due to ileus
Postoperative nausea and vomiting prophylaxis	Need for rescue therapy
Narcotic-sparing analgesia	Pain scores; patient satisfaction; rate of opioid-associated adverse events
Guided fluid management	Fluid overload–related complications; rate of acute kidney injury; need for rescue diuresis/resuscitation
Early feeding	Ileus rate; alteration in diet due to failure; length of stay
Early ambulation	Length of stay; rate of pneumonia/deep vein thrombosis; fall rate

# PERFORMANCE MEASUREMENT AND IMPROVEMENT IN SURGERY

*Andrew M. Ibrahim • Justin B. Dimick*

## INTRODUCTION

Surgeons are under enormous pressure from multiple healthcare stakeholders to measure and improve their performance. Government regulators are publicly reporting patient outcomes and satisfaction scores.<sup>1</sup> Payers are reducing reimbursements based on quality measurements.<sup>2</sup> Licensing boards and professional societies are revising member certification to increasingly include performance evaluation.<sup>3</sup> Patients are now searching online for information about surgeon outcomes to guide where they seek care.<sup>4</sup> Surgeons themselves have created quality collaboratives to share best practices and improve their own performance.<sup>5,6</sup> In short, we are in an era of unprecedented focus on evaluating and reporting the work of surgeons.

Despite the widespread interest in measuring and improving surgical

quality, little consensus exists on what measures to follow or which strategies to implement. In this chapter, we describe the general principles of performance measurement in surgery, including how to choose among measures. We then outline the benefits and drawbacks of different performance improvement strategies.

## **PERFORMANCE MEASUREMENT IN SURGERY**

Establishing accurate measurement of surgical quality is essential to any attempt at improving performance. The following sections describe the key principles to understanding the underlying methodology and options for performance measurement.

### **Understanding Variation in Outcomes**

Some hospitals and surgeons seem to simply do better than others, and this reality creates an opportunity to learn and improve from the best performers. However, reliably and fairly identifying high and low performers can be challenging. In addition to the quality of care provided, patient outcomes can also be highly influenced by chance and case mix. To understand how best to measure quality, it is important first to explore why outcomes vary across hospitals and surgeons.

### **SAMPLE SIZE AND THE PROBLEM OF CHANCE (“JUST BAD LUCK”)**

Variation in outcomes across surgeons and hospitals may be the result of good or bad luck. The role of chance becomes important in low-volume procedures (eg, pancreatectomy) or when the event rate is low (eg, death after a cholecystectomy). Good or bad luck can result in either a type 1 or type 2 error.

Type 1 errors occur when extreme outcomes—*good or bad*—are attributed to quality when they actually are simply due to chance. Consider, for example, the “zero-mortality paradox” observed in Medicare claims data.<sup>7</sup> A hospital with a 0% mortality rate 3 years in a row for pancreatic resection

might be considered the highest quality; however, in a subsequent year, it might have a 30% higher mortality rate than other hospitals. The apparent paradox is explained by the fact that most hospitals with a 0% mortality rate simply have a low case volume and good luck, and thus, this rate does not accurately reflect the quality provided at these hospitals. In other words, the difference between a low-volume hospital (eg, 5 pancreatectomies a year) having a 0% mortality rate (no deaths) or 20% mortality rate (1 death) is more likely due to chance rather than quality. Thus, reporting a mortality rate of either 0% or 20% does not accurately represent the quality provided at a hospital.

Type 2 errors occur when real differences in quality are difficult to detect because of limited sample size. Widely recognized in clinical trials as being “underpowered” (ie, sample is not large enough to find differences), limited sample size is commonly overlooked in surgical quality improvement initiatives. For example, a review of quality indicators recommended by the Agency for Healthcare Quality and Research found that only a small minority of hospitals have adequate surgical volume to detect meaningful differences in mortality rates.<sup>8</sup> Thus, although there may be real differences in quality between hospitals, a type 2 error prevents them from being detected.

## **THE ROLE OF CASE MIX (“BUT MY PATIENTS ARE SICKER”)**

When presented with their own outcomes data, surgeons with worse outcomes often intuitively reply, “But my patients are sicker.” Without question, patient characteristics, including their comorbid conditions, functional status, procedure indications, and so on, play a role in patients’ outcomes and should be accounted for when measuring outcomes. How much patient characteristics matter, however, depends on the comparison being made.

Adjustment for case mix (the type or mix of patients) is most important when there are strong underlying differences in the patients being compared. For example, comparing groups of patients in 2 different surgical intensive care units should be adjusted for case mix. The age, Acute Physiology and Chronic Health Evaluation (APACHE) score, and health profiles of the patients in an intensive care unit may vary widely and contribute significantly to the variation in their outcomes. Similarly, adjusting for case mix is

appropriate when comparing the outcomes of a tertiary referral hospital (which treats many complex cases) to those of a smaller community hospital (which may only operate on generally healthier patients requiring less complex procedures).

The importance of case-mix adjustments may be overstated when making procedure-specific comparisons. For example, the unadjusted coronary artery bypass grafting (CABG) mortality rates in the state of New York in 2001 ranged from <1% to 4%. When the outcomes were risk-adjusted for patient factors, the variation remained essentially unchanged.<sup>9</sup> In other words, little of the variation in mortality rates could be explained by the underlying case mix because patients who undergo CABG have a relatively similar profile. This is not meant to downplay the role of risk adjustment but only to point out that, in many cases, case mix has a much smaller role than previously thought.

## What Performance Should Be Measured? The Structure, Process, Outcomes Framework

Described first by Donabedian in 1998, the “Structure, Process, Outcomes” model is the most common framework used for quality improvement in health care.<sup>10</sup> Each category has its own benefits and limitations, which are described below in the context of surgery (Table 4-1).

**TABLE 4-1: APPROACHES TO MEASURING PERFORMANCE IN SURGERY:  
STRUCTURE, PROCESS, OUTCOMES**

Type of Measure	Examples	Advantages	Disadvantages
Structure	Hospital volume	Strong predictor of hospital outcomes	Does not discriminate individual providers
	Ratios	Inexpensive to measure	Difficult to make actionable
Process	Administration of preoperative antibiotics	Actionable targets	Few “high-yield” processes are known
	Removal of Foley by postoperative day 2	Less influenced by error or patient risk factors	Mixed data on correlation to outcomes
	Postoperative resumption of preoperative $\beta$ -blocker		
Outcomes	30-day mortality rate	Strong “buy-in” from providers on importance	Needs detailed information to risk adjust
	Surgical site infection rate	Seen as the “bottom line” by most stakeholders	Not as reliable in low-volume settings
	Rates of readmission		

## STRUCTURE

Structure refers to measurable attributes of a surgeon (eg, years of training, specialty service availability) or hospital (eg, number of inpatient beds, procedure volume). The primary benefit of this approach is that the data are easily collectable. Studies that described the association of better pancreas surgery outcomes with high-volume centers used this approach. Although the structure approach does well to predict outcomes across hospitals, it provides little actionable information within a hospital or about individual providers.

## PROCESS

Process describes the measurable steps involved in the patient’s care. Performing certain process measures should translate to improved patient outcomes (eg, giving preoperative heparin to reduce risk of a postoperative thromboembolism). Administrators are particularly drawn to these measures because they are readily actionable and measurable. Despite the anticipated benefit, very few “high-yield” process measures have been identified to correlate with improved patient outcomes.

## OUTCOMES

Outcomes represent the end result of care. In surgery, the most common outcomes of interest are mortality and postoperative complications. These tend to have the most face validity with surgeons who often care most about

the “bottom line.” Unfortunately, comparing outcomes fairly requires high case volume (which many hospitals or individuals do not have) and detailed patient information to appropriately risk adjust. For example, comparing a process measure between 2 hospitals may only require, for example, the percentage of patients who appropriately received heparin before surgery. However, to compare the outcome (eg, rates of thromboembolism), one would need not only data on the outcome but also data on known risk factors (eg, obesity, physical inactivity, history of thromboembolism) to allow for risk adjustment and fairer comparisons. Thus, more data (and, therefore, often more resources) are required to compare outcomes performance.

## **Choosing the Right Measurement Approach**

With limited resources to collect data, it can be challenging to choose where efforts should be focused. Should a surgeon be evaluated based on process measures such as preoperative antibiotic administration? Or should we instead focus on the “bottom line” of the outcomes and assess surgical site infection rates? Although there are judgment calls about which should be valued over the other, there are also real statistical limitations that should help inform the choice.

Choosing the right measure will depend on the characteristics of the procedure and our ability to find meaningful differences. Statistically speaking, the more often something occurs, the easier it is to detect. Therefore, one should ask the following 2 questions: (1) How often is the procedure performed? (2) How often does the adverse event occur? Consider the following 4 categories and when structure, process, or outcomes would be an appropriate measurement approach (Fig. 4-1).<sup>11</sup>

**FIGURE 4-1** Choosing the right measure: Structure, process, outcomes. The operative risk and operative volume should both be taken into consideration when choosing the right performance measure. RNY, Roux-en-Y. (Data from Birkmeyer JD, Dimick JB, Birkmeyer NJ: Measuring the quality of surgical care: structure, process, or outcomes? *J Am Coll Surg* 2004 Apr;198(4):626-632.)

## 1. HIGH-VOLUME, HIGH-RISK PROCEDURES SHOULD BE APPROACHED USING OUTCOMES MEASURES

Examples of high-volume procedures with higher adverse event rates include colectomy and gastric bypass. Because they are performed fairly often and adverse events are fairly common (eg, surgical site infections after colectomy are as high as 30%), there is enough statistical power to find meaningful differences in *outcomes*. Although there may be a large enough case volume to look at a *process* measure, such as preoperative antibiotic administration, the adverse outcomes occur more frequently and would be more efficient to detect.

## 2. HIGH-VOLUME, LOW-RISK PROCEDURES SHOULD BE APPROACHED USING PROCESS MEASURES

Consider a high-volume procedure with a low adverse event rate, such as an inguinal hernia repair. Measuring an outcome such as mortality would not be helpful because it almost never occurs, even with a high case load.

Alternatively, if we focus on a *process* measure (eg, appropriate use of preoperative antibiotics), we are much more likely to find a difference in rates between providers or hospitals.

### **3. LOW-VOLUME, HIGH-RISK PROCEDURES SHOULD BE APPROACHED WITH STRUCTURE MEASURES**

When a procedure is low volume with a high adverse event rate (eg, esophagectomy), neither outcomes nor process measures make sense statistically to find differences in quality. Instead, focusing on a structure approach has been shown empirically to be the best predictor of future performance.<sup>12</sup>

### **4. LOW-VOLUME, LOW-RISK PROCEDURES SHOULD BE LOW PRIORITY FOR QUALITY MEASUREMENT**

Finally, limited priority should be given to operations that are low volume and low risk (eg, Spigelian hernia repair). Efforts to evaluate these procedures are lower yield than the previously described categories.

## **Special Considerations When Measuring Outcomes**

Of the 3 types of measures (structure, process, and outcomes), measuring outcomes is perhaps the most challenging. As mentioned earlier, advanced statistical modeling techniques are needed when assessing outcomes to account for small sample sizes and imbalances in patient risk. Increasing progress is being made in our ability to address these limitations.

### **SMALL SAMPLE SIZE CAN BE ADDRESSED WITH RELIABILITY ADJUSTMENT**

Because many hospitals individually may have lower volume, it can be difficult to determine if their outcomes truly reflect their performance or are due to “statistical noise” (ie, chance). Reliability adjustments attempts to

address this by averaging the individual hospital outcomes rate with the outcomes rate of all the hospitals combined in a weighted fashion based on volume. For hospitals with higher volume, more weight is placed on the individual hospital than the overall rate. Conversely, lower volume hospitals have less weight placed on the individual rate and more placed on the overall rate. This results in “shrinkage” of the variation displayed, and lower volume hospitals move closer to the population mean. In a sense, this gives hospitals or surgeons the benefit of the doubt of performing “average” until they have enough volume to stratify themselves as a high or low outlier. One advantage of this approach is that it prevents us from prematurely labeling high or low outliers unfairly. On the other hand, depending on the adjustment threshold used, it may prevent us from seeing differences that actually exist.

## **CASE MIX CAN BE ACCOUNTED FOR WITH RISK ADJUSTMENT**

Accounting for case mix is important to understanding the variation in patient outcomes. How much “adjustment” is necessary continues to be refined. For example, when comparing patients undergoing a similar procedure who are likely more homogenous, a model may only need a few adjustment variables (eg, age, sex, race). Conversely, comparison across hospitals that perform different procedures may require more adjustment variables (eg, age, sex, race, operation type, admission type). Although previous models have used as many 21 variables in their risk adjustments, when making only procedure-specific comparisons, similar results can be obtained with just 5 variables.<sup>13</sup> Our ability to find more efficient modeling strategies such as these will help reduce the burden of future data collection.

## **STRATEGIES FOR IMPROVING PERFORMANCE IN SURGERY**

With accurate measurement in place, how can we improve performance? Incentives are rapidly increasing to implement strategies for improving care. The largest payer in the United States, the Centers for Medicare and Medicaid Services, established a Linking Quality to Payment initiative whereby providers are reimbursed based on specific performance measures.<sup>2</sup>

Example schemes such as “pay-for-performance” and “bundled payments” have been piloted and focus specifically on surgical procedures.<sup>14,15</sup> As payment reform continues to move toward rewarding better quality, surgeon leaders will be expected to initiate and understand quality improvement programs. In the following sections, we describe the benefits and drawbacks of the most common strategies (Table 4-2).

**TABLE 4-2: ADVANTAGES AND DISADVANTAGES OF DIFFERENT PERFORMANCE IMPROVEMENT STRATEGIES FOR SURGERY**

Strategy	Examples	Advantages	Disadvantages
Public reporting	Hospital Compare website ProPublica Scorecard  Cardiac surgery in New York	Influences hospital administration Incentivizes hospital improvements to attract patients	Controversial “fairness” of methodology Unclear if actually influences patients’ location of care decisions Could encourage “gaming” to avoid higher-risk patients
Selective referral	Bariatric centers of excellence  Hospital network regionalization	Improved outcomes for complex operations Maximizes surgeon and hospital expertise	May limit access for minority and rural patient populations Less benefit for common procedures
Outcomes feedback	American College of Surgeons National Surgical Quality Improvement Program	Rigorous methodology that is accepted by most clinicians  Can serve as basis to evaluate different QI interventions	Feedback alone does not result in improvement  Data collection can be resource intensive and expensive
Quality collaboratives	Michigan Surgery Quality Collaborative American Hernia Society Quality Collaborative	Impact individual surgeons  Quickly disseminate best practices	Requires high degree of social capital and buy-in May take long time to develop
Video and coaching	Intraoperative coaching  “Postgame analysis” of surgery video	Technical ability correlations to outcomes Very grannual to improve individual surgeons	Resource intensive Methodology still in its infancy

## Public Reporting

Public reporting involves making information about hospital or surgeon quality openly available. Examples include the Centers for Medicare and Medicaid Services Hospital Compare website and the privately run ProPublica Surgeon Scorecard.<sup>1,4</sup> A potential advantage of these programs is that patients will act like consumers and seek out the best quality care. This in turn should motivate both surgeons and hospital quality improvement teams

to attract patients. At present, there is little evidence regarding whether patients know how to interpret these data or if they even use the data to choose their location of care. In addition, surgeons have pointed out significant methodologic limitations of these reporting mechanisms.<sup>16</sup>

Although debates about the methods and quality of public reporting continue, the response from hospitals cannot be ignored. In 1989, the state of New York was the first to publicly report mortality rates after CABG. Shortly thereafter, many hospitals with poor outcomes completely overhauled their cardiac programs by recruiting outside personnel and investing in new infrastructure.<sup>17</sup> Similar responses from hospitals were catalyzed by the 2005 launching of the federal government's Hospital Compare website. Indeed, much of the quality improvement infrastructure prevalent within hospitals now that we take for granted was established in response to public reporting.<sup>18</sup> Even if the up-and-coming forms of public reporting (eg, provider reviews on Yelp or Facebook) do not influence patients, they are likely to shape how hospital administrators make quality improvement decisions.

## Selective Referral

Selective referral means restricting patients to locations where there are dedicated resources and expertise for a specific problem. Unlike public reporting, which is simply encouraging movement to high-quality centers, selective referral is enforced by payers who will only reimburse at a chosen location. For example, the bariatric surgery coverage decision by the Centers for Medicare and Medicaid Services established in 2006 only reimbursed for bariatric procedures at "centers of excellence."<sup>19</sup> This approach was intended to maximize surgeon and hospital expertise to take advantage of the known association between high procedure volume and better outcomes. In the case of bariatric surgery, this strategy did not work as intended, and later studies demonstrated no benefit over institutions that were not deemed centers of excellence.<sup>20</sup> In addition, in the case of bariatric surgery, restricting surgical care to specific centers limited access disproportionately for minority populations.<sup>21</sup>

Although selective referral is not ideal for all procedures, it is finding its place for complex operations. Many insurers are adopting The Leapfrog

Group recommendations to restrict reimbursement for high-risk procedures (eg, esophagectomy, pancreatectomy) to centers with high volume and other specific safety standards.<sup>22</sup> Similarly, major hospital systems that are rapidly consolidating have adopted a “volume pledge” to regionalize complex operations within their network.<sup>23</sup> Because this approach works best for high-risk operations that have a known volume-to-outcome relationship (eg, CABG, pancreatectomy), it has little role for a majority of procedures that are common or that have low adverse event rates. Applying selective referral to low-risk procedures could also severely limit access and place unnecessary burden on patients to travel while resulting in minimal or no benefit in outcomes.

## Outcomes Feedback

Providing hospitals and surgeons with feedback on their outcomes is the most commonly used strategy for surgical quality improvement. The largest example is the American College of Surgeons National Quality Improvement Program, which provides over 600 hospitals with outcomes data. The program allows hospitals to measure their own performance and benchmark across centers throughout the country. An advantage of this specific approach is the rigorous methodology used to report fair, validated, and risk-adjusted outcomes. A major drawback of the system, however, is the significant cost and resources required to collect the relevant data.

Although the use of outcomes feedback has been widely adopted, it faces important challenges that need to be addressed. First, participation in a feedback program alone does not lead to quality improvement.<sup>24</sup> Hospitals with this approach in place should also be implementing other strategies such as coaching low-performing surgeons, improving safety culture within high-risk wards, benchmarking through regional collaboratives, or implementing evidence-based perioperative guidelines. It cannot be stressed enough that although measurement of performance is necessary, by itself, it is not sufficient for improvement. Second, many data collection and reporting systems are still too inefficient and place a significant resource burden on hospitals. Efforts to improve risk adjustment methodology and streamline reliable data collection should be prioritized to reduce these financial barriers to participation.

## Quality Collaboratives

Quality collaboratives are groups of surgeons or hospitals that meet regularly to share data and implement best practices. Most collaboratives form around a geographic region (eg, Michigan Surgery Quality Collaborative) or a specific surgical field (eg, American Hernia Society Quality Collaborative). Effective groups rely on a shared clinical registry that captures detailed patient information and their outcomes across multiple institutions. Members identify and share effective practices through regular face-to-face meetings, site visits, and conference calls. These serve as a basis for them to develop future targeted interventions that are evaluated, adjusted, and shared in a similar fashion. This cycle of evaluation, intervention, and dissemination allows for rapid and iterative quality improvement. Because this approach is driven largely by clinicians “on the ground,” it has face validity and focuses on problems relevant to day-to-day patient care. Furthermore, by incorporating multiple hospital systems, the collaborative can benefit from a breadth of expertise that, when shared, tremendously benefits patient care.

Creating an effective quality collaborative requires a unique combination of financial and social resources. A significant amount of capital is needed to maintain a clinical registry and subsidize surgeon time outside of the operating room to participate in collaborative events. Even with supportive administrators, collaboratives often need to look for novel funding outside of their institutions. For example, the Michigan Surgery Quality Collaborative has been able to demonstrate benefits to payers by reducing complications such that they are significantly supported by both federal research grants and private insurers.<sup>6</sup> Beyond financial capital, collaboratives require a significant amount of social capital among surgeons who may be from competing hospital systems. Creating a sense of community and engagement requires time to develop trust, considerable effort, and effective leadership.

## Video Analysis and Coaching

The most recent addition to quality improvement strategies is the use of video technology and coaching. Unlike other approaches that focus on care before the operation (eg, process measures, checklists) or after the operation (eg, postoperative complications, failure to rescue), video coaching is focused on the operation itself. How individual surgeons execute their technical skill has

long been a “black box” not well captured in operative reports or outcomes. Recently, however, researchers have been able to use video recording to objectively measure surgeon technical skill during laparoscopic gastric bypass procedures, and they found that variation in skill correlates with patient outcomes (Fig. 4-2).<sup>25</sup> Building on this discovery, specific coaching paradigms that incorporate “postgame” video coaching by peer surgeons have been created to improve individual surgeon performance.<sup>26,27</sup> In doing so, it has revealed a whole new range of variables (eg, handling of tissue, type of stapler, efficiency of sewing) that were previously unable to be measured.

**FIGURE 4-2** Surgeon skill and postoperative complication rates. Surgeons were evaluated using Objective Structured Assessment of Technical Skills (OSATS); those in the top quartile were identified as “high-skill surgeons” and those in the bottom quartile as “low-skill surgeons.” Complication rates after laparoscopic Roux-en-Y gastric bypass surgery were risk-adjusted and reported by surgeon skill level. All differences in this figure were significant,

$P < .001$ . (Data from Birkmeyer JD, Dimick JB, Birkmeyer NJ: Measuring the quality of surgical care: structure, process, or outcomes? *J Am Coll Surg* 2004 Apr;198(4):626-632.)

Despite the enthusiasm for how video coaching could improve surgical quality, the field itself is still in its infancy. To date, only a handful of operations have been examined with this approach, and we are still waiting on long-term trials to determine whether video-based coaching can ultimately improve patient outcomes. It is likely that multiple iterations will be needed before it can be scaled up and widely implemented. Nonetheless, once matured, this area has potential to become part of credentialing and continuing education for attending surgeons. In addition, it may be a source of novel innovation for surgical technique as we gather more granular data about the highest performing surgeons.

## CONCLUSION

Pressure on surgical leaders to understand and implement performance measurement and improvement programs is at an all time high. Over the past decade, a robust body of scholarly work has advanced our understanding of measurement and improvement in surgical populations. No single measurement approach or improvement strategy is best, and each surgeon, specialty, department, and hospital will need to tailor their efforts based on their goals, as discussed earlier. The pressures from patients, payers, regulators, and specialty societies will only continue to grow and will make performance improvement central to our profession.

# ENDOSCOPY AND ENDOSCOPIC INTERVENTION

*Nabil Tariq • Jeff Van Eps • Brian J. Dunkin*

Over the past several decades, flexible endoscopy has shifted the management of numerous gastrointestinal diseases from the surgeon to the endoscopist. What had started as a diagnostic discipline has now become one of advanced therapeutic potential. The concept of performing endoscopic surgery has become a reality with the advancement of endoluminal therapies for neoplasia, gastroesophageal (GE) reflux, motility disorders like achalasia and gastroparesis, and obesity. With advanced endoscopic tools at our disposal, endoscopic therapies are increasingly used as rescue therapies as well, especially after foregut surgical interventions. This chapter will address the indications and techniques for upper and lower flexible endoscopy as well as the recent advances in interventional endoscopy.

## THE FLEXIBLE ENDOSCOPE

### Imaging

The flexible endoscope was initially developed in 1957 as an imaging device dependent on the delivery of light and transmission of the image along multiple bundles of chemically treated glass fibers. The fiberoptic bundle is 2 to 3 mm wide and is composed of 20,000 to 40,000 individual fine glass fibers, each approximately 10  $\mu\text{m}$  in diameter.<sup>1</sup> When using a fiberoptic endoscope, the endoscopist views the image through the eyepiece at the instrument head, or alternatively, a video camera can be affixed to the eyepiece to transmit the image to a video monitor. The majority of endoscopes in use today are videoscopic, although in many parts of the world, fiberoptic systems are still the standard. In these videoscopic systems, the visualized image is created from reflections onto a charge coupled device (CCD), which is a chip mounted at the end of the endoscope, rather than via the fiberoptic bundles. The CCD chip has thousands of pixels (light-sensitive points), which directly increase image resolution.<sup>2</sup>

In narrow-band imaging (NBI) endoscopy, filtered light is used to preferentially enhance the mucosal surface, especially the network of superficial capillaries. NBI is often combined with magnification endoscopy. Both adenomas and carcinomas have a rich network of underlying capillaries and enhance on NBI, thereby appearing dark brown against a blue-green mucosal background.<sup>3</sup> The use of white light as well as NBI has enabled endoscopists to provide an immediate assessment of small colonic lesions without histopathologic evaluation.<sup>4</sup> Gastric mucosal abnormalities are also differentiated by NBI with and without magnification endoscopy.<sup>5</sup> NBI can also differentiate squamous from nonsquamous epithelium to help identify Barrett's esophagus (Figs 5-1 and 5-2).

**FIGURE 5-1** Standard white light versus narrow-band imaging of the distal esophagus in patients with Barrett esophagus.

**FIGURE 5-2** Differentiation of the squamous and columnar mucosa is easily seen in the narrow-band image.

## **Endoscope Anatomy**

Flexible endoscopes are being created in a wide variety of lengths and diameters, with an assortment of channel numbers and sizes, adjunct imaging modalities, and intrinsic and extrinsic scope mechanics for reducing scope

looping and providing improved scope advancement.

Uniformly, the knobs for controlling manipulation of the scope tip are located on the right side of the headpiece, with an internal larger knob for upward and downward deflections and an external smaller knob that manipulates the tip to the left and right. Locks accompany each knob to hold the deflection in position when needed. The ability for greater degree of deflection of the endoscope occurs with upward rather than downward manipulations. There is no variability in deflection provided by the right-left knob. In addition to manipulation of the deflecting knobs, significant scope rotation can be achieved by torquing the endoscope, altering the endoscopist's stance, or rotating the headpiece while inserting or withdrawing the shaft of the endoscope.

There are 2 buttons on the front of the scope headpiece responsible for tip cleaning, air insufflation, and suction. The suction channel also functions as the biopsy channel so that any endoscopic tools placed into the biopsy channel will limit the ability to suction fluids through the endoscope. A small button on the front of the handpiece above the suction button allows for freezing of the image and digital recording by pressing the image capture button on the back of the handpiece. The endoscope is held in the left hand regardless of the individual physician's hand dominance. The internal up and downward deflection knob is controlled by the left thumb, while the air, water, and suction are controlled by the left index and middle fingers. The smaller left-right knob is usually manipulated by the right hand.

One of the challenges in modern endoscopy, especially colonoscopy, is the formation of undesired loops in the shaft of a flexible scope. Loop formation impedes expeditious and safe passage to the cecum by transmitting the force of insertion to the colon wall or mesentery rather than to forward progression. One technical advance that aims to prevent loop formation is a variable stiffness endoscope.

## **Variable Stiffness Endoscopes**

Conventional colonoscopes have a static level of column strength throughout the length of the insertion tube. The column strength determines the amount of buckling of the instrument that occurs during insertion and the level of elasticity that remains during reduction of loops. Variable stiffness endoscopes permit alteration of the column strength through an adjustable

tensioning coil (Fig. 5-3). The data from studies comparing variable stiffness colonoscopes to conventional scopes are inconclusive. Some studies report faster cecal intubation using variable stiffness endoscopes with less need for adjunct maneuvers, while other similar studies report no significant differences.<sup>6,7</sup>

**FIGURE 5-3** The variable stiffness control is seen at the base of the head piece of the colonoscope.

## **Endoscopic Education**

Recent mandates from the American Board of Surgery now require surgical residents to graduate with an increased number of flexible endoscopy cases (50 colonoscopies, 35 esophagogastroduodenoscopies [EGDs]). To provide this experience and to improve the overall endoscopic education of surgery

residents, a comprehensive curriculum was needed.<sup>8</sup> An iteration of such a curriculum might include periodic simulation training for first-year residents, formal endoscopy rotations for junior residents, and intraoperative and advanced endoscopy for senior and chief residents.<sup>9</sup>

This is now coming into effect as the Flexible Endoscopy Curriculum (FEC). This curriculum will apply to all residents completing their general surgery residency in 2018 or later. This curriculum has 5 levels that are completed as the resident progresses through the 5 clinical years of surgical residency.<sup>10</sup> To complete level 5, residents have to complete and pass the **Fundamentals of Endoscopic Surgery™ (FES)** program offered by SAGES. It is similar to the Fundamentals of Laparoscopic Surgery (FLS) that is currently required for all residents.

Efforts to improve endoscopic training have led to the development of computer simulators for teaching endoscopic skills. Currently, simulators are available for training in flexible sigmoidoscopy, gastroscopy, endoscopic retrograde cholangiopancreatography (ERCP), endoscopic ultrasound (EUS), and colonoscopy.<sup>11</sup>

## **PATIENT ASSESSMENT, SEDATION, AND MONITORING**

### **Patient Assessment**

Although both upper and lower endoscopy can be performed unsedated, the majority of patients undergoing endoscopic procedures receive agents to provide conscious sedation. Preprocedural patient risk assessment, intra-procedural cardiopulmonary monitoring, and postprocedural recovery are vital to the performance of safe and effective endoscopic interventions. Preprocedural evaluation for American Society of Anesthesiology (ASA) risk classification and Mallampati score have become standard guidelines for most endoscopy units.<sup>12</sup> Elderly patients or those with preexisting cardiopulmonary conditions are at increased risk for these complications, as are those undergoing more extensive endoscopic interventions. Patients with diseases associated with the oropharynx or trachea and those with morbid obesity, sleep apnea, or neuromuscular degenerative diseases require extra

vigilance during endoscopic procedures.<sup>13</sup>

As bariatric surgery is being increasingly performed, so is endoscopy in those patients by surgeons. This is both for preoperative assessment and subsequently for abnormal symptoms or complications. The challenges in morbidly obese patients include a more difficult airway, sleep apnea, possible pulmonary hypertension, difficulty in bag-mask ventilation and rescue techniques, and difficulty in monitoring.

## Monitoring

Monitoring should be performed before, during, and after the procedure by a dedicated endoscopy assistant. Signs that are routinely monitored include the patient's level of consciousness, degree of pain, vital signs, and respiratory status.<sup>14</sup> Supplemental nasal oxygen is required to decrease the frequency of desaturation during endoscopic procedures. The patient's oxygenation status and cardiac electrical activity are also monitored by equipment throughout the procedure. It must be understood that pulse oximetry levels can rule out hypoxia, but hypoventilation and resultant hypercarbia can still go undetected. The ASA does recommend capnography if there is a positive screen for sleep apnea. In addition, external suction for clearing oropharyngeal secretions must be immediately available and within reach of the endoscopic assistant.

## Sedation

Sedation is a drug-induced state of depressed consciousness. It provides relief of discomfort and anxiety and allows the endoscopist to focus on the procedure. It is important to become familiar with stages of sedation ([Table 5-1](#)) if one is going to be involved in administering it.<sup>15</sup>

**TABLE 5-1: FOUR STAGES OF SEDATION**

	Responsiveness	Airway	Spontaneous Ventilation	Cardiovascular Function
Minimal sedation	Normal response to verbal stimulation	Unaffected	Unaffected	Unaffected
Moderate sedation	Purposeful response to verbal or tactile stimulation	No intervention required	Adequate	Usually maintained
Deep sedation	Purposeful response after repeated or painful stimulation	Intervention may be required	May be inadequate	Usually maintained
General anesthesia	Unarousable even with painful stimuli	Intervention often required	Frequently inadequate	May be impaired

Data from Gross JB, Bailey PL, Connis RT, et al. Practice guidelines for sedation and analgesia by nonanesthesiologists, *Anesthesiology* 2002 Apr;96(4):1004-1017.

Moderate sedation, formerly known as conscious sedation, is the most frequent stage for routine endoscopy. For more complex interventional procedures, deep sedation may be needed with an anesthesia provider managing the sedation because the airway may be compromised. It is easy to progress from moderate to deep sedation, and the team must be prepared for that.

The combination of narcotics (analgesia) and benzodiazepines (sedation and amnesia) is commonly used to provide sedation during endoscopic procedures.<sup>16</sup> Although propofol has a more rapid onset and shorter half-life, its routine use during endoscopic procedures has been widely reserved for those performed in an operating room with an anesthesiologist.<sup>15,17,18</sup> Reversal agents (antagonists) for both class of drugs are now available and should be immediately ready for delivery in patients who show signs of oversedation. Titration of medications delivered in small increments allows for the safe performance of sedated endoscopy, especially in older patients with slower circulatory distribution.

Cardiopulmonary issues are the most commonly reported complications with endoscopic procedures. These complications include aspiration, oversedation, hypotension, hypoventilation, arrhythmia, bradycardia (vasovagal), and airway obstruction. Many of the latter are associated with use of intravenous moderate (formerly “conscious”) sedation, defined as decreased consciousness associated with preservation of protective reflexes. [Table 5-2](#) shows risk factors for adverse events. It is especially important to note that many obese patients and other with sleep apnea may not be able to have appropriate bag-mask ventilation without an oral or nasal airway in place. A long nasal trumpet is especially useful in obese patients even without bag-mask ventilation. It may be best to involve anesthesia providers if the clinical risk factors in [Table 5-2](#) below are present.

**TABLE 5-2: POSSIBLE CLINICAL RISK FACTORS FOR GASTROENTEROLOGIST-ADMINISTERED ENDOSCOPIC SEDATION IN OBESE PATIENTS**

- American Society of Anesthesiologists Physiologic Classification of IV or V
- Sleep apnea requiring CPAP
- Previous problems with procedural sedation or anesthesia
- The use of sedatives and analgesics
- Procedures that will require deep sedation (at a minimum), such as ERCP or EUS
- Problematic or altered oropharyngeal anatomy
  - Mallampati grade III or IV
  - Dysmorphic facial features
  - Neck mass
  - Tracheal deviation
  - Micro- or retrognathia
  - Trismus
  - <3 cm mouth opening

## UPPER GASTROINTESTINAL ENDOSCOPY

### Indications

The indications for upper gastrointestinal (UGI) endoscopy (EGD) can be divided between those for diagnosis and those to provide for potential therapy. Diagnostic EGD is used for the evaluation or surveillance of patients who present with “alarm symptoms” (Table 5-3) as do those with abnormal or inconclusive radiographic studies. Follow-up evaluations for ulcers or surveillance for patients with Barrett esophagus are also indications. Therapeutic upper endoscopic interventions include the management of bleeding, removal or ablation of premalignant or malignant lesions, management of UGI obstructions, leaks or fistulae, and the creation of enteral access for supplemental feeding or decompression. EGD indications also now

include treatment of disorders such as achalasia and gastroparesis through intramural surgery and interventions for GE reflux disease (GERD). Endoscopic bariatric therapies are increasingly being adopted as well.

**TABLE 5-3: INDICATIONS FOR EGD (“ALARM” SYMPTOMS)**

1. Abdominal complaints not responsive to appropriate empiric therapy
  2. Weight loss
  3. Early satiety
  4. Odynophagia
  5. Dysphagia
  6. Persistent nausea and vomiting
  7. Hematemesis/melena
  8. Foreign body impaction
  9. Iron deficiency or unexplained chronic anemia
- 

## **Contraindications**

The contraindications to EGD are related to the patient’s associated comorbidities, underlying gastrointestinal disorders, or the patient’s inability to tolerate conscious sedation. Recent myocardial infarction, pneumonia, and recent foregut surgical procedure are relative contraindications for EGD, and the risks and benefits need to be weighed on an independent basis for each patient to determine appropriateness. A recent surgical anastomosis is most likely safe at any time during the postoperative period to be evaluated endoscopically, remembering that tissue strength will be weakest on postoperative days 5 to 7.

Coagulopathy secondary to thrombocytopenia, liver failure, renal failure, and exogenous use of anticoagulants and platelet-inhibiting agents are relative contraindications for a diagnostic EGD but absolute contraindications for a therapeutic intervention. Patient noncooperation and inability for a patient to be safely sedated due to high cardiopulmonary risk are also contraindications to EGD. Respiratory depression secondary to medications and inability to maintain an airway can occur in these high-risk patients. Preassessment with ASA classification and Mallampati scores will help

predict this high-risk group. Patients with suspected perforation or caustic ingestion injury should not undergo EGD unless there are plans to provide palliative therapy such as endoscopic closure or stent placement.

## **Patient Preparation**

UGI endoscopy requires very little preparation other than fasting of solid food for 6 to 8 hours and liquids for 2 to 4 hours. Removable dentures and dental implants must be taken out to avoid dislodgement and aspiration during the procedure. The role of lavage in patients with bleeding is debatable, and if large-volume lavage is to be used, care must be taken to avoid aspiration, including the judicious use of endotracheal intubation. If intervention is anticipated, a recent coagulation profile and platelet count should be within safe ranges. The use of topical pharyngeal anesthetic spray is necessary in unsedated procedures in order to suppress the gag reflex and is used based on physician preference for sedated cases.

The use of prophylactic antibiotics is rarely indicated for EGD, except in the scenario of esophageal sclerotherapy, dilation, and percutaneous endoscopic gastrostomy (PEG) tube placement. Discussion with the cardiologist as to the role of antibiotics is recommended for patients with prosthetic heart valves, previous endocarditis, systemic pulmonary shunts, or recent vascular prostheses.

## **Basic Endoscopic Techniques for EGD**

The forward-viewing endoscope is preferred for routine diagnostic endoscopy. It should be noted that the medial duodenal wall, at the site of the ampulla, is preferentially seen with a side-viewing endoscope. More recently, the use of small-diameter, 5-mm transnasal endoscopes has allowed for the safe performance of unsedated endoscopy.

After appropriate preprocedural patient assessment and informed consent, the patient is routinely placed in a left side down lateral decubitus position. Patients undergoing PEG procedure or other therapies requiring access to the abdominal wall are left supine. Prior to delivery of sedation, a baseline set of vitals is taken, and it is confirmed that the equipment is in proper working order and that potentially necessary endoscopic tools are readily available.

Following the slow delivery of medications, titrating the doses as needed based on the individual patient needs, the distal several centimeters of the endoscope are lubricated avoiding the actual tip of the endoscope because this will obscure the image and, even with irrigation, will make visualization difficult.

Intubation of the esophagus is best accomplished under direct vision by advancing the endoscope over the tongue, past the uvula and epiglottis, and then posterior to the arytenoid cartilages. This maneuver will impact the endoscope tip at the cricopharyngeal sphincter and allow entry into the cervical esophagus with gentle forward pressure once the patient swallows. Blind insertion with the endoscopist's hand in the patient's pharynx is not recommended, as this is more dangerous for both the patient and the endoscopist. However, when intraoperative endoscopy is being done in an intubated and paralyzed patient, giving the endoscope a slight bend at the tip conforming to the shape of the pharynx and pushing forward gently while giving a jaw thrust can be helpful at times but has to be done carefully and without much resistance.

Once in the cervical esophagus, the instrument is advanced under direct vision, taking care to survey the mucosa during both insertion and withdrawal. The distance to the squamocolumnar junction (SCJ), the "Z-line," where the white squamous esophageal mucosa meets the red columnar gastric epithelium, is recorded in the procedure report. The site of the diaphragmatic crura (hiatus) should also be recorded and is seen as impression into the esophageal or gastric lumen. This point can be accentuated by asking the patient to sniff while the area is visualized. The endoscope is then advanced into the gastric lumen under direct visualization. Unlike colonoscopy where there is a requirement for significant torquing or twisting of the scope, due to fixation of the esophagus in the mediastinum, EGD manipulations can be more directly achieved with deflection of the wheels and movement of the handpiece ("dancing with the scope").

After aspirating any gastric contents, the 4 gastric walls are surveyed using combinations of tip deflection and shaft rotation, insertion, or withdrawal. During upper endoscopy, the endoscope will naturally follow the greater curvature as it advances toward the antrum, and this is called the "long position." This affords an end-on view of the pylorus, which is approached directly. Passage through the pylorus can usually be facilitated by gentle pressure and air insufflation. Entry into the duodenal bulb is recognized by

the typical granular, pale mucosa without the folds of the valvulae connivente. Finally, the second portion of the duodenum is entered with the associated folds, by deflecting the tip up and to the right. In addition, rotating the handpiece to the right will help facilitate this maneuver. Withdrawal of the endoscope at this point while keeping the tip deflected leads to paradoxical advancement of the endoscope down the duodenum. Withdrawal of the endoscope places the shaft along the lesser curvature of the stomach and allows for this paradoxical forward advancement of the tip. This is referred to as the “short position.” All areas should be carefully surveyed again as the endoscope is withdrawn.

The final component of a diagnostic EGD is evaluation of the cardia, fundus, and incisura along the lesser curvature. With a forward-viewing endoscope, these sites are visualized by a retroflexion maneuver with full upward tip deflection (Figs 5-4 and 5-5).

**FIGURE 5-4** Retroflex view in the stomach, here revealing a large type III paraesophageal hernia.

**FIGURE 5-5** In another retroflex view, an intact surgical fundoplication is seen.

## Techniques of Endoscopic Tissue Sampling

Sampling of tissue is most frequently obtained by passage of a spiked forceps via the endoscope's biopsy channel. Multiple biopsies should usually be obtained. For ulcers, one should biopsy the edge of the lesion in at least 4 quadrants. Standard biopsy techniques are quite superficial; however, if deeper biopsies are desired, these can be obtained by using either a jumbo forceps or the practice of repetitive biopsies at the same site, which will lead to a deeper sampling.

Surveillance in diseases such as ulcerative colitis and Barrett esophagus requires a standardized sampling technique. Ulcerative colitis protocols recommend biopsies every 10 cm throughout the entire colon, and Barrett sampling per the Seattle protocol requires at minimum 4-quadrant biopsies every 1 cm using a jumbo forceps. The goal of these sampling techniques is to identify the presence of dysplastic tissue necessitating further intervention.

Tissue and lesions can also be sampled by the use of brush cytology. In this technique, a sleeved brush is passed through the biopsy channel of the scope and rubbed forcefully over the desired site. The brush head is extended, stirred in a fixative solution to be spun down for cell evaluation, and then transected and dropped into fixative for direct cytologic analysis. The sensitivity and specificity of this technique are dependent on direct approximation to the diseased mucosa and should not replace a directed biopsy if attainable.

## **THERAPEUTIC ENDOSCOPIC INTERVENTIONS**

### **Management of Bleeding**

Endoscopy plays a critical role in evaluation and treatment of UGI bleeding. The degree of rapidity of UGI bleeding varies from severe with gross hematemesis to mild, presenting as either heme-positive stools or iron deficiency anemia. The timing for EGD should be based on each individual clinical scenario, understanding that endoscopy is both a diagnostic and a therapeutic tool. In all patients, hemodynamic stabilization and correction of any sources for ongoing coagulopathy are a priority.

Endoscopic hemostatic therapies can be divided into thermal and nonthermal categories. In addition, these hemostatic options can be further delineated based on specific ideal applications. There are associated risks with each of these techniques, which must be understood to allow for appropriate tool selection. It is also possible to treat bleeding with combined modalities such as coagulation and injection or clipping and injection. When comparing individual therapeutic techniques, there is very little difference between them in terms of providing successful hemostasis. In fact, numerous studies demonstrate the superiority of combined over single hemostatic therapy. Given the relatively high success rates of controlling UGI bleeding by endoscopic modalities, it is appropriate to pursue endoscopic means whenever available before seeking surgical or interventional radiology options.<sup>19</sup>

## THERMAL TECHNIQUES

Thermal therapies control hemorrhage by inducing tissue coagulation, collagen contraction, and vessel shrinkage. Thermal energy is delivered via a contact or a noncontact device. Thermal therapies are successful in 80% to 95% of cases, with a rebleed rate of 10% to 20%. These techniques are easy to use and safe, with a perforation rate of 0.5%, although this is dependent on the site of the gastrointestinal tract, with the cecum more likely to result in perforation than a thicker organ such as the stomach.<sup>20</sup>

**Contact Thermal Techniques.** Contact or coaptive techniques involve the use of probes passed via the biopsy channel, which allow for pressure tamponade of the bleeding point with simultaneous application of thermal energy for coagulation. The firmer one applies the device to the tissue, the greater is the depth of energy penetration. In addition, the tamponade not only improves visualization but also reduces the “heat sink” effect of active bleeding, and thereby improves the efficiency of the coagulation process. Multipolar (bipolar) cautery (Fig. 5-6) and heater probe devices are used most commonly, although monopolar cautery via a biopsy forceps or snare may also be employed, albeit with a potentially higher risk of injury. The heat generated, which can reach several thousand degrees, is sufficient to cause full-thickness tissue damage, so care is required when using this modality.

**FIGURE 5-6** The bipolar endoscopic cautery device.

Both cautery and heater probe units allow pulse irrigation to be performed for visualization and clot clearance via foot pedal control. Variables important in achieving hemostasis include probe size, force of application, power setting, and duration of energy delivery.<sup>20,21</sup> Vessels of up to 2 mm in diameter appear to be able to be well controlled by these techniques, although the overall surface area treated by these devices is limited by the size of the probes.

**Noncontact Thermal Techniques.** Argon plasma coagulation (APC) is a technique in which thermal energy is applied to tissue via ionized argon gas. This technique has the disadvantage of not allowing a tamponade effect, but conversely is not prone to adherence of the probe to the hemostatic

coagulum. The gas has an effect of clearing luminal liquid from the point of application; however, due to the high pressure of gas delivery, one must be careful to avoid overdilatation of the lumen by using frequent suctioning during APC usage. It is more widely used in most centers than laser and, in limited studies, appears to have similar efficacy to contact probes.<sup>21</sup>

APC is particularly well-suited for settings where large mucosal areas require treatment such as gastric antral vascular ectasia (GAVE) (Fig. 5-7), or where the risk of deeper thermal injury leading to perforation is of heightened concern, for example, cecal angiodysplasia.

**FIGURE 5-7** Endoscopic image of gastric antral vascular ectasia (GAVE) representing a diffuse disease best treated with argon plasma coagulation.

## **NONTHERMAL TECHNIQUES**

**Injection Sclerotherapy.** Injection therapy is performed by passage of a catheter system through the biopsy channel of the endoscope. There is an internal 5-mm needle that can be advanced and withdrawn as needed. The sclerosant is injected submucosally. Injection therapy at 3 or 4 sites surrounding a bleeding site prior to contact thermal techniques may prove more effective, as the created eschar is occasionally removed inadvertently affixed to the treating probe. If tamponade is provided first with injection therapy, bleeding following initial thermal therapies can be reduced. The amount injected varies with different agents, and it must be remembered that systemic absorption will occur. Dilute 1:10,000 epinephrine solution is the most commonly used agent and should be limited to less than 10 mL total volume. Other agents available include absolute alcohol, thrombin in normal saline, sodium tetradecyl sulfate, and polidocanol.<sup>19,20</sup> For esophageal varices, injections are begun just above the GE junction. Sclerosants can be injected either directly into the varix or along side it, intravariceal or paravariceal. Variceal banding with endoscopic band ligators, although associated with a slightly higher rate of rebleeding, has predominantly supplanted injection sclerotherapy due to lower complication rates. In the absence of active bleeding or stigmata of bleeding, prophylactic endoscopic variceal eradication should not be performed because of the high risks of complications associated with the procedures. In patients with severe variceal bleeding or recurrent bleeding following endoscopic therapies, other options such as transjugular intrahepatic portosystemic shunt (TIPS) or surgical portosystemic shunting should be considered (see [Chapter 46](#)).

For gastric varices, injection with cyanoacrylate has been recently shown to be more efficacious than band ligation.<sup>22,23</sup> Many case series report a success rate of 90% or higher in arresting bleeding in gastric varices with injection cyanoacrylate or thrombin. Although most of the data have been from Europe where histoacryl (*N*-butyl-2-cyanoacrylate) is used, similar success has been reported using Dermabond (2-octyl cyanoacrylate) in the United States. Cyanoacrylate therapy appears to be superior to sclerotherapy or band ligation for controlling acute gastric variceal hemorrhage and also at preventing rebleeding.<sup>22,23</sup>

## **Endoscopic Ligation Techniques**

***Endoscopic Band Placement.*** Endoscopic band ligating systems are readily

available, provide an alternative for management of variceal and nonvariceal bleeding, and are routinely used in conjunction with endoscopic mucosal resection (EMR) techniques. This technique is based on the ability to suction tissue into a cap placed at the tip of the endoscope and then, with the turning of a control knob, fire a small tightly constricting rubber band. Single-band devices were initially developed for the treatment of esophageal varices, but there are now numerous multiband ligating systems. This innovation provided an alternative to injection sclerotherapy, and although it proved to be slightly less effective in preventing recurrent bleeding, complications such as stricture formation have been dramatically reduced. Applications for endoscopic banding include treatment of internal hemorrhoids, Dieulafoy ulcers, esophageal and gastric varices, and mucosal neoplasia in conjunction with EMR.<sup>24</sup>

***Endoscopic Suture Placement.*** Pretied endoscopic loops can also be applied through a standard endoscope biopsy channel and can be used for ligation of pedunculated structures before or after endoscopic resection. These single-application devices are similar to laparoscopic endoloops, although they are nylon sutures, and instead of an actual slip knot, a plastic cinching device holds the loop in place once deployed. Use of a double channel endoscope, allowing for a 2-handed technique to grasp the desired tissue and deliver it through the opened loop, is preferred. Similar to clips, these sutures will routinely slough off the tissue in 1 to 2 weeks.

An endoscopic suturing device currently in clinical use is the OverStitch (Apollo Endosurgery). Although used more often for intraluminal closure, it has been used for bleeding control as well. It is loaded onto a double-lumen scope (GIF 2T160, Olympus Corporation, Tokyo, Japan). The principle is similar to the laparoscopic Endo Stitch with a detachable needle tip that carries an absorbable or nonabsorbable suture. There is a tissue helix device that comes through the channel as well for retracting tissue closer to the device for deeper purchase by the suture. It is shown in [Fig. 5-8](#). The sutures can be placed in a short running fashion or individual interrupted sutures without removing the device. Its use in acutely bleeding patients has been very limited due to logistical difficulties of specialized equipment and technical complexity required to use it. It has been used for control of bleeding after endoscopic resections such as EMR or endoscopic submucosal dissection (ESD).<sup>25</sup>

**FIGURE 5-8** OverStitch endoscopic suturing system. (Used with permission from Apollo Endosurgery, Austin, TX).

**Endoscopic Clipping.** Endoscopic clip placement is an effective method to control bleeding and can be used safely at multiple sites throughout the gastrointestinal tract.<sup>26-28</sup> Frequently, more than 1 clip is necessary at the site of bleeding (Fig. 5-9). The depth of tissue obtained by endoscopic clip placement is quite superficial, with only the mucosa routinely being captured. Clips are placed via the biopsy channel of the scope and come with varied application and shape qualities. Rotatable clips as well as clips that can be opened and closed prior to final positioning are available. In addition, clips with both 2 arms and 3 arms, as well as those that have single-use and multiple-use deployment systems, are manufactured. These clips can effectively control bleeding and usually fall off in 1 to 2 weeks. Cases of clips remaining at the site with and without mucosal overgrowth months after placement have been reported.

**FIGURE 5-9** Endoscopic image of multiple clips placed to provide hemostasis.

Over-the-scope clips, as the name implies, go over the scope and are similar to band ligators in initial setup. The Ovesco clip is currently available in the United State and is a nitinol-based bear claw type of clip, as shown in [Figs 5-10 to 5-12](#).

**FIGURE 5-10** (A) Over-the-scope (OTS) clip device. (B) OTS clip preloaded onto a clear cap. (Reproduced with permission from Song LM, Levy MJ: Emerging endoscopic therapies for nonvariceal upper gastrointestinal bleeding, *Gastroenterol Clin North Am* 2014 Dec;43(4):721-737.)

**FIGURE 5-11** OTS clips with 3 types of teeth. (Reproduced with permission from Song LM, Levy MJ: Emerging endoscopic therapies for nonvariceal upper gastrointestinal bleeding, *Gastroenterol Clin North Am* 2014 Dec;43(4):721-737.)

**FIGURE 5-12** Tripronged anchor device. (Reproduced with permission from Song LM, Levy MJ: Emerging endoscopic therapies for nonvariceal upper gastrointestinal bleeding, *Gastroenterol Clin North Am* 2014 Dec;43(4):721-737.)

The clips come in 3 sizes and can go on a therapeutic or diagnostic scope. Clip deployment is similar to band ligation with a string wire attached to a deployment wheel. The target lesion can be suctioned in the cap, or if it is indurated and scarred tissue, it can be engaged in a tripronged anchoring device to bring the tissue in for clipping.

Reports of its clinical efficacy have been limited to small case series, but they are encouraging, with an overall success rate of 71% to 100% for bleeding lesions.<sup>25</sup> The clip has been used both as a primary modality and for rescue.

## **Endoscopic Mucosal Resection**

The treatment of premalignant and superficial cancers can now be managed

by endoscopic resective techniques. EMR has been employed for adenomas, dysplastic lesions, and early-stage carcinomas, including lateral spreading tumors.<sup>29</sup> Carcinomas without submucosal invasion or nodal spread might be amenable to EMR. Although these diseases are less commonly seen in Western societies, the use of these techniques is routine throughout Asian populations for treatment of esophageal and gastric lesions. Conversely, colonic lesions in Western countries are routinely managed with these modalities. Computed tomography (CT) scan and EUS are recommended to assess for nodal disease prior to EMR. Multiple technical variations of EMR for the upper and lower tract have been developed, including submucosal injection, “suck-and-cut,” “suck-and-ligate,” and strip biopsy.

## **SALINE LIFT EMR**

The most commonly performed EMR technique employs submucosal injection of a fluid followed by electrosurgical polypectomy. Initially the margins of the lesion are clearly delineated, and the periphery is marked using a short burst of electrocautery. A standard sclerotherapy needle is then used to perform a submucosal injection. The most commonly used fluid is saline with or without epinephrine, although hyaluronic acid, glycerol, and dextrose have all been described. A bleb is created with the submucosal injection creating space between the line of resection and the muscularis propria of the organ, and the lesion is resected (Figs 5-13 to 5-15). Repeat injection of agent is commonly needed due to absorption as well as diffusion of the fluid. Injection beyond the lesion first allows for better imaging of the tissues. Intralesional injection can also be used prior to resection. One caveat to this technique is that if the submucosal injection does not result in elevation, one must consider that this mass is an invasive lesion and should not be resected endoscopically. Multiple biopsies as well as EUS should be performed.

**FIGURE 5-13** Sessile colon polyp prior to saline lift EMR polypectomy.

**FIGURE 5-14** Sessile colon polyp following saline submucosal injection.

**FIGURE 5-15** Saline lift EMR polypectomy of sessile colon polyp. Resected polyp is seen in the distance and the polypectomy site in the foreground.

### **“SUCK-AND-CUT” EMR**

The “suck-and-cut” technique uses a specially designed cap attached to the tip of the endoscope. A submucosal injection may be created a priori, and the lesion is sucked into the cap. A snare affixed to the cap is used to encircle the lesion, which is then resected by application of electrocautery. Similar to any thermal technique, risk of perforation exists. In addition, the depth of tissue acquisition is not well controlled, and care should be taken to avoid inadvertent perforation, especially in thinner walled organs such as the cecum.

### **“SUCK-AND-LIGATE” EMR**

The “suck-and-ligate” technique transforms a sessile or nodular lesion into an artificial pedunculated polyp, which can then be resected with standard

polypectomy techniques. A band ligating device is attached to the tip of the endoscope, and the tissue is sucked into the cap and a band is placed at the base of the lesion. This is done with or without saline lift injections prior to banding. This serves to separate the mucosal lesion from the submucosa, permitting safe resection using a standard polypectomy snare.

The most frequent complications of EMR are bleeding and perforation. Immediate bleeding can be controlled with endoscopically placed clips or injection of dilute epinephrine. Electrocautery should be used judiciously after EMR because the thin submucosa and serosa are susceptible to full-thickness injury with cautery. Delayed bleeding often requires repeat endoscopy with injection therapy or clip application, although angiography and embolization may be an alternative. Perforations can also be managed endoscopically with endoscopic clips as well as temporary enteral stent placement to cover the site of perforation.

## **ENDOSCOPIC SUBMUCOSAL DISSECTION**

An extension of EMR that has been recently reported for endoscopic resection of more extensive lesions is ESD. Using a combination of needle cautery and blunt endoscope cap dissection, large segments of tissue can be resected. Two-handed techniques using a double-channel scope is vital. Circumferential segments of tissue can be removed, although these are lengthy and very challenging procedures. The advantage of ESD is that it represents a more classic oncologic maneuver, as compared to the piecemeal resection that occurs with other EMR techniques, in that margins as well as lesion depth can be more accurately pathologically evaluated. Complications are higher than for the other EMR techniques, including bleeding, perforation, and stricture formation, which can occur in almost 20% of cases.<sup>29</sup>

## **ENDOSCOPIC MUCOSAL ABLATION**

Endoluminal therapies for ablation of mucosal-based diseases such as Barrett esophagus have recently seen great advances. Previously, photodynamic therapy (PDT) was the principal technique used, but the associated complications and the side effects related to the delivery of the sensitizing agent were high. Endoscopic radiofrequency ablation (RFA) has largely

replaced it and gained acceptance for treatment of intestinal metaplasia as seen in Barrett esophagus.<sup>30</sup> Its unique design incorporates bipolar radiofrequency energy and applies it directly to the esophageal epithelium for ablation. A balloon-based system, as well as a directed planar electrode device implementing this technology, has been used in this form of therapy. The balloon-based model has proved to be safe for Barrett's esophagus.<sup>29</sup> The HALO<sup>90</sup> system (BÂRRX Medical, Sunnyvale, CA) is an endoscopic RFA device composed of an ablation electrode that is mounted to the end of a flexible endoscope. The system comes in HALO<sup>360</sup>, HALO<sup>90</sup>, and HALO<sup>60</sup> sizes depending on the degrees of circumference to which it needs to be applied. The HALO<sup>360</sup> applies circumferential energy, and the rest are more focal. The energy is directed uniformly to a depth of around 0.5 mm. This endoscopic RFA technology also delivers a controlled amount of energy to the tissue that is predetermined prior to firing, thereby limiting unintentional transmural and potentially extraluminal injury.

Several studies have proven feasibility and safety for this novel therapy, with very few documented cases of postprocedural stricturing, as had been seen with PDT.<sup>31-33</sup> For Barrett esophagus with low-grade dysplasia, RFA is becoming the therapy of choice to prevent progression to high-grade dysplasia or adenocarcinoma, which can be as high as 9.1% per year.<sup>34</sup> Recent data show RFA to be very effective in eradication of low-grade dysplasia and even intestinal metaplasia. Most studies have reported eradication rates of >90% for low-grade dysplasia and >77% for intestinal metaplasia.<sup>34,35</sup> A recent multicenter study, one of the largest studies yet, demonstrated the effectiveness of RFA in low-grade dysplasia by showing that the estimated cumulative risk of recurrence within 3 years was decreased in the RFA group at 2.9% versus 33% in the surveillance group.<sup>35</sup> The durability of RFA has been shown to be very good as well, with studies showing >98% eradication of dysplasia at 2 years and over 80% to 90% eradication of intestinal metaplasia.<sup>34,35</sup>

For high-grade dysplasia, endoscopic therapy involves EMR of visible or nodular lesions and RFA ablation of any residual Barrett mucosa. It is also been shown to be very effective in high-grade dysplasia. In several recent trials, eradication of dysplasia occurred in 74.4% to 100% of patients and eradication of intestinal metaplasia occurred in 41% to 100% of patients, whereas progression to cancer was seen in only 3% of patients at 12

months.<sup>34</sup>

## Endoscopic Enteral Access

Endoscopic access to the gastrointestinal tract has become one of the most common endoscopic procedures now performed. What had previously required surgical intervention is routinely managed endoscopically. Gastric access (PEG), jejunal access (direct percutaneous endoscopic jejunostomy [PEJ]), or a combination of both (PEG with jejunostomy tube extension [PEG-J]) can be provided. Indications for access include supplemental feeding, decompression, fixation of structures, and access for medications. There are only a few absolute contraindications to endoscopic enteral access including esophageal obstruction and limited life expectancy. Patients with expected survival of less than 4 weeks should not undergo these procedures. Relative contraindications requiring individual patient selection include severe malnutrition, ascites, prior abdominal surgery, prior gastric resection, peritoneal dialysis, coagulopathy, and gastric malignancy.

### PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

PEG is now the preferred method for long-term feeding in patients who are unable to swallow or who require supplemental nutrition or chronic gastric decompression. PEG may be preferable to surgical gastrostomy since it is safe, less expensive, and less invasive. A variety of PEG techniques are available including “pull,” “push,” and “introducer.” “Pull” and “push” techniques require passage of the tube via the oropharynx, and it is proposed that infectious risks and seeding of oropharyngeal cancers might be increased as compared to the “introducer” technique, where the tube is placed percutaneously through the abdominal wall under endoscopic guidance. This theory has yet to be proven in randomized prospective trials.

Prior to any PEG procedure, a single dose of prophylactic cephalosporin (or equivalent) should be given intravenously. The patient is placed in the supine or semi-Fowler position with the head elevated and the arms held with soft restraints, after which the abdomen is prepared and draped using sterile technique. The endoscope is then passed into the stomach, which is distended with air insufflation. It is recommended to perform a brief but complete endoscopic evaluation of the esophagus, stomach, and duodenum to rule out

any coexistent disease that might require treatment or complicate the PEG procedure. The assistant then presses on the abdomen with a single finger and the impact against the anterior gastric wall should be noted. Ideally, this point should be 2 to 3 cm below the costal margin, and the maximal point of impression may be on either side of the abdominal wall or subxyphoid. Light transillumination from within the stomach to the skin surface may aid in identifying a safe landmark. Finally, it is imperative to perform a “safe tract” technique to assure that there is no intervening hollow viscus between the stomach and anterior abdominal wall. After anesthetizing the skin, a syringe with saline or local anesthetic is passed through the abdominal wall at the selected site while aspirating. As soon as air is appreciated in the syringe, the tip of the needle should be simultaneously visualized by the endoscopist in the gastric lumen. If not, an alternative site needs to be selected.

The endoscopist now passes a polypectomy snare through the endoscope channel at the selected intragastric site. A small transverse incision (approximately 7-9 mm) in the skin is created, and the assistant then inserts a 14-gauge intravenous cannula through the incision into the gastric lumen. The snare is then tightened around the cannula, and the inner stylet is removed.

**“Pull” PEG.** In the “pull technique,” a long looped suture is placed through the cannula, after which the snare is released. The suture is then firmly grasped with the polypectomy snare. The endoscope and the tightened snare are removed together, bringing the suture out of the patient’s mouth. The suture is secured to a well-lubricated gastrostomy tube at its tapered external end. The assistant then pulls on the suture until the attached tube exits the abdominal wall. The endoscope is then reinserted and used to view the tube’s inner bolster (Fig. 5-16) as the stomach is loosely seated against the abdominal wall and the tube is properly positioned. This second intubation of the endoscope can be aided by grasping the PEG bumper with the snare passed through the endoscope. With withdrawal of the PEG through the mouth and out the abdominal wall, the endoscope is reintroduced into the esophagus. The snare is opened after esophageal intubation. The external bumper is placed loosely so that there is no tension at the PEG site and the endoscope is then removed.

**FIGURE 5-16** Second intubation is recommended after PEG placement to confirm the position of the internal bumper and to exclude any postprocedural bleeding.

**“Push” PEG.** In the “push technique,” a guide wire rather than a looped suture is inserted through the cannula and pulled out the patient’s mouth. The gastrostomy tube, called a Sachs-Vine tube, has a long tapered tip, which can be pushed over the wire until it exits the abdominal wall. A second endoscopic intubation is recommended similar to the “pull” technique.

**“Introducer” PEG.** In the “introducer technique,” a guide wire is passed through the cannula placed into the stomach under endoscopic guidance. An introducer with a peel-away sheath is then passed over this wire, allowing removal of the wire and introducer. A Foley catheter or other similar gastrostomy tube is then placed through the sheath, its balloon is inflated, and the sheath is removed. The catheter is then secured to the abdominal wall. The placement of T-tags prior to performance of the introducer PEG can help to secure the stomach to the abdominal wall.

**Laparoscopic-Assisted PEG.** In patients with morbid obesity, prior surgery,

or intrathoracic gastric positioning, where safe access cannot be adequately determined by routine endoscopic techniques, simultaneous laparoscopy and endoscopy can be performed to complete the PEG safely. In this way, a long spinal needle can be passed under direct laparoscopic view from the abdominal wall into the gastric lumen and the PEG can be completed as described above.

**Interventional Radiology–Assisted PEG.** In patients with a “hostile” abdomen secondary to malignancy, multiple prior surgeries, or obesity where safe access cannot be endoscopically determined and laparoscopy would be challenging, a percutaneous intragastric pigtail catheter can be placed by interventional radiology under CT or ultrasound guidance. Using a rendezvous technique, a guide wire is advanced through the pigtail during upper endoscopy, and the PEG is completed.

**PEG with Jejunostomy Tube Extension.** In patients who fail to tolerate gastric feedings due to severe GE reflux or gastroparesis, transpyloric feeding can be provided via a jejunostomy tube passed through the existing PEG. There are no prospective randomized trials, however, showing a difference between intragastric and transpyloric feeding, in terms of incidence of aspiration pneumonia. The majority of cases of aspiration pneumonia are related to aspirated oropharyngeal secretions in a patient unable to protect his or her own airway.

PEG-J placement is achieved by passing a jejunal feeding tube through the PEG lumen (a 24-Fr PEG tube accommodates up to a 12.5-Fr J-tube; a standard 20-Fr PEG tube accommodates an 8.5-Fr J-tube). Endoscopically, the jejunal tube is guided into the duodenum under direct vision. A loop suture on the tip of the jejunostomy tube can be grasped by an endoscopic clip, and once in the distal duodenum, the clip is deployed onto the small bowel mucosa to secure the tube in place. These clips routinely fall off in 1 to 2 weeks, but this technique allows for easier removal of the endoscope from the duodenum without simultaneous inadvertent withdrawal of the J-tube at the end of the procedure. If there is no suture loop at the end of the jejunal tube extension, then one can be placed using a suture that easily forms a loop that will maintain its shape such as a polydioxanone (PDS) or prolene suture.

## **DIRECT PERCUTANEOUS ENDOSCOPIC**

## JEJUNOSTOMY TUBE

In patients with confirmed aspiration secondary to GE reflux of intragastric feedings, direct PEJ rather than PEG-J is of benefit. Feedings beyond the ligament of Treitz are associated with a lower incidence of GE-induced aspiration as compared to simple postpyloric feeding.<sup>36</sup> Direct PEJ, however, is associated with increased procedural risks including bleeding, inadvertent viscus injury, and leakage.<sup>37-40</sup> Performance of direct PEJ requires both endoscopic and fluoroscopic guidance. Using a pediatric colonoscope, the proximal jejunum is intubated, and the tip of the endoscope is fluoroscopically visualized. Abdominal wall depression with a hemostat is performed at this site to try to identify a loop of small bowel adjacent to the abdominal wall. Safe tract techniques are then used to access the identified bowel, and a “pull” PEJ is performed with either a 16- or 20-Fr tube. Second intubation with the endoscope to the PEJ site is mandatory to assure intraluminal positioning of the jejunostomy tube bumper. The authors only perform direct PEJs in a limited subset of patients. These include patients with a prior surgical jejunostomy tube that has been removed and who now need repeat access. The site of prior J-tube is usually adherent to the abdominal wall and decreases chance of surrounding viscus injury. Patients with prior esophagectomy with previous J-tubes are usually good candidates. We have also placed them in patients after a Roux-en-Y gastric bypass if they have an antecolic and antegastric Roux limb. In such patients, the Roux limb is anterior and usually up against the abdominal wall proximally 10 to 15 cm past the gastrojejunostomy. Since the small bowel loop at the gastrojejunostomy is fixed, the chance of the jejunal loop twisting around a narrow anchoring point such as a PEJ is less of a concern.

**Foreign Body Extraction.** Foreign bodies are ingested predominantly by 2 groups of patients: children (age 1-5 years) who accidentally swallow an object and adults who are obtunded or inebriated, have a psychiatric disorder, or are prisoners.<sup>41,42</sup> Food impaction may occur in patients who have an underlying benign or malignant esophageal stricture or in patients with esophageal motility disorders.<sup>43</sup> In addition, patients who are edentulous or have poor fitting dental prostheses are at risk for food impaction of poorly chewed meat boluses. Evidence of respiratory compromise or an inability to handle one’s own secretions indicates an immediate need for endoscopic

evaluation and extraction of the object.

When performing endoscopic extraction, protection of the airway is of vital importance. Endotracheal intubation is required in patients who are unable to handle their own secretions. An endoscopic overtube should be considered when there is concern for dropping pieces into the airway such as when removing sharp objects or multiple fragments. In addition, practicing with a similar foreign body prior to an attempted removal will allow for selection of the most appropriate endoscopic tool.

Coins represent the most common object swallowed by children, and if seen to be in the esophagus, they should be removed promptly due to the risk of pressure necrosis and fistula formation.<sup>41</sup> The coin is localized and grasped with a polypectomy snare, net, or rat-tooth or tenaculum forceps. A Foley catheter is not recommended since it does not control the object well during removal and the object could become dislodged into the airway.

In the adult population, meat impaction represents the most common foreign body and should be removed if it remains for longer than 12 hours due to the risk of pressure necrosis.<sup>41</sup> Gentle scope advancement at the level of the obstruction can often assist in passage of the food bolus. Piecemeal removal with baskets, nets, and snares may be needed, with care being taken to avoid passage of the foreign body into the airway. If the bolus should pass, EGD is still indicated to rule out an associated esophageal lesion.<sup>43</sup>

Use of an overtube or protective endoscopic hood may greatly facilitate removal of sharp objects such as toothpicks, fish or chicken bones, needles, and razor blades. When removing sharp objects, it is important to follow the tenet of always having the sharp end trailing. If necessary, sharp objects can be carefully pushed into the stomach, rotated, and then brought out with the pointed end trailing.

Ingested button batteries must be removed immediately to prevent viscus injury secondary to a corrosive burn. These batteries usually pass readily in other parts of the gastrointestinal tract without causing harm, although all mucosal surfaces must be examined endoscopically to identify any resultant injury.

When encountered, cocaine-filled packets should never be removed endoscopically because of the risk of breakage. Close observation and expectant management is more appropriate, with expedient surgical intervention for any signs of bag rupture or bowel obstruction.

Following any foreign body removal, the endoscopist must exclude any associated underlying disease such as stricture, neoplasm, or motility disorder (Fig. 5-17). In addition, one must be aware of the possibility of delayed viscus injury secondary to pressure necrosis resulting in partial- or full-thickness injury. Emergent contrast study or CT should be used as needed to evaluate for these complications. Repeat endoscopy, motility study, or elective contrast studies may also be required based on patient's history or continued symptoms.

**FIGURE 5-17** Classic eosinophilic esophagitis seen in a patient with history of dysphagia and prior food bolus. Endoscopic biopsies with identification of increased eosinophils confirms the diagnosis.

Other nonobstructing foreign bodies may be identified in postsurgical patients. Intraluminal suture migration may lead to symptoms of pain or dysphagia. (Fig. 5-18). Removal with endoscopic scissors may relieve the patient's symptoms of pain or dysphagia.

**FIGURE 5-18** Sutures can be seen at the site of a prior gastrojejunostomy.

**Endoscopic Dilation.** Endoscopic dilation can be performed for any enteral stricture that can be accessed by endoscopic means. The endoscopic component of dilation may include identification, passage of a guide wire, or delivery of a dilating balloon via the endoscope channel. Strictures secondary to ischemia, inflammation, radiation, neoplasm, and postsurgery are all amenable to endoscopic dilation. The use of fluoroscopy as an adjunct to endoscopic dilation is believed to decrease the risk of perforation, although this has not been fully proven in randomized prospective trials.<sup>44</sup> In addition, the type of sedation used depends on the clinical status of each individual patient, as those with tight esophageal strictures may be best served with elective airway protection.

Although several types of dilators have been used, the 2 most common

dilators used are the guide wire–driven type, which applies both axial and radial forces, and the balloon type, which applies only radial forces. Treatment is safer when performed by incremental dilations over successive sessions. A general approach is to limit the number of dilations to 3 successive balloon or dilator sizes in 1 session. Injection of steroid solutions (Kenalog) into the stricture may reduce the severity of postdilation inflammation, scarring, and restructure. The frequency of dilation will depend on the severity of the stricture and the patient’s symptoms.

Balloon dilators are used for short strictures, stenotic stomas, and achalasia. These dilators can be passed over a previously placed guide wire and are delivered through the endoscope’s therapeutic channel. Fluoroscopic guidance for balloon dilation allows the endoscopist to gauge several components of the procedure. First, it assures the positioning of the balloon in the viscus lumen. Second, if contrast is injected in the balloon as the dilating fluid, expansion of the balloon fully can be appreciated. This is termed “waist ablation” and refers to the full dilation of the balloon at the site of the stricture. The balloon changes from an hour glass appearance to a full elliptical-shaped figure.

Long, complex strictures may be less responsive to endoscopic dilation and may also require repeat treatments. Aggressive biopsying of the mucosa after dilation is necessary in cases of unclear etiology. Complications secondary to endoscopic dilation include bleeding, perforation, mucosal tears, and recurrent structuring.

Commonly encountered strictures also include post–bariatric surgery strictures. They can occur after a Roux-en-Y gastric bypass or, less commonly, after a sleeve gastrectomy. The stricture rate after a Roux-en-Y gastric bypass can be 4% to 6%.<sup>45,46</sup>

Early strictures (<90 days postoperatively) respond very well to balloon dilation, with over with over 90% responding to endoscopic intervention. Late strictures have a much higher failure rate and often require surgery.<sup>47</sup> If the scope cannot get through the anastomosis, then it is best to use a wire-guided balloon with fluoroscopic guidance. The internal diameter of even a 25-mm circular stapler is only around 16 mm, so dilation is typically done until 12 to 15 mm if the starting diameter was not very small. Otherwise, a graded approach with initial dilation to 10 mm and then repeating the scope in 1 to 2 weeks and dilating to 15 mm should be done. The overall perforation rate is approximately 2% to 3%, so caution is warranted while

dilating.<sup>46</sup>

Sleeve stenosis is slightly less common and can occur in 1% to 3% of patients.<sup>48</sup> Due to the high volume of sleeves being done currently, sleeve stenosis is going to be encountered more often. These can be harder to treat and do not respond well to standard controlled radial expansion balloon dilations. Endoscopic success rates are higher with dilation using 30-mm achalasia balloons.<sup>49</sup>

**Enteral Stent Placement.** Over the past several years, endoscopic stent technology has made impressive strides in providing tools for increasingly complex clinical scenarios. Both the delivery systems and the stents themselves have gone through significant changes and allowances for treatment of a multitude of benign and malignant disease processes. Strictures, leaks, fistulae, and obstructing neoplasms have all been approached with enteral stents.<sup>50-57</sup>

**Stent Delivery Systems.** Based on the location of the gastrointestinal tract that is to be treated, as well as the characteristics of the stent desired, endoscopic stent deployment is either through-the-scope (TTS) or wire guided. TTS stents are delivered through the endoscope channel and are routinely a 10-Fr system and require a therapeutic scope. Only uncovered self-expanding metal stents (SEMS) have a TTS characteristic. The remainder of stents all use wire-guided systems and are placed under fluoroscopic guidance. Stent delivery systems are further categorized as proximal or distal deploying based on which end of the stent is opened first. In patients undergoing stent placement in the proximal esophagus, proximal deploying stents are preferred. Otherwise, most stent systems use a distal deployment pattern. Non-TTS stents are limited to the esophagus including the esophagogastric junction. In patients following gastric resection, these systems can also traverse a gastrojejunal anastomosis. TTS systems, conversely, can reach any site in the gastrointestinal tract that can be accessed by a therapeutic endoscope.<sup>50</sup>

**Stent Characteristics.** Covered endoscopic stents have been created for the sole purpose of temporarily bridging esophageal and proximal anastomotic leaks and fistulae.<sup>52</sup> The fully covered nature of the stent impedes tissue ingrowth as would occur with an uncovered enteral stent, and thereby allows

removal after 2 to 3 months once the fistula has been cured. With the increased frequency of bariatric procedures, anastomotic complications secondary to Roux-en-Y bypass are routinely managed with placement of endoscopic stents.

Removable stents are subdivided into plastic or hybrid based on the underlying structural platform. As stated earlier, fully covered silicone stents, which are self-expandable but require the use of a large deployment system, can reach as far as the proximal stomach. Similarly, covered SEMS (hybrid) stents are also placed outside of the endoscope under fluoroscopic guidance and can reach the proximal stomach as well. The greatest problem with these stents is the high risk of migration.<sup>52</sup> If placed across a gastrojejunostomy, this can result in small bowel impaction of a migrated stent, resulting in the need for surgical extirpation. Bleeding, perforation, and obstruction are far less common complications. Stent migration has been shown to be significantly reduced in several recent publications with the use of the Apollo OverStitch endoscopic suturing device described earlier in the chapter. It has been reported to decrease migration rates of 30% to 60% down to around 10%.<sup>58,59</sup> Some fully covered stents such as the EndoMAXX (Merit Medical) have antimigration struts to decrease migration rates, but data are still pending on their efficacy. Outside the United States, larger stents, such as the MEGA stent (TaeWoong Medical, South Korea), have been developed that are longer and with a larger diameter, which can be useful to treat leaks such as sleeve gastrectomy leak with possibly less migration.<sup>60,61</sup>

Uncovered enteral stents, using TTS deployment systems, are not intended for removal and can be placed for temporary relief of benign and malignant strictures throughout the gastrointestinal tract.<sup>50,51,53,54</sup> They are associated with increased tissue ingrowth and occlusion as compared to covered stents but have a lower rate of migration. In unresectable disease states, palliation of obstruction with enteral stents can provide an alternative to surgical bypass procedures. In addition, endoscopic stent placement in patients with obstructing colon lesions can allow for immediate decompression followed by semielective resection and primary anastomosis, rather than an initial diverting stoma.<sup>56,57</sup>

## **Endoluminal Treatment of GERD**

Numerous endoluminal treatments for GERD have been introduced over the past 10 to 15 years and have had varied clinical success. These technologies were based on suturing, tissue bolstering, or energy delivery. Unfortunately, due to many factors including marginal patient improvement, limited physician acceptance, severe complications, and corporate financial difficulties, most of these treatments are not presently available in the United States. Examples of each of these modalities include the EndoCinch plication device, the NDO endoscopic plication system, the Gatekeeper reflux repair system, and Enteryx polymer injections. Two endoscopic options that are being used clinically in the United States are the Stretta procedure and transoral incisionless fundoplication (TIF) using the EsophyX device.

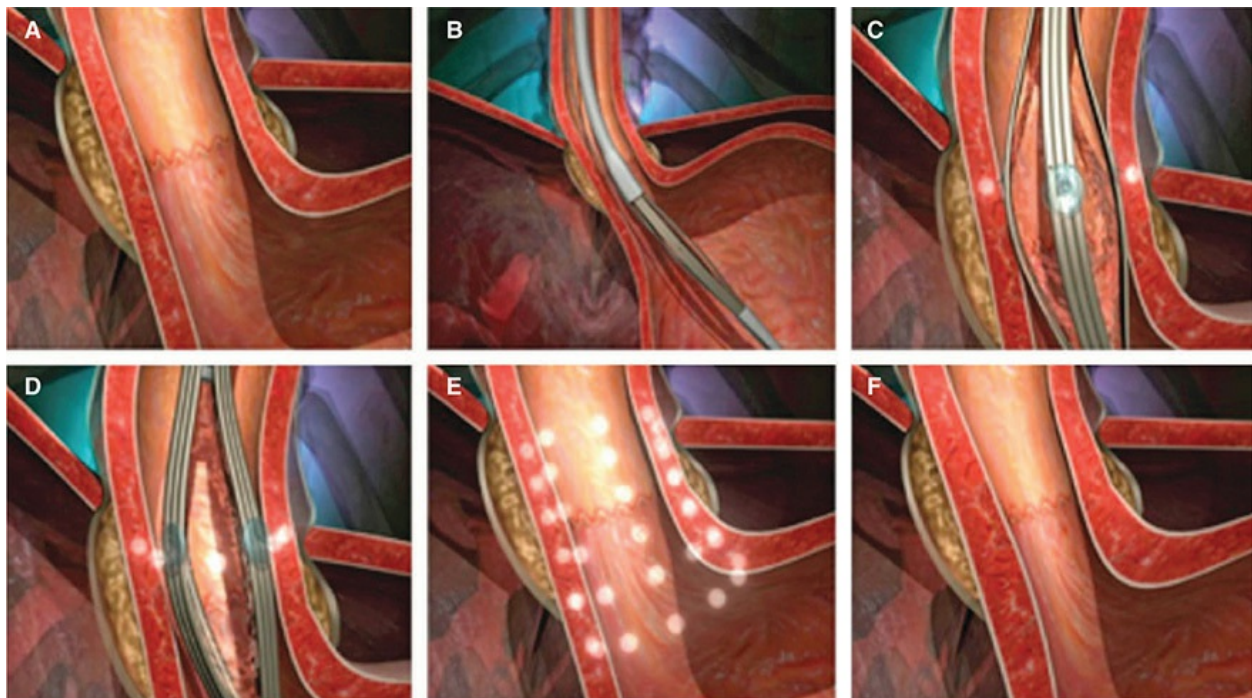

## **STRETTA**

Recent technologic advances have made the next advent in minimally invasive surgery, natural orifice surgery, a reality. Two such advances that are changing foregut surgery are the Stretta and EsophyX procedures. The Stretta (Curon Medical, Sunnyvale, CA) procedure is an endoluminal electrosurgical system that uses thermocouple-controlled radiofrequency energy delivered to smooth muscle in the area around the lower esophageal sphincter (LES) complex via an endoscopic balloon-tipped catheter (Figs 5-19 and 5-20). Introduced originally in an open-label study in 2000 to 2001, Stretta is one of the more widely studied minimally invasive treatment modalities for GERD available.<sup>62</sup> It represents an alternative for patients who are either intolerant to or have an incomplete response to proton pump inhibitor (PPI) therapy or other antisecretory drugs and prefer an alternative to invasive surgery or an anatomic implant. One advantage of this technique is that it has been proven safe and effective for use even in patients who have undergone prior bariatric surgery, including fundoplication, providing an alternative to surgical revision or lifelong PPI therapy but not precluding a patient from future surgical treatment if desired.<sup>63-65</sup> As Yeh and Triadafilopoulos<sup>66</sup> describe, exclusion criteria for Stretta include the following: hiatal hernia  $\geq 2$  cm, active grade III to IV esophagitis, Barrett esophagus (metaplasia or dysplasia), and collagen vascular disease. Delayed gastric emptying is commonly found in patients suffering from GERD, but its existence does not preclude eligibility for performing Stretta. Clinically significant gastroparesis is a rarely reported and typically transient

complication of Stretta, and in fact, the procedure has been shown to normalize gastric emptying in certain patients.<sup>66,67</sup>

**FIGURE 5-19** Patient selection criteria for the Stretta procedure. (Reproduced with permission from ©2018 Restech | Mederi-RF, LLC, Houston, TX).

**FIGURE 5-20** The Stretta procedure. (A) Normal naïve appearance of the gastroesophageal junction. (B) Positioning of balloon-basket assembly catheter at the squamocolumnar junction (SCJ). (C-E) Inflation of balloon

causing radial contact of radiofrequency (RF) electrode delivery sheaths with tissue and subsequent delivery of RF energy ablation circumferentially above and below SCJ and onto gastric cardia. **(F)** Resultant tissue effect of ablation causes enhanced lower esophageal sphincter (LES) muscle mass and pressure, collagen production/contraction, and increased tensile strength with decreased LES compliance, thus decreasing reflux episodes. (Reproduced with permission from ©2018 Restech | Mederi-RF, LLC, Houston, TX.)

The delivery catheter is introduced over a guide wire within a soft, 6-mm shaft as a “balloon-basket assembly” with a maximum inflation diameter of 3 cm and 4 radial electrode delivery sheaths, along with a specialized suction irrigation system.<sup>68</sup> After identifying the SCJ endoscopically, the proximal end of the balloon is placed 1.0 cm above the SCJ where it is then inflated, allowing each of the 5.5-mm curved needle electrodes to enter the surrounding tissue. Radiofrequency energy is delivered over a 90-second period with ongoing tissue temperature monitoring before the balloon is deflated and its associated needle electrodes retract. The catheter is rotated 45 degrees before applying the next series of thermal injuries in similar fashion. Typically this process is repeated approximately 14 to 20 times, extending anatomically from approximately 0.5 cm above to 1.5 cm below the SCJ, followed by additional firings to the gastric cardia.<sup>69,70</sup> The entire procedure can be done under conscious sedation in about 60 minutes. The primary aim of this technique is to decrease LES compliance and limit its transient, untimely relaxations that cause symptoms of GERD. The heat generated induces collagen production and subsequent contraction, effectively increasing LES muscle mass while shrinking other tissues, causing improved tensile strength and limited sphincter compliance.<sup>66,71</sup>

Several early retrospective studies and randomized controlled trials examined the effectiveness of the Stretta procedure up to 12 months after treatment and demonstrated efficacy as measured by a variety of factors, including PPI requirement, GERD health-related quality of life (HRQL) scores, overall patient satisfaction, and endoscopic factors such as esophageal acid exposure, gastritis scoring, and LES pressure.<sup>72-76</sup> Recent long-term efficacy studies confirm the durability of this endoscopic procedure. Three separate studies evaluated patients 48 months after Stretta treatment, and all revealed persistent, significant improvement in patient satisfaction and HRQL scores, and the majority of patients (78%-86.4%) were still off of PPI

therapy.<sup>67,77-80</sup> This is comparable if not superior to reported rates of long-term antacid use after fundoplication (23% PPI use and 41% all antacid use), although this may be deceiving because many patients who take antacids after fundoplication do not have objective evidence of ongoing reflux.<sup>81,82</sup>

A systematic review and meta-analysis published in 2017 showed some mixed results. Twenty-eight studies (4 randomized controlled trials, 23 cohort studies, and 1 registry) with a total of 2468 patients were analyzed. Pooled results showed that although Stretta improved HRQL and standardized heartburn scores, 49% of the patients still required PPIs at follow-up. Endoscopic therapies such as Stretta may represent a growing paradigm shift in the armamentarium of antireflux therapy from traditional invasive surgical procedures. It may also be helpful as a procedure in rescue therapy after other surgical procedures, such as for recurrent symptoms after fundoplication, as well as after certain bariatric procedures. Reflux is increasingly common after a sleeve gastrectomy, and currently, there is a multicenter trial that is under way to investigate its efficacy in such patients.

## **ESOPHYX**

The EsophyX system (Endogastric Solutions) represents an alternative to classic laparoscopic antireflux surgery via endoluminal fundoplication, or TIF. This device attempts to create a nipple valve similar to that created with fundoplication via a series of serosa-to-serosa plications, that effectively wrap the stomach fundus around the cardia. This TIF procedure has evolved clinically over time from a first generation TIF 1.0 gastro-gastric plication at the Z line, to the subsequent TIF 2.0 that creates a longer 3-4cm valve beginning above the Z line and a superior rotational element of 270-310 degree esophago-gastric plication. It is a disposable device that is placed axially atop a standard endoscope introduced orally and advanced to the level of the Z line and beyond.<sup>83</sup> Two separate physicians are typically required to perform the operation—one to control the endoscope and one to control the device. As Testoni and Vailati<sup>84</sup> describe, the EsophyX instrument consists of “a handle with controls, a 18-mm diameter chassis through which control channels run and a standard front view 9-mm diameter endoscope can be inserted; the tissue invaginator, constituted of side holes located on the distal part of the chassis, to which external suction can be applied; the tissue mold, which can be brought into retroflexion and pushes tissue against the shaft of

the device; a helical screw, which is advanced into the tissue and permits to retract the tissue between the tissue mold and the shaft; two stylets, which penetrate through the plicated tissue and the tissue mold, over them polypropylene H-shaped fasteners can be deployed; a cartridge containing 20 fasteners” (Figs 5-21 and 5-22). With the anesthetized patient in the left lateral decubitus position, the endoscope and device are advanced to the level of the stomach under direct visualization. Along with significant bleeding, esophageal perforation has been identified as a potential serious complication, and extra care should be exercised during insertion of the device-endoscope combination. The esophageal invaginator component engages the esophagus at or above the Z line and reduces a (small) hiatal hernia if present with distal device advancement.<sup>83</sup> To effectively reconstruct the GE junction, an omega-shaped valve similar to surgical fundoplication is created by grasping gastric fundal tissue between the main body and tissue mold of the device beginning posteriorly at the greater curve and firing a series of full-thickness polypropylene fasteners across the grasped tissues, forming an abutted serosa-serosa tissue flap.<sup>83</sup> The procedure proceeds anteriorly until a 2- to 6-cm flap and 200- to 310-degree (normally 270 degrees) fundoplication is created.<sup>83,85</sup> The EsophyX device is removed and the repair investigated for quality with the remaining endoscope. The entire procedure takes about 1 hour, with an average of 14 fasteners fired.<sup>85</sup>

Step 1

The EsophyX<sup>®</sup> Device, with the flexible endoscope placed down the center channel of the device, is introduced through the mouth into the esophagus as one unit. The endoscope is retroflexed and device is positioned at the gastroesophageal junction (GEJ) to rebuild the valve.

Step 2

A full thickness tissue fold at the GEJ is retracted, wrapped and secured using SerosaFuse<sup>®</sup> implantable fasteners—equivalent to 3-0 sutures—to create an esophagogastric plication.

Step 3

The valve is extended and approximately 20 fasteners are delivered to form at 270° wrap. The TIF<sup>®</sup> 2.0 procedure reconstructs the primary components of the antireflux barrier, creating a tight 3cm length valve enveloping the distal esophagus below the diaphragm.

**FIGURE 5-21** Schematic representation of the EsophyX procedure. Step 1: The EsophyX device enters the esophagus through the mouth and is positioned at the gastroesophageal junction. Step 2: The device wraps the fundus around the distal esophagus and fastens and tissue fold; this step is then repeated multiple times to reconstruct a robust tight valve. Step 3: Endoscopic appear of the new valve at the end of TIF. (©2018 from EndoGastric

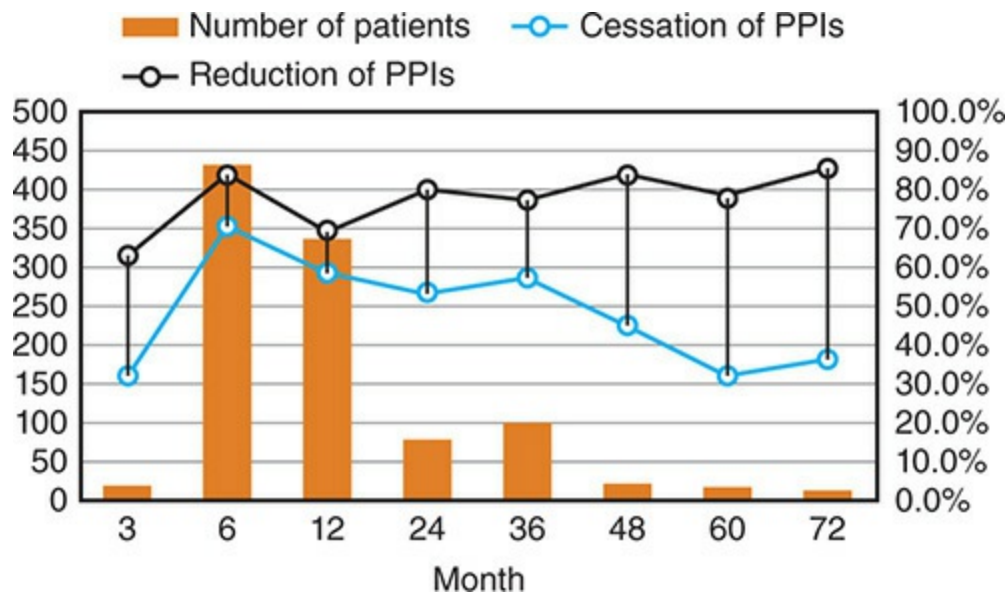

**FIGURE 5-22** The EsophyX system is used for endoluminal fundoplication. (©2018 from EndoGastric Solutions Inc., Redmond, WA.)

All patients should have preoperative endoscopy and esophageal manometry performed, because increased failure rates are witnessed in patients with esophageal dysmotility and hiatal hernias >2.0 cm in length.<sup>84,86</sup> In addition, cases of severe preoperative PPI-refractory disease seem less likely to be successfully treated by EsophyX, and standard surgical repair shows trends of superior long-term, symptom-free recovery.<sup>84,87</sup> Meanwhile, the number of fasteners used is predictive of success, with more fasteners (14-20) connected with decreased failure rates.<sup>86</sup> Although some discrepancy existed among early studies examining the short-term efficacy of EsophyX, a recent systematic review showed an overall patient satisfaction rate of 72%, overall rate of PPI discontinuation of 67%, a 7.2% failure rate, and a 3.2% incidence of major complications at a mean follow-up of 8 months.<sup>86</sup> Other studies evaluating long-term outcomes as long as 3 years postoperatively have shown sustained improvement in GERD HRQL scores but lower rates of persistent PPI discontinuation of approximately 40% (42%-71%); 70% to 75% of patients were either off PPI or their dose was halved, with

approximately 25% (21%-31%) of patients requiring the same dose as preoperatively.<sup>84,86,88,89</sup> Reintervention with laparoscopic fundoplication for patients with TIF failure has demonstrated efficacy but is associated with higher complication rates such as GE perforation and abscess formation.<sup>90,91</sup>

Outcomes at 3 and 5 years have been recently reported from a prospective, randomized controlled trial called TEMPO (TIF EsophyX vs. Medical PPI Open Label). This was an open-label TIF versus PPI trial with cross over at 6 months of the PPI patients to TIF. Primary outcomes evaluated troublesome regurgitation and atypical symptoms at 3 and 5 years postoperatively, while secondary outcomes evaluated included symptom scores such as GERD-HRQL, PPI use, reoperation, and patient health outcomes satisfaction. TIF 2.0 performed quite well, with elimination of troublesome regurgitation in 90% of patients at 3 years, and 86% at 5 years, atypical symptom relief in 88% at 3 years and 80% at 5 years, and 66% of patients were off of PPI therapy (insert prior reference #92 here along with the new reference listed below). Three patients (5%) underwent reoperation, opting for fundoplication. A decrease in the total GERD-HRQL score was seen from 22.2 to 6.8 at 5 years ( $P < .001$ ).<sup>92</sup> A total of 5 randomized controlled trials using TIF were published between 2014 and 2015.<sup>93</sup> A subsequent systematic review and meta-analysis that included 13 prospective observational studies showed reduction in total number of reflux episodes and reduction in acid exposure compared to sham without PPI.<sup>93</sup> PPI usage is shown in Fig. 5-23.

**FIGURE 5-23** Long-term outcomes of PPI use after TIF in prospective

observational studies. (Reproduced with permission from Huang X, Chen S, Zhao H, et al. Efficacy of transoral incisionless fundoplication (TIF) for the treatment of GERD: a systematic review with meta-analysis, *Surg Endosc* 2017 Mar;31(3):1032-1044.)

Although most patients had reduction in PPI usage, cessation of PPIs showed a reduction over time and peaked at approximately 70% at 6 months but decreased to 40% or below for the limited number of patients who had a 5- and 6-year follow-up. Some of the longest outcomes available are for TIF 1.0, which was used in 5 of the 18 studies in this review, whereas 13 studies used the TIF 2.0 with the esophagogastric plication. Taken together, these data appear to support TIF 2.0 with EsophyX as a relatively safe and efficacious procedural alternative to invasive fundoplication, but such outcomes will need to be followed over time.

## **Endoluminal Bariatric Therapies**

The field of endoluminal bariatrics has been rapidly expanding lately. There is increasing recognition that some weight loss interventions need to be available that may have lower efficacy than surgery but have lower costs and lower risk. The spectrum of intervention is shown in [Fig. 5-24](#).<sup>94</sup> Endoscopic bariatric therapies may be less invasive, cheaper, reversible, and repeatable. They may serve as a primary therapy, as a bridge to bariatric or other surgeries, or as a rescue or revisional procedure for prior bariatric surgery. They can consist of restrictive, metabolic, and aspiration therapy.

**FIGURE 5-24** Therapeutic approach to obesity treatment. The effect of endoscopic bariatric treatment for weight loss is greater than that of drugs but lower than that of bariatric surgery, but endoscopic bariatric treatment features fewer complications than bariatric surgery. BPD, biliopancreatic diversion; DS, duodenal switch; RYGB, Roux-en-Y gastric bypass; VBG, vertical band gastroplasty. (Reproduced with permission from Choi SH, Chun HJ. Recent trends in endoscopic bariatric therapies, *Clin Endosc* 2017 Jan;50(1):11-16.)

## INTRAGASTRIC BALLOONS

Three US Food and Drug Administration (FDA)–approved gastric balloons are now available in the United States. These include the Orbera (Apollo Endosurgery), Reshape Duo (Reshape Medical), and Obalon (Obalon Therapeutics). These can be inserted with a catheter-based delivery system that is placed side by side along the endoscope, as in the Orbera or Reshape balloons, shown in [Fig. 5-25](#). The Obalon balloon is initially swallowed in an absorbable capsule that is attached to a microcatheter that is then used to inflate balloon. Retrieval for all the balloons is endoscopic and usually at 6 months, at least in the United States where they are approved to be left in for 6 months.<sup>95</sup>

## GASTROINTESTINAL ENDOSCOPY

The Orbera, previously known as the Bioenterics balloon, has had the largest worldwide experience. Although it has been modified over the years, it has been used in Europe and elsewhere for over 20 years. The weight loss results from these balloons are modest compared to bariatric surgery but are acceptable and are around 25% of excess weight.<sup>94,95</sup>

## ENDOSCOPIC SLEEVE GASTROPLASTY

This is an endoscopic gastric volume reduction most commonly performed now with the Apollo OverStitch device described earlier, although other devices have been used as well (Fig. 5-26). Results are mainly from small case series and are better than intragastric balloons, with excess weight loss in the 30% to 40% range.<sup>95</sup> Because these are supposed to be full-thickness sutures, a few complications, such as abscess and bleeding from splenic injury, have been reported but are rare.<sup>96,97</sup>

**FIGURE 5-26** An illustration of the suturing sequence for the creation of the endoscopic sleeve gastropasty. (Reproduced with permission from Abu Dayyeh BK, Rajan E, Gostout CJ: Endoscopic sleeve gastropasty: a potential endoscopic alternative to surgical sleeve gastrectomy for treatment of obesity, *Gastrointest Endosc* 2013 Sep;78(3):530-535.)

## ASPIRATION THERAPY

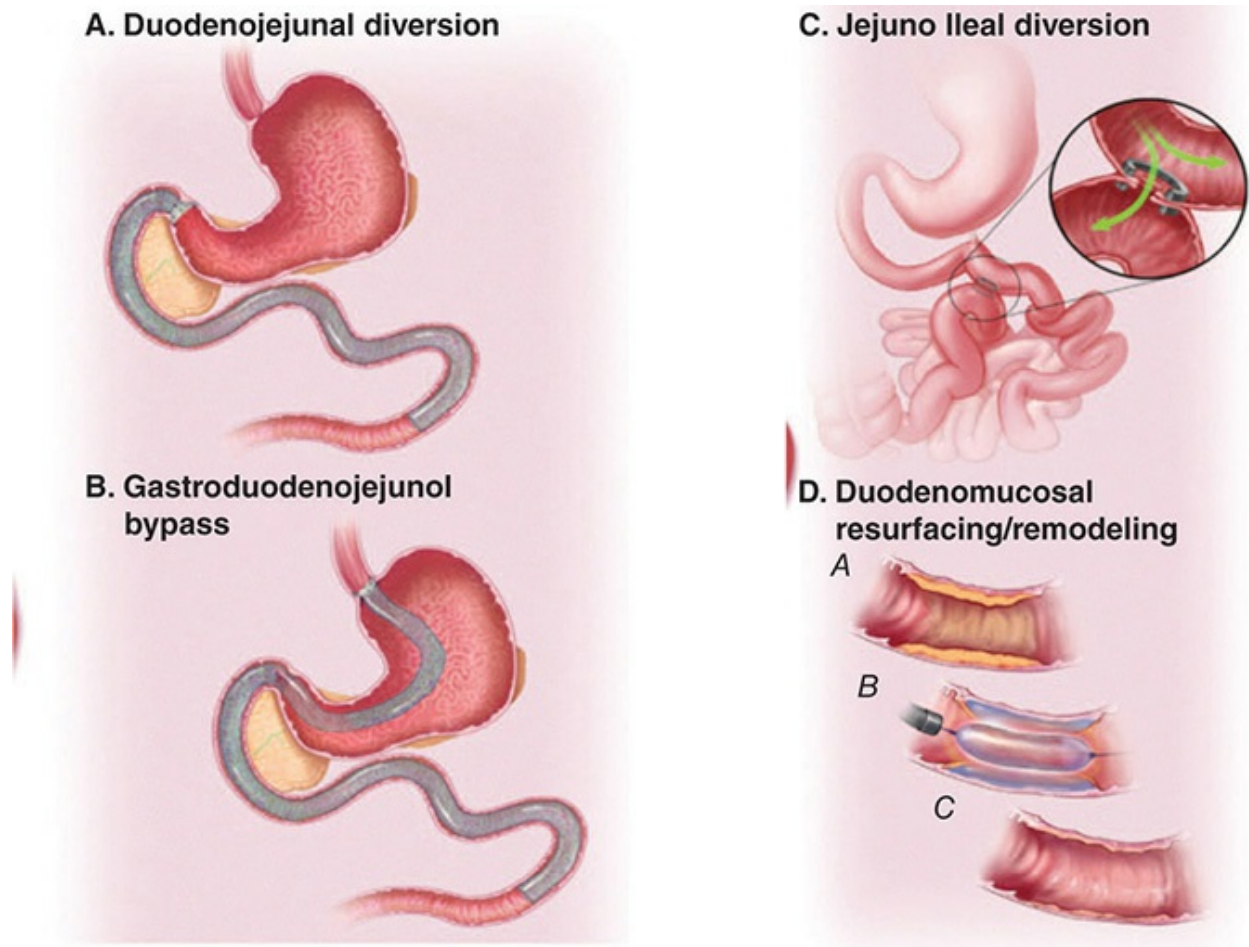

Recently the FDA approved a gastrostomy tube–type device that is a PEG-like silicone tube. It was approved for patients with a body mass index of 35 to 55 kg/m<sup>2</sup> and removes about 30% of ingested food approximately 30 minutes after eating by attaching a small portable suction pump to the tube, as shown in Fig. 5-27. Early weight loss results have been impressive and better than intragastric balloons.<sup>98</sup>

**FIGURE 5-27 (A)** Aspiration therapy (AT) device. **(B)** Aspiration tube (A-tube) in the stomach. (Reproduced with permission from ASGE Bariatric Endoscopy Task Force; ASGE Technology Committee, Abu Dayyeh BK, et al: Endoscopic bariatric therapies, *Gastrointest Endosc* 2015 May;81(5):1073-1086.)

## SMALL BOWEL ENDOSCOPIC BARIATRIC THERAPIES

None of these therapies have been FDA approved as of early 2017, but they are actively being studied (Fig. 5-28).<sup>99</sup> Small bowel endoscopic bariatric therapies include the duodenojejunal (EndoBarrier; GI Dynamics) and the gastroduodenojejunal bypass liners (ValenTx).

**FIGURE 5-28** Endoscopic small bowel therapies. (Reproduced with permission from Abu Dayyeh BK, Edmundowicz S, Thompson CC. Clinical practice update: expert review on endoscopic bariatric therapies, *Gastroenterology*. 2017 Mar;152(4):716-729.)

The EndoBarrier duodenojejunal liner is a 65-cm plastic liner anchored in the duodenal bulb with a nitinol crown like a stent (Fig. 5-29). It is placed with endoscopic and fluoroscopic guidance with a catheter delivery system beside the scope. Excess weight loss was approximately 25%, and a pivotal multicenter randomized controlled trial was under way in the United States but was stopped before completion due to higher than expected hepatic abscess rate. There have been favorable results from of metabolic effects on hemoglobin A1c. The ValenTx gastroduodenojejunal liner is anchored in the distal esophagus and is 120 cm long. There are ongoing efficacy studies under way.

**FIGURE 5-29** The Endobarrier. (Used with permission from GI Dynamics, Inc. Lexington, MA.)

Intestinal bypass procedures are being performed with endoscopic placement of self-assembling magnets that eventually erode through and pass and leave a viable anastomosis to be formed. Endoscopic metabolic therapy is also being administered through a procedure known as duodenal mucosal resurfacing or remodeling. In this endoscopic procedure, a thermal ablation is done of the superficial duodenal mucosa with hot water through a catheter after a saline lift of the mucosa. Its effects may be mostly metabolic with beneficial effects on glucose metabolism.

## ENDOSCOPIC INTRAMURAL SURGERY

There currently are 2 natural orifice transluminal endoscopic surgery procedures that are increasingly being adopted. These are per-oral endoscopic myotomy (POEM) and per-oral pyloromyotomy (POP; also known as G-POEM). Up until the past few years, management of achalasia consisted of botulinum toxin injection, pneumatic balloon dilation, and surgical intervention with Heller myotomy. Dr. Haruhiro Inoue from Japan helped

develop POEM and bring it into widespread clinical use (Fig. 5-30).<sup>100,101</sup> Although initially it was reserved for patients without sigmoid-type achalasia, it is now applicable to all patients with achalasia as a primary procedure or as a rescue after failed prior therapies, including failure after Heller myotomy.<sup>100,101</sup>

**FIGURE 5-30** Steps in per-oral endoscopic myotomy. **(A)** Entry to the submucosal space is made after submucosal injection with saline. **(B)** The submucosa is progressively dissected distally along the muscular layer, using spray coagulation at 50 W (ERBE VIO300D), creating a submucosal tunnel extending beyond the gastroesophageal junction. **(C)** Myotomy of the circular esophageal and gastric muscle bundles is performed under direct vision. **(D)** After myotomy has been successfully completed, the mucosal entry site is closed with hemostatic clips from the distal to the proximal end of the mucosal fenestration. (Reproduced with permission from Inoue H, Sato H, Ikeda H, et al: Per-Oral Endoscopic Myotomy: A Series of 500 Patients, *J Am Coll Surg*. 2015 Aug;221(2):256-264.)

The patients are prepared by having them on a liquid diet for 1 to 2 days prior to the planned procedure. If significant food retention is suspected, then an endoscopy 1 to 2 days prior is done to help clear it. Patients then remains on a liquid diet until the POEM. To reduce aspiration, endoscopic suction can be performed prior to general anesthesia but is not always done.

The procedure is done under general anesthesia. A forward-viewing endoscope is used with a transparent oblique distal cap attachment. Carbon dioxide is used for insufflation. The flow is set to a lower flow rate of approximately 1.2 L/min. First, a submucosal tunnel is created. This is started by a submucosal saline injection with indigo carmine or methylene blue around 14 cm proximal to the GE junction. A 2-cm longitudinal mucosal incision is then made and entry into the submucosal space obtained. A triangle tip knife is used for cutting. A long submucosal tunnel is then created similar to ESD, using the cap for retraction and the triangle tip knife for tissue division. It is extended to around 3 cm beyond the GE junction onto the stomach. Division of the circular muscle is then started 3 cm distal to the mucosal entry. This division of the circular muscle is continued distally until approximately 2 cm past the GE junction. The mucosal entry site is then closed with regular clips.

Worldwide experience has been rapidly increasing with POEM. Inoue et al<sup>100</sup> have published their initial experience with 500 patients with achalasia and reported both short-term and long-term results (1- and 3-year follow-up). Table 5-4 summarizes the results, with median Eckardt score improving from 6 to 1 at 2 month and remaining at 1 at 1 to 2 years and even at 3 years for the few patients who had 3-year follow-up. In addition, the LES pressure was reduced from a median of 25.4 to 11.9 mm Hg at 1 to 2 years. GERD symptoms were present in 16.8% to 21.3% of patients.<sup>100</sup>

**TABLE 5-4: TREATMENT OUTCOMES: ECKARDT SCORE, LOWER ESOPHAGEAL SPHINCTER PRESSURE, AND REFLUX ESOPHAGITIS**

Variable	Before POEM	2 mo After POEM	1–2 y After POEM	3 y After POEM	P Value for Change at 3 y
Eckardt score, median (range)	6 (5–8)	1 (0–2)	1 (1–2)	1 (1–2)	<0.0001
LES pressure, mm Hg, median (range)	25.4 (18.2–35.3)	13.4 (10.5–16.4)	11.9 (7.0–15.9)	11.7 (9.6–14.9)	<0.0001

LA, Los Angeles classification; LES, lower esophageal sphincter; POEM, per-oral endoscopic myotomy. Reproduced with permission from Inoue H, Sato H, Ikeda H, et al: Per-Oral Endoscopic Myotomy: A Series of 500 Patients, *J Am Coll Surg*. 2015 Aug;221(2):256-264.

POP, or G-POEM, is also an emerging treatment option for refractory gastroparesis. It is done along similar principles as POEM. A long overtube is usually used, but as more experience is being obtained, it is being done without one as well. A mucosal incision is made around 5 or 6 cm from the pylorus. A submucosal tunnel is created, and a pyloromyotomy is done as described earlier for POEM. The mucosal incision is then closed with clips. Early results have been encouraging. Gonzalez et al<sup>102</sup> reported on a series of 12 patients who underwent POP. Their gastroparesis cardinal symptoms index score improved from  $3.5 \pm .8$  to  $0.9 \pm 0.9$  (1 month) and  $1.1 \pm 1.5$  (3 months) ( $P < .001$ ). Gastric emptying studies normalized in 75% of patients, and 85% of the patients felt significantly better. Technical success was 100%, and no adverse events were reported.<sup>102</sup> Several other authors have reported similar success rates.<sup>103,104</sup>

## ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

### History

William McKune, a surgeon, along with Paul Shorb, a gastroenterologist, were the first physicians to perform ERCP. In 1968, they reported on 4 cases of endoscopic identification and catheter placement into the ampulla of Vater. For the first time, imaging of the pancreatic ductal system could be seen and used for diagnostic purposes. Several years later in the mid-1970s, German and Japanese physicians described their experience in endoscopic sphincterotomy, the first therapeutic extension of ERCP. Other endoscopic adjuncts, including stone lithotriptors, plastic and expandable metal stents, and intraductal imaging tools, have fully changed ERCP from a diagnostic tool into one that is predominantly therapeutic.

### Indications

There are numerous indications for ERCP, as listed in [Table 5-5](#). ERCP, however, is preferentially used as a therapeutic tool due to the high risk of serious complications.<sup>105</sup> In patients in whom a diagnostic imaging of the

pancreaticobiliary tree is desired, magnetic resonance cholangiopancreatography (MRCP) should be used.<sup>106</sup> Prior to cholecystectomy for symptomatic cholelithiasis, the presence of persistent jaundice or cholangitis is the indication for preoperative ERCP. Finally, as the number of patients undergoing bariatric procedures (Roux-en-Y gastric bypass) increases, access to the ampulla has become more challenging. Identification and access to the remnant stomach routinely require surgical or radiologic intervention for performance of ERCP.

**TABLE 5-5: INDICATIONS FOR ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY**

1. Suspected choledocholithiasis
2. Identification and management of malignant or benign strictures
3. Investigation of abnormal radiographic imaging of the biliary tree
4. Persistent jaundice
5. Evaluation and treatment of sphincter of Oddi dysfunction (SOD)
6. Evaluation and treatment of pancreatic or biliary ductal injury/trauma or leaks
7. Treatment for identified ampullary adenoma
8. Recurrent or idiopathic pancreatitis
9. Treatment of complications of chronic pancreatitis including stones and/or strictures
0. Treatment for pancreatic fluid/cyst or pancreatic necrosis
1. Cytology of suspected pancreatic cancer and other pancreatic malignancies

## **Patient Preparation**

Patient preparation, sedation, and monitoring for ERCP are similar to those for other upper endoscopic procedures, although the patient is routinely placed in the prone position. Patients may require general anesthesia for airway protection, as a result of inability to tolerate conscious sedation, for expected lengthy or more complicated ERCP interventions, or in the presence of multiple comorbid diseases. ERCP can be performed in a supine position, although this can make the procedure more challenging, as in patients

undergoing ERCP at the time of laparoscopic cholecystectomy.

## Techniques of ERCP

ERCP is performed using a side-viewing scope and requires both endoscopic and fluoroscopic skills for interpretation and intervention. As stated earlier, ERCP is predominantly a therapeutic technique. The scope is initially passed into the esophagus blindly to a position beyond the upper esophageal sphincter and then rapidly advanced into the proximal stomach where any residual secretions should be aspirated. Unlike a forward-viewing endoscope, the pylorus cannot be visualized during intubation with a side-viewing scope. Upward deflection of the side-viewing endoscope with continued advancement will allow easy passage into the duodenal bulb.

To manipulate around the superior duodenal angle, the endoscope is turned to the right, and the tip is deflected upward to reach the second portion of the duodenum. The endoscope is then withdrawn during this maneuver, leaving the scope in the ideal “short-scope” position.

With the “short-scope” position, the endoscopist views the papilla directly along the medial duodenal wall. Very minute movements of the tip and further withdrawal of the scope will bring the papilla into view. Fluoroscopy can also be used to determine appropriate scope position and to help identify the site of the major papilla. After the papilla is visualized, it is then cannulated using one of the various types of catheters available. As the majority of ERCP cases are potentially of a therapeutic nature, most endoscopists will start with a pull wire sphincterotome. Guide wire–assisted cannulation has also become a popular practice for several reasons. First, it may minimize the overall volume of contrast required, thereby hopefully decreasing the rates of pancreatitis and cholangitis. Second, it may increase the efficiency of selectively cannulating the desired duct. Finally, it can help maintain access into the duct during catheter exchanges.

Selective cannulation of the biliary and pancreatic ducts depends on the angle of the catheter and the position of the scope tip. The pancreatic duct tends to enter the papilla in a relatively perpendicular fashion at the 1 o’clock position. In contrast, the bile duct runs toward 11 o’clock below the “lip” of the papilla.

ERCP represents an endoscopic and radiographic intervention, and proper

radiologic technique is critical to obtaining interpretable radiographs. Artifacts such as air bubbles, streaming and layering of contrast, and contrast spillage into the duodenum should be recognized and avoided.

## **ERCP Therapeutic Interventions**

### **SPHINCTEROTOMY**

There are 2 types of sphincterotomy that can be performed—needle knife sphincterotomy (precut sphincterotomy) or pull wire sphincterotomy. Needle knife sphincterotomy is performed when deep selective cannulation is unable to be obtained, and can be done over a previously placed stent or guide wire, or when an impacted common bile duct (CBD) stone is protruding through the ampulla (Fig. 5-31). This technique is more technically challenging and also has a higher risk of bleeding, pancreatitis, and perforation. Pull wire sphincterotomy, conversely, requires deep selective cannulation with or without previous wire placement (Figs 5-32 and 5-33).

**FIGURE 5-31** An impacted common bile duct stone seen extruding through the ampulla. This is best treated by needle knife sphincterotomy to allow release of the stone.

**FIGURE 5-32** Following deep selective cannulation of the bile duct, a sphincterotomy is performed with a pull wire sphincterotome.

**FIGURE 5-33** Postsphincterotomy image of the major papilla.

Indications for sphincterotomy include treatment of sphincter of Oddi dysfunction (SOD), improved access for stone removal or stent placement, and recurrent pancreatitis. To perform sphincterotomy, the pull wire is tightened, bowing it against the papillary roof. Current is then applied while maintaining gentle upward force on the wire and gently lifting the sphincterotome, making the incision in small increments.

## **MANAGEMENT OF CHOLEDOCHOLITHIASIS**

In expert hands, over 90% of bile ducts can be successfully cleared of calculi with balloon catheters or Dormia baskets, resulting in an overall ductal clearance rate approximating 85% (Figs 5-34 and 5-35). Stone size is often a limiting factor, as stones greater than 2 cm in diameter often require fragmentation prior to removal. The other reasons for unsuccessful ERCP include patient intolerance, inability to identify or access the papilla, and

inability to selectively cannulate the desired duct.

**FIGURE 5-34** ERCP radiographic image of a distal common bile duct stone.

**FIGURE 5-35** Following sphincterotomy (seen in the upper right-hand portion of the image) and balloon sweeping, the extracted common bile duct stone is seen in the duodenum.

## **MANAGEMENT OF ACUTE CHOLANGITIS**

Endoscopic biliary drainage has now been clearly shown to be the procedure of choice for patients with acute suppurative cholangitis. In critically ill patients, simple endoscopic stenting or nasobiliary drainage, with or without sphincterotomy, should be performed. Complete clearance of the duct is not necessary as long as drainage had been achieved. Stone extraction can be performed after the patient has stabilized, at the time of stent removal 4 to 6 weeks later.

## **MANAGEMENT OF ACUTE GALLSTONE PANCREATITIS**

Patients with biliary pancreatitis can typically be managed conservatively, saving ERCP for patients with worsening pancreatitis or concomitant evidence of biliary obstruction secondary to choledocholithiasis.<sup>107</sup> In these cases, early ERCP and sphincterotomy can significantly reduce morbidity and mortality.<sup>107,108</sup> In patients who are not an operative candidate for a cholecystectomy, ERCP and sphincterotomy are effective in minimizing the risks of pancreatitis.

## ENDOPROSTHESIS INSERTION

Currently available endoprotheses or stents vary in their composition, shape, size, length, deployment system, and method of anchorage. The indications for stent insertion include cholangitis, benign/malignant biliary or pancreatic duct stricture, biliary or pancreatic duct leak, retained/unremovable CBD stones, and prophylactic pancreatic duct stent placement for pancreatitis protection.<sup>108-111</sup> In patients with biliary fistulae, the goal of the stent is to equilibrate the biliary and duodenal pressures to facilitate closure of the leak (Figs 5-36 to 5-38).

**FIGURE 5-36** ERCP revealing extravasation of contrast from an accessory

duct leak.

**FIGURE 5-37** Following a 6-week course of biliary stenting, the leak has resolved.

**FIGURE 5-38** Transpapillary biliary stent placement for treatment of the biliary leak.

Straight plastic biliary stents are temporary and must be changed every 3 to 6 months.<sup>108</sup> Obstructive jaundice and cholangitis are common sequelae of occluded stents. Placing multiple stents may increase the length of overall patency, as bile can traverse around and between the stents even if the stent lumen becomes obstructed. SEMS carry a longer patency rate of 9 to 12 months as compared to plastic stents.<sup>109,110</sup> Uncovered metal stents are less likely to migrate as compared to covered ones, but have a shorter patency rate due to the allowance for ingrowth of tissue or tumor. Newer fully covered self-expanding metal biliary stents also allow for delayed removal and can therefore be used in the management of chronic benign strictures.

Patients undergoing endoscopic palliation for obstructive jaundice secondary to malignancy who are not operative candidates may be better served with SEMS rather than plastic stents due to the decreased need for repeat endoscopic intervention in patients with a limited life expectancy.<sup>109</sup> If patients have both a biliary and duodenal obstruction secondary to

malignancy, it is important to place the biliary SEMS prior to the duodenal stent because access to the papilla becomes very challenging. Palliation of unresectable malignant biliary obstruction in elderly high-risk patients appears to be one of the most significant indications for biliary endoprosthesis (Fig. 5-39).

**FIGURE 5-39** Distal common bile duct stricture secondary to a pancreatic head malignancy.

In addition to biliary disorders, ERCP has been employed in the management of benign and malignant pancreatic disorders (Figs 5-40 and 5-41). Pancreatic duct stenting can be used successfully to decompress the ductal system, to bypass ductal leaks and strictures, and to treat pancreatic fistulas. Patients with pancreatic divisum may be treated with minor papilla stenting or sphincterotomy.

**FIGURE 5-40** Radiographic image of a pancreatic duct wire prior to stent placement.

**FIGURE 5-41** Temporary plastic 5-Fr pancreatic stent in place.

## **ENDOSCOPIC PSEUDOCYST DRAINAGE/NECROSECTOMY**

The management of pancreatic pseudocysts and necrotic debris is one of the more recent advances in the therapeutic armamentarium of the endoscopist. Pancreatic pseudocysts can be approached in a transpapillary or a transvisceral fashion based on the location and nature of the pseudocyst. Many pseudocysts have direct connection to the main pancreatic duct and are referred to as “communicating” pseudocysts. If wire access can be obtained via the pancreatic duct into the cyst cavity, a pancreatic stent can be placed to allow for drainage of the cystic cavity. Although this may result in initial resolution of the cyst, a high recurrence rate exists due to the continued communication to the ductal system. After drainage, subsequent stenting of the pancreatic duct across the site of leakage may be required.

Pancreatic pseudocysts directly adjacent to an endoscopically approachable lumen (ie, stomach, duodenum) may be amenable to a transvisceral approach.<sup>112-115</sup> Assuring maturity of the cyst, absence of concern for neoplasm, and no evidence of actual infection are important factors to determine prior to endoscopic drainage. The use of EUS is an invaluable adjunct to this procedure for several reasons.<sup>113,115</sup> It can rule out intervening organs or vasculature, determine if there is extensive debris rather than simple fluid collections, and assure proximity of the cyst to the selected viscus. EUS aspiration followed by guide wire placement is followed by tract dilation and eventual pigtail stent placement. Stents are removed in 6 to 12 weeks after confirming resolution of the pseudocyst.

Patients with pancreatic necrosis rather than simple pseudocyst formation have also been approached endoscopically.<sup>116-120</sup> Similar to transvisceral cyst drainage, EUS guidance is used to confirm the presence of a collection of debris, and following tract dilation, the endoscope is advanced directly into the adjacent cavity. Tissue is then removed using a combination of irrigation/suction and snare/basket tissue debridement. Stents are placed to maintain the tract to allow for serial debridement of the necrotic tissue.

Recently lumen-apposing, covered, self-expanding metal stents (LACSEMS) have been used for endoscopic drainage of pseudocysts. Intermittent debridement can be done through them as well. Fully covered metal stents have been used as well but may end up being replaced by the LACSEMS as more experience is obtained with them. Initial data from small case series show that they can have a high technical success rate of over 90% in appropriately selected patients and successful drainage in over 90% as well.<sup>121</sup> However, there are some recent reports that describe concerns with bleeding.<sup>122</sup> There are also published data that show that these stents may be no better than plastic stents, so the jury is still out on lumen-apposing metal stents.<sup>123</sup>

## **Complications of ERCP**

### **POST-ERCP PANCREATITIS**

The occurrence of ERCP-induced pancreatitis is associated with both procedural factors and patient factors. Although the precise factor leading to

postprocedural pancreatitis has yet to be elucidated, many factors including complex interventions such as manometry, multiple pancreatic cannulations or injections, excess delivery of thermal energy, and placement of covered SEMS have all been implicated. Prophylaxis with antibiotics, steroids, somatostatin, xanthine oxidase inhibitors, and immunologic agents such as interleukin-1 have been investigated in multiple prospective comparative trials without success in reduction of pancreatitis.<sup>124</sup> Patient factors associated with pancreatitis include SOD, idiopathic pancreatitis, and the prior history of acute or chronic pancreatitis.<sup>124</sup> The use of short-term prophylactic pancreatic stent placement may eventually be proven beneficial in patients following higher risk procedures or who have comorbid disease states that increase their risk for post-ERCP pancreatitis.

Bleeding following endoscopic sphincterotomy occurs in approximately 1% of all cases and can occur immediately or up to 2 weeks after procedure. Hemorrhage should be initially managed by repeat endoscopic intervention. Injection sclerotherapy, balloon tamponade, and endoscopic clip placement are the most common and effective ways to manage this complication.<sup>125</sup> If unsuccessful, angiographic embolization should be used before proceeding to surgical intervention.

Perforation is the least common complication and may occur secondary to the ERCP intervention (wire placement, cannulation, or sphincterotomy) or the actual advancement of the endoscope. Endoscope-induced perforations can occur at the level of the cervical esophagus due to the blind nature of the initial passage of the side-viewing endoscope, or in the duodenum, usually on the lateral aspect opposite the papilla. Proximal esophageal perforations usually can be managed with antibiotics, NPO status, and cervical drainage as needed. Duodenal perforations secondary to the endoscope may result in a large rent of the lateral wall and may require more aggressive therapy including surgical drainage or, in more serious situations, duodenal diversion techniques.

Perforations secondary to ERCP manipulations may occur in the periampullary duodenum or in the biliary tree. Perforations of the bile duct secondary to guide wires or catheter systems are rare but can result in bile peritonitis. Small perforations and leaks in patients without clinical deterioration can usually be managed with transpapillary stent placement and image-guided peritoneal drain placement as needed. CT scans are vital in the

management of these patients.<sup>126</sup> Microperforation of the duodenum can lead to extensive retroperitoneal, intraperitoneal, mediastinal, and subcutaneous air, which appears very concerning, but as long as the patients are clinically stable, this situation can routinely be managed conservatively with antibiotics, NPO status, and close observation. Conversely, patients identified to have retroperitoneal or intraperitoneal fluid collections will most likely require aggressive drainage via either surgical or image-guided techniques. Emergent resective therapy (pancreaticoduodenectomy) should be avoided in these situations.

## SMALL BOWEL ENTEROSCOPY

Up until recently, the small bowel had been an elusive part of the gastrointestinal tract in terms of diagnostic and therapeutic endoscopic intervention. The advent of capsule endoscopy has permitted the endoscopist to obtain recorded images of the lumen of the small bowel for identification of obscure sites of bleeding, inflammatory changes, and neoplasia. Unfortunately, there was no potential for tissue sampling or providing therapy. This deficiency has now been addressed with the progression of deep bowel enteroscopy.

Previous endoscopic approaches to evaluate the small bowel included Sonde enteroscopy and push enteroscopy. Both of these were very challenging, time-consuming, often unsuccessful, and provided limited alternatives for therapy. Intraoperative enteroscopy, either transoral or transanal, allowed for the manual pleating of the small bowel on the enteroscope, but was also very challenging.<sup>127</sup> Therapy would be provided surgically after the offending site was identified endoscopically. Intraoperative endoscopic evaluation of the small bowel can also be performed via an enterotomy in the midportion of the bowel allowing the endoscope to be advanced both proximally and distally. One of the undesired consequences of intraoperative endoscopy is massive bowel distention. The use of carbon dioxide (CO<sub>2</sub>) insufflation rather than air insufflation has been shown to minimize the overall distention and length of time for resolution of this problem. Many endoscopists are looking to use CO<sub>2</sub> for all endoscopic interventions, especially those that are expected to be of longer duration.

Several new endoscopic systems have been developed and used for the

evaluation and treatment of small bowel disease. Double-balloon endoscopy and single-balloon endoscopy have allowed the endoscopist to fully evaluate the small bowel, obtain tissue samples, and provide therapy for processes such as bleeding, obstruction, and occult neoplasia.<sup>128-136</sup> In addition, in patients following surgical resection and reconstruction (ie, Roux-en-Y bypass, long afferent limb), balloon enteroscopy can allow access into the desired segment of the small bowel.<sup>133</sup>

## LOWER GASTROINTESTINAL ENDOSCOPY

The field of therapeutic lower endoscopy originated in 1975 when Shinya and Wolff reported the first series of colonoscopic polypectomies.<sup>137</sup> This groundbreaking report transformed colonoscopy from a purely diagnostic tool into an interventional modality. Since then, therapeutic colonoscopy has expanded to include resection of large neoplastic lesions and stenting for management of strictures, obstructions, and bleeding. Advances in instrumentation and technique will continue to broaden the applications of interventional colonoscopy, possibly even using the colon as a portal to the peritoneal cavity.

### Indications

Screening colonoscopy has become the standard of care for evaluation of average-risk patients over the age of 50.<sup>138-141</sup> Prior screening tools such as fecal occult blood testing, sigmoidoscopy, and digital rectal exams no longer are considered effective screening tools.<sup>142</sup> CT colonography, however, has gained some support due to improved abilities to identify colonic neoplasia; however, smaller lesions are still somewhat a challenge for this imaging tool. The indications for colonoscopy are listed in [Table 5-6](#).

**TABLE 5-6: INDICATIONS FOR COLONOSCOPY**

#### Diagnostic

1. Evaluate and confirm radiographic findings
2. Identify suspected polyps

3. Unexplained gastrointestinal bleeding or iron deficiency anemia
4. Colon cancer screening and surveillance
5. Follow-up after intervention for polyp or cancer
6. Surveillance of inflammatory bowel disease
7. Significant unexplained diarrhea
8. Preoperative/intraoperative localization of lesions

### **Therapeutic**

1. Control bleeding
2. Polypectomy
3. Remove foreign body
4. Reduce sigmoid volvulus
5. Decompress pseudo-obstruction (Ogilvie's)
6. Dilate or stent strictures/stenoses (malignant and benign)

---

## **Contraindications**

The contraindications for colonoscopy are in part similar to those for EGD and are related to the patient's associated comorbidities, underlying gastrointestinal disorders, or inability to tolerate conscious sedation. As with EGD, recent myocardial infarction, pneumonia, and recent colorectal surgical procedure are relative contraindications for colonoscopy, and the risks and benefits need to be weighed on an independent basis for each patient to determine appropriateness. A recent surgical anastomosis is most likely safe at any time during the postoperative period to be evaluated endoscopically, remembering that tissue strength will be weakest on postoperative days 5 to 7.

Coagulopathy secondary to thrombocytopenia, liver failure, renal failure, or exogenous use of anticoagulants and platelet-inhibiting agents is a relative contraindication for a diagnostic colonoscopy but an absolute contraindication for a therapeutic intervention. Patient noncooperation and the inability for a patient to be safely sedated due to high cardiopulmonary risk are also contraindications to colonoscopy. Respiratory depression secondary to medications and inability to maintain an airway can occur in

these high-risk patients even though there is no transorally placed scope. Preassessment with ASA classification and Mallampati scores will help predict this high-risk group. Patients with suspected perforation, ischemic colitis, acute diverticulitis, or toxic megacolon should not undergo colonoscopy unless there are plans to provide immediate therapy such as endoscopic closure or stent placement or surgical intervention.

## **Patient Preparation**

Most endoscopic evaluations of the lower gastrointestinal tract can be done under conscious sedation on an outpatient basis. Unsedated colonoscopy can be performed safely but requires a compliant, nonanxious patient, who understands that prior abdominal surgery as well as female gender increases the need for conversion to sedated endoscopy.

The day before the examination, the patient should begin a light diet with only clear liquids at lunch. The most common bowel preparation for colonoscopy uses a sodium sulfate–based electrolyte solution containing polyethylene glycol as an osmotic agent (eg, GoLYTELY). Alternative regimens including magnesium citrate and multiple enema solutions have also been described. In addition to different agents for prep, endoscopists have also used varied timing for preps with the use of split doses, with the final dose being given 4 hours before the scheduled procedure. Fleet Phospho-Soda, a small-volume prep, is no longer an alternative due to the rare occurrence of cardiac complications, but there are other small-volume preps available.

Prophylactic antibiotics are usually not required for colonoscopy. Although diagnostic procedures can be performed in patients on anticoagulative therapy, these medications should be withdrawn if polypectomy or other therapeutic procedures are expected to be performed. Aspirin therapy, unlike other anticoagulative medications, probably does not alter the risk of postpolypectomy bleeding.

## **Basic Endoscopic Techniques—Colonoscopy**

When performing colonoscopy, there are several universal principles to the technique similar to upper endoscopy, but there are also several specific

caveats to assure performance of a safe procedure. Due to the tortuosity of the colon and the lack of fixation, manipulations such as scope torquing, loop reduction, patient position changes, and abdominal wall manual pressure are vital to the performance of colonoscopy. One other difference from upper endoscopy is the lack of reliability of correlation of shaft length inserted and actual anatomic position in the colon. Therefore, understanding specific colonoscopic landmarks is very important to interpreting actual lower gastrointestinal anatomy. In addition, surgical alterations to the anatomy must be recognizable (Fig. 5-42).

**FIGURE 5-42** An end-to-end stapled anastomosis at the rectosigmoid level is seen in this image.

A digital rectal examination should always be performed prior to initiating the colonoscopic exam. This provides lubrication of the anal canal, relaxes the anal sphincters, provides evaluation of the prostate and lower rectal vault, and assesses the patient's level of sedation. The endoscope is introduced either by direct straight insertion or by rubbing the tip of the endoscope along the perineal body with the right index finger. Once reaching the anal verge,

the tip of the endoscope is directed into the anal canal.

Once in the rectal vault, insufflation is initiated to allow view of the lumen. Although mucosal inspection occurs during advancement, principal evaluation for pathology occurs on scope withdrawal after the cecum is reached. Gentle advancement of the colonoscope is now performed. If the lumen is lost to view, termed a “red out,” the scope is slightly pulled back and the wheels deflected in combination with scope torque to reestablish the lumen. Passage of the scope into the sigmoid colon can be challenging in patients with prior abdominal surgery, morbid obesity and a large pannus, or multiple diverticula (Fig. 5-43). Abdominal compression and patient position change to supine may assist in this maneuver. Rarely, a “slide-by” maneuver is required to overcome the tight angulation in and out of the sigmoid colon. This technique entails careful insertion without complete luminal view but with appearance of the mucosa sliding by the scope. During all portions of the colonoscopy, however, increased patient discomfort, “redded out view,” and excessive scope resistance with advancement are markers to the endoscopist to pull back one’s colonoscope.

**FIGURE 5-43** Multiple diverticula seen in the sigmoid colon.

Exiting the sigmoid colon may require building up a “loop.” This may lead to increased patient discomfort and may require additional medication. Once access into the descending colon is achieved, the loop is reduced by gentle withdrawal and slight torquing of the scope. Adding variable stiffness to the scope, if available, will now allow advancement in a 1-to-1 fashion to the splenic flexure; 1-to-1 refers to equal scope tip advancement with scope insertion. The descending colon is usually quite straight, and the splenic flexure is identified by the extraluminal blue hue as well as the tight turn encountered as one enters into the distal transverse colon. Suctioning and scope withdrawal will assist in maintaining positioning beyond the splenic flexure.

Introduction of the scope, again with the addition of variable stiffness, should allow 1-to-1 progress through the transverse colon, which is easily identified by the triangular configuration. As one proceeds toward the hepatic flexure, the blue hue of the liver becomes apparent. At this time, paradoxical motion routinely will occur with scope introduction. Access into the ascending colon usually requires the endoscopist to make a sharp deflection at the hepatic flexure followed by withdrawal of the scope and simultaneous suctioning. The ascending colon may have a yellow discoloration due to the continued passage of succus entericus despite a complete bowel preparation. Asking the patient to take a deep breath as well as placing them in supine position may assist in this maneuver. Eventually, the cecum is identified by the ileocecal valve, appendiceal orifice, cecal strap, abdominal wall transillumination, and right lower quadrant palpation (Figs 5-44 and 5-45). Intubation of the ileum, however, is the only way to confirm 100% that you have actually reached the cecum. The terminal ileum can be intubated by deflecting the tip toward the ileocecal valve, gently withdrawing the scope, and prying open the upper lip of the valve. Throughout this maneuver, air insufflation is used. The scope is then slowly advanced into the terminal ileum.

**FIGURE 5-44** The cecum is seen here, identified by the ileocecal valve, appendiceal orifice, and classic cecal strap.

**FIGURE 5-45** Classic lipomatous appearance of the ileocecal valve helps differentiate it from other colonic folds.

The goal of the endoscopist is to reliably and safely gain access into the cecum, confirming one's position, and then performing a slow careful withdrawal evaluating the entire mucosal surface. Areas of excess stool must be flushed clear, and extra care must be taken at the flexures and around larger folds to investigate for underlying disease. Retroflexion of the endoscope, which had been used for evaluation of the rectal vault, is now being performed with some regularity in the cecum and flexures, as well as to see behind larger folds. Manipulation by patient position change, as with upper endoscopy, may aid in visualization of areas with excess stool. Retroflexion in the rectum can be done at the beginning or at the end of the procedure (Fig. 5-46). The colonoscope is withdrawn into the anal canal and then carefully advanced for several centimeters. Full upward deflection along with clockwise torquing and gentle advancement will result in the scope looking back toward the distal rectum and dentate line.

**FIGURE 5-46** Retroflexed view in the rectal vault identifying the dentate line and excluding any anorectal disease not able to be seen on anteflex view.

## Complications

Complications specifically related to colonoscopy include hemorrhage and perforation. The former is most unusual following diagnostic colonoscopy, occurring in 0% to 0.07% of cases. Hemorrhage in this setting is usually intra-abdominal such as following injury to the colon mesentery or to the capsule of the spleen, resulting from the use of excessive force during manipulation. Hemorrhage is seen more often following polypectomy (1%-3%).<sup>143</sup> Postpolypectomy bleeding can be immediate or delayed and can occur up to 2 weeks after the procedure. Repeat colonoscopy is recommended for hemodynamic instability, transfusion requirement, and continued or recurrent episodes of bleeding.

Perforation is the most common complication of colonoscopy, occurring in <1% of cases.<sup>142</sup> These injuries are caused by mechanical or pneumatic pressure and are most common at the rectosigmoid or sigmoid–descending

colon junctions along the antimesenteric border at the site of scope looping. Alternatively, cecal perforation can occur if the colon is excessively insufflated across a more distal nontraversable obstruction. In patients with a competent ileocecal valve, there is a resultant trapping of air between the distal obstruction and the valve, which prevents release of the insufflated air into the small bowel.

Therapeutic colonoscopy can also be complicated by perforation, at the site of therapy, as well as the other previously reported sites. Reported incidences are rare (<1%), with the greatest risks occurring with the removal of sessile polyps. Following polypectomy, patients occasionally develop localized pain secondary to peritoneal irritation, along with fever, tachycardia, and leukocytosis. There is usually no evidence of diffuse peritonitis or overt perforation (ie, no “free air”). This syndrome has been labeled postpolypectomy syndrome and is probably attributable to a transmural electrocoagulation injury with microperforation. Patients usually can be managed conservatively with antibiotics, analgesics, and close observation with serial exams. Symptoms usually resolve within 48 to 72 hours and rarely are surgical interventions needed.

In patients with a suspected perforation, CT studies are recommended to evaluate for abscess formation or intra-abdominal fluid collections. Intra-abdominal fluid collection is a more concerning finding, and these patients require close observation with a low tolerance for surgical intervention. It is important to base therapy on individual patient status, however, rather than just radiographic studies. The presence of intraperitoneal or retroperitoneal air in the absence of clinical peritonitis or hemodynamic instability does not warrant surgical exploration. Perforations that are recognized at the time of a colonoscopy, especially smaller ones after therapeutic intervention such as polypectomy, can be closed with regular hemostatic clips, over-the-scope clips such as the Ovesco overclip, or endoscopic suturing such as with the OverStitch, which have been described earlier in the chapter. The reach may be limited to more distal colon for the OverStitch.

## **Polypectomy**

By far, the most commonly performed colonoscopic intervention is polypectomy. When performed at regular intervals, removing adenomatous polyps has been shown to significantly reduce the incidence of colon

cancer.<sup>107</sup> Small sessile lesions are amenable to hot or cold biopsy polypectomy. For hot polypectomy, standard biopsy forceps without spike are attached to an electrocautery unit set at 10 to 20 W. The polyp is grasped and lifted from the surrounding mucosa, and monopolar cautery is applied in short bursts until the base of the polyp whitens. The biopsy forceps are sharply withdrawn and the polyp is then removed through the working channel of the colonoscope. Polypectomy serves to biopsy the polyp and ablate any residual tissue, thereby diminishing the risk of progression to carcinoma. Due to the concern for delayed bleeding following sloughing of the eschar as well as the risk of perforation, many endoscopists are now adopting cold polypectomy techniques. Several series have shown no difference in the rates of bleeding, and it presents a more easily evaluable specimen to the pathologist without cautery artifact.

Pedunculated polyps are suitable for snare polypectomy (Fig. 5-47). The base of the polyp is encircled with the snare several millimeters below the head-stalk junction. This allows removal of a portion of the stalk for pathologic evaluation to rule out invasion of the lamina or muscular layers, identifying a more advanced neoplasm. Cautery is applied as the snare is gradually closed, thus severing the polyp and cauterizing the base. Broader-based pedunculated polyps may be managed with placement of an endoscopic pretied endoloop proximal to the site of resection to help minimize bleeding. These loops usually will slough off within several weeks and pass spontaneously.

**FIGURE 5-47** Small pedunculated polyp amenable to snare polypectomy technique.

Sessile polyps are frequently more difficult to manage than pedunculated polyps. Small sessile lesions may be captured in a single application of a snare and resected, with (hot) or without (cold) cautery, while larger lesions might require resection in a piecemeal fashion. Piecemeal resection provides for removal of a larger lesion along with ablation of residual tissue, but may make pathologic interpretation more challenging.<sup>144</sup>

Resection of sessile polyps poses a higher risk of colonic perforation than pedunculated polyps. Given that, EMR has been developed to minimize the risk of perforation and ensure complete resection of the lesion. This is provided by submucosal injection of saline to create a cushion between the mucosa and muscularis to help minimize the risk for perforation.<sup>144-147</sup> Lesions that do not easily elevate may have a component of invasive carcinoma, and these tumors should be biopsied and tattooed, rather than attempted to be endoscopically resected. Following removal of large sessile lesions, APC ablation of the site has been proposed to minimize adenoma

recurrence.

## **POLYP RETRIEVAL**

Small polyps may be retrieved through the suction channel of the endoscope and captured in a trap. Larger polyps may be recovered in a net placed through the working channel of the endoscope or apposed to the tip of the endoscope by constant application of suction and then withdrawn with the scope. Marking the site of resection with a carbon particle–based tattoo via a sclerotherapy needle will allow for more accurate surveillance, as well as to guide surgery if the polyp proves to be malignant. Injections should be placed at multiple sites circumferentially to allow for the most reliable visualization at the time of surgery or during subsequent surveillance endoscopy.

## **POLYP SURVEILLANCE**

Over the past 15 years, much has been learned about the nature of the adenoma carcinoma sequence, leading to ongoing changes in the recommendations for polyp surveillance. Average-risk patients with satisfactory bowel preps require repeat surveillance in 10 years, while patients with poorer preps might be recommenced to have a shorter interval of 5 to 7 years.<sup>138,140-142</sup> Hyperplastic polyps carry an undetermined risk for and association with advanced neoplasia, although there has been some suggestion that left-side hyperplastic lesions have a more aggressive nature than those in the rectosigmoid. Similar to fundic gland polyps of the stomach, these lesions may be sampled but do not need to be fully removed. Tubular adenomas, tubulovillous adenomas, and villous adenomas warrant a surveillance colonoscopy at 5, 3, and 1 year, respectively.<sup>138</sup>

## **EMR and ESD in Colon**

Significant advancement in endoluminal techniques for colorectal application has been made since the turn of the century. Increased implementation of techniques such as EMR and ESD has given the surgical endoscopist additional noninvasive tools to safely treat increasingly difficult benign and malignant colorectal lesions. EMR has its origins in Japan for the treatment of early gastric cancer, with subsequent implementation in Western nations

for benign diseases such as Barrett esophagus with dysplasia and gastrointestinal adenomas.<sup>148,149</sup> Technically challenging lower GI lesions such as flat and large sessile polyps not amenable to snare polypectomy have historically caused endoscopists great strife, leaving surgical referral as the only option after incomplete resection due to the elevated risk of malignancy harbored in such polyps. Yet with the knowledge that neoplastic lesions with <1 mm of submucosal invasion are unlikely to have lymph node metastases, endoscopic methods that allow adequate resection of these lesions have become increasingly valuable by saving the resources and morbidity associated with a surgical procedure that would otherwise be necessary.<sup>150</sup> EMR is indicated for lesions that are limited to the mucosa and <2 cm in size, although it has been successfully used even for much larger cancers and adenomas. Although EMR can be used to obtain pathologic samples for diagnosis, prior biopsy showing intramucosal carcinoma or adenoma often precedes performance of an EMR procedure with curative intent.

The endoscopic appearance of lesions can give valuable information predicting a lesion's depth of invasion, likelihood to harbor underlying malignancy, and thus, expected utility of performing EMR of the lesion. The Paris classification system (Table 5-7) provides a standardized way of categorizing nonpolypoid lesions, and lesions classified as Is or Ip typically are not included in EMR literature because these can often be treated by snare polypectomy. The appearance of associated colonic pit patterns has been shown to correlate with underlying histopathologic structure (Table 5-8) and, with the help of magnified colonoscopy, can be used to identify candidate lesions for EMR.<sup>151,152</sup> Chromoendoscopy serves as a diagnostic adjunct by using a diluted stain like Lugol's solution (UGI) or 0.1% to 0.5% indigo carmine that collects within mucosal depressions to highlight the surface abnormalities and borders of lesions that are otherwise difficult to appreciate, making resection margins easier to identify. This is usually done via dye injection through a separate working port prior to lifting of the lesion as described subsequently. Magnified colonoscopy using NBI has shown similar efficacy as chromoendoscopy in determining pit patterns and discerning neoplastic lesions.<sup>153</sup>

**TABLE 5-7: NONPOLYPOID POLYP CLASSIFICATION BASED ON THE PARIS CRITERIA**

Classification	Definition
Type 0 lesions	Superficial protruding or nonprotruding lesions
0-I	Protruding lesions
0-Is	Protruding, sessile lesion
0-Ip	Protruding, pedunculated lesion
0-II	Nonprotruding, nonexcavated lesions
0-IIa	Nonprotruding, slightly elevated lesion
0-IIb	Nonprotruding, flat lesion
0-IIc	Nonprotruding, slightly depressed lesion
0-III	Excavated lesions, ulcerated or depressed

**TABLE 5-8: CLASSIFICATION OF COLONIC POLYP PIT PATTERN**

Classification	Pit Pattern	Histopathologic Association
Type I	Round and regular	Normal tissue
Type II	Larger, star-shaped or onion-like	Normal tissue
Type III	Elongated and large	Adenoma
Type IIIs	Small and short	Early carcinoma
Type IV	Branched long pits	Adenoma
Type V	Irregular	Carcinoma or dysplasia

Reproduced with permission from Kelley KA, Tsikitis VL: Endoluminal Therapy in Colorectal Cancer, *Clin Colon Rectal Surg.* 2016 Sep;29(3):216-220.

Although general anesthesia may be used, EMR can typically be easily performed under moderate sedation using fentanyl or midazolam. Full-thickness resection of the affected mucosa down to the middle or deep submucosal level is implied with EMR and can be accomplished via one of a few available techniques, including injection-assisted EMR, strip biopsy, EMR-C (special cap), and ligation-assisted and underwater EMR. The common principle of these variable methods is to provide some separation of

the superficial lesion from the deeper submucosal layer(s) before ensnaring and removing it with an energy source. The most common method, injection-assisted EMR, is based on the work of Kudo<sup>154</sup> and involves a 5- to 50-mL injection of some aqueous solution into the loose connective tissue of the submucosal layer, providing a lifting cushion that facilitates full inclusion of the lesion during subsequent snare polypectomy. The injection is typically begun at the most distal part of the lesion from the colonoscope, and normal saline is the most common solution but may be limited by rapid absorption requiring multiple injections, leading to investigative use of other solutions such as glycerol, hyaluronic acid, fibrinogen-based products, and even autologous blood.<sup>155</sup> Strip biopsy, also called the “injection-lift-cut” technique, entails grasping the lesion to be removed on tension before ligating it. This method is used less frequently because it commonly leaves pieces of the lesion remaining that must be subsequently removed piecemeal by methods such as APC or hot biopsy forceps. EMR-C incorporates a special capped snare that opens at the distal cap end where tissue is aspirated before the snare tightens and the lesion excised with cautery. However, EMR-C been associated with increased risk of perforation, and its use is now limited primarily to the rectum because of its extraperitoneal location.<sup>152</sup> Ligation-assisted EMR involves the placement of 1 or more bands in similar fashion to banding for variceal bleeding to isolate the mucosa and submucosa with or without submucosal injection prior to snare polypectomy.<sup>156</sup> In underwater EMR, luminal air is replaced by 500 to 1000 mL of water, and the mucosal/submucosal layers “float” away from a muscularis propria that remains flat while immersed, allowing for snare excision without submucosal injection.<sup>152,156,157</sup> This technique has the theoretical advantage of avoiding inadvertent introduction of neoplastic cells into deeper tissues, and some studies suggest improved rates of complete resection and diminished recurrence compared to classic lifting techniques.<sup>156</sup> One primary risk of EMR is bleeding, ranging from 0% to 22% according to literature and rarely significant enough to require reintervention, whereas perforation remains a rare complication with an incidence of less than 0.2%.<sup>152</sup> Recent studies show that placement of hemoclips at the time of EMR for large polyps effectively diminishes risk for clinically significant delayed bleeding from 9.7% to 1.8% compared to unclosed defects.<sup>158</sup> For lesions that are too large or otherwise difficult to remove en bloc with EMR, ESD may be employed as

an alternative to invasive surgical resection.

ESD was first used on local gastric cancers >2 cm but has more recently been successfully applied to similar lower gastrointestinal tract lesions. In comparison to UGI applications, anatomic factors of the colorectum, including thinner walls, more complex tortuosity, narrow lumen, and longer relative length, make ESD in this location more technically challenging and risky and thus limit the breadth of its implementation.<sup>159,160</sup> Colonic ESD is primarily performed by experts in Japan, where the Japan Colorectal ESD Standardization Implementation Working Group has concluded “that any lesion difficult to remove en bloc should be considered a candidate for ESD.”<sup>152,160</sup> Candidate lesions have been further defined as those that are large in size (>2 cm) or pseudodepressed lateral-spreading tumors, 0 to I lesions or those with a VI-type pit pattern with adenocarcinoma suspected, recurrent lesions after EMR, carcinoma with less than 1000 μm of submucosal penetration, postbiopsy mucosal lesions with fibrotic changes, or an adenoma that exhibits a nonlifting sign (insufficient mucosal lifting after injection, signifying adhesion of some etiology to the deeper underlying layers of the bowel wall).<sup>152,159</sup>

ESD employs similar equipment to EMR, including injection solution, a high-frequency power supply, a transparent tip to produce adequate submucosal tension, an electro-surgical device, and hemostatic forceps. Several electro-surgical devices are available for ESD and generally fall into 1 of 2 larger categories—needle knife (single instrument capable of injection and dissection) or grasping (scissors) type—the details of which are beyond the scope of this text and can be found elsewhere. The most common ESD procedural sequence begins with submucosal elevation and injection followed by mucosal incision with a hook knife, circumferential submucosal dissection with an insulated tip knife for en bloc resection, and completion of wound bed hemostasis with a small cup hemostatic forceps.<sup>152</sup> With the deeper level of dissection, perforation is the most feared complication and occurs more frequently than with EMR, with a reported incidence of 4% to 10% in the colon and 6% to 18% in the rectum.<sup>152,161,162</sup> Bleeding rarely occurs with colonic dissections, with an incidence of 0% to 2%, but remains a significant risk during rectal dissection, occurring in 13% to 28.6% of cases.<sup>152,161,163</sup> Altogether the data suggest that ESD may only be safe and appropriate for resection of colonic and not rectal polyps, which is likely to

be supplanted for such application by the advent of transanal endoscopic microsurgery.

## Lower Gastrointestinal Bleeding

Sources of lower gastrointestinal bleeding include UGI bleeding, infection, ischemia, neoplasia, diverticulosis, angiodysplasia, and anorectal disease. A detailed history of the nature of bleeding is vital to the management of patients with lower gastrointestinal bleeding, identifying underlying coagulopathy, recent surgical or colonoscopic interventions (polypectomy), and associated comorbid diseases. Blood is a very active cathartic, and colonoscopy can be performed in the unprepped colon with extensive bleeding.<sup>164-166</sup> Otherwise, a rapid prep over 3 to 4 hours can be used in patients with less aggressive bleeding prior to endoscopic evaluation. The endoscopist must compare the need for a more urgent intervention versus the necessity of a more adequately cleared mucosal surface.

Colonoscopic therapy for lower gastrointestinal hemorrhage within 6 to 24 hours of admission has been shown to diminish rates of rebleeding and reduce the necessity for urgent surgical intervention.<sup>164</sup> Various methods are available for hemostasis including thermal and nonthermal devices and are described in the preceding sections of this chapter. One must always remember, however, that the colon wall is thinner, especially on the right side, as compared to the stomach. Depth of penetration of the varied thermal endoscopic devices must be closely considered to avoid full-thickness perforations.

Diverticular disease is the most frequent cause of lower gastrointestinal hemorrhage. Up to 75% of diverticular bleeds are self-limited, but in patients with transfusion requirements, massive hematochezia, or hemodynamic instability, colonoscopy may aid in confirming diagnosis, identifying the site, achieving hemostasis, and limiting patient morbidity.<sup>164-168</sup> Locating the precise site of bleeding may be difficult in the face of multiple diverticula and a blood-stained colon. The bleeding diverticular vessel is frequently at the lip of the diverticulum, although bleeding vessels in the dome of the diverticulum may also occur. The use of endoscopic clips and ligation bands for treatment of bleeding diverticula has also been reported.<sup>167,168</sup>

Vascular ectasia or angiodysplasia, commonly in the right colon but also

routinely multicentric, is another common cause of lower gastrointestinal hemorrhage. APC is invaluable in this situation, but care should be taken to avoid excessive distension of the bowel, as the argon gas accumulates and could lead to perforation.<sup>169</sup> Other thermal endoscopic contact probes, as described in previous sections of this chapter, can also be used.

## **Colonoscopic Decompression**

Mechanical or nonmechanical obstructions with unrelieved distention of the colon, in addition to leading to patient discomfort, can result in bowel ischemia, perforation, and death. In patients with colonic distention secondary to acute pseudo-obstruction, Ogilvie syndrome, colonoscopy provides both a diagnostic and therapeutic potential. Underlying etiologies including ischemia, infectious colitis, or an unsuspected obstructing lesion must be excluded.

Conservative treatment is initially indicated in patients with benign abdominal exams, clinical stability, and cecal diameters less than 12 cm. Patients should be maintained NPO, electrolyte imbalances corrected, narcotics withdrawn, and one should consider possible placement of nasogastric and rectal tubes.

Colonoscopic decompression is done without a routine bowel preparation, thus limiting the overall mucosal evaluation. The endoscope is advanced, with limited air insufflation, as far proximally as can be achieved without excessive bowel wall tension, minimizing any risk for perforation. Decompression is then performed upon withdrawal of the colonoscope, suctioning both fluid and intraluminal air. Although the cecum is the optimal endpoint, successful decompression can also be achieved with a less complete colonoscopy. Evaluation of visualized segments of the colon for ischemia and/or mechanical obstruction, possibly requiring stent placement or dilation, is crucial. It must be understood that repeat colonoscopic decompression is routinely required in patients with pseudo-obstruction, and they should be watched closely for several days.

## **Enteral Stents**

Colonic stenting can provide relief of malignant colon obstruction or benign

stricture and serve either as palliation or as a bridge to operation.<sup>170-175</sup> Permanent SEMT stents are commonly used in large bowel obstruction. TTS stents are placed under endoscopic and fluoroscopic guidance. The malignant stricture is located endoscopically, and a guide wire is passed through the narrowed lumen (Figs 5-48 and 5-49). Contrast is injected into the bowel lumen, typically through an ERCP catheter, to define the borders of the stricture. If possible, the proximal and distal extents of the stricture are marked by injecting submucosal contrast. The stent is then placed over the wire, positioned properly, and deployed (Fig. 5-50). SEMS have shown efficacy in reducing the need for emergency operation in acute large bowel obstruction.<sup>170,171,173</sup> In patients who are not candidates for operation, metal stents may serve a palliative purpose.<sup>172</sup> Stenting is generally safe, although perforation has been reported in up to 10% of cases. Migration of stents can also occur, although this is less likely due to tissue in-growth, which can also lead to subsequent stent occlusion.

**FIGURE 5-48** An obstructing sigmoid colon cancer prior to stent placement.

**FIGURE 5-49** Guide wire placement across the obstructing lesion.

**FIGURE 5-50** Following stent deployment, obstruction is relieved as seen

by the large volume of liquid stool.

## FUTURE DEVELOPMENTS

The future developments in endoscopy will be based on advancements of both the tools and the applications available to endoluminal therapy. As surgery becomes less invasive with the advancement of laparoscopy, endoscopy is taking on an increasingly more invasive and therapeutic role. Intraluminal, intramural, and transluminal procedures are being developed with the goal of further supplanting surgery. The interest in natural orifice transluminal endoscopic surgery united surgeons and gastroenterologists with the desire to access the abdominal cavity via naturally existing orifices including the stomach, colon, bladder, and vagina. The obvious limitations to natural orifice transluminal endoscopic surgery were based on the lack of adequate and appropriate endoscopic equipment. The accessories were too flimsy to perform intra-abdominal manipulation of tissue, and the endoscopes were too flexible, inhibiting access and stable positioning once in the abdominal cavity. It was apparent early on that stable platforms would be necessary, along with endoscopic tools for cutting, hemostasis, and tissue manipulation. Scissors, suturing devices, bipolar forceps, and grasping devices are a few of the novel instruments that have been added to the endoscopist's armamentarium.

These tools, however, will more likely impact intraluminal and intramural endoscopic surgery.<sup>136</sup> The ability to perform full-thickness resection, intraluminal anastomoses, and closure of perforations are all procedures that are on the horizon, and in selected patients at certain centers, some procedures such as POEM and POP are already being done. It is imperative that surgeons stay abreast of the numerous advancements in these technologies.

# FUNDAMENTALS OF LAPAROSCOPIC SURGERY

*Fernando Mier • John G. Hunter*

The field of minimally invasive surgery has evolved and grown over the past 3 decades. This was made possible by developments in technology and was fueled by patient demands for less painful operations and quicker postoperative recovery.

Minimally invasive approaches are now widely used for gastrointestinal, bariatric, hernia, and solid organ surgery. It is the surgeon's responsibility to become familiar with the new set of techniques and instruments, as well as knowing when to apply them and when to convert to an open operation. Furthermore, understanding how to use and troubleshoot the equipment used in these procedures is critical for any surgeon who performs minimally invasive surgery.

## PREOPERATIVE CONSIDERATIONS

### **Patient Selection**

As in all surgery, choosing the right operation for the patient is the first step.

Since all laparoscopic surgery of the abdomen requires the use of general anesthesia, the ability to tolerate anesthesia is an absolute requirement. Patients with impaired exercise tolerance or a history of shortness of breath will need a preoperative consultation with a cardiologist or pulmonologist. Patients with severe carbon dioxide (CO<sub>2</sub>) retention can be difficult to manage intraoperatively because the use of carbon dioxide for pneumoperitoneum exacerbates the condition. By increasing the minute ventilation and decreasing the CO<sub>2</sub> pneumoperitoneum from 15 to 8 to 10 mm Hg, one can control metabolic acidosis. Rarely, when these measures are ineffective at controlling hypercarbia, we have resorted to using nitrous oxide (N<sub>2</sub>O) for peritoneal insufflation. While not suppressing combustion (as does CO<sub>2</sub>), N<sub>2</sub>O supports combustion no more than air and has been proven safe for laparoscopic use. A single, blind, randomized trial has demonstrated that N<sub>2</sub>O pneumoperitoneum is associated with decreased postoperative pain compared with CO<sub>2</sub>.<sup>1</sup>

When deciding if a patient is a suitable candidate for a laparoscopic procedure, it is important to assess patient or procedure characteristics that will lengthen the operative time sufficiently to nullify the benefits of laparoscopy. If the laparoscopic operation takes substantially longer than the open equivalent or is more risky, then it is not prudent to proceed laparoscopically. A history of a prior open procedure or multiple open procedures can make access to the abdomen difficult and will be discussed in detail later in this chapter. Adhesions and scarring in the surgical field from prior surgery can make laparoscopic surgery very difficult and may require use of many novel dissecting and coagulating tools. Operating on patients with severe obesity is challenging specifically because torque on transabdominal ports leads to surgeon fatigue and diminishes surgical dexterity. In addition, the long distance from the insufflated abdominal wall to the abdominal organs can make laparoscopic surgery a “far reach.” Special long ports and instruments are available to overcome this difficulty.

Inability to obtain an adequate working space makes laparoscopic surgery impossible. This is encountered most commonly in patients with dilation of the intestine from bowel obstruction. Often, laparoscopic lysis of adhesions for distal bowel obstruction is not technically feasible.<sup>2</sup> Some patients with appendicitis will have sufficient small bowel dilation that laparoscopic access to the right iliac fossa is not possible. Many laparoscopic procedures create

working spaces in extraperitoneal locations. An example is the laparoscopic hernia repair usually performed in the anterior preperitoneal space of Retzius; this may require the use of a balloon dissector to create the space followed by low-pressure insufflation. There are fewer physiologic consequences than with a pneumoperitoneum, but CO<sub>2</sub> can spread widely through the soft tissues, causing subcutaneous emphysema.

## **Patient Positioning**

We rely on gravity for retraction of the abdominal contents to provide exposure. Sometimes this requires steep positional changes, and care must be taken to prevent nerve complications or neuropathies after laparoscopic surgery as in open surgery. Patients must be positioned properly at the beginning of the procedure, making certain that all pressure points are padded. Peroneal nerve injury is caused by lateral pressure at the knee and may occur when the table is “airplaned” to the side with a retractor holding the patient in place. Femoral and sciatic neuropathies are similar in that they are due to compression. Padding the retractor arms and securing the patient to the table can prevent these neuropathies.

It is best if the arms can be tucked for most laparoscopic procedures so that the surgeon may move freely up and down the table in order to line up instruments and the target tissue. This is most important for procedures in the pelvis, where the surgeon will want to stand adjacent to the contralateral thorax. However, even with upper abdominal laparoscopy, tucked arms allow more optimal positioning of instrument columns and monitors. If there is a need to extend the arms on arm boards, one must be very careful to avoid a brachial plexus injury that occurs when the arm is extended greater than 90 degrees at the shoulder. Usually, at the start of a procedure, the arm positioning is safe, but it may change as the patient slides down on the table. For this reason, when reverse Trendelenburg is expected, we place footplates at the feet. This prevents sliding on the table and does not cause any discomfort to the patient because it is much like standing. We secure the ankles as well to be sure they do not “twist” during the procedure. There are footplates available for split-leg tables that can be used when operating on the upper abdomen and steep reverse Trendelenburg is needed.

There may be an increased incidence of deep venous thrombosis after

laparoscopic surgery that is due to pooling of blood in the venous system of the lower extremities. Venous return is impaired by compression of the iliac veins from the elevated intra-abdominal pressure exerted by the pneumoperitoneum. In addition, the positional effects of placing the patient in a steep reverse Trendelenburg position lead to further distension of the venous system. All patients undergoing laparoscopic procedures in reverse Trendelenburg, even short procedures such as laparoscopic cholecystectomy, should have sequential compression devices placed before the procedure begins, although this does not improve femoral blood flow entirely.<sup>3</sup> Patients at high risk for developing deep venous thrombosis should be treated with subcutaneous anticoagulants as either fractionated or unfractionated heparin.<sup>4</sup> This includes patients undergoing lengthy procedures, patients with malignancy, obese patients, patients with a prior history of deep venous thrombosis or pulmonary embolism, and patients in whom ambulation after surgery will be delayed.<sup>5</sup>

Laparoscopic surgery is associated with a high incidence of postoperative nausea and vomiting. A recent review asserts that serotonin receptor antagonists such as ondansetron (Zofran, GlaxoSmithKline) appear to be the most effective and should be considered for routine prophylaxis.<sup>6</sup> Another prospective, blinded, randomized trial showed a decrease in postoperative nausea and vomiting when low-dose steroids were given to all patients.<sup>7</sup> There was no increased infection rate in the group that received steroids. Other preventive measures include ensuring adequate hydration<sup>8,9</sup> and decompression of the stomach with an orogastric tube before the end of the procedure. Intravenous nonsteroidal anti-inflammatory drugs (NSAIDs) such as ketorolac provide superb pain relief and diminish the need for postoperative narcotics, which may help to prevent nausea and vomiting.

## **INTRAOPERATIVE CONSIDERATIONS**

### **Port Placement**

#### **SITE SELECTION**

Proper placement of ports is important to facilitate completion of the laparoscopic procedure. The location of port sites depends on the type of

procedure; the primary port should be placed with this in mind. We do not always place the primary port at the umbilicus but rather judge which site is best for the camera or which is the safest site for the primary puncture in a previously operated abdomen. The first laparoscopic port can be positioned anywhere in the abdomen after pneumoperitoneum has been created. The additional or secondary ports should not be placed too close to each other. The optimal pattern of port placement should form an equilateral triangle or a diamond array around the operative field. This “diamond of success” takes into account the optimal working distance from the operative target for each instrument and the telescope (Fig. 6-1). In laparoscopy, the standard instrument length is 30 cm. To produce a 1:1 translation and movement from the surgeon’s hands to the operative field, the fulcrum of the instrument should be 15 cm from the target. A similar separation of the 2 working ports (surgeon’s left and right hands) ensures that these 2 instruments will not be involved in “sword fighting” and that the angle between the 2 instruments at the target will be optimal (between 60 and 90 degrees). The secondary port site is chosen, and the abdominal wall is transilluminated to avoid large abdominal wall vessels.<sup>10,11</sup> The trocar is watched laparoscopically as it enters into the abdomen, and care is taken to avoid injuring the abdominal contents. During the procedure, the area beneath the primary trocar site is inspected for unexpected injuries.

**FIGURE 6-1** The “diamond of success” for optimal placement of laparoscopic ports. (Reproduced with permission from Hunter JG, Trus TL, Branum GD, et al: Laparoscopic Heller myotomy and fundoplication for achalasia, *Ann Surg.* 1997 Jun;225(6):655-664.)

## **PORT CHARACTERISTICS**

There is a wide variety of ports, each with different characteristics, available on the market. The bladed trocars cut the abdominal wall fascia during entry. Because the nonbladed trocars do not cut the abdominal wall as much, they

make smaller defects in the abdominal wall and may be less prone to hernia formation in the future. The most commonly used bladed ports have a shield that retracts as the blade is pushed through the fascia of the abdominal wall, and then it engages once inside the abdomen. When first introduced to the market, the shields were called safety shields, but they have lost that designation because the shield provides little protection. The nonbladed trocars come in many forms. One nonbladed trocar is used in the Step system (Covidien, Mansfield, MA), a modified Veress needle that locks inside an expandable sheath. Once inside the abdomen, the Veress needle is removed, and a blunt port is passed into the sheath that guides the port by dilating radially.<sup>12</sup> The Ethicon nonbladed trocar has a rough edge of plastic that is twisted and pushed through the layers of the abdominal wall. None of these technologies have proven safer than the more economical reusable nonshielded bladed trocar systems made by most instrument companies (Fig. 6-2).

**FIGURE 6-2** Various trocars for the introduction of laparoscopic ports through the abdominal wall. There are bladed and nonbladed types. Of the bladed trocars, there are shielded and nonshielded types. The Veress needle with a radially dilating sheath used in the Step system is an example of a nonbladed trocar. (Reproduced with permission from Chandler JG, Corson SL, Way LW. Three spectra of laparoscopic entry access injuries, *J Am Coll Surg.* 2001;April;192(4):478–490.)

Important characteristics of a port need to be considered when choosing which port to use. The advantage of a port introduced with a nonbladed trocar is that the abdominal wall defect is smaller, which does not allow gas to leak from the abdomen during the procedure. Because the fascia is not cut, there is a lower risk of port-site hernia, and the fascia of most 10-mm incisions does not have to be closed. In addition, these ports tend not to slip out of the abdominal wall during manipulation. Other considerations when choosing a port are the size of the external component, the smoothness of entry and exit of the instruments and specimens, and whether an external reducer cap is needed.

## **ACCESS OR PLACEMENT OF THE FIRST PORT**

No single access technique has emerged as the safest and best technique.<sup>13,14</sup> The techniques for abdominal access include direct-puncture and open-access techniques.<sup>15</sup> The direct-puncture technique can be performed either by direct trocar insertion without pneumoperitoneum or by first obtaining pneumoperitoneum using a Veress needle and then inserting the first trocar directly. The latter technique is performed most commonly in the United States. Each technique has a specific pattern of complications that must be considered when choosing among them.

The Veress needle access was first described in 1938.<sup>16</sup> This technique involves direct insertion of a needle into the peritoneum after lifting the abdominal wall with towel clips or a firm grip. The optimal site for insertion of the Veress needle is through the central scar at the umbilicus. One can make either a vertical skin incision through the umbilicus, hiding the incision in the base, or a curvilinear incision in an infraumbilical or supraumbilical position. Nevertheless, insertion of the Veress needle should be aimed at the central scar, where the layers of the abdominal wall are fused. This does not mean, though, that the first port inserted must be at the umbilicus. Advocates state that the benefits of this technique are the ability to place the initial port anywhere on the abdomen, that it is relatively quick, and that the skin and fascial openings are smaller, which prevents CO<sub>2</sub> leakage during the procedure.

For safe Veress needle insertion, first one must be certain to check the stylet and needle patency, especially when reinserting it after an unsuccessful initial pass. The Veress needle is available either as a reusable or disposable

product and comes in 2 sizes, both long and short. The spring mechanism that pushes the stylet out, thus protecting bowel from the needle, must be tested when using the reusable Veress needle.

The safest technique requires stabilizing the abdominal wall (we prefer penetrating towel clips in nonobese patients). It is important to have control over the force and depth of insertion of the needle. This is aided by either placing your wrist against the patient's abdomen or using the nondominant hand to support the hand wielding the needle. It is sometimes necessary to raise the operating table to achieve the proper control. One must be mindful of the fact that the most common catastrophic complication from Veress needle insertion is injury to major vessels. The trajectory of the needle should not be angled toward the aorta or iliac vessels (Fig. 6-3).

**FIGURE 6-3** Proper Veress technique in the left upper quadrant using the dominant hand with the wrist stabilized on the patient. The nondominant hand is used to stabilize the abdominal wall.

After placement of the Veress needle, one should perform an aspiration test by connecting a syringe filled with saline to the top of the Veress needle and aspirate. Aspiration of air, blood, or bile signifies incorrect placement and should prompt serious concern for an unexpected injury. If there is no

aspirate, saline should be injected and should flow easily. The saline should flow down the Veress needle into the peritoneal cavity without pressure, a qualitative measure. Removing the plunger from the syringe and watching the saline level drop briskly may achieve a quantitative assessment of patency. If the saline flows slowly or not at all, the needle is likely in the wrong position, that is, up against an intra-abdominal organ, or it is in the preperitoneal space. Alternatively, the tip may be occluded with fat, or the system may have an “air lock.” To test this, inject a little bit of fluid again gently, and retest by removing the plunger and allowing the saline to drop into the abdomen.

The Veress needle then is connected to the insufflation tubing. The expected initial insufflation pressure, assuming proper placement, should be less than 5 to 6 mm Hg. Abnormally high insufflation pressure is an indication that something is not right.<sup>17</sup> Because the insufflator is usually set to allow a maximum pressure of 15 mm Hg, a value greater than this suggests that the patient is not anesthetized adequately and is contracting his or her abdominal muscles. If the insufflator records a pressure of 15 mm Hg, there are a few explanations. The most ominous cause would be incorrect placement into an intra-abdominal organ. More likely, the Veress needle tip may be against omentum or is in the preperitoneal space. The insufflation line may be occluded at the stopcock, or there may be a kink in the tubing.

Direct trocar insertion without first establishing pneumoperitoneum is not used as frequently because many surgeons think that it is dangerous given that the bladed trocar must be pushed into the abdomen with significant force to penetrate the abdominal wall. Surgeons unfamiliar with the technique worry about injury to bowel and vessels when using excessive force. There are, however, many surgeons who perform this technique with no increased complication rate, confirming its safety.<sup>18-22</sup> Still other surgeons believe that the open-access technique that involves a “minilaparotomy” is the safest.<sup>15,23-25</sup>

The open, or Hasson, technique was first described in 1974.<sup>15</sup> A 1- to 2-cm skin incision is made at the umbilicus, and the soft tissue is divided to identify the abdominal wall. The fascia and muscles are opened with a knife, and the peritoneum is identified and grasped with Kocher or Allis clamps. A 0-0 absorbable suture is placed through the fascia, and the Hasson port is secured to the fascial sutures. Later, these sutures can be used to close the abdominal wall. The insufflation tubing is attached to the sideport of the trocar, and the abdomen is insufflated rapidly to 15 mm Hg.

Newer trocars, called *optical trocars*, allow visualization of the tip of the trocar as it passes through the layers of the abdominal wall (Fig. 6-4). A straight-viewing 0-degree scope is placed inside a clear trocar that is available with and without a bladed tip. Safe introduction of an optical trocar is a skill that requires judgment and experience and can best be learned in patients with no prior surgery after insufflation is established. Success depends on the operator's ability to see each of the layers of tissue, although visualization does not imply safety.<sup>26</sup> It is useful for the surgeon to have command of several access techniques because there is no single technique that is best for all circumstances.<sup>27</sup>

**B**

**FIGURE 6-4** Optical trocar. (All rights reserved. Used with the permission of Medtronic.)

## **DIFFICULT ACCESS**

Access can be the most challenging aspect of the procedure in some patients no matter which technique is used. This is especially true in obese patients. First, the site of the central scar is often judged inaccurately because the umbilicus is in a caudad position owing to the loose panniculus. Additionally, there is an increased distance between the skin and the abdominal wall fascia. The Veress needle may not penetrate the abdominal wall. If an open-access technique is chosen, it may be difficult to expose the abdominal wall through a small incision. Degenerated fascia in obese patients will make the abdominal wall bounce against the needle or finger, making its identification difficult. Raising the skin with penetrating towel clips does not facilitate this exposure and, in fact, distorts the anatomy, making it more difficult to identify the fascia. Sometimes a modified technique described by Vakili and Knight can be helpful.<sup>28</sup> This is a combination of open and Veress techniques in which a small skin incision is made in obese patients. Kochers are used to hold the abdominal wall fascia up, and a Veress needle is passed through the abdominal wall.

Access is also difficult in patients who have had prior surgery through a midline incision. In these patients, it is unsafe to perform the Hasson technique through the midline site because of the potential for adhesions of bowel to the posterior surface of the abdominal wall. Injury can occur when dividing the fascia or when sweeping adhesions away with a finger. It is difficult to perform the open technique at sites other than the umbilicus because of the multiple layers of the abdominal wall. In these patients, we prefer to place the Veress needle in the next safest location, which is the left upper quadrant along the costal margin. One must be certain that the table is flat because the spleen and liver are injured more easily in patients in the reverse Trendelenburg position. One must be certain that the stomach is decompressed with an orogastric tube before inserting the Veress needle in the left upper quadrant. Once insufflation is obtained, a port can be placed into the abdomen away from the previously operated field. We prefer entering with a 5-mm step port followed by a 30-degree 5-mm scope. Other surgeons recommend use of optical trocars in this situation.

## **FASCIAL CLOSURE**

Care should be taken to prevent port-site hernias, which occur in 0.65% to 2.80% of laparoscopic gastrointestinal operations,<sup>29</sup> because they can lead to

bowel obstruction, incarceration, and/or Richter hernias. All defects created with a 10-mm or greater bladed trocar should be closed, although this is not necessary when using some of the newer nonbladed trocars that create smaller fascial defects.<sup>30,31</sup> Most 5-mm defects do not require fascial closure in adults, although there are reported cases of hernias at these sites.<sup>9,32,33</sup> Because there is always a possibility of formation of a port-site hernia, the smallest possible port always should be used. When a port is manipulated excessively or has to be replaced multiple times, there may be a larger than expected fascial defect that may require closure. Additional recommendations are to place ports lateral to the rectus muscles when possible.<sup>34</sup> At the conclusion of the procedure, removal of ports from the abdomen should be observed to be certain that omentum or abdominal contents are not brought up through the abdominal wall.

Fascial closure can prevent trocar-site hernia.<sup>35</sup> A number of port-site closure devices have been developed<sup>36</sup> because small laparoscopic incisions make it difficult to close the abdominal wall with round needles. The closure devices function like crochet needles, passing a suture through the abdominal wall on one side of the fascial incision. The suture end is released intra-abdominally under laparoscopic visualization, and the needle is removed. The needle is replaced (without suture) on the other side of the incision, and the free end is secured and pulled back out through the abdominal wall. A knot is then tied that closes the trocar site, as viewed laparoscopically (Fig. 6-5).

**FIGURE 6-5** Using the inlet device, the suture is passed through the abdominal wall on one side of the fascial incision. The suture end is released intra-abdominally under laparoscopic visualization, the suture then is pulled out on the other side of the incision using the device, and a knot is tied.

## TROCAR INJURY

The overall risk of a trocar injury to intra-abdominal structures is estimated to be between 5 in 10,000 and 3 in 1000.<sup>14</sup> Almost all injuries occur during primary trocar insertion. According to Chandler and colleagues,<sup>14</sup> the most commonly injured organ is the small bowel (25.4%), followed by the iliac artery (18.5%), colon (12.2%), iliac vein (8.9%), mesenteric vessels (7.3%), and aorta (6.4%). All other organs were injured less than 5% of the time. The mortality from trocar injury is 13%, with 44% owing to major vessel injury, 26% to bowel injury with delayed diagnosis, and 20% to small bowel injury. Major vascular injuries are noticed immediately and require rapid conversion to laparotomy. They are managed by applying pressure when possible to allow the anesthesia team to maintain and correct volume and prepare for

rapid blood loss. Then the surgeon gets control of inflow and outflow to permit repair of the injury. Unfortunately, many bowel injuries are not recognized at the time of the procedure, and nearly half are not noticed until more than 24 hours postoperatively. This obviously leads to severe sequelae and may be prevented by careful dissection and inspection at the conclusion of the procedure.

## EQUIPMENT

The complexity of minimally invasive surgery has increased and so has the technology surrounding it. This technology is generally taken for granted; however, as surgeons who perform minimally invasive surgery, we have the obligation to understand all of the technology that surrounds our specialty. This allows the surgeon to optimize the safety, cost-effectiveness, and efficiency of these procedures.

The imaging system is composed of the following 7 components: laparoscope, light source, fiber-optic light cable, camera head, video signal processor, video cable, and monitor. This results in numerous different places where the image or picture can be compromised. Understanding the video system will allow the surgeon to do basic troubleshooting.

## Laparoscopes

Laparoscopes come in a variety of shapes and sizes, offering several different angles of view. The standard laparoscope consists of a metal shaft 24 cm in length containing a series of quartz-rod lenses that carry the image through the length of the scope to the eyepiece. The telescope also contains parallel optical fibers that transmit light into the abdomen from the light source via a cable attached to the side of the telescope. Telescopes offer either a straight-on view at 0 degrees or can be angled at 25 to 30 or 45 to 50 degrees. The 30-degree telescope provides a total field of view of 152 degrees compared with the 0-degree telescope, which only provides a field of view of 76 degrees (Fig. 6-6).

**FIGURE 6-6** The 30-degree telescope (**A**) provides a total field of view of 152 degrees compared with the 0-degree telescope (**B**), which provides a field of view of only 76 degrees. (© KARL STORZ SE & Co. KG, Germany.)

The most commonly used telescope has a diameter of 10 mm and provides the greatest light and visual acuity. The next most commonly used telescope is the 5-mm laparoscope, which can be placed through one of the working ports for an alternative view. Smaller diameter laparoscopes, down to a 1.1-mm scope, are available and are used mostly in children. They are not used commonly in adult patients because of an inability to direct enough light into the larger abdominal cavity. The camera is attached to the eyepiece of the laparoscope for processing.

## Light Sources

Simply put, without light there would be no laparoscopy. High-intensity light is created with bulbs of mercury, halogen vapor, or xenon. The bulbs are available in different wattages—150 and 300 W—and should be chosen based on the type of procedure being performed. Because light is absorbed by

blood, any procedure in which bleeding is encountered may require more light. We use the stronger light sources for all advanced laparoscopy. Availability of light is a challenge in many bariatric procedures where the abdominal cavity is large. The light is carried to the fiberoptic bundles of the laparoscope via a fiberoptic cable. The current systems create even brightness across the field. It is important to mention that a lighted laparoscope or fiberoptic cable can burn through the drapes or the patient's skin after less than 30 seconds of direct contact. This must be avoided.

## Video Camera

A high-resolution video camera is attached to the eyepiece of the telescope and acquires the image for projection on the monitor. The video image is transmitted via a cable to a video unit, where it is processed into either an analog or a digital form. Analog is an electrical signal with a continuously varying wave or shift of intensity or frequency of voltage. Digital is a data signal with information represented by ones and zeros and is interpreted by a computer. These are the methods by which the picture is transmitted to the video monitor. The camera and cable are designed so that they can be sterilized in glutaraldehyde.

The camera iris directly controls the amount of light processed by opening the aperture of the camera. The gain controls the brightness of the image under conditions of low light by recruiting pixels to increase signal strength. Clearly, this step results in some loss of image resolution. This increases light but results in a grainy picture with poorer resolution. It also may create a loss of color accuracy owing to amplification of the noise-to-signal ratio.

Three-dimensional camera systems have been introduced for over a decade without substantial interest. These systems usually required surgeons to wear special glasses or head-up displays that allowed the integration of two image channels into a single image. Multiple authors have advocated for the use of 3-dimensional camera systems; however, limited data support the cost-effectiveness, and side effects for surgeons can occur with use, including eye strain, headache, dizziness, and disorientation. Recent advancements in technology may stimulate the rebirth of this concept. With newer systems, 3-dimensional laparoscopy appears to improve speed and decrease performance errors compared to traditional (2-dimensional) laparoscopy. In addition, the side effects from 3-dimensional laparoscopy seem to have been reduced with

newer technology. However, most studies comparing these 2 image systems were done in a simulated setting, and more clinical studies are needed.<sup>37</sup>

## **Video Monitors**

High-resolution video monitors are used to display the image. Optimal monitor size varies but ranges from 19 to 21 in. Smaller monitors may be used if placed close to the operative field. Larger monitors provide little advantage outside of a display setting. Cathode-ray monitors (analog) are being replaced rapidly by flat-panel (digital) displays with excellent color and spatial resolution. These monitors may be positioned optimally when hung from the ceiling on light booms.

## **Insufflators**

An insufflator delivers gas from a high-pressure cylinder to the patient at a high rate with low and accurately controlled pressure. Some insufflators have an internal filter that prevents contamination of the insufflator with the gas from the patient's abdomen and similarly filters any particulate matter that may be freed from the inside of an aging gas cylinder. Others require use with disposable insufflator tubing that has a filter on it. Some insufflators provide heated or humidified gas, but clinical benefit due to these theoretically desirable features has yet to be proven.

## **INSTRUMENTATION**

The instruments used in laparoscopic surgery are similar to those of open surgery at the tips but are different in that they are attached to a long rod that can be placed through laparoscopic ports. Standard-length instruments possess a 30-cm-long shaft, but longer instruments (up to 45 cm in length) have been developed for bariatric surgery. The handles come in many varieties and must be chosen based on comfort and ergonomics, as well as the need for a locking or nonlocking mechanism. The shaft of most hand instruments is 5 mm wide; however, some specialized dissectors are available only in a 10-mm width. Pediatric laparoscopy instrumentation is generally 2 to 3 mm in diameter (Fig. 6-7). There are many types of bowel graspers with

different types of teeth (Fig. 6-8). The most atraumatic grasper has small, smooth teeth like a Debakey forceps. This has the advantage of not tearing the tissues and can be used on almost all organs. We use the Hunter grasper (Jarit), which, like a Debakey, can be used to grasp bowel and also can be used to grasp a needle. An additional benefit is that the tip is blunt and not prone to causing tissue trauma. Another commonly used bowel grasper is the Glassman (Storz), which is atraumatic and is slightly longer than the standard-sized Hunter grasper. It is fenestrated and cannot be used to grasp a needle. For some tissues, these instruments do not “grip” well enough, and bigger teeth or a different tip, such as those of Allis and Babcock clamps, is preferred. We reserve these larger-toothed instruments only for organs that are being removed, such as the gallbladder, or for thicker tissue, such as the stomach. The rule is to be gentle because small injuries can take a relatively long time to fix laparoscopically.

**FIGURE 6-7** Instrument handles and tips. (© KARL STORZ SE & Co. KG, Germany.)

**FIGURE 6-8** Atraumatic bowel graspers.

The most commonly used dissector is the Maryland dissector (Fig. 6-9). It is useful for dissecting small ductal structures such as the cystic duct and can be used when dissecting vessels. Another use for the Maryland dissector is that it can be attached to monopolar cautery and used to grasp and cauterize a bleeding vessel (this should not be done with bowel graspers). The Maryland dissector should not be used to grasp delicate tissue because too much pressure is applied over a very small area, much like erroneously using a Kelly clamp for grasping tissue. Very delicate right-angle dissectors can be used for renal, adrenal, and splenic vessels and are less traumatic than the Maryland dissector because there are no ridges.

**FIGURE 6-9** Maryland dissector.

## Hemostasis

Hemostasis can be achieved using current from a monopolar electrosurgical generator applied to common instruments and controlled with a foot pedal. One of the most useful instruments for dissection is a disposable hook attached to the hand-held Bovie device for dissection (Valley Labs/Conmed and others). If a vessel has been transected and is bleeding but is too large to control with monopolar electrosurgery, a pretied lassolike suture (Endo-loop, Ethicon Endosurgery) can be helpful. Laparoscopic clips are handy for small identifiable vessels but should not be used when a vessel is not identified. The clip is only 7 mm in length and is not useful for vessels larger than this. When the vessel is not clearly identified but the bleeding site is, ultrasonic shears and some bipolar instruments such as the LigaSure device (Covidien, Mansfield, MA) can be helpful. These instruments have the advantage of facilitating dissection while providing hemostasis for larger bleeding vessels.

## Monopolar Electrosurgery

Although hemostasis is obtained using the same electrosurgical generator that is used in open surgery, there are hazards that are unique to minimally invasive surgery. The most frequently used method of delivering electrosurgery is monopolar. The desired surgical effect is hemostasis, and this is obtained by production of heat. Alternating current at 50,000 Hz (household current is 60 Hz) is generated and travels through an active electrode. The active electrode can be a Bovie tip in open surgery or, in laparoscopy, an instrument that is connected to the generator by the monopolar cord. The current passes into the target tissue at sufficiently high current density to cause a great deal of heat. Depending on tissue heating, coagulation, fulguration, or vaporization of the tissue occurs. The circuit is completed by the return of the electrons broadly spread through the tissue (insufficiently dense to cause any adverse effect) back to the generator via the return electrode (grounding pad).

In open surgery, monopolar current sometimes is passed from the active electrode (Bovie tip) to the patient via another conductive instrument, the forceps. This is called *direct coupling*. In laparoscopy, it is not prudent to touch the active electrode (an activated instrument) on or near other conductive instruments within the abdominal cavity, that is, the laparoscope

or other working instruments. Direct coupling in minimally invasive surgery always should be avoided because injury may occur out of the surgeon's field of view. It is also not prudent to activate the generator in "midair" because the current may travel out of the surgeon's field of view to a crack in the insulation of a laparoscopic instrument. This results in transfer of current to a small area that generates heat and can produce an injury. All laparoscopic instruments should be checked for cracks in the insulation before being used.

## **Ultrasonic Shears**

Before the introduction of ultrasonic shears, larger vessels had to be tied off individually. This was very tedious laparoscopically, especially with the division of short gastric vessels during fundoplication. The development of the ultrasonic shears was revolutionary, allowing surgeons to divide larger vessels quickly and dissect simultaneously. Ultrasonic energy or sound waves are used to ablate, cauterize, and cut tissues. A generator produces a 55.5-kHz (55,500 Hz) electrical signal that travels via a cable to a piezoelectric crystal stack mounted in the transducer. The crystal stack converts the electrical signal to mechanical vibration at the same frequency. The ultrasonic vibration is amplified as it traverses the length of the titanium probe that is the active blade of the scalpel. Shearing forces separate tissue and heat the surrounding tissue, thereby coagulating and sealing blood vessels without burning. Damage to adjacent tissues is low, although the active blade can become quite hot, and burn injuries can occur.

## **Bipolar Electrosurgery**

Bipolar electrosurgery coagulates tissue by passing a high-frequency, low-voltage electric current between 2 directly apposed electrodes. Laparoscopic general surgeons use it much less frequently because an additional maneuver must be made to divide the tissue. The LigaSure, a newer bipolar device, coagulates larger vessels (up to 7 mm in diameter) and seals tissue and has a knife available for subsequent division of the tissue between the jaws of the forceps. The instrument makes a sound when the tissue within the jaw has been coagulated safely. The advantage is that division of larger vessels can be performed safely. Unfortunately, it is relatively slow to use as a dissecting instrument, and the tip is not very useful for dissection because it is straight

and wide.<sup>38</sup> It does not produce a large amount of heat, and damage to surrounding tissues is low.

## SUTURING

Intracorporeal suturing may be out of the realm of the fundamentals of a laparoscopic surgery chapter. However, obtaining this skill is critical for successful performance of many laparoscopic procedures. A fundamental skill of laparoscopic surgery is the ability to place a suture accurately and tie a knot with a needle holder and a standard surgical suture. This skill can be mastered easily with a training box. Various suture aids have been developed, such as the EndoStitch (USSC), and can be used as a substitute. However, these devices are expensive, and the range of suture and needle sizes and types is limited. Many surgeons believe that an extracorporeal knot is acceptable because it is easier to create a knot outside the patient and slide it down with a knot pusher. In most settings, this is not true because securing an extracorporeal knot creates “sawing” of the tissue as the suture is pulled through or around it. This often results in tissue tearing. For interrupted suturing, the sliding square knot is the simplest most secure knot to master (Fig. 6-10).

## THE PHYSIOLOGIC EFFECTS OF PNEUMOPERITONEUM

The pneumoperitoneum has many effects that are only partially known despite years of study in humans and in animal models. There are effects resulting from the pressure within the abdomen and effects resulting from the composition of the gas used, generally CO<sub>2</sub>. The effects of pneumoperitoneum can be divided into local effects and systemic effects from hypercarbia.

## Local Effects

The pressure within the abdomen from pneumoperitoneum decreases venous return by collapsing the intra-abdominal veins, especially in volume-depleted patients. This decrease in venous return may lead to decreased cardiac output. To compensate, there is an elevation in the heart rate, which increases myocardial oxygen demand. High-risk cardiopulmonary patients cannot always meet the demand and may not tolerate a laparoscopic procedure.<sup>39</sup> In volume-expanded healthy patients with full intra-abdominal capacitance vessels (veins), the increased intra-abdominal pressure actually may serve as a pump that increases right atrial filling pressure.<sup>40</sup>

Through a different mechanism associated with catecholamine release triggered by CO<sub>2</sub> pneumoperitoneum, heart rate rises along with systemic vascular resistance. This may lead to hypertension and impair visceral blood flow. It is not uncommon after the induction of pneumoperitoneum for the heart rate to rise along with the mean arterial pressure. This leads to a minimal effect in a young, healthy patient<sup>41</sup>; however, in elderly, compromised patient, the strain on the heart can lead to hypotension, end-organ hypoperfusion, and ST-segment changes.

To minimize the cardiovascular effects of pneumoperitoneum, it is important that patients have adequate preoperative hydration. By insufflating the abdomen slowly, the vagal response to peritoneal stretching may be diminished and vagally mediated bradycardia avoided. Additionally, if cardiovascular effects are noted during insufflation or during the maintenance of pneumoperitoneum, the insufflation pressures should be lowered from the usual 15 to 12 mm Hg, or pneumoperitoneum should be evacuated while the anesthesiologist sorts out the cardiovascular changes. Taking patients out of the steep reverse Trendelenburg position can help to increase venous return. Sometimes these effects can last for hours after desufflation.

The elevated intra-abdominal pressures restrict movement of the diaphragm, which reduces diaphragmatic excursion. This is represented as a decrease in functional residual capacity and pulmonary compliance and an increase in inspiratory pressure. Overall, there is no significant change in the physiologic dead space or shunt in patients without cardiovascular compromise. Bardoczky and colleagues<sup>42</sup> studied 7 healthy patients undergoing laparoscopy with CO<sub>2</sub> pneumoperitoneum. After the induction of

pneumoperitoneum, peak airway and plateau airway pressures increased by 50% and 81%, respectively. Bronchopulmonary compliance decreased by 47% during the period of increased intra-abdominal pressure. After desufflation, peak and plateau pressures remained elevated by 36% and 27%, respectively, for 2 to 6 hours. Compliance remained at 86% of the preinsufflation value.

Urine output often is diminished during laparoscopic procedures and usually is the result of diminished renal blood flow owing to the cardiovascular effects of pneumoperitoneum and direct pressure on the renal veins.<sup>43</sup> In addition to direct effects, elevated intra-abdominal pressure results in release of antidiuretic hormone (ADH) by the pituitary, resulting in oliguria that may last 30 to 60 minutes after the pneumoperitoneum is released. Aggressive fluid hydration during pneumoperitoneum increases urine output.<sup>43</sup> Positional changes can affect the collection of urine in the Foley catheter and must be taken into consideration if anuria is noted.

## **Systemic Effects**

### **HYPERCAPNIA**

Hypercapnia and acidosis are seen with pneumoperitoneum and are likely due to the absorption of CO<sub>2</sub> from the peritoneal cavity. In the ventilated patient, increasing respiratory rate or vital capacity must compensate for these changes. At extremes, increases in tidal volume may risk barotraumas, and increases in respiratory rates diminish time for gas mixing, increasing dead-space ventilation. A first steady state in PaCO<sub>2</sub> is reached around 15 to 30 minutes after introduction of the pneumoperitoneum. After this period, increases in PaCO<sub>2</sub> suggest that existing body buffers (>90% exist in bone) have been exhausted. Sudden increases may be related to port slippage and extraperitoneal or subcutaneous diffusion of CO<sub>2</sub>. This will resolve spontaneously once the port is repositioned.

Hypercapnia and acidosis that are difficult to control may follow, especially in elderly patients, those undergoing long operations, and patients with pulmonary insufficiency. Our response to this is to desufflate the abdomen for 10 to 15 minutes. If reinsufflation results in recurrent hypercapnia, then we change insufflation gases (see above) or convert to an

open operation. Acidosis can persist for hours after desufflation. Other complications of pneumoperitoneum that are less frequent but may be life threatening include CO<sub>2</sub> embolism and capnothorax.

## **CARBON DIOXIDE EMBOLUS**

The incidence of clinically significant CO<sub>2</sub> embolism is very low, although recent reports using more sensitive tests suggest that tiny bubbles of gas are present commonly in the right side of the heart during laparoscopic procedures. Clinically important CO<sub>2</sub> embolism may be noted by unexplained hypotension and hypoxia during the operation. There is a characteristic millwheel murmur that can be detected with auscultation of the chest. This is produced by contraction of the right ventricle against the blood–gas interface. Usually the anesthesiologist notes an exponential decrease in the end-tidal CO<sub>2</sub>, which is consistent with complete right ventricular outflow obstruction. The mainstays of treatment are immediate evacuation of the pneumoperitoneum and placement of the patient in the left lateral decubitus, head down (Durant) position. This allows the CO<sub>2</sub> bubble to “float” to the apex of the right ventricle, where it is less likely to cause right ventricular outflow tract obstruction. It is important to administer 100% oxygen and hyperventilate the patient during this period. Additionally, aspiration of gas through a central venous line may be performed.

## **CAPNOTHORAX/PNEUMOTHORAX**

Capnothorax can be caused by CO<sub>2</sub> escaping into the chest through a defect in the diaphragm or tracking through fascial planes during dissection of the esophageal hiatus. It also can be due to opening of pleuroperitoneal ducts most commonly seen on the right side. Pleural tears during fundoplication can lead to pneumothorax, and additionally, the usual causes of pneumothorax, such as ruptured bullae, may be the etiology. The effects of CO<sub>2</sub> gas in the chest usually are noted as decreased O<sub>2</sub> saturation (a result of shunting induced by lung collapse), increased airway pressure, decreased pulmonary compliance, and increases in CO<sub>2</sub> and end-tidal CO<sub>2</sub>. The treatment is to desufflate the abdomen, stop CO<sub>2</sub> administration, correct the hypoxemia by adjusting the ventilator, apply positive end-expiratory pressure

(PEEP), if possible, and decrease the intra-abdominal pressure as much as possible. The recommendation is to avoid thoracentesis because this usually resolves with anesthetic management. We generally evacuate the capnothorax directly at the end of the procedure with a red rubber catheter placed across the diaphragm (through the pleural defect) and brought out a trocar site. The external end of the catheter is placed under water as the lung is inflated and then removed from the water when the bubbles stop. We do not obtain chest radiographs in the recovery room after these maneuvers if there is no evidence of hypoxia on 2 L/min of O<sub>2</sub> flow. Patients should be maintained on supplemental oxygen to help facilitate absorption of the CO<sub>2</sub> from the pleural space.

## **SPECIAL CONSIDERATIONS**

### **Pregnancy**

There are many advantages of using laparoscopy in a pregnant patient. These include decreased fetal respiratory depression, lower risk of wound complication, and improved visualization with decreased uterine mobilization or irritation. The later may result in lower rates of spontaneous abortion and preterm delivery. Historical recommendations were to delay any surgical intervention until the second trimester; however, recent literature has shown that laparoscopic surgery can be performed safely during any trimester. Intra-abdominal access can be safely accomplished with an open (Hasson) technique, and the location of access should be adjusted according to uterine fundal height. Finally maternal and fetal monitoring should be part of any pregnant patient's care and should continue throughout the hospitalization. Obstetric consultation should be obtained; however, it should not delay the treatment of any acute abdominal process because such delay may increase the risk of maternal and fetal morbidity and mortality.<sup>44</sup>

## **CONCLUSIONS**

Although minimally invasive surgery is firmly established in modern surgery, its safe performance can be ensured only with mastery of the basics. Basic

skills used in laparoscopy include evaluation of a patient based on a new set of considerations, safe use of devices for abdominal access and instrumentation, and mastery of complex manual skills and intraoperative assessment of novel physiologic parameters. Laparoscopic surgery has become the gold standard approach to several operations and will only be employed more in the future as technical innovations allow us to care for our patients in new and better ways.

# MINIMALLY INVASIVE APPROACHES TO CANCER

*Jonathan C. King • Herbert J. Zeh, III*

## INTRODUCTION

Laparoscopy has evolved tremendously in the past 40 years, from a diagnostic tool to a surgical platform with nearly as many therapeutic applications as open surgery. In the most capable hands the only current primary limitation to minimally invasive approaches to most gastrointestinal (GI) cancers is the size of the incision required for removal of the specimen(s). However, it is clear that the most advanced techniques require extensive training and operative skill to perform safely and consistently on unselected patients. Given these skill sets are not realistically achievable by many surgeons, some techniques such as minimally invasive esophageal, hepatic, and pancreatic resections will remain in the purview of highly specialized practitioners. More recently, laparoscopy is being supplanted by the addition of the robotic minimally invasive platform with its promise of improved surgical exposure and increased instrument dexterity. It seems likely that with the continued advancement of technology in the field, the frontier of minimally invasive surgery will continue to expand.

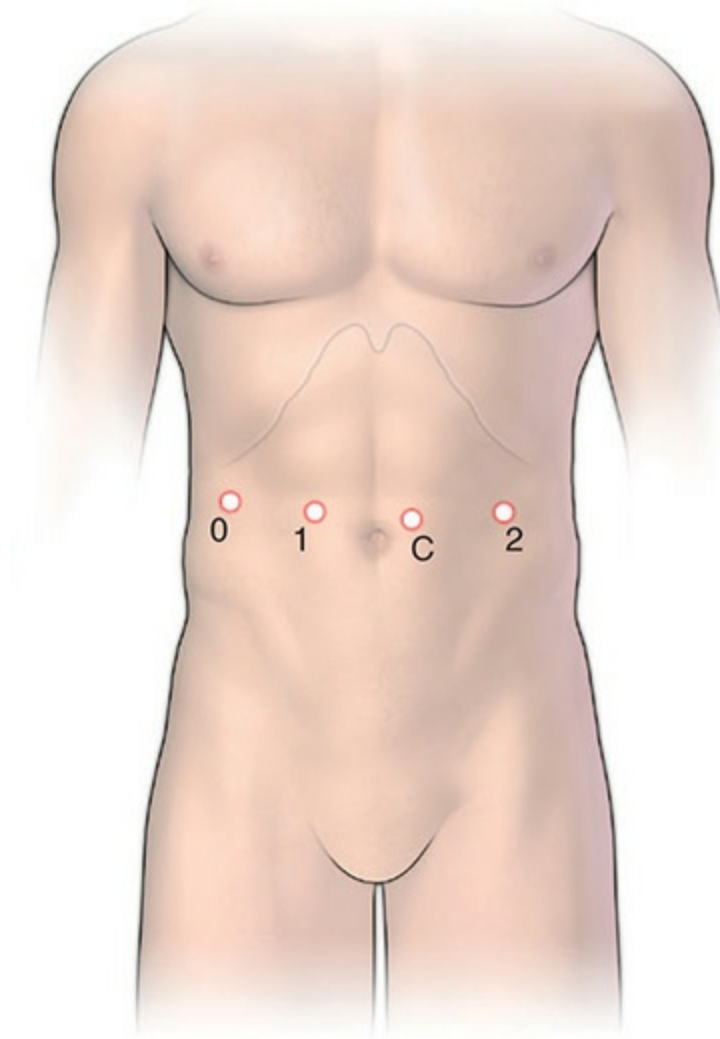

While advanced laparoscopic and robotic-assisted techniques require highly specialized skill sets, diagnostic and staging laparoscopy techniques have broad clinical applicability to many GI malignancies, are easily performed, and often provide valuable information that directly impacts clinical decision making. Here we describe the use of laparoscopy in the diagnosis and treatment of common GI malignancies.

## **DIAGNOSTIC/STAGING LAPAROSCOPY**

Preoperative history and physical examination are performed with particular attention to cardiopulmonary comorbidities, coagulopathy, and overall functional/nutritional reserve as with any open surgery. As laparoscopy is nearly always performed under general anesthetic and with CO<sub>2</sub> insufflation of the abdomen, there can be significant physiologic stress, particularly in patients with limited cardiopulmonary reserve. In most cases these comorbidities may be mitigated, allowing safe conduct of operation.

The patient is positioned supine, pressure points padded, and secured to the operating table. Arms may be extended or tucked according to surgeon preference and region(s) of the abdomen to be explored. After induction of anesthesia with medical paralysis, the peritoneum is accessed via either an open (Hasson) or closed (Veress or optical separator trocar) technique. Initial access is commonly at the umbilicus for Hasson and Veress techniques when there have been no prior operations, otherwise access may be gained through a paramedian incision (Fig. 7-1). Optical separators are best utilized in the left upper quadrant through the rectus muscle where adhesions are typically sparse. The authors prefer an optical trocar technique in most instances. CO<sub>2</sub> insufflation at 12 to 15 mm Hg is used except where cardiopulmonary disease prohibits full insufflation and lower pressures of 10 to 12 mm Hg may be used.

**FIGURE 7-1** Port placement; C = camera; 1,2 – working ports; O = optional – placed at discretion of surgeon based on need for retraction or an additional assistant instrument.

A 30-degree 5-mm scope is inserted and initial inspection commenced with attention to the presence of ascites, omental/peritoneal nodules, or liver masses. Next, additional trocars are placed in a manner that allows the region of primary interest to be examined with a head-on view and instrument ports to be aligned with the viewing angle (Fig. 7-1). The number and size of additional trocars will depend on the need for biopsies and other interventions, though a complete diagnostic laparoscopy with cup biopsies of the liver or peritoneum will generally require two additional 5-mm trocars. If peritoneal cytology is to be performed, it is done prior to manipulation or dissection of tissues by instilling 250 mL normal saline into each of the upper

quadrants and aspiration into a Lugol's trap.

Examination of the peritoneum is performed systematically, beginning in the right upper quadrant. With the patient in reverse Trendelenberg positioning and the right side tilted upward, the right lobe of the liver is gently retracted to allow examination of the surface of the diaphragm and then elevated to view the undersurface of the liver, gallbladder, and porta hepatis (Fig. 7-2). Next, with the left side elevated, the left hemidiaphragm and left lateral segment of the liver are examined. Great care is taken not to damage the spleen with inadvertent or overly aggressive manipulation. Elevation of the left lateral segment reveals the hepatogastric ligament (Fig. 7-3), which may be opened along the pars flaccida to gain access to the lesser sac and allow biopsy of hepatic, celiac, and left gastric artery lymph nodes if indicated.

**FIGURE 7-2** Laparoscopic “palpation” of the liver. Note mucinous tumor adherent to the left lobe of the liver and ligamentum teres.

With the patient in neutral positioning, the omentum is reflected upward, exposing the transverse colon, which is elevated allowing inspection of the transverse mesocolon and the ligament of Treitz—sites of potential locally advanced disease or lymphadenopathy in pancreatic cancer or lymphoma, for

example (Fig. 7-3). The small intestine may be examined from ligament of Treitz to ileocecal valve at this time as well. Finally, the patient is placed in Trendelenberg position and the small bowel and colon swept out of the pelvis to facilitate examination of the peritoneum and for females, pelvic organs (Fig. 7-4).

**FIGURE 7-3** Pars flaccida of the lesser omentum with caudate lobe visible beneath.

**FIGURE 7-4** Carcinomatosis and ascites in the pelvis.

Laparoscopic ultrasound (LUS) may be performed to examine the liver, lymph nodes (peri-portal, celiac, peri-aortic, etc.) or other solid organs, including the pancreas, though this requires opening the gastrocolic ligament along the greater curve of the stomach to gain access to the lesser sac. Liver ultrasound in particular allows identification and core-needle biopsy of parenchymal masses not apparent on visual inspection.

Upon completion of the examination of the peritoneum, the insufflation is released and the trocars are withdrawn under direct vision, taking care to inspect for bleeding. Fascial incisions of 10 mm or more are closed to prevent herniation of abdominal contents.

## **LAPAROSCOPY AS A DIAGNOSTIC/STAGING TOOL**

### **Esophageal/Gastric Malignancy**

Squamous cell carcinoma and adenocarcinoma of the proximal and middle

one-third of the esophagus is associated with a lower likelihood of liver metastases and peritoneal disease,<sup>1</sup> and thus diagnostic laparoscopy is seldom useful unless there is suspicion of metastatic disease or inconclusive cross-sectional imaging. For adenocarcinoma of the distal esophagus and gastroesophageal (GE) junction, the National Comprehensive Cancer Network (NCCN) guidelines currently recommend a metastatic workup including PET/CT.<sup>2</sup> PET imaging aids in the detection of lymph node metastases and metastatic disease when compared with CT and endoscopic ultrasound (EUS), though its accuracy is still modest at 70% to 82%.<sup>3,4</sup> Currently, staging laparoscopy is an optional part of the staging assessment on the basis that its role is poorly defined with some evidence for and some evidence against its routine use.

de Graff et al. performed staging laparoscopy in 416 patients with esophageal and GE junction tumors that were resectable by CT criteria. They found 84 (20.2%) patients had unresectable disease identified at laparoscopy (locally advanced in 17, lymph node disease in 14, and metastases in 63) that precluded resection. Twenty-seven patients who went on to have laparotomies had unresectable disease (metastases in 11 and locally advanced disease in 16), yielding a sensitivity of laparoscopy of 88%. As mentioned earlier, the yield of staging laparoscopy for proximal and mid-esophageal tumors and for squamous cell carcinoma was low (laparoscopy changed management in 0/28 and 1/33 cases, respectively).<sup>5</sup> Neither CT/PET nor EUS was used for the preoperative staging evaluation in this study. Both have been shown to improve the ability to predict resectability and are in routine use today. As a result, the utility of routine staging laparoscopy is probably overestimated in this case.

The addition of LUS to standard staging laparoscopy has been reported by Wakelin et al. Endoscopic ultrasound was better at determining T stage except where stricture prevented complete examination. However, LUS was complementary to CT for assessment of metastatic disease. They reported an accuracy of staging laparoscopy with LUS of 81% for detection of metastatic disease compared to 72% for CT.<sup>6</sup> LUS was ineffective in evaluating tumors above the diaphragm. In practice, LUS is unlikely to provide additional information except in instances where EUS is unable to be performed.

Recent studies have provided important information about the negative prognostic significance of positive peritoneal cytology, which increases the

importance of laparoscopy as a staging tool. Nath et al. evaluated 255 patients with esophageal ( $n = 82$ ), GE junction ( $n = 48$ ), and gastric ( $n = 125$ ) cancers and no evidence of unresectability on preoperative EUS and CT (without PET). They found 48 patients (18.8%) with macroscopic metastatic disease and another 15 (5.9%) with positive cytology. Gastric cancer patients had radiographically occult metastatic peritoneal disease 28.8% of the time.<sup>7</sup> The authors found no difference in survival between patients with macroscopic metastatic disease and only positive cytology (median survival 9 vs 13 months;  $p = 0.52$ ) which led them to conclude curative resection should not be performed for patients with positive peritoneal cytology.

Nearly identical findings were reported by Convie et al. with macroscopic metastases in 22.6% of gastric adenocarcinoma patients and 11.8% of esophageal carcinoma ( $n = 136$  adenocarcinoma, 22 squamous). Cytology was positive in an additional five gastric and six esophageal carcinoma patients. The authors found positive cytology to be an equally poor prognostic sign as macroscopic metastatic disease.<sup>8</sup>

Another study by Munasinghe et al. demonstrated that the location of lavage and collection of the cytology specimen is important, with the greatest yield coming from lavage and aspiration of the subphrenic region (sensitivity 90.7%), while pelvic samples have lower sensitivity (76.7%). In a study of 316 patients with esophageal, GE junction, and gastric cancers, pelvic aspiration alone understaged patients 23.3% of the time. The yield of staging laparoscopy alone was 8.9% and the addition of cytology identified another 13.6% of patients with advanced disease, for a total yield of 22.5%. Patients in this study were staged preoperatively with CT, EUS, and PET-CT providing evidence that staging laparoscopy, particularly in combination with cytology, provides meaningful information, even in the era of advanced cross-sectional imaging.<sup>9</sup>

Neoadjuvant chemotherapy and chemoradiation protocols are increasingly being investigated and implemented,<sup>10,11</sup> and though overall outcomes appear to be improved there are some patients who progress while receiving neoadjuvant therapy. The role of repeat staging laparoscopy with peritoneal cytology was investigated by Cardona et al., who found that 7% of patients had radiographically occult metastatic disease at the time of repeat laparoscopy, though cytology was only positive in the absence of macroscopic metastatic disease in one patient. They concluded that repeat

staging laparoscopy was warranted but performing cytology was not, given its low yield.<sup>12</sup>

## Primary and Secondary Hepatobiliary Malignancy

Preoperative imaging techniques have comparatively low sensitivity for detecting metastatic and locally invasive disease in hepatobiliary malignancies such as gallbladder carcinoma and hilar cholangiocarcinoma (HC). As an example, the sensitivity of PET/CT for unresectability of gallbladder carcinoma in one recent study was only 56%,<sup>13</sup> and the accuracy of predicting resectability of cholangiocarcinoma (either hilar or intrahepatic) was 72.4% for PET/CT in another study.<sup>14</sup> A recent expert panel consensus statement on intrahepatic cholangiocarcinoma concluded in part: "...a substantial number of unresectable patients will benefit from staging laparoscopy... [and] staging laparoscopy should be routinely utilized in high-risk patients (i.e. patients with multicentric disease, high CA 19-9, questionable vascular invasion or suspicion of peritoneal disease)..."<sup>15</sup>

Goere et al. performed staging laparoscopy in 39 patients with gallbladder carcinoma, intrahepatic cholangiocarcinoma (IHC), and HC.<sup>16</sup> All patients had triple-phase contrast CT and 90% had MRI prior to staging laparoscopy. They found metastatic disease or cirrhosis precluding resection in 14 patients (36%). Another nine patients were found to be unresectable on laparotomy, primarily because of vascular invasion or lymph node metastases. Only one patient had peritoneal metastases that were missed on laparoscopy and two patients had previously unrecognized liver metastases. The yield of laparoscopy was highest for gallbladder carcinoma (62%, accuracy 83%) while the yield for IHC (yield 36%, accuracy 67%) and HC (yield 25%, accuracy 45%) was somewhat lower. The authors recommended that staging laparoscopy be performed routinely for gallbladder carcinoma and IHC and selectively for HC.

Similarly, D'Angelica et al. studied the role of staging laparoscopy for both primary and secondary hepatobiliary malignancy in 401 patients and found a yield of 21% and an accuracy of 54.9%.<sup>17</sup> Ninety-seven percent of study patients had preoperative CT, 45.9% had MRI, and 86.7% had two or more studies. The yield was highest for gallbladder carcinoma at nearly 50% and lowest for primary hepatocellular carcinoma (<20%) and metastatic

colorectal cancer (10%). Overall accuracy for staging laparoscopy was 54.9% with most failures due to vascular invasion or lymph node metastases. The authors also performed LUS in 168 patients, and 25 (14.9%) of these yielded additional findings not seen on laparoscopy, with 8 LUS exams primarily responsible for preventing laparotomy. Finally, the authors found morbidity and hospital length of stay were significantly less in unresectable patients who were spared a laparotomy (morbidity 9.5% vs 27.5% and hospital stay 3 days vs 9 days).

In a study by Russolillo et al., 100 patients with preoperative imaging suggesting resectable gallbladder carcinoma, HC, or borderline resectable IHC (defined as a tumor larger than 10 cm or adjacent to or infiltrating the inferior vena cava, a major hepatic vein, bile duct confluence, or a first-order Glissonian pedicle) underwent staging laparoscopy combined with LUS.<sup>18</sup> The overall yield and accuracy of laparoscopy was 18% and 60%, respectively. This was increased to a yield of 24% and accuracy of 80% with the addition of LUS. In the six patients who had false negative staging laparoscopies with LUS the reason for failure was peritoneal metastases ( $n = 2$ ), lymph node metastases ( $n = 2$ ), or vascular invasion ( $n = 2$ ). Of note, the only factor that predicted the failure of staging laparoscopy with LUS to identify unresectable disease was preoperative biliary drainage.

## **Pancreatic Malignancy**

A recent Cochrane review reported a meta-analysis of 15 studies including 1015 patients over a period of 26 years (1986-2012) to determine the diagnostic accuracy of laparoscopy for resectability of pancreatic or periampullary malignancy following CT scanning.<sup>19</sup> They found the pretest probability of unresectable disease after CT scanning alone was 40.3% and the cumulative sensitivity of diagnostic laparoscopy was 68.7% (95% confidence interval [CI] 54.3%-80.2%). Thus the post-test probability of unresectable disease was 17%. The authors concluded that 23 laparotomies could be avoided for every 100 patients by performing laparoscopy in conjunction with CT scan. A subgroup analysis of only pancreatic cancer patients found similar results.

These data indicate that routine laparoscopy prior to planned laparotomy should be strongly considered given the fairly high likelihood of undetected

metastatic disease. However, it is important to note that over half of the patients included in the meta-analysis were from studies published 15 years or more prior to the current study. In modern practice, the advent of multidetector helical CT scans and multiphase contrast administration protocols have increased the sensitivity of cross-sectional imaging considerably, allowing for the detection of more subtle metastatic disease as well as locally advanced disease that would preclude resection. Modern CT provides a sensitivity and specificity of 85% and 82%, respectively, for vascular involvement<sup>20</sup> and 88% and 89% for detection of liver metastases.<sup>21</sup> As a result, diagnostic laparoscopy is not a compulsory prelude to laparotomy in many practitioners' hands.

Staging laparoscopy may be performed on a more limited basis when the pretest probability of metastatic or locally advanced disease is high, as when the CA19-9 is markedly elevated. This was studied by Maithel et al., who found that serum CA19-9 values greater than 130 U/mL were predictive of unresectability, particularly for distal cancers. The most common site of unresectable disease was metastatic disease in the liver or peritoneum.<sup>22</sup> Another more recent study found a CA19-9 value of 215.37 had a sensitivity of 72.7% and specificity of 52.3% for radiographically occult metastatic disease seen at time of laparoscopy.<sup>23</sup> Of note, 5% to 10% of patients do not have the Lewis antigen required to express CA19-9 and thus will not have elevated CA19-9 values, regardless of their resectability. As a result, a low CA19-9 value should not preclude diagnostic laparoscopy if preoperative imaging is equivocal. Diagnostic laparoscopy may also provide higher yield, and should be utilized when there is a question of unresectable disease on preoperative imaging.

Some metastatic disease on the posterior surface of the liver or on the retroperitoneum abutting the duodenum may not be visible at the time of standard diagnostic laparoscopy. Schnelldorfer et al. reported a series of 274 patients who underwent either initial staging laparoscopy followed by laparotomy (if laparoscopy was negative) or initial laparotomy. Both groups had radiographically occult metastatic disease 11% of the time, though only 2% of patients were found to have metastases on laparoscopy. The remaining 9% had metastases that were identified only on laparotomy. These were found on the posterior surface of the liver, paraduodenal retroperitoneum, proximal jejunal mesentery, and in the lesser sac. The authors argued that advanced laparoscopic techniques to mobilize and expose these areas are

warranted to identify more subtle metastatic disease.<sup>24</sup> More extensive laparoscopic dissection such as a Kocher maneuver and mobilization of the right lobe of the liver should be reserved for cases in which there is concern preoperatively for unresectable disease, and should only be performed by experienced laparoscopists with advanced laparoscopy capabilities.

Several studies have examined the use of LUS to evaluate the liver for subcapsular/parenchymal metastases not visible on laparoscopy as well as for vascular invasion or non-regional lymph node metastases (ie, celiac/para-aortic). Piccolboni et al. performed diagnostic laparoscopy with LUS in 18 consecutive patients, four of whom had inconclusive findings of unresectable disease on preoperative imaging. LUS identified parenchymal liver metastases in two patients and vascular involvement precluding resection in another two. The authors concluded LUS was a necessary adjunct to laparoscopy in order to determine resectability for the four patients with equivocal preoperative imaging.<sup>25</sup> A larger study of 305 patients found the overall accuracy of preoperative CT for predicting resectability was 68.6%, and diagnostic laparoscopy with LUS increased this to 81%. Importantly, 4/49 patients who were deemed unresectable by CT were found to be resectable by LUS. Diagnostic laparoscopy and LUS influenced operative management 13.4% of the time.<sup>26</sup>

Another study by Barabino et al. examined the role of LUS in the eras before and after the introduction of multidetector CTs. Prior to modern CT the authors performed LUS routinely and found that LUS changed the surgical strategy 30% of the time and accurately predicted resectability in 96% of patients thought to be resectable on preoperative imaging and 95% of patients who were deemed “doubtful” preoperatively. The overall yield of LUS was 45%. Following the advent of multidetector CT, the utility of LUS was curtailed significantly and the yield dropped to 1.8%.<sup>27</sup> While the authors concluded LUS should not be a routine part of the workup for pancreatic cancer, they acknowledged that in certain cases of equivocal preoperative CT imaging it may be useful to prevent an unnecessary laparotomy.

The use of peritoneal cytology for the staging of pancreatic cancer has not been well defined. Positive peritoneal cytology may be found in 7% to 30% of diagnostic laparoscopies performed for known pancreatic malignancy and there may be an increased incidence of positive peritoneal cytology for distal

cancers.<sup>28,29</sup> The clinical impact of positive peritoneal cytology is not defined, however, with some studies suggesting a higher likelihood of unresectability, limited survival, or subsequent peritoneal metastasis,<sup>30</sup> while others show no difference in either survival or subsequent occurrence of metastases.<sup>31</sup> At this time, conclusions cannot be made regarding the prognostic significance of positive cytology or the clinical utility of performing cytology as part of a diagnostic or staging workup.

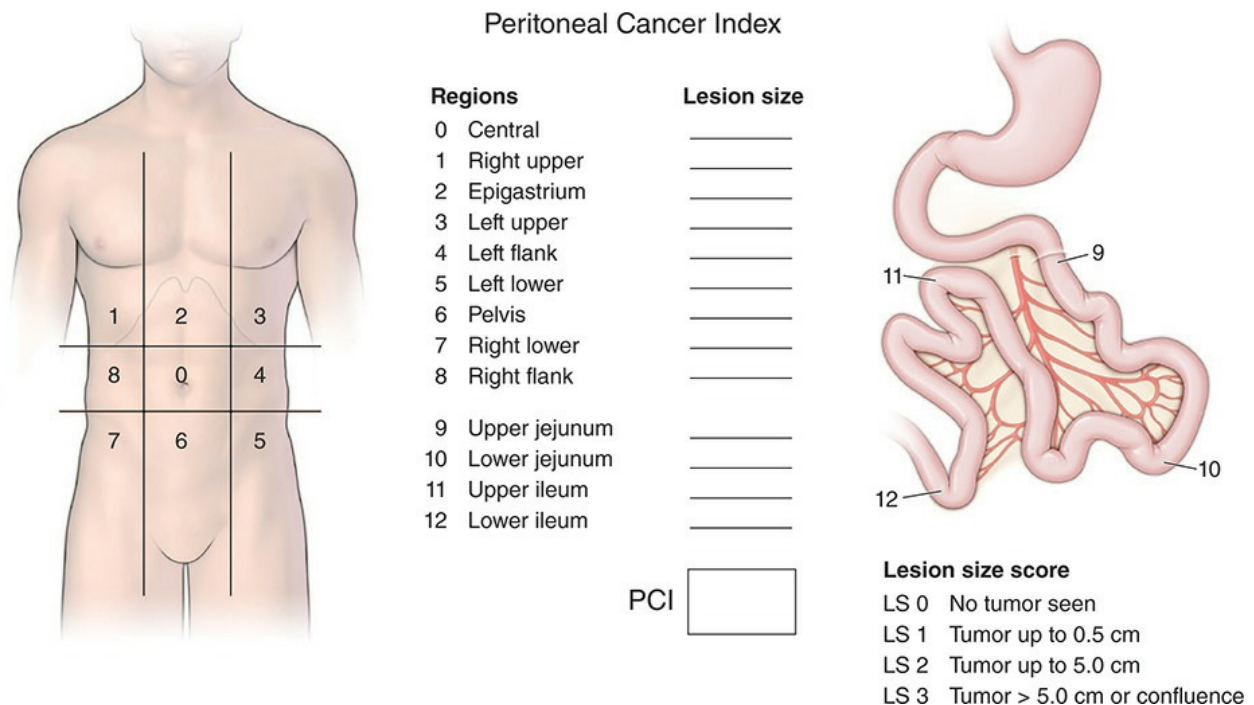

## Colorectal Carcinoma

Laparoscopic surgery for colorectal carcinoma is well established and validated by numerous well-designed and executed randomized controlled trials (RCTs) (read below). Therefore, laparoscopic colectomy approaches standard-of-care status for practitioners who have undergone appropriate training. For those who have not, open colectomy is still indicated, and diagnostic laparoscopy may be helpful prior to planned resection. For patients who have obstructing tumors or bleeding, diagnostic laparoscopy will not change management and is not appropriate. In otherwise asymptomatic individuals it may identify carcinomatosis or liver metastases that would be best treated with neoadjuvant chemotherapy prior to an attempt at resection. Thankfully, the incidence of acute obstruction of partially- or near-obstructing tumors while receiving chemotherapy is low, making pretreatment diversion or colectomy for “impending obstruction” unnecessary for most asymptomatic individuals.<sup>32</sup>

Modern CT scans are effective at determining the presence of liver metastases with a sensitivity of 75% and specificity of 88%.<sup>33</sup> The detection of carcinomatosis by CT scanning is less exact with an overall sensitivity of 79%, though the majority of detected lesions were 5 cm or more in this study.<sup>34</sup> Smaller lesions are considerably less reliably detected on preoperative CT.<sup>35</sup> We suggest diagnostic laparoscopy be considered for asymptomatic patients undergoing open colectomy in whom there is a concern for metastatic disease on preoperative CT (indeterminate liver lesion(s), ascites, possible omental/peritoneal disease) and who would be eligible for neoadjuvant chemotherapy. If neoadjuvant chemotherapy is not a consideration, management will not be changed and open resection should proceed without laparoscopy.

## Disseminated Intraperitoneal Malignancy

Diagnostic laparoscopy may be performed prior to planned laparotomy for cytoreductive surgery with hyperthermic intraperitoneal chemoperfusion (CRS/HIPEC) to evaluate the extent of small bowel serosal involvement and the extent of disease overall (termed peritoneal carcinomatosis index [PCI]) (Fig. 7-5). These factors weigh heavily on the technical feasibility of performing cytoreductive surgery and the prognosis following CRS/HIPEC. While preoperative cross-sectional imaging with CT or MRI are mandatory components of the diagnostic workup, PCI has been shown to be poorly estimated by CT, particularly for smaller lesions <0.5 cm where CT sensitivity is 11%.<sup>35</sup> Diagnostic laparoscopy with biopsy is also important as either a planned prelude to immediate laparotomy or as a staging tool performed independently from a therapeutic procedure. Biopsies are performed to determine tumor grade and to obtain tissue for additional pathologic examination such as immunohistochemistry when the site of primary tumor is uncertain.

**FIGURE 7-5** Peritoneal cancer index (PCI).

The role of diagnostic laparoscopy has been studied by Jayakrishnan et al., who found that laparoscopy as either an immediate prelude to laparotomy or

as a separate procedure prevented an unnecessary laparotomy in 27.7% (18/73) of cases.<sup>36</sup> The reasons for aborting laparotomy were for excess PCI (>19) in 11 patients and absence of carcinomatosis in 7. Similarly, Iversen et al. found that implementing routine diagnostic laparoscopy to evaluate extent of disease spared 18 of 45 (40%) patients from a nontherapeutic laparotomy.<sup>37</sup>

## MINIMALLY INVASIVE SURGERY AS A THERAPEUTIC TOOL FOR CANCER

As noted earlier, there are myriad applications of laparoscopy as a therapeutic modality for treatment of abdominal malignancies. While it is beyond the scope of this chapter to describe the minimally invasive approaches for each, we aim to highlight the indications and outcomes here. Many of these techniques remain formidable challenges to incorporate into a practice of unselected patients, even for experienced laparoscopists. As a result, all of the data presented subsequently is subject to the caveat that acceptable perioperative and long-term oncologic outcomes for laparoscopic cancer operations are dependent on the experience of the surgeon, and many of these procedures should only be performed by surgeons with advanced training in minimally invasive surgery.

### Esophagectomy/Gastrectomy

Minimally invasive esophagectomy (MIE) has been studied extensively with retrospective and nonrandomized prospective studies but only one randomized controlled trial.<sup>38</sup> This study examined short-term outcomes and found significantly decreased pulmonary complications at 2 weeks and while in-hospital (34% for open and 12% for MIE). Secondary outcomes included hospital length of stay, estimated blood loss, short-term quality of life, postoperative pain, and vocal cord paralysis, all of which were decreased in the MIE group. From an oncologic standpoint there was a trend toward more margin-negative (R0) resections in the MIE group (84% vs 92%,  $p = 0.080$ ), and number of lymph nodes sampled was similar between the two groups. MIE was associated with longer operative times (329 min vs 299 min;  $p = 0.002$ ). Analysis of long-term outcomes and survival has been performed by

meta-analyses showing equivalent survival between the two techniques at 30 days and 1, 2, 3, and 5 years.<sup>39</sup> However, meta-analyses have been hampered by significant heterogeneity of the studies due to many differences in perioperative management as well as multiple techniques for both open and MIE that are reported.

Laparoscopic or robotic-assisted minimally invasive gastrectomy for gastric cancer has also been reported extensively in the literature with retrospective studies but few RCTs. A recent meta-analysis of studies comparing short-term outcomes for laparoscopic distal gastrectomy (LDG) with open distal gastrectomy (ODG) included 6 RCTs and 19 observational studies ( $n = 3055$  patients) and found that LDG was associated with similar perioperative mortality and major surgical complications but decreased overall complications, medical complications, minor surgical complications, estimated blood loss, and hospital length of stay.<sup>40</sup> Operative time was longer and lymph node retrieval was less for LDG. The authors did note that the majority of the studies were performed in Eastern centers with primarily early-stage cancers, which may limit the generalizability to Western centers with higher body mass index (BMI) patients and more locally advanced disease.

Long-term outcomes for laparoscopic gastrectomy have also been analyzed by meta-analysis. Chen et al. evaluated 23 studies with 7336 patients and found that 5-year overall survival, recurrence, and cancer-related death were similar between laparoscopic and open approaches.<sup>41</sup> However, given the retrospective nature of the studies included and variability in study design, there was significant confounding in the comparability of the groups as well as for extent of lymphadenectomy. At this time, in the absence of rigorous RCT data, there does not appear to be any evidence for poorer long-term outcomes associated with the laparoscopic approach. Short-term outcomes appear to be slightly better in terms of hospital stay, postoperative pain, blood loss, and minor complications.

Data evaluating the short-term and long-term outcomes of total gastrectomy are also lacking, with only nonrandomized, retrospective data at this time.<sup>42-44</sup> As with LDG, total gastrectomy appears to be safe with comparable long-term oncologic outcomes when performed by experienced surgeons.

Palliation of obstructing distal gastric cancers may be performed by

laparoscopic gastrojejunostomy and has been reported by Choi<sup>45</sup> and others.<sup>46,47</sup> The laparoscopic approach to palliative gastrojejunostomy is generally associated with faster return to oral intake (2.9 days vs 4.7 days).<sup>45</sup> It is theorized that reduced incision size could also allow faster initiation of chemotherapy postoperatively, though this has not been studied in a comparative fashion.

## **Liver/Biliary Resection**

Laparoscopic liver surgery is a formidable challenge and continues to grow and evolve as new techniques are developed and new technology emerges. Issues regarding minimally invasive liver and biliary surgery have been addressed in a recent consensus conference.<sup>48</sup> Multiple retrospective comparison studies have been performed as well as some prospective, nonrandomized studies, but no RCTs to date have compared outcomes between open and laparoscopic techniques. Meta-analyses compiling data from studies comparing laparoscopic to open hepatectomy for malignancy have shown decreased operative blood loss and hospital length of stay, with similar rates of postoperative complications and oncologic outcomes.<sup>49</sup> Morise et al. also found consistently lower rates of postoperative ascites and liver failure in patients with hepatocellular carcinoma and concomitant chronic liver disease who underwent laparoscopic hepatectomy.<sup>50</sup> Laparoscopic hepatectomy for metastatic colorectal cancer (mCRC) was associated with less blood loss, transfusions, and hospital length of stay with similar operative times and equivalent disease-free and overall survival at 1, 3, and 5 years when compared to open resection in a recent meta-analysis by Schiffman et al.<sup>51</sup>

Robotic-assisted hepatectomy has been retrospectively compared to laparoscopic resection and found to be equivalent in terms of perioperative outcomes including operative blood loss, negative margin rate, complication rate, 30- and 90-day mortality, and hospital length of stay. There is a significantly longer operative time associated with robotic resections, though a greater number of resections were able to be completed in a totally minimally invasive fashion with the robotic platform (93% vs 49.1%).<sup>52</sup>

## Pancreatectomy

As with hepatectomy, laparoscopic major pancreatectomy is a challenging undertaking. The laparoscopic pancreaticoduodenectomy (PD) is considered by some to be the Mt. Everest of minimally invasive surgery. Only a handful of highly skilled laparoscopic surgeons are able to consistently perform the operation with acceptable morbidity, mortality, conversion rates, and oncologic outcomes.<sup>53</sup> Kendrick et al. reported their series of 108 laparoscopic PD versus 214 open PD and found significantly decreased hospital length of stay (6 days vs 9 days;  $p < 0.001$ ) and similar rates of perioperative morbidity, including pancreatic fistula. Progression-free survival was significantly longer in the laparoscopic group but overall survival was similar. The authors noted a significantly larger proportion of patients did not receive adjuvant chemotherapy within 90 days in the open group, perhaps explaining the more rapid cancer progression (12% vs 5%).

Robotic-assisted pancreatic surgery has emerged as a powerful platform to perform complex operations minimally invasively. The report of 250 procedures published by Zureikat et al. illustrates the variety of applications that are well suited to the robotic platform (Table 7-1).<sup>54</sup> In their experience, the incidence of Clavien grade 3 and 4 complications (14%, 6%, respectively), International Study Group on Pancreatic Fistula (ISGPF) grade C pancreatic fistula (4%), and 30- and 90-day mortality (0.8%, 2%, respectively) all approximated or improved upon published norms. Although overall operative times were long (mean 529 min for PD) they decreased steadily throughout the study period, and in the last 50 PD cases of the series the median operative time was 360 minutes.

**TABLE 7-1: SHORT-TERM OUTCOMES FOR ROBOTIC-ASSISTED PANCREATECTOMIES**

	Entire Cohort n = 250	Whipple n = 132	Distal n = 83	Central n = 13	Enucleation n = 10	Total n = 5	Appleby n = 4	Frey n = 3

Adapted with permission from Zureikat AH, Moser AJ, Boone BA, et al: 250 robotic pancreatic resections: safety and feasibility, *Ann Surg.* 2013 Oct;258(4):554-559.

In comparison to laparoscopic PD, laparoscopic distal pancreatectomy has been adopted relatively broadly and has been shown to be safe, with similar rates of operative and perioperative complications, including pancreatic fistula and less operative blood loss, earlier time to oral intake, and decreased hospital length of stay compared to open distal pancreatectomy.<sup>55</sup> Oncologic outcomes are not as well studied, though a single-institution report of laparoscopic ( $n = 131$ ), robotic ( $n = 37$ ), and open ( $n = 637$ ) distal pancreatectomies found similar margin-negative resection rates for the three groups,<sup>56</sup> though there were fewer lymph nodes harvested with the laparoscopic technique (15.4 vs 10.4 vs 12 for LDP, ODP, RDP;  $p = 0.04$ ). In another single-institution, retrospective study Fernández-Cruz et al. found the median survival for patients undergoing LDP for adenocarcinoma was 14 months with adjuvant 5-FU.<sup>57</sup> Although there was no comparison group, the authors commented that this approximates the survival of patients undergoing ODP for pancreatic cancer. The robotic platform may offer some advantages over the laparoscopic platform, especially when applied for pancreatic cancer.<sup>58</sup>

Palliative procedures for periampullary malignancy are not as common in the current era of endoluminal duodenal stents and percutaneous or endoscopic biliary stents.<sup>59,60</sup> There remain, however, indications for surgical bypass of either enteric obstruction, biliary obstruction, or both, such as failure of endoscopic methods. Furthermore, surgical means of palliation tend to be more durable and require less subsequent intervention or hospitalization,<sup>59,60</sup> which is an important consideration given that advances in chemotherapeutics may help patients with unresectable disease to live longer. Laparoscopic methods for biliary and enteric (laparoscopic gastrojejunostomy [GJ]) bypass have been described and compared to both

open bypass and endoscopic bypass methods.<sup>47,61,62</sup> Generally, endoscopic means of palliation are preferred to surgical methods (both open and laparoscopic) due to increased complications and hospitalization time associated with surgical procedures.<sup>63,64</sup> Laparoscopic bypass may be considered for patients in whom endoscopic means are impossible (ie, biliary obstruction with prior Roux-en-Y) or if impending obstruction is found at the time of diagnostic/staging laparoscopy, though this should be rare in the era of high-quality cross-sectional imaging.

## Colon/Rectal Resection

Laparoscopic colectomy is perhaps the most well-studied laparoscopic cancer operation. High-quality data including multiple RCTs and meta-analyses have validated laparoscopic colectomy as a safe and effective treatment for colon cancer. In one meta-analysis of 12 RCTs, laparoscopic colectomy was associated with lower operative blood loss, decreased postoperative pain, faster return of bowel function and resumption of oral diet postoperatively, and shorter hospital length of stay (Table 7-2).<sup>65</sup> Morbidity and mortality were similar, as were cancer-related outcomes of overall survival and disease-free survival.

**TABLE 7-2: SHORT-TERM OUTCOMES OF LAPAROSCOPIC COLECTOMY**

	ORT (min)		EBL (mL)		LN Excised (n)		Analgesic Use		POD 1 Pain		Normal Diet		Hospital Stay (d)		Readmission (%)

Abbreviations: LS, laparoscopic surgery; OS, open surgery; ORT, operating room time; EBL, estimated blood loss; LN, lymph node; POD, postoperative day. Adapted with permission from Reza MM, Blasco JA, Andradas E, et al: Systematic review of laparoscopic versus open surgery for colorectal cancer, *Br J Surg*. 2006 Aug;93(8):921-928.

It should be noted that recently some investigators have questioned the purported safety of laparoscopic colectomy and proctectomy. Sammour et al.

performed a meta-analysis of RCTs and found that for colorectal cancer operations, the laparoscopic approach was associated with an increased risk of intraoperative complications (OR 1.55,  $p = 0.009$ ) and bowel injury (OR 2.28,  $p = 0.006$ ). There were no differences noted for hemorrhage or solid organ injury.<sup>66</sup> These data highlight the importance of the need for experienced surgeons with advanced laparoscopy skills.

Robotic-assisted proctectomy has become a common approach to rectal cancer and has been reported extensively in the literature, though randomized studies are lacking. A meta-analysis of seven retrospective and nonrandomized case-control studies comparing laparoscopic and robotic-assisted proctectomy found a decrease in the rate of conversion to open operation for robotic-assisted surgeries but similar outcomes in terms of blood loss, hospital stay, and pathologic variables.<sup>67</sup>

Palliative procedures for obstructing colorectal carcinoma have been described<sup>68</sup> and can be performed as safely as open operations in the hands of experienced laparoscopists. The main challenges involve limited “working space” due to varying degrees of small bowel and/or colonic dilation that result from the obstruction. For patients who are receiving chemotherapy, simple proximal diverting loop colostomy for an obstructing rectosigmoid cancer can be sufficient and avoid the potential morbidity associated with formal resection. Obstructing right-sided lesions can be associated with a closed-loop obstruction if the ileocecal valve is competent, and this situation is usually best managed with a formal resection with reanastomosis. Transverse colon lesions may be approached with either loop colostomy or resection, depending on patient condition and feasibility of resection.

Mucinous ascites resulting from end-stage disseminated colorectal carcinoma is a dreadful condition which is difficult to palliate. Due to the viscosity of the mucin, it is not amenable to paracentesis or percutaneous drain placement, and medical therapies such as diuretics do not address the issue either (Fig. 7-6). Some have advocated laparoscopic-assisted evacuation of mucinous ascites as a method to provide relief.<sup>69</sup> Morbidity is low and the procedure can be safely repeated as necessary, given the mucin will reaccumulate over time.

**FIGURE 7-6** Mucinous ascites.

## CONCLUSIONS

Minimally invasive surgery is a valuable tool in the armamentarium of the cancer surgeon. As a staging and diagnostic tool it is complementary to cross-sectional imaging, and when applied rationally it provides valuable information while minimizing morbidity for cancer patients, where quality of life and the time lag to chemotherapy are very real concerns. Therapeutic uses of laparoscopy and robotic-assisted surgery for cancer operations continue to grow and evolve; the valid concerns regarding minimally invasive techniques for oncologic procedures have been addressed by several RCTs (ie, esophagectomy, colectomy). The sum total of the literature to date does not support worse oncologic outcomes for minimally invasive cancer surgery. In fact, it is likely that surgical approaches to local control of GI malignancies will be less important than improvements in systemic therapy in terms of overall survival, as has been the case in the treatment of breast cancer. At the same time, improved patient-centered outcomes seen with minimally invasive techniques have the potential to translate to better tolerance of—and increased rates of administration—for life-prolonging

adjuvant chemotherapy. Despite these advances reported in the literature, it remains essential that individual practitioners attempting these complex procedures obtain necessary training and a level of laparoscopic skill that allows for safety and maintenance of oncologic principles.

# ROBOTICS IN GASTROINTESTINAL SURGERY

*Yanghee Woo • Yuman Fong*

## INTRODUCTION

Innovations in robotic technology are transforming the way surgeons operate in the 21st century. Robotic surgical platforms grant surgeons access to modern-world defining robotic engineering and computer programming, which enhance the surgeon's operative view and augment his or her manual dexterity.<sup>1-3</sup> These surgical tools were developed with the goal of helping surgeons overcome the limitations of laparoscopy and to facilitate the broader adaptation of minimally invasive surgery to include more complex abdominal procedures.<sup>4-8</sup> The technologic superiority of robotic surgical platforms over existing open and laparoscopic instruments is undisputed, with the potential to harvest significant advantages for the surgeon and, ultimately, translate them for improved patient outcomes.

As with all new technology, however, robotic surgery poses novel challenges for general surgeons as we begin to define its role in our clinical

practices, discern its optimal application for our patients, and determine its benefits and disadvantages.<sup>9-11</sup> Familiarity with robotic surgical systems, the current uses, its optimum utilization, and potential future applications can facilitate the employment of the robotic surgical platforms for gastrointestinal procedures. In this chapter, we will cover the development of the robotic surgical technology and the inherent advantages of the da Vinci Surgical Systems (Intuitive Surgical, Sunnyvale, CA). The chapter will explore how surgeons can exploit specific technologic innovations of the da Vinci robotic surgical platforms in robotic Heller myotomy with fundoplication, radical gastrectomy with lymphadenectomy, and robotic colorectal resections with total mesorectal excision. We will review the results of existing studies focusing on the clinical outcomes of these select robotic gastrointestinal surgeries alone and in comparison to open and laparoscopic approaches. Finally, the chapter will highlight a few distinct features of robotic surgery and possible future applications.

## **EVOLUTION OF THE ROBOTIC SURGICAL SYSTEMS**

### **Development of Robotic Surgical Technology**

Robotic surgery is the utilization of specifically designed robotic surgical platforms to perform minimally invasive surgical procedures. The foundation of the robotic surgical technology is derived from the innovations of a military project endorsed by the National Aeronautics and Space Administration (NASA). The Defense Advanced Research Project Administration (DARPA) funded the research project in the 1970s.<sup>3,12</sup> At the time, the aim of the surgical robotics project was to enable telesurgery—to create a robot that could be manipulated to care for astronauts in space aircrafts and soldiers in the battlefield without the physical presence of a surgeon alongside the patient. In 2002, the first robot-assisted telesurgery on a human, a cholecystectomy, was performed using the ZEUS system (Computer Motion, Goleta, CA).<sup>13</sup> The surgeon, Dr. Jacques Marescaux, was seated at the “surgeon-side” subsystems located in New York City with a “patient-side” robot with the patient in Strasbourg, France.

Although the Zeus Robotic Surgical System is no longer used, several companies continued to develop surgical robotics; and currently, all robotic gastrointestinal operations are performed with the da Vinci Surgical Systems.<sup>14-17</sup> They are the only robotic platforms available for abdominal surgery in the adult and pediatric populations. Since the Food and Drug Administration approved Intuitive Surgical's da Vinci S System in the year 2000, 3 generations of da Vinci Surgical Systems, each with increasingly more sophisticated features, have been developed: the S System (2003), the Si System (2009), and the Xi System (2014).

## **da Vinci Surgical Systems**

The da Vinci Surgical Systems are composed of the surgeon console and the patient-side cart. Similar to laparoscopic surgery, trocars are used as smaller incisional points of entry into the peritoneal cavity. The trocars and the surgical instruments, including the camera, are then attached to robotic arms, which are a part of the patient-side cart. Unlike both open and laparoscopic operations, the primary surgeon is not at the patient's side but controls the operation from a distance. The surgeon operates seated at the console controlling the instruments attached to the patient-side cart (Fig. 8-1).

A

B

**FIGURE 8-1** **A.** Surgeon at the console in control of the Da Vinci robotic surgical system. **B.** Multi-arm robotic system in use.

Once seated at the console with the head rested on the viewing piece, the surgeon gains complete control of the robot arms with the ability to manipulate the 4 inserted instruments. Bilateral hand and foot controls require the surgeon to coordinate both hand and foot movements throughout the robotic procedure to manipulate the camera position, focus, distance, and angle along with 3 other instruments. A surgeon, resident, or a physician's assistant with varying degrees of training, experience, and robotic and laparoscopic expertise should assist the primary surgeon at the patient bedside to exchange the instruments, clean the camera lens, help suction, and create exposure of the operative field when necessary during the procedure (Fig. 8-2). The more complex the operation and the less experienced the primary surgeon, the more experienced the bedside assistant should be.

**FIGURE 8-2** Surgical assistant manipulating robotic arm.

## **Enhanced Robotic Features**

The robotic surgical platforms possess several key innovations ([Table 8-1](#)).<sup>5,12</sup> Predominantly, the advancements of robotic surgical platforms over the conventional laparoscopic instruments are its uniquely engineered attributes. These robotic features include the 3-dimensional (3D) high-definition camera with up to 10× magnification of the surgical anatomy. The surgeon has complete control of the camera for timely adjustments of the operative view either during a pause or simultaneously with active maneuvering of 2 other robotic arms. In addition, the scaling of motion and filtering of the surgeon's tremor allow for increased precision and accuracy of movements unaffected by the fulcrum effect or human fatigue.

**TABLE 8-1: TECHNOLOGIC FEATURES OF DA VINCI ROBOTIC SURGICAL SYSTEM**

Technology	Features	Clinical Advantages
Enhanced visualization	3-dimensional high-definition operative view Up to 10x magnified view of surgical anatomy Steady camera control	Enables a significantly enhanced view of the operative field Enables close-up examination of the surgical anatomy Eliminates the distortion and limited depth perception of 2-dimensional laparoscopy
Superior dexterity	Tremor filter Scaling of motion  EndoWrist with 7 degrees of instrument articulation	Elimination of the physiologic shaking of the hands Precision and accuracy of dissection around major vessels and tissue layers More freedom to maneuver in narrow areas and ability to reach around difficult angles
Improved intraoperative decision making	Near-infrared visual capability (Firefly)  Simultaneous multidisplay view (Tilepro)	Capability to see fluorescent light to identify structures with uptake of fluorescent particles like indocyanine green including vessels, lymph nodes, biliary tree, and tumor Able to view intraoperative endoscopic ultrasound and other images on the operative screen while performing the procedure

The EndoWrist (Intuitive Surgical) function providing 7 degrees of articulation is another significant technologic improvement of robotic surgery over the existing laparoscopic instruments. The ability to articulate beyond the human wrist, which only has 3 degrees of freedom during cutting, sealing, and dissecting, exists in all robotic instruments except in the robotic camera, the Harmonic Ultrasound Shears, and the stapler. Moreover, the surgeon has control of 4 arms of the robotic platform.

Several additional robotic features are available to aide in intraoperative decision making. Tilepro (Intuitive Surgical) is a multidisplay imaging program that allows for simultaneous viewing of other images (intraoperative ultrasound and endoscopies and preoperative radiologic images) that can be activated any time during the operation. In addition, the robotic camera has near-infrared optical capabilities, which allow the surgeon to see fluorescent light for delineation of surgical anatomy including lymph nodes, lymphatic drainage, blood vessels, and the entire biliary tree.

## **CURRENT APPLICATION OF ROBOTIC SURGERY IN GASTROINTESTINAL DISEASES**

While the initial robotic system was intended for cardiac surgical procedures, the use of the robotic surgical platforms has been used in most surgical subspecialties including urologic, gynecologic, thoracic, vascular, transplant,

and general surgeries. In addition, until recently, the field of robotic surgery was dominated by robotic prostatectomies and benign and malignant gynecologic procedures.<sup>18-22</sup> However, with the availability of additional features and greater number of instruments better suited for general surgery on each new robotic surgical platform (Si System and the Xi System), general surgeons are performing numerous complex robotic operations.<sup>23-27</sup>

Surgeons in the United States and around the world have performed a wide range of general surgical procedures with robotic assistance (Table 8-2). The robotic general surgical procedures reported to treat diseases in the foregut include Heller myotomies, hiatal hernias, antireflux surgeries (eg, Nissen fundoplication, partial funduplications), bariatric surgery (eg, Roux-en-Y gastric bypass, sleeves), splenectomies, gastrectomies (eg, radical subtotal distal, total, or proximal gastrectomies), and lymph node dissections. For hindgut diseases, surgeons have used robotic assistance in performing simple right and left colectomies and more complex rectal resections (low anterior resection and abdominoperineal resections) with total mesorectal excisions.

**TABLE 8-2: ROBOTIC ABDOMINAL OPERATIONS**

### **Foregut/Upper Abdominal Operations**

Heller myotomy

Antireflux surgery

Bariatric surgery (Roux-en-Y gastric bypass, sleeves)

Radical gastrectomy (subtotal distal, total, D2 lymphadenectomy)

Splenectomy

### **Hepatopancreaticobiliary Operations**

Liver resection

Pancreatic resections (pancreaticoduodenectomy, central and distal pancreatectomy, portal vein reconstruction)

Cholecystectomy (simple, radical)

### **Colorectal Operations**

Right colectomy

Left colectomy

Low anterior resection  
Abdominoperineal resection  
Total mesorectal excision

**Other**

Hernias (inguinal, ventral incisional, hiatal)  
Thyroidectomy

---

Combined operations, such as colectomies with hepatectomies for metastatic colon cancer and gastrectomies with cholecystectomies for biliary disease and obesity or gastric cancer, have also been reported. Experienced surgeons are performing an increasing number of other more complex hepatopancreaticobiliary operations including liver resections, pancreatic resections (proximal, central, and distal pancreatectomies), and pancreatic resections with venous reconstructions. As pioneering surgeons explore and demonstrate the safety and feasibility of numerous robotic procedures for gastrointestinal diseases, the minimally invasive benefits of robotic surgery as an alternative to laparoscopy are quickly being revealed under critical evaluation.

## **Rationale for the Robotic Approach**

### **BENEFITS OF MINIMALLY INVASIVE SURGERY**

Since the first use of laparoscopy in 1982 for an “endoscopic” appendectomy,<sup>28</sup> minimally invasive surgery has earned a prominent place in the armamentarium of general surgeons and has proven its effectiveness in conferring clinical benefit to our patients. For years, pioneering surgeons who used this revolutionary method of operating in the abdomen through small incisions with long stick-like instruments while watching a 2-dimensional view of the operative anatomy experienced significant controversy and criticism regarding its safety, feasibility, increased cost, increased complication rates, and unknown long-term outcomes.<sup>29</sup> With increasing surgeon experience, large retrospective studies and well-designed prospective clinical trials have clearly defined the benefits of minimally invasive surgery for patients undergoing abdominal operations for both benign and malignant gastrointestinal diseases.<sup>30-34</sup>

The short-term benefits attributed to the decreased trauma of a minimally invasive procedures include shorter hospital stays, less blood loss, decreased pain, earlier return to daily activities, and smaller scars.<sup>35</sup> Further support for minimally invasive surgery comes from comparable long-term oncologic outcomes of cancer patients treated with laparoscopic surgery versus open operations.<sup>36-39</sup> The conclusion of the studies is that if surgeons adhere to oncologic principles during laparoscopic surgery as they do through the open approach, patients gain the benefits of the short-term postoperative outcomes without compromising the long-term oncologic outcome.

The laparoscopic approach to abdominal operations to treat certain benign diseases such as cholecystectomy, reflux surgery, and morbid obesity has become standard of care with relatively quick adaptation periods.<sup>40-43</sup> Unfortunately, despite studies to demonstrate improved outcome of minimally invasive surgery, in more complex abdominal operations, the widespread utilization of laparoscopy remains limited. In fact, only 10% of gastric cancer and 15% to 20% of colon cancer operations are performed minimally invasively (laparoscopically) in the United States. The limitations of laparoscopic instrumentation and the steep learning curve of the advanced laparoscopic skills are barriers to widespread use of the laparoscopic approach to complex abdominal operations.<sup>44-48</sup>

## **CHALLENGES OF LAPAROSCOPY**

Several formidable impediments to the broader adaptation and greater application of laparoscopy for abdominal operations exist and hinder surgeons from providing the well-accepted benefits of minimally invasive surgery to our patients. Especially for complex gastrointestinal operations, not only is substantial training required to learn the laparoscopic techniques, but also surgeons must gain high-volume experience to master the laparoscopic approach for any specific procedure. This steeper learning curve translates into longer laparoscopic operative times when compared to the open operations. In addition, experienced laparoscopic surgeons have suffered from the long-term detrimental effects of the poor ergonomics of laparoscopic instruments. Robotic surgery offers surgeons access to new technology to overcome these limitations and overcome the disadvantages of laparoscopy.<sup>49,50</sup>

## **ADVANTAGES OF ROBOTIC SURGICAL SYSTEMS**

Enhanced robotic features may offer the surgeon several advantages to overcome the difficulty of applying minimally invasive techniques during these complex gastrointestinal procedures. The entire procedure is performed with a 3D view of the operative field, which provides depth perception more closely resembling an open operation as opposed to the 2-dimensional flat view of the laparoscopic screens. More importantly, the 3D view is magnified and can be angled 30 degrees in several directions to see points of the operative field not readily observed during an open operation.

At all points during the operation, the surgeon has control of the camera. This allows the surgeon the ability to manipulate the camera to any position he or she wants at the exact time he or she needs. In addition, when the camera is not being repositioned, it remains steady without any unwanted movements since the robotic arm holding the camera does not fatigue as a human assistant would. This permits a well-coordinated steady 3D magnified operative view throughout the entire surgical procedure.

In fact, the surgeon controls 3 other robotic arms as well. Although only 2 instruments can be manipulated at the same time, a feature to shift control between 2 arms allows the surgeon to position 1 of the arms for retraction and helps improve exposure prior to dissection of a certain area. For example, this feature can be optimized during the suprapancreatic portion of the D2 lymph node dissection during a radical gastrectomy for locally advanced gastric cancer. The third robotic arm holding a Cadere forceps gently retracts the pancreas in the caudal direction to expose of the celiac axis and splenic artery. The exposure is maintained while the other 2 other arms holding operative instruments carry out that portion of the procedure by dissecting, cutting, burning, ligating, clipping, and providing additional retraction.<sup>51,52</sup>

One of the major advantages of the robotic EndoWrist capability is dissection or suturing in narrow operative fields such as working in a male pelvis during robotic total mesorectal excision.<sup>26,53,54</sup> The robotic arms have been found to be facile in the narrow pelvis where open surgery is a challenge and where laparoscopic rectal or perirectal dissection is difficult to perform. Both the EndoWrist instruments and the tremor filter in this area have been noted to be of utility around nerve-sparing procedures of the total mesorectal excision<sup>55</sup> and during the precise cutting of the esophageal muscles in a Heller myotomy.<sup>56,57</sup> In addition, the Large Needle Driver and

the Mega Suture Needle Driver are EndoWristed with 7 degrees of articulation providing natural turning of the suture at many angles, which facilitates quicker and more precise suturing of bowel or vessels during these gastrointestinal operations.

Among the many robotic surgical procedures already performed, the gastrointestinal procedures during which the surgeon can maximize the robotic technology for both the patient and the surgeon benefit can be exemplified in representative operations such as the robotic Heller myotomy with fundoplication, robotic radical gastrectomy with D2 lymphadenectomy, and robot-assisted colorectal resection with total mesorectal excision. As general surgeons continue to gain more experience with the robotic approach, we are affectively harvesting the novel technology afforded by the robotic surgical platforms for the surgeon benefit with the potential to translate them into improved patient outcomes.

## RESULTS OF CLINICAL STUDIES

In general, surgeons can perform complex operations with increasing ease and precision with the use of the robotic surgical systems over conventional laparoscopy. Current studies of robotic operations for gastrointestinal diseases demonstrate the robotic approach to be safe and feasible and to provide our patients the benefits of minimally invasive surgery with improved outcomes compared to open operations (Table 8-3).<sup>58-60</sup> Moreover, robotic surgeons uniformly report the use of robotic surgical systems to enhance the operative experience and confer an operative advantage during abdominal operations over laparoscopic approaches. Although, robotic surgery has not yet demonstrated any substantial improvement in clinical outcomes when compared to laparoscopy in general, with improved understanding of the superior robotic technology, surgeons have begun to harvest its advantages for specific operations.

**TABLE 8-3: ADVANTAGES AND DISADVANTAGES OF ROBOTIC SURGERY COMPARED TO OPEN AND LAPAROSCOPIC APPROACH**

### **Robotic Advantage Over Open Surgery**

1. Smaller incisions

2. Less blood loss
3. Shorter hospital stay
4. Decreased pain
5. Decreased surgical site infections
6. Decreased systemic complications
7. Decreased incisional hernia rates
8. Earlier return to daily activities
9. Improved cosmetic outcome

### **Robotic Advantage Over Laparoscopy**

#### ***For the surgeon***

1. 3-Dimensional magnified high-definition view
2. Control of 4 arms
3. Improved ergonomics
4. Shorter learning curve
5. Improved accuracy and precision of dissection

#### ***For the patient***

1. Less intraoperative blood loss
2. Improved procedure-specific short-term outcomes
  - a. Heller myotomy—lower esophageal perforation
  - b. Radical gastrectomy—lower learning curve
  - c. Total mesorectal excision—lower conversion rate

### **Disadvantages of Robotic Surgery**

1. Longer operative time
  2. Additional training
  3. Higher cost
- 

## **Heller Myotomy for Achalasia: Improved Precision During Myotomy**

Robotic surgical platform allows for precise dissection of esophageal muscle layers during robotic Heller myotomy, providing an opportunity for surgeons to gain improved surgical outcomes for patients being treated for achalasia. The laparoscopic approach to Heller myotomy has become the standard

treatment for achalasia since the minimally invasive approach demonstrated improved outcomes when compared to the open Heller myotomies.<sup>61,62</sup> The esophageal perforation rate for laparoscopic Heller myotomy, however, remains 5% to 10%, leaving room for significant improvement.<sup>63,64</sup> The technically challenging portion of this procedure is the requirement for precise dissection and cutting of the esophageal muscle layers without damage to the underlying esophageal mucosa. Surgeons have achieved a 0% esophageal perforation rate using the robotic surgical platforms.<sup>65-69</sup>

The initial report of a successful robotic-assisted Heller myotomy published in 2001 by Melvin et al<sup>70</sup> has been followed by several series and comparative studies. Talamini et al<sup>1</sup> reported the safety and feasibility of robotic gastrointestinal procedures in 2002 including 5 successfully performed Heller myotomies. In a series of 104 patients undergoing robot-assisted Heller myotomy (RAHM), Melvin et al<sup>67</sup> reported a 0% esophageal perforation rate with an improvement in the average operative time from 162.63 minutes to 113.50 minutes over a 2-year period. A multi-institutional retrospective study involving 3 institutions comparing 59 RAHM with 62 laparoscopic Heller myotomy patients resulted in similar statistically significant differences in esophageal perforation rates of 0% and 16%, respectively.<sup>65</sup> This group also found that although the initial robotic operations had longer operative times, the average operative times of the last 30 robotic cases did not differ significantly from the laparoscopic approach. The surgeons attribute the improved outcome to the enhanced robotic visualization of muscular layers and improved control of the robotic instruments.<sup>69</sup>

## **Robotic Surgery for Gastric Cancer: Shorter Learning Curve for Robotic D2 Lymphadenectomy**

Minimally invasive gastric cancer operations provide significantly improved short-term patient outcomes without compromising the long-term effectiveness of properly performed radical gastrectomy with lymphadenectomy when compared to the traditional open surgery.<sup>61-75</sup> Unfortunately, the technical difficulty of performing an extended lymphadenectomy, recommended for all surgically resectable patients with

stage II or greater gastric cancer, is well recognized. Even in open radical gastrectomies for gastric cancer, performing D2 lymphadenectomy (removal of all soft tissue containing the lymph nodes that drain the stomach) requires fine dissection around the hepatoduodenal ligament and the celiac axis and along the splenic vessels and is known to have high morbidity and mortality rates in previously published Western studies.<sup>76,77</sup> For laparoscopic approach to this procedure, experienced gastric cancer surgeons report the learning curve plateau to be over 50 cases.<sup>78-81</sup> This is a major challenge because the incidence of gastric cancer in the United States is low, with only a few experienced surgeons able to offer the minimally invasive approach to their gastric cancer patients.<sup>82</sup>

With the advent of robot-assisted gastric cancer operations, there is a real potential for increasing the percentage of minimally invasive surgeries performed for gastric cancer. The advantages of the robotic surgical platform for gastric cancer operations are several. First, in order to perform a proper minimally invasive D2 lymphadenectomy, the procedure requires 5 ports and 2 skilled assistants, one to drive the camera and other to retract, expose, and suction. With the robotic surgical platform, the surgeon has control of 4 of these 5 arms, providing a steady and readily manipulated camera for the optimum operative view at all times, the ability to create your own retraction, and exposure with the third arm while operating with 2 arms with instruments that have the capacity to articulate around vessels and other tissues.

Second, the robotic camera offers a superior view of the surgical anatomy, and the enhanced dexterity provides the surgeon great assistance during the D2 lymphadenectomy, which requires precise dissection along the pancreas and major vessels including the anterior superior pancreaticoduodenal vein on the head of the pancreas, hepatic artery, portal vein, common hepatic artery, celiac artery, left gastric artery, splenic artery and vein, and at times splenic hilum (lymph node station #10 during total gastrectomies).<sup>83,84</sup> Robotic gastric cancer surgeons have emphasized the importance of these perceived superiorities of the robotic technology in helping them perform better operations.

Robotic surgery for gastric cancer was first reported by Hashizume in Japan (2002)<sup>85</sup> and then by Giuliantti in the United States (2003)<sup>15</sup> and has since been adopted by many experienced surgeons to perform radical gastrectomies with D2 lymphadenectomies (Table 8-4).<sup>86-90</sup> The single-

institution safety and feasibility studies were quickly followed by comparative studies, which demonstrated the robotic surgical advantages of minimally invasive surgery in gastric cancer patients (Table 8-5).<sup>91-100</sup> To date, most of the studies evaluating robotic surgery in the United States include a small number of cases, with the largest study composed of 98 patients who underwent robotic distal (n = 59), total (n = 38), or proximal (n = 1) gastrectomies over a 10-year period by Giulianotti's group. With an average follow-up of over 3 years, the study demonstrated comparative long-term oncologic outcome to laparoscopic and open operations. The 5-year cumulative survival rates for patients with stage IA, IB, II, and III disease were 100%, 84.6%, 76.9%, and 21.5%, respectively.<sup>101</sup>

<sup>a</sup>P  $\leq$  .05.

The largest study overall and the only multi-institutional prospective comparative study was conducted in South Korea.<sup>100</sup> These and other studies demonstrate robotic gastrectomy for gastric cancer to provide the same minimally invasive benefits to the patient as laparoscopic surgery over open approaches and include less intraoperative blood loss, shorter hospital stay, decreased use of pain medicine, and early return of gastrointestinal function. When compared to laparoscopy, there are no significant differences in the average number of lymph nodes retrieved, percentage of positive surgical margins, or long-term survival, representing adherence to oncologic principals during surgery without compromise in oncologic outcome. However, the robotic approach for gastric cancer, as for treatment of other diseases, has repeatedly been shown to have longer operative times and higher costs.<sup>100,102</sup>

Another notable advantage of robotic surgery for gastric cancer is its learning curve.<sup>47,103-105</sup> Similar to other studies evaluating the learning curve of robotic surgery versus laparoscopic approach to numerous procedures, the learning curve of robotic radical gastrectomy seems to demonstrate an easier and quicker adaptation when compared to laparoscopy. A shorter robotic

gastrectomy learning curve for an already complex and difficult procedure can increase the number of surgeons who are willing and able to offer a minimally invasive approach and its benefits to patients with gastric cancer.

Thorough understanding of principles of gastric cancer treatment, including strict adherence to the oncologic principles, and proper training in robotic gastric cancer surgery are the keys to providing the benefits of short-term robotic surgical outcomes and ensuring the long-term survival benefits of a proper cancer operation.

## **Total Mesorectal Excision for Rectal Cancer: Lower Conversion Rates and Ease of Adoption**

Total mesorectal excision (TME), the standard surgical technique for locally advanced low rectal cancer, is a technically difficult procedure due to the meticulous dissections that are required in a narrow pelvis for preservation of the autonomic nerves and the mesorectal fascial envelope.<sup>106-108</sup> The technical challenges of a TME are even more pronounced during laparoscopy, which has limited the broad adoption of minimally invasive surgery for rectal cancer operations for over a decade.<sup>109</sup> With the introduction of the robotic surgical systems, surgeons have employed robotic assistance as an alternative minimally invasive approach to overcome some of the challenges of laparoscopic rectal surgery.

Randomized controlled trials have validated the postoperative benefits of laparoscopic rectal surgery along with its oncologic safety.<sup>45,110-116</sup> However, due to the technical difficulty of the procedure and limitations of laparoscopic instruments, surgeons performing laparoscopic nerve-sparing TME have experienced an initial high conversion rate of 34% (mean, 14.5%; range, 0%-35%) and high positive circumferential margins (12%).<sup>112-116</sup> Similar to the challenges faced by gastric cancer surgeons with D2 lymphadenectomy, colorectal surgeons report that laparoscopic TME for cancer is feasible but technically difficult with a steep learning curve (50-150 cases).<sup>117-121</sup> In contrast, the conversions rates for robotic TME are reported to be between 0% and 9.8% and the learning curve to be less than 20 cases.<sup>122-128</sup> With consistently lower rates of open conversions and shorter learning curves, robotic surgical platforms may enable an increasing number of surgeons to perform TMEs for rectal cancer.

Those who perform robotic colorectal surgery emphasize the surgical advantages gained from the enhanced features of the robotic surgical systems, especially the surgeon-controlled 3D optics and steady retraction during robotic TME. Since the initial experience of robotic rectal resection 10 years ago in 2003 by Delaney et al<sup>129</sup> and the first case report of low anterior resection with TME with nerve preservation reported in 2007, several other studies evaluating the application of robotic assistance in performing TME have been conducted (Table 8-6).<sup>130-136</sup> A study from Korea and another from Italy demonstrated the reduced rate of open conversion in robotic TME when compared to the laparoscopic approach. All studies showed no differences in morbidity, number of retrieved lymph nodes, circumferential margin positivity, and length of hospital stay. The only randomized study of 18 patients treated with robotic tumor-specific mesorectal excision or conventional laparoscopic surgery by Baik et al<sup>137</sup> reported a significantly shorter length of stay ( $8.7 \pm 1.3$  days vs  $6.9 \pm 1.3$  days;  $P < .001$ ) with no difference in operative time or conversion rate.

**TABLE 8-6: SELECTED OUTCOMES FOR ROBOTIC TOTAL MESORECTAL EXCISION COMPARED WITH LAPAROSCOPIC APPROACH**

Reference	Country	Approach	No. of Patients <sup>a</sup>	Op Time	Conversion Rate (%)	Positive CRM (%)	No. of LNs	LOS (days)	Leak Rate (%)

<sup>a</sup>Table includes comparative studies with  $\geq 20$  patients.

<sup>b</sup> $P \leq .05$ .

Two meta-analyses are available to provide an overview of the available studies.<sup>138,139</sup> A meta-analysis by Trastulli et al<sup>134</sup> of 8 studies comparing

344 robotic versus 510 laparoscopic rectal cancer resections found an open conversion rate from robotic rectal surgery of 2% compared to 7.5% in the laparoscopic group ( $P = .0007$ ).<sup>134</sup> While operative times were longer in the robotic group than the laparoscopic group, the leak rates (6.4% vs 6.8%) and overall complication rates (19.7% vs 18.8%) were comparable. A more recent study analyzing 4 randomized controlled trials comparing robotic ( $n = 111$ ) versus laparoscopic ( $n = 117$ ) rectal surgery with TME, which included the Baik trial, revealed significantly lower blood losses, conversion rates, and times to recovery of bowel function for the robotic rectal surgery.<sup>135</sup>

A subpopulation of patients who may particularly benefit from robotic versus laparoscopic TME is obese patients.<sup>123</sup> Obesity increases the rate of open conversion from laparoscopic surgery, increases circumferential margin positivity, and results in worse clinical and oncologic outcomes. Analysis of 30 obese patients and 72 nonobese patients who received robotic TME revealed no statistical difference in circumferential margin positivity (3.3% vs 1.3%,  $P = 1$ ) and anastomotic leak rates (3.3% vs 7.3%,  $P = 1$ ) and a trend toward increased open conversion in the obese group (10% vs 2.5%,  $P = .15$ ).<sup>140</sup> High-level evidence comparing robotic versus laparoscopic surgery for rectal cancer will be available from the ROLARR trial, an international multicenter randomized controlled trial.

In the past decade, surgeons using the robotic platforms of the da Vinci systems have demonstrated safety, feasibility, and comparable clinical outcomes for their patients when compared to the laparoscopic approach. Robotic surgeons uniformly acknowledge the significant operative advantage afforded by the enhanced features of robotic surgical platforms when performing complex minimally invasive operations such as the RAHM, robotic D2 lymphadenectomy, and robotic TME. Furthermore, robotic surgery has a quicker learning curve and adaptation to minimally invasive surgery compared with the laparoscopic approach, introducing the possibility of broader adaptability of minimally invasive surgery for more complex abdominal operations.<sup>141</sup> Robotic surgery grants surgeons another option of offering minimally invasive surgery and its benefits to their patients.

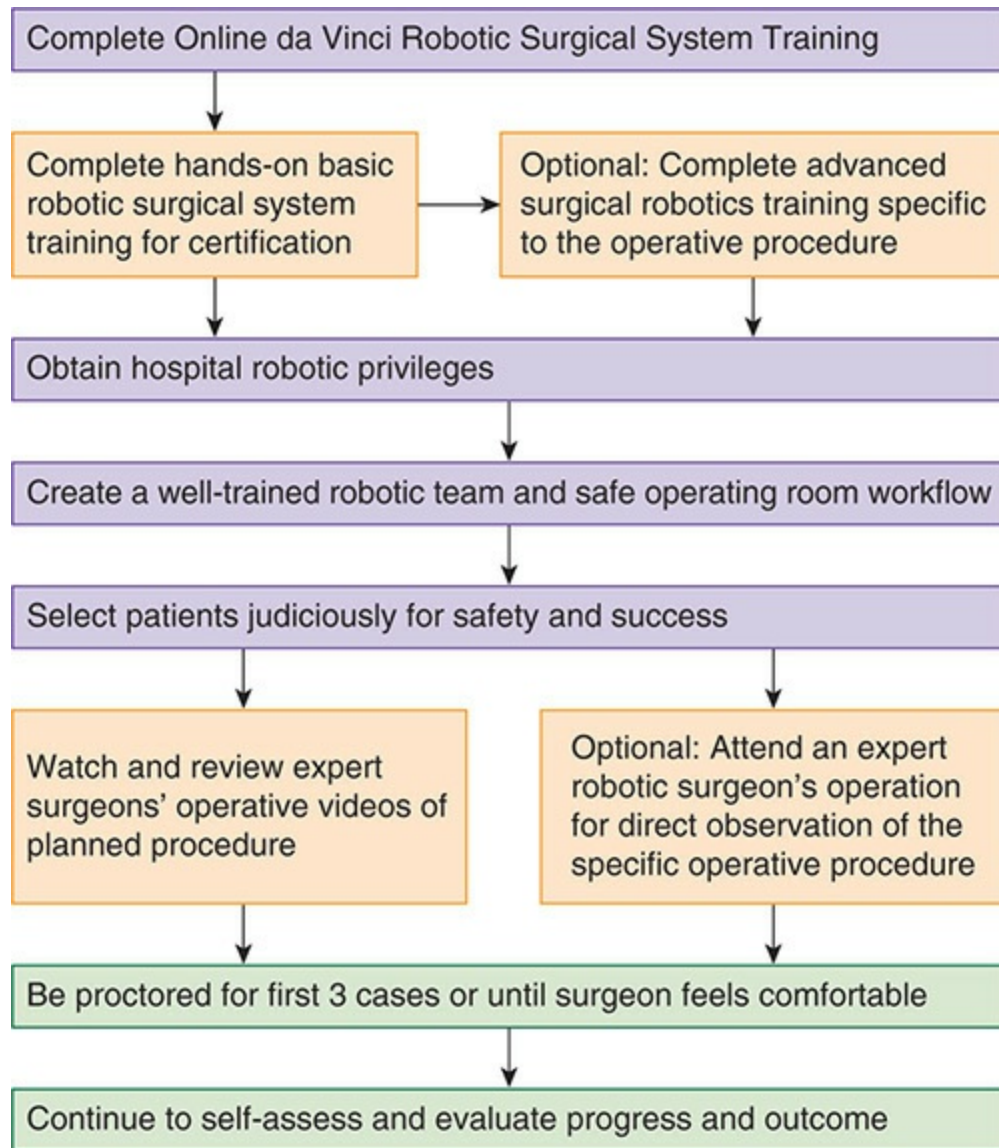

Much like when laparoscopy began to challenge the century-old tradition of open operations, the controversy over the efficiency of complex robotic operations when compared to the laparoscopic approach will continue to fuel debate and lead to additional studies. As the disadvantages of longer

operative time, limited training opportunities, and increased cost of the new technology are still being addressed, the decision to perform robotic gastrointestinal operations is based largely on the perceived advantages for the surgeon and the expected improved postoperative patient outcomes of minimally invasive surgery in general.

## **DECISION TO USE THE ROBOTIC APPROACH**

For now, a surgeon's decision about whether or not to offer a robotic operation for surgical diseases of the gastrointestinal tract is based on the surgeon's access to the robotic system and his or her knowledge, training, and experience. For over 100 years, the sole surgical approach was the conventional open method. In more recent years, with the application of laparoscopy and then with robotics, there is an additional level of decision making that is required when a surgeon thinks about how he or she will perform the necessary operation, whether it will be an open, laparoscopic, or robotic approach, and when and why he or she will offer the robotic approach over conventional laparoscopy or traditional open operations.

To have the robotic option and to be able to offer a choice to the patient, the surgeon must first decide to incorporate robotic surgery into his or her practice, become familiar with the robotic surgical platform (Fig. 8-3) and the appropriate use and application of the robotic instruments, and understand the technologic advantages it may offer. Second, he or she must be well trained on the use of the robotic surgical system and the selected robotic procedures and create a well-trained robotic operating room team (bedside assistant, scrub nurse, circulator). Third, he or she should critically evaluate the results of available studies. Fourth, the surgeon should constantly reevaluate and self-assess. Fifth, the surgeon should determine the benefits and disadvantages of the robotic approach in his or her own hands.

**FIGURE 8-3** Setting up a surgical robotic system.

## FUTURE APPLICATIONS

The application of robotic technology in gastrointestinal surgery is in its nascent stages. With only 1 company producing robotic surgical platforms, less than 5% of general surgery being performed with robotic assistance, and only 20% of all robotic surgery being performed by general surgeons, the optimal translation of the robotic technology into clinical surgical practice has yet to be reached. Even in the current da Vinci Surgical Systems, several innovative features exist that have yet to find wide utility. For example, the Tilepro

program on all the da Vinci surgical systems offers the potential to integrate multiple views into the surgeon's console screen and the assistant's monitors to provide real-time view of the operative field, along with other real-time images such as intraoperative ultrasound findings or intraoperative endoscopic images.<sup>142,143</sup> In addition, this same function allows the surgeon to view preoperatively obtained images such as a computed tomography scan of the patient or an angiogram of the abdominal vasculature.<sup>144-146</sup>

In addition, the robotic camera has near-infrared viewing capabilities, a feature that can easily be turned on and off during an operation. After injection of indocyanine green, its uptake can be visualized during the operation to identify vessels, the biliary tree, and lymph nodes depending on the timing and mode of injection.<sup>147-150</sup> Preliminary reports of the use of fluorescence imaging during robotic gastrointestinal surgery have demonstrated that near-infrared imaging can be used to identify the perfusion of the rectal stump during colorectal surgery, helping surgeons identify proper resection margin to avoid devascularized anastomoses. The proper clinical applications of these features of robotic technology have potential to increase patient safety and surgeon's efficiency during the operation.

## CONCLUSIONS

Robotic surgery for gastrointestinal procedures promises the advantages of novel technology with potential for significant benefits to the general surgeons and our patients. So far, robotic gastrointestinal surgery has been found to be safe and feasible and to provide perceived advantages to the surgeon with an improved learning curve for the approach over laparoscopy. Moreover, robotic surgery demonstrates clinical outcomes equivalent those of laparoscopic surgery. No doubt the technology is superior to that provided by laparoscopic instruments. However, the future of robotic surgery will depend on the surgeon's ability to translate the technology into meaningful and specific benefits for the patients.

## GASTROINTESTINAL CONDITIONS

### **Pyloric Stenosis**

Hypertrophic pyloric stenosis occurs in 1.5 to 4 in 1000 live births, and more recent population-based studies suggest the incidence is decreasing over time. It remains a common cause of neonatal emesis and typically presents in the third to fifth week of life. The emesis is typically nonbilious and projectile, although some jaundiced infants may have emesis that has bilious appearance. Hypertrophic pyloric stenosis (HPS) occurs more frequently in male newborns, although providers should be aware that a patient whose mother had pyloric stenosis as an infant has a fourfold incidence of HPS. The precise etiology of the hypertrophied pylorus is unclear, but what was once thought to be an inherently congenital problem is now understood to be an acquired condition. The causes of pyloric stenosis are likely multifactorial, including both genetic and environmental causes. Caretakers often describe projectile nonbilious vomiting and infants present with dehydration and electrolyte imbalances. Physical exam may reveal a sunken fontanelle, lethargy, visible intestinal peristalsis, and in some infants a palpable “olive.”

The “olive” is frequently appreciated by experienced examiners. A nasogastric tube is sometimes necessary to decompress the stomach while the hungry child is calmed by being allowed to drink glucose water, thereby allowing an exam which reveals the presence of an “olive.” The exam is best performed by standing to the right of the child, placing the left hand behind the lower back, and palpating just to the left of the midline with the right hand. The primary physiologic disturbance is hypokalemic hypochloremic metabolic alkalosis, which occurs due to the gastric losses from unremitting emesis. Evaluation should include a renal function panel and imaging. At centers where immediate ultrasound is not available and an “olive” is not palpated, an upper gastrointestinal (UGI) study may be obtained to delineate the obstruction and hypertrophied pylorus. Although exact size criteria vary by institution, it is commonly accepted that muscle wall thickness greater than 3 mm and length greater than 14 mm is abnormal in infants under 30 days old (Fig. 9-1). Infants who are diagnosed with pyloric stenosis must be adequately resuscitated before proceeding to the operating room for pyloromyotomy. The anesthetic risk is heightened when the patient’s bicarbonate level is 30 or greater, as the body attempts to compensate for the metabolic alkalosis with respiratory acidosis, which is accomplished with decreased respiratory drive or hypoventilation. Resuscitation goals should include correcting the metabolic alkalosis and additional electrolyte disturbances such as hypokalemia. Infants should be voiding adequately as a marker of resuscitation as well prior to the operating room. The surgical treatment of HPS is a pyloromyotomy performed laparoscopically or open. The pylorus is incised longitudinally so as to divide the hypertrophic fibers, but avoiding perforation of the mucosa. The hypertrophied wall is then spread until the entire length of the pylorus allows for bulging of the mucosa from the circular muscle fiber of the stomach to just proximal to the duodenum (Fig. 9-2). The risk for perforation is highest at the duodenal end of the pyloromyotomy, and standard teaching suggests that ongoing feeding intolerance following operation is associated with inadequate proximal pyloromyotomy. Inspection of the mucosa can detect bile if a perforation occurred, and some surgeons will also test the pyloromyotomy with insufflation of the stomach while clamping the duodenum distally. If a perforation is identified, the opening should be closed by approximating the mucosa to the seromuscular edge. Patients often do well postoperatively and are best fed ad lib, or on a fast feeding protocol to reach goal in order to

allow for discharge home. Many patients have emesis postoperatively due to edema of the pylorus after manipulation, and parents should be prepared for this expected outcome. Postoperative ultrasound and UGI will demarcate persistent pyloric stenosis even in the setting of adequate pyloromyotomy. Thus, in most cases, watchful waiting is the best course of action with postoperative feeding intolerance. If a perforation has occurred intraoperatively, patients are left with a nasogastric tube and a UGI is performed postoperatively with feeding advancement once a negative study is obtained.

**FIGURE 9-1** Pyloric channel visualized by ultrasound showing an elongated, thickened pylorus highly suggestive of pyloric stenosis. Pyloric length greater than 14 mm and thickness greater than 3 mm are considered criteria diagnostic for pyloric stenosis on ultrasound.

**FIGURE 9-2** Laparoscopic pyloromyotomy showing spreading of the muscle fibers using blunt graspers. Adequate myotomy is done when the mucosa can be seen bulging through the myotomy and the two sides of muscle can be moved against each other without any restriction.

## **Necrotizing Enterocolitis**

Necrotizing enterocolitis (NEC) is the most common surgical emergency in the neonate and can have lifelong morbidity for affected newborns. NEC is an acquired disease mostly of extremely low birth weight infants (<1000 g). Other risk factors include patent ductus arteriosus treated with indomethacin and enteral feeding with formula. Extensive research has demonstrated the relationship of inflammatory factors, bacterial insults, immune alterations, and environmental genetic roles that may give rise to the mucosal insult in NEC. Providers should be aware of the clinical presentation of an infant with NEC including blood in the stool, bilious emesis, abdominal distention, and abdominal wall discoloration (Fig. 9-3). Neonates may also present with hemodynamic instability, respiratory failure, apnea, bradycardia, neutropenia, leukocytosis, thrombocytopenia, and metabolic acidosis. Plain film radiographs may reveal dilated intestinal loops, bowel wall thickening, pneumatosis intestinalis, portal venous gas, and free peritoneal air. Ultrasound may demonstrate similar findings.

**FIGURE 9-3** Abdominal discoloration in a neonate with NEC.

The majority of infants are treated with medical management including discontinuation of enteral feeding, nasogastric decompression, resuscitation, correction of electrolyte abnormalities, and antibiotic initiation. Indications for operative treatment include decline in hemodynamic stability, worsening physical exam, or pneumoperitoneum. The objective in operative treatment is to diagnose the source of sepsis and resect necrotic bowel, and may include a second-look operation in order to limit bowel resection (Fig. 9-4). The patient may be left with one or multiple enterostomies. In unstable low birth weight infants, a drain may be placed in the right lower quadrant in lieu of a formal operation. Most neonates will physiologically improve following drain placement. However, some may go on to decline clinically, and in this case a formal exploration is indicated. Postop care should focus on stabilizing the patient and providing parenteral nutrition, with the plan to close the

enterostomy at 6 to 8 weeks after the initial resection. Contrast study is utilized to evaluate for distal points of obstruction since it is common for strictures to form in NEC despite an initial grossly normal appearance of the distal bowel.

**FIGURE 9-4** Intraoperative finding of thinned, necrotic intestinal wall in a neonate affected by NEC.

## **Short Bowel Syndrome**

Short bowel syndrome (SBS) is a condition in which an impaired or limited length of intestine reduces the absorption of nutrients from enteral sources. SBS can occur due to loss of bowel length in the setting of NEC, midgut volvulus, gastroschisis, and with bowel dysfunction such as with motility disorders. The actual length may vary in those pediatric patients affected by SBS, and is impacted positively by the presence of the ileocecal valve as well as a functional colon. Patients with SBS are dependent on total parenteral nutrition (TPN) and may eventually tolerate feeds entirely via an enteral route. The ability to tolerate enteral feeds is dependent on the proportion of small bowel remaining when compared to that expected. Bowel lengthening procedures such as the serial transverse enteroplasty (STEP) and Bianchi procedures depend on the fact that the bowel dilates in the setting of SBS. Such bowel lengthening procedures, along with the development of optimal medical management—associated emergence of centers with SBS programs have been shown to enhance survival in patients with SBS. When necessary, small bowel transplantation, sometimes with liver transplantation, is an option, with an improving 5-year survival in patients with refractory SBS and/or liver failure.

## **Severe Reflux/Gastrointestinal Reflux Disease**

Gastrointestinal reflux disease (GERD) is a relatively common diagnosis in pediatric patients, and as many as 7% of children and infants are diagnosed with GERD. Infants present to the pediatrician with symptoms of reflux including emesis, retching, back arching, and sometimes more severe symptoms such as apparent life-threatening events (ALTE). Many infants and children experience physiologic reflux, which is not considered pathologic. However, if reflux interferes with adequate nutrition and growth or causes aspiration, esophagitis, or hospitalization, medical intervention should be initiated. Medical treatment may not be effective for all infants and children with GERD, and surgical intervention is considered for these patients. It is not entirely understood why some otherwise normal children develop pathological GERD. Children with esophageal atresia (EA), congenital heart defects, and neurological impairment experience an increased incidence of GERD. The Nissen fundoplication is indicated in children with failed medical

management of GERD and who are at risk for complications of reflux if left untreated. The fundoplication is performed laparoscopically or open, and a 360-degree wrap is typically performed. However, in some cases where the esophagus is dysfunctional (such as with EA), or where the patient's stomach may be small or tubular in shape, a partial wrap, such as a Thal wrap, may be considered. Outcomes favor surgical intervention over long-term medical management. However, the evidence is limited to retrospective data without long-term outcomes. It should be recognized that many children, especially <1 year of age, may simply grow out of their reflux and may not need fundoplication.

## **ABDOMINAL WALL DEFECTS**

### **Gastroschisis**

Gastroschisis is an abdominal wall defect that occurs in the developing embryo and is thought to be a failure of the lateral folds to completely approximate. It affects approximately 5 in 10,000 infants and is associated with maternal factors such as low socioeconomic status, use of tobacco, low maternal age, environmental exposures such as solvents, colorants, and medications such as cyclooxygenase inhibitors and decongestants. Prenatal diagnosis is made via in utero ultrasound. At one time the thought was that Cesarean section may be indicated to prevent injury to the exposed bowel. However, there are no data to support either early vaginal or Cesarean section delivery. Most infants do not have associated anomalies, and of those that do, intestinal atresia is the most common, occurring in 10% to 15% of patients with gastroschisis.

The infant with gastroschisis should be delivered in a center with a neonatal ICU and access to pediatric surgery. A nasogastric tube should be placed to decompress the bowel. Dehydration and hypothermia from insensible fluid and heat losses are prevented by immediate administration of intravenous fluids, wrapping the viscera with a moist gauze dressing, and placement of the lower portion of the newborn's body in a bowel bag. The viscera should be supported so that they remain on top of the abdomen, rather than falling over to the side, to avoid venous outflow obstruction, which can augment bowel edema. Broad-spectrum antibiotics are administered.

Once the infant is resuscitated, the viscera are examined for evidence of atresia, mesenteric injury, or bowel compromise. Rectal irrigation is often performed to aid in evacuating meconium to reduce the visceral volume, and a Foley catheter is inserted to decompress the bladder. The bowel is often thickened, probably due to contact with the amniotic fluid, such that individual bowel loops are poorly defined (Fig. 9-5). If an atresia is suspected at the time of birth, primary abdominal wall closure is still first achieved in the majority of patients. If an atresia is then confirmed in the postnatal period, re-exploration with repair of the atresia should be performed at 3 to 6 weeks. In some circumstances, an enterostomy is required, especially in the setting of obvious atresia or compromised bowel.

**FIGURE 9-5** Gastroschisis patient with bowel that appears matted together.

Primary closure of the abdominal wall is successful in approximately 80% of newborns. “Sutureless” closure using the umbilical stalk may be successful in neonates with adequate abdominal wall compliance and a small defect (Fig. 9-6). While the fascia has traditionally been closed with sutures at birth,

recent experience has suggested success with using the umbilicus to patch the fascial defect. During attempted reduction of the viscera, it is vital to recognize any compromise in physiologic status of the neonate during closure such as significant increase in airway pressures, unstable hemodynamics, or development of acidosis due to excess intra-abdominal pressure. Examination of the newborn's lower body may demonstrate edema and cyanosis due to venous congestion. If signs of increased abdominal pressure are observed, the bowel should be removed to decompress the abdomen and a silo placed.

A

B

C

**FIGURE 9-6** **A.** Viable bowel being reduced into the abdominal cavity. **B.** Reduced bowel without concern for excessive tension on the abdominal wall. **C.** Closure of the abdominal wall defect with umbilical stalk; also called “sutureless” closure.

If the bowel cannot be safely reduced, a staged closure using a prosthesis is useful (Fig. 9-7). Spring-loaded, preformed silos are now available in different sizes and are easy to place, which precludes the need to manually construct a silo. In some cases, the abdominal wall defect is enlarged to avoid a funnel type configuration of the silo, which could lead to compression of the bowel at the base of the silo with ischemia and necrosis. The silo is wrapped in betadine-moistened gauze to prevent infection and suspended from the over-bed warmer in order to encourage gravity-assisted reduction of the remaining viscera. The viscera are gradually reduced by compressing or twisting the silo and tying an umbilical tape sequentially lower on the silo once every 12 to 24 hours. Use of a silo may be associated with a decrease in time on the mechanical ventilator and time to initial and full feedings. The viscera are usually reduced within a week such that the base of the silo is flat. The patient is then taken back to the operating room and the fascia closed. The edge of the opening is incised and the fascia identified circumferentially. Vicryl sutures are then placed to close the fascia; this is often done in a horizontal fashion because the tension is less than with a vertical fascial closure. Fascial closure sometimes leads to physiologic compromise. In that case, a Vicryl or a biosynthetic mesh (Surgisis ES; Cook Tissue Engineering Products, Bloomington, IN) may be sewn to the fascia, although a ventral hernia may result. This includes infants in whom the bowel cannot be completely reduced and those with concern for ischemic bowel, because a silo allows one to directly monitor the bowel status.

A

B

**FIGURE 9-7** Gastroschisis bowel in a silo. **A.** Closure with mesh pieces

sewn to the fascia and to each other to form a contoured silo for the patient.  
**B.** Preformed silo with spring loading on the internal portion of the silo.

Following reduction of the viscera, return of GI function often is delayed: median time to initiation of feedings is 15 days, with full enteral intake achieved by 22 days. Nearly all patients with gastroschisis require nutritional support with parenteral nutrition and central venous access. Postoperative bowel obstruction is relatively uncommon, and an upper GI contrast study is performed after approximately 2 to 3 weeks when GI function fails to normalize. If the silo separates from the fascia, a pseudomembrane has usually formed beneath the silo, which can be allowed to granulate. Skin graft closure of the abdominal wall is possible once infection has been resolved using topical silver sulfadiazine.

Survival is over 90%. However, the complications that arise pose a considerable threat in the neonate with gastroschisis. NEC may occur during advancement of enteral feeds after gastroschisis closure. Neonates with gastroschisis may be at increased risk of developing NEC due to enhanced mucosal permeability, intestinal dysmotility, or intestinal atresia. Patients with gastroschisis who develop NEC have lower birth weight and are more likely to be formula fed. An enterocutaneous fistula may develop from an anastomotic leak or intestinal injury. Malrotation, if not corrected at the time of the initial operation, may rarely result in jejunal obstruction due to Ladd bands or volvulus. SBS may occur as a result of bowel dysfunction or loss of bowel due to atresia or one of the complications outlined previously. By 6 months of age, intestinal function, in general, has returned to normal. GERD is observed in 16% of patients with gastroschisis, likely related to the presence of increased intra-abdominal pressure.

## **Omphalocele**

Omphalocele differs from gastroschisis in that it consists of an abdominal wall defect at the umbilicus, a peritoneal and amnion covering or sac, a normal umbilical cord that attaches to the sac, and umbilical vessels that radiate over the defect (Fig. 9-8). Patients with omphalocele have a ruptured sac in approximately 10% of cases; however, the underlying diagnosis is still contrasted from gastroschisis due to the characteristics noted above. The liver is within the defect in approximately half of the patients.

**FIGURE 9-8** Omphalocele with intact sac containing bowel and solid viscus.

Approximately 30% to 60% of newborns with omphalocele present with concomitant anomalies which may be a source of major morbidity and mortality. Congenital heart disease occurs in 20%, abnormal karyotypes are observed in 29%, and the Beckwith–Wiedemann syndrome is seen in 10% of patients. Patients with Beckwith–Wiedemann may have macroglossia, leading to airway obstruction, and may also present with hypoglycemia, which requires prompt preoperative recognition and treatment.

The initial management of omphalocele is similar to that described for gastroschisis. Hypothermia and dehydration are avoided and treatment with broad-spectrum antibiotics is initiated. Endotracheal intubation and mechanical ventilation may be required if respiratory distress is present, often related to underlying pulmonary hypoplasia. Infants born with giant or large omphalocele greater than 4 to 6 cm in size and/or having the liver in a central position have an increased association with pulmonary hypoplasia and respiratory distress and therefore may require prolonged support with mechanical ventilation. During initial resuscitation, the sac is left intact and is covered with saline-soaked gauze to prevent desiccation and to decrease heat and fluid losses. Evaluation for other chromosomal and developmental

anomalies, especially those related to congenital heart disease, is undertaken.

If the defect is <4 cm in size, it is considered a hernia of the umbilical cord. Closure of a defect of this size is often straightforward and may be amenable to primary closure. Omphaloceles >4 cm are typically more challenging and complicated to manage, and are associated with a poorly developed peritoneal cavity (Fig. 9-4). Skin coverage of the omphalocele defect is the primary goal.

Traditionally, the omphalocele sac is excised during staged reduction, except for where it is adherent to the liver. Excision of the sac in that location could result in liver injury and bleeding. Should bleeding occur, pressure and clot-enhancing agents should be applied. Unfortunately, once the sac is excised, there is time pressure to achieve visceral reduction. Instead, surgeons have recommended leaving the sac intact and sequentially gathering the sac to achieve reduction (Fig. 9-9). Once reduction is accomplished, the fascia may be closed as described for a gastroschisis. A currently popular approach is to use external compression by wrapping of the omphalocele to augment reduction of the viscera while allowing the sac to epithelialize over several months. Application of Silvadene rather than mercurochrome, which can cause mercury poisoning, results in eschar formation of the sac. Contraction and flattening of the omphalocele is often the result, although a ventral hernia usually remains.

**FIGURE 9-9** Large omphalocele wrapped with gauze and elastic wrap.

When these approaches do not work, or in the case of a ruptured omphalocele, the skin–amniotic junction is incised circumferentially and the fascia mobilized; caution should be exercised when dissecting over the superior aspect of the liver since the hepatic veins are often superficial in this location because of the downward position of the liver in the omphalocele. If care is not exercised, injury to and bleeding from the hepatic veins can result. Examination of the diaphragm should be performed to check for the presence of an associated defect. With a large omphalocele, primary closure is rarely possible. Thus, a silo is created from Dacron-reinforced silastic or Gore-Tex (W.L. Gore and Assoc., Inc.; Newark, DE) and is sewn to the fascial edges. The mesh is sequentially gathered in the midline until the fascial edges are nearly approximated. During this process, one must balance aggressively tightening the mesh with avoiding undue tension on the mesh: excess tension could lead to premature separation of the mesh from the fascia. The patient should also be monitored for evidence of high intraabdominal pressure

resulting in hypercarbia, oliguria, hemodynamic compromise, and acidosis. Such high pressures could compromise ventilation, renal blood flow, cardiac output, intestinal perfusion, and venous drainage from the lower extremities. Once it is nearly approximated, the fascia can then be closed with removal of the mesh, although a reasonable option is to close the skin while leaving part of the mesh in place. If the mesh separates, granulation tissue often remains underneath. This presents a challenging wound care problem: application of homograft and other artificial wound coverings may be considered. One option is to allow the wound to epithelialize. An alternative is split-thickness skin graft placement, which is often effective once any wound infection is controlled.

As with gastroschisis, return of gastrointestinal function is often delayed in patients with a large omphalocele. Parenteral nutrition is initiated within the first few days of life, requiring early central venous access. Mechanical bowel obstruction can occur, but is unusual. Lung and chest wall hypoplasia and chronic respiratory insufficiency are reasonably common among patients with giant omphaloceles, and tracheostomy tube placement may be required. Staged reduction in patients with giant omphalocele applies pressure upon the diaphragm, which complicates lung dysfunction.

Survival is 80% to 90%, and mortality is impacted primarily by the associated anomalies. In children with omphalocele, the incidence of gastroesophageal reflux (GER) is high (43%), likely due to the elevated intraabdominal pressure. Ventral hernias often result when a nonsurgical approach is employed. A staged approach to closure of the ventral hernia will be required in those with massive ventral hernias. The incidence of cryptorchidism is increased in patients with omphalocele (16%); this is thought to be related to decreased intraabdominal pressure during the typical period of physiologic in-utero testicular descent.

## **INTESTINAL OBSTRUCTION IN THE NEONATE**

### **Malrotation**

At approximately 8 to 10 weeks of development, the midgut rotates 270

degrees counterclockwise, which leads to fixation of the proximal small bowel at the ligament of Treitz, attachment of the cecum and right colon in the right lower quadrant, and broad fixation of the base of the small bowel mesentery to the retroperitoneum. If this rotation fails to occur, the small intestine remains on the right side of the abdomen, the cecum is typically at a location other than the right lower quadrant, and the bowel remains unfixed. The entire midgut is mobile and prone to rotation on a central axis or volvulus, which is the mode of presentation in 85% of newborns and 31% of patients of all ages. Volvulus may compromise superior mesenteric artery (SMA) inflow and venous blood outflow, leading to ischemia or necrosis of the entire small intestine and transverse colon. In addition, peritoneal bands known as Ladd bands, which are responsible for drawing the cecum into the right lower quadrant, cross over and may partially obstruct the distal duodenum and proximal small bowel. Eighty-nine percent of patients with symptomatic malrotation present in the first year of life, with 50% in the first week and 65% in the first month, leaving only 11% to present after the first year. An occasional older patient presents with intermittent midgut volvulus and recurrent abdominal pain that may mimic other common causes of an acute abdomen.

The failure to recognize this entity promptly may result in the loss of the entire midgut. The primary symptom of acute midgut volvulus is sudden onset of bilious vomiting; therefore it is essential the provider consider the diagnosis of malrotation in any infant with bilious vomiting. With midgut volvulus, as the distal bowel empties, the abdomen is often scaphoid rather than distended. Physical examination is unexpectedly without peritonitis until later in the process when intestinal ischemia and necrosis develop. At that point, abdominal distension, tenderness, and hematochezia are often present. As the course progresses, hypovolemia, shock, and acidosis ensue. To avoid these sequelae, an emergent contrast UGI study should be performed. UGI evaluation of the course of the duodenum demonstrates that the duodenojejunal junction remains to the right of the midline, and the normal posterior and cephalad fixation of the duodenum at the ligament of Treitz is absent (Fig. 9-10). If volvulus is present, a corkscrew appearance of the duodenojejunal junction is noted. Ultrasound may be helpful in diagnosing midgut volvulus by identifying an abnormal SMA and superior mesenteric vein (SMV) relationship as well as inability to identify the duodenum passing behind the SMA.

**FIGURE 9-10** Contrast study showing lack of duodenal sweep across midline, a key objective finding of malrotation.

Midgut volvulus is a surgical emergency. Once the diagnosis of malrotation is made in the symptomatic patient, immediate laparotomy is indicated even if radiologic and clinical signs of volvulus are absent (Fig. 9-11). The child should be rapidly resuscitated either in the operating room or while preparing the operating room. A Ladd procedure consists of the following: (i) exploration of the midgut; (ii) counterclockwise derotation of a midgut volvulus (if present); (iii) performance of a Kocher maneuver with

division of Ladd bands; (iv) broadening of the mesentery of the proximal jejunum and the transverse colon by division of adhesions between these two structures—along with subsequent general bowel adhesion formation, broadening the mesentery will reduce the incidence of recurrent volvulus (Fig. 9-12); (v) return of the intestine to the abdomen without any twists in the mesentery, and placement of the cecum in the left lower quadrant to further broaden the mesentery; and (vi) appendectomy because of the potential of a difficult diagnosis of appendicitis in the future with the inappropriate location of the appendix. Failure to completely detorse the bowel or lyse all of Ladd bands may result in persistent obstruction or recurrence of volvulus. There is no evidence to support fixation of the intestine to the retroperitoneum. If compromised bowel is noted, a second look at 24 hours is an option to minimize the amount of bowel resected and short gut syndrome. If the surgeon encounters grossly necrotic bowel it may be necessary to resect and plan for reexploration at 24 hours. Performance of an ileostomy is usually necessary only if there is continued question of intestinal viability at reexploration. Necrosis of the entire midgut makes survival unlikely; resection of the entire midgut is associated with high morbidity and lifelong parenteral nutrition or small bowel transplantation in most cases. Postoperative complications may occur such as recurrence of midgut volvulus; although infrequent, <2% of patients have recurrence and it is thought to be related to a failure to lyse all the Ladd bands. Adhesive bowel obstruction occurs in 1% to 10% of patients, and perioperative mortality is 4% and is primarily associated with sepsis from massive intestinal necrosis. Mortality is at least 50% in those with extensive (>75%) small bowel infarction. Mortality may be also increased in those with congenital heart disease. One review of patients with malrotation and heterotaxy identified nearly 10% in-hospital mortality, due to cardiac causes in those who underwent a Ladd procedure. However, the authors noted that the deaths were not due to the Ladd procedure and that 27% of the patients with heterotaxy and symptomatic malrotation had midgut volvulus. In another study, 18% of patients with heterotaxy died after a Ladd procedure: all deaths occurred more than 1 month after the operation and were due to the underlying cardiac disease. It is therefore important for the surgical and cardiology teams to discuss the potential risks and benefits of a Ladd procedure in patients with congenital heart disease and asymptomatic malrotation.

**FIGURE 9-11** Malrotation with volvulus: The axis of volvulus is the narrow mesentery of the nonrotated intestine; the segment of intestine to the right appears dusky and compromised secondary to volvulus. Healthy proximal bowel is seen to the left.

**FIGURE 9-12** Malrotation after Ladd's procedure with widening of the mesentery.

## **Esophageal Atresia/Tracheoesophageal Fistula**

Providers may be aware of the potential for the diagnosis of esophageal atresia (EA) from a diagnostic ultrasound performed during gestation

demonstrating polyhydramnios. Postnatally, a neonate may have difficulty handling secretions and may have symptoms of choking or coughing with feeding. Usually an unsuccessful attempt is made at passing a nasogastric or orogastric tube. Curling of the tube in the dilated proximal esophageal pouch may be seen on plain radiograph and is pathognomonic for EA (Fig. 9-13). The neonate is always at risk for aspiration, especially if EA goes unrecognized. In addition, gastric secretions may reflux into the lungs through a distal tracheoesophageal fistula (TEF), if present, and lead to further lung contamination and the development of pneumonia. Maintaining the newborn in a strict 30-degree to 45-degree upright position will inhibit reflux of gastrointestinal contents into the tracheobronchial tree. Intravenous antibiotics should be administered prophylactically if the patient exhibits signs of pneumonia. Mechanical ventilation should be performed only if necessary because of the risk of ventilation through a TEF leading to gastric distention, and potentially, perforation. Respiratory insufficiency, especially in the setting of prematurity and respiratory distress syndrome (RDS), may be associated with a decrease in pulmonary compliance. In that setting, the TEF competes with and prevents adequate pulmonary ventilation. Occlusion of the TEF via lower esophageal occlusion with a balloon catheter introduced through a gastrostomy site or thoracotomy with division of the fistula may be required with or without performance of an esophageal anastomosis (esophagogastrostomy).

**FIGURE 9-13** Esophageal atresia with tracheoesophageal fistula. A nasogastric tube placed into the proximal pouch that appears to be folding on itself (black arrow). Air within the stomach and bowel is highly suggestive of a communication between the trachea or airway and the gastrointestinal tract,

likely in form of a tracheoesophageal fistula.

Air in the abdomen on radiograph suggests the presence of a distal TEF (85%), and the absence of distal air indicates a pure EA (7%) (Fig. 9-14). Radiologic evaluation, performed with careful administration of contrast medium into the upper pouch with the patient sitting upright to avoid aspiration, will verify the diagnosis of EA and identify a proximal TEF, which is present in approximately 1% of patients. Proximal fistulas are frequently missed at the time of operation because the fistula may be proximal, above the level of routine dissection. The presence of a small proximal pouch suggests that a proximal fistula may be present and that the anastomosis may be under tension. Bronchoscopy may help to identify a proximal fistula in the operating room prior to repair of the EA/TEF. However, bronchoscopy may miss small proximal fistulas, and contrast study of the proximal pouch appears to be an equally useful adjunctive test with low risk of aspiration when appropriately performed (Fig. 9-15).

**FIGURE 9-14** Pure esophageal atresia. A retractor is seen coiled in the proximal pouch (white arrow). There is a paucity or lack of air in the stomach or bowel, suggestive of lack of a fistula between the trachea and esophagus.

**FIGURE 9-15** Pouchogram showing contrast filling within the proximal pouch without evidence of a fistula between the pouch and airway.

Greater than half of the patients with EA/TEF have associated anomalies. Approximately 15% of patients have a constellation of findings compatible

with the VATER or VACTERL association (vertebral defects, anal atresia, cardiac anomalies, TEF and EA, renal defects, and limb abnormalities). The most common anomalies are cardiac (38%) and are responsible for many of the deaths associated with EA and TEF. Renal anomalies occur in 17% of patients.

In general, patients with EA and a distal TEF have adequate esophageal length to allow primary reconstruction. A repair is generally planned within the first 24 to 48 hours unless contraindicated by prematurity, the presence of congenital heart disease, or critical illness rendering the operative and anesthetic risks unacceptable. In that case, temporizing with proximal pouch repleg suction and a gastrostomy tube with plans for delayed repair may be the best strategy. When repair is performed, an approach through the right chest using a muscle-sparing incision is typically performed with access via the fourth intercostal space. The presence of a right aortic arch, found in 2% of patients with the EA/TEF anomaly, should be identified on echocardiography so that the surgical team can consider a left thoracic approach. A retropleural approach is historically used in order to contain a potential leak, although there is no evidence to suggest that such an approach is beneficial. The distal TEF is identified in the region of the carina and is divided. Prior to division of the fistula, maintenance of oxygenation may be tenuous and requires that the surgeon intermittently allow expansion of the right lung; this problem usually resolves once the fistula is ligated. A few millimeters of esophageal tissue are left on the trachea during division of the TEF in order to avoid compromise of the tracheal lumen. The tracheal closure is checked for an air leak with saline submersion and application of sustained airway pressure. The distal esophagus can be mobilized with minimal risk of devascularization. The proximal esophageal pouch can be identified by having the anesthesiologist advance a catheter placed through the mouth into the pouch. A suture is placed in the apex of the proximal pouch for manipulation in order to avoid trauma due to repeated grasping of the tissue. The pouch is mobilized in the upper mediastinum; care is taken while mobilizing the anterior esophagus because of the risk of entry into the membranous trachea. Use of cautery should be limited, especially in the apex of the thorax, because of the risk of thermal injury to the recurrent laryngeal nerves. An esophagoesophagostomy is performed, taking care to ensure that sutures include the full thickness of the esophagus. Some patients with EA and a distal TEF will have a longer gap between the proximal and distal

esophagus (>2 vertebral bodies). The anastomosis may be performed under tension. Some surgeons maintain the patient sedated with the head in flexed position to decrease postoperative anastomotic tension. If the gap between the upper and lower pouches is long enough, the TEF may be ligated and divided and the distal pouch tacked to the prevertebral fascia, with reconstruction performed after 8 to 12 weeks. A nasogastric tube is passed through the anastomosis into the stomach to ensure patency of the distal esophagus. Gastrostomy tubes may be indicated if the presence of other anomalies suggests that prolonged tube feeding will be required. A drainage tube is typically placed near, but not on, the anastomosis at the end of the operation to contain postoperative anastomotic leaks. Small openings in the pleura are unimportant and should not be closed when a retropleural approach is used. Oropharyngeal suctioning is limited to <6 cm from the lips in order to avoid trauma to the anastomosis. An esophageal contrast study is performed approximately 1 week after operation. If the anastomosis is intact, feedings are initiated, antibiotics are discontinued, and the retropleural chest tube is removed. Complications include anastomotic leaks, which occur in 16% of cases and typically resolve without intervention. Silk sutures are associated with a two- to threefold increase in the incidence of anastomotic leak. Postoperative strictures may be found in up to 40% of cases and are often associated with leaks, anastomotic tension, and GER. GER occurs in up to 70% of patients with EA/TEF and may require a fundoplication, which may result in dysphagia by augmenting the esophageal dysfunction typically associated with an EA/TEF.

In patients with isolated EA without a TEF (pure esophageal atresia), the distal esophagus is typically short, which precludes immediate repair. Patients with pure esophageal atresia that are not amenable to a primary approach may be repaired at 8 to 12 weeks with a delayed primary anastomosis. The management involves initial placement of a gastrostomy tube, allowing for growth of the proximal and distal pouch over the ensuing 3 months prior to an attempt at a primary repair (Fig. 9-16). Daily dilation of the proximal pouch may enhance lengthening. There are other alternative approaches that may be required, including proximal pouch myotomies to extend length. However, these may be associated with complications such as leaks, strictures, outpouching of the esophagus at the site of the myotomy, and esophageal dysfunction. In patients with very long gaps, replacement of the esophagus with a natural conduit such as the stomach, colon, or even the

small bowel may be the best option.

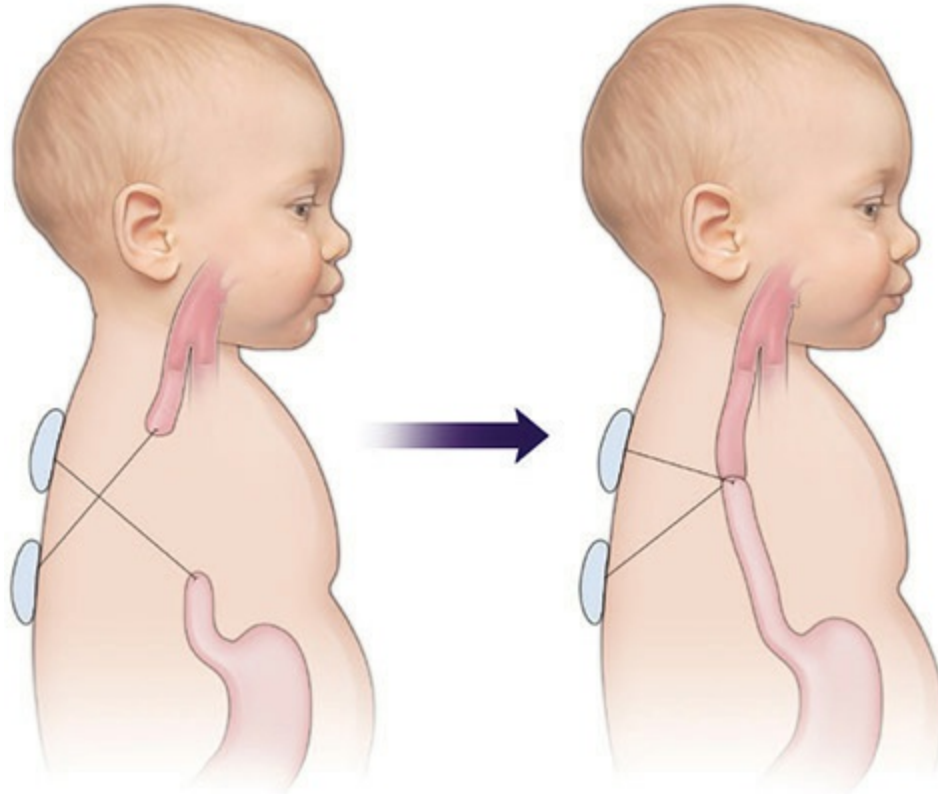

**FIGURE 9-16** **A.** Gap assessment done in pure esophageal atresia at 1 month of age. This is performed by inserting a pediatric endoscope into the gastrostomy that was created for feeding at the time of diagnosis, and inserting a second radio-opaque dilator or instrument into the proximal pouch at the same time under fluoroscopy. **B.** Gap assessment at 2 months.

Other techniques are available that may lengthen the esophagus, including the Kimura procedure, in which an esophagostomy is formed on the chest and sequentially lengthened every 2 to 3 weeks by advancing the esophagostomy inferiorly along the chest wall. This technique allows sham feedings, which are important for normal feeding development to take place.

Another more recent approach to augment esophageal length was developed by Foker. With this approach, continuous traction is used to slowly approximate the proximal and distal ends of the esophagus, followed by performance of an anastomosis (Fig. 9-17). The traction is applied by sutures placed on the ends of the esophagus which are brought out through the lateral, superior, and inferior rib interspaces, respectively. Tension is steadily applied to allow for growth and eventual approximation. With the Foker technique, the patient is at risk for postoperative strictures and reflux that can be managed with dilations and fundoplication, respectively. If the sutures pull through the ends of the esophagus there is the potential for esophageal leak.

Options when this complication occurs are to replace the sutures with repair of the leak (if present) or to convert to a cervical esophagostomy with plans for esophageal reconstruction later.

**FIGURE 9-17** Foker procedure: Sutures are placed into the ends of the proximal pouch and the distal esophagus and brought out through the chest externally. These are then tightened intermittently until the two ends of the esophagus are adjacent to each other and the gap is closed.

In general, all attempts are made to salvage the native esophagus. However, when the esophagus cannot be approximated or if complications of stricture, recurrent GER, or esophageal dysfunction persist, esophageal replacement is an alternative. Right or left colon, jejunum, or the stomach, either as a reversed-gastric tube or a gastric transposition, can be used. Although an effective solution to establishing esophageal continuity, the complication rate with esophageal replacement is substantial and includes an anastomotic leak rate of approximately 30%, stricture formation in 20% to 60%, and a mortality of 5%. Anastomotic leaks almost always resolve spontaneously. A variety of options are available for esophageal replacement.

When a colon conduit is used, it can consist of right or left colon and be placed behind the hilum of the lung on either side or in a substernal position, although the latter is associated with a higher stenosis rate. A vagotomy is effective in preventing the development of ulcers when a colon conduit is used. The colon may become redundant in the chest (sink trap deformity), leading to dysfunction and stasis (16%). Reoperation is necessary in approximately 50% of patients and is most often performed to redo the esophagocolic or cologastric anastomoses due to strictures or to correct the redundancy. Gastrocolic reflux may also occur, and approximately 20% will ultimately require replacement of the colon graft, which is best managed by performance of a gastric transposition or a free jejunal graft.

Another option for esophageal replacement is the reverse gastric tube, which is formed by creating a tube from the greater curvature of the stomach. This is most often brought up to the neck through what would have been the esophageal bed. Complications are leak from the long suture line and compromise of the stomach size, especially in newborns with a diminutive stomach. Finally, gastric transposition is a successful option because the blood supply to the stomach is excellent and the operation is technically easier than other alternatives. This option can be used even when previous operations have been performed on the stomach. The right and left gastroepiploic arteries are maintained intact while the stomach is otherwise mobilized. The distal esophageal segment is excised and the fundus is brought through the posterior mediastinum, which limits the potential complication of gastric distension. The posterior aspect of the stomach must be anchored to the sternocleidomastoid muscles in the infant and to the prevertebral fascia in the older patient to prevent retraction of the stomach into the thorax. A pyloromyotomy should be performed to enhance gastric emptying. The dumping syndrome occurs in a minority of patients in the postoperative period but typically resolves over the first year. Care must be taken to avoid a twist in any of the conduits performed, which may result in ischemia or obstruction. Dissection must be maintained on the proximal esophagus to avoid injury to the recurrent laryngeal nerves.

The simultaneous presentation of EA/TEF and duodenal atresia is a challenging clinical situation. Duodenal atresia occurs in 10% of patients with isolated EA, and the lack of air in the GI tract in the setting of EA without a TEF can delay the diagnosis of duodenal atresia until a gastrostomy tube is placed. An intraoperative contrast study at the time of gastrostomy

tube placement helps to identify this combined anomaly, although this is not routinely performed. Imperforate anus, which is part of the VACTERL constellation of findings, should be typically addressed by performing a colostomy.

Patients with a TEF but no EA (4%) often have episodes of gastric distention during crying and choking, recurrent pneumonia, and cyanotic spells during feeding. The diagnosis is best made by a contrast swallow or bronchoscopy, which may demonstrate the H-type fistula between the trachea and esophagus. A Fogarty catheter may be placed through the fistula at the time of bronchoscopy to help with identification of the fistula at operation. Ligation of the fistula is usually performed via a right cervical approach. The recurrent laryngeal nerve must be identified to prevent injury, the most common complication of this procedure. Recurrence of the fistula is rare.

Overall survival rate is 95%. Mortality is usually secondary to associated anomalies and is increased with the presence of major cardiac disease and birth weight <1500 g (Table 9-1). One of the most difficult decision-making situations involves the premature newborn with RDS and EA/TEF because the associated ventilator leak through the fistula increases with airway pressure escalation; therefore, ligation of the fistula is ideally performed before compromised respiratory status precludes a safe operation, requiring close monitoring and keen judgement. Early thoracotomy and ligation of the fistula provides an ability to ventilate and prevents gastric distension, though this decision must be weighed against the overall clinical status of the neonate.

**TABLE 9-1: PREDICTORS OF SURVIVAL FROM AN ESOPHAGEAL ATRESIA ANOMALY**

Group	Total, <i>n</i>	Dead, <i>n</i>	Survival rate (%)
I. Birth weight >1500 g without major congenital heart disease	293	10	97
II. Birth weight <1500 g or major congenital heart disease	70	29	59
III. Birth weight <1500 g and major congenital heart disease	9	7	22

Immediate postoperative complications include small anastomotic leaks on postoperative contrast study in 15% of EA/TEF patients with primary repair. Almost all small leaks will resolve spontaneously with continuation of IV antibiotics and chest tube drainage. A repeat study is performed 1 week later, and oral feedings are held until the leak resolves. Disruption of the anastomosis occurs in approximately 5% due to excess tension, ischemia, or poor surgical technique, and presents with persistent pneumothorax, respiratory distress, pleural effusion, and/or sepsis. The disruption should be managed with either direct repair, preferably with reinforcement of the anastomosis with an intercostal muscle flap or a pleural or pericardial patch, or with formation of a cervical esophagostomy and placement of a gastrostomy tube with subsequent esophageal replacement. Stricture formation occurs in approximately 15% of cases and is often associated with a prior anastomotic leak. Most strictures are responsive to repeated antegrade dilatation initially at a frequency of approximately every 2 to 3 weeks. Esophagoscopy should be performed before dilatation to assess the anastomotic caliber and after to ensure that full-thickness perforation has not occurred. Hurst-Maloney dilators may be sequentially passed to dilate a slightly narrowed stricture. In narrow strictures, a wire passed under endoscopic and/or fluoroscopic guidance will allow safe passage of sequentially larger Savory dilators or balloon dilators under fluoroscopic guidance to safely enlarge the anastomosis. Contrast injection at the end of the dilatation can be performed to identify a leak at the site of the stricture. Occasionally, refractory strictures may require resection or even esophageal

replacement. Refractory strictures may be due to the presence of reflux, which occurs frequently in patients with EA/TEF. Strictures due to GER usually respond to dilatation once a fundoplication has been performed. Thus, the presence of GER should be investigated if a stricture does not respond after two or three dilatations.

Leak from the trachea or compromise of the tracheal lumen is unusual but requires operation in the former and bronchoscopic evaluation in the latter. Recurrent TEF occurs in 3% of cases, is usually associated with a postoperative leak, and requires reoperation. Recurrent pneumonia, coughing, and choking are frequently noted. Esophagram with the patient prone and/or with balloon catheter obstruction of the distal esophagus during esophageal contrast administration can enhance identification of the fistula. Bronchoscopy with attempts at passage of a catheter through a potential fistula or instillation of dilute methylene blue into the trachea with esophageal assessment for the presence of blue dye will frequently reveal the presence of a recurrent TEF. High-resolution CT may help to identify a recurrent fistula or a missed proximal fistula. Thoracotomy with fistula ligation is required. A 2 Fr balloon catheter should first be passed through the fistula under bronchoscopic guidance to allow intraoperative identification of the fistula. Once the fistula is ligated, a pleural or pericardial flap should be interposed between the trachea and esophagus to help prevent recurrence. Injection of fibrin glue into the fistula may result in closure of the communication without thoracotomy.

The most common long-term problems associated with EA include GER (40%–70%), tracheomalacia (16%), and esophageal dysfunction. GER is likely due to the tension placed on the distal esophagus with compromise of the native antireflux mechanisms and shortening of the intra-abdominal esophagus. Recurrent pneumonia, reactive airway disease, cyanotic spells, and persistent anastomotic stricture can be symptoms/signs of GER in the EA/TEF patient. GER symptoms are present in at least 20% to 40% of adult patients with previous EA/TEF. Evaluation with upper GI contrast study and/or 24-hour pH probe may document the diagnosis. GER is typically first managed with prokinetic agents and proton pump inhibitors, although approximately 30% to 40% of patients require a fundoplication. A 360-degree Nissen fundoplication is most frequently performed, although a Nissen fundoplication may exacerbate the esophageal dysfunction associated with EA/TEF. Under those circumstances, recurrent reflux, esophageal

dilation and dysfunction, and dysphagia may result in an adverse outcome. A Thal fundoplication is a reasonable alternative because of the partial nature of the wrap, but the failure rate has been high. As a result, most surgeons prefer to perform a “floppy” Nissen fundoplication. Because studies have demonstrated a relatively high incidence of Barrett’s esophagitis among patients with repaired EA/TEF (5%–7%), long-term endoscopic surveillance is important.

Tracheomalacia results in stridor and a barking cough in newborns, although some patients may present with apnea, as the result of a weakness in the tracheal wall such that the anterior and posterior tracheal walls coapt during expiration. Bronchoscopy during spontaneous breathing demonstrates the collapse in the distal third of the trachea. Mild symptoms in most patients can be followed, with expected resolution as the patient grows. Life-threatening symptoms require operation in 6%. An aortopexy, in which the anterior aspect of the aortic arch is approximated to the posterior sternum, is effective in almost all patients at resolving the symptoms of tracheomalacia. A Palmaz airway stent or tracheostomy may be of benefit should the aortopexy prove to be inadequate. Frequently, it is difficult to determine whether the symptoms observed are due to tracheomalacia or GER.

Esophageal dysmotility is present in the majority of EA/TEF children, and 40% to 75% of adult EA/TEF patients have mild-to-severe dysphagia and esophageal dysmotility. In most cases, the dysphagia is tolerable and in infants can be managed by slowing the pace of feeding and feeding while the patient is sitting up. Scoliosis develops in 8% of patients, probably due to fusion of the ribs at the site of the thoracotomy, which prevents ipsilateral spine growth. Anterior chest wall deformities are observed in 20%, though a muscle sparing or thoracoscopic (see below) approach may decrease the incidence of this complication. Foreign body impaction occurs in 13% of patients with corrected EA/TEF, usually during the child’s first 5 years of life.

A thoracoscopic approach has been advocated by some centers to avoid the complications associated with the thoracotomy. In a multi-institutional retrospective review of 104 patients who underwent thoracoscopic EA/TEF repair, 11.5% developed an early leak or stricture and a third needed esophageal dilation at least once. Two infants developed a recurrent fistula and 24% required a subsequent laparoscopic fundoplication. In another retrospective comparison of the thoracoscopic and open techniques, a

minimally invasive approach allowed decreased postoperative narcotic use, shorter time to extubation, earlier feeding by mouth, and decreased length of stay, without an increase in operative time, anastomotic leak, stricture, or mortality.

## **Duodenal Obstruction (Duodenal Atresia)**

Congenital duodenal obstruction occurs in 1 in 5000 to 10,000 live births. Most causes of obstruction are atresia (76%) and duodenal webs (23%). A common area of duodenal obstruction is the second portion of the duodenum, as this site is a hub of embryological activity in the growing fetus. Duodenal atresia results from failure of recanalization of the duodenal lumen, while duodenal stenosis and webs result from incomplete recanalization of the duodenal lumen.

Congenital duodenal obstruction can broadly be divided into intrinsic and extrinsic causes. Intrinsic causes include the presence of a duodenal web (18%), stenosis, or atresia (10%). Extrinsic causes include annular pancreas (36%) or the presence of Ladd bands (36%). Preduodenal portal vein is a rare cause of extrinsic duodenal obstruction ([Fig. 9-18](#)). These causes develop in the embryological period, intrinsic being specifically tied to the period where recanalization takes place in the proximal gastrointestinal tract (GIT). Both categories may appear similar on diagnostic studies, making distinguishing them difficult until the time of operation.

**FIGURE 9-18** Preduodenal portal vein (black arrow) represents an uncommon cause for extrinsic duodenal obstruction.

Duodenal webs occur with an estimated incidence of 1 in 10,000 to 1 in 40,000 live births. Simplistically, webs occur from incomplete recanalization of the duodenum during fetal development, which results in a thin, membranous web of mucosa and submucosa, with the muscular layer being absent. They are often congenital in origin, although NSAIDs have been implicated as a causative agent. Duodenal webs are frequently associated with other congenital anomalies such as Down syndrome (21%) and cardiac anomalies, to name a few.

The presence of a duodenal obstruction may be appreciated on prenatal ultrasound by the presence of polyhydramnios of unspecified etiology, which is seen in about two-thirds of patients, or a dilated stomach and duodenum (ultrasound equivalent of a “double-bubble” seen on x-ray; see below). About half of the patients with duodenal atresia are premature (<37 weeks’ gestation); therefore, issues related to prematurity such as retinopathy, intracranial bleeding, and respiratory insufficiency must also be addressed when present.

Typical presenting symptoms in the first 1 to 2 days of life include feeding

intolerance and emesis, which is usually bilious unless the obstruction is proximal to the ampulla of Vater, which it may be in 5% to 10% of cases. Following birth, plain abdominal radiographs demonstrate the classic “double-bubble” (air-filled, dilated stomach and proximal duodenum with paucity of distal gastrointestinal air) in 77% of patients (Fig. 9-19). Air can be used as a contrast agent by injecting 20 mL through the nasogastric tube during performance of the radiograph. The distal small intestine and colon remain gasless with a duodenal atresia. In contrast, in the setting of a duodenal web with an opening or a malrotation with Ladd bands or volvulus, gas is often present in the downstream GI tract. The importance of the distinction is that the urgency with which operation is performed is reduced if malrotation with volvulus is excluded from the differential. However, in most cases prompt, if not emergent, surgical intervention is still appropriate. If a classic double-bubble is observed, further radiographic study is unnecessary as this has been accepted as a diagnostic sign of duodenal obstruction.

**FIGURE 9-19** Supine abdominal x-ray on neonate showing double bubble appearance. Dilated stomach (**A**) with repleg tube within stomach and dilated duodenum (**B**).

A UGI series is the study of choice if there is concern for malrotation with volvulus. This study can initially be performed with injection of air through the nasogastric tube, as mentioned earlier, followed by serial imaging to monitor progression of the air into the distal GIT. If air is seen distally, this would prompt further investigation with an UGI series with a water-soluble contrast medium such as gastrograffin to rule out malrotation or Ladd's bands as a potential cause of proximal GIT obstruction. The diagnosis of malrotation is made by examining the position of the duodenojejunal

junction: it should be to the left of the vertebral pedicles, heading posteriorly at the level of the duodenal bulb.

Surgical repair for duodenal obstruction classically consists of a right supraumbilical incision with mobilization of the duodenum with duodenoduodenostomy. However, with technological advances and growing surgical skills, laparoscopic approaches to correction of duodenal obstruction have become more favorable. Regardless of approach, the essential steps to the procedure remain the same. After a Kocher maneuver, the markedly dilated proximal duodenum and the decompressed distal duodenum are identified and mobilized (Fig. 9-20). A duodenoduodenostomy is performed by creating an incision on the dilated proximal duodenum in a horizontal or perpendicular axis to the small bowel and incising the distal decompressed bowel in a longitudinal manner. These incisions are then used to create the duodenoduodenostomy.

**FIGURE 9-20** Duodenal obstruction caused by annular pancreas. Proximal dilated portion (A) will be anastomosed to distal collapsed portion (B).

In the case of duodenal webs, the most difficult maneuver involves determining the site of the obstruction, as a “windsock” deformity may be present, making the origin of the atresia or stenosis proximal to the change in caliber of the duodenum. One must be certain that a corrective procedure is not performed distal to the actual site of obstruction. To avoid this complication, a small longitudinal incision may first be made along the anterolateral, distal aspect of the dilated portion of the duodenum. The anterolateral aspect is used in order to avoid the ampulla of Vater during subsequent anastomosis. A catheter is passed proximally and distally to

identify the location of the obstruction. Alternatively, a small gastrotomy may be performed and a catheter passed distally into the duodenum. Gentle pressure applied to the catheter at the site of obstruction may demonstrate the site of attachment of a windsock by the presence of an indentation on the surface of the dilated duodenum.

If a simple web is present, the longitudinal incision can be extended across the anterolateral aspect of the web and the web incised after identification of the ampulla of Vater. Identification of the ampulla is best performed by compressing the gallbladder and observing the site of bile drainage into the duodenum. The ostium of the ampulla of Vater is often located at the base of or even within the web. In most cases excision of the web is ill-advised, and incision of the anterolateral aspect of the web is carefully performed after identification of the ampulla of Vater in order to avoid injury to, or obstruction of, the biliary tract. Incision of the anterolateral aspect of the web is easiest when an opening is present, because the ampulla will be medial to the opening. Transverse closure of the longitudinal incision, as in a Heinek-Mikulicz pyloroplasty, effectively bypasses the obstruction once the web is partially incised. Alternatively, bypass of the obstructing lesion, with a duodenoduodenostomy, is performed. As described earlier, an anastomosis between a transverse incision in the proximal dilated duodenum and a longitudinal incision in the distal duodenum is commonly used. The initial exploratory duodenal incision allows correct placement of the second incision for this anastomosis either distal or proximal, depending on where the obstruction is located. The proximal incision is extended horizontally just above the obstruction and the distal in a longitudinal direction starting just downstream from the obstruction. The proximal duodenal incision is approximately 1 cm in length and maintained on the anterolateral aspect of the duodenum to avoid injury to the biliary tract or the pancreas during suture placement. The distal incision is also approximately 1 cm in length and placed on the antimesenteric border. In the rare circumstance where a wide gap exists between the ends of the duodenum, a loop of proximal jejunum may be brought to the duodenum through the mesocolon for a duodenojejunostomy.

Although rare, a distal atresia is present in up to 3% of cases; thus, in an open procedure the rest of the small bowel should be examined. One approach is to inject saline through the entire bowel via a catheter placed through the duodenal incision prior to anastomosis.

Morbidity and mortality for these infants are frequently due to complications from prematurity, trisomy 21, congenital heart disease, and other associated anomalies. Feeding is often delayed for days to weeks (mean of 13 days) due to duodenal dysfunction in the proximal dilated duodenum. Clinicians may need to increase feeds slowly and to tolerate higher volumes of feeding residuals in the newborn after operation. Some surgeons suggest that placement of a transanastomotic feeding tube at the time of correction of the duodenal atresia allows earlier initiation of feeding, while others suggest otherwise. Some surgeons perform a resection of the redundant duodenum (duodenoplasty) at the time of the initial operation (Fig. 9-21). Rarely is reoperation required in the newborn period. Upper GI contrast studies should be performed only if feeding intolerance persists for a number of weeks. Chromosomes should be assessed for trisomy 21, which is present in 21% of patients with duodenal obstruction.

**FIGURE 9-21** Duodenoplasty done to decrease the amount of redundant duodenum at the time of surgical repair.

Postoperative complications can be divided into early and late complications. Early complications include anastomotic obstruction (3%), congestive heart failure (9%), prolonged ileus (4%), pneumonia (5%), and

superficial wound infection (3%). Late complications include reoperation for adhesive obstruction in 15%, blind loop syndrome or bile reflux gastritis in 22%, GERD unresponsive to medical management that requires antireflux surgery (Nissen fundoplication) in 5%, duodenal dilation in 22%, diminished peristalsis in 20%, delayed emptying in 12%, and luminal narrowing in 7%. Late duodenal dysmotility resulting in mega-duodenum will require tapering duodenoplasty in 4% of patients. The operative and late mortality rates are largely due to complex congenital heart anomalies. The overall long-term survival is 86%.

Laparoscopic approaches to repair of duodenal webs and atresia have been described with similar operative time, improved cosmesis, minimal morbidity, and potentially quicker return of bowel function.

## Jejunoileal Atresia

Jejunoileal atresia (JIA) is estimated at an incidence of 1 to 3 per 10,000 live births. Among cases of jejunoileal obstruction, atresia occurs in 95%, while stenosis occurs in 5%. The etiology of JIA differs from that of duodenal atresia. JIA commonly result from ischemic insults such as volvulus (27%), malrotation (19%), gastroschisis (17%), and intussusception (2%) that may occur in utero. There appears to be equal distribution among males and females. Maternal smoking and cocaine use during pregnancy have been implicated in JIA. Associated anomalies are rare; however, conditions such as cystic fibrosis, gastroschisis, and malrotation have been noted in about 10% of patients.

Inheritable causes for JIA have been published. A rare entity, hereditary multiple intestinal atresia (HMIA), is an autosomal recessive disorder described in French Canadians. HMIA has been associated with combined immunodeficiency, and is almost always fatal.

The diagnosis of bowel obstruction is made with assistance of fetal ultrasound in 29% of cases via identification of enlarged loops of bowel in conjunction with polyhydramnios, although about 50% of such positive scans are false-positive studies. Postnatally, the diagnosis can be made by plain radiography when a large loop of dilated, air-filled bowel is noted (Fig. 9-22). If such very large, dilated loops are noted, further preoperative diagnostic studies are not mandatory to confirm JIA. A water-soluble contrast enema is done to rule out colonic pathology, which is often missed during operative

exploration. This often demonstrates a diminutive and unused colon. Peritoneal calcification is noted in 12% of patients, indicating prior in utero perforation and saponification of fat from pancreatic enzymes in the extruded meconium. The presence of calcifications is suggestive of meconium peritonitis, which is associated with an in-utero bowel perforation that may be due to one of many causes, sometimes resulting in JIA.

**FIGURE 9-22** Abdominal x-ray showing dilated bowel loops, suggestive of bowel obstruction. Black arrow points to a calcified lesion within the abdominal cavity, indication of meconium peritonitis.

Different types of JIA are observed. The four main types are as follows. Type I (membranous) occurs in 23%, type II (fibrous cord) in 27% ([Fig. 9-23](#)), and type IIIa (mesenteric gap) in 18%. Type IIIb, the “apple-peel” or

“Christmas-tree” deformity, occurs in approximately 10% of cases. This type is associated with atresia near the ligament of Treitz, and precarious, retrograde blood supply from the ileocolic, middle colic, or right colic arterial distribution to the distal bowel. The deformity is associated with a longer length of hospital stay, multiple operations, and decreased survival compared to other atresias. Type IV is associated with multiple atresias and is observed in 24% of cases.

**FIGURE 9-23** Intestinal atresia. Arrows point to multiple atretic segments; likely type 2 atresia.

Clinical presentation of JIA may consist of a newborn with bilious vomiting, abdominal distention, and a history of prenatally visualized dilated loops or maternal polyhydramnios. Presenting signs may differ based on the level of the atretic segment or segments. In proximal atresias, newborns may not demonstrate abdominal distention and may have in-utero polyhydramnios. In contrast, with distal atresias newborns may manifest abdominal distention and failure to pass meconium. As long as radiologic findings exclude malrotation with volvulus, intravenous fluids may be administered, a nasogastric tube placed, and a timely, but not emergent, operation performed. Over 50% of patients with JIA require parenteral

nutrition. Central venous access should be established before or at the time of operation in anticipation of prolonged parenteral nutrition support.

Operative approach to JIA can be either open or laparoscopic. In the open approach, the bowel is eviscerated and any twists reduced via a supraumbilical transverse incision. Trans-umbilical approaches with and without laparoscopy have also been described for simple intestinal atresia, with repair performed following evisceration through the umbilical incision. Examination for malrotation must be deliberate so that this anomaly is not missed. With terminal ileal or colonic atresia, a seromuscular biopsy of the rectum can be performed just proximal to the peritoneal reflection to evaluate for Hirschsprung disease (HD). As 6% to 20% of newborns may have more than one atresia, it is important to interrogate the distal bowel for any other atretic segments. To do so, a 10 Fr catheter is placed into the small bowel distal to the atresia and saline gently infused until it reaches the terminal ileum. If no contrast enema was performed, saline is infused to the rectum to rule out the presence of another atretic segment of bowel.

The dilated proximal segment should be resected to a reasonable caliber of bowel to prevent subsequent anastomotic dysfunction, since the massively dilated proximal bowel has abnormal smooth muscle and ineffective peristalsis (Fig. 9-24). This entails resection of the most bulbous end of the proximal bowel, placement of a 20 Fr catheter into the proximal end, and resection of the excess caliber of bowel using suture or stapling techniques. A discrepancy in caliber between the proximal and distal bowel will still be present, and therefore a proximal end to distal oblique anastomosis is performed by resecting the proximal bowel at a 90-degree angle and the distal bowel at an oblique angle. An antimesenteric incision on the distal bowel can equalize the caliber. The bowel anastomosis is very similar to a vascular anastomosis and is performed with one layer of interrupted 5-0 Vicryl suture starting at the mesenteric border. The closure is continued three-fourths of the way around, at which point the closure is started in the other direction. It is critical that the final sutures are not placed near the antimesenteric area of the bowel, as this might compromise the distal lumen. If resection would compromise bowel length, an antimesenteric tapering enteroplasty of the proximal bowel can reduce the lumen size.

**FIGURE 9-24** Bulbous end of atretic segment of intestine (arrows).

In patients with compromised blood supply or in the setting of meconium ileus or meconium peritonitis, it may be reasonable to perform a double-barrel enterostomy instead of an anastomosis.

If an apple-peel deformity is noted with tenuous blood supply to the distal bowel, an anastomosis may be performed while being careful to avoid a twist in the distal bowel mesentery. Alternatively, forming a proximal enterostomy while leaving the distal bowel intact is a reasonable option.

In patients with gastroschisis, the thickened bowel often precludes resection and anastomosis. In this case, the bowel is reduced and the atresia addressed approximately 3 weeks later, when the bowel inflammation and thickening have resolved. Patients with meconium ileus and all others with volvulus and atresia should have a workup for cystic fibrosis. Suction rectal biopsy to evaluate for HD should be performed in patients with colonic atresia and those with volvulus and atresia in the terminal ileum.

Postoperative complications include adhesive bowel obstruction (24%), functional obstruction at the site of the anastomosis (9%), and the occasional anastomotic leak or stricture (4%). There is a reported higher incidence of anastomotic leak in those patients diagnosed with HD and JIA. Prolonged

dysfunction of the proximal dilated intestine is quite common, and days to weeks may pass before enteral feeds are tolerated. Evaluation for bowel obstruction by contrast enema or UGI contrast study should be performed after a few weeks if enteral feeds are not tolerated. Typically, a contrast study demonstrates a widely patent anastomosis. If the anastomosis is patent and feeding intolerance persists, a revision of the anastomosis with resection of additional bowel and/or performance of an enteroplasty to reduce the proximal bowel caliber may be required. Anastomotic complications, such as a leak, may be indicated by persistent pneumoperitoneum or, more commonly, by development of a fistula. If sepsis is present, operative intervention is required. If not, antibiotic treatment and parenteral nutrition typically allow resolution of the leak and fistula. Rarely, a leak is present with an associated abscess which requires drain placement.

Bacterial overgrowth is a long-term complication that manifests as vomiting, diarrhea, and abdominal distension. Bacterial overgrowth is treated with antibiotics with aerobic and anaerobic coverage, and if acute and severe, a short course of broad-spectrum intravenous antibiotics. Occasionally, resection of a dilated segment or enteroplasty will be required to resolve recurrent bacterial overgrowth. Chronic blood loss from the anastomosis or an adjacent ulcer can occur many years after the initial operation. Although the exact etiology is unclear, this is thought to be due to ischemia at the anastomosis. Resection and revision of the anastomosis is curative, although the ulcer may be near but not at the anastomosis and can therefore easily be missed.

Survival has increased in recent years to approximately 85% to 90%. Even those with an apple-peel deformity are expected to survive and, despite early morbidity, will likely have an excellent long-term outcome. The perioperative mortality of approximately 1% is mainly related to associated anomalies such as congenital heart disease and sepsis. The long-term causes of death are mainly related to the SBS observed in 25% of patients with JIA. Parenteral nutrition has markedly enhanced outcome in patients with atresia. However, those patients with short bowel syndrome and long-term dependency on parenteral nutrition may endure numerous episodes of catheter sepsis, likely related to translocation of enteric organisms. Vitamin deficiencies can also occur and levels should be evaluated regularly. In addition, cholestasis from parenteral nutrition with associated liver failure is a potentially lethal complication in infants that is not as prevalent in adults. Improved bowel

lengthening procedures such as the STEP procedure and improved medical care have enhanced the lifespan of patients with SBS. Although much improved, liver and small bowel transplantation have not yet had a consistent impact upon outcome in SBS patients.

## **Meconium Ileus**

Meconium ileus is present in approximately 10% to 20% of newborns with cystic fibrosis. The reported incidence of meconium ileus is 1 in 3000 live births. Approximately 80% of newborns with meconium ileus will have underlying cystic fibrosis. The presence of thick, tenacious meconium in the intestines resulting from secretion of viscous intestinal mucus, an abnormal concentrating process in the proximal bowel, and impaired pancreatic enzyme secretion can result in a bowel obstruction in patients with meconium ileus. An adolescent variant of meconium ileus, distal intestinal obstruction syndrome (DIOS), is seen in 9% of patients with cystic fibrosis who develop thickened succus, which can result in bowel obstruction.

Meconium ileus is divided into simple and complex. The simple form consists of obstruction of the terminal ileum and occurs in 55% of cases. In the complex form, meconium-filled bowel may twist and produce a volvulus, resulting in ischemic necrosis with associated perforation (19%) and/or atresia (48%). Perforation, with intraperitoneal dissemination of sterile meconium, may lead to isolated regions of calcification (meconium peritonitis) or even the development of a large meconium-containing pseudocyst (19%). Extraintestinal anomalies are uncommon with meconium ileus, other than its association with cystic fibrosis and related sequelae.

Clinical presentation of the newborn with meconium ileus is similar to that of distal bowel obstruction, with emesis (which may be bilious), intolerance of feeds, and failure to pass meconium in the first 24 to 48 hours of life. The hallmark of the newborn with meconium ileus is abdominal distention at birth, with multiple doughy loops of dilated bowel noted on palpation (Fig. 9-25). A nasogastric tube is inserted for gastric decompression.

**FIGURE 9-25** Distended abdomen with dilated loops visible and palpable on examination.

UGI series is not the primary investigation of choice for meconium ileus because the contrast administered from above may not progress beyond the point of inspissated meconium and, depending on contrast progression, may provide minimal information. However, importantly, UGI with a water-soluble contrast agent may help rule out malrotation and volvulus as a cause

of bilious emesis.

For simple meconium ileus, a contrast enema can be both diagnostic and therapeutic (Fig. 9-26). Gastrograffin, hypaque, or Conray may be used to perform the study; the osmolarity of the contrast agent does not appear to be of importance. A small, unused microcolon is noted with thick, inspissated meconium in the terminal ileum. The distal small bowel must be filled or the study is unlikely to be therapeutic. The hypertonicity of the gastrograffin likely draws fluid into the bowel lumen, which aids in mobilizing the meconium. As such, the newborn undergoing such studies must be kept warm and well hydrated during and following the study: typical fluid requirements are greater than the normal neonate, and attention must be paid to urine output. Contrast studies are effective at relieving the obstruction in 40% to 60% of patients with simple meconium ileus. Additional enemas may be performed over the ensuing days as long as progress is made with meconium being mobilized and evacuated, and complications such as perforation, worsening abdominal distension, or sepsis, are not encountered.

**FIGURE 9-26** Contrast enema study with gastrograffin showing multiple stool balls (arrow).

Additional investigations such as sweat chloride test and suction rectal biopsy are needed in patients to diagnose underlying cystic fibrosis or HD in patients with findings consistent with meconium ileus. A sweat chloride test may be inconclusive if performed in the first 3 weeks of life due to inadequate sweat production in newborns; therefore, a repeat sweat test and

confirmatory cytogenetics are useful, as up to 21% of patients with meconium ileus will not have laboratory or other clinical evidence of cystic fibrosis. Newborn screening with immunoreactive trypsinogen and CFTR gene mutations can increase the sensitivity. Trypsinogen, the precursor to trypsin, is elevated in patients with cystic fibrosis.

If contrast enemas are unsuccessful, operative intervention primarily consists of evacuation of the obstructing meconium from the terminal ileum (Fig. 9-27). An enterotomy is performed in the dilated ileum just proximal to the change in lumen caliber, providing access to evacuation of meconium by external massage and irrigation of the bowel via an 8 to 10 Fr catheter with warm saline, 2% to 4% *N*-acetylcysteine, or gastrograffin. Thick meconium is evacuated through the enterotomy or flushed into the colon. The appendix can be removed and a catheter placed into the base of the appendix to flush the terminal ileum and colon. A contained perforation may sometimes be seen at the time of laparotomy. If the meconium cannot be successfully evacuated, the bowel has been compromised, or an atretic or stenotic segment is identified, the involved segment of ileum should be resected. One option is to perform a simple end-to-end anastomosis after evacuation of distal meconium, because the long-term surgical morbidity is lower than with an enterostomy. If peritonitis, bowel compromise, concern for bowel dysfunction, or concurrent medical problems make an anastomosis tenuous, formation of an ileostomy with an adjacent mucous fistula is an alternative, with plans for establishing bowel continuity in 4 to 6 weeks. A primary anastomosis decreases the hospital length of stay and avoids a second laparotomy; however, nearly 31% require reoperation for postoperative bowel obstruction from adhesions and strictures in this population.

A

B

**FIGURE 9-27** Meconium ileus with removal of meconium ball (**A**) and evacuation of inspissated meconium (**B**).

Meconium ascites or a meconium pseudocyst may be the result if an in-utero perforation has occurred ([Fig. 9-28](#)). The goal of surgery in the setting of meconium ascites or a pseudocyst is to identify the site of perforation and to ensure bowel continuity. In many cases, an ileostomy is required. The rind that forms the pseudocyst is left on the bowel, thus avoiding injury. In general, careful blunt dissection allows separation of the loops of bowel until the entire small bowel is mobilized.

**FIGURE 9-28** Meconium ileus with contained perforation (arrow). The proximal bowel appears dilated with distal bowel appearing normal in caliber.

Recent improvements in perioperative care and management of patients with cystic fibrosis have resulted in nearly 100% survival rates. Dilute 10% *N*-acetylcysteine may be administered through the nasogastric tube after resolution of the obstruction to prevent recurrent inspissated secretions. Anastomotic leak is unusual. Postoperative care is specifically aimed at treatment of pulmonary problems, with excellent pulmonary hygiene and administration of antibiotics. Parenteral nutrition is administered until enteral feeding of a predigested, low long-chain fatty acid formula, such as Pregestimil, is tolerated. Oral pancreatic enzyme administration is necessary with the initiation of feeding. Closure of the ileostomy, if present, is often accompanied by bowel dysfunction. One option to determine if the patient is ready for ostomy closure is refeeding of the ileostomy output via the mucus fistula. Refeeding the distal limb has been shown to be safe even in premature neonates while decreasing parenteral nutrition requirements, preventing disuse atrophy, and facilitating subsequent reanastomosis.

Long-term complications are related to the cystic fibrosis and its treatment. Early diagnosis of cystic fibrosis and treatment using enzymes in

patients with meconium ileus has been shown to improve long-term growth and prevent malnutrition. In matched cohorts of patients with cystic fibrosis with and without meconium ileus, there is no difference in long-term outcomes regarding nutritional status and hepatobiliary and pulmonary function.

DIOS may be associated with inadequate enzyme replacement or fluid intake and is usually successfully managed with administration of gastrograffin as an enema or orally. Colonic strictures, known as CF fibrosing colonopathy, can occur in association with high-dose enzyme administration and require operative colonic resection. Rectal prolapse can occur between 1 to 3 years of age, and generally resolves with oral enzyme therapy or rectal cautery and sclerotherapy. Intussusception and biliary disease can also occur in patients with cystic fibrosis.

## **Meconium Plug Syndrome**

Meconium plug syndrome (MPS) is reported with an incidence of 1 in 500 to 1000 live births. There have been reported associations between HD (43%) and cystic fibrosis (38%) in patients with MPS. This syndrome is common in infants of diabetic mothers (40%–50%) and is synonymous with small left colon and functional colonic obstruction in the newborn. MPS is also seen in infants with neurological depression at birth or who are hypotonic for other reasons.

The clinical presentation of MPS may be similar to meconium ileus, with abdominal distention, failure to pass meconium within the first 24 to 48 hours, and intolerance of feeds with emesis, which may be bilious. Distinguishing between these two diagnoses lies in identifying the area of intestinal obstruction. In meconium ileus, the meconium causes obstruction in the ileum, leading to dilated small bowel and a microcolon, whereas in MPS, plugs are seen in the colon which may be of normal size.

Abdominal x-ray (AXR) can be used as an initial surveyor of bowel dilatation in the search for possible etiology of bowel obstruction in the distended neonate. Although there are no particular signs on AXR, dilated bowel and the presence of stool within the colon with normal-caliber small bowel may be suggestive of MPS. Plain imaging is followed by contrast enema studies using a water-soluble contrast. As explained earlier in meconium ileus, this may be both diagnostic and therapeutic, as enema

studies may show meconium “plugs” within the colon, which may be evacuated with the enema study. Rectal irrigations should subsequently be performed until there is clinical evidence of normal bowel evacuation and improvement in the abdominal distention. Repeat enema studies may be needed. The small, contracted portion of the descending colon in these infants has led to the term neonatal small left-colon syndrome, which is associated with maternal diabetes.

Investigations for associated disease such as cystic fibrosis and HD should be undertaken in the clinically stable child. Sweat test and confirmatory tests for cystic fibrosis such as cytogenetics may be utilized. Suction rectal biopsy should be performed in these patients to rule out HD.

Surgical intervention is rarely necessary. If surgical intervention is required, it is usually secondary to underlying etiologies such as cystic fibrosis and HD.

## **Small Left Colon**

Newborns with this process will present with signs and symptoms consistent with intestinal obstruction. Contrast (water-soluble) enema demonstrates a small-caliber, smooth, rounded left colon with a normal large intestine proximal to the splenic flexure. This abnormality is often found in infants with diabetic mothers. Contrast enema is often curative and the caliber of the left colon subsequently normalizes over the ensuing weeks to months.

## **Hirschsprung Disease**

Hirschsprung disease (HD) refers to congenital aganglionosis of the intestine occurring in approximately 1 in 5000 live births. Neuroblasts derived from neural crest precursors normally migrate within the submucosal and intermuscular planes of the gut to the rectum by the 12th week of gestation. Arrest of this caudal migration results in ineffective peristalsis in the distal segment of bowel accompanied by increased tone. Seventy-seven percent of cases are “short segment” and located in the rectosigmoid region.

Approximately 10% of cases will involve the entire colon. Rarely, extensive small bowel aganglionosis may be encountered. Approximately 50% of patients with HD are diagnosed in the newborn period and often present with

symptoms of abdominal distention, bilious vomiting, and constipation with delayed passage of meconium beyond 48 hours of life.

Unrecognized HD in infancy has been associated with a 25% to 30% mortality. Eighty percent of those patients with HD are male, and the incidence of HD among preterm newborns is rare.

AXR may be done as the initial test in a child presenting with abdominal distention and intolerance of feeds. This may show a dilated distal colon and accumulation of stool within the colon. A barium enema of the unprepared colon may demonstrate the presence of a transition zone between distal areas of intestinal spasm (aganglionic) and proximal regions of dilated bowel (ganglionic) (Fig. 9-29). However, an obvious transition zone requires time to develop and may not be present in the neonate with HD. Contrast studies may show narrowing of the colon in its entirety, an entity known as total colonic HD (Fig. 9-30). Evaluation with rectal manometry demonstrates internal sphincter contraction rather than relaxation during periods of transient rectal distention in the patient with HD. Diagnosis of HD is dependent upon the demonstration of the absence of ganglion cells with the presence of enlarged, non-myelinated nerves on rectal biopsy (Fig. 9-31). The biopsy must be obtained at least 1.5 cm. above the dentate line and may be evaluated by standard hematoxylin and eosin stain or by the Meier–Ruge stain for acetylcholinesterase, which is increased in specimens with HD. Evaluation for calretinin, which is decreased in the setting of HD, may aid in diagnosis. A suction rectal biopsy is typically performed utilizing an apparatus that entrains a piece of the mucosa and submucosa of the rectum within a guillotine-like device, which excises and captures the sample. If the suction rectal biopsy does not provide an adequate sample, then a trans-anal, full-thickness incisional biopsy should be performed in the operating room.

**FIGURE 9-29** Contrast enema showing dilated proximal colon with narrowed distal segment, seen in Hirschsprung disease. Black arrow points to likely transition zone.

**FIGURE 9-30** Total colonic Hirschsprung disease.

**FIGURE 9-31** Hirschsprung disease transition zone. Antimesenteric stitches from intraoperative full thickness biopsies of colon wall.

Hirschsprung's associated enterocolitis occurs in approximately 40% of patients diagnosed with HD. Abdominal distention, fever, and diarrhea with foul-smelling, explosive, loose stools may be indicative of the presence of enterocolitis. This can result in ischemia and necrosis of the bowel above the aganglionic segment with secondary perforation. Even if bowel ischemia is not present, enterocolitis may be associated with septicemia and even death.

Medical treatment of HD once diagnosed is ineffectual and may be dangerous if enterocolitis intercedes. Standard treatment includes performance of a left lower quadrant transverse incision with initial inspection for evidence of a transition zone. Prior barium enema provides correct identification of the transition zone in 80% of patients, which may simplify intraoperative exploration. Seromuscular biopsy specimens are evaluated by frozen section for evidence of the presence of ganglion cells (Fig. 9-32). A loop colostomy is performed in the most proximal region of the normally innervated bowel. This is known as a "leveling colostomy" and allows decompression of the bowel with normalization of intestinal caliber over the ensuing 6 to 8 weeks.

**FIGURE 9-32** Histological slide of a suction rectal biopsy done on a patient diagnosed with Hirschsprung disease. This is characterized by lack of ganglion cells and elevated acetyl cholinesterase (AChE) on staining. Black arrow points to a hypertrophied nerve.

Definitive surgical correction can be done with one of three common procedures. Initially the Swenson procedure was described, where the aganglionic distal segment is dissected out from its pelvic attachments and removed. The distal margin of this dissection is usually 1 to 2 cm above the dentate line. Following this, the proximal ganglionated portion and the distal anal cuff are anastomosed in an end-to-end fashion.

The Duhamel operation consists of removing the defective or aganglionated portion of the colon, but the reconnection is done via an end-to-side anastomosis. An incision is made in the rectum 1 cm proximal to the dentate line. The ganglionated segment of bowel is passed through the bloodless pre-sacral space posterior to the rectum and an anastomosis in end-to-side fashion to the incision in the rectum is performed. A stapling device is utilized to increase the size of the anastomosis between the aganglionated rectum and the ganglionated portion of bowel. This allows formation of a large “neo-rectum,” which is formed anteriorly by the aganglionated rectum and posteriorly by the normal, ganglionated bowel. The third variation, or the Soave procedure, consists of resection of the extrapelvic aganglionic segment

and creation of an aganglionated cuff by removing the mucosa of the rectum but leaving the external layers of the rectum intact. This is done to mitigate injury that could be caused by pelvic dissection in the Swenson procedure. The ganglionated segment is then pulled through this cuff and anastomosed approximately 1 to 2 cm above the dentate line.

Confidence in the accuracy of pathologic identification of normal, ganglionated bowel on frozen section is necessary before a primary endorectal pullthrough may be performed.

Mortality is rare except in the setting of enterocolitis. Postoperative complications, including anastomotic leaks, strictures, intestinal obstruction, and pelvic abscesses occur in approximately 5% of patients. Postoperative enterocolitis occurs in approximately 40% of patients regardless of the corrective procedure utilized. The incidence of enterocolitis appears to decrease with age. Overall, approximately 80% to 90% of patients followed beyond 5 years of age have normal evacuation and continence.

## **Imperforate Anus**

Imperforate anus consists of an arrest of the normal descent of the rectum to the perineum. Patients may be divided into those in which the end of the rectum is above the sphincter muscles (high), partially through (intermediate), or fully through the sphincter muscles (low). From a clinical point of view, it is only necessary to distinguish between those patients with low anomalies from those that have intermediate/high anomalies. It is important to note that males frequently have high/intermediate lesions, while females have a preponderance of low malformations. A low lesion in a male may be discerned by the presence of a thin membrane covering the anus, often with visible dark meconium underneath or an anocutaneous fistula in the midline along the perineal or scrotal raphe ([Fig. 9-33](#)). In the female patient, a perineal or vaginal vestibular fistula almost always indicates the presence of a low lesion. Therefore, in both males and females, the absence of a fistula or anal membrane suggests the presence of an intermediate/high lesion.

**FIGURE 9-33** Low imperforate anus with meconium tracking up median raphe and penile shaft.

The majority of those male patients with an intermediate/high anomaly will have an associated fistula to the genitourinary tract, typically a rectoprostatic or rectobulbar urethral fistula. The presence of the imperforate anus should be apparent at initial newborn exam, although lesions associated with a large perineal fistula or “ectopic anus” can be easily missed. If a low malformation is present, passage of meconium via a sizeable perineal or vestibular fistula may allow adequate decompression of the gastrointestinal tract. If not, symptoms of obstruction with abdominal distention and bilious vomiting may occur.

Investigational studies for imperforate anus may start with a cross-table prone film to attempt to document the distance between the distal end of the rectum and the anal opening. This is done by placing the newborn in the prone position for about 15 minutes to allow intraluminal air to travel upward. A radio-opaque marker is placed on the expected location of the anal opening, based on physical exam. These cross-table views in prone position can be utilized to assess the distance between the rectum and anal opening (Fig. 9-34). Ultrasound examination via a transperineal or infracoccygeal route has merit in identifying the distal end of the rectum facilitating

measurement between the rectum and anal dimple, although there may be considerable technician variability in conducting the exam. Other modalities such as CT or MRI are rarely used in the initial diagnostic workup for imperforate anus, but may provide additional anatomical details. MRI has been found to be superior to CT scan in terms of soft tissue anorectal assessment and avoidance of radiation.

**FIGURE 9-34** Invertogram with radio-opaque marker to show likely position of anal dimple externally. End of rectal pouch is designated with black arrow.

Occasionally, a low lesion may be ascertained by (i) needle aspiration of the perineum with documentation of return of meconium from the rectum within 1 to 2 cm or (ii) ultrasound evaluation of the perineum, which allows visualization of a distal rectal pouch and documentation of the distance between anal dimple and rectum. Radiologic evaluation in conjunction with physical exam will allow a low lesion to be discerned in most cases. However, if diagnosis of a low lesion cannot be established, then the newborn should be considered to have an intermediate/high anomaly.

As many as 70% of newborns with imperforate anus will have additional associated anomalies. Specifically, those malformations which constitute the

VATER or VACTERL association should be ruled out in all patients with imperforate anus. A baseline echocardiogram, spinal ultrasound, and renal ultrasound are performed. Treatment of imperforate anus depends on the level and type of lesion identified in the diagnostic studies outlined previously. If an obstructive anomaly is present, oro- or nasogastric suction should be utilized along with administration of antibiotics. Operation may await completion of diagnostic studies assessing for associated anomalies.

Sacral ratios are calculated by measuring the distance between key bony points on anteroposterior and lateral views of pelvic radiographs. The ratios provide additional information that may predict subsequent continence. Pena introduced this ratio with the concept that those children with absence of numerous sacral elements will likely have neurological aberrancies that may affect future continence even after surgical correction.

All high/intermediate lesions are initially managed with a colostomy followed by elective performance of a distal colostogram to ascertain the specific lesion and to document the presence and location of a fistula. Corrective operation is dictated by the location of the lesion (high, intermediate, or low). For high lesions, performance of a posterior sagittal anorectoplasty (PSARP) may be accomplished at 3 to 6 months of life. This procedure involves division of the perineum from the anterior border of the external sphincter muscle to the coccyx with division of all muscles of continence, including the levator ani, in the midline. The rectum and fistulous connection between the urogenital and gastrointestinal tract is identified, divided, and closed. The rectum is then approximated to the anus as the levator ani and associated muscles of continence are reconstructed in the midline around the rectum.

Innovative, minimally invasive approaches have come into play for most centers that take care of these patients. Laparoscopy-assisted anorectoplasty (LAARP) uses laparoscopic dissection to isolate the rectal pouch and to identify and ligate the fistula. External identification of the anal dimple is done using the Pena<sup>®</sup> neurostimulator. A skin opening is made, and blunt dissection is used to create a tract from the external opening through the perineum, along the projected tract of the sphincter complex. A trocar is then passed through this tract, with laparoscopic guidance, between the bellies of the pubococcygeus muscle. The neo-rectum is then pulled through this tract through the sphincter muscle complex. MRI-assisted LAARP (MRI-LAARP) is a novel method of surgical correction for patients with imperforate anus

that utilizes MRI imaging to guide the sequential advancement of an MRI-compatible needle through the epicenter of the sphincter complex. The external sphincter complex is identified with the neurostimulator, and an MRI-compatible needle is passed through with sequential imaging of the sphincter complex to ensure that the needle is traversing through the epicenter of the complex. The laparoscopic portion of the case proceeds in a fashion similar to the LAARP. The neorectum is then pulled through the sphincter complex and anastomosed to the anal canal in the perineum (Fig. 9-35).

**FIGURE 9-35** **A.** Placement and advancement of the needle into the sphincter complex (depicted with red arrow). The needle appears larger than it actually is due to “blooming” artifact. **B.** Needle in place after advancement through the sphincter complex.

Most low malformations may be definitively repaired in the newborn period. In both males and females an anal membrane may be punctured and dilated. A perineal fistula is addressed by incision of the skin and rectum back to the posterior margin of the external sphincter with suture approximation of the rectal mucosa to the skin (cutback anoplasty) (Fig. 9-36). In the female, mobilization of a vestibular fistula requires posterior transposition of the fistula to the proper site of the anus. This latter procedure is somewhat more complex, and therefore is usually performed at 2 to 3 months of age.

**FIGURE 9-36** Completed anal anastomosis after cutback anoplasty.

The postoperative mortality of 10% to 30% is usually due to associated anomalies, mostly cardiac. Problems with rectal prolapse or anal stenosis may be observed in 5% to 10% of infants. All patients should undergo progressive anal dilatation beginning 3 weeks after operation and continuing through the following year. Patients should be followed carefully for evidence of genitourinary problems and should be placed on prophylactic antibiotics in the initial newborn period if an intermediate/high lesion is identified.

Newborns with low malformations have an excellent outlook, with fecal continence documented in 95% of patients. Constipation may, however, be a problem in those patients with low lesions and vestibular fistulas. Approximately 50% to 70% of patients with intermediate/high anomalies have good results with only occasional soiling noted. The remaining 30% to 50% of patients have fair to poor results, with varying degrees of continence. The majority of these patients may be managed with a bowel program consisting of enemas, laxatives, or constipating agents. The functional results are mostly related to the presence of sphincter muscle hypoplasia and abnormal sacral innervation which is observed in patients with

intermediate/high anomalies.

## **ABDOMINAL WALL**

# INCISIONS, CLOSURES, AND MANAGEMENT OF THE ABDOMINAL WOUND

*Robert E. Roses • Jon B. Morris*

## INCISIONS

The planning, execution, and closure of an incision have an enormous impact on the outcome of an abdominal operation. The high combined incidence of surgical site infection, wound dehiscence, and hernia formation suggests a dominant contribution of wound complications to surgical morbidity. Moreover, the quality of exposure provided by an incision influences outcome in ways that defy easy quantification. An incision must provide access to the site of abdominal pathology and allow ready extension if greater exposure is required. Indeed, the adequacy of an incision is determined above all else by the safety with which an operation can be undertaken. Nothing should compromise this, and a larger incision or even, on occasion, a second incision, should be created without hesitation if exposure is inadequate. Notwithstanding this, the incision should be executed in a fashion that anticipates a secure wound closure and interferes as little as possible with the

function and cosmesis of the abdominal wall. While the vertical midline incision remains most popular and is, perhaps, the most versatile, a variety of other incisions may have distinct advantages in specific settings.

## Choice of Incision

Abdominal incisions can be vertically, transversely, or obliquely oriented. The avascular linea alba affords the vertical midline its superior flexibility. Indeed, when optimal exposure of the entire abdominal cavity is necessary (eg, exploration for abdominal trauma), the vertical midline incision is preferred and can be extended superiorly to the xiphoid process and inferiorly to the symphysis pubis. Resection of the xiphoid may afford even better superior exposure when needed. Alternatively, vertical incisions may be placed in a paramedian position, an approach that was previously more popular than it is today but continues to have its proponents. Transverse and oblique incisions can be placed in any of the 4 quadrants of the abdomen depending on the site of pathology. Common examples include the Kocher subcostal incision for biliary surgery, the Pfannenstiel infraumbilical incision for gynecologic surgery, and the McBurney and Rocky-Davis incisions for appendectomy. A bilateral subcostal incision affords excellent exposure of the upper abdomen. Alternatively, when superior exposure of upper abdominal organs (eg, the esophagogastric junction) is required, thoracoabdominal incisions may be used. Retroperitoneal and extraperitoneal structures (eg, the kidney, adrenal gland, and aorta) may be readily exposed through abdominal wall incisions; often obliquely oriented or curvilinear flank incisions are used. Recently, J- or L-shaped incisions have gained popularity for exposure of the upper quadrants of the abdomen and for hepatic resection in particular.

The relative merits and disadvantages of vertical versus transverse incisions remain subjects of active debate. Proponents of transverse incisions argue that they anticipate a more secure closure than with vertical incisions—a hypothesis supported by anatomic and surgical principle. The fascial fibers of the anterior abdominal wall are oriented transversely or obliquely. Transverse incisions, therefore, parallel this orientation and allow for ready reapproximation with sutures placed perpendicular to the fibers. In contrast, vertical incisions disrupt fascial fibers and must be reapproximated with sutures placed between fibers.<sup>1</sup> In the latter case, the absence of an anatomic

barrier may predispose to tearing of tissues, resulting in dehiscence or hernia formation. Despite these concerns, little evidence supports a substantial benefit of transverse incisions, and proponents of vertical incisions argue that larger transverse incisions obligate division of muscle fibers with greater functional consequences and leave fewer options for remediation when hernias do develop. A number of retrospective clinical studies and a meta-analysis do suggest that transverse incisions are superior to vertical incisions with regard to long-term and short-term outcomes (eg, postoperative pain, pulmonary complications, and frequencies of incisional hernia and dehiscence).<sup>1</sup> However, prospective data have been less definitive. One randomized controlled trial compared vertical and transverse incisions with regard to the frequency of evisceration; no significant difference in outcome was observed with either technique.<sup>2</sup> In a more recent prospective randomized trial, no significant differences in 30-day mortality, pulmonary complications, median length of hospital stay, median time to tolerate solid food, and incisional hernia formation at 1 year were observed. More wound infections were seen with transverse incisions.<sup>3</sup>

Controversy also persists regarding the relative advantages of midline versus paramedian incisions. The theoretical advantage of a paramedian over a midline incision is a diminished risk of wound dehiscence and incisional hernia owing to the presence of rectus muscle interposed between layers of divided fascia. In practice, when these incisions are reopened, the medial edge of the rectus muscle is frequently adherent to the anterior or posterior sheath incision and does not effectively buttress the wound. The potential advantages of the paramedian incision have also been investigated in prospective randomized trials, which have failed to demonstrate an advantage with regard to wound failure rates.<sup>4</sup> A “lateral paramedian incision” refers to a vertical incision created several centimeters lateral to the location of the traditional paramedian incision.<sup>5</sup> One randomized prospective study suggested a statistically significant decrease in the incidence of incisional hernia following closure of lateral paramedian incisions (0%) compared to medial paramedian incisions (14.9%) and midline incisions (6.9%).<sup>6</sup>

In the patient who has had prior abdominal surgery, the cosmetic advantages of reentering the abdomen through a preexisting scar must be balanced against the challenges associated with dissection in a reoperative field. Close proximity of a new incision to an old one should be avoided in

order to minimize the risk of ischemic necrosis of intervening skin and fascial bridges.

## Preparation of the Surgical Site

Prior to incision, the surgical field is prepared with antiseptic solution and draped in order to reduce skin bacterial counts and the likelihood of subsequent wound infection. Shaving prior to operation has been associated with an increased rate of surgical site infection and should, therefore, be avoided. If hair at the surgical site will interfere with accurate wound closure or precludes easy application of the sterile preparation, the use of clippers is preferred to a razor.<sup>7</sup> A variety of antiseptic solutions are commonly used to prepare the skin, including povidone-iodine, alcohol, and chlorhexidine. The efficacy of povidone-iodine depends on the release of the active iodine from a carrier molecule. The solution should, therefore, be applied several minutes prior to incision to maximize its efficacy. The use of chlorhexidine gluconate has been associated with greater reductions in skin bacterial counts and lower rates of surgical site infection when compared to povidone-iodine in a number of studies<sup>8-11</sup> and is emerging as the preferred skin antiseptic.

## Incisions: Technical Considerations

### VERTICAL INCISIONS

**Midline Incision.** The midline incision allows rapid access to and adequate exposure of almost every region of the abdominal cavity and retroperitoneum. It is typically associated with little blood loss and does not require transection of muscle fibers or nerves. The upper midline incision (ie, above the umbilicus) may be used to expose the esophageal hiatus, abdominal esophagus and vagus nerves, stomach, duodenum, gallbladder, pancreas, and spleen (Fig. 10-1). The lower midline incision (ie, below the umbilicus) provides exposure of lower abdominal and pelvic organs. When broad exposure is required, as in an exploration for trauma, the midline incision can be extended to the xiphoid process superiorly and to the pubic symphysis inferiorly.

**FIGURE 10-1** Epigastric midline incision: surface markings.

In creating a midline incision, the operating surgeon and assistant apply opposing traction to the skin on both sides of the abdomen. The skin is then incised with a scalpel. Gauze pads are applied to the skin edges to tamponade bleeding cutaneous vessels, and gentle lateral traction is placed on the subcutaneous fat on both sides of the incision. The incision is then carried down to the linea alba using either electrocautery or a scalpel; the decussation of fascial fibers in the upper abdomen serves as an important landmark for the midline. The linea alba, extraperitoneal fat, and peritoneum are then divided sequentially. If exposure of both the upper and lower peritoneal cavities is required, the incision is carried around the umbilicus in a curvilinear fashion. The peritoneum itself is best divided with scissors or scalpel to avoid coagulation injury to underlying intra-abdominal organs. In addition, safe entry may be facilitated by picking up a fold of peritoneum, palpating it to ensure that no bowel has been drawn up, and sharply incising the raised fold. The falciform ligament is best avoided by entering the peritoneum to the left of the midline in the upper abdomen. To avoid injuries to the bladder, the peritoneum is entered in the upper portion of the incision. After a small opening is created in the midline, it is enlarged to accommodate 2 fingers that are then used to protect the underlying viscera as the

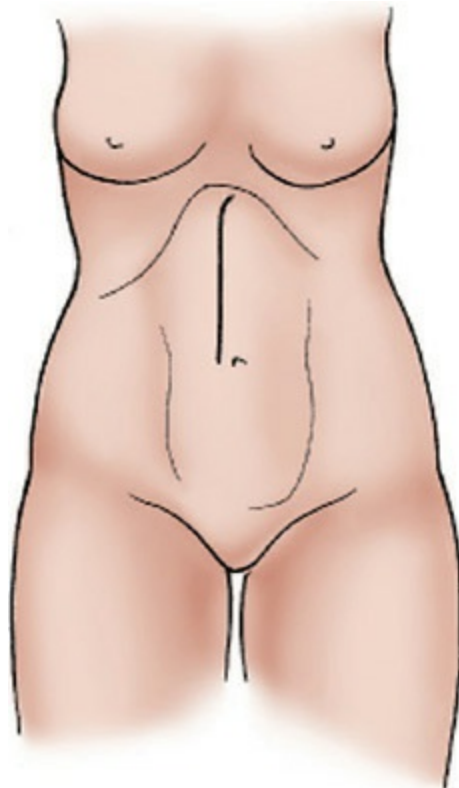

peritoneum is further divided along the length of the wound (Fig. 10-2).

**FIGURE 10-2** Vertical midline incision: the linea alba and peritoneum are divided.

**Paramedian Incision.** Paramedian incisions are vertical incisions placed either to the right or left of the midline on the abdominal wall. Like midline incisions, paramedian incisions obviate division of nerves and the rectus muscle and may be made in the upper or lower abdomen. Superiorly, additional access can be obtained by directing the upper portion of the incision along the costal margin toward the xiphoid process (Fig. 10-3). The anterior border of the rectus sheath is exposed and incised across the entire length of the wound. The medial aspect of the anterior rectus sheath is then dissected away from the rectus muscle to its medial edge (Fig. 10-4).

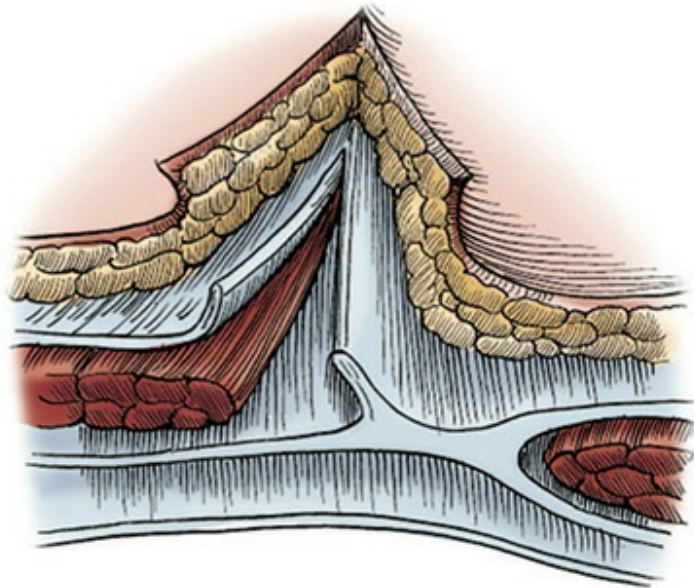

Particular care must be taken during this dissection in the upper abdomen where tendinous inscriptions that attach the rectus muscle to the anterior fascia are associated with segmental vessels. These vessels should be ligated when encountered. Once free, the rectus muscle is retracted laterally. The posterior sheath (above the arcuate line) and peritoneum are then incised to gain entry into the abdomen. During creation of a paramedian incision in the lower abdomen, the inferior epigastric vessels may be encountered and must be ligated prior to division (Fig. 10-5).

**FIGURE 10-3** Upper paramedian incision: surface markings. Additional exposure can be obtained by sloping the upper portion of the incision upward toward the xiphoid process.

A

B

**FIGURE 10-4** **A.** Paramedian incision: dissection of the rectus muscle from the anterior rectus sheath. **B.** Paramedian incision in transverse section.

**FIGURE 10-5** Lower paramedian incision. **A.** Surface markings. **B.** Incision of the rectus sheath. **C.** Retraction of the rectus abdominis muscle. **D.** Location of the branches of the inferior epigastric vessels that run across the lower portion of the incision. **E.** Peritoneum opened. **F.** The peritoneum is incised for the full length of the wound.

**Vertical Muscle-Splitting Incision.** The vertical muscle-splitting incision is made in much the same way as the traditional paramedian incision except that

the rectus muscle is split, rather than retracted laterally. This wound can be opened and closed quickly and is of particular value in reopening a previous paramedian incision where dissection of the rectus muscle away from the rectus sheath can be difficult. Longer incisions should be avoided, however, because they result in significantly more bleeding and sacrifice of nerves that may lead to muscle atrophy and weakening of the corresponding area of the abdominal wall.

## **TRANSVERSE AND OBLIQUE INCISIONS**

Transverse and oblique incisions generally follow Langer's lines of tension and allow a more cosmetic closure than do vertical incisions. Importantly, the rectus muscle has a segmental innervation derived from intercostal nerves that enter the rectus sheath laterally. Transverse or slightly oblique incisions through the rectus largely spare these nerves. Provided that the anterior and posterior fascia is closed, the rectus muscle can be divided transversely without significantly compromising the integrity of abdominal wall.

Although properly placed transverse incisions can provide exposure of specific organs, they may be limiting when pathology is located in both the upper and lower abdomen.

**Kocher Subcostal Incision.** A right subcostal incision is used commonly for operations in which exposure of the gallbladder and biliary tree is necessary. The left-sided subcostal incision is used less often, mainly for splenectomy or left upper quadrant masses. A bilateral subcostal incision provides excellent exposure of the upper abdomen and can be employed for hepatic resections, liver transplantation, total gastrectomy, and anterior access to both adrenal glands.

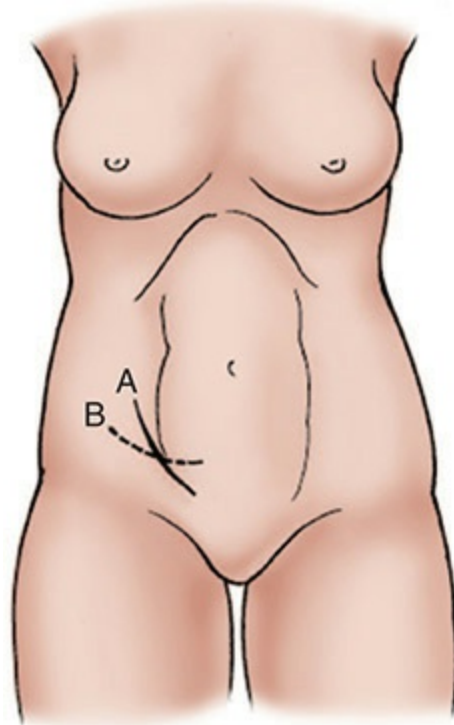

The standard subcostal incision begins at the midline, 2 fingerbreadths below the xiphoid process, and is extended laterally and inferiorly, parallel to the costal margin (Fig. 10-6). The incision should not be placed too far superiorly because sufficient fascia must be preserved to allow a secure abdominal closure. Following incision of the rectus sheath along the plane of the skin incision, the rectus muscle is divided using electrocautery or ligatures to control branches of the superior epigastric artery. The peritoneum is then divided in the plane of the skin incision. The incision can be extended beyond the lateral aspect of the rectus muscle if necessary to facilitate

exposure.

**FIGURE 10-6** Kocher incision. **A.** Surface markings. **B.** Division of the rectus and medial portions of the lateral abdominal muscles.

**McBurney and Rockey-Davis Incisions.** Originally described by Charles McBurney in 1894,<sup>12</sup> the muscle-splitting right iliac fossa incision known as the *McBurney* incision is well suited for appendectomy. This incision is oriented obliquely. The McBurney incision has largely been supplanted by the Rockey-Davis incision, which is oriented transversely as opposed to obliquely, allowing for better cosmesis (Fig. 10-7).

**FIGURE 10-7** Surface markings of the right iliac fossa appendectomy incisions. **A.** The classic McBurney incision is obliquely placed. **B.** The Rockey-Davis incision is transversely placed in a skin crease.

The suspected position of the appendix and the thickness of the abdominal wall influence the placement of the incision as well as its length. Examination of the anesthetized patient's abdomen will often reveal a mass, guiding placement of the incision directly over the appendix. If no mass is palpable, the incision is centered over McBurney's point at the junction of the middle and outer thirds of the line between the umbilicus and the anterior superior iliac spine. If the patient is obese or if extension of the incision is anticipated,

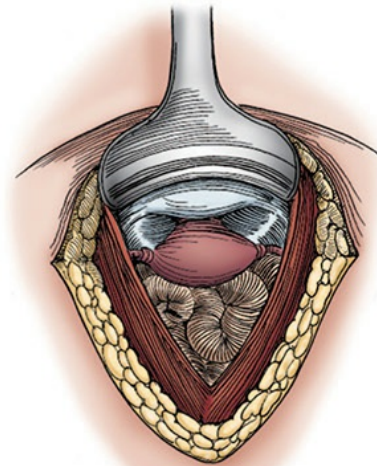

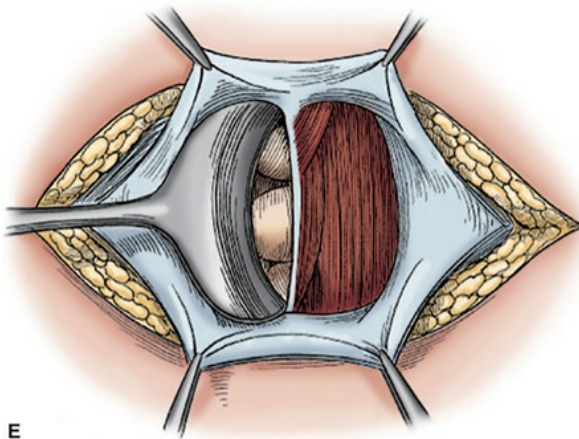

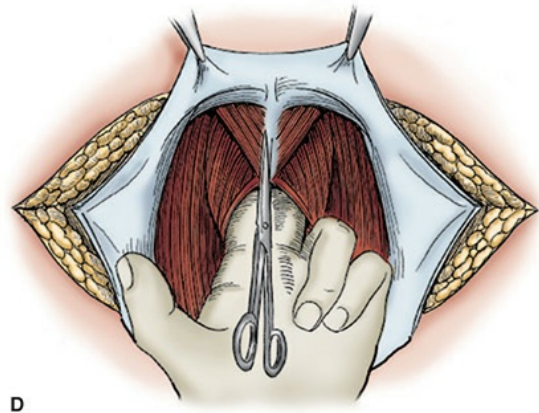

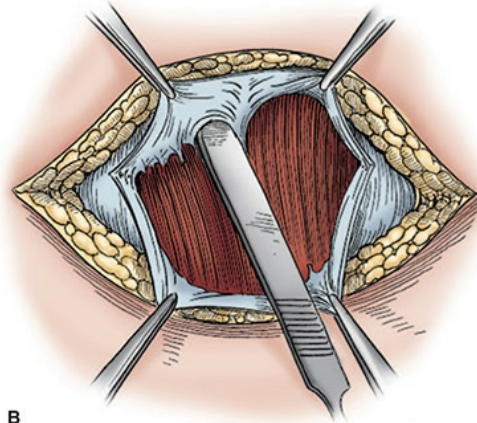

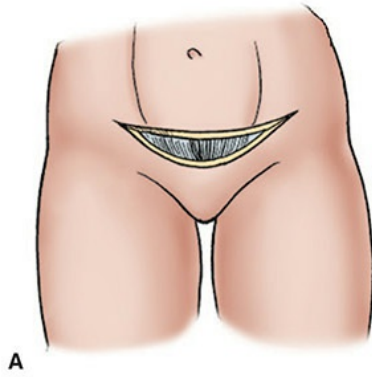

the incision should be placed obliquely, allowing ready lateral extension.

After skin and subcutaneous tissues are incised, the external oblique aponeurosis is exposed and divided parallel to the direction of its fibers to reveal the underlying internal oblique muscle. At a point adjacent to the lateral border of the rectus sheath, a small incision is made in the internal oblique muscle, which is similarly opened in the direction of its fibers. Once the underlying transversalis muscle is exposed, it is split to reveal the transversalis fascia and peritoneum. These are sharply divided, and the appendix and cecum are exposed (Fig. 10-8). If further exposure is necessary, the wound can be enlarged by dividing the rectus sheath, retracting the rectus muscle medially, and extending the peritoneal defect. If the operation requires extension of the wound laterally, this can be accomplished through division of the oblique muscles.

**FIGURE 10-8** McBurney muscle-splitting incision. **A.** Division of the external oblique aponeurosis. **B.** The internal oblique and transversus muscles are split. **C.** The index fingers of each hand enlarge the opening. **D.** Incision of the peritoneum. **E.** Exposure of the appendix.

**Pfannenstiel Incision.** The Pfannenstiel incision is used frequently for gynecologic operations and for access to the retropubic space (eg, for extraperitoneal retropubic prostatectomy). The skin incision is placed in the interspinous crease above the symphysis pubis. The anterior rectus sheath is exposed and divided transversely. The superior and inferior leaflets of the divided sheath are dissected from the underlying rectus muscles superiorly to the umbilicus and inferiorly to the pubic symphysis. The recti are retracted laterally and the peritoneum is opened vertically in the midline. At the inferior aspect of the wound, the bladder is protected to avoid injury (Fig. 10-9). An advantage of this incision is that it affords a cosmetic closure because it is placed in a skin crease at the level of the belt line; however, exposure may be somewhat limited.

**FIGURE 10-9** Pfannenstiel incision. **A.** Skin incision. **B.** Horizontal division of the anterior rectus sheath and developing fascial flap. **C.** Dividing in the midline and entering the peritoneal cavity. **D.** Opening midline. **E.** Lateral retractors are placed for exposure. **F.** Inferior retractors placed for exposure. **G.** Closure midline and inferior rectus.

## **ABDOMINOTHORACIC INCISIONS**

The thoracoabdominal incision provides enhanced exposure of upper abdominal organs. A left thoracoabdominal incision is useful for access to the left hemidiaphragm, gastroesophageal junction, gastric cardia and stomach, distal pancreas and spleen, left kidney and adrenal gland, and aorta. A right thoracoabdominal incision can be used to expose the right hemidiaphragm, esophagus, liver, portal triad, inferior vena cava, right kidney, right adrenal gland, and proximal pancreas. These incisions are reserved for circumstances in which an operation cannot safely be performed through an abdominal incision, as they are theoretically associated with increased morbidity relating to a more difficult pulmonary recovery and risk of phrenic nerve injury.

The patient is placed in the “corkscrew” position on the operating room table to enhance access to both the abdominal and thoracic cavities. The abdomen is tilted approximately 45 degrees from the horizontal plane, and the thorax is oriented in full lateral position (Fig. 10-10A). Positioning is aided by the use of a bean bag. The abdominal part of the incision may consist of a midline or upper paramedian incision, which allows exploration of the abdomen. The incision is extended obliquely along the line of the eighth interspace just beneath the inferior pole of the scapula (Fig. 10-10B). Alternatively, an oblique upper abdominal incision can be used and extended directly into the thoracic portion of the incision.

**FIGURE 10-10** Anterolateral thoracoabdominal incision. **A.** The “corkscrew” position, with the thorax in the lateral position and the abdomen at 45 degrees from the horizontal plane. Appropriate positioning on the

operating table is essential to prevent injury to the brachial plexus and minimize pressure on peripheral nerves. **B.** The abdominal incision is made first, usually a vertical midline incision that is extended into the chest through the eighth intercostal space. The pleural space is then entered. **C.** The diaphragm is usually opened in a radial fashion with an incision directed toward the esophageal or aortic hiatus. **D.** The diaphragm can alternatively be opened with a hemielliptical incision 2 to 3 cm from the lateral chest wall; this incision preserves phrenic nerve function, which is of particular importance in patients with impaired pulmonary function. (Reproduced with permission from Baker RJ, Fischer JE: *Mastery of Surgery*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

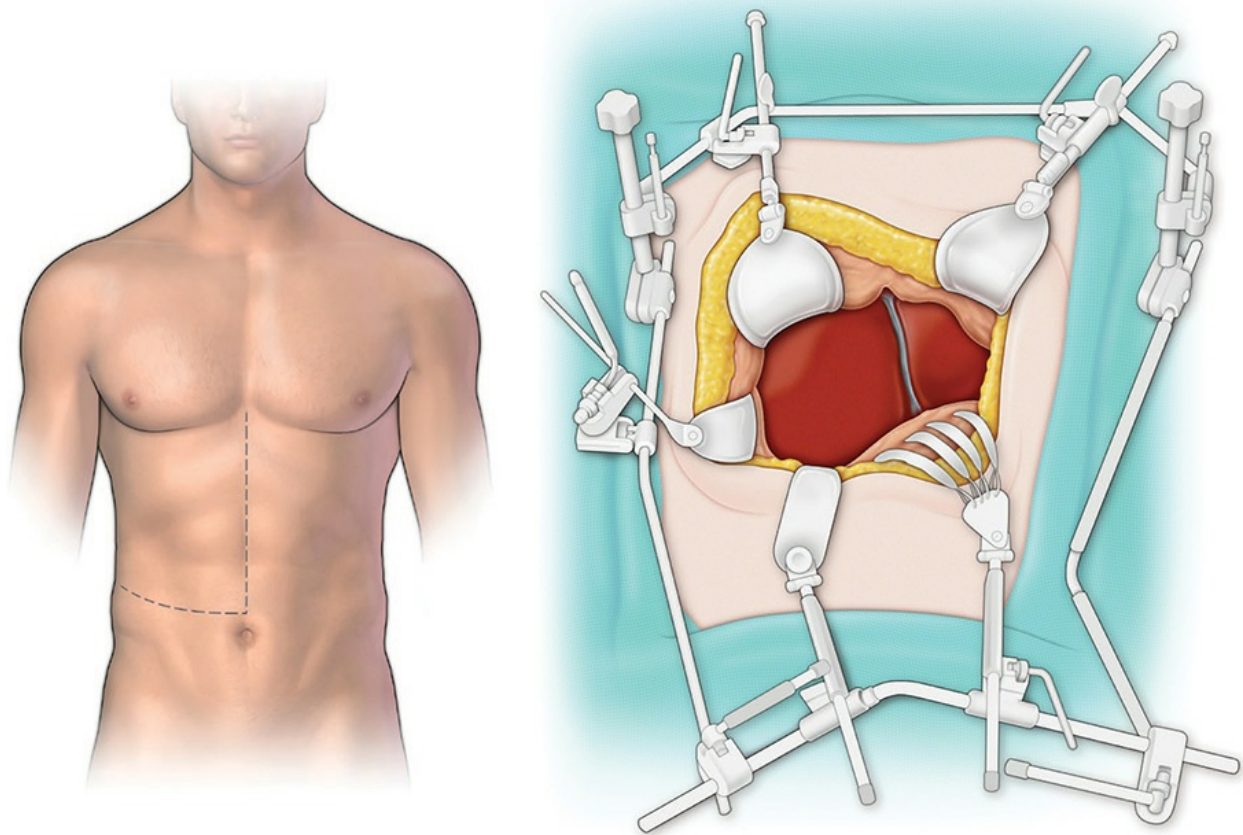

After entry into the peritoneal cavity through the abdominal portion of the incision, the incision is extended onto the chest wall and the latissimus dorsi and serratus anterior muscles, and then the external oblique muscle and aponeurosis are divided. The intercostal muscles of the eighth interspace are divided to allow entry into the chest cavity, and the incision is extended across the costal margin, which is divided with a scalpel. It is often useful to resect a short segment of costal cartilage to facilitate closure of the chest wall. A self-retaining rib retractor is inserted, and the intercostal space is gently spread. The diaphragm is either incised radially toward the esophageal or aortic hiatus or in a curvilinear fashion if less exposure is required. This incision also preserves phrenic nerve function and is useful for patients with pulmonary compromise.<sup>13</sup>

At the completion of the operation, chest tubes placed in the pleural cavity are brought out through the chest or upper abdominal wall through separate incisions. The diaphragm is repaired in 2 layers using nonresorbable sutures. Pericostal sutures are placed to reapproximate the ribs. The chest muscles and abdominal wall are then closed in layers.

## **L- AND J-SHAPED INCISIONS**

L- or J-shaped incisions were first described by Masatoshi Makuuchi and have gained considerable popularity for upper abdominal surgery and liver resection in particular.<sup>14</sup> These incisions, which extend from xiphoid to the umbilicus and across the right or left hemirectus in transverse fashion, have several theoretical and real advantages. Transverse division of the rectus

muscle preserves segmental innervation and may minimized postoperative muscle atrophy. Moreover, by combining vertical and transverse components, an abdominal wall flap is created that can be retracted superiorly yielding wide exposure without division of both sides of the rectus. Optimal exposure requires appropriate placement of retractors; use of a retractor system that can be contoured to the incision (eg, the Thompson retractor system, Thompson Surgical Instruments [Traverse City, MI], or other table-based self-retaining systems) is helpful in this regard (Fig. 10-11). Appropriate alignment of the closure is facilitated by initial placement of interrupted sutures at the edge of the rectus muscle, junction of the transverse and vertical portions of the incision, and superior aspect of the vertical incision. Running closure of the fascial layers can then be undertaken. The interrupted sutures are tied prior to skin closure and reinforce the running closure.

**FIGURE 10-11** This incision begins at the xiphoid, extends to just above the umbilicus, and then extends laterally to the right. A left sided (L-shaped incision) can be created for left upper quadrant exposure. Exposure can be

optimized with judicious use of a flexible retractor system.

## **RETROPERITONEAL AND EXTRAPERITONEAL INCISIONS**

Retroperitoneal and extraperitoneal approaches to the abdomen have several advantages over transperitoneal exposures. Manipulation and retraction of intra-abdominal viscera are limited, and the risk of postoperative ileus is reduced. Hemorrhage is more likely to be tamponaded in the retroperitoneum than when it occurs in the peritoneal cavity. Retroperitoneal and extraperitoneal approaches can be used for operations on the kidney, ureter, adrenal gland, bladder, splenic artery and vein, vena cava, lumbar sympathetic chain, abdominal aorta, and iliac vessels, and on groin hernias.

**Retroperitoneal Approach to the Lumbar Area.** The retroperitoneal approach to the lumbar area is frequently used for aortic surgery, nephrectomy, lumbar sympathectomy, and ureterolithomy. The patient is positioned with the operative side elevated 30 to 45 degrees with the knees and hips flexed. The incision extends from the lateral margin of the rectus sheath at the level of the umbilicus toward the twelfth rib for approximately 12 to 14 cm (Fig. 10-12). A portion of the twelfth rib is resected if necessary. The external oblique, internal oblique, and transversalis muscles are exposed, and divided in the direction of their fibers. The retroperitoneum is entered and the peritoneum and retroperitoneal fat are swept anteriorly. The lower pole of the kidney, ureter, and sympathetic chain are easily identified. The vena cava is exposed on the right, and the aorta is exposed on the left. If the peritoneum is unintentionally entered, it is closed immediately with continuous absorbable suture. At the conclusion of the procedure, the retroperitoneal fat and viscera fall back into place and the muscles of the abdominal wall are reapproximated in layers.

**A** **B**  
**FIGURE 10-12** **A.** Left lumbar approach to the retroperitoneum. **B.** The peritoneum has been bluntly dissected from the retroperitoneal structures with the preperitoneal fat and soft tissue. Origins of the celiac, superior mesenteric, left renal, and inferior mesenteric arteries are shown. (Reproduced with permission from Baker RJ, Fischer JE: *Mastery of Surgery*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

**Posterior Approach to the Adrenal Glands.** With the posterior approach, dissection is performed entirely in the retroperitoneal space. The patient is placed in the prone jackknife position. A curvilinear incision is made beginning on the tenth rib approximately 3 fingerbreadths lateral to the midline and carried inferiorly and laterally toward the iliac crest, ending

approximately 4 fingerbreadths lateral to the midline (Fig. 10-13). The subcutaneous tissues are divided to expose the posterior layer of the lumbodorsal fascia. This fascia and the fibers of the latissimus dorsi muscle, which originate from it, are divided. The erector spinae muscle is exposed and retracted medially to uncover the twelfth rib and the middle layer of the lumbodorsal fascia. The attachments of the erector spinae to the twelfth rib are divided with electrocautery; the vessels and nerves that penetrate the fascia are secured with clamps and ligated. The twelfth rib is then resected. Gerota's fascia is exposed by incising the lumbodorsal fascia along the lateral margin of the quadratus lumborum muscle. The intercostal neurovascular bundle should now become visible directly below the bed of the resected twelfth rib. The intercostal vessels are clamped, divided, and ligated, and the intercostal nerve is retracted downward. The posterior fibers of the diaphragm are identified and divided where they insert on the periosteum of the twelfth rib. The lower margin of the lung will enter the field with hyperinflation. If the pleura is inadvertently injured, the resulting pneumothorax is handled at closure by insertion of a large-bore rubber catheter into the pleural cavity that is brought out through the wound. After closure of the fascial fibers around the catheter, the lung is hyperinflated evacuating all air from the pleural space, and the catheter is briskly removed.

**FIGURE 10-13** The posterior approach to the kidney and adrenal. **A.** J-shaped incision over the tenth to twelfth ribs, extending inferiorly 6 to 10 cm below the twelfth rib. **B.** Resection of the twelfth rib facilitates exposure. **C.** The diaphragmatic attachment to the twelfth rib is taken down, with care taken not to enter the pleura. If the pleura is opened, the wound closure is performed over a pleural suction catheter, which is removed with simultaneous positive airway pressure by the anesthetist as the skin is being closed. (Reproduced with permission from Baker RJ, Fischer JE: *Mastery of Surgery*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

**Retroperitoneal Approach to the Iliac Fossa.** The retroperitoneal approach to the iliac fossa provides access to the bladder, distal ureter, and common, internal, and external iliac vessels. It is often employed for surgery on the

iliac arteries and for kidney transplantation. It may also be used to drain psoas or retrocecal abscesses and to resect retroperitoneal tumors. The skin incision is oriented obliquely and extends from approximately 2 cm above the anterosuperior iliac spine to a point just lateral to the pubic symphysis (Fig. 10-14). The incision can also be extended superiorly as far as the costal margin if necessary. The external oblique, internal oblique, and transversus abdominis muscles are divided in line with the skin incision. The retroperitoneum is entered and the retroperitoneal fat and peritoneum are swept superomedially. If the peritoneum is inadvertently entered, it is closed immediately. At the conclusion of the procedure, the retroperitoneal fat and viscera fall back into place and the muscles of the abdominal wall are reapproximated in layers.

**FIGURE 10-14** Right lower quadrant extraperitoneal approach to the iliac vessels, ureter, and bladder. **A.** The skin incision may be shorter than depicted in thinner patients or if an abscess is to be drained. **B.** Peritoneum is retracted medially by blunt dissection, which exposes the psoas muscle and gonadal artery and vein, shown anterior to the ureter. (Reproduced with permission from Baker RJ, Fischer JE: *Mastery of Surgery*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

## LAPAROSCOPIC INCISIONS

As with open abdominal incisions, laparoscopic access must allow optimal exposure without unnecessarily compromising abdominal wall function or cosmesis. Laparoscopic incisions may be placed anywhere on the abdominal wall. When appropriate, laparoscopic incisions should allow for ready extension should conversion to open operation become necessary.

Additionally, laparoscopic access may be combined with small open incisions that accommodate appliances through which a hand can be inserted into the peritoneal cavity without the loss of pneumoperitoneum. Such *hand-assisted laparoscopic* approaches are frequently associated with shorter operative times than are purely laparoscopic approaches and may have particular advantages for operations in which a larger incision is necessary to remove the surgical specimen (eg, laparoscopic colectomy) and more complex procedures.<sup>15</sup> The initial step of any laparoscopic procedure is the establishment of pneumoperitoneum. This can be achieved using an open or closed technique. Access is most often obtained at a site just above or below the umbilicus—the thinnest portion of the abdominal wall and a central location from which all quadrants of the abdominal cavity can be visualized. Other sites are preferable in specific circumstances (eg, left upper quadrant access in a patient with a previous midline incision).

## INITIAL ACCESS

The open approach involves the creation of a small incision, generally 1.5 cm, through which the abdominal fascia is grasped with straight clamps and elevated toward the wound. Exposure of the fascia is often enhanced with the use of S-shaped retractors. The fascia and then peritoneum are divided under direct vision. Abdominal entry is confirmed by digital palpation. Heavy stay sutures are then placed in each fascial edge and are lifted up while a blunt-tipped (Hasson) obturator and cannula are inserted through the opening in the abdominal wall. The stay sutures are then wrapped around the struts on the cannula to secure it in position. Insufflation tubing is then attached to the cannula and the obturator is withdrawn. Carbon dioxide (CO<sub>2</sub>) is insufflated into the abdomen to a pressure of 12 to 15 mm Hg.

The closed technique involves the passage of a sharp needle (*Veress needle*—a spring-loaded needle with an inner blunt tip) through the

abdominal wall into the abdominal cavity. A small skin incision is made in the skin through which the needle is inserted, generally at an angle of 45 degrees to the abdominal wall; an angle of 90 degrees is sometimes necessary in the obese patient. As the needle passes through the fascia and then the peritoneum, a sensation of overcoming resistance is appreciated, often reinforced by an audible *click* as the blunt tip of the needle springs forward. A 10-mL syringe containing 5 mL of saline is attached to the end of the needle and is aspirated. If enteric contents, blood, or urine is not aspirated, the saline is instilled through the needle. If the needle is appropriately placed in the peritoneal cavity, saline should pass through the needle without resistance and the meniscus should descend down the hub of the needle when the syringe is detached (the so-called *drop test*); free descent of the meniscus sometimes requires manual elevation of the abdominal wall. The presence of significant resistance in the syringe or failure of the meniscus to descend usually indicates extraperitoneal placement or apposition of the needle against the underlying omentum and usually mandates replacement. Insufflation tubing is then attached to the needle. An initial pressure reading of less than 10 mm Hg further suggests appropriate placement, whereas higher pressures generally indicate extraperitoneal placement. Once satisfactory placement of the needle has been achieved, CO<sub>2</sub> is insufflated through the needle to a pressure of 12 to 15 mm Hg. Then needle is then removed, and a cannula and sharp trocar are inserted through an appropriately sized skin incision.

A variety of instrumentation has been developed to facilitate the closed approach. This includes expandable sheaths that are introduced over the needle and can accommodate larger ports that dilate open the fascial opening (or *radially expanding trocars*), and devices that dilate the fascial opening under direct vision (or *optical access trocars*). Such instrumentation may also obviate formal fascial closure because the resulting fascial defect is small after removal of the port.

The open approach holds the theoretical advantage of minimizing the potential for injury to intra-abdominal visceral and vascular structures. Disadvantages include the generally longer associated operative time and the occasional need for larger skin incisions, particularly in obese patients. In contrast, the closed approach is generally faster and may allow better cosmesis. Contraindications to the closed approach include the suspected or known presence of extensive intra-abdominal adhesions and pregnancy.

However, in patients who have had limited prior surgery, the closed approach may be used to gain access at a site remote from the previous surgical site. The safety of open and closed approaches has been compared in several studies. A large retrospective review of closed laparoscopy in 489,335 patients and open laparoscopy in 12,444 patients suggested higher rates of visceral and vascular injury in closed laparoscopy. Rates of visceral and vascular injury were 0.083% and 0.075% after closed laparoscopy and 0.048% and 0% after open laparoscopy, respectively ( $P = .002$ ). Mortality rates after closed and open laparoscopy were not statistically different.<sup>16</sup> Notably, this small difference was not evident in several other meta-analyses.<sup>17,18</sup>

## **PLACEMENT OF ADDITIONAL PORTS**

The approach to the placement of secondary cannulas is highly surgeon and operation specific. Some basic principles, however, should always be adhered to. These include the following: (1) all cannulas should be inserted with the aid of laparoscopic visualization; (2) cannulas must be placed far apart from one another to avoid frequent crossing of instruments (generally 10 cm or more apart); and (3) cannulas should be placed at a distance from the operative site, which maximizes range of motion at the cannula site and minimizes operator discomfort (approximately 15 cm). In addition, skin incisions, while often small, should never compromise easy passage of trocars through the abdominal fascia. Undue resistance at the level of the skin can undermine the surgeon's control of the trocar as it passes through the peritoneum and lead to injury of underlying viscera or vascular structures.

## **CLOSURE OF ABDOMINAL INCISIONS**

As noted above, wound complications make a dominant contribution to surgical morbidity. Indeed, wound infection is the most common early complication and incisional hernia is the most common long-term complication of open abdominal surgery. Multiple factors contribute to the incidence of wound failure including diabetes mellitus, malnutrition, obesity, and corticosteroid use. Surgical technique, too, appears to influence rates of wound failure; however, there has been little consensus regarding the optimal approach to closure. An evolving literature focuses on the relative merits of

multiple-layered versus single-layer closure, closure with different suture materials, and interrupted versus continuous closures.

## Closure of the Fascia

The abdomen can be closed in multiple layers or en mass. The former technique reconstructs the anterior and posterior aponeurotic sheaths separately, with the posterior layer generally incorporating the peritoneum. Mass closure involves a single-layer closure of all layers and may or may not include the peritoneum. Numerous clinical trials have compared multiple layered to mass abdominal closure. Some studies have shown an increased incidence of dehiscence and incisional hernia formation with multiple layered closure,<sup>19,20</sup> while other studies show no difference in the incidences of these complications.<sup>21</sup> Given the shorter time required to close the fascial layers en mass, this method is generally preferred.

The relative advantages of resorbable versus nonresorbable sutures for use in closing the fascia have long been debated. Opponents of closure with nonresorbable suture invoke higher rates of suture sinus formation and increased postoperative pain; the incidences of these complications have been estimated at 8% and 17%, respectively. In contrast, it has been suggested that closure with resorbable suture may lead to increased incidences of dehiscence and hernia formation due to an intrinsic loss of tensile strength during the postoperative period. While these complications are certainly seen with increased frequency when absorbable catgut suture is used,<sup>21</sup> the literature has not consistently borne out an association between wound failure and the use of resorbable sutures such as polyglycolic acid (Dexon), polyglactic acid (Vicryl), polydioxanone (PDS), and polyglyconate (Maxon).<sup>22-27</sup> In particular, several studies comparing permanent (Prolene, Ethicon, or nylon) versus slowly absorbable sutures (PDS and Maxon) have failed to demonstrate any advantage to the use of nonresorbable suture. There may be some advantage to the use of slowly resorbable compared to rapidly resorbable suture; one study demonstrated a significant decrease in the rate of hernia formation when slowly resorbable sutures (PDS and Maxon) were used compared to more rapidly resorbable sutures (catgut, Dexon, and Vicryl) ( $P = .009$ ).<sup>27,28</sup> Nonresorbable sutures do appear to be associated with a higher incidence of suture sinus formation. This association may be greatest

with multifilament permanent sutures, which may abet bacterial ingrowth and infection.<sup>23,26</sup> Table 10-1 shows the rates of resorption for different suture materials.<sup>35</sup>

**TABLE 10-1: RATE OF RESORPTION OF DIFFERENT SUTURE MATERIALS**

<b>Suture Material</b>	<b>Time Until Total Resorption (Days)</b>
Rapidly resorbable	
Catgut	15
Chromic catgut	90
Polyglycolic acid (Dexon)	20
Polyglactin 910 (Vicryl)	60-90
Slowly resorbable	
Polydioxanone (PDS)	180
Polyglyconate (Maxon)	180
Nonresorbable	
Nylon (Nurulon)	—
Polypropylene (Prolene)	—
Polyethylene (Ethibond)	—
Polyamide (Ethilon)	—

Dexon (Davis & Geck, Wayne, NJ), Vicryl (Ethicon, Somerville, NJ), PDS (Ethicon), Maxon (Davis & Geck), Nurulon (Ethicon), Prolene (Ethicon), Ethibond (Ethicon), and Ethilon (Ethicon).

Reproduced with permission from van't Riet M, Steyerberg EW, Nellensteyn J: Meta-analysis of techniques for closure of midline abdominal incisions, *Br J Surg* 2002 Nov;89(11):1350-1356.

It has been suggested that a continuous, running closure will result in a more durable wound than an interrupted closure. The former may allow the more even distribution of tension across the suture line with less resultant tissue strangulation and wound disruption. The obvious disadvantage of a continuous closure is its dependence on a single suture. The majority of studies comparing interrupted and continuous closure, however, demonstrate similar incidences of wound dehiscence, incisional hernia, wound infection, wound pain, and suture sinus formation.<sup>27,29-32</sup> One recent randomized trial

compared interrupted and continuous closure with resorbable suture. No significant difference in the rates of incisional hernia, dehiscence, or wound infection were observed.<sup>33</sup> A more recent randomized study indicated that smaller (5 mm every 5 mm) compared to larger fascial bites (1 cm every 1 cm) resulted in fewer hernias.<sup>34</sup>

In summary, an evidence-based approach to laparotomy closure narrowly favors the use of nonresorbable or slowly resorbable sutures in order to minimize the risk of hernia formation. The latter is preferred because of the lower associated risk of suture sinus formation and decreased postoperative pain. A running closure is associated with either an equivalent or lower risk of hernia formation and, given the ease and speed with which it can be performed, is to be preferred. Importantly, undue tension should not be placed on the running closure to avoid strangulation of the fascia.

## **Technique of Mass Closure of the Abdomen**

When closing a midline laparotomy incision, 2 size #0 looped or size #1 nonlooped slowly resorbable monofilament sutures are generally used. One suture is anchored at the upper extent and one at the lower extent of the wound. A malleable retractor can be used to protect the underlying viscera while the fascia is closed. The suture is passed in a continuous or interrupted manner, taking full-thickness bites of the linea alba fascia incorporating both the anterior and posterior rectus aponeuroses (Fig. 10-15). An assistant holds steady tensions on the suture while the closure progresses. Repetitive relaxation and application of tension of the suture are avoided to limit injury to the fascia. Likewise, it is unnecessary and probably counterproductive to overly tighten the suture as closure progresses, as this may lead to fascial necrosis. This point has been illustrated in a study associating evisceration and hernia formation with a lower suture length-to-wound length ratio.<sup>36</sup> The 2 sutures are run toward one another and then tied together in the center of the wound.

**FIGURE 10-15** Mass closure of the midline abdominal incision.

## Skin Closure

A number of skin closure techniques can be used following clean (class I) or clean-contaminated (class II) operations; these include interrupted suture, subcuticular suture, stapled, and adhesive glue. Three randomized controlled studies have compared stapled to subcuticular suture closures. Both techniques are associated with equivalent rates of wound infection.<sup>37-39</sup> Two of the studies suggested that subcuticular suture closure is associated with less postoperative pain than is stapled closure.<sup>37,39</sup> Two studies also demonstrated a superior cosmetic result early following suture closure; however, this difference was insignificant by 6 months after operation.<sup>38,39</sup>

Glues are used with increasing frequency for skin closure. Advantages of glues include ease and rapidity of application and simplification of wound care; generally, no additional dressing is required. Closure with glues has been compared to traditional skin closure methods in several clinical trials.

Wound durability appears to be comparable,<sup>40,41</sup> although there are conflicting data on cosmesis and postoperative pain.<sup>41,42</sup> If the surgical site is contaminated (class III or class IV wound), the skin should be left open to heal by secondary intention or by delayed primary skin closure.<sup>43</sup>

## Retention Sutures

The incidence of fascial dehiscence after major abdominal operations is 1% to 3% and is associated with a mortality rate of 15% to 20%.<sup>44</sup> Several patient-related factors are associated with an increased risk of fascial dehiscence. These include advanced age, male sex, malnutrition, anemia, and steroid use; however, local mechanical factors and closure technique appear to have a greater influence on rate of dehiscence.<sup>44</sup> Placement of drains or ostomies through the main incision compromises fascial integrity and should be avoided. Wound sepsis and increased intra-abdominal pressure, whether from ileus, bowel obstruction, atelectasis, or after hernia repair, also compromise the integrity of a fascial closure. Indications for prophylactic placement of retention sutures at initial operation remain controversial. The purpose of retention sutures in this setting is to relieve tension along the suture line in order to prevent significant wound disruption and evisceration in the patient at high risk.

There has been only 1 randomized trial comparing closure with and without retention suture placement; Hubbard and associates could not identify a benefit of retention suture closure over standard mass closure of the abdominal wall.<sup>45</sup> The potential disadvantages of retention sutures, however, are well known and include entrapment of underlying viscera, increased postoperative pain, poor cosmesis, and leakage of intraperitoneal fluid through the wound.<sup>46</sup> Some surgeons advocate primary closure with retention sutures in selected circumstances. In a retrospective study of midline abdominal wound dehiscence, Makela and colleagues<sup>47</sup> identified preoperative variables that are significantly associated with fascial disruption; these include hypoalbuminemia, anemia, malnutrition, chronic pulmonary disease, and emergent operation. For patients with 3 or more of these preoperative risk factors, this group recommended internal retention suture closure.<sup>47</sup>

When employed, retention sutures are placed across the wound prior to

formal fascial closure. Interrupted permanent monofilament sutures are passed through skin and fascia approximately 2 cm from the wound margin at intervals of several centimeters. Placement is facilitated by the use of a long cutting needle. It may be advantageous to omit the peritoneum from the retention closure in order to protect underlying viscera from injury or entrapment. After conventional closure of the fascia, the sutures are threaded through rubber tubing bolsters or commercially available plastic bolster devices and tied at the skin level.

## **Mesh and Biologic Implant Placement**

Placement of a mesh underlay represents an alternative approach to the prophylactic placement of retention sutures for the *at-risk* abdominal closure.<sup>48,49</sup> In addition, the occasional operation that requires resection of a significant portion of the abdominal wall as well as transection of bowel sometimes necessitates the placement of a prosthesis in a potentially contaminated field. Interposition placement of resorbable mesh accepts a hernia that will require complex abdominal wall reconstruction to repair. Moreover, high rates of fistula formation and mesh infection have been described with resorbable as well as nonresorbable mesh in this setting.<sup>49</sup> Biologic implants such as human and porcine acellular dermal allografts are an attractive alternative to meshes when faced with a difficult-to-close abdominal wall, particularly in the setting of contamination. As with resorbable meshes, underlay rather than interposition placement likely yields a much more durable result. While the use of these products in acute clinical settings has been described,<sup>50</sup> there are few definitive data to guide selective application of such techniques. More complex abdominal reconstructions using component separation techniques, releasing incisions, or rectus mobilization in conjunction with mesh or biologic implants may be undertaken in appropriately selected patients when primary closure is not possible. More often, such approaches are used in a delayed fashion after development of an abdominal wall hernia.<sup>51</sup>

## **Closure of Laparoscopic Incisions**

The closure of laparoscopic incisions poses particular challenges.

Reapproximation of the fascia is made more challenging in the presence of small skin incisions, which limit visualization. While small fascial defects may be left open, any fascial defect 10 mm or greater in the midline or below the arcuate line should generally be closed to reduce the risk of port-site hernia formation.<sup>52</sup> The use of radially expanding trocars obviates the need for formal closure in many cases, although larger midline defects still generally require suture reapproximation.<sup>53-55</sup>

While sometimes challenging, particularly in obese patients, secure reapproximation of the fascia, usually with several interrupted sutures, can usually be achieved under direct visualization. Alternatively, a variety of instrumentation may be used to facilitate closure, usually in combination with laparoscopic visualization and maintenance of pneumoperitoneum. The Endoclose device (Tyco Healthcare, Mansfield, MA) has a sharp tip that also functions as a grasper. The tip of a suture is grasped with the device and driven through the fascia adjacent to the cannula (and fascial defect) under laparoscopic visualization. The end of the suture is left free inside the abdomen. The grasper is then placed through the fascia a second time on the opposite side of the defect, and the free end of the suture is grasped inside the abdominal cavity and pulled out through the fascia. The suture is then tied to close the defect. The Carter-Thomason System (Inlet Medical, Eden Prairie, MN) additionally includes a needle director that is inserted through the fascia instead of the cannula, which ensures that adequate fascia is obtained by directing the needle at an appropriate angle and may expedite closure.<sup>56</sup>

## **Temporary Closure of the Abdomen**

Despite the frequent misconception that temporary abdominal closure techniques are a recent innovation, such approaches have long been used. Indeed, Pringle reported his experience with temporary packing of hepatic injuries in 1908.<sup>57</sup> In 1913, Halsted recommended interposition of a nonadherent layer between the injured liver and packs.<sup>58</sup> Such an approach did fall out of favor in the period following the Second World War due to the very high observed incidences of late hemorrhage and sepsis. However, beginning in 1973 with a report by Lucas and Ledgerwood, a number of investigators suggested the feasibility and utility of temporary abdominal closure, particularly in the setting of massive traumatic injury.<sup>59-61</sup> In 1993,

Rotondo and Schwab introduced the term *damage control* and outlined a 3-phase approach to the management of major abdominal injuries. The first phase consists of rapid control of hemorrhage and contamination followed by temporary abdominal closure; the second focuses on the restoration of normal body temperature, correction of coagulopathy, and optimization of ventilation; and the third involves removal of abdominal packs, definitive operation, and abdominal closure. In their initial series, Rotondo and Schwab<sup>62</sup> demonstrated a marked survival advantage in patients with major vascular injury and 2 or more visceral injuries treated using the damage control approach (10 of 13 patients, 77%) compared to those definitively closed at the time of initial operation (1 of 9 patients, 11%;  $P < .02$ ). The applications of this approach have broadened with greater experience. Patients who may benefit from this damage control approach include those at risk of developing abdominal hypertension (eg, hypothermia, coagulopathy, acidosis, large transfusion requirement) and those who require a *second-look laparotomy* (eg, intestinal ischemia).

This approach has necessitated the evolution of temporary closure techniques. These range from the very simple and inexpensive (eg, towel clip closure, running nylon suture close) to more sophisticated commercially available vacuum-assisted closure (VAC) systems. No single approach is clearly superior, and multiple techniques may have advantages in specific clinical settings. The Bogotá bag uses a large intravenous bag secured to the skin or fascia. Impermeable plastic drapes may be used alternatively in a similar fashion. This approach is fast and inexpensive, minimizes fluid losses, and is easily removed. It may be less durable than other closures; tearing of sutures through the periphery of the bag can result in evisceration. Absorbable meshes such as polyglactin 910 (Vicryl; Ethicon, Somerville, NJ) and polyglycolic acid (Dexon; Davis & Geck, Danbury, CT) can be sutured to the skin or fascia. This approach allows for a degree of flexibility as definitive closure can subsequently be undertaken without removal of the mesh. Alternatively, the mesh can serve as a bed for the elaboration of granulation tissue. If reapproximation of the fascia is not feasible or needs to be substantially delayed, a skin graft can be placed over the granulation bed. A variation on mesh closure uses the *Wittman patch*—a device made of 2 adherent sheets of biocompatible polymeric material. The edges of the patch are sewn to the surrounding abdominal fascia. As edema resolves, the fascial edges are gradually reapproximated by drawing the 2 sheets closer together

and cutting away excess material.

An increasingly popular alternative to these temporary closures has been termed the *open abdomen technique*.<sup>63</sup> Generally, a nonadherent barrier (eg, a towel covered with an adhesive plastic drape) is placed on top of the intra-abdominal contents, below the fascia. Jackson-Pratt drains are placed above this barrier to control drainage and maintain the integrity of an adhesive dressing placed over the entire wound and skin (Fig. 10-16). This dressing is readily applied, inexpensive, and facilitates multiple reexplorations. Loss of abdominal domain can be limited with the additional placement of *lacing* across the wound, which generally involves vessel loops laced through skin staples placed along the edges of the wound that can be progressively tightened as intra-abdominal hypertension resolves. Maintenance of the open abdomen may be facilitated with the use of the commercially available abdominal VAC. The abdominal VAC is composed of a barrier enveloped in nonadherent plastic that is placed over the intra-abdominal contents below the fascial edges. A polyurethane sponge is cut to the size of the wound and placed over the barrier. The sponge is then covered with an adherent dressing. A small defect is created in the dressing, and suction tubing with an adherent appliance is applied over this defect and attached to a vacuum device. Drainage is drawn out through the sponge through the vacuum tubing and into a vacuum canister. This system is particularly useful when multiple reexplorations are anticipated. In addition, loss of abdominal domain is minimized by the negative pressure exerted on the dressing. While the use of the abdominal VAC may facilitate a more delayed definitive closure, the risk of injury to underlying viscera and fistula formation does increase with additional dressing changes.<sup>64</sup> Therefore, in the patient who cannot undergo definitive closure after approximately 1 week, transition to a Vicryl mesh closure may be advantageous.

the barrier. (Used with permission from Benjamin Braslow, MD.)

## MANAGEMENT OF THE POSTOPERATIVE WOUND

### Dressing the Wound

At the conclusion of a procedure, a sterile dressing is typically applied to the wound before removal of the sterile drapes. Theoretically, this dressing prevents bacterial colonization of the wound during the initial 24 to 48 hours of healing, allowing for epithelialization and the formation of coagulum. Before application of the dressing, excess antiseptic solution should be washed off with sterile saline. In general, the dressing should be secured without the use of excessive tape, which may be irritating to the skin. In most cases, the dressing can be removed within 48 hours of application. This practice is supported by studies from the 1960s documenting that exposure of clean, closed wounds to the atmosphere on postoperative day 2 is not associated with an increased incidence of infection.<sup>65</sup> In many cases, after closure of a clean wound, no dressing is necessary. Indeed, in a randomized study of patients undergoing either inguinal hernia repair or high saphenous ligation, there was no significant difference in the rate of wound infection whether wounds were immediately exposed, covered with a dry gauze dressing, or covered with an occlusive film dressing.<sup>66</sup>

A variety of dressing types are used in the management of surgical wounds and may have advantages in some specific clinical settings. A simple dry dressing comprised of gauze secured with sparing use of tape is generally sufficient. Wet-to-dry dressings are commonly used to dress open and contaminated wounds; mechanical debridement of the wound results from removal of dried packing material with adherent devitalized tissue. Enzymatic agents (eg, papain/urea [Accuzyme]) may be used in conjunction with wet-to-dry dressings to gently debride fibrinous exudate. In addition, application of broad-spectrum antibacterials (eg, silver sulfadiazine) may limit bacterial colonization and promote wound healing.

Recently, VAC dressings have gained great popularity for the management of open wounds. The VAC dressing has 3 components: (1) the

VAC sponge, which is applied directly to the wound bed; (2) an occlusive dressing, which is applied over the sponge to seal it to the surrounding skin; and (3) a suction pump, which provides regulated negative pressure through the sponge. The VAC dressing has been used extensively in a variety of clinical setting and appears to promote granulation tissue formation and wound contraction. A major advantage of the VAC is the need for fewer dressing changes compared with conventional wet-to-dry dressings. As discussed earlier, the VAC has become a prominent part of the armamentarium for treating abdominal wounds that cannot be definitively closed at the time of initial operation.

## Surgical Site Infections

Surgical site infections (SSIs) are the most common nosocomial infections in surgical patients. It has been estimated that each SSI results in 7.3 additional inpatient days and adds over \$3000 to the hospital charges.<sup>43</sup> The bacterial colony count at the surgical site makes a dominant contribution to the risk of wound infection; colony counts per gram of tissue of  $10^5$  or greater are associated with a markedly increased risk. In the presence of a foreign body, however, a much lower count may lead to infection. Other risk factors for the development of wound infections include advanced age, obesity, diabetes mellitus, smoking, malnutrition, altered immune response, preoperative hospitalization, presence of infection at a remote body site, length of operation, and use of surgical drains.<sup>43</sup>

SSIs are subdivided into 2 categories: incisional and organ/space (Table 10-2). Incisional SSIs are limited to the surgical site. They are further divided into superficial SSIs, which involve the skin and subcutaneous tissue, and deep SSIs, which involve the fascial and muscle layers. Organ/space SSIs can involve any part of the anatomy that was manipulated during the surgery except the incision.

**TABLE 10-2: CRITERIA FOR DEFINING SURGICAL SITE INFECTIONS (SSIs)**

**Incisional SSI**

<b>Superficial Incisional</b>	<b>Deep Incisional</b>	<b>Organ/Space SSI</b>
Infection occurring within 30 days of surgery, <b>and</b> Infection involves only skin and subcutaneous tissue; <b>and</b> At least 1 of the following: 1. Purulent discharge 2. Organisms isolated from aseptically cultured fluid or tissue 3. At least 1 sign of infection: pain or tenderness, localized swelling, redness, or heat <b>and</b> the incision is deliberately opened by surgeon unless the incision is culture negative 4. Diagnosis of SSI by the surgeon or attending physician	Infection occurring within 30 days of surgery; or within 1 year of operation if implants are in place; <b>and</b> Infection involves deep soft tissue; <b>and</b> At least 1 of the following: 1. Purulent discharge 2. Deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least 1 of the following symptoms: fever (>38°C), localized pain, or tenderness unless the site is culture negative 3. Evidence of deep infection on direct examination, during reoperation, or on radiologic examinations 4. Diagnosis of SSI by the surgeon or attending physician	Infection occurs within 30 days of surgery, or within 1 year of operation if implants are in place; <b>and</b> Infection involves any part of anatomy that was manipulated during an operation, other than the incision; <b>and</b> At least 1 of the following: 1. Purulent drainage that is placed through a stab wound into the organ space 2. Organism isolated from an aseptically cultured fluid or tissue 3. Evidence of deep infection on the direct examination, during reoperation, or on radiologic examinations 4. Diagnosis of SSI by the surgeon or attending physician

Wounds can be classified by degree of contamination (Table 10-3). The risk of a postoperative SSI reflects, in part, the wound classification; however, infection rates vary widely within each classification group.<sup>67,68</sup> Other risk-scoring systems have, therefore, been developed to better anticipate the risk of wound infections. Examples of such scoring systems are the SENIC (Study of the Efficacy of Nosocomial Infection Control) and NNIS (National Nosocomial Infection Surveillance) risk indexes. The SENIC system predicts risk associated with abdominal surgery, operations lasting longer than 2 hours, contaminated or dirty wound classifications, and operation on patients with 3 or more discharge diagnoses.<sup>67</sup> The NNIS system predicts risk associated with American Society of Anesthesiologists preoperative assessment scores of greater than 2, wound classifications of contaminated or dirty, and increased duration of the operation.<sup>68</sup>

**TABLE 10-3: CLASSIFICATION OF SURGICAL WOUNDS**

Type of Wound	Definition	Risk of SSI
Class I: Clean	An uninfected operative wound in which no inflammation is encountered and respiratory, alimentary, genital, or uninfected urinary tract is not entered. They are primarily closed and, if necessary, drained with close drainage.	1%-5%
Class II: Clean-contaminated	An operative wound in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination. In particular, surgeries involving the biliary tract, appendix, vagina, and oropharynx are included in this category provided no evidence of infection or a major break in technique is encountered.	2%-9%
Class III: Contaminated	Open fresh accidental wounds. In addition, surgery with major breaks in sterile technique (eg, open cardiac massage) or gross spillage from the gastrointestinal tract and incisions in which acute, nonpurulent inflammation is encountered are included in this category.	3%-13%
Class IV: Dirty-infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera.	3%-13%

The organisms most commonly responsible for SSIs are *Staphylococcus aureus* and coagulase-negative staphylococci. After abdominal surgery, infection with enteric organisms (*Escherichia coli* and *Enterobacter* species) is also prevalent. The Centers for Disease Control and Prevention recommendations for the prevention of SSIs are summarized in [Table 10-4](#).<sup>43</sup> The use of preoperative prophylactic antibiotics in all clean-contaminated and clean cases with associated risk factors is recommended. The antibiotic of choice for most upper gastrointestinal procedures is cefazolin or a comparable first-generation cephalosporin. For colorectal surgery, metronidazole is added to this regimen. The administration of a mechanical and oral antibiotic bowel preparation has been recommended prior to colorectal surgery, although this practice has been challenged by recent meta-analyses suggesting no benefit.<sup>69,70</sup> Preoperative intravenous antibiotics should be administered 30 to 60 minutes before the incision is made to allow the agent to reach maximal tissue concentration. In obese patients, the antibiotic should be adjusted appropriately. For long procedures, the antibiotic should be readministered after every 2 half-lives to maintain an effective serum concentration.

**TABLE 10-4: CENTERS FOR DISEASE CONTROL AND PREVENTION (CDC) RECOMMENDATIONS TO PREVENT SURGICAL SITE INFECTIONS (SSIs)**

## Preoperative Factors

Preparation of the patient:

1. Identify and treat all infections remote from the surgical site and postpone elective surgery until infection has resolved.
2. Do not remove hair unless it interferes with surgery.
3. If hair is to be removed, remove immediately preoperatively using clippers.
4. Ensure good blood glucose control in diabetic patients and avoid hyperglycemia.
5. Encourage cessation of tobacco use (at least for 30 days before surgery, if possible).
6. Do not withhold blood products, as transfusion does not affect rates of SSI.
7. Require the patient to shower or bathe with an antiseptic solution the night before surgery.
8. Remove gross contamination from the surgical site before performing antiseptic skin preparation.
9. Use an appropriate antiseptic solution for skin preparation.
10. Apply preoperative antiseptic solution for skin preparation in concentric circles moving outward toward the periphery.
11. Keep the preoperative hospital stay as short as possible.

Hand/forearm antiseptics for surgical team:

1. Keep nails short and do not wear artificial nails.
2. Perform a preoperative scrub for at least 2-5 minutes up to the elbows.
3. After performing the surgical scrub, keep the hands up and away from the body (elbows flexed) so that the water runs from the tips of fingers toward the elbows. Dry hands with a sterile towel and don a sterile gown and gloves.
4. Clean underneath each fingernail.
5. Do not wear hand or arm jewelry.

Management of infected or colonized surgical personnel:

1. Educate and encourage surgical personnel who have signs and symptoms of a transmissible infectious illness to report promptly to their supervisor and occupational health personnel.
2. Develop well-defined policies concerning patient care responsibilities when personnel have potentially transmissible infectious conditions. These policies should govern (1) responsibility of personnel in using health services and reporting illness, (2) work restrictions, and (3) clearance to resume work after an illness that required work restriction. The policies should also identify staff members who have the authority to remove personnel from duty.
3. Obtain appropriate cultures and exclude from duty surgical personnel who have draining skin lesions until infections have been ruled out or until these personnel have received adequate therapy and infection has been resolved.
4. Do not routinely exclude surgical personnel who are colonized with organisms such as *Staphylococcus aureus* or group A streptococci, unless they have been linked epidemiologically to dissemination of the organism.

Antibiotic prophylaxis:

1. Administer a prophylactic antimicrobial agent only when indicated, and select it based on its efficacy against the most common pathogens causing SSIs for a specific operation, and in accordance with published recommendations.
2. Administer by the intravenous (IV) route the initial dose of prophylactic antimicrobial agent, timed such that bactericidal concentration of the drug is established in serum and tissue when the incision is made. Maintain therapeutic levels of the agent in serum and tissues throughout the operation and for a few hours after the incision has been closed.
3. Before elective colorectal operations, in addition to the above measures, mechanically prepare the bowel by using enemas and cathartic agents. Give nonabsorbable oral antimicrobial agents in divided doses on the day before the operation.
4. For high-risk cesarean sections, administer the prophylactic antimicrobial agent immediately after the umbilical cord is clamped.
5. Do not routinely use vancomycin for prophylaxis.

## Intraoperative

Ventilation:

1. Maintain positive-pressure ventilation in the operating room with respect to the corridors and adjacent area.
2. Maintain a minimum of 15 air changes per hour, of which at least 3 should be fresh air.
3. Filter all air, recirculated and fresh, through the appropriate filters per the American Institute of Architects' recommendations.
4. Introduce all air at the ceiling and exhaust air near the floor.
5. Do not use ultraviolet radiation in the operating room.
6. Keep operating suite doors closed except as needed for passage of equipment, personnel, or patients.
7. Consider performing orthopedic implant operations in an operating suite supplied with ultraclean air.
8. Limit the number of personnel entering the operating room.

Cleaning and disinfection of environmental surfaces:

1. When visible soiling or contamination of surfaces or equipment with blood or other body fluids occurs during an operation, use an Environmental Protection Agency (EPA)-approved hospital disinfectant to clean the affected areas before the next operation.
2. Do not perform special cleaning (in addition to cleaning with routine EPA-approved hospital disinfectant) or closing of operating rooms after contaminated or dirty operations.
3. Do not use tacky mats at the entrance to the operating room suite or individual operating rooms for infection control.
4. Wet vacuum the operating floor with an EPA-approved disinfectant after the last operation of the day or night.

Microbiological sampling:

1. Do not perform routine environmental sampling of the operating room.

Sterilization of surgical instruments:

1. Sterilize all surgical instruments according to published guidelines.
2. Perform flash sterilization only for patient care items that will be used immediately. Do not flash sterilize for reasons of convenience or to save time.

Surgical attire and drapes:

1. Wear a surgical mask that fully covers the mouth and nose when entering the operating room if an operation is about to begin or is under way, or if sterilized instruments are exposed. Wear the mask throughout the operation.
2. Wear a cap or hood to fully cover hair on the head and face.
3. Do not wear shoe covers for prevention of SSIs.
4. Wear sterile gloves if scrubbed as a surgical team member. Put on gloves after donning the sterile gown.
5. Use surgical gowns and drapes that are effective barriers when wet.
6. Change scrub suits that are visibly soiled, contaminated, and/or penetrated by blood or other potentially infectious material.

Asepsis and surgical technique:

1. Adhere to principles of asepsis when placing intravascular devices, placing spinal or epidural anesthesia catheters, or dispensing or administering IV drugs.
2. Assemble sterile equipment and solutions immediately prior to use.
3. Handle tissue gently, maintain effective hemostasis, minimize devitalized tissue and foreign bodies, and eradicate dead space at the surgical site.
4. Use delayed primary skin closure or leave an incision open if the surgeon considers the surgical site to be heavily contaminated.
5. If drain is necessary, use closed suction drain, and place it through a separate incision distant from the operating incision. Remove the drain as soon as possible.

**Postoperative Incision Care**

1. Protect an incision that has been closed primarily with a sterile dressing for 24-48 hours postoperatively.
2. Wash hands before and after dressing changes and before and after any contact with surgical site.
3. When an incision dressing must be changed, use sterile technique.
4. Educate the patient and family regarding proper incision care, symptoms of SSI, and the need to report such symptoms.

**Surveillance**

1. Use CDC definitions of SSI without modification for identifying SSIs among surgical inpatients and outpatients.
2. For inpatient cases, use direct prospective observation, indirect prospective detection, or a combination of both for the duration of the patient's hospitalization.
3. When postdischarge surveillance is performed for detecting SSIs following certain operations, use a method that accommodates available resources and data needs.
4. For outpatient cases, use a method that accommodates available resources and data needs.
5. Assign a surgical wound classification upon completion of an operation. A surgical team member should make the assignment.
6. For a patient undergoing an operation chosen for surveillance, record those variables shown to be associated with increased risk of SSI.
7. Periodically calculate operation-specific SSI rates stratified by variables shown to be associated with increased risk of SSI.
8. Report appropriately stratified operation-specific SSI rates to surgical team members. The optimum frequency and format of such rate computations will be determined by stratified case load sizes and the objectives of local, continuous quality improvement initiatives.

The treatment for incisional SSIs includes removal of skin stitches or staples to allow drainage of any underlying collection. Antibiotics are indicated in the presence of cellulitis. The effective use of antibiotics depends on (1) appropriate coverage of the offending organisms and (2) maintenance of an adequate tissue concentration of the drug. Cefazolin or an equivalent first- or second-generation cephalosporin is appropriate for uncomplicated incisional SSI. Wound cultures are obtained in the presence of purulence and are used to guide antibiotic selection. Following abscess drainage, wounds are left open and allowed to close by secondary intention.

Deep space SSIs also require drainage. Increasingly, this is achieved by percutaneous placement of a drain under computed tomography or ultrasound guidance. Deep space infections that are not amenable to percutaneous drainage require operative drainage. Broad-spectrum antibiotics are indicated until culture data are obtained, at which point the spectrum should be narrowed to target the offending organism.

## NECROTIZING WOUND INFECTIONS

Necrotizing soft tissue infections are a heterogeneous group of clinical entities<sup>71</sup>; however, several fundamental concepts govern the treatment of all. Paramount is early identification followed by operative debridement and initiation of antibiotic therapy. Patients often present early in the postoperative period (ie, within 48 hours) with incisional pain followed by the rapid onset of signs and symptoms of sepsis. While the incision may initially appear benign, more often, serous drainage is noted. Patients may also present with bullae or blebs, crepitus, cutaneous anesthesia, and cellulitis that is refractory to antibiotic therapy.<sup>72</sup> Tenderness that extends beyond the borders of the apparent cellulitis suggests progression of the infection to the deeper cutaneous layers and should raise suspicion for an early necrotizing process. Importantly, fewer than 40% of patients exhibit the classic symptoms and signs described, and a high degree of suspicion should be maintained in the postoperative patient with early signs of sepsis.<sup>73,74</sup>

In the absence of characteristic clinical features, diagnosis can be challenging. An elevated white blood cell (WBC) count ( $\geq 15,400/\mu\text{L}$ ) and hyponatremia (serum sodium level  $< 135$  mmol/L) are sensitive markers for the presence of a necrotizing soft tissue infection; however, they are fairly nonspecific.<sup>75</sup> Imaging studies, including plain x-ray and computed tomography, may reveal the presence of soft tissue gas, although this finding is present in a minority of cases.<sup>72,76</sup> The reported sensitivity of magnetic resonance imaging for diagnosis of necrotizing soft tissue infection ranges from 89% to 100%, and its specificity ranges from 46% to 86%.<sup>77,78</sup> However, the frequent presence of subcutaneous air in an early postoperative wound precludes reliable imaging in most cases, and more importantly, imaging may delay appropriate treatment.

In suspected cases, immediate surgical exploration and debridement are recommended and constitutes the most important single therapy. *Clostridium perfringens* and group A  $\beta$ -hemolytic streptococci are the most frequently implicated organisms, but necrotizing infections are often polymicrobial. A sample of debrided tissue should be sent for Gram stain and culture, and initial therapy should have a broad spectrum of coverage (eg, penicillin, clindamycin, and an aminoglycoside). Following initial debridement, the wound should be reexamined frequently. Any evidence of extension of the necrotizing process should prompt further debridement. Although the initial

management of all necrotizing infections is essentially the same, there are several specific clinical entities that deserve special mention, as they may require unique therapies.

**Gas Gangrene.** Gas gangrene infection after abdominal surgery results from contamination with clostridia, typically from the alimentary tract or biliary system. Patients usually present with severe wound pain often associated with fever and tachycardia. Such wounds often appear edematous and erythematous; they later become dusky and necrotic. Wound crepitus and foul-smelling watery discharge, so-called “dishwater drainage,” are characteristic. Early surgical intervention with debridement of all infected and nonviable tissue is recommended in suspected cases. Although there have been no controlled clinical trials, there is some evidence that hyperbaric oxygen is of considerable value in treating clostridial infection and reduces the mortality rate by some reports from 66% to 23%.<sup>79</sup> The potential benefits of hyperbaric oxygen include improved leukocyte function and increased tissue oxygen levels, which is bactericidal for *Clostridium perfringens* and bacteriostatic for other anaerobic bacteria.<sup>80</sup>

**Necrotizing Fasciitis.** This syndrome has been divided into 2 subcategories depending on the implicated organisms. Type I necrotizing fasciitis is a polymicrobial process; type II necrotizing fasciitis is caused by group A streptococci.<sup>71,81</sup> Polymicrobial necrotizing infections are generally slowly progressive and affect the total thickness of the skin, but do not involve the deep fascia. Purulence may or may not be present. Most often, such infections are heralded by a nonspecific cellulitis around the wound that slowly extends over days. Later, the central area of the cellulitis becomes purple and then develops typical features of gangrene. These infections are referred to as Fournier gangrene when they affect the perineum. The causative organisms are usually a mixture of anaerobes, gram-negative rods, and *Enterococcus* species. Broad-spectrum antibiotics should be initiated early and then tailored pending the result of microbial cultures.

Necrotizing infections caused by group A streptococci are more rapidly progressive and can involve the subcutaneous fat, the superficial fascia, and the deep fascia. Early in the process, the overlying skin is often intact, but later, it may become compromised following interruption of the deep blood supply. The condition is clinically distinguished from gas gangrene by the

absence of crepitus and muscle involvement. Early operative exploration is recommended in suspected cases. Group A *Streptococcus* is highly sensitive to penicillin; however, the addition of clindamycin appears to have clinical benefit.<sup>81</sup> Treatment must include early surgical exploration with debridement of involved tissues.

## Seroma and Hematoma

Superficial seroma formation is exceedingly common but rarely has significant clinical consequence. Most seromas can be observed; the rare large seroma that causes troubling symptoms (eg, discomfort) or is cosmetically unacceptable to the patient can usually be managed with a single aspiration or serial aspirations in the office. Refractory large seromas can be treated with percutaneous placement of a drain, which is maintained until the output is low (usually <30 mL/d), or, rarely, excision (ie, capsulectomy).

The more liberal use of aspirin, clopidogrel (Plavix), and heparins in the perioperative period have likely resulted in an increase in the incidence of wound hematoma following abdominal surgery, now in the range of 4% to 8%.<sup>82,83</sup> Small wound hematomas are of little consequence and usually resolve without intervention. If larger, hematomas may lead to compromise of the overlying skin or predispose to infection. Such hematomas can be aspirated with a large-bore needle or evacuated by opening the wound. If the overlying skin is under tension or ongoing extravasation of blood is noted, hematomas are often better managed in the operating room where active bleeding, if encountered, can be controlled. Reclosure over a drain may limit subsequent seroma accumulation and preserve the integrity of the skin.

## Stitch Abscess

Stitch abscesses or suture sinuses are most often seen at approximately the tenth postoperative day, but may occur earlier or weeks after operation. Stitch abscesses may be superficial or deep. When superficial, they typically present as brown or mauve-colored circumscribed blisters in the line of the incision. The associated pain can be resolved by incising the overlying skin, evacuating the contents, and, if possible, excising residual suture material. Antibiotic treatment is rarely necessary. Deeper stitch abscesses typically

present with an indurated mass. As noted earlier, the use of nonabsorbable suture, such as polypropylene, has been associated with an increased incidence of deep stitch abscesses when compared to closure with a slowly absorbing suture such as polydioxanone.<sup>35,84</sup> When permanent suture has been used, treatment requires removal of the residual suture material.

## Wound Dehiscence and Evisceration

Separation of abdominal wounds (ie, dehiscence) with or without protrusion of intra-abdominal contents (ie, evisceration) is a cause of considerable morbidity and mortality. Historically, wound dehiscence rates of up to 10% were reported; contemporary series estimate an incidence between 1% and 3%.<sup>85,86</sup> Mortality associated with dehiscence has been estimated at 16%.<sup>84</sup> The mean time to wound dehiscence is 8 to 10 days after operation.<sup>35,87</sup> Classically, dehiscence is heralded by a sudden rush of pink serosanguinous discharge from the wound. Sometimes, acute presentation with a large subcutaneous hematoma or tympanitic swelling that distends the wound reflecting herniation of bowel through the abdominal fascia is also noted.

As noted earlier, the literature on abdominal closure appears to favor a running mass closure with slowly resorbable or nonresorbable sutures. Notwithstanding such technical considerations, a variety of patient-associated risk factors for dehiscence are recognized and include advanced age (>65 years), hypoalbuminemia, wound infection, ascites, obesity, steroid use, chronic obstructive pulmonary disease, pneumonia, cerebrovascular accident with residual deficit, anemia (ie, hematocrit <30), prolonged ileus, coughing, emergency operation, and operative time greater than 2.5 hours.<sup>47,86,88</sup> Although some surgeons advocate prophylactic placement of retention sutures in those at high risk for dehiscence, as discussed earlier, there are few data to support this practice.

The cornerstone of treatment of a disrupted wound is immediate reclosure; this is particularly true when dehiscence occurs early in the postoperative period. If evisceration is present, the wound and protruding viscera should be bathed with warm normal saline solution and covered with large sterile dressing prior to prompt transport to the operating room. In the operating room, the prolapsed bowel is restored to the abdominal cavity. Residual suture material is extracted, and necrotic wound edges are debrided.

Reclosure of the fascia is then performed, typically using a monofilament nonabsorbable suture such as polypropylene. Although some surgeons advocate interrupted closure of the fascia following dehiscence, 2 retrospective analyses have failed to demonstrate a reduction in the incidence of late ventral hernia formation with this technique compared to a running closure.<sup>35,87</sup> The advantage of retention suture placement in this setting is similarly unproven. Retrospective analyses fail to demonstrate any benefit, although a reduction in recurrent evisceration is frequently invoked. Retention sutures are associated with increased discomfort for the patient.<sup>46</sup> Placement of resorbable mesh as an underlay may serve to reinforce the abdominal closure.

On occasion, if the dehiscence is small, the patient is critically ill, or there is no evisceration, nonoperative management is appropriate. In such cases, the wound is packed with a moist sterile dressing. An abdominal binder can be used for further support. The dressing should be changed at regular intervals until the wound fills in with granulation tissue. In some cases, delayed reclosure of the skin can be carried out at this stage. Alternatively, the use of a VAC dressing has been described in this setting.<sup>89</sup>

## Incisional Hernia

Incisional hernia formation is the most common long-term complication of abdominal surgery. Documented rates of incisional hernia formation vary widely in the literature. After midline laparotomy, more than 10% of patients develop a hernia.<sup>90</sup> Major risk factors include obesity, diabetes, emergency surgery, postoperative wound dehiscence, smoking, and postoperative wound infection.<sup>90-92</sup> Repair is discussed extensively elsewhere in this text.

# INGUINAL HERNIA

*Natalie Liu • Jacob A. Greenberg • David C. Brooks*

A hernia is defined as an area of weakness or complete disruption of the fibromuscular tissues of the body wall. Structures within the cavity contained by the body wall can pass through, or herniate through, such a defect. While the definition is straightforward, the terminology is often misrepresented or misused. It should be clear that *hernia* refers to the actual anatomic weakness or defect, and *hernia contents* describes those structures that pass through the defect.

Inguinal hernias are among the oldest known afflictions of humankind, and surgical repair of the inguinal hernia is the most common general surgery procedure performed today.<sup>1</sup> Despite the high incidence, the technical aspects of inguinal hernia repair continue to evolve with new surgical advancements.

## INGUINAL HERNIA

### History

The word “hernia” is derived from a Latin term meaning “a rupture.” The earliest reports of abdominal wall hernias date back to 1500 BC. During this early era, abdominal wall hernias were treated with trusses or bandage

dressings. The first evidence of operative repair of a groin hernia dates to the first century AD. The original hernia repairs involved wide operative exposures through scrotal incisions requiring orchiectomy on the involved side. Centuries later, around 700 AD, principles of operative hernia repair evolved to emphasize mass ligation and en bloc excision of the hernia sac, cord, and testis distal to the external ring. The first report of groin hernia classification based on the anatomy of the defect (ie, inguinal versus femoral) dates to the 14th century, and the anatomical descriptions of direct and indirect types of inguinal hernia were first reported in 1559.

Bassini revolutionized the surgical repair of the groin hernia with his novel anatomical dissection and low recurrence rates. He first performed his operation in 1884, and published his initial outcomes in 1889.<sup>2</sup> Bassini reported 100% follow-up of patients over a 5-year period, with only five recurrences in over 250 patients. This rate of recurrence was unheard of at the time and marked a distinct turning point in the evolution of herniorraphy. Bassini's repair emphasizes both high ligation of the hernia sac in the internal ring as well as suture reinforcement of the posterior inguinal canal. The operation also utilizes a deep and superficial closure of the inguinal canal. In the deep portion of the repair, interrupted sutures affixing the transversalis fascia medially to the inguinal ligament laterally repair the canal. This requires an incision through the transversalis fascia. The external oblique fascia provides the superficial closure.

In addition to Bassini's contributions, Lotheissen in 1898 introduced the first true Cooper's ligament repair, which affixes the pectineal ligament to Poupart's ligament and thereby repairs both inguinal and femoral hernia defects. McVay further popularized the Cooper's ligament repair with the addition of a relaxing incision to reduce increased wound tension.

The advances in groin hernia repair in the century following Bassini have shared the primary goal of reducing long-term hernia recurrence rates. To this end, efforts have been directed toward developing a repair that imparts the least tension on the tissues that are brought together to repair the hernia defect. Darn repairs were first introduced in the early 20th century to reduce wound tension by using either autologous tissue or synthetic suture to bridge the gap between fascial tissues. Muscle and fascial flaps were also attempted without consistent success. In 1918, Handley introduced the first use of silk as a prosthetic darn, with nylon following several years later. However, it was found that heavy prosthetic material increased the risk of wound infection,

and silk suture ultimately lost its strength over time. The use of autologous or synthetic patches was also attempted in order to reduce wound tension and improve rates of recurrence. The first patches, beginning in the early 20th century, consisted of silver wire filigree sheets that were placed along the inguinal canal. Over time, the sheets suffered from metal fatigue, leading to hernia recurrence. Reports of the wire patches eroding into adjacent inguinal structures and even the peritoneal cavity caused yet more concern with this technique. In 1958, Usher introduced the modern synthetic patch, made of a plastic monofilament polymer (polyethylene). Lichtenstein further popularized this technique after developing a sutureless hernia repair using a plastic mesh placed across the inguinal floor.

In the search for a technical means to reduce recurrence, emphasis was also placed on a meticulous dissection that would avoid placement of a prosthetic mesh. The most popular version was the Shouldice technique, initially introduced in 1958, which was in essence a modification of the Bassini operation. This technique involves precise dissection of the entire inguinal floor and closure of the inguinal canal in four layers. The transversalis fascial layer itself is closed in two running layers, as opposed to the single layer of interrupted suture advocated by Bassini. While the operation can be technically challenging to the beginner, it has been associated with excellent long-term outcomes and the lowest reported recurrence rates for non-mesh repairs.

Today, laparoscopic and robotic techniques have been validated as safe and effective in the treatment of groin hernias and as a result, have become commonplace. The laparoscopic approaches were initially developed in the early 1990s when laparoscopic techniques diffused throughout other specialties of general surgery. Robotic inguinal hernia repair has become an area of significant growth in the recent past and continues to grow in volume yearly.

## **Epidemiology**

Seventy-five percent of all abdominal wall hernias are found in the groin, making it the most common location for an abdominal wall hernia. Of all groin hernias, 95% are hernias of the inguinal canal, with the remainder being femoral hernia defects. Inguinal hernias are nine times more common in men than in women. Although femoral hernias are found more often in women,

the inguinal hernia is still the most common hernia in women.<sup>3</sup> The overall lifetime risk of developing a groin hernia is approximately 27% in males and 3% in females.<sup>4</sup> There is also clearly an association between age and hernia diagnosis. After an initial peak in the infant, the prevalence of groin hernias increases with advancing age. On average, the prevalence of hernias is 1.3% for all ages, but increases to 3% in those over the age of 45. In the same way, the complications of hernias (incarceration, strangulation, and bowel obstruction) are found more commonly at the extremes of age. Interestingly, the incidence of inguinal hernia repair actually decreases over the age of 80 for both men and women.<sup>5</sup> It is hypothesized that this is likely due to the increase in comorbidities that supersede the need for hernia repair.

Currently in this country, approximately 800,000 operations for inguinal hernia repair are performed annually.<sup>6</sup> Overall, the lifelong cumulative incidence of an initial unilateral or bilateral inguinal hernia repair in adults is 42.5% for men and 5.8% for women.<sup>5</sup> Nevertheless, in the retrospective review by Zendejas, it was seen that the incidence of inguinal hernia repair is downtrending over time. The etiology of this pattern requires more investigation, but is theorized to be due to a multitude of factors such as the popularization of watchful waiting, as described later, and the increased use of mesh repair which decreases recurrences and need for reoperation.

## **Anatomic Classification**

A thorough classification system has been developed to assist in the proper diagnosis and management of the inguinal hernia. All hernias can be broadly classified as congenital or acquired. It is thought that the vast majority of inguinal hernias are congenital in nature. Acquired groin hernias develop after surgical incision and manipulation of the involved abdominal wall tissues. Given the paucity of primary groin incisions utilized in modern general surgery, acquired hernias of the inguinal or femoral region are rare.

Inguinal hernias are further divided by anatomical location into direct and indirect types. This differentiation is based on the location of the actual hernia defect in relation to the inferior epigastric vessels. The inferior epigastric vessels are continuous with the superior epigastric vessels that originate from the internal mammary artery cephalad and ultimately course caudally to become the common femoral artery and vein. These vascular

structures make up the lateral axis of Hesselbach's triangle, which includes the lateral border of the rectus sheath as its medial border and the inguinal (Poupart's) ligament itself as the inferior border. Hernias that develop lateral to the inferior epigastric vessels are termed *indirect* inguinal hernias, and those that develop medial to the vessels are *direct* inguinal hernias. In this way, direct hernia defects are found *within* Hesselbach's triangle. Hernias of the femoral type are located caudal or inferior to the inguinal ligament and medial to the femoral vessels.

The indirect inguinal hernia develops at the site of the internal ring, or the location where the spermatic cord in men and the round ligament in women enters the abdomen. While these may present at any age, indirect inguinal hernias are thought to be congenital in etiology. The accepted hypothesis is that these hernias arise from the incomplete or defective obliteration of the processus vaginalis during the fetal period. The processus is the peritoneal layer that covers the testicle or ovary as it passes through the inguinal canal and into the scrotum in men or the broad ligament in women. During development, the internal ring closes, and the processus vaginalis becomes obliterated following the migration of the testicle into the inguinal canal. The failure of this closure provides an environment for the indirect inguinal hernia to develop. In this way, the remnant layer of peritoneum forms a sac at the internal ring through which intra-abdominal contents may herniate, thereby resulting in a clinically detectable inguinal hernia. Anatomically, the internal ring is lateral to the external ring and the remainder of the inguinal canal, thus explaining the lateral relationship of the indirect inguinal hernia to the inferior epigastric vessels. It is noteworthy that indirect inguinal hernias develop more frequently on the right, where descent of the gonads occurs later during fetal development.

Direct inguinal hernias, in contrast, are found medial to the inferior epigastric artery and vein, and within Hesselbach's triangle. These hernias are acquired and only rarely found in the youngest age groups. They are thought to develop from an acquired weakness in the fibromuscular structures of the inguinal floor, so that the abdominal wall in this region can no longer adequately contain the intra-abdominal contents. The exact relationship between direct inguinal hernias and heavy lifting or straining remains unclear, and some studies suggest that the incidence of direct hernias is no greater in people in professions that routinely involve heavy manual labor.<sup>7</sup>

While femoral hernias account for less than 10% of all groin hernias, their

presentation can be more acute in nature. In fact, it is estimated that up to 40% of femoral hernias present as emergencies with hernia incarceration or strangulation.<sup>3</sup> In this way, femoral hernias may also present as bowel obstructions. The empty space through which a femoral hernia forms is medial to the femoral vessels and nerve in the femoral canal and adjacent to the major femoral lymphatics. The inguinal ligament forms the cephalad border of the empty space. However, while the empty space is inferior to the inguinal ligament, the herniated contents may present superior to the ligament, thereby making an accurate diagnosis difficult.

Femoral hernias are much more common in females than males, although inguinal hernias are still the most common hernia in women. The predilection for femoral hernias in women may be secondary to less bulky groin musculature or weaknesses in the pelvic floor tissues from previous childbirth. It has also been shown that previous inguinal hernia repair may be a risk factor for the subsequent development of a femoral hernia.<sup>3</sup>

Despite the pervasiveness of groin hernias and repairs, there lacks standardization regarding classification of groin hernias. There exist many various classification and grading systems describing inguinal hernias. Early classifications were first seen in the 1960s, and then modified by various groups, including Rutkow and Robbins, Lichtenstein, Nyhus, Zollinger, and Stoppa. Given the variations between individual classifications, the European Hernia Society (EHS) published a simplified yet comprehensive classification based on the Aachen classification.<sup>8</sup> The EHS grading system describes three characteristics of hernias: whether the hernia is primary or recurrent; the size from 0 to 3, with 0 as no hernia, 1 as <1.5 cm (one finger-width), 2 as <3 cm (two finger-widths), 3 as >3 cm (more than two finger-widths), and × as not investigated; and anatomic location, with L being lateral or indirect, M being medial or direct, and F being femoral. While no consensus exists among surgeons regarding a preferred classification system, it is recommended that the EHS classification be used as a standard to allow for better comparison of hernias and their treatments among various institutions.<sup>9</sup>

## **Anatomy of the Groin**

The boundaries of the inguinal canal must be understood to comprehend the principles of hernia repair. In the inguinal canal, the anterior boundary is the

external oblique aponeurosis; the posterior boundary is composed of the transversalis fascia with some contribution from the aponeurosis of the transversus abdominis muscle; the inguinal and lacunar ligaments impart the inferior border; and the superior boundary is formed by the arching fibers of the internal oblique musculature.

The internal (or deep) inguinal ring is formed by a normal defect in the transversalis fascia through which the spermatic cord in men and the round ligament in women passes into the abdomen from the extraperitoneal plane. The external (or superficial) ring is inferior and medial to the internal ring and represents an opening of the aponeurosis of the external oblique. The spermatic cord passes from the peritoneum through the internal ring and then caudally into the external ring before entering the scrotum in males.

From superficial to deep, the surgeon first encounters Scarpa's fascia after incising the skin and subcutaneous tissue. Deep to Scarpa's layer is the external oblique aponeurosis, which must be incised and spread to identify the cord structures. The inguinal ligament represents the inferior extension of the external oblique aponeurosis, and extends from the anterior superior iliac spine to the pubic tubercle. The medial extension of the external oblique aponeurosis forms the anterior rectus sheath. The iliohypogastric and ilioinguinal nerves, which provide sensation to the skin, penis, and the upper medial thigh, lie deep to the external oblique aponeurosis in the groin region. The internal oblique aponeurosis is more prominent cephalad in the inguinal canal, and its fibers form the superior border of the canal itself. The cremaster muscle, which envelops the cord structures, originates from the internal oblique musculature. The transversus abdominis muscle and its fascia represent the true floor of the inguinal canal. Deep to the floor is the preperitoneal space, which houses the inferior epigastric artery and vein, the genitofemoral and lateral femoral cutaneous nerves, and the vas deferens, which traverses this space to join the remaining cord structures at the internal inguinal ring.

## **Etiology**

The indirect inguinal hernia, the most common form of groin hernia across all ages and genders, is thought to be congenital in etiology. The processus vaginalis is the pocket of peritoneum that forms around the testicle as it descends through the internal ring and along the inguinal canal into the

scrotum during the 28th week of gestation. The primary etiology behind the indirect inguinal hernia is believed to be a patent processus vaginalis, which in essence represents a hernia sac. In this way, the hernia defect is the internal ring itself, and the sac is preformed but never closed at the end of gestation. Once intra-abdominal contents find their way into the sac, an indirect inguinal hernia is formed.

However, not every person with a patent processus vaginalis develops an inguinal hernia during his or her lifetime. Thus, other predisposing factors must aid in indirect inguinal hernia formation. It is commonly thought that repeated increases in intra-abdominal pressure contribute to hernia formation; hence, inguinal hernias are commonly associated with pregnancy, chronic obstructive pulmonary disease, abdominal ascites, patients who undergo peritoneal dialysis, laborers who repeatedly flex abdominal wall musculature, and individuals who strain from constipation. It is also thought that collagen formation and structure deteriorates with age, thus explaining increased hernia formation in older individuals.

Several inborn errors of metabolism can lead to hernia formation. Specifically, conditions such as Ehlers–Danlos syndrome, Marfan syndrome, Hunter syndrome, and Hurler syndrome can predispose to defects in collagen formation, resulting in weaknesses in the abdominal wall. There is also evidence that cigarette smoking is associated with connective tissue disruption, and not surprisingly, hernia formation is more commonly found in the chronic smoker.

## **Clinical Manifestations**

The groin hernia can present in a variety of ways, from the asymptomatic hernia to frank peritonitis in a strangulated hernia. Many hernias are found on routine physical examination or on focused examination for an unrelated complaint. These groin hernias are usually fully reducible and chronic in nature. Such hernias are still referred for repair since they invariably develop symptoms, and asymptomatic hernias still have an inherent risk of incarceration and strangulation, albeit low.<sup>10,11</sup>

The most common presenting symptomatology for a groin hernia is a bulge associated with a dull feeling of discomfort or heaviness in the groin region that is exacerbated by straining the abdominal musculature, lifting

heavy objects, or defecating. These maneuvers worsen the feeling of discomfort by increasing the intra-abdominal pressure and forcing the hernia contents through the hernia defect. Pain develops as a tight ring of fascia outlining the hernia defect compresses intra-abdominal structures with a visceral neuronal supply. With a reducible hernia, the feeling of discomfort resolves as the pressure is released when the patient stops straining the abdominal muscles. The pain is often worse at the end of the day, and patients in physically active professions may experience the pain more often than those who lead a sedentary lifestyle.

Overwhelming or focal pain from a groin hernia is unusual and should raise the suspicion for hernia incarceration or strangulation. An incarcerated hernia occurs when the hernia contents are trapped in the hernia defect so that the contents cannot be reduced back into the abdominal cavity. The tight circumferential pressure applied by the hernia defect serves to impede the venous outflow from the hernia contents, resulting in congestion, edema, and tissue ischemia. Ultimately, the arterial inflow to the hernia contents is compromised as well, resulting in tissue loss and necrosis, termed strangulation of the hernia.

All types of groin hernias are at risk for incarceration and strangulation, although the femoral hernia seems to be predisposed to this complication. Incarceration and strangulation of a groin hernia may present as a bowel obstruction when the tight hernia defect constricts the lumen of the viscus. Hence, all patients presenting with bowel obstruction require a thorough physical examination of the groin region for inguinal and femoral hernias.

The physical exam differs between an incarcerated and a strangulated hernia. The incarcerated hernia may be mildly tender due to venous congestion from the tight defect. If there is no bowel in the hernia sac, an incarcerated groin hernia may alternatively present as a hard, painful mass that is tender to palpation. The strangulated hernia will be tender and warm and may have surrounding skin erythema secondary to the inflammatory reaction from the ischemic bowel. The patient with the strangulated hernia may have a fever, hypotension from early bacteremia, and a leukocytosis. The incarcerated hernia requires operation on an urgent basis within 6 to 12 hours of presentation. If the operation is delayed for any reason, serial physical exams are mandated to follow any change in the hernia site indicating the onset of tissue loss. The strangulated hernia clearly requires emergent operation immediately following diagnosis.

It may also be difficult to differentiate fat from bowel contents in the hernia sac; incarcerated omental fat alone can produce significant pain and tenderness on physical exam, similar to incarcerated bowel.

## **Pregnancy and Groin Hernia**

Not surprisingly, groin hernias during pregnancy may become symptomatic. This is related to the increased intra-abdominal pressure from the growing fetus and enlarging uterus. The symptomatic groin discomfort may become positional later in pregnancy as the uterus shifts location with movement. While the risks of complications of groin hernias still exist during pregnancy, the enlarging uterus may in theory protect against incarceration by physically blocking the intra-abdominal contents from the inlet of the defect.

In general, elective repair of groin hernias during pregnancy is not recommended, even if they become increasingly symptomatic. However, emergent repair of the incarcerated or strangulated hernia is undertaken as needed.

## **Physical Examination**

As with any hernia, the groin hernia should be properly examined with the patient in the standing position. This allows the hernia contents to fill the hernia sac and make the hernia more obvious on physical examination. Some hernias, however, may be easily identifiable in the supine position. It should be noted that the exact anatomical classification of the inguinal hernia (ie, indirect versus direct) is difficult to accurately predict based on physical exam alone, and likely not clinically relevant, as all repair techniques should address both direct and indirect inguinal hernias.

In the male patient, using the second or third finger, the examiner should invaginate the scrotum near the external ring and direct the finger medially toward the pubic tubercle. The examiner's finger will thus lie on the spermatic cord with the tip of the finger within the external ring. The patient is then asked to cough or perform a Valsalva maneuver. A true inguinal hernia will be felt as a silk-like sensation against the gloved finger of the examiner. This is the infamous "silk glove" sign.

The female patient does not have the long and stretched spermatic cord to

follow with the examiner's finger during the physical examination. Instead, two fingers can be placed along the inguinal canal, and the patient is asked to cough or strain. If present, the examiner should feel the sensation of the hernia sac against the gloved finger. Particular attention in the female patient should be paid to the location of the sensation. Femoral hernia sacs will present medial and just inferior to the lower border of the inguinal ligament, while inguinal hernias will present superior to the lower border of the inguinal ligament.

While the physical examination does not differ in the infant, it can be more challenging to elicit the hernia impulse given the compressed groin anatomy of the young child. It is well known that a groin hernia can be more readily diagnosed in the infant who is actively crying and hence increasing the intra-abdominal pressure through flexion of the abdominal wall musculature.

The examination for the femoral hernia in both genders involves palpation of the femoral canal just below the inguinal ligament in the upper thigh. In this way, the most easily palpable landmark is the femoral artery, which is located lateral in the canal. Medial to the femoral artery is the femoral vein, and the femoral empty space is just medial to the vein. This area can be located easily, palpated with two fingers, and then examined closely while the patient coughs or strains. In general, a focused groin hernia examination should involve the investigation for both inguinal and femoral hernias in both genders.

## **Treatment**

The treatment of all hernias, regardless of their location or type, is surgical repair. Elective repair is performed to alleviate symptoms and to prevent the significant complications of hernias, such as incarceration or strangulation. While the limited data available on the natural history of groin hernias show that these complications are rare, the complications are associated with a high rate of morbidity and mortality when they do occur. At the same time, the risks of elective groin hernia repair, even in the patient with a complicated medical history, are exceedingly low. Outcomes of surgical repair are generally excellent with minimal morbidity and relatively rapid return to baseline health.

The major risk with delayed surgical repair is the risk of incarceration

and/or strangulation. It is not possible to reliably identify those hernias that are at an increased risk for these complications. It is known that the risk of incarceration of a hernia is greatest soon after the hernia manifests itself. This is likely due to the fact that at the early stage of the hernia, the defect is small and fits tightly around the hernia sac; therefore, any contents that fill the sac may quickly become trapped within the hernia. Over time, the hernia defect stretches due to the tissue that enters and leaves the sac with changes in intra-abdominal pressure. After 6 months, the risk of hernia incarceration decreases from 5% per year to 1% to 2% per year. In general, the larger the palpable defect on physical examination, the lower the risk of incarceration. Clearly, all risks of tissue loss aside, elective hernia repair is still preferred over emergent repair.

While elective hernia repair is recommended, for those with minimal symptoms who do not wish to undergo surgical intervention, watchful waiting is a reasonable and safe option. In the watchful waiting trial, 720 men with minimally symptomatic or asymptomatic inguinal hernias were enrolled and randomized to either watchful waiting or open surgical repair.<sup>10</sup> The study showed that watchful waiting is a safe alternative to surgery. After 4 years, only two patients required emergent operation for either acute incarceration without strangulation or bowel obstruction and only a total of three patients required emergency operations at 7 years.<sup>10,11</sup> This changed the traditional idea that all groin hernias should be repaired immediately. Nevertheless, it should be noted that while watchful waiting is safe with low risk of need for emergent surgery, 68% of patients who waited eventually underwent surgical repair, most commonly due to worsening hernia-related pain. It was also seen that men older than 65 years of age had increased rates of surgical repair than younger men for pain (79% crossover to surgical repair vs 62%). Therefore, while watchful waiting is a safe option, the majority of patients will likely experience progression of symptoms that may require surgical repair. As a result, elective hernia repair still remains the preferred treatment and should be offered to all surgical candidates.

## **Anesthesia**

Groin hernia repair can be performed using a variety of anesthesia options, including general, regional (such as spinal or epidural), and local

anesthesia.<sup>12</sup> Laparoscopic repairs usually require general anesthesia in order to provide the complete muscle relaxation needed to achieve insufflation of the preperitoneal or peritoneal space.

Open groin hernia repairs are frequently performed using either regional or local anesthesia. Local anesthesia with controlled intravenous sedation, referred to as monitored anesthesia care, is often preferred in the repair of the reducible inguinal hernia. Its advantages include the ease of induction and awakening, the short postanesthesia recovery period, and the fact that its intensity can easily be titrated up or down based on patient comfort levels intraoperatively. The only major disadvantage to this approach is in patients who experience considerable pain during repairs of large groin hernias.

In groin hernia repair, local anesthesia can be administered either as a direct infiltration of the tissues to be incised or as a local nerve block of the ilioinguinal and iliohypogastric nerves. The latter is associated with improved local pain control, but may be difficult to achieve. The local nerve block also spares the soft tissue edema from diffuse infiltration of local anesthesia.

Spinal or continuous epidural anesthesia allows the surgeon greater freedom to maneuver within the operative field since the anesthetized region is larger than in local anesthesia. However, these modes of anesthesia carry their own infrequent risks such as urinary retention, prolonged anesthetic effect, hypotension, and spinal headache. They may also be associated with longer in-hospital recovery times on the day of surgery.

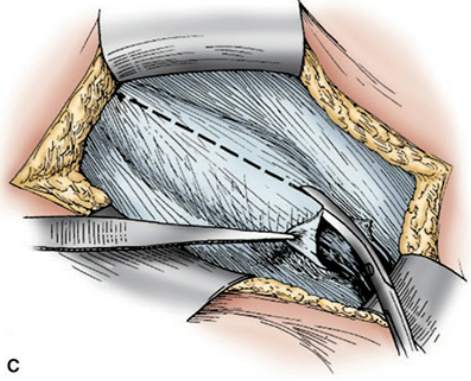

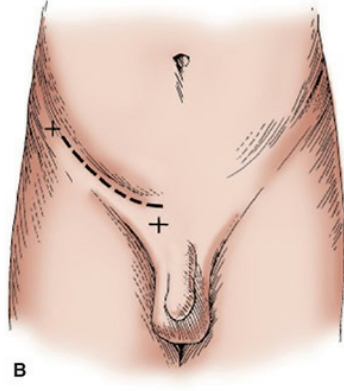

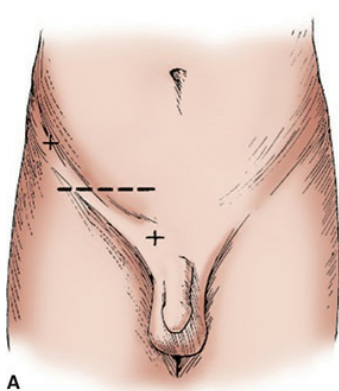

A randomized trial of local, regional, and general anesthesia in 616 adult patients undergoing open inguinal hernia repair in 10 hospitals found that local anesthesia was superior in the early postoperative period.<sup>13</sup> Compared to those who received regional or general anesthesia, patients who received local anesthesia had less postoperative pain and nausea, shorter time spent in the hospital, and fewer unplanned overnight admissions (3% vs 14% and 22%, respectively).

## **Operative Techniques**

Successful surgical repair of a hernia depends on a tension-free closure of the hernia defect to attain the lowest possible recurrence rate. Previous efforts to simply identify the defect and suture it closed resulted in unacceptably high recurrence rates of up to 15%. Modern techniques have improved upon this

recurrence rate by utilizing the placement of mesh over the hernia defect, or in the case of laparoscopic repair, behind the hernia defect. One exception to this rule is the classic Shouldice repair, which uses meticulous dissection and closure without mesh placement to obtain a consistently low recurrence rate. Another benefit of the tension-free closure is that it has been shown to cause significantly less pain and discomfort in the short-term postoperative period.

**Figure 11-1** illustrates the essential steps to the modern open inguinal hernia repair. All of the open anterior herniorrhaphy techniques begin with a transversely-oriented, slightly curvilinear skin incision of approximately 6 to 8 cm, positioned one to two fingerbreadths above the inguinal ligament. Dissection is carried down through the subcutaneous and Scarpa's layers. The external oblique aponeurosis is identified and cleaned so that the external ring is identified inferomedially. Being careful to avoid injury to the iliohypogastric and ilioinguinal nerves, the aponeurosis is incised sharply and opened along its length through the external ring with fine scissors. The nerves underlying the external oblique fascia are then identified and preserved without mobilization to decrease the risk of post-herniorrhaphy inguinodynia. Additionally, the iliohypogastric nerve and the genital branch of the genitofemoral nerve should be identified and preserved without mobilization in order to retain their protective investing fascial layers. The soft tissue is cleared off the posterior surface of the external oblique aponeurosis on both sides and the spermatic cord is mobilized. Using a combination of blunt and sharp dissection, the cremaster muscle fibers enveloping the cord are separated from the cord structures and the cord itself is isolated. At this point, it is possible to accurately define the anatomy of the hernia. An indirect hernia will present with a sac attached to the cord in an anteromedial position extending superiorly through the internal ring. A direct inguinal hernia will present as a weakness in the floor of the canal posterior to the cord. A pantaloon defect will present as both a direct and indirect defect in the same inguinal canal.

**FIGURE 11-1** Adult hernia incision and dissection. **A.** Transverse incision. **B.** Curved skin crease incision. **C.** The aponeurosis of the external oblique is incised along the direction of its fibers. **D.** The inguinal canal is exposed and the spermatic cord mobilized. **E.** The spermatic cord has been skeletonized, and the internal ring and posterior wall of the canal (the transversalis fascia) have been defined. **F.** A medium-sized sac has been dissected free of the cord elements. **G.** The sac has been invaginated. **H.** A long or complete sac is being dissected free close to the internal ring. **I.** The sac has been transected.

The specifics of the common modern techniques for hernia repair will be discussed further.

## THE SHOULDICE TECHNIQUE

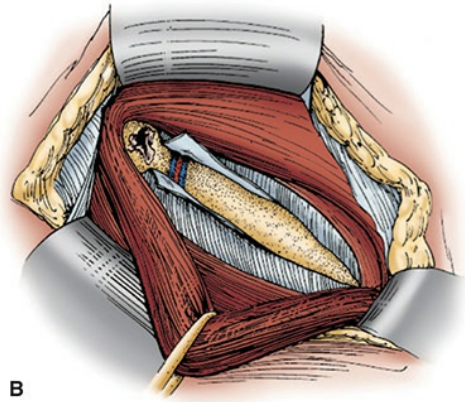

The Shouldice technique is commonly used for open repair of inguinal

hernias and is the most popular pure tissue hernia repair. It is in essence the modern evolution of the Bassini repair performed in a multilayered fashion. Both operations use a tightening of the internal ring and closure of the transversalis fascia to the inguinal ligament as their primary tenets of hernia repair.<sup>14</sup>

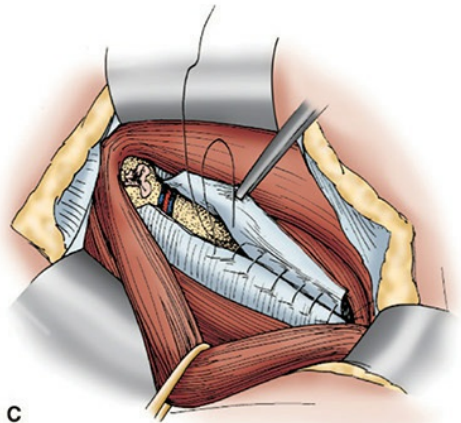

Figure 11-2 illustrates the basic steps in the Shouldice repair. After suitable exposure and isolation of the cord, a pair of scissors is passed posterior to the transversalis fascia beginning at the medial pillar of the internal ring and extending inferomedially to the pubic tubercle. In this way, the transversalis fascia is separated from the preperitoneal fat plane. Care must be taken at this stage to preserve the inferior epigastric vessels that reside in the preperitoneal space. The transversalis fascia is then opened with scissors along the entire inguinal floor from internal ring to pubic tubercle, and the posterior surface of the transversalis is cleaned of its preperitoneal attachments. As the first layer of the repair, the free edge of the lower transversalis flap is sutured in a continuous, imbricated fashion behind the upper flap to the posterior surface of the upper transversalis fascia and the lateral component of the posterior rectus sheath. This running suture layer is started medially at the pubic tubercle and carried up to and through the internal ring, thereby tightening the transversalis fascia around the cord at its entrance to the inguinal canal. The first layer is not tied but continued in a running fashion from lateral to medial as a second layer closing the upper transversalis flap to the base of the lower edge as well as the inguinal ligament. This second layer progresses medially to the pubic tubercle where it is tied to the original tail that started the first layer. The third layer of continuous suture starts at the tightened internal ring and brings together the conjoined tendon (the internal oblique and transversus abdominis aponeuroses) medially with the inguinal ligament laterally. This layer is run down to the pubic tubercle, and returns back to the internal ring as the fourth layer including the anterior rectus sheath medially with the posterior aspect of the external oblique aponeurosis laterally. The cord can now be relaxed gently on the new inguinal floor, and the external oblique aponeurosis is closed in one to two additional continuous layers extending down to the external ring to reapproximate this structure. The original descriptions of the operation by Shouldice used continuous stainless steel wire suture for all four layers of repair, although surgeons commonly use permanent synthetic suture today.

The Shouldice Hospital reports excellent long-term outcomes from their technique with recurrence rates less than 1% in selected patients.<sup>15,16</sup> These results have not been achieved with any other pure tissue technique. The operation is well tolerated by most patients using local anesthesia only. From the multiple, overlapping, continuous suture lines, Shouldice proponents argue that any tension brought about in this type of closure is dispersed throughout the entire inguinal canal. The dissection is complicated, however, and requires excellent surgical technique and anatomic awareness. Moreover, other surgeons utilizing the Shouldice method have not achieved recurrence rates this low. Thus, the low rate of recurrence associated with the Shouldice technique likely depends on the level of surgical expertise and the patient selection. In one report of 183 inguinal hernia repairs using the Shouldice technique under local anesthesia, the recurrence rates for beginners versus more experienced surgeons were 9.4% versus 2.5%, respectively.<sup>17</sup>

A recent meta-analysis conducted by the Cochrane Collaboration compared the Shouldice technique with other open techniques for inguinal hernia repair.<sup>18</sup> The analysis incorporated results from 16 different randomized or quasi-randomized studies and compared 2566 hernias repaired via the Shouldice technique with 1121 hernias repaired with mesh and 1608 hernias repaired with other non-mesh techniques. The recurrence rate for the Shouldice repair was significantly higher than mesh repair (odds ratio 3.8), but significantly lower than non-mesh repair (odds ratio 0.62). There were no significant differences between the groups with respect to complications, length of stay, or chronic pain following herniorrhaphy. Thus, the Shouldice technique is less preferable than mesh repairs with respect to recurrence, but appears to be the repair of choice in situations where mesh cannot be implanted.

## **THE COOPER'S LIGAMENT REPAIR**

The Cooper's ligament repair is the only open tissue-based technique that definitively repairs both inguinal and femoral hernia defects in the groin. The operation is often named after Chester McVay, who popularized the operation in the 1940s and introduced the concept of the relaxing incision to decrease the tension from the repair. The repair is also a primary tissue repair in that no mesh is utilized.

The Cooper's ligament repair begins similar to the Shouldice procedure, and exposure and isolation of the cord is performed. The transversalis fascia is then opened and cleaned posteriorly. At this time, Cooper's ligament is identified and dissected free of its fibrous and fatty attachments. The defects are repaired by using interrupted suture to affix the upper border of the transversalis fascia to Cooper's ligament beginning medially at the pubic tubercle and continuing until the femoral sheath is reached. At this point, the femoral canal is closed by carefully suturing Cooper's ligament to the femoral sheath. The repair is continued by transitioning anteriorly from Cooper's ligament with interrupted sutures between the transversalis fascia and the iliopubic tract laterally until the entrance point of the cord is reached. In this way, the closure creates a new and tighter internal inguinal ring around the cord.

The Cooper's ligament repair frequently requires a relaxing incision because this pure tissue repair is associated with significant tension created by closing all three groin hernia defects. After the transversalis fascia has been mobilized, and prior to the closure of the fascia to Cooper's ligament, a 2- to 4-cm vertical incision is made at the lateral border of the anterior rectus sheath beginning at the pubic tubercle and extending superiorly. The relaxing incision can be left open since the rectus muscle should protect against any herniation; alternatively, some surgeons argue for placement of a mesh over the relaxing incision since hernia formation can occur at this site.

The Cooper's ligament repair is an outstanding technique for a femoral hernia and is associated with excellent long-term results in experienced hands. Disadvantages of the repair include a longer operating time, a more extensive dissection, the potential for vascular injury and thromboembolic complications from the femoral vessels, and a longer postoperative recovery phase.

## **Prosthetic Repairs**

Polypropylene mesh is the most common prosthetic used today in mesh repairs of the inguinal hernia. The two most common prosthetic repairs are the Lichtenstein<sup>19</sup> and the “plug and patch” repair as described by Gilbert<sup>20</sup> and popularized by Rutkow and Robbins.<sup>21</sup>

The type of mesh to be used during prosthetic inguinal hernia repairs deserves a brief discussion. The most common and preferred mesh for groin hernia repair is a polypropylene woven mesh marketed under a variety of names. Polypropylene is preferred because it allows for a fibrotic reaction to occur between the inguinal floor and the posterior surface of the mesh, thereby forming scar and strengthening the closure of the hernia defect. This fibrotic reaction is not seen to the same extent with other varieties of prosthetic, namely, expanded polytetrafluoroethylene (PTFE) mesh. PTFE is sometimes used for repair of ventral or incision hernias in which the fibrotic reaction with the underlying serosal surface of the bowel is best avoided. In addition, multiple studies demonstrate that lightweight versions of polypropylene have been associated with a decreased risk of chronic groin pain following inguinal hernia repair and are preferred to heavier weight versions of the same mesh.<sup>22–25</sup>

There are limited prospective, randomized data comparing the recurrence rate of open repairs with and without mesh. An attempted meta-analysis concluded that mesh repair was associated with fewer overall recurrences, although the authors report that formal analysis was limited by the lack of available study data.<sup>26</sup> In the review by Cochrane Collaboration and EU Hernia Trialists Collaboration, it was shown that there were lower rates of recurrence following mesh repair than non-mesh repair.<sup>25</sup> A review of 26,000 inguinal hernia repairs from Denmark further found that mesh repairs had a lower reoperation rate than conventional open repairs.<sup>27</sup> Therefore, the EHS recommends open mesh repair over open non-mesh repair; if non-mesh repair is considered, the Shouldice technique is the recommended procedure.<sup>9</sup> More than 90% of groin hernia repairs performed in the United States in the modern era utilize mesh placement.<sup>6</sup>

## **THE LICHTENSTEIN TECHNIQUE**

The Lichtenstein inguinal hernia repair was the first pure prosthetic, tension-free repair to achieve consistently low recurrence rates in long-term outcomes

analysis. This operation begins with the incision of the external oblique aponeurosis and the isolation of the cord structures. Any indirect hernia sac is mobilized off the cord to the level of the internal ring. At this point, a large mesh tailored to fit along the inguinal canal floor is placed so that the curved end lies directly on top of the pubic tubercle. The mesh patch extends underneath the cord until the spermatic cord and the tails of the mesh patch meet laterally. Here, an incision is made in the mesh, and the cord is inserted between the tails of the mesh, thereby creating a new, tighter, and more medial internal ring. The tails are sutured together with one nonabsorbable stitch just proximal to the attachment of the cord. The mesh is then sutured in a continuous or interrupted fashion to the pubic tubercle inferiorly, the conjoint tendon medially, and the inguinal ligament laterally. Care must be taken not to incorporate the iliohypogastric nerve during fixation of the cephalad portion of the mesh, and thus identification of this nerve prior to mesh fixation is strongly advised.

Rutkow and Robbins have reported interesting and effective advances in the Lichtenstein technique. The “plug and patch” repair, as illustrated in [Figure 11-3](#), represents a tension-free herniorrhaphy and can even be performed without sutures. In this technique, the patch is placed in a similar fashion to the modern Lichtenstein repair as it lies along the inguinal canal from the pubic tubercle medially to beyond the cord laterally. In addition, a mesh plug in the form of an umbrella or cone is snugly fit up and into the internal ring. In this way, the repair goes beyond just a tightening of the internal ring, but serves to close the ring around the spermatic cord. Modifications of this operation exist and are practiced commonly by general surgeons. The patch and plug can be sutured to the surrounding inguinal canal tissue in an interrupted or continuous fashion. Alternatively, both prostheses can be placed in appropriate position with no suture affixment. In this way, the body’s natural scarring mechanism will hold both pieces of mesh in place over time. Wide internal ring defects, often caused by large or chronic indirect sacs, may require one or two sutures to tack the plug in place to avoid slippage into the canal anteriorly or the retroperitoneal space posteriorly. While this technique is employed by many surgeons, mesh plugs may be associated with an increased rate of nociceptive chronic groin pain and should likely be avoided in thin patients who are more likely to sense a meshoma.

**FIGURE 11-3** The sutureless “patch and plug” tension-free inguinal hernia repair. **A.** The polypropylene mesh “umbrella plug” being passed through the internal ring. **B.** The “umbrella plug” has opened behind the transversalis fascia. **C.** The polypropylene mesh laid down onto the posterior wall of the inguinal canal (the transversalis fascia). Note the end tails of the mesh patch

embracing the cord.

## **THE PREPERITONEAL APPROACH**

The preperitoneal space is found between the transversalis fascia and the peritoneum itself. The actual groin hernia defect is located anterior to this space, whether the defect exists in the internal ring (indirect inguinal hernia) or through the transversalis floor of the inguinal canal (direct inguinal hernia). Several authors, including Rives, Nyhus, Stoppa, and Kugel, advocate the use of a preperitoneal or posterior approach to repair of the inguinal hernia. They argue that this approach is more effective than the traditional anterior herniorrhaphy because a repair in the preperitoneal plane fixes the hernia defect in the space between the hernia contents and the hernia defect. In contrast, the anterior approach does not keep the hernia contents from contact with the defect, but rather fixes the hernia defect anterior to the defective anatomy. The operation is also advocated for difficult inguinal hernia recurrences, since the posterior approach will usually remain open and without scar following a previous anterior hernia repair. The original operation as described by Nyhus repairs the hernia primarily with suture, although more recent modifications incorporate a mesh patch posterior to the floor of the inguinal canal. As described later in this chapter, the standard laparoscopic technique for inguinal hernia repair is based entirely on the preperitoneal hernia repair.

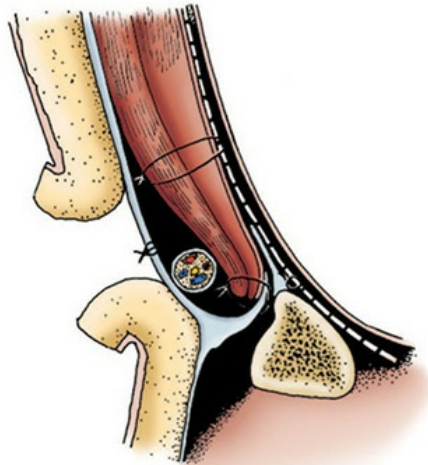

Figures 11-4 and 11-5 illustrate the preperitoneal repair as described by Rives.<sup>28</sup> In the preperitoneal hernia repair, the incision is usually made transversely in the lower quadrant 2 to 3 cm cephalad to the inguinal ligament. The incision is made slightly more medial than the anterior approach so that the lateral border of the rectus muscle can be exposed after incising the anterior rectus sheath. Once the muscle is exposed, retraction of the rectus muscle medially allows for careful opening of the posterior rectus sheath and entry into the preperitoneal space. The inferior epigastric vessels and the cord can be visualized in this space. The cord usually does not require extensive manipulation or dissection since the usual cord attachments (lipoma and cremaster fibers) are found in the anterior layers of the inguinal canal. In this way, the approach also avoids exposure to the sensory nerves of the inguinal canal.

**A**

**B**

**FIGURE 11-5** **A.** The lower midline incision used for the preperitoneal approach to inguinal hernia repair. **B.** Another view of the points of attachment of the mesh in the preperitoneal plane.

Once the preperitoneal space has been entered and exposed, the specific repair to be performed depends on hernia anatomy. For direct defects, the sac is inverted back into the peritoneal cavity but does not need to be excised. The transversalis fascia is then reapproximated over the inverted sac using interrupted sutures; in this way, the upper border of the transversalis fascia is affixed to the lower border composed of the iliopubic tract. For indirect defects, the sac is reduced off of the cord and a high ligation of the sac is performed at the sac neck; ironically, with this approach, the “high ligation” is actually a “posterior” ligation, since the surgeon ideally should transect the sac just above the preperitoneal fat, which is situated along the inferior border of the exposed field. Once the sac has been ligated, the defect in the internal ring is repaired from the posterior plane using interrupted suture to affix the ring leaflets of the transversalis fascia to the iliopubic tract thereby tightening the ring itself.

Modifications of this approach using the prosthetic mesh patch are relatively straightforward. The mesh patch is placed underneath the transversalis fascia and directly on the preperitoneal fat. This patch, if placed completely over the inguinal region, covers any peritoneum that could potentially form a hernia sac through the myopectineal orifice.

## **THE ONSTEP TECHNIQUE**

The Onstep technique is a novel method of hernia repair initially described by Lourenco and da Costa in 2013. It is in essence a modified preperitoneal approach that also utilizes a prosthetic mesh for a tension-free repair.<sup>29</sup> Similar to a preperitoneal repair, the Onstep procedure involves an incision two finger-widths lateral to the midline and two finger-widths superior to the pubic symphysis, more cranial than the incision seen with the Lichtenstein repair. Dissection is then taken down through subcutaneous tissue, Scarpa’s fascia, and the anterior surface of external oblique aponeurosis to expose the internal oblique aponeurosis. The space between the internal and external obliques is then bluntly dissected and the cord elevated out of the incision. If an indirect hernia is encountered, the hernia contents are reduced and the sac ligated or excised. If a direct hernia is encountered, the hernia sac is dissected from surrounding tissues and both the hernia sac and contents are reduced back into the abdominal cavity. After management of the hernia sac and contents, the transversalis fascia is bluntly perforated over the pubis and the

dissection bluntly continued to the posterior surface of the pubic bone in order to find the preperitoneal space. The mesh used in the original description of the Onstep procedure is the PolySoft™ hernia patch. The medial aspect of the mesh is placed in the preperitoneal space, while the lateral tails of the mesh, created by cutting an axial slit into the mesh, enclose the spermatic cord and lie in the plane between the internal and external obliques.<sup>30</sup>

In the original study published by Lourenco and da Costa, 693 patients underwent the Onstep procedure, with an overall complication rate of 1.0% at 1 year. Five patients experienced early complications of seroma, hematoma, and wound infection. Four patients had residual pain at 6 months; three of these patients required reoperation and removal of the recoil ring in the mesh under local anesthesia, with resolution of the pain by 12 months. The recurrence rate was found to be 0.6%; all recurrences occurred in the first 2 months after surgery. The Onstep procedure was further studied in 80 patients at Herlev Hospital in Copenhagen, which showed that with 85% follow-up, 95.5% reported no pain after an Onstep repair.<sup>31</sup>

## Laparoscopic Repair

Laparoscopic groin hernia repair was first performed by Ger in 1979, although it is only within the past decade and a half that laparoscopic hernia repair has become more accepted. The laparoscopic approach to hernia repair has since evolved into a common and effective procedure. Today, the laparoscopic approach comprises approximately 20% to 25% of groin hernia operations, and 80,000 to 100,000 laparoscopic hernia repairs are performed annually in the United States. The most important difference between the laparoscopic and open approaches for inguinal hernia repair is anatomical: the laparoscopic approach uses mesh to repair the hernia defect in a plane posterior to the defect (either in the preperitoneal space or from within the peritoneal cavity), whereas the open approaches repair the hernia anterior to the defect.

Three different techniques exist for laparoscopic repair of groin hernias. The transabdominal preperitoneal (TAPP) repair involves standard laparoscopy with access into the peritoneal cavity and placement of a large mesh along the anterior abdominal wall, thereby repairing the hernia

posterior to the defect. This technique was the first laparoscopic hernia repair to be performed. Ports are generally placed through the umbilicus and then laterally at the midclavicular line at the level of the umbilicus. The hernia defect is usually well visualized from within the peritoneal cavity. After both inguinal regions have been inspected and laparoscopic adhesiolysis performed if necessary, the median umbilical ligament (the urachal remnant), the medial umbilical ligament (the remnant of the umbilical artery), and the lateral umbilical fold (the reflection of peritoneum over the inferior epigastric vessels) are identified. The parietal layer of peritoneum is then incised from the medial umbilical ligament out laterally toward the anterior superior iliac spine superior to the hernia defect and reflected inferiorly, thereby exposing the hernia defect, the epigastric vessels, Cooper's ligament, the pubic tubercle, and the iliopubic tract. The cord structures are then dissected free of their peritoneal attachments. The bladder is subsequently mobilized in the space of Retzius in order to visualize Cooper's ligaments on both sides. In a direct hernia, the peritoneal sac is pulled back within the peritoneal cavity with gentle traction to separate the thin peritoneal layer from the equally thin layer of transversalis fascia anterior to it. In an indirect hernia, the peritoneal sac is retracted off of the cord structures and pulled back within the peritoneal cavity. Alternatively, in the setting of a large chronic indirect hernia, the sac can be divided distally to the internal ring so that only the proximal portion of the sac needs to be mobilized for the repair. A large polypropylene or polyester mesh patch is then placed between the peritoneum and the transversalis fascia that covers the entire myopectineal orifice. The mesh is stapled or tacked to the pubic tubercle medially, Cooper's ligament inferiorly, and the anterior superior iliac spine laterally. Alternatively, anatomic or self-gripping meshes can be utilized without any additional fixation. The incised peritoneal flap is then closed over the mesh via suturing or tacking.

With increasing popularity of robotic-assisted surgery, it is not surprising that this technology has spread to the surgical repair of hernias, with the development of robotic-assisted TAPP. Robotic TAPP was first performed concomitantly during robotic-assisted radical prostatectomies. These initial studies showed great success, demonstrating no complications of mesh placement, wound infection, chronic pain, and fluid collections, and a 2.6% recurrence rate.<sup>32</sup> This led to further experiences with robotic TAPP, which has been described to have better visualization of surgical field and improved maneuverability compared with traditional laparoscopy. Port placement,

dissections, and repair of the hernia are similar to that of laparoscopic TAPP as described previously. In the results published by Escobar Dominguez and associates, 123 hernias in 78 patients were repaired with robotic TAPP using the da Vinci platform.<sup>33</sup> Forty-five of these procedures were bilateral robotic herniorrhaphies. Results showed no mortalities or conversions to open procedures. The complication rate was 11.5%, similar to the published TAPP and total extraperitoneal (TEP) complication rates of 8% to 28% and 4% to 24%, respectively, leading to the conclusion that robotic TAPP is a safe and effective method of hernia repair.

Recently, with improvement in robotic technologies, there has also been the development of robotic-assisted single-site hernia repair, which utilizes a single umbilical port, as opposed to the traditional three ports described in robotic TAPP. In a case study by Bosi and associates, they describe use of robotic-assisted single-site hernia repair for bilateral inguinal hernia repair that demonstrated no postoperative complications.<sup>34</sup> However, it should be noted that robotic TAPP is limited by high operating costs and need for robotic training by the surgical team.

The intraperitoneal onlay mesh technique (IPOM) was developed as a simplified version of the TAPP repair. In this technique, laparoscopic exposure is obtained directly into the peritoneal cavity as in the TAPP. However, this technique does not require an extensive mobilization of the peritoneal flap and dissection of the preperitoneal space. Rather, a large mesh is simply stapled or sutured directly posterior to the peritoneum to repair the hernia. In theory, once the peritoneum scars to the mesh after allowing for connective tissue ingrowth, the peritoneum will not be mobile enough to herniate through the actual defect and intra-abdominal pressure will keep the abdominal contents posterior to the mesh patch. The disadvantage of this procedure is that there is direct exposure of mesh to the intra-abdominal contents and therefore a high risk of adhesion formation and possible erosion of the mesh into bowel contents. Another potential disadvantage of the IPOM is that in large inguinal hernias, the mesh and peritoneum may herniate through the defect together, thereby negating any protective effect imparted by the mesh patch. Therefore, at the present time, this procedure is thought to be experimental only.

While the TAPP repair has been shown to be effective, there is a risk that the prosthetic mesh will be in direct contact with the bowel, and significant concern has been raised about the potential for intra-abdominal adhesions

postoperatively.<sup>35</sup> Although enthusiasm for this technique has waned in recent years with the advent of TEP laparoscopic approaches to inguinal hernia repair, studies have shown no difference in short- or long-term outcomes between TAPP and TEP.<sup>36</sup>

The TEP approach to laparoscopic inguinal hernia repair is currently the most popular laparoscopic technique. This repair is performed entirely within the preperitoneal space and does not involve the peritoneal cavity when performed correctly. In this technique, the surgeon carefully develops a plane between the peritoneum posteriorly and the abdominal wall tissues anteriorly, thus insufflating the preperitoneal space. An incision is made inferior to the umbilicus, and the anterior rectus sheath on the ipsilateral side is incised. The rectus muscle is retracted laterally, and the preperitoneal space is bluntly dissected to allow placement of a balloon port to facilitate insufflation. Once the space has been insufflated, two additional ports are placed in the midline between the umbilicus and the pubic symphysis. In experienced hands, this approach provides for excellent visualization of the groin anatomy, and the dissection proceeds in a similar fashion to the TAPP. The TEP repair allows a large prosthetic mesh to be placed through a laparoscopic port into the preperitoneal space, and it is then positioned deep to the hernia defect to repair the hernia from a posterior approach.<sup>37</sup>

There are a few prospective, randomized data available to adequately judge short- and long-term results of the different laparoscopic inguinal hernia techniques. A systematic review by the Cochrane Collaboration in 2005 found that among the several nonrandomized trials, TAPP was associated with an increased rate of port site herniation and visceral organ injury.<sup>38</sup> This review concluded that there are insufficient data from prospective, randomized trials to make firm conclusions about the relative effectiveness of the TEP and TAPP procedures. A recent review published in 2015 studied 17,587 patients between 2009 and 2013 who underwent laparoscopic inguinal hernia repair, either TAPP or TEP.<sup>39</sup> There were no differences between intraoperative complications between TAPP and TEP. However, despite a higher rate of postoperative complications in TAPP versus TEP (3.97 vs 1.70, respectively), there were no differences in the reoperation rate for complications. When the increased rate of postoperative complications was further studied, it was found that these complications were more commonly associated with larger hernia defects, scrotal hernias, and

older age, all of which were seen more commonly in the TAPP repair group.

Furthermore, many reviews have shown no statistically significant differences in rates of recurrence and chronic groin pain between TAPP and TEP repair.<sup>36</sup> Two studies have shown that while there are increased rates of short-term postoperative pain with TAPP, there are no differences in pain with longer follow-up (after 180 days).<sup>40,41</sup> Thus, it can be concluded that the long-term outcomes between TAPP and TEP are comparable in terms of recurrence rate, chronic pain, and postoperative complications.

There are emerging data comparing laparoscopic techniques to open inguinal hernia repair, although the evidence is far from definitive. While there are multiple meta-analyses in the literature, only two truly compare the laparoscopic hernia technique with a tension-free open repair. A meta-analysis of 29 randomized trials in 2003 found that laparoscopic hernia repair was associated with earlier discharge from the hospital, quicker return to normal activity and work, and fewer postoperative complications than open repair.<sup>42</sup> However, in these data there was a trend toward an increase in the risk of recurrence after laparoscopic repair. A separate meta-analysis reviewing 41 published randomized trials found no significant difference in risk of recurrence between the two approaches.<sup>43</sup> Laparoscopic repair was associated with a quicker return to function and less postoperative pain, but also was found to have a higher risk of visceral and vascular injuries. A more recent multicenter, randomized trial that analyzed long-term hernia results in over 2000 patients in 14 Veterans Affairs hospitals found that laparoscopic hernia repair was associated with a higher recurrence rate among primary hernias, but was equivalent to open repair in recurrent hernias.<sup>44</sup> In all of these studies, the laparoscopic repair was noted to take more time in the operating room. Proper laparoscopic technique also appears to play a significant role in recurrence rates. In a randomized, multicenter trial comparing 665 TEP versus 705 Lichtenstein repairs with 5-year follow-up, authors initially found that the recurrence rate following TEP (3.5%) was significantly higher ( $P = 0.008$ ) than that following Lichtenstein (1.2%).<sup>45</sup> However, when they removed a single surgeon who was responsible for 33% of all the recurrences in the TEP group, the cumulative recurrence rate for TEP was lowered to 2.4% and was not statistically different from the Lichtenstein group. It has further been reported that there is a significant learning curve inherent in the laparoscopic approach when compared to open

approach.<sup>46</sup> Clearly, more definitive multicenter data from surgeons experienced in both procedures are needed to reach formal conclusions about the utility of both hernia approaches.

There have also been multiple studies looking at rates of chronic pain of laparoscopic versus open hernia repair. Chronic pain is one of the most common postoperative complaints after hernia surgery. A study in 2008 initially showed that TEP had increased rates of chronic testicular pain, while open repair had increased rates of impaired inguinal sensation.<sup>47</sup> However, a more recent randomized controlled trial showed that TEP had lower rates of long-term postoperative pain and exercise limitations at 1 year when compared with open Lichtenstein repair.<sup>48</sup>

A separate issue that deserves further study in laparoscopic hernia repair is the anatomical disturbance of the space of Retzius. This area, first described by Retzius in the 19th century, is the prevesical space located anterior and lateral to the bladder. Suprapubic prostatectomy is performed with dissection through this space, and this operation may be made more difficult following laparoscopic hernia repair.

## **SURGICAL COMPLICATIONS OF GROIN HERNIA**

Although groin hernia repair is associated with excellent short- and long-term outcomes, complications of the procedure exist and must be recognized.

### **Recurrence**

Recurrence of the hernia in the early postoperative setting is rare. When this does occur, it is often secondary to deep infection, undue tension on the repair, or tissue ischemia. Clearly, all of these etiologies raise the concern for a technical complication on the part of the surgeon, either in the handling of the groin tissues or the placement of mesh or suture. The patient who is overactive in the immediate postoperative setting may also be at risk for early hernia recurrence. It is thought that early exercise disrupts the suture or mesh in the repair before it has had an opportunity to hold tissue in place and promote scar tissue formation, leading to early recurrences. In the initial postoperative setting, patients may also develop seromas along the planes of

dissection as well as fluid in the obliterated hernia sac. These benign consequences of surgery must be differentiated from the more worrisome early recurrence.

Tension is an important, if not the primary, etiology of hernia recurrence. Tissues repaired under undue tension will tend to pull apart, even if sutures or mesh have been affixed to them. In addition, tension at the site of suture may lead to ischemia at the point where the suture pulls against the tissue, thereby further weakening the hernia repair. Sutures can also cut out or fall apart, especially if placed in a continuous fashion, when tensile force predominates. The role of excessive tissue tension in promotion of hernia recurrence is the basic rationale behind the modern, tension-free and increasingly suture-free hernia repairs advocated by hernia experts such as Lichtenstein and Rutkow.

The size of the hernia defect is proportional to the risk of hernia recurrence. Larger hernias have an increased rate of recurrence postoperatively. This is most likely due to the nature of the surrounding fascial tissues that are critical to the strength and reliability of the repair. As large hernias stretch and attenuate the surrounding fascial planes, these tissues are correspondingly weaker when repaired with suture or mesh. The weakened tissue may also be relatively ischemic at the time of hernia repair, although this has not been adequately studied.

An emergency operation for strangulated or incarcerated hernia may increase the risk of postoperative recurrence. This likely occurs due to the inherent inflammation, tissue ischemia, and fascial edema associated with the strangulated hernia, all of which provide an environment that causes the hernia repair to be placed through unhealthy tissue or at increased tension.

A hernia that is overlooked in the operating room also represents a potential etiology of hernia recurrence, although this should not be a major concern for the modern hernia surgeon. Most of the repairs in the current era emphasize the repair of both an indirect and direct defect through strengthening of the internal ring and inguinal canal floor, respectively.

A final etiology of hernia recurrence pertains to tobacco use and smoking. The relationship between smoking and hernia formation as well as recurrence was first reported in 1981. Further research has identified proteolytic enzymes that may degrade the connective tissue components, leading to weakened tissues and increased recurrences.<sup>49</sup>

## Infection

Infection of the hernia wound or mesh is an uncommon postoperative complication but represents another etiology of hernia recurrence. In specialized hernia practices, the incidence of wound infection following inguinal hernia operation is 1% or less. When an infection does occur, skin flora are the most likely source, and appropriate gram-positive antibiotics should be initiated. Patients who undergo mesh placement during groin herniorrhaphy are at a slightly higher risk of postoperative wound infection. It is often difficult to determine whether the mesh itself is infected or if just the skin or soft tissue anterior to the layer of mesh is infected. However, even if mesh is present, most postoperative groin hernia infections can be treated with aggressive use of antibiotics after the incision is opened and drained expeditiously.<sup>50</sup> Mesh removal in the acute setting is rarely indicated. When this is mandated, primary closure or redo herniorrhaphy with a synthetic tissue substitute may be warranted and a preperitoneal approach may be necessary. Chronic mesh infections will generally present as a persistent draining sinus; these will often require mesh removal for adequate treatment.

Seromas and hematomas are frequent complications in the postoperative setting. Seromas form in the dead space remaining from a wide dissection during the hernia repair or when fluid fills the distal remnant of the hernia sac. While the sac is often ligated or excised during open herniorrhaphy, it remains in place following laparoscopic repair, and the filling of the remnant sac with seroma-type fluid has been termed a pseudohernia. This must be differentiated from the more concerning complication of the early recurrent hernia. Defined fluid collections infrequently require drainage or aspiration, as most will reabsorb or drain through the incision on their own.

Hematoma formation must be assiduously avoided during groin hernia repair. This is especially true in the anticoagulated patient, and therefore it is recommended that patients temporarily stop taking aspirin and clopidogrel at least 1 week prior to their operation. Hematoma formation may be minor, leading only to ecchymoses and wound drainage. The ecchymosis often spreads inferiorly into the scrotal plane in a dependent fashion. The hematoma usually resolves in days to weeks following repair, and supportive management for pain control, including scrotal elevation and warm packs, is all that is required. On the other hand, a large volume of hematoma is concerning, as it may serve as a nidus for infection deep in the hernia wound

and may risk secondary infection of the prosthetic mesh. Additionally, hematoma formation following laparoscopic repair can result in a hemodynamically significant amount of blood pooling in the preperitoneal area. This is due to the fact that in laparoscopic repair, the space of dissection is more generous compared to open repairs, allowing more room for blood and fluid collections. Therefore, hemostasis at the end of a groin hernia repair is paramount to achieve effective wound healing.

## **INGUINODYNIA**

Chronic groin pain following inguinal hernia repair, termed inguinodynia, is defined as pain that persists greater than 3 months following repair. There are two forms of inguinodynia: nociceptive and neuropathic. Nociceptive groin pain stems from the foreign body sensation created by mesh implantation, while neuropathic groin pain is caused by direct nerve injury during repair or delayed structural changes in the nerves resulting from inflammation created by proximity to mesh. Inguinodynia is common in varying degrees following groin herniorrhaphy.<sup>51</sup> Often, neuropathic pain will follow the known dermatomal distribution of the regional nerves, including the ilioinguinal, iliohypogastric, genital branch of the genitofemoral nerve, and the lateral femorocutaneous nerves. Dermatomal mapping can be performed in the office to determine which nerves may be affected.<sup>52</sup> During open hernia repair, the ilioinguinal, iliohypogastric, and the genitofemoral nerves are most commonly injured, while the lateral femorocutaneous nerve or genitofemoral trunk is more commonly injured during laparoscopic herniorrhaphy. Nerve injury is usually due to entrapment of a portion of the nerve in the mesh or suture line placed in one of the soft tissue layers but can also be caused by tacks utilized for mesh fixation during laparoscopic repair.

Neuropathic pain following open repair can be prevented by meticulously identifying all three nerves and avoiding overt manipulation of the nerves during operative dissection. This helps to preserve the investing fascial layer of the nerves and reduces their risk of harm from exposure to the mesh. The ilioinguinal and iliohypogastric nerves are generally injured during elevation of the external oblique fascial flaps or during mesh fixation, while the genitofemoral nerve is most likely to be injured during the isolation of the cord and stripping of the cremaster muscle fibers. If the nerves have been mobilized and are found to be at risk for injury to their investing fascia, they

can then be intentionally sacrificed at time of surgery. The result of this maneuver is a region of sensory deprivation in the distributions of these nerve structures, namely, on the inner upper thigh and the hemiscrotum. However, the sensory deprivation is thought to be better tolerated by the patient than the chronic and persistent pain attributed to nerve entrapment in scar or mesh. In laparoscopic repair, nerve injury can be prevented by avoiding tack or staple placement below the iliopectic tract or in the region of the inguinal canal where the iliohypogastric and ilioinguinal nerves are susceptible to risk on the anterior side of the transversalis fascia.

Unlike neuropathic pain, nociceptive groin pain will generally not follow a dermatomal distribution. Patients will usually complain of a fullness or pressure in their groin, especially while bending over. Individuals who underwent repair with a mesh plug may be at increased risk for nociceptive groin pain due to the presence of the meshoma within the inguinal canal. CT or MRI can be obtained to help identify the presence of a meshoma, and surgery should be performed to remove the contracted piece of mesh.

Inguinodynia should first be managed conservatively, with attempts at local anesthetic injection in the affected groin. The injection of local anesthesia along the known course of a nerve serves as both a diagnostic and therapeutic maneuver. In some cases, temporary control of the chronic pain with local anesthesia may reduce or altogether eliminate the sequelae of chronic groin pain. For those who have initial but short-lived success with nerve injection, radiofrequency or nerve ablation may be attempted. When this conservative approach does not succeed, groin reexploration can be performed to ligate or excise affected nerve branches. This is clearly not the preferred first option, since the groin wound has abundant scar tissue, and previously undamaged nerve structures may be placed at additional risk. In those patients who do not fit a pattern of either neuropathic or nociceptive groin pain, surgery should be avoided as their chances of success are extremely limited. Instead they should be referred to physical therapy and a chronic pain practitioner for medical management of inguinodynia.

## **Bladder Injury**

The urinary bladder may be inadvertently injured during dissection of a direct inguinal hernia sac, but only rarely during repair of an indirect defect. The bladder can also participate in a sliding hernia, so that a portion of the bladder

wall is adherent to the sac in a direct defect. Because of the potential for this complication, direct sacs should be inverted into the peritoneal cavity so that excessive dissection can be avoided. If bladder injury takes place, the sac should be opened and the bladder injury repaired in two layers using an absorbable suture. Post-repair, a urethral catheter is generally placed for a minimum of 7 to 14 days.

## **Testicular Injury**

Testicular swelling and atrophy are seen after inguinal hernia repair. Edema of the scrotum or testis may be secondary to edema or hematoma of the inguinal canal that tracks inferomedially to the scrotum in a dependent fashion. Alternatively, a tender testicle or an atrophic testicle may be secondary to injury to the blood supply to the genitals during dissection and isolation of the cord. In most cases, this is not an emergency in the adult patient, and the testes will atrophy without significant infectious complications so that orchiectomy is rarely necessary. A testicle that is tender on examination may require ultrasonographic imaging to rule out testicular torsion or a corresponding abscess. Necrosis of the testes, a very rare complication of groin hernia repair, usually requires orchiectomy to avoid infectious complications.

In the pediatric patient, traction on the cord in the cephalad direction can cause the testes to migrate into the inguinal canal and out of the scrotum. For this reason, the scrotum is often prepped sterilely in the pediatric inguinal hernia operation, and the testes is confirmed to be in appropriate position by palpation at the end of the hernia repair. If the testes remain in the inguinal canal following herniorrhaphy, this may require manipulation of the testes further down the canal and into the scrotum using a long atraumatic forceps or a choker instrument.

## **Vas Deferens Injury**

Injury to the vas is a rare complication of groin hernia surgery in the male patient. Transection of the vas is the most serious form of this injury; this requires urologic consultation and likely immediate reanastomosis in the child or young adult, but may only require ligation of both ends in the older

adult patient. Minor injuries to the vas can be avoided by using gentle, atraumatic traction only and by avoiding complete grasping or squeezing of the vas. The most worrisome sequela of vas deferens obstruction or transection is the formation of antisperm antibodies in the serum, leading to infertility.

## THE STRANGULATED GROIN HERNIA

The strangulation of a groin hernia is a complication of the hernia itself rather than of a hernia repair. This pathophysiologic process is associated with a high rate of morbidity and mortality, especially in the elderly population with multiple comorbidities. The risk of strangulation is highest in the first months to years after the initial presentation of a reducible hernia. Gallegos and associates estimated the probability of inguinal hernia strangulation over time to be 2.8% over 3 months and 4.5% at 2 years.<sup>53</sup> It is likely that with time, the hernia contents weaken the hernia defect and widen the hernia neck so that the sac is no longer compressed as tightly, thereby decreasing the opportunity for incarceration and strangulation to take place.

The mortality from a strangulated hernia is related to the duration of the strangulation and the age of the patient. A longer duration of strangulation leads to a greater degree of tissue edema, ischemia, and risk of outright necrosis. Therefore, a strangulated hernia clearly represents a surgical emergency. The incarcerated hernia without overt signs of strangulation on examination and laboratory analysis should undergo attempts at reduction, often requiring conscious sedation to minimize discomfort. After the hernia is reduced, the repair can take place 1 to 2 days later, usually during the same inpatient hospitalization, to minimize risk of recurrent incarceration leading to strangulation.

Surgery for an incarcerated inguinal hernia is most often performed under general anesthesia given the high likelihood that bowel resection will need to be performed. Epidural or spinal anesthesia may suffice in select cases, but local anesthesia should not be employed. The location of the incision depends on the diagnosis and clinical assessment. In those patients who are unlikely to have ischemic bowel present within the hernia sac, an inguinal incision will likely be successful in both reducing the hernia contents and repairing the hernia defect. If nonviable bowel is found on exploration of the inguinal

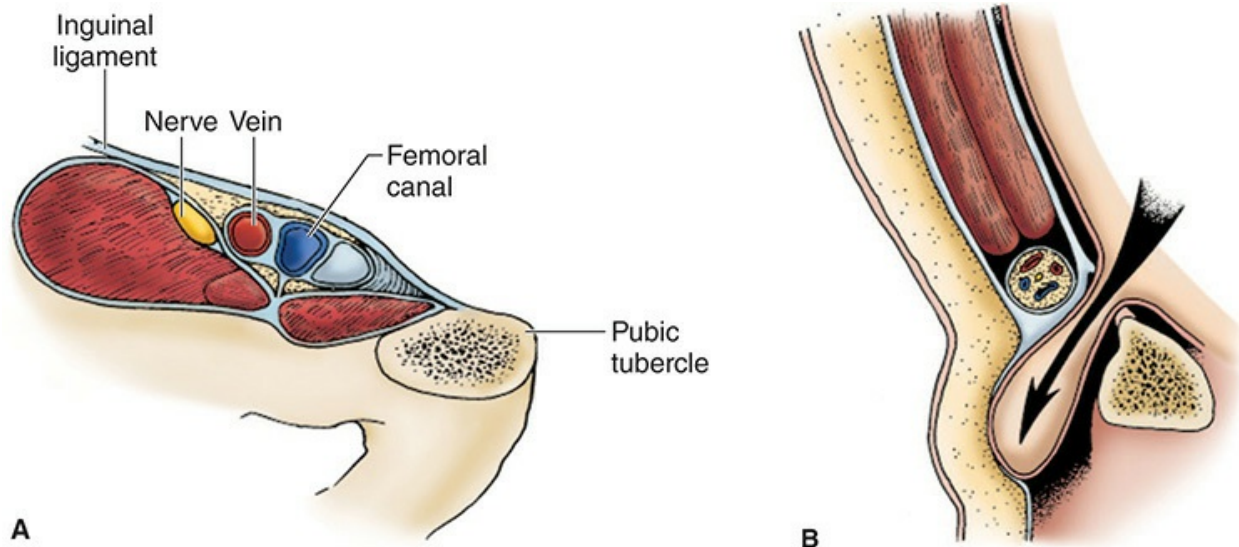

canal, the resection and anastomosis can take place deep to the transversalis fascia in the preperitoneal space, or a midline incision can be made. If the initial physical examination yields signs of ischemic bowel that may necessitate resection, a midline laparotomy can be performed and the hernia repaired in the inguinal canal using a tissue repair after the laparotomy is closed. A helpful alternative is the preperitoneal hernia repair, which can be used to evaluate the bowel and repair the hernia defect, yet can also be easily converted to an intraperitoneal exposure if extensive bowel resection and anastomosis is required. Placement of prosthetic mesh should be avoided when possible in strangulated hernia repair given the increased risk of bacterial translocation and wound infection.

## FEMORAL HERNIA

The femoral hernia is the second most common abdominal wall hernia, although it makes up only 5% to 10% of all hernias. The femoral hernia is more common in females than males, by a ratio of approximately 4:1.

### Anatomy and Etiology

Figure 11-6 illustrates the anatomy of the femoral hernia. The defect through which a femoral hernia occurs is in the medial femoral canal. The anterior boundary of this defect is the inguinal ligament, the lateral boundary the femoral vein, the posterior boundary the pubic ramus and Cooper's ligament, and the medial boundary the lacunar portion of the inguinal ligament. This space is obviously tight and does not have room to expand when hernia contents fill the sac, since the boundaries are either ligamentous, bony, or the fibrous femoral sheath and its vessels. Therefore, femoral hernias have a high propensity for incarceration and strangulation. Gallegos and associates have reported the cumulative probability of femoral hernia strangulation to be 22% in the first 3 months following diagnosis and 45% at nearly 2 years.<sup>53</sup> Therefore, repair of a known femoral hernia is mandatory to avoid this highly morbid complication.

**FIGURE 11-6** The anatomy of the femoral hernia. **A.** The structures posterior to the inguinal ligament. **B.** The femoral hernia passing through the femoral canal and bulging in the groin below the inguinal ligament.

In contrast to the inguinal hernia, the femoral hernia is unlikely to be of congenital etiology. The incidence of femoral hernia in infancy and childhood is exceedingly low, around 0.5%. In addition, there is no embryologic mechanism for a preexisting sac of peritoneum in the femoral canal. The hernia defect most often presents in middle-aged to older women, suggesting that the natural loss of tissue strength and elasticity is a primary etiology.

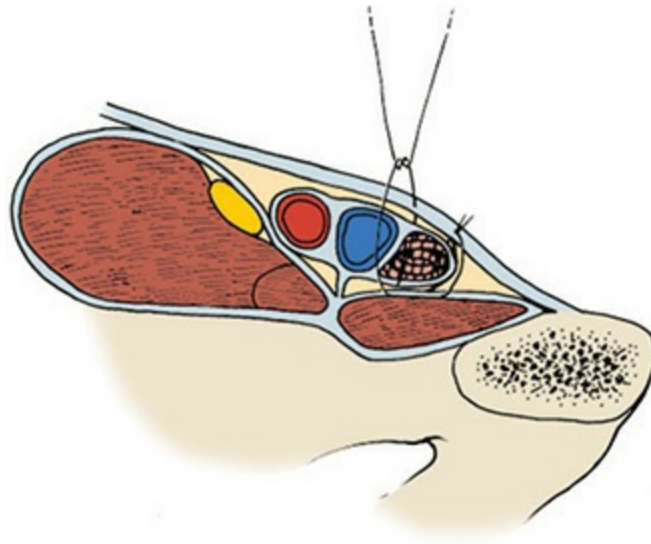

## Clinical Presentation

The femoral hernia often presents as a small bulge just below the medial groin crease. It is often difficult to reduce on initial presentation.<sup>54</sup> The hernia usually extends caudad as the sac increases in size with abdominal contents but may extend up and over the inguinal ligament anteriorly. Not uncommonly, the femoral hernia presents acutely with strangulation given its anatomic limitations. The differential diagnosis for a femoral hernia includes femoral lymphadenopathy, groin lipoma, or a soft tissue mass of benign or rarely malignant nature.

## Treatment

The operative approach to repairing the reducible femoral hernia differs from inguinal hernia repair in several ways. The incision is usually centered transversely just below the inguinal ligament, although a standard groin hernia incision may still afford exposure to the defect. The simplest approach is anterior to the inguinal ligament. Here, the sac can often be found, dissected, and reduced into the peritoneal cavity. Repair of the defect can be performed using a Cooper's ligament repair as described earlier, by affixing the transversalis fascia to the Cooper's ligament medially and the iliopubic tract laterally up to the internal ring. Alternatively, a simple suture repair can be performed by tacking the inguinal ligament anteriorly to Cooper's ligament posteromedially to close the defect. A third option is a purse-string suture placed first anteriorly into the inguinal ligament, then through the lacunar ligament medially, the pectineal ligament posteriorly, and finally through the fascia medial to the femoral vein and back to the inguinal ligament. All of these techniques can successfully close the femoral hernia defect.

A unique complication from suture repair of the femoral hernia defect is bleeding from an aberrant obturator artery. This vessel originates from the inferior epigastric rather than the internal iliac artery and traverses a space medial to the femoral hernia defect adjacent to the pubic ramus. The medial suture placed in femoral hernia repair can injure an aberrant obturator artery if present. A simple and possibly safer way to repair the femoral defect is a mesh plug placed from cephalad to caudad to obstruct the defect and promote scar tissue formation. This technique, shown in [Figure 11-7](#), has been reported by Lichtenstein with excellent results and low rates of recurrence.<sup>55</sup>

**FIGURE 11-7** The Lichtenstein polypropylene plug for repair of a femoral hernia.

If the femoral hernia sac is large and filled with voluminous intra-abdominal contents, a preperitoneal repair should be considered. In this way, the transversalis fascia is opened and the preperitoneal plane is entered. This approach is particularly useful during repair of a strangulated hernia since there is more space to allow for inspection of the bowel to ensure viability. Bowel resection, if needed, can also take place in the preperitoneal space prior to full reduction of the hernia contents.

Traditionally, femoral hernias have been repaired with an open primary suture repair. However, recently laparoscopic techniques are becoming more popular. Similar to inguinal hernias, femoral hernias can be repaired laparoscopically by a TAPP approach or a TEP repair. Both techniques are identical to the TAPP and TEP procedures for an inguinal hernia repair; in all of these repairs, the entire myopectineal orifice should be dissected out and covered with a large piece of mesh in the preperitoneal space. In addition, studies have shown that even laparoscopic approaches can be used to repair incarcerated femoral hernias safely and effectively.<sup>56</sup>

When comparing open to laparoscopic repair of femoral hernias, a large prospective cohort study in Denmark comprising over 3970 femoral hernia repairs showed that laparoscopic repair had lower risks of reoperation for a recurrent femoral hernia. The study also showed that laparoscopic repair had lower rates of developing an inguinal hernia at the incision site.<sup>57</sup> There were no differences in the rates of chronic pain between open and laparoscopic

repair. Therefore, the procedure of choice for femora hernia repair is a laparoscopic approach.

# PERSPECTIVE ON INGUINAL HERNIAS

*Parth K. Shah • Robert J. Fitzgibbons, Jr.*

## INTRODUCTION

In the 20th century the diagnosis and management of an inguinal hernia was based on the following 2 concepts: (1) all groin hernias should be repaired at diagnosis to prevent a hernia accident (defined as strangulation and/or bowel obstruction) and (2) the Bassini classical sutured repair or one of its modifications, such as the Shouldice technique, is the preferred operation by most surgeons. However, the past 25 years have seen a dramatic shift in many aspects of groin hernia management, including indications for surgery, replacement of the tissue repair with the prosthetic-based tension-free repair, and the application of laparoscopic and now robotic principles. In this chapter, we will try to emphasize some important concepts in the management of inguinal hernia as discussed by the authors and provide a different point of view in certain other areas.

## ETIOLOGY

Male gender, increasing age, and a family history of groin hernias are proven risk factors for groin hernias in adults.<sup>1,2</sup> Smoking, thoracic or abdominal aortic aneurysm, history of open appendectomy, and peritoneal dialysis have also been implicated as causes of hernia.<sup>1-3</sup> Intra-abdominal tumor, ascites, chronic obstructive pulmonary disease, chronic constipation, pregnancy, and chronic urinary retention may lead to progression. Surprisingly, the role of obesity does not seem to be as significant and may actually be protective.<sup>4,5</sup> At the molecular level, disorders of collagen metabolism in the extracellular matrix can lead to a decreased type I (strong) to type III (weak) collagen ratio. Similarly, abnormal protein metabolism related to the matrix metalloproteinases responsible for collagen degradation and restoration can lead to connective tissue disorders such as osteogenesis imperfecta, Marfan syndrome, and Ehlers-Danlos syndrome.<sup>6-9</sup>

Whether weight lifting is a risk factor remains controversial. A recent systematic review revealed inconclusive results about whether occasional heavy lifting, repeated heavy lifting, or a single strenuous lifting episode can lead to the development of groin hernia.<sup>10</sup> The fact that weight lifters do not have increased incidence of inguinal hernias supports this result.<sup>4</sup>

## **PREGNANCY AND GROIN HERNIA**

Pregnant patients occasionally present with a swelling in the groin that by physical examination appears to be an obvious inguinal hernia. Before recommending surgical correction, it is imperative that varicosities of the round ligament be ruled out by ultrasound. There have been multiple case reports and small series of pregnant patients undergoing groin exploration only to find this condition.<sup>11</sup>

## **DIAGNOSIS**

None of the currently available groin hernia classification systems have been accepted as a gold standard, and differentiating a direct from indirect hernia is now more of an exercise for medical students and trainees. Imaging helps differentiate an inguinal from a femoral hernia in clinically occult hernias, but significant operator variability mars the utility of ultrasonography in these cases. Studies support the use of magnetic resonance imaging (MRI) over

ultrasonography or computed tomography (CT) scan for such occult hernias.<sup>12</sup>

## **MANAGEMENT OF INGUINAL HERNIAS**

### **Watchful Waiting**

Historically, routine surgical repair soon after diagnosis has been the recommended treatment for an inguinal hernia based on the fact that managing an inguinal hernia electively is much simpler than managing a hernia accident emergently. This concept has now been challenged as randomized controlled trials have shown that patients with minimally symptomatic inguinal hernias can be safely watched and operation deferred. However, long-term follow-up studies have demonstrated that the majority of patients undergoing watchful waiting (WW) will cross over to surgery because of symptom progression. It must be emphasized that WW is not recommended for any femoral hernia because of the significant risk of hernia accident. WW is also not an option for females primarily because of the difficulty in accurately differentiating their femoral hernias from inguinal hernias by means of physical examination.<sup>13-16</sup>

### **Surgical Considerations**

#### **ANESTHESIA**

Despite the fact that local anesthesia is safer and results in less urinary retention, the vast majority of inguinal herniorrhaphies are performed under general or regional (epidural or spinal) anesthesia, as shown by epidemiologic data from Europe.<sup>17</sup> Currently, regional anesthesia is felt to be the least safe and is recommended only in unusual circumstances.

#### **SURGICAL TECHNIQUES**

Numerous named operations for the repair of an inguinal hernia can be found in the literature, making a detailed description of all of them impractical. Indeed, over 70 named nonprosthetic tissue repairs have been described since

Bassini introduced the concept in 1887.<sup>18</sup> In Table 12-1, we classify these various procedures based on the space they are performed in (anterior or preperitoneal), the type of repair (tissue or prosthetic), and whether they are conventional or robotic. Since most of the named operations are minor modifications of the established ones, representative procedures have been selected for Table 12-1 and are described in some detail below.

 **TABLE 12-1: SURGICAL REPAIR TECHNIQUES FOR INGUINAL HERNIAS**

	Nonprosthetic	Prosthetic
Conventional anterior	Marcy Bassini Maloney darn Shouldice McVay repair Desarda	Lichtenstein tension-free hernioplasty Plug and patch
Conventional preperitoneal		Anterior approach: Read-Rives Posterior approach: Wantz/Stoppa/Rives (also known as giant prosthetic reinforcement of visceral sac) Nyhus-Condon (iliopubic tract repair) Kugel/Ugahary
Combined anterior and preperitoneal prosthetic Laparoscopic/robotic inguinal herniorrhaphy		Bilayer prosthetic repair Transabdominal preperitoneal Totally extraperitoneal

**Anterior Repairs.** There are several steps common to all anterior repairs, whether prosthetic or nonprosthetic:

1. *Cutaneous incision:* Identification of the anterior superior iliac spine, symphysis pubis, and pubic tubercle.
2. *Incision of external oblique:* Exposure of the external oblique aponeurosis and incision through the superficial ring of the inguinal canal.
3. *Isolating the cord structures:* Lifting the cord structures from the inguinal canal at the pubic tubercle and then dissecting laterally to the deep inguinal ring, completely isolating the cord structures.
4. *Nerve disposition:* Routine division of the iliohypogastric and the ilioinguinal nerves is performed by some at this point but is not generally advised.
5. *Separation of the cremaster muscle from the sac:* The cremaster muscle is incised longitudinally for the length of the cord. If a lipoma of the cord is

found, it is removed.

6. *Isolation of the spermatic cord from the sac:* The cord should be dissected to determine if there is an indirect sac even if there is an obvious direct inguinal hernia. If an indirect sac is found, it should be ligated as proximal as possible and the distal end amputated. Many surgeons now prefer to simply reduce the sac back into the preperitoneal space, feeling that either opening or excising the sac is unnecessary.
7. *Reconstruction of the inguinal floor:* This step varies.
8. *Closure of the external oblique aponeurosis:* The external oblique aponeurosis is closed and the external ring is reconstructed.

### **Conventional Anterior Nonprosthetic Repair**

***The Marcy Repair.*** This simple repair is for children and adolescents. It involves high ligation of a hernia sac and narrowing of the internal ring by suturing the muscular and fascial layer to displace the cord structures laterally.

***The Bassini Repair.*** Traditionally the essential step in reconstructing the inguinal floor in the Bassini operation has been that “the canal is repaired by interrupted sutures affixing the transversalis fascia medially to the inguinal ligament laterally.” Perhaps a more accurate description would be to substitute the term “triple layer (transversalis fascia, transversus abdominis muscle, and the internal oblique muscle)” for “transversalis fascia” because this step is considered the reason for the extremely low recurrence rate reported. When the procedure was exported to North America, the transversalis fascia was not opened for fear of bladder or vascular injury in favor of a “good stuff to good stuff repair,” probably accounting for the poorer results. The Bassini repair and its numerous modifications have now been shown to have a higher recurrence rate than tension-free prosthetic repairs in population-based studies and meta-analyses.<sup>19-22</sup>

***The Maloney Darn.*** This operation is of historical interest because it involves the use of several continuous rows of monofilament nonabsorbable polypropylene sutures between the “conjoint tendon” and the iliopubic and the inguinal ligament, in effect constructing a lattice. It is considered the precursor of the prosthetic repairs but is rarely used today.

***The Shouldice Operation.*** The 4 suture line repair is now considered the gold standard tissue repair, with a comparable recurrence rate as the prosthetic repairs when performed in specialty clinics.<sup>23,24</sup>

***McVay Cooper Ligament Repair.*** This is a tissue repair that addresses femoral hernias. Beginning at the pubic tubercle, sutures are placed between the transversus abdominis arch and the Cooper ligament until the femoral vein is reached. The femoral canal is closed by transition sutures between the Cooper ligament and the femoral sheath. The repair is then continued laterally along inguinal ligament as in the Bassini operation. A relaxing incision in the anterior rectus sheath is always used. Increased pain and recurrence due to the tension in this repair are not uncommon.

***Desarda Repair.*** This tissue repair, which is based on suturing a flap of external oblique aponeurosis to the inguinal ligament, has gained a following among certain groups of surgeons and patients.<sup>25-27</sup>

### **Conventional Anterior Prosthetic Repair**

***Lichtenstein's Tension-Free Hernioplasty.*** The transversalis fascia is not opened in this repair, but a large space is created beneath the external oblique aponeurosis extending from a point 2 cm medial to the pubic tubercle and extending laterally to the anterior superior iliac spine. This space is then bridged by suturing a large prosthesis (13 × 8 cm or greater) at least 2 cm medial to the pubic tubercle to the anterior rectus sheath, and then the same suture is continued in a locking fashion securing the inferior edge of the prosthesis to either side of the pubic tubercle and then the inguinal ligament and tied at the internal ring. The mesh is then slit laterally to accommodate the cord structures to create 2 tails. The wider superior tail and narrower inferior tail are tucked underneath the external oblique aponeurosis to the level of the anterior superior iliac spine with the superior tail overlapping the inferior. A single interrupted suture through the lower edge of the upper tail, the lower edge of the lower tail, and the shelving edge of the inguinal ligament creates a shutter valve around the cord, which also causes a domelike buckling effect over the direct space, thereby preventing tension in upright position. Loose interrupted sutures are used to secure the superior and medial edges to the internal oblique muscle and anterior rectus sheath,

respectively. An additional suture between the posterior surface of the mesh and the Cooper ligament is used to secure any concomitant femoral hernia.

***Plug and Patch Technique.*** As mentioned by Liu and colleagues, the plug is fixed with 3 to 4 interrupted sutures and the patch positioned in a sublay technique without additional fixation. We concur completely that these mesh plugs can occasionally be responsible for postherniorrhaphy groin pain and have to be explanted.

**Conventional, Preperitoneal, Nonprosthetic Repair.** The Nyhus-Condon repair was based on the importance of the iliopubic tract and is of historical interest only.

**Conventional, Preperitoneal, Prosthetic Repair.** Theoretically, intra-abdominal pressure should cause better apposition between a prosthesis and the abdominal wall because the device is on the abdominal side of the musculoaponeurotic structures of the groin, resulting in a lower recurrence rate compared to the anterior approaches. However, the recurrence rate has now become so low with any of the modern prosthetic approaches that this consideration is no longer valid.

***Anterior Approach (Read-Rives).*** In this procedure, the prosthesis is placed in the preperitoneal space deep to the inferior epigastric vessels and is secured with 3 sutures placed at the pubic tubercle, at Cooper ligament, and in the psoas muscle laterally. Parietalized cord structures are then replaced over the closed transversalis fascia.

***Posterior Approach (Stoppa).*** Also known as giant prosthetic reinforcement of visceral sac (GPRVS), in this approach, a large permanent prosthesis is used to reinforce the preperitoneal space over the weakened transversalis fascia, giving an extensive overlap of the Fruchaud myopectineal orifice and making the type of hernia (direct, indirect, or femoral) repaired irrelevant.<sup>28</sup> Stoppa favored this approach for bilateral inguinal hernias and used a chevron-shaped prosthesis that was only secured at its superior border with 3 sutures from medial to lateral near the linea alba, semilunar line, and anterior superior iliac spine. Wantz is credited with popularizing a unilateral version.<sup>29</sup>

***Kugel/Ugahary.*** Kugel repair involves using a specially designed deformable prosthesis that can be inserted through a small incision made above the internal ring, which springs open in the preperitoneal space to provide a wide overlap of the myopectineal orifice. An initial version of the prosthesis was recalled because the memory recoil ring, which opens the patch after it has been inserted into the preperitoneal space, would occasionally break, resulting in serious complications such as bowel perforation. The memory ring was subsequently redesigned. Ugahary repair allows a wide overlap with mesh inserted in the preperitoneal space through a small incision kept open using special retractors.

A transrectus sheath extraperitoneal procedure (TREPP), a transinguinal preperitoneal procedure (TIPP), and the Onstep procedure are some other popular modifications, but they will not be described in detail here.<sup>30</sup>

### **Combined Anterior and Preperitoneal Prosthetic Repair**

***Bilayer Prosthetic Repair.*** A specially designed dumbbell-shaped bilayered prosthesis made of polypropylene is used, with one layer in the preperitoneal space to overlap the direct and indirect space as well as the Cooper ligament and the other in the conventional extraperitoneal space. It is secured with sparse interrupted sutures at the pubic tubercle, midpoint of the inguinal ligament, and internal oblique muscle. The concern with this technique is that because both the anterior and posterior spaces are violated, repair of a recurrent hernia may be compromised.

***Laparoscopic Repairs.*** The laparoscopic repairs are technically more demanding, and initial results with the procedures were sometimes less than desirable. This was due to a number of technical reasons including incomplete dissection, missed hernias, insufficient size of the prosthesis or an insufficient overlap of the prosthesis over the hernia defect, mesh migration and improper fixation in cases where fixation was needed, and most importantly, a limited surgeon experience with the technique.

As experience has been gained, these problems have been solved, and the operations are increasing in frequency. This trend will probably continue as new trainees enter the market. The best indications include recurrent hernias where the preperitoneal space has not been previously dissected, bilateral hernias where the repair of both sides can be performed through the same

access sites, in association with another laparoscopic procedure performed at the same time, and in patients with sliding hernias, especially when reducible.<sup>31,32</sup> Relative contraindications include previous surgery in the retroperitoneal space, intra-abdominal adhesions, scrotal hernia, incarcerated inguinoscrotal hernia, and the presence of ascites. A systematic review of literature revealed that the operative time was increased with a laparoscopic repair, but less postoperative pain promoted a faster return to usual activity.<sup>33</sup> The intraperitoneal onlay mesh (IPOM) repair, the only true minimally invasive laparoscopic groin hernia repair, is now rarely performed, which is somewhat surprising given its popularity for ventral/incisional hernia.

***Transabdominal Preperitoneal (TAPP).*** The TAPP and total extraperitoneal (TEP) procedures are identical in the way the repairs are ultimately accomplished. The only difference is the method of entrance into the preperitoneal space. For the TAPP, a conventional laparoscopy is performed, and then the peritoneum is divided beginning at the medial umbilical ligament about 2 cm above the hernia defect and extending laterally in a horizontal direction toward the anterior superior iliac spine. A radical dissection of the preperitoneal space is then accomplished exposing the inferior epigastric vessels, Cooper ligament, and the symphysis pubis, reducing the direct or indirect sacs as they are encountered. It is important to adequately mobilize the inferior peritoneal flap away from the internal spermatic vessels and the vas deferens to prevent roll up of the prosthesis when the peritoneum is eventually closed. Dissection inferior to the iliopubic tract laterally should be minimized to avoid neurovascular injuries.

Indirect sacs are more difficult to deal with because of the difficulty in separating them from the cord structure, especially in chronic hernias. A large inguinoscrotal sac does not need to be removed in its entirety and can be divided at a convenient point along the cord structures with the proximal side ligated and the distal side left widely opened to avoid the excessive incidence of hydrocele and vascular disruption in the distal cord that could lead to various testicular complications. The robotic modification of this technique is becoming increasingly popular. In addition to the improved 3-dimensional optics, because manipulations are made at the tips of the robotic instruments, there is less torqueing at the laparoscopic cannula sites, which might translate into less pain.

Most surgeons now prefer a larger prosthesis and fewer fixations with

tacks to lessen postoperative pain. Care should be taken to avoid the Triangle of Doom (site of femoral vessels medially inferior to the iliopubic tract) and the Triangle of Pain (site of lateral cutaneous nerve of thigh or branches of genitofemoral nerves laterally inferior to the iliopubic tract).

***Total Extraperitoneal (TEP).*** An incision is made at the umbilicus, as if one were planning to perform open laparoscopy. The rectus sheath is opened on one side, and the rectus muscle is retracted laterally. Blunt dissection is then begun in the space between the rectus muscle and the posterior rectus sheath with or without the use of a dissecting balloon. Once the space is large enough, 2 additional cannulas are placed in the midline, one approximately 5 cm above the symphysis pubis and the other midway between the umbilicus and the symphysis pubis. The dissection of the preperitoneal space is completed under direct vision. The rest of the procedure is identical to the TAPP. Although literature generally favors TEP over TAPP for avoiding the complications associated with entering the peritoneal cavity, including visceral or vascular injury, adhesion formation, and trocar site hernias, there are insufficient data to conclude whether TAPP or TEP is superior. The choice is largely based on the surgeon's comfort level and background training.<sup>34,35</sup>

## Sports Hernias

The term *sports hernia* is confusing because, by definition, although presenting with typical symptoms of an inguinal hernia, patients with this condition do not have a hernia either by physical examination or imaging studies; hence, a much better term is *athletic pubalgia*. The exact pathogenesis is more a matter of speculation than fact, but most agree that shear force across the pubis leads to stretching or tearing of the rectus muscle and/or the musculoaponeurotic structures that make up the inguinal canal.<sup>36</sup> It should be treated surgically only after all attempts at conservative management with analgesics and anti-inflammatory medications, physical therapy, and core strengthening exercises have failed.

Operations similar to a Bassini anterior approach without mesh, involving tightening various attachments around the pubis through imbrication of the inguinal floor to the inferolateral border of the rectus abdominis, pubis, and inguinal ligament and reattachment of the inferolateral edge of the rectus

abdominis muscle to the fascia of the pubis and anterior ligaments, have been recommended.<sup>37</sup> A prospective cohort study has reported excellent results with earlier return to sporting activity with a laparoscopic preperitoneal operation with mesh.<sup>38</sup> This has also been reported in other smaller series. However, many authorities question these results because the preperitoneal approach does not address the basic pathology, which is disruption of the attachments noted earlier.

# VENTRAL AND ABDOMINAL WALL HERNIAS

*Andrew Bates • Mark Talamini*

## INTRODUCTION

The term *hernia* is used to describe a weakness or defect of the abdominal wall, through which abdominal contents can protrude. It is important to note the distinction between the *hernia defect* and *hernia contents*, as surgical repair is generally more concerned with the former, with a few exceptions. Abdominal wall defects arise at areas of weakness in the abdominal wall. These areas include sites of previous surgery, the umbilicus, as well as areas of weakened abdominal and/or flank musculature such as in lumbar hernias.<sup>1</sup>

Patients may unknowingly have an abdominal wall or fascial defect that only becomes apparent after intraabdominal or preperitoneal contents pass through the hernia defect. This is especially true of umbilical hernias, which are the most common type of ventral abdominal hernia.<sup>2</sup>

# UMBILICAL HERNIA

The umbilicus is a natural area of weakness in the anterior abdominal wall. Located in the linea alba, it is technically a scar, located at the point of passage of the umbilical vessels through the abdominal wall while in utero. The fascial edges of the hernia develop by the third week of gestation, with the umbilical cord developing by week five. The extra-abdominal rotation of the intestine occurs between the sixth and tenth weeks of gestation, with fascial defect fusing thereafter. A hernia occurs after this area fails to close or later stretches and reopens as an adult. These hernias have been documented as early as the ancient Egyptians, with the first known repair occurring in the first century AD by Celsus. The first series of primary suture repairs were reported by Mayo in 1901,<sup>3</sup> a technique that largely remains consistent today for small defects.

## Incidence

A wide estimated range of neonatal incidence exists for umbilical hernias. In Caucasian babies, the reported incidence is 10% to 30%. For unknown reasons, the incidence in African-American children is higher. Prematurity and family history of umbilical hernia are known risk factors.

The vast majority of congenital umbilical defects close as infants grow into early childhood. In fact, once children are entering school age, only about 10% of previously diagnosed defects remain on physical exam. For this reason, most pediatric surgeons recommend deferring repair for uncomplicated umbilical defects. The current recommended age for surgical repair in the pediatric literature is at least 2 to 3 years, with many surgeons advocating for even later.

Umbilical hernias diagnosed in adulthood tend to be acquired in nature, and therefore it is more difficult to establish a true incidence. A female predominance exists, with a female:male ratio of 3:1. Also, medical comorbidities or physiologic factors that increase intraabdominal pressure confer a higher incidence of umbilical hernia.<sup>2</sup> These include pregnancy, obesity, abdominal ascites, chronic obstructive pulmonary disease, or persistent bowel distension or obstruction. In the adult patient, hernia formation seems to be the result of repeated stress on an already vulnerable

area.

## Clinical Manifestations

An umbilical hernia is typically not difficult to diagnose, and the list of differential diagnoses is short. On physical exam, the practitioner will appreciate a soft mass overlying or adjacent to the umbilicus. Most hernias are reducible and contain only preperitoneal fat or omentum, although some may contain bowel, and caution should be exercised when attempting reduction. In most cases, the fascial defect can be palpated and the defect size estimated. While uncommon, other conditions at the umbilicus may mimic a hernia; an abdominal wall varix, granuloma, or peritoneal tumor implant (Sister Mary Joseph's nodule) all can be misdiagnosed as an umbilical hernia.

Most umbilical defects do not warrant surgical repair since the majority are small and asymptomatic. However, if the defect is causing discomfort, increasing in size, obstructing bowel, or compromising the overlying skin, surgery is indicated. Many patients will request repair upon hearing they have a previously unknown hernia; in these cases, the patient should be counseled appropriately by an experienced surgeon.

Umbilical hernias secondary to chronic liver failure and ascites represent a special circumstance. First, any Childs classification confers a higher risk of postoperative mortality and morbidity. Second, in this patient population, the risk of hernia recurrence is significantly elevated.<sup>4</sup> Furthermore, the risk of prosthetic mesh infection, if used, is higher. For these reasons, surgical repair in these patients should be reserved for cases of acute incarceration or progressively symptomatic hernias. These patients should have an explanation of the full spectrum of surgical risk prior to deciding on a treatment.

## Treatment

In the patient with a small umbilical hernia, a short curvilinear incision is made just inferior to the umbilicus. Dissection is carried through the subcutaneous tissues and down to the fascial level. The neck of the sac is then encircled with a hemostat. After the sac is dissected free of its umbilical skin attachments, it can be reduced or inverted completely into the peritoneal

cavity or incised to explore the contents of the hernia sac. In this way, the redundant portion of the sac can be excised using electrocautery. The fascial defect is then closed transversely with interrupted sutures in an interrupted, figure-of-eight, or horizontal mattress fashion. The skin of the umbilicus is tacked to the fascia layer using a single absorbable suture. This operation is usually performed under local, local with sedation, or general anesthesia depending on patient factors and the size/morphology of the defect. The traditional “vest-over-pants” technique originated by Mayo<sup>3</sup> is less commonly utilized since overlapping fascial closures have been shown to weaken the overall wound strength in hernia repair.

In large defects where fascial reapproximation results in significant tension, a prosthetic mesh may be used.<sup>6</sup> Mesh cones were used in the past but are generally not recommended currently due to risk of migration and recurrent hernia. Composite meshes that are made with protective bioabsorbable layers allow for the mesh to be placed as an underlay in the peritoneal cavity with significant, usually 4 to 5 cm, fascial overlap in all directions. An overlay mesh with uncoated synthetic mesh is also an option to help reinforce the fascial closure. The techniques utilizing prosthetic mesh, including retrorectus and preperitoneal mesh placement, are described in more detail later in the chapter.<sup>5</sup>

## INCISIONAL HERNIA

### Incidence

Incisional hernias have been reported in 10% to 20% of patients following laparotomy, with at least one-third of these patients presenting 5 to 10 years postoperatively. It is estimated that over 100,000 incisional hernia repairs are performed in the United States alone.<sup>7-10</sup> Unsurprisingly, the rate of incisional hernias is lower following minimally invasive surgeries. Recent data have suggested the means of fascial closure following laparotomy greatly influences the rate of incisional hernia repair, with the traditional “1 cm bite, 1 cm travel” producing higher levels of tissue ischemia than a “small, frequent bite” technique. This technique also limits the degree of fascial disruption during normal patient motion. Transverse laparotomies, although rarely performed in the adult population, may also protect against

incisional hernia, possibly due to the two-layer fascial closure and the robust vascularity of the rectus muscles.<sup>11,12</sup>

Multiple risk factors for incisional hernia have been identified, including obesity, wound infection, diabetes, smoking, immunosuppression medication, ascites, advanced age, and poor nutritional status. Many of these factors predispose to an environment of relative ischemia or deficiency in macromolecules necessary for wound healing. Wound infection has the strongest association with a subsequent hernia, and as such, most surgeons advocate for early reopening and drainage of infected surgical wounds to improve healing.<sup>13–16</sup>

Normal wound healing produces long-term collagen deposition and remodeling that maintain the strength of the scar. However, the resulting mature scar is only 80% as strong as the native presurgical fascia. Thus, every surgical wound represents an area of relative weakness that can be exacerbated over time with repeated strain.

## Clinical Manifestations

Most patients with an incisional hernia will present with a palpable bulge underlying a previous abdominal incision.<sup>7</sup> The hernia may present with varying degrees of discomfort. Occasionally, the patient may also voice cosmetic concerns as the hernia becomes increasingly protuberant. Some patients may present acutely with an incarcerated hernia or symptoms of a bowel obstruction such as nausea, vomiting, or obstipation. Less commonly, the overlying skin may be subject to an increasing degree of pressure secondary to the hernia, possibly compromising the dermal vascular plexus leading to “paper thin” skin or skin erosion.

On physical examination, the hernia sac should be palpable, and depending on morphology, an attempt should be made to approximate the fascial edges. Examination can be significantly impaired by an obese body habitus. It is especially important to examine the entirety of the abdominal wall, especially along the same incision, to identify other occult defects which are often present.

Extremely large incisional hernias may present with a large proportion (25% or more) of the abdominal viscera within the hernia sac, a condition commonly referred to as “loss of domain.”<sup>17,18</sup> These hernias typically have a

fascial defect greater than 10 cm in diameter. Multiple physiologic changes occur in these patients as a result, most notably musculoskeletal, alimentary, and pulmonary dysfunction. The position of the bowel within the hernia sac leads to chronic venous and lymphatic congestion as well as chronic bowel dilation. Over time this leads to bowel thickening, congestion, and dysfunction. The weight of the hernia sac coupled with the disruption of the abdominal core muscles also predisposes to a hyperlordosis of the lumbar spine that can lead to chronic back pain. Lastly, the drop in intraabdominal pressure that results following extra-abdominal migration into the hernia sac alters the normal pulmonary mechanics and physiologic pressures that drive respiration. Many of these patients require intensive pulmonary care.

## **Treatment**

The treatment of ventral hernias has undergone significant changes in the past 20 years, driven by advances in technology, materials, and “rediscovered” surgical techniques such as the classic retrorectus repair popularized by Rives and Stoppa.

### **MESH SELECTION**

Incisional hernias are, by definition, areas of poor fascial healing and weakness. Therefore, for most clean cases, prosthetic mesh is recommended. The material used will ultimately depend on the location of mesh implantation and the degree of possible contamination.<sup>19</sup> For example, synthetic polypropylene should not be used in the peritoneal cavity due to the risk of fistulization or adhesion to the bowel. Also, permanent synthetic mesh, at this time, is not recommended in contaminated cases.

Biologic meshes have been used in contaminated fields as an alternative to synthetic mesh. However, current data show higher rates of wound complications and hernia recurrence with biologic mesh compared to synthetic mesh. Biologic meshes also carry greatly increased material cost. Absorbable mesh, such as Vicryl, is a much cheaper temporary solution in contaminated fields.<sup>19</sup>

Synthetic meshes are available in a variety of materials, sizes, and weight. The most commonly used materials are polypropylene, polyester, and ePTFE. Large-pore mesh offers decreased surface area to harbor infection but retains

significant strength. Recent data have shown acceptable rates of mesh infection, about 6%, when lightweight, macroporous polypropylene was used in clean-contaminated fields, although this remains controversial. Composite synthetic meshes are also offered with a protective visceral coating that allows safe placement in the peritoneal cavity.<sup>19–21</sup>

## MESH LOCATION

The various positions for mesh placement are listed in [Table 13-1](#).<sup>5</sup> The common theme underlying mesh placement is complete defect coverage with wide fascial overlap. Intraperitoneal placement is performed easily but suffers from high rates of mesh migration, and due to decreased tissue ingrowth, higher mesh infection rates. Preperitoneal and retrorectus positioning benefits from the increased vascularity of their respective spaces, as well as decreased fixation requirement, but requires more dissection to perform. Onlay mesh placement requires the elevation of lipocutaneous flaps and has higher rates of surgical site occurrences, but has experienced a resurgence in recent years as it is best suited for uncommon hernia sites such as the flank.

**TABLE 13-1: MESH POSITIONING**

<b>Mesh Position Nomenclature</b>	<b>Anatomic Location</b>
Onlay	Anterior to anterior rectus fascia
Retrorectus/sublay	Posterior to rectus abdominis muscle/ anterior to posterior rectus fascia
Preperitoneal	Posterior to posterior rectus fascia/anterior to peritoneum
Intraperitoneal	Posterior to peritoneum

Most laparoscopic repairs involve intraperitoneal onlay mesh (IPOM) placement, with good results. However, increasing numbers of surgeons have begun to use minimally invasive techniques to place mesh in the preperitoneal or retrorectus position.

## **OPEN REPAIR—UNDERLAY**

The traditional open repair, using prosthetic mesh, utilizes an overlay mesh position with multiple points of transfascial fixation with nonabsorbable sutures.<sup>22,23</sup> An incision should be made in the previous abdominal scar (excising the scar, if necessary) and dissecting down to the hernia sac. Great care should be taken when entering the hernia sac, as abdominal viscera might be adhered to the parietal peritoneum. Once the peritoneal cavity is entered, all intraabdominal adhesions should be mobilized at least 5 cm away from the fascia defect.

A mesh approved for intraperitoneal placement, such as composite meshes or ePTFE, should be selected and appropriately sized for the defect, allowing for at least 4 cm fascial overlap on all sides. The mesh should be secured to the fascia using several interrupted nonabsorbable sutures around the perimeter of the mesh. Once all sutures are placed, the mesh should be significantly taut so that defect closure, if feasible, does not produce inappropriate laxity in the prosthetic. If fascial closure is not possible, it is important for the mesh to be taut so as not to produce a “pseudorecurrence” of a bulging prosthetic through the open hernia defect.

Multiple layers of tissue, including Scarpa’s fascia and subcutaneous fat, should be closed over the mesh to help protect the prosthetic from infection.

## **OPEN REPAIR—RETRORECTUS**

The classically described retrorectus repair was independently developed by Jean Rives and Rene Stoppa in the 1960s. While technically more demanding, the repair benefitted from a two-layer fascia closure as well as placement of the prosthesis within the highly vascular retrorectus space, which promotes more robust tissue ingrown in the mesh and protection from infection.<sup>24–26</sup> This technique was initially abandoned by minimally invasive surgeons with the rise of intraperitoneal onlay mesh placement, but the more recent growth in robotic surgery has led to the adoption of retrorectus dissection using minimally invasive techniques.

The abdomen is entered in a similar fashion as for the onlay technique. However, it is also possible to accomplish the dissection without violating the peritoneal cavity at all. The medial edge of the rectus sheath is identified and incised, and this incision is extended along the length of the hernia defect.

The rectus abdominis muscle should then be easily identified and its fibers bluntly swept anteriorly. This plane should be developed laterally to the lateral border of the rectus sheath, taking care not to injure the neurovascular bundles penetrating the muscle. Once this dissection is completed on both sides of the defect, the two sides are connected in the upper and lower midline. The posterior fascia can then be closed using a running absorbable suture. An uncoated medium-weight mesh is then selected and sized to fit on top of the posterior closure. Although no fixation is absolutely necessary, if such fixation is desired, transfascial nonabsorbable sutures can be secured to the mesh and brought through the anterior sheath. Once the mesh is in place, the anterior sheath is then closed using either permanent or slowly-absorbing suture.

## **ANTERIOR COMPONENT SEPARATION**

“Separation of components” was first described by Ramirez in 1990<sup>27</sup> as a method for increasing laxity of the abdominal fascia to achieve tension-free midline closure. The original description of the technique did not include the use of mesh. However, since then, the component separation has been coupled with underlay mesh or the retrorectus technique to allow for midline closure along with prosthetic reinforcement.

To start the procedure, the anterior fascia is identified and secured. The plane between the anterior fascia and the subcutaneous tissues is then incised and large lipocutaneous flaps are developed. This is continued lateral to the rectus sheath. The lateral border of the rectus sheath is then manually identified and a superficial fascial incision is made 1 to 2 cm lateral to the rectus sheath. This incision should only divide the external oblique aponeurosis. Once in this space, a clamp can be used to assist in extending the division the entire craniocaudal length of the hernia defect. The procedure should then be completed on the opposite side.<sup>27</sup>

With the anterior component separation, the surgeon can achieve up to 10 cm of fascial advancement on each side. However, the creation of large lipocutaneous flaps does predispose the patient to wound complications such as seroma, abscess, and skin necrosis. Most centers consider active tobacco use an absolute contraindication, and most require a hemoglobin A1c less than 7.<sup>28</sup>

## **POSTERIOR COMPONENT SEPARATION**

The posterior component separation, or transversus abdominis release (TAR), was developed by Yuri Novitsky and Michael Rosen as a solution to the wound morbidity and mesh limitations of the anterior component technique.<sup>29,30</sup> The technique creates an “extension” of the retrorectus plane developed in the Rives–Stoppa repair, allowing for mesh placement posterolateral to the psoas muscle as well as creating fascial advancement by releasing the attachment of the transversus abdominis muscle.

Once the retrorectus space has been developed in the previously described Rives–Stoppa repair, the posterior lamella of the internal oblique aponeurosis (above the arcuate line) is then incised approximately 1 cm medial to the neurovascular bundles along the length of the hernia to expose the transversus abdominis muscle fibers. These fibers are divided superiorly and inferiorly to then enter the preperitoneal space. This plane can then be bluntly developed by sweeping the transversus abdominis fibers laterally to create an appropriately-sized mesh pocket. Any holes in the peritoneum or fascia should be closed with absorbable suture.<sup>30</sup>

The posterior fascia is then closed at the midline using a running absorbable suture. After the prosthetic mesh is placed, it can be fixed using transfascial sutures, biologic glue, or nothing at all. The anterior fascia is then closed over the mesh using running suture. Some practitioners advocate for the placement of drains within the retrorectus space, although their utility and safety have been questioned.

## **LAPAROSCOPIC INTRAPERITONEAL REPAIR**

The first laparoscopic ventral hernia repair was described in 1993 and utilized ePTFE fixed to the abdominal wall with staples. Since then, while the basic technique has not significantly changed, multiple advances have been made with mesh materials and fixation techniques.<sup>31–34</sup>

In order to repair midline defects, the abdomen is typically accessed through lateral ports on the right or left side of the abdomen. The abdominal wall is then completely cleared of all adhesions in the area of the hernia repair. The defect is then measured and an appropriately sized mesh is selected to allow for at least 4 cm of fascial overlap post-repair. The selected mesh must be safe for contact with abdominal viscera. Composite meshes or

ePTFE are all suitable but each material has its own set of drawbacks and limitations. While many fixation techniques have been used, we believe that a moderate amount of transfascial fixation is necessary to prevent mesh migration. It is important to note that the peritoneum is a mobile structure lacking in tensile strength, and should not be relied upon for permanent mesh fixation.

At least four nonabsorbable sutures should be preplaced at the cardinal points of the mesh prior to insertion into the abdomen. Once in the abdomen, the mesh should be unfurled and each transfascial suture should be brought out through a small skin incision or puncture using a suture passer. Once all sutures are in place, the mesh can then be “parachuted” up to the abdominal wall and tied down to the fascia. A “double ring” or “double crown” of tacks can then be used to flatten the mesh against the wall and eliminate any gaps along the edge.

Closure of the defect prior to mesh insertion is preferable, although not required. Current data show that primary closure does not affect recurrence rates but may reduce postoperative seroma formation.

## **SPIGELIAN HERNIA**

A Spigelian hernia occurs along the linea semilunaris, where the aponeuroses of the oblique and transversus abdominis muscles fuse just lateral to the rectus sheath.<sup>35</sup> Spieghel originally described this fascia as a zone of transition between the posterior rectus sheath and the lateral abdominal wall musculature. The linea semilunaris varies in width along its craniocaudal extent, becoming widest where it intersects the arcuate line just below the level of the umbilicus. Because of this widening, Spigelian hernias occur more frequently (~90%) at this location where the fascia may be more attenuated<sup>35</sup> (Fig. 13-1). Spigelian hernias in the upper abdomen are rare and typically represent mislabeled lateral incisional hernias.

**FIGURE 13-1** Most common location for Spigelian hernias.

In the most common types of Spigelian hernias, the external oblique aponeurosis remains intact with an underlying posterior defect. This is because the anterior sheath undergoes little anatomic rearrangement at the arcuate line, in contrast to the posterior fascia. As a result, a combination of preperitoneal or intraabdominal contents may protrude through the deepest layers of abdominal fascia but not completely into the subcutaneous space. This may have diagnostic implications to be discussed later. However, a rare subset of Spigelian hernias may in fact penetrate through all layers of the abdominal wall ([Fig. 13-2](#)).

**FIGURE 13-2** The Spigelian hernia. **A.** Breaching the Spigelian fascia. **B.** The most common type has passed through the transversus abdominis and the internal oblique aponeuroses and is spreading out in the interstitial layer posterior to the external oblique aponeurosis. **C.** The less common type in the interstitial layer between the transversus abdominis aponeurosis and the

internal oblique muscle. **D.** The least common subcutaneous type.

## Incidence

True Spigelian hernias are well described but not common. Over 1000 cases have been reported in the surgical literature, but the true incidence is difficult to ascertain due to difficulties in diagnosis and frequent mislabeling of incisional hernias (such as trocar site hernias). True Spigelian hernias have been estimated to constitute less than 1% of all abdominal wall hernias, with a slight female predisposition.

## Clinical Manifestations

The physical exam of a Spigelian hernia may reveal a vague fullness or lump just lateral to the rectus muscle. Due to a likely intact external oblique fascia, the examiner may not be able to feel the edges of a defined fascial defect. Depending on symptomatology, the area may be tender to manipulation. It should be noted that about 20% of Spigelian hernias present with acute incarceration. As with all hernias, patients with connective tissue disorders, diabetes, smoking history, or history of trauma to the area are more likely to develop Spigelian hernias, although the low incidence makes study of patient demographics difficult.

Diagnosis is greatly aided by imaging modalities.<sup>36</sup> Ultrasound offers a cheap first-line modality that allows the examiner to visualize the abdominal fascia layers. Computed tomography is also easily obtainable in most centers. It allows the practitioner to visualize the entire abdominal wall to plan for repair, but does expose the patient to ionizing radiation.

## Treatment

Spigelian hernias should be repaired due to their higher risk of incarceration and vague physical diagnosis. Surgical repair can be performed via open or minimally invasive techniques. There are little data on the benefits of prosthetic mesh in these hernias due to their rarity. However, for moderately-sized defects (>2 cm) we recommend prosthetic reinforcement in open and minimally invasive cases.<sup>37-39</sup>

Open repair involves a direct cutdown (typically transverse) overlying the hernia and the opening of the external oblique fascia to expose the posterior wall defect. The surgeon can then utilize a sublay technique or place the mesh anterior to the posterior fascia following primary closure. The external fascia is then closed primarily.

Minimally invasive repair is most commonly performed transabdominally but may also be attempted extraperitoneally by accessing the space of Retzius. If approaching the repair from the peritoneal cavity, an IPOM may be placed. Alternatively, a peritoneal flap can be created with development of the preperitoneal space and reduction of the hernia sac prior to the insertion of mesh. If placing mesh in the preperitoneal space, a coated, or composite, mesh is not necessary.

## LUMBAR HERNIA

The lumbar region is bordered by the 12th rib superiorly, the iliac crest inferiorly, erector spinae muscles posteriorly, and the line between the tip of the 12th rib and anterior superior iliac spine (ASIS) anteriorly.<sup>40</sup> Within this region, muscle groups run obliquely, and it is this “criss-crossing” of muscles that creates two potential triangles for hernia formation. The triangle of Petit is more inferior and is bordered by posterior edge of the external oblique muscle anteriorly, the anterior edge of the latissimus dorsi posteriorly, and the iliac crest inferiorly. Hernias through Petit’s triangle are more common than those through Grynfeltt’s triangle. The triangle of Grynfeltt, more superior than Petit, is bordered by the 12th rib, the serratus posterior inferior muscle, the posterior border of the internal oblique, and by the quadratus lumborum and erector spinae muscles (Fig. 13-3).

**FIGURE 13-3** The anatomy of the lumbar hernia illustrating the superior and inferior lumbar triangles.

## Incidence

Lumbar hernias are well-recognized but rare, occurring most commonly in patients over 50 years in age. There is a slight male predominance, as well as a slightly higher incidence of left-sided hernias. These hernias are most commonly acquired rather than congenital, occurring after surgical access or trauma.

## Clinical Manifestations

Lumbar hernias may present as a palpable mass or lump in the lumbar space. Patients may complain of discomfort or changes in size. Due to the complex anatomy of the retroperitoneum, most lumbar hernias do not contain bowel but may contain fat, or in severe cases, retroperitoneal organs such as the kidneys. Lumbar hernias rarely cause strangulation due to the absence of rigid fascia and the relative pliability of muscle. Most of these hernias are diagnosed by CT scan.

## Treatment

Once discovered, surgical repair should be offered to patients with symptomatic hernias. Repair may be attempted via open or minimally invasive methods. Each repair should involve the patient positioned in the lateral decubitus position.

Open repair involves a direct cutdown over the hernia and dissection to the lumbar musculature.<sup>40,41</sup> Once the defect has been identified, the hernia sac should be completely reduced under the musculature. If the defect is small, it can be reapproximated using multiple interrupted nonabsorbable sutures. However, in larger defects, the plane underlying the lumbar musculature should be developed and a prosthetic mesh placed with ample (4 cm) overlap. While mesh fixation is not required, especially if the overlying muscles are subsequently reapproximated, multiple absorbable sutures may be placed. An alternative to the sublay mesh technique is the overlay position, which involves the muscle closure followed by mesh reinforcement, fixated with multiple nonabsorbable sutures.

The repair of lumbar hernias through minimally invasive techniques most commonly requires peritoneal access. The lumbar space can be developed by first incising the peritoneal reflection tethering either the right or left colon. Once in this space, dissection can be continued to the psoas muscle posteriorly. Once the defect is identified and the hernia sac reduced, the muscle edges should be brought together with nonabsorbable suture and an uncoated mesh can be placed with minimal fixation. The peritoneal flap is then closed with suture or tacks.

## EPIGASTRIC HERNIA

An epigastric hernia is a defect between the umbilicus and xiphoid process in the midline of the abdomen.<sup>42</sup> The entity was first described in 1285 by Villeneuve, but not until 1802 was a successful repair performed, by Maunior. These defects are typically elliptical in shape and oriented horizontally. It is believed that these defects are more acquired in nature rather than congenital, since they are rare in children. Previous surgery, trauma, or repeated straining and/or intraabdominal pressure have all been implicated in their formation.

## Incidence

The estimated incidence of epigastric hernias in the United States is between 2% and 3%, with a male-to-female ratio of 3:1. These hernias are more likely to present in middle age and are relatively rare in children.

## Clinical Manifestations

The epigastric hernia presents similarly to other ventral or incisional hernias. The patient may complain of a symptomatic bulge in the upper abdomen. In contrast with more inferior defects, epigastric hernias are less likely to contain bowel. Rather, they are more likely to contain omentum or preperitoneal fat. For this reason, epigastric hernias are often missed on laparoscopy due to the lack of a peritoneal hernia sac. The examining clinician should assess for reducibility, tenderness, and any change in size or morphology from previous examinations.

## Treatment

The treatment of epigastric hernias is essentially the same as other ventral abdominal wall hernias. For smaller hernias, typically less than 2 cm, a primary suture repair may be an acceptable option. However, for larger defects, a prosthetic mesh should be placed to achieve a lower recurrence risk.

The placement of mesh in the upper abdomen is often complicated by limits on mesh fixation.<sup>42</sup> For subxiphoid defects, the falciform ligament often obstructs mesh placement. Furthermore, transfascial fixation is not feasible above the costal margin. Therefore, for epigastric defects where the proximity to the costal margin limits adequate mesh overlap on the superior margin, we recommend a laparoscopic repair with the placement of a preperitoneal mesh. This peritoneal flap may be extended onto the diaphragm, and mesh positioning can be completed with minimal fixation. Following the mesh placement, the peritoneal flap is then closed with absorbable suture or tacks. If mesh overlap along the superior aspect is not a concern, a laparoscopic IPOM procedure may also be performed after dividing the falciform ligament to facilitate mesh placement.

# PERSPECTIVES ON LAPAROSCOPIC INCISIONAL HERNIA REPAIR

*Camille Blackledge • Mary T. Hawn*

## INTRODUCTION

Incisional hernias are a common complication of midline laparotomies, with a reported incidence of 9% to 20%.<sup>1</sup> Over 100,000 incisional hernia repairs are performed annually in the United States alone.<sup>2</sup> Since the introduction of laparoscopic incisional hernia repair (LIHR) by LeBlanc in 1993, the approach has gained popularity with general surgeons as a preferred technique for selected incisional hernia repairs.<sup>3</sup>

As LIHR becomes more common in the armamentarium of general surgeons, more information has become available regarding the benefits of laparoscopic hernia repair. However, only a small number of randomized trials exist comparing open hernia repair to laparoscopic repair. These studies have mixed results, with no clear consensus proving that one should replace

the other as a standard approach to incisional hernias. Thus, it is important for general surgeons to be familiar with both techniques of hernia repair, as well as risks and benefits of both. This chapter will focus on the advantages and disadvantages of LIHR, discuss technical considerations, and review the literature on outcomes.

## **ADVANTAGES OF LAPAROSCOPIC VENTRAL HERNIA REPAIR**

Early studies demonstrated a decrease in wound complications, hospital stay, operative times, and recurrence rates with LIHR compared to open primary repair.<sup>4,5</sup> However, more recent studies have found decreased wound complications and length of hospital stay with LIHR, with no difference in recurrence rates.<sup>6-8</sup> The smaller incisions used for the laparoscopic approach are thought to be the major factor leading to decreased wound complications. Studies have demonstrated a decreased rate of surgical site infection in laparoscopic versus open incisional hernia repair (2.3% vs 9.2%, respectively),<sup>9</sup> including superficial and deep surgical site infections as well as wound disruption.<sup>10</sup> Large tissue flaps are not raised during LIHR, thereby obviating the need for postoperative surgical drains and further decreasing the risk of wound complications. In contrast to the known benefits of laparoscopic approach for other surgeries, it was thought that the smaller incisions used in LIHR would result in less postoperative pain than open repair. However, recent studies demonstrate either an increase or no difference in early postoperative pain compared to open procedures.<sup>7</sup>

## **DISADVANTAGES OF LAPAROSCOPIC INCISIONAL HERNIA REPAIR**

One of the most feared complications of LIHR is an intestinal injury. Enterotomies can occur during initial trocar placement, lysis of adhesions, and intestinal manipulation. Laparoscopic adhesiolysis has been associated with an increased risk of unrecognized bowel injuries compared to open techniques.<sup>6,11</sup> The incidence of enterotomy has been reported as 7.9% for laparoscopic repair compared to 7.3% for open repair.<sup>12</sup> Injuries most

commonly occur in the small intestine. A missed intestinal injury can have harmful effects, including mesh infection, sepsis, and even death. The mortality of an unrecognized injury is 7.7%, compared to 1.7% for an injury recognized intraoperatively.<sup>11</sup> If recognized at the time of surgery, it is at the discretion of the surgeon to attempt laparoscopic repair or convert to an open procedure. If recognized in the postoperative period, operative management with intestinal repair, source control, and removal of the mesh is typically mandated.

Most hernia defects are not reapproximated with the laparoscopic technique, causing patients to potentially have a persistent bulge after laparoscopic repair. Often, this is confused with a recurrent hernia, and patients should be counseled appropriately. It also leaves a dead space, which can increase the risk of developing a postoperative seroma. Most seromas can be observed without intervention; however, symptomatic ones may require percutaneous drainage. Again, patients should be advised that they may have a persistent mass following laparoscopic repair that decreases in size and usually disappears over time. The risk of seroma formation can be decreased by placement of a compressive abdominal binder.

## **PATIENT SELECTION**

Identifying appropriate patients for the laparoscopic approach includes determining the size of the defect, the ability to get lateral to the defect, adequate tissue for mesh fixation, extent of prior surgical procedures, and experience of the surgeon. Novice surgeons should select low-risk hernias for their initial procedures. These would include small, uncomplicated, reducible, midline, periumbilical hernias with healthy overlying skin and no prior history of peritonitis. With increased experience, surgeons can extend the laparoscopic approach to more complicated presentations, but even the most experienced surgeons would not choose a laparoscopic approach for patients with open skin lesions, fistulas, or massive loss of domain.

## **TECHNICAL CONSIDERATIONS**

Care is taken when selecting the method of entry for the initial placement of the trocars. Consideration must be given to the location of the hernia to be

repaired as well as previous surgical procedures and incisions. For instance, if the patient had a right colectomy via a midline incision, then initial trocar placement should be on the left side of the abdomen to avoid potential adhesions related to the right-sided dissection. The trocars should be placed laterally at least 5 cm from the nearest fascial defect. The contents of the hernia sac should be carefully reduced and adhesiolysis carried out using blunt or sharp techniques. To avoid delayed perforation, energy devices are used sparingly and only when no intestine appears to be involved. It is essential to inspect the reduced contents to assess for intestinal injury before proceeding to mesh placement. The abdomen should be carefully examined to avoid missing any hernia defects as this can increase the risk of recurrence.

The use of synthetic mesh in open incisional hernia repair has been demonstrated to decrease the recurrence rate when compared to primary repair. Laparoscopic primary repair without mesh has been described; however, there is a paucity of data to support its routine use.<sup>13,14</sup> Incorporating synthetic mesh in LIHR is considered a standard of care and is used in most laparoscopic repairs. The type of mesh chosen is based on the surgeon's preference, but certain considerations should be made when making a selection. The location of the mesh will be intraperitoneal; as such, it will be in contact with visceral surfaces. Dual-sided meshes were created for the purpose of allowing appropriate tissue ingrowth on the peritoneal surface and preventing adhesion formation on the visceral surface. The types of mesh and materials available are beyond the scope of this chapter and constantly evolving; however, surgeons performing LIHR should be familiar with mesh approved for use in the abdominal cavity.<sup>15</sup> Once identified, the defect is measured and a mesh size appropriately chosen for a minimum of a 3- to 5-cm overlap.

There has been some debate about the necessity of transfascial sutures. The controversy stems from the pain caused by these sutures. However, they facilitate centering the mesh about the hernia defect and add to the stability of the mesh. Transfascial sutures have been associated with decreased recurrence rates compared to tacker fixation alone.<sup>16</sup> However, a meta-analysis comparing suture fixation to tacker fixation alone demonstrated decreased operative times and postoperative pain with the tacker, with no difference in recurrence rates.<sup>17</sup> It is the authors' preference to use transfascial sutures placed every 4 to 6 cm. The sutures are placed extracorporeally and mapped to the abdominal wall to ensure the mesh

overlap is a minimum of 3 cm in all directions. Tacks are then used to secure the edges of the mesh circumferentially.

Occasionally, drains are placed in large defects to prevent seroma formation, but they are typically not needed for LIHR. Patients can be discharged home the same day but are often kept overnight for adequate pain control. The use of an abdominal binder is recommended with larger defects to stabilize the abdominal wall and decrease the risk of seroma formation.

## **SHORT-TERM FOLLOW-UP**

A multicenter Veterans Administration randomized controlled trial comparing laparoscopic ventral incisional hernia repair to open mesh repair demonstrated lower complication rates in the laparoscopic group with an earlier time to resume work activities. However, the time to resume daily activities was similar in both groups.<sup>7</sup> Other studies have demonstrated no difference in postoperative pain or recovery at 3 weeks, and patients who underwent an LIHR reported better physical function.<sup>18</sup> Overall, laparoscopic repair has been associated with lower 30-day morbidity than open repair.<sup>19</sup>

## **LONG-TERM FOLLOW-UP**

Recurrence rates of 2.7% and 15.5% at follow-up greater than 20 months have been reported for LIHR.<sup>20,21</sup> Five-year recurrence rates are reported at 29%.<sup>22</sup> Risk factors for recurrence include large defects, obesity, previous open repairs, and perioperative complications.<sup>5</sup>

## **CONCLUSION**

There are no data to establish that laparoscopic incisional hernia repair is superior to open incisional hernia repair for use in all incisional hernias. When selecting LIHR, many factors should be taken into consideration such as hernia size, location, recurrence, and comorbid conditions. It is imperative that surgeons understand when LIHR is likely to be beneficial compared with open repair. Careful selection of appropriate patients, vigilance during the enterolysis, and proper surgical technique can ensure a successful hernia

repair.

# INTESTINAL STOMAS

*Cindy Kin • Mark Lane Welton*

## INTRODUCTION

Permanent or temporary fecal diversion is necessary for the surgical management of a wide variety of colorectal conditions including bowel obstruction, low pelvic anastomoses, poor sphincter function, difficult bowel regimen in spinal cord injury, rectal cancers and other pelvic malignancies, inflammatory bowel disease, perineal soft tissue infection, decubitus ulcers, and traumatic perineal injury.

Intestinal stomas carry significant social implications, and the prospect of having one commonly engenders very strong reactions from patients and their families. Many are initially filled with a sense of dread over “the bag.” However, for many patients, having an intestinal stoma can dramatically improve quality of life and allow them to regain control over their lives. For example, those with poor bowel function causing frequency, urgency, or incontinence may find themselves spending hours each day in the bathroom, fearful of leaving the house, and anxious when they are not near a bathroom. An intestinal stoma can allow them to reintegrate into normal life. While a well-functioning and well-placed stoma is compatible with an excellent quality of life, a poorly constructed stoma that cannot be reliably pouched can

wreak havoc on a patient's life.

The goal of this chapter is to serve as a resource for surgeons who create and close stomas, so that their patients can have the best possible functional outcome. The chapter discusses preoperative planning and decision-making, technical details of how to create intestinal stomas, and management of stoma complications.

The main technical principles for optimal stoma construction include proper stoma siting on the abdominal wall, adequate mobilization of the bowel, preservation of blood supply, and eversion of the bowel wall during stoma maturation. The important nontechnical considerations include providing education and support for patients with stomas, and knowing how to manage stoma-related complications.

Stoma construction requires attention not only to the bowel anatomy but also the abdominal wall anatomy. The most ideal segment of colon to use for a colostomy is the descending colon or proximal sigmoid colon, as using the distal end of a floppy sigmoid colon increases the risk of prolapse. For ileostomy creation, the most distal segment of small bowel that will reach through the abdominal wall should be used. Often it is necessary to ligate mesenteric vessels for oncologic or mobilization purposes. Ensuring that the marginal artery is intact for colostomies and that the arcade of ileal vessels is intact for ileostomies is critical for preventing stoma ischemia. The length and thickness of the mesentery affect whether the stoma will reach through the abdominal wall adequately to create a stoma that is not under tension. A short, thick mesentery may require more extensive mobilization to create a good stoma. Abdominal wall thickness and contour are important considerations during stoma creation. Thick abdominal walls require more mobilization of the bowel so that the stoma will reach through the abdominal wall without tension. Creases and scars on the abdominal wall surface play a major role in choosing the optimal site for the stoma.

## **PREOPERATIVE CONSIDERATIONS**

### **Enterostomal Therapists**

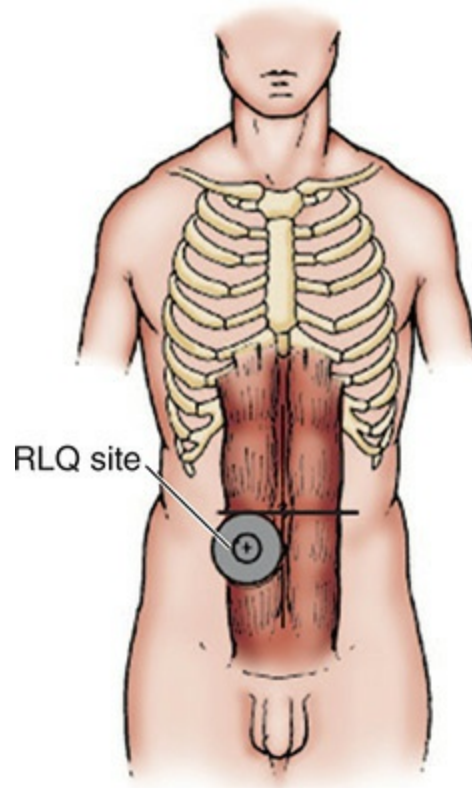

The surgeon's greatest ally in the work of taking care of patients with intestinal stomas is the enterostomal therapist (ET), a nurse specializing in the

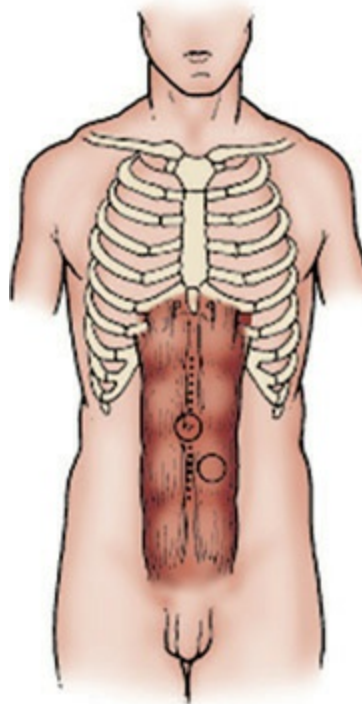

care of stomas. Patients undergoing elective operations in which a permanent or temporary stoma is planned should undergo preoperative counseling by both their surgeon and an ET. Dedicated care by a specialized ET is associated with better quality of life for patients with new stomas, measured by less self-consciousness and fearfulness, improved facility with stoma care, less pain, and better sleep.<sup>1</sup> Emotional or social support services may be necessary for ostomates in the preoperative or postoperative period, as many patients, especially women, struggle with coping and adjustment issues, poor body image, depression, and challenges with sexuality and intimacy.<sup>2</sup> In addition to providing prospective ostomates with support and education, ETs are also trained to mark appropriate stoma sites.

## Stoma Site Marking

Patients who undergo preoperative marking for stomas are more likely to be able to independently care for their stomas, have more predictable pouching with regard to length of time and leaks, and resume normal life after surgery.<sup>3</sup> Surgeons who perform these operations must also be skilled in choosing optimal ostomy sites, as a preoperative ET session is not always feasible due to timing of operative intervention and scarce resources. The optimal site for an intestinal stoma is within the rectus abdominis muscle, free of creases, and visible to the patient. The most commonly chosen stoma site is in the outer third of the rectus muscle, at the summit of the infraumbilical fat pad. Ileostomy sites are usually in the right lower quadrant, and colostomy sites are usually in the left lower quadrant (Figs. 15-1 and 15-2). However, obesity, prior scars, or other patient-related factors will often necessitate stoma placement in other locations (Fig. 15-3). Additional considerations are noted in Table 15-1. Except in cases involving the sickest of patients, surgeons should be able to mark at least one optimal site before emergent operations. If the patient is able to sit up, then the surgeon can ensure the absence of creases through the planned site and that the patient will be able to see and manage the stoma. A more detailed procedure for marking the stoma site in the elective setting is described in Table 15-2. Preoperative stoma site marking is associated with a lower risk of postoperative complications, improved postoperative quality of life, and higher levels of independence in care.<sup>4,5</sup>

**FIGURE 15-1** Placement of ileostomy in the right lower quadrant, within the rectus muscle and at the apex of the infraumbilical fat mound.

**FIGURE 15-2** Placement of colostomy in the left lower quadrant, within the rectus muscle and at the apex of the infraumbilical fat mound.

**FIGURE 15-3** Creases, scars, and obesity affect the optimal placement of stomas.

**TABLE 15-1: KEY CONSIDERATIONS FOR CHOOSING AN OPTIMAL STOMA SITE**

1. The stoma should be located in the outer third of the rectus abdominus muscle.
2. Physical characteristics of the torso: a protuberant abdomen or large pannus, abdominal folds, scars, location of the costal margin and iliac crest, pendulous breasts, and hernias.
3. Patient characteristics: mobility (wheelchair-bound), posture (kyphosis), dexterity, vision.
4. Patient preference for location, based on belt line and other individual factors.
5. Surgical considerations: type of stoma (loop vs end), segment of intestine to be used for the stoma, continent vs incontinent, need for both fecal and urinary stomas.

**TABLE 15-2: PROCEDURE FOR MARKING THE STOMA SITE**

1. Explain the purpose of preoperative stoma marking to the patient, and invite the patient to participate in the process.
  2. Examine the surface of the abdomen in various positions. Take note of folds, creases, scars, and contour. Take note of waistbands and any other accessories on the torso such as braces or other ostomy pouches.
    - When the patient is fully clothed in a seated position, note the position of the waistband and any associated abdominal folds.
    - If the patient uses a wheelchair or other assistive devices, examine them in their normal position and posture.
    - All clothing covering the abdomen (shirt and pants) should be completely removed.
    - Examine the abdomen while the patient is standing up, lying down, sitting, and bending forward. Note any changes in folds, creases, and contour.
  3. Identify the lateral edge of the rectus abdominis muscle by having the patient lie down and raise the head to look down at the feet.
  4. Mark one or more spots on the skin within the rectus abdominis muscle, at least 2 inches away from the midline, on a flat surface, away from scars or creases, and on the appropriate side for the planned operation. The highest priority is a flat surface for pouching.
  5. Have the patient lie down, sit up, bend forward, and stand up, checking to make sure the area around the mark(s) remains a flat pouching surface, free of creases, in all positions.
  6. Make sure the patient can see the mark(s) when they are lying down, sitting up, and standing up.
  7. Stoma placement in the upper abdominal quadrants may be more easily seen and accessed for the patient with a large, protuberant abdomen.
  8. If there is more than one option for stoma placement, number them in order of patient preference. Take into account where the waistband normally sits, and try to avoid that as a stoma site.
-

## Bowel Preparation

Mechanical bowel preparation and nonabsorbable oral antibiotics are recommended prior to elective colorectal operations, as they are associated with lower rates of surgical site infections, anastomotic leak, ileus, and readmission.<sup>6-8</sup> The original Nichols and Condon oral antibiotic regimen from the 1970s of neomycin and erythromycin base can still be used, or metronidazole can be used in place of erythromycin base.<sup>9</sup> Table 15-3 describes the options for mechanical bowel prep and oral antibiotic regimens. Mechanical bowel prep in the absence of oral antibiotics is not recommended. Mechanical bowel prep and oral antibiotics may not be necessary in all types of colorectal operations; this regimen was not shown to decrease complications in patients undergoing total colectomy,<sup>7</sup> and should not be used in patients with ileostomies.

**TABLE 15-3: PREOPERATIVE MECHANICAL BOWEL PREP AND ORAL ANTIBIOTIC REGIMENS**

### **Commonly Used Mechanical Bowel Preparations**

Polyethylene glycol 3350 and electrolytes (GoLYTELY® and Colyte®): 8 oz. every 10 minutes until 4L consumed or rectal effluent clear.

Polyethylene glycol 3350, sodium chloride, sodium bicarbonate, potassium chloride (NuLYTELY®): 8 oz. every 10 minutes until 4L consumed or rectal effluent clear.

Polyethylene glycol 3350, sodium sulfate, sodium chloride, potassium chloride, sodium ascorbate, and ascorbic acid (MoviPrep®): 8 oz. every 15 minutes until 1L consumed.

Suprep® (sodium sulfate, potassium sulfate, magnesium sulfate): 6 oz. the evening before, 6 oz. the morning of procedure.

Magnesium citrate: 10 oz. magnesium citrate with 8 oz. water every hour for 4 hours; repeat regimen 4 hours later.

### **Oral Antibiotic Regimens**

Neomycin 1 gram orally at 2 pm, 3 pm, and 10 pm  
PLUS

Erythromycin base 1 gram orally at 2 pm, 3 pm, and 10 pm  
OR

Metronidazole 500 mg orally at 2 pm, 3 pm, and 10 pm

---

## **COLOSTOMY**

### **End Colostomy**

#### **INDICATIONS**

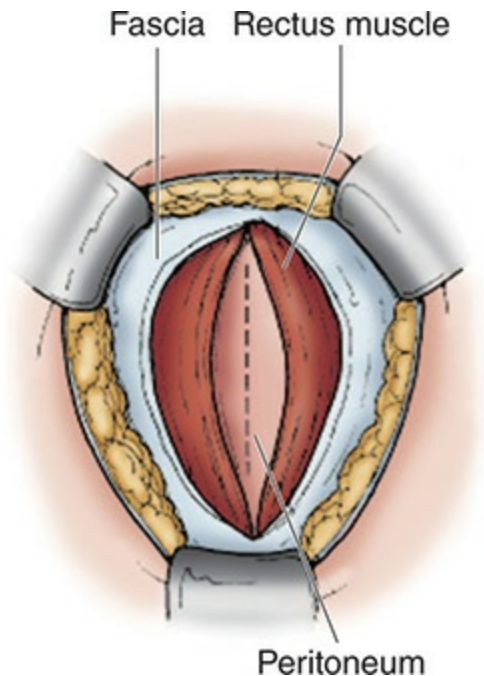

The most common operations that involve the creation of an end colostomy are abdominoperineal resection of the rectum and Hartmann's procedure, in which proctectomy and/or sigmoidectomy is performed without colorectal anastomosis. Patients who undergo reoperation for takedown of a leaking colorectal anastomosis also require creation of an end colostomy. Another indication for end colostomy is the need for complete temporary or permanent fecal diversion for nonobstructive pathology such as a rectourethral or rectovaginal fistula, necrotizing soft tissue infection of the

perineum, or severe trauma to the rectum, anus, or perineum.<sup>10</sup> A devastating consequence of landmines is severe lower extremity, pelvic, and perineal trauma sustained by both military personnel and civilians in conflict zones. Extensive perineal trauma requires early fecal diversion with end colostomy to completely prevent stool from contaminating the perineal wound.<sup>11,12</sup> In such cases, the benefit of complete fecal diversion outweighs the slightly greater difficulty in closing end colostomies than closing loop colostomies. If takedown of an end colostomy is planned, consider covering the distal staple line and wrapping the colostomy in an adhesion barrier such as Seprafilm<sup>®</sup> to decrease adhesions to both structures. These measures may facilitate subsequent laparoscopic and open procedures. Another option for cases of extensive perineal injury is the divided loop colostomy, which we discuss in a subsequent section. An end colostomy is not an acceptable solution for a distal obstruction, as stapling off the distal side of the colon will create a closed loop between the staple line and the obstruction, which may eventually result in perforation at the staple line.

## **OPEN TECHNIQUE**

Place Kocher clamps on the dermis and on the fascia of the abdominal wall, on the side of the planned stoma, to stabilize the layers of the abdominal wall in relation to each other. With another hand in the abdomen, hold a folded laparotomy sponge firmly up against the anterior abdominal wall at the planned stoma site, to ensure that no inadvertent bowel injury occurs during the creation of the stoma defect. Excise a disk of skin at the previously marked stoma site. Some surgeons prefer to core out the subcutaneous fat, while others prefer to incise the fat and spread it apart using Army-Navy or lateral retractors to expose the fascia. Once the fascia is exposed, make a vertical or cruciate incision to expose the underlying rectus muscle. Place a curved Mayo clamp through the rectus muscle, and open the clamp to spread the muscle fibers medially and laterally, exposing the posterior rectus sheath. Make a vertical or cruciate incision in the posterior sheath, exposing the laparotomy sponge that is being pushed against the inside of the anterior abdominal wall (Fig. 15-4).

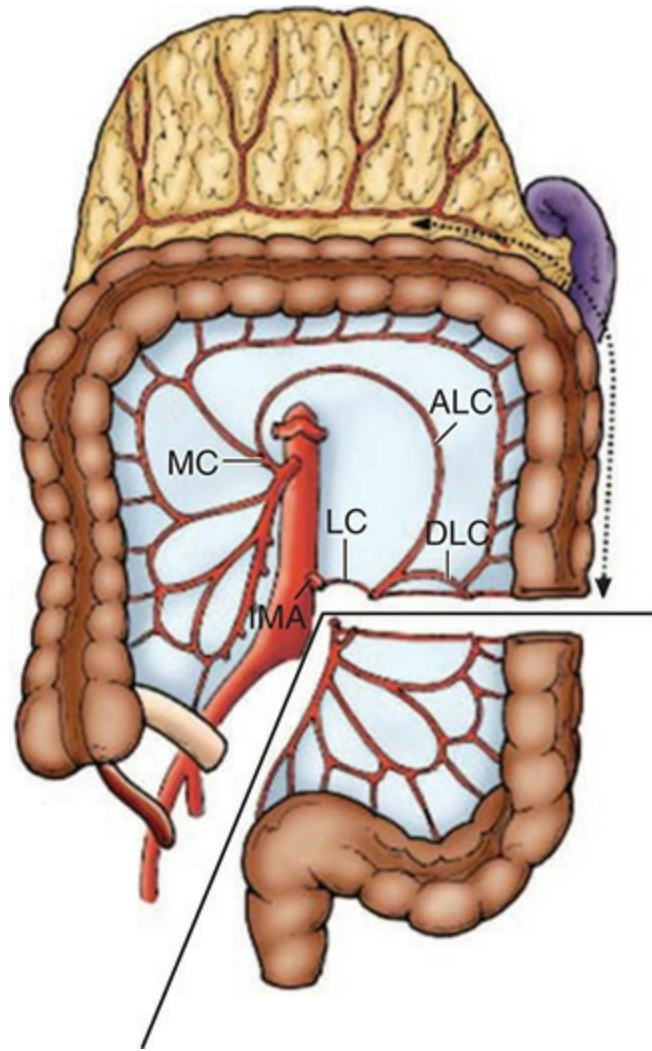

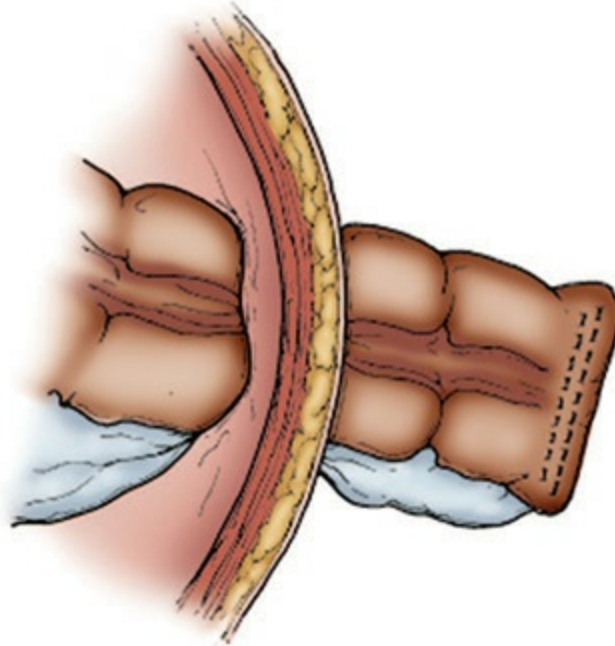

**FIGURE 15-4** Creation of the stoma defect.

Pass the Mayo or large Peon clamp, depending on body habitus, through the defect and bring the end of the clamp through the midline incision. Use the clamp to hold up the abdominal wall to expose the stoma defect from the inside, to facilitate a check for hemostasis, as there may be some hemorrhage from the muscle fibers or inferior epigastric branches. Dilate the defect to two to three fingerbreadths, depending on the size of the surgeon's fingers and the caliber of the bowel.

Ensure that the colon is oriented correctly and that there is adequate mobilization of the colon to bring it through the abdominal wall without tension. If proctectomy with ligation of the inferior mesenteric artery is being performed, then the left colon will need to be mobilized adequately and used for the stoma, as the sigmoid colon blood supply may be compromised in this case (Fig. 15-5). Insert a Babcock clamp through the stoma defect to grasp the end of the colon. Gently bring the colon through the defect by guiding it with the Babcock while pushing it from the inside of the abdomen (Fig. 15-6). Excess traction with the Babcock will result in a tissue trauma. Ensure that at least a few centimeters of colon sit without tension above the skin, and that it is well-perfused. Insert a finger alongside the colon through the stoma defect to ensure that the defect is not too tight.

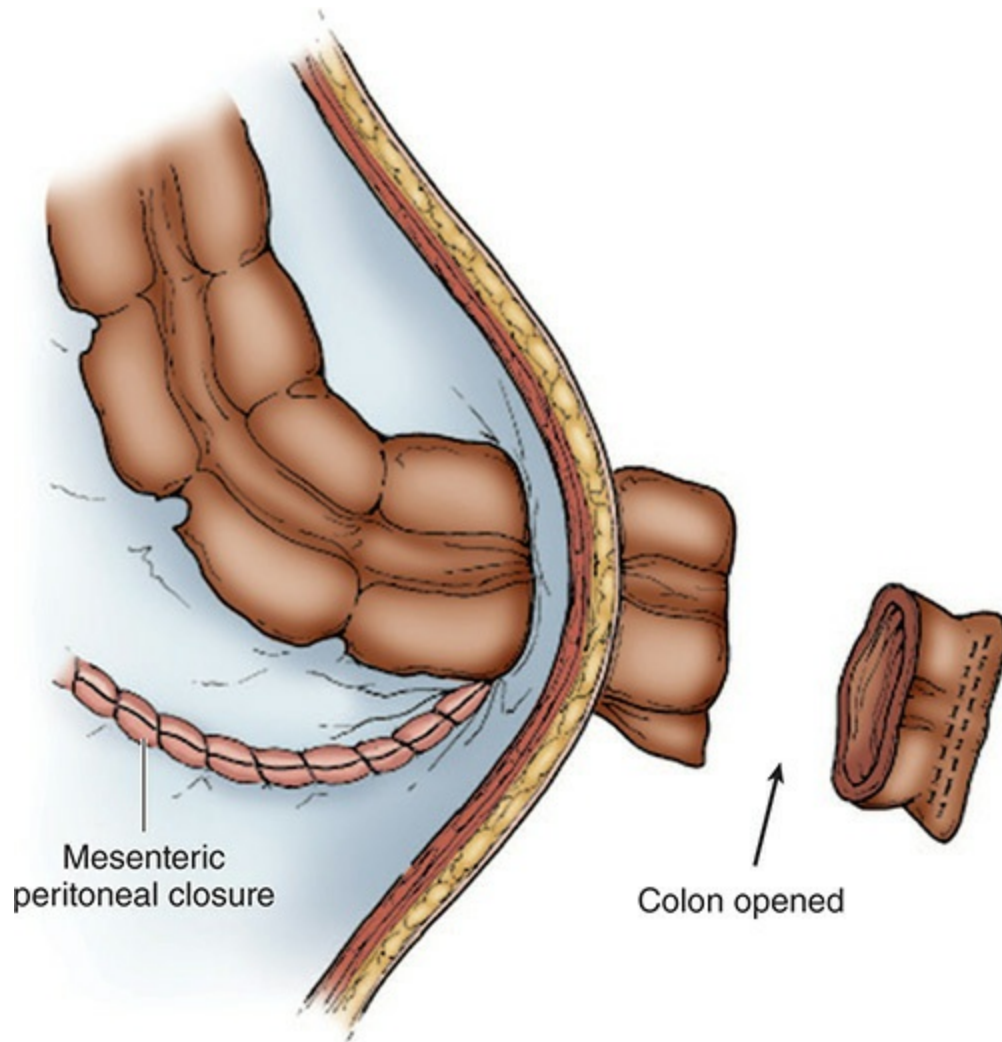

**FIGURE 15-5** Be sure to mobilize the left colon for the colostomy if high ligation of the inferior mesenteric artery was performed, to avoid stoma ischemia.

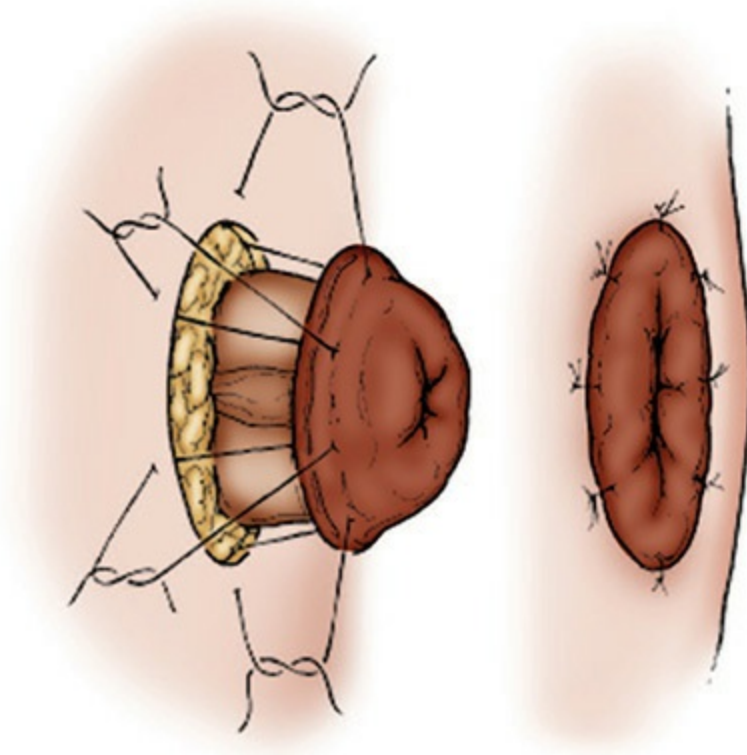

**FIGURE 15-6** Bring the end of the colon and its mesentery through the stoma defect, ensuring that there is adequate length so that there is no tension. This will prevent stoma retraction.

Some surgeons suture the free edge of the colon mesentery to the lateral abdominal wall, but this technique has not been shown to reduce the risk of bowel obstruction, hernia, or prolapse (Fig. 15-7). After abdominal closure, remove the staple line from the end of the colon and place absorbable sutures of 3-0 Chromic or 3-0 Vicryl in all four quadrants through the full thickness of the colon wall and to the dermis or epidermis. Then place additional sutures between those four stay sutures (Fig. 15-8). Some surgeons will create a colostomy that is slightly budded so that it protrudes slightly from the level of the skin, while others prefer a skin-level colostomy. For obese patients in whom the risk of retraction is higher, and for patients with underlying gastrointestinal disorders that may lead to liquid stool output, budded stomas are preferable to skin-level stomas for improved pouching.

**FIGURE 15-7** Suturing the free edge of the colon mesentery to the lateral abdominal wall may close the lateral space, but it has not been shown to reduce the risk of bowel obstruction, hernia, or prolapse.

**FIGURE 15-8** Interrupted two-point absorbable sutures are used to mature the colostomy.

Prophylactic mesh placement at the time of primary stoma creation may prevent parastomal hernia. The use of a retromuscular polypropylene mesh to reinforce the abdominal wall around the stoma was not associated with higher rates of infection or stricture in the multicenter randomized controlled PREVENT trial.<sup>13</sup> Multiple randomized controlled studies have examined the risk of parastomal hernia with or without prophylactic mesh placement. While results vary across studies, it does appear that there is likely to be an advantage for parastomal hernia prevention in patients who undergo prophylactic mesh placement.<sup>14-19</sup> Long-term results of the ongoing PREVENT trial are pending.

The two methods for placing prophylactic mesh around a colostomy are the Sugarbaker and keyhole techniques. The modified Sugarbaker technique uses an intraperitoneal onlay mesh covering the stoma defect and the most distal segment of the colon before it exits the abdominal wall via the stoma defect.<sup>20</sup> The mesh maintains the colon in a lateral position and acts as a tunnel through which the distal colon travels before exiting through the abdominal wall as the stoma. The mesh is affixed with transfascial sutures.

The keyhole technique uses mesh with a hole or cruciate defect corresponding to the stoma defect, allowing the colon to pass through the mesh. The mesh can be placed against the peritoneal surface of the anterior abdominal wall or in the retromuscular space.<sup>15</sup>

Another technique to reduce the risk of stoma prolapse or parastomal hernia is the creation of an extraperitoneal tunnel from the stoma defect to the lateral abdominal wall. The opening in the peritoneum is lateral to the rectus muscle and the colon runs through a tunnel between the peritoneum and rectus muscle before exiting through the stoma defect. Several studies have shown that the extraperitoneal route compared to transrectus placement reduces the risk of stoma prolapse and parastomal hernia.<sup>21–23</sup>

To create the extraperitoneal tunnel, make the stoma defect as usual in the skin and fascia and spread the rectus muscle to expose the posterior rectus sheath. Instead of incising this layer, continue the dissection laterally within this plane, separating the rectus muscle away from the peritoneum. Make a vertical incision in the peritoneum at the lateral end of the extraperitoneal tunnel. The peritoneal incision must be large enough to accommodate the colon and not cause an obstruction. Bring the colon through the extraperitoneal tunnel and up through the stoma defect. Check to make sure that there is enough space within the tunnel so that a finger can be inserted alongside the colon within the tunnel, and make sure that the tunnel does not cause kinking of the colon that may cause an obstruction.

Placement of prophylactic mesh and creation of an extraperitoneal tunnel may be helpful in reducing parastomal hernia risk for patients with permanent colostomies, but should be avoided for those with temporary colostomies as the colostomy reversal process will be much more difficult.

## **LAPAROSCOPIC TECHNIQUE**

The stoma defect can be made during pneumoperitoneum by excising a disk of skin and subcutaneous tissue at the previously marked site, dividing the fascia, spreading the muscle, and incising the peritoneum. Use two fingers to dilate the stoma defect and maintain pneumoperitoneum. After making the stoma defect, bring the end of the colon through the defect while ensuring proper orientation with laparoscopic vision. Slide a Babcock clamp through the stoma defect alongside the fingers to grasp the colon under laparoscopic vision, and then bring the end of the colon through the defect. If the end of

the colon reaches through the stoma defect while the abdomen is insufflated, then the colon is adequately mobilized. It is important to remember that pneumoperitoneum stretches the abdominal wall, and may thus make the stoma defect larger under insufflation than it will be after desufflation. Thus, confirm that the stoma defect is adequately sized by ensuring that an index finger can be passed through the defect alongside the stoma after desufflation.

Prophylactic mesh reinforcement of the stoma defect using the modified Sugarbaker or keyhole technique is amenable to a laparoscopic or robotic approach. Fixation of the mesh with both tacks and transfascial sutures mirrors the standard technique of minimally invasive ventral hernia repair. Ensure that the tacks and sutures do not violate the bowel, and that the tunnel is wide enough to accommodate the colon.

Creation of an extraperitoneal tunnel is also amenable to a minimally invasive approach. Create the stoma defect through the skin, fascia, and muscle, but not through the peritoneum. Laparoscopically Incise the peritoneum lateral to the stoma defect to form the proximal opening of the tunnel. Create the extraperitoneal tunnel by passing a curved Mayo clamp between the rectus muscle and posterior rectus sheath. Dilate that tract so that it is broad enough to accommodate the colon without causing an obstruction. Then, bowel graspers can be used to bring the end of the colon into the proximal opening of the tunnel, and a Babcock clamp can be passed through the tunnel from the stoma defect to bring it through the tunnel and out the defect.

## **TECHNIQUE FOR TAKEDOWN OF AN END COLOSTOMY**

Preoperative contrast enema or flexible sigmoidoscopy prior to colostomy closure is critical for assessing the rectal stump for length, leaks, and strictures. Colonoscopy of the proximal colon may be necessary if not done recently. Mobilize the colostomy by making a circumferential incision in the peristomal skin, leaving a 3-mm rim of skin on the bowel to aid in retraction. Place Allis clamps on the skin rim for retraction and sharply dissect the bowel free from the surrounding soft tissue and fascial defect. Staple the end of the colon closed and re-prep the abdomen. Drop the colon into the abdomen if full mobilization from the abdominal wall was possible.

Open or laparoscopic approaches are options for the remainder of the operation, depending on the surgeon's expertise and the density of intra-abdominal adhesions. For laparoscopic cases, place a "glove port" through the stoma site to allow for insufflation. Place a small ringed wound protector through the stoma site. Place the wrist of a size 6 glove over the outer ring and roll the wrist of the glove down with the outer ring, creating an air-tight seal. Place up to three ports of any size through the fingers of the glove by cutting off the fingertips, and tying the ports in place with 0-silk ties. Place additional ports through the abdominal wall as needed. Mobilize the small bowel out of the pelvis to expose the rectal stump. Identify the top of the rectal stump and its staple line. Ensure that neighboring structures, including the vagina, seminal vesicles, bladder, and ureters, are out of the way. Mobilize the colon proximal to the stoma in order to create a tension-free colorectal anastomosis. Once this is accomplished, a side-to-end or end-to-end anastomosis can be created, using the circular EEA stapler. If the anastomosis is low or otherwise high risk, and a proximal diverting loop ileostomy is indicated, then consider bringing the loop ileostomy through the existing stoma defect.

If diversion is not necessary, close the fascial defect with interrupted 0-Vicryl sutures. Cinch the skin defect with a 2-0 Vicryl purse-string placed in the dermal layer. This closure allows for drainage and healing by secondary intention in order to prevent wound infection, while minimizing the size of the scar.

## **Loop Colostomy**

### **INDICATIONS**

The primary indication for loop colostomy is a distal obstruction requiring temporary or palliative fecal diversion. Patients with symptomatic fistulas between the rectum and urethra, bladder, or vagina may also find relief with a loop colostomy. A downside of using the colon rather than the ileum for diversion in the case of fistula is the potential compromise of a segment of colon that may be needed to reach a low pelvic anastomosis for the purposes of reconstruction. Other indications for loop colostomy include trauma to the extraperitoneal rectum or perineum, and complicated soft tissue infection of the perineum requiring significant debridement.<sup>10-12</sup> A loop colostomy may

divert a high-risk distal anastomosis, but a loop ileostomy is the more common choice. As a loop colostomy may be incompletely diverting if the posterior wall sits below skin level, ongoing distal fecal drainage may require conversion to an end colostomy.

The ideal segment of colon to use for a loop colostomy is the sigmoid, as it is the most mobile part of the distal colon. In cases of unresectable obstructing lesions at the splenic flexure or left colon, or when the sigmoid is not available for use, the use of the transverse colon may be necessary. Loop transverse colostomies are associated with a high rate of complications including prolapse and pouching difficulties due to liquid output, and should be avoided unless absolutely necessary. Strong consideration should be given to a diverting loop ileostomy rather than a diverting transverse colostomy, as loop ileostomies are associated with lower complication rates and do not compromise subsequent definitive colorectal procedures.

## **OPEN TECHNIQUE**

Make the stoma defect in the fashion described for end colostomy. Mobilize the loop of sigmoid or transverse colon so that it will reach through the abdominal wall. Make a defect at the junction between the colon and the mesentery, and pass a ½-inch umbilical tape or Penrose drain through this defect. Prior to bringing the bowel through the abdominal wall, wrap the bowel in Seprafilm to facilitate the takedown procedure. Use an umbilical tape or Penrose drain to guide the loop of colon through the stoma defect while pushing it out from the inside of the abdomen (Fig. 15-9). Excess traction on the umbilical tape or Penrose drain may cause tearing of the bowel or mesentery. After closing the abdominal incision, mature the loop colostomy. Some surgeons prefer the use of stoma rods that can be placed through the mesentery defect to replace the umbilical tape. Transversely incise the antimesenteric border of the distal side of the loop. This division should be more than half the bowel circumference so that the functioning proximal limb and nonfunctioning distal limb are separated. Suture the free edge of the bowel to the dermis or epidermis with interrupted 3-0 Chromic sutures. Eversion of the proximal limb, and making sure the posterior wall is at least at the level of the fascia, will prevent stool from passing into the distal limb.

**FIGURE 15-9** Use an umbilical tape to guide the loop of colon through the stoma defect while pushing it out from the inside of the abdomen. Excess traction on the umbilical tape may cause tearing of the bowel or mesentery.

## LAPAROSCOPIC TECHNIQUE

If a laparoscopic approach is safe and feasible, mobilize the loop of colon adequately to reach the anterior abdominal wall while the abdomen is insufflated. Make the stoma defect and dilate it to two to three fingerbreadths under pneumoperitoneum, and slide a Babcock clamp alongside the fingers to grasp the mobilized loop of colon. Bring the loop gently through the stoma defect. Check laparoscopically to determine the orientation of the colon, and mature the proximal side.

A single-port or reduced-port laparoscopic technique using the planned stoma site as the port site results in fewer or no additional incisions aside from the stoma defect itself.<sup>24</sup> The additional cost of a single-port access system can be avoided by using a glove port as described in the previous section.

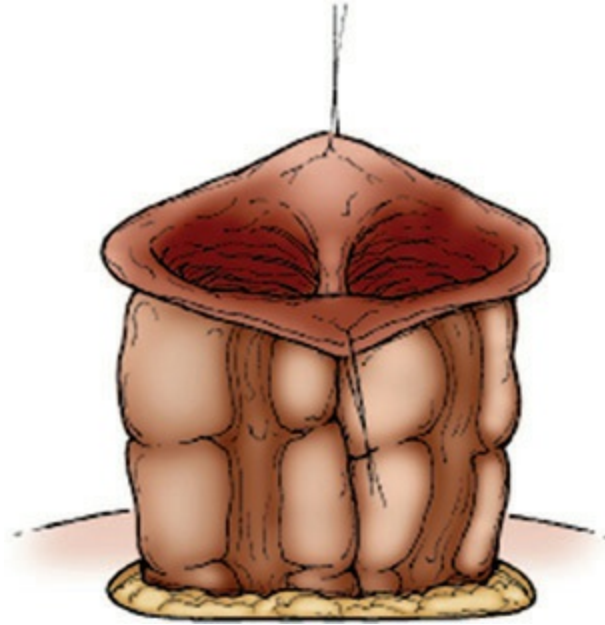

## TECHNIQUE FOR CLOSURE OF LOOP COLOSTOMY

Loop colostomy closure starts with a circumferential incision around the

colostomy, about 3 mm from the mucocutaneous junction. Use this skin edge for retraction by placing Allis clamps on it while sharply dissecting the bowel wall away from the subcutaneous tissue and fascia. In the rare event that this dissection is so difficult that mobilization of the colon from the abdominal wall is not possible through the stoma site, a midline incision may be necessary. When the colon is completely mobilized from the abdominal wall, unvert the proximal and distal bowel edges (Fig. 15-10). Examine the bowel wall for partial- or full-thickness defects and repair them transversely with interrupted 3-0 Vicryl sutures. If the colon is largely intact, then resection is not necessary. Trim away the skin edge, leaving only a transverse defect in the antimesenteric aspect of the colon (Fig. 15-11). Close the defect transversely using interrupted 3-0 absorbable seromuscular sutures (Fig. 15-12). To handle a significant size discrepancy between the proximal and distal limb, make a longitudinal slit in the antimesenteric side of the smaller limb (Cheatele slit). Match the apex of the Cheatele slit to the midpoint of the larger caliber bowel edge. Close the defect transversely. A stapled closure using a linear noncutting stapler to close the bowel transversely is another option (Figs. 15-13 and 15-14). A final option is to create a side-to-side stapled anastomosis by firing a linear cutting stapler down the lumens of the proximal and distal limbs and closing the end of the anastomosis with a linear stapler.

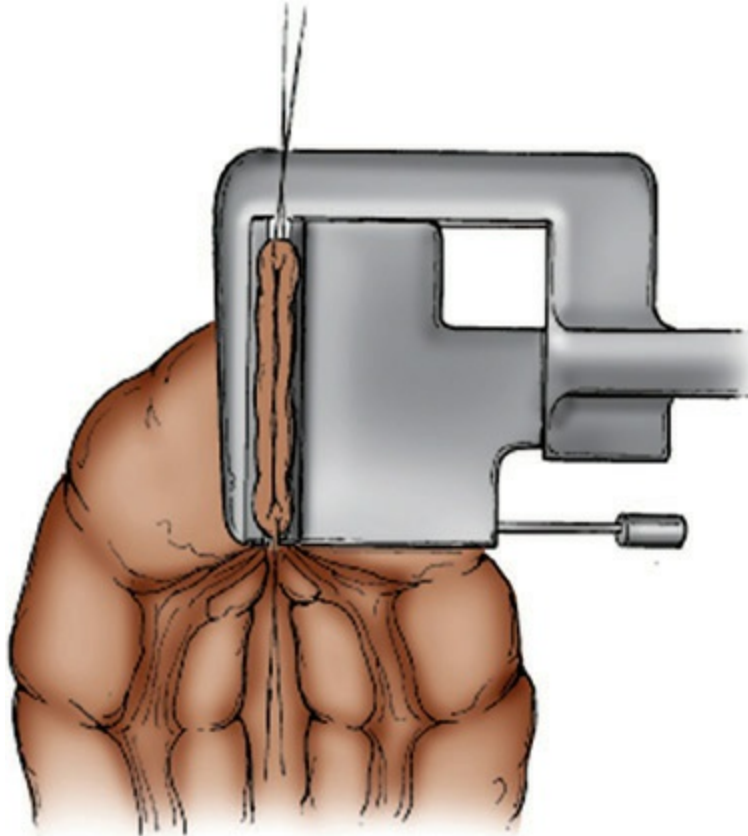

**FIGURE 15-10** To take down a loop colostomy, completely mobilize the bowel from the surrounding subcutaneous tissue and fascia.

**FIGURE 15-11** Trim away the skin edge, leaving only a transverse defect in the antimesenteric aspect of the colon.

**FIGURE 15-12** Close the defect transversely with interrupted seromuscular sutures using 3-0 absorbable sutures.

**FIGURE 15-13** A linear stapler can also be used to close the defect.

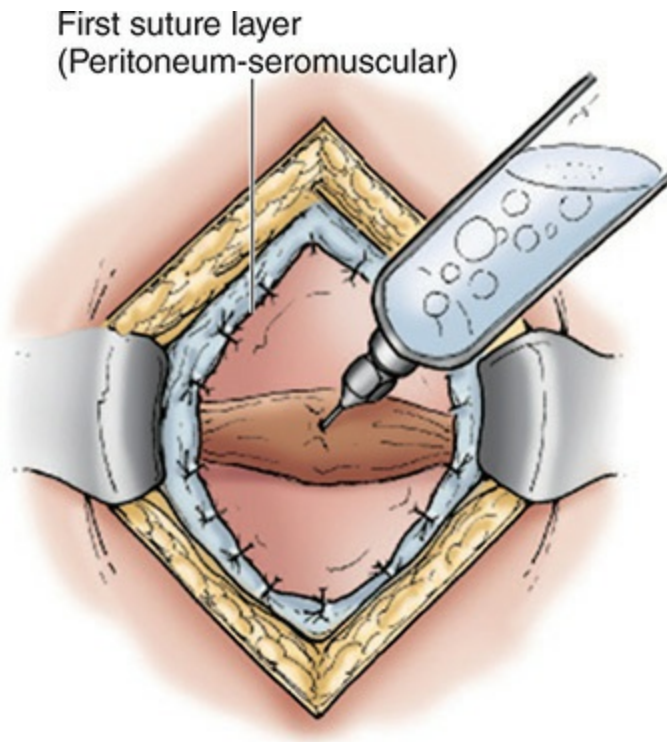

**FIGURE 15-14** A linear stapler can also be used to close the defect.

If resection of a colon segment is necessary due to injuries sustained during mobilization of the colostomy, then create the anastomosis in a handsewn end-to-end fashion, or a stapled side-to-side fashion. Closure of the fascial defect and skin is described in the previous section.

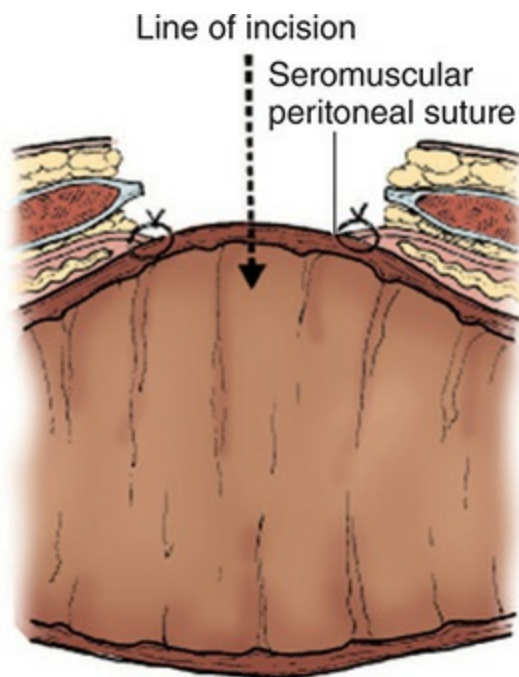

## Blowhole Colostomy

The original blowhole colostomy described by Turnbull was for the indication of toxic megacolon due to severe ulcerative colitis. Combined with loop ileostomy, blowhole colostomy is a minimally invasive way to decompress the colon and allow these very sick patients to recover until they are stable enough to undergo colectomy.<sup>25</sup> With modern management of ulcerative colitis, we rarely encounter this clinical situation, but a blowhole colostomy may be a lifesaving intervention in the very critically ill patient with toxic colitis or obstruction who is too unstable to undergo resection or a formal colostomy.

The blowhole colostomy is a minimally invasive way to decompress the colon. First, localize the transverse colon by taping a coin on the patient's epigastrium and taking an abdominal film. Determine the location of the transverse colon by using the location of the coin in relation to the most dilated part of transverse colon as a guide. With local anesthetic, make an incision in the mid-epigastrium right over the transverse colon. Incise the fascia and peritoneum to expose the serosa of the transverse colon. Place interrupted sutures of 3-0 Vicryl between the seromuscular layer of the bowel and the peritoneum to secure the colon to the abdominal wall and to isolate this window of bowel from the rest of the abdominal cavity. The colon will be very thin walled and prone to tearing, and is likely to leak gas or stool through the needle holes. Then, decompress the gas in the dilated colon using a large-bore needle (Fig. 15-15). Place another layer of interrupted 3-0 Vicryl sutures between the seromuscular layer of the bowel and the fascia. Incise the colon and suction out the gas and stool that is under pressure (Figs. 15-16 through 15-18). Place interrupted sutures between the full thickness of the bowel wall edge to the skin<sup>26</sup> (Figs. 15-19 through 15-21).

**FIGURE 15-15** Place interrupted sutures between the peritoneum and the bowel to quarantine the bowel. Decompress the gas out of the colon using a large-bore needle.

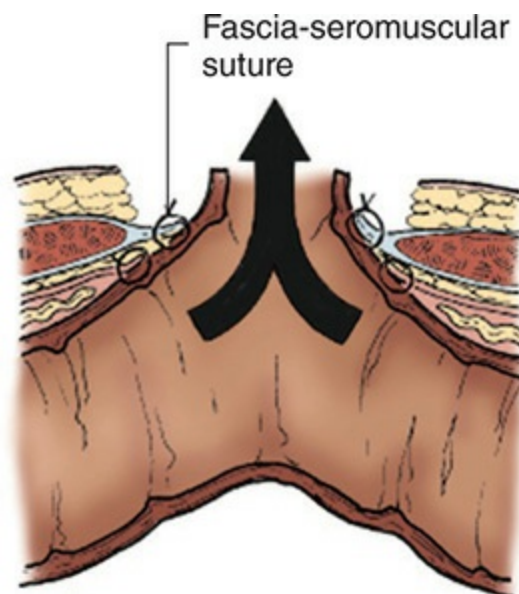

**FIGURE 15-16** After placing another layer of interrupted sutures between the fascia and the bowel, incise the bowel wall and suction out more colonic

contents.

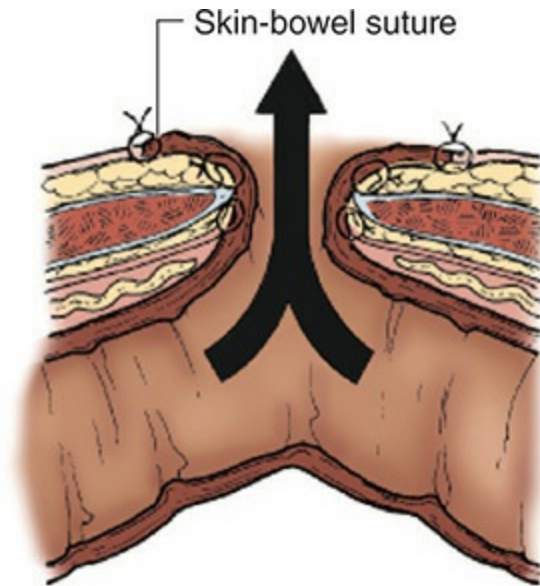

**FIGURE 15-17** After placing another layer of interrupted sutures between the fascia and the bowel, incise the bowel wall and suction out more colonic contents.

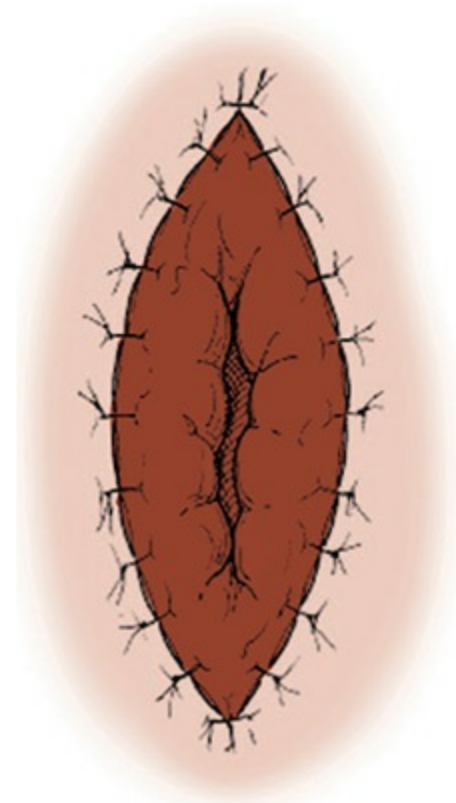

**FIGURE 15-18** After placing another layer of interrupted sutures between the fascia and the bowel, incise the bowel wall and suction out more colonic contents.

**FIGURE 15-19** Place interrupted sutures between the full thickness of the bowel wall edge and the skin edge.

**FIGURE 15-20** Place interrupted sutures between the full thickness of the bowel wall edge and the skin edge.

**FIGURE 15-21** The blowhole colostomy is located usually in the midline epigastric position.

## **Divided Loop Colostomy (Separated Loop Colostomy)**

### **INDICATIONS**

The indications for a divided loop colostomy are similar to those for a loop colostomy, which include a distal obstruction, a symptomatic fistula between the rectum and urethra, bladder, or vagina, trauma to the extraperitoneal rectum or perineum, and complicated soft tissue infection of the perineum with a large perineal wound.<sup>10–12</sup> The benefit of a divided loop colostomy over a loop colostomy is more definitive fecal diversion. A divided loop colostomy has two advantages over an end colostomy: reversal of a divided loop colostomy can be performed through the stoma site, and it can be used in the case of distal obstruction since the distal limb remains open.

## **TECHNIQUE**

Mobilize the loop of colon, create the stoma defect, and bring the loop of colon through the defect in the same fashion as a loop colostomy. Make a defect in the mesentery adjacent to the bowel wall, avoiding the mesenteric vasculature. Divide the colon with a linear cutting stapler. Excise the corner of the distal staple line and suture the bowel wall to one side of the stoma defect, creating a mucus fistula. Remove the entire staple line of the proximal limb, and mature the colostomy with interrupted full-thickness 3-0 Chromic sutures to the skin. Part of the colostomy will be adjacent to the mucus fistula. Suture the bowel wall edges together.

Converting a loop colostomy to a divided loop colostomy is indicated if there is persistent and symptomatic drainage of feces distally, which occurs because the posterior wall of the loop colostomy has fallen below the level of the fascia. Incise the stoma circumferentially at the mucocutaneous junction. Sharply dissect the bowel free of the surrounding subcutaneous tissue and fascia to bring the entire width of the colon above the skin level. Create a defect in the mesentery adjacent to the bowel and divide it with a linear cutting stapler. Mature the colostomy and the mucus fistula.

## **Loop-End Colostomy**

### **INDICATIONS**

A patient with a short colonic mesentery and/or thick abdominal wall that precludes the end of the colon to reach through the abdominal wall may require a loop-end colostomy. The segment just proximal to the distal end of the colon will often reach farther through the abdominal wall than the end.

### **TECHNIQUE**

Mobilize the colon and create a stoma defect. Make a defect at the bowel-mesentery border and pass a ½-inch umbilical tape or Penrose drain through the defect. Use this to guide the loop of colon through the defect while pushing the colon and mesentery from the inside. Wrap the bowel in Seprafilm prior to passing through the abdominal wall if the stoma is temporary. Exchange the umbilical tape for a stoma rod and suture it in place. Divide the colon transversely at the distal side of the loop. Mature the stoma

as a loop colostomy.

## **Colostomy Function**

Colostomy function varies greatly among patients and depends on several factors, including diet and fluid intake, and preexisting bowel habits. While most patients wear stoma appliances at all times, a smaller proportion of patients choose to irrigate their colostomies to reduce the need to wear an appliance. Colostomy irrigation is a daily high-volume enema and gives patients control over the timing of bowel movements. Patients who irrigate successfully may only need to wear a bandage or a gauze pad over the colostomy for the rest of the day. Patients who use colostomy irrigation have decreased flatus and odors, and higher quality of life compared to those who do not use irrigation. Water or agents such as polyethylene glycol or glyceryl trinitrate solution are the irrigants most commonly used.<sup>27,28</sup>

## **ILEOSTOMY**

The consistency of ileostomy output is more watery, and the composition is more caustic to the skin. These two differences increase the risk for pouch leaks and subsequent skin breakdown in patients with ileostomies compared to those with colostomies. It is very important that ileostomies be budded to allow the os to be above the surface of the skin and within the pouch, decreasing the risk of pouch leakage.

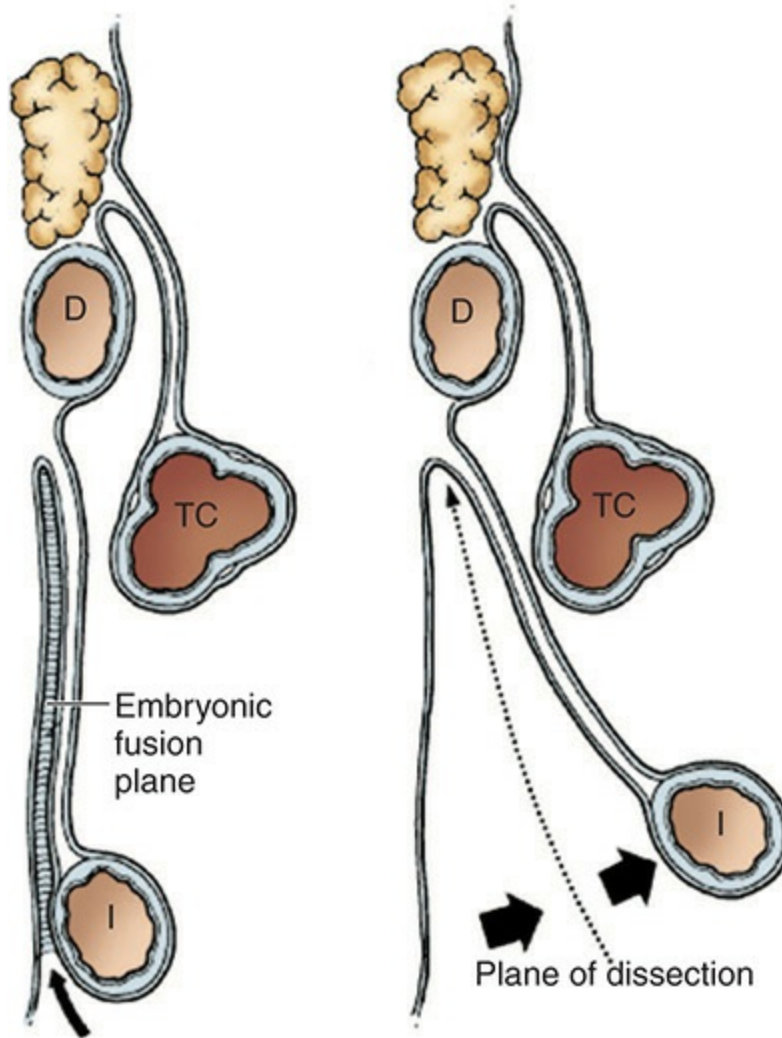

## **End Ileostomy**

### **INDICATIONS**

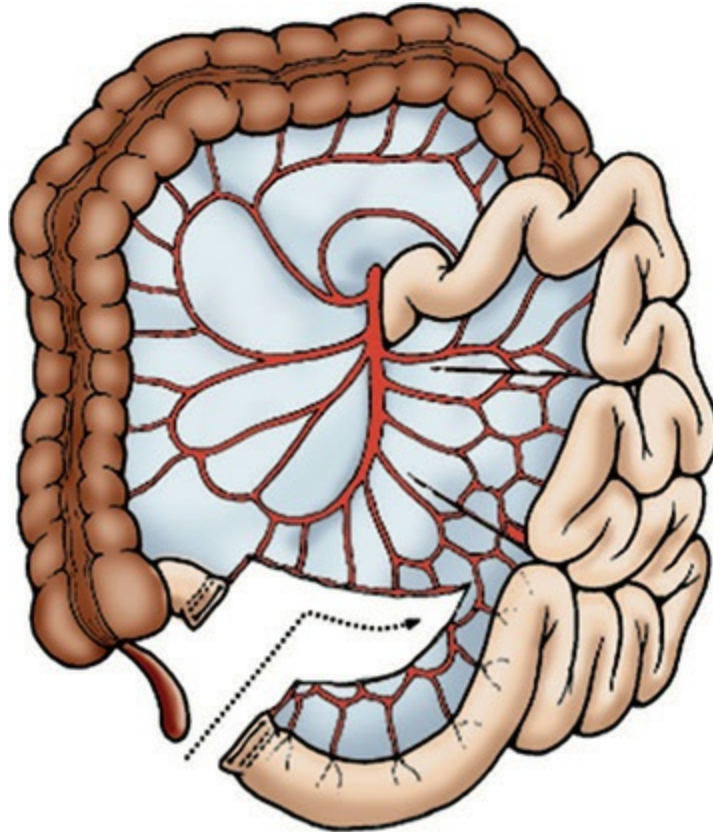

Patients undergoing total colectomy or total proctocolectomy without restoration of intestinal continuity require end ileostomy. Disease processes include ulcerative colitis, Crohn's colitis, familial adenomatous polyposis, ileocolic anastomotic leak requiring reoperation and takedown of the anastomosis, and colonic inertia without ileorectal anastomosis.

### **TECHNIQUE**

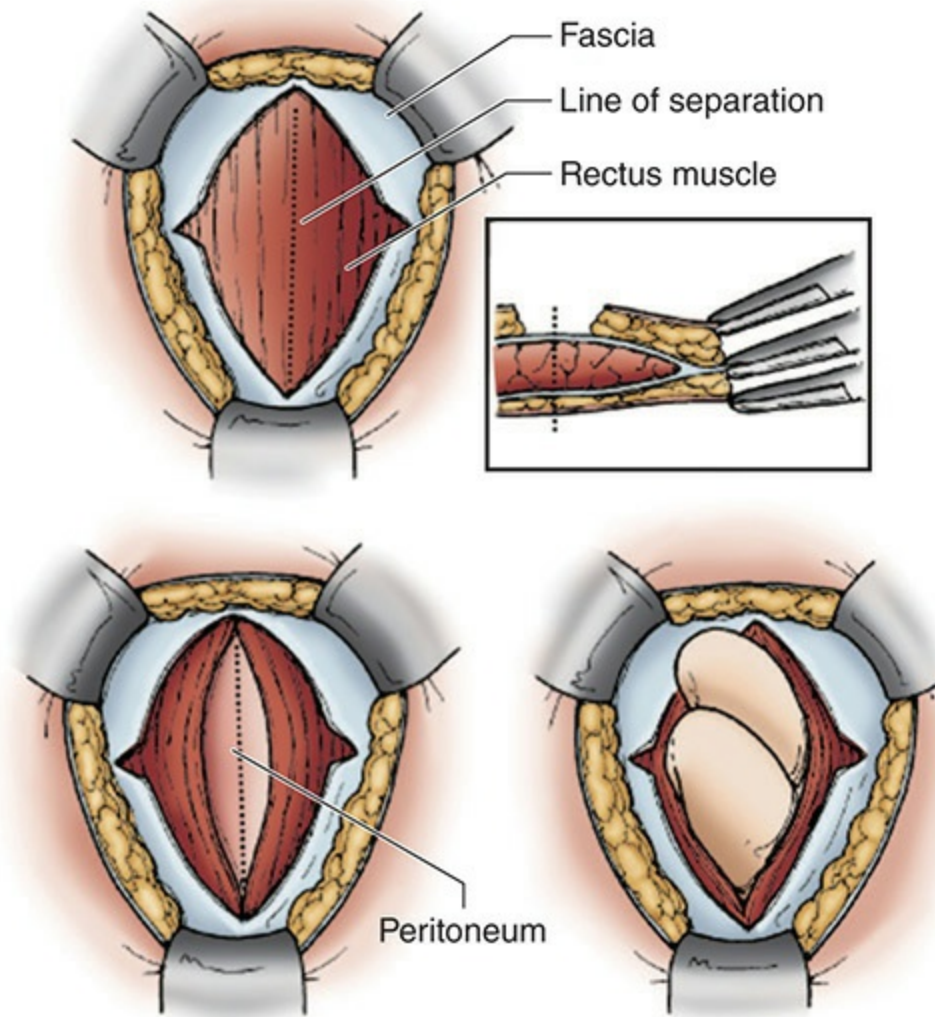

Mobilize the ileal mesentery off the retroperitoneum up to the duodenum so that the end of the ileum will reach through the anterior abdominal wall (Fig. 15-22). Ensure that there is adequate blood supply to the ileum by preserving the arcade of mesenteric vessels adjacent to the end of the ileum (Fig. 15-23). Make the stoma defect as described for a colostomy, but only dilate to two fingerbreadths (Fig. 15-24). If the end ileostomy is temporary, wrap the stoma in Seprafilm to facilitate subsequent takedown, and then gently guide the ileum through the defect (Fig. 15-25). After closing the abdominal wall, mature the ileostomy by removing the staple line and placing four sutures of 3-0 Chromic full-thickness through the free edge of the ileum, through the seromuscular layer at the base of the stoma, and the dermis. Holding these sutures out, use the back of a small forceps inserted under the free edge to gently create a budded configuration by everting the bowel. Tie down these sutures and place additional sutures full thickness through the free edge of bowel and to the dermis (Figs 15-26 and 15-27).

**FIGURE 15-22** Mobilize the ileal mesentery off the retroperitoneum so that the end of the ileum will reach through the anterior abdominal wall without tension.

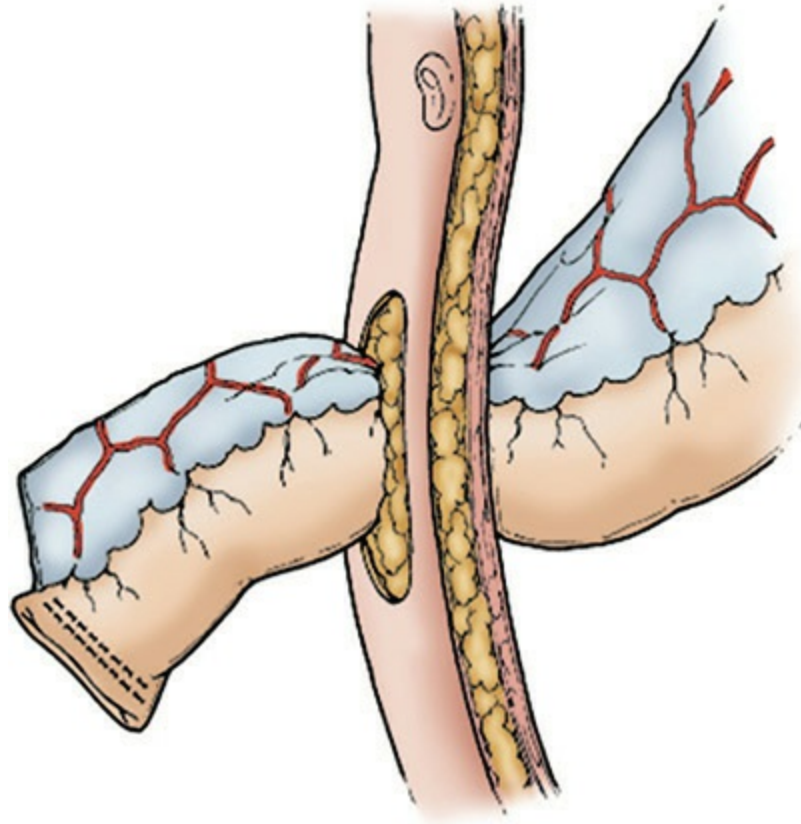

**FIGURE 15-23** Preserve the arcade of mesenteric vessels adjacent to the end of the ileum.

**FIGURE 15-24** The Kocher clamps will keep the fascial layers in line. The anterior rectus sheath is incised, the muscle is spread, and the peritoneum is incised to make the stoma defect.

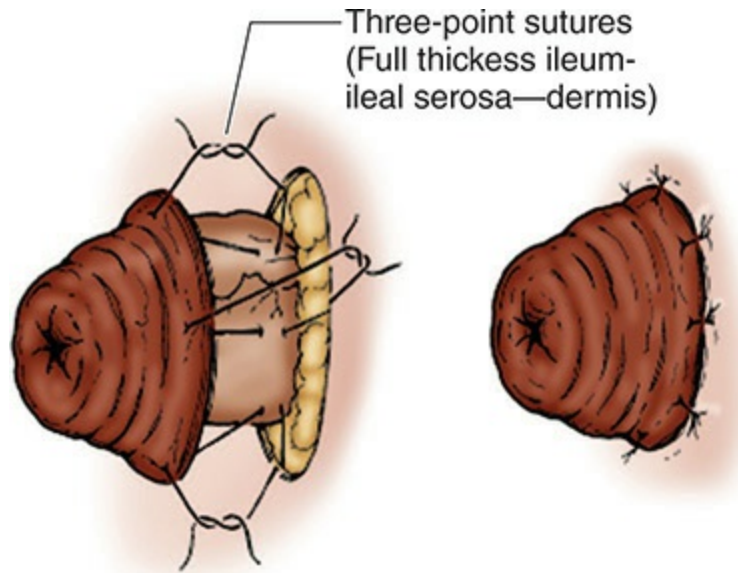

**FIGURE 15-25** Bring the ileum with its blood supply through the stoma defect.

**FIGURE 15-26** Remove the staple line from the end of the ileum.

**FIGURE 15-27** Evert the end of the ileum with interrupted 3-0 Chromic sutures, through the full thickness of the bowel wall edge to the dermis of the skin.

## TECHNIQUE FOR END ILEOSTOMY TAKEDOWN

The technique for taking down an end ileostomy involves mobilizing the ileostomy from the skin, subcutaneous tissue, and fascia as one would do for a colostomy. Use sharp dissection to turn the everted end of the bowel inside. Check for any full- or partial-thickness defects in the bowel wall. Close the end of the ileum by stapling it with a linear cutting stapler. Re-prep the abdomen and change to sterile gloves and instruments before making the abdominal incisions needed for the anastomosis. To maintain pneumoperitoneum at the stoma site with the laparoscopic approach, either close the stoma site fascia with interrupted 0-Vicryl before insufflation or use the stoma site as a port site.

## Loop Ileostomy

### INDICATIONS

The indications for a loop ileostomy include a distal colonic obstruction in the setting of an incompetent ileocecal valve, a distal colorectal anastomosis with a high risk for an anastomotic leak, severe perianal Crohn's disease,

perineal or perianal trauma, perineal wounds that require fecal diversion, and fistulas between the bowel and genitourinary tract which are not ready for definitive repair.

## TECHNIQUE

Choose as distal a segment of ileum as possible that will reach without tension through the abdominal wall. Place orienting sutures of loosely tied knots to prevent inadvertent maturation of the distal side (Fig. 15-28). Make a small defect in the mesentery just adjacent to the bowel wall, taking care not to damage the mesenteric vasculature. Bring a ½-inch umbilical tape or Penrose drain through this defect.

**FIGURE 15-28** Select the most distal segment of ileum that will reach

without tension through the abdominal wall, and place orienting proximal and distal sutures on the bowel wall.

The ileostomy defect is created in the same manner as for an end ileostomy. The chosen loop of ileum is wrapped in Seprafilm and brought through the ileostomy defect using the tape to guide the loop through the abdominal wall while pushing the loop of bowel through the defect from the inside out. Placing excess traction on the bowel and mesentery can cause the mesentery or bowel wall to tear. The mesentery–bowel junction should be at the level of the skin.

After fascial closure and before stoma maturation, some surgeons prefer to place a stoma rod through the mesenteric defect to prevent ileostomy retraction. In obese patients it is critical to sew the rod or Robnel to the skin, as it might otherwise fall into the abdominal cavity, necessitating reoperation. Remove the stoma rod 3 to 5 days after the operation.

Mature the loop ileostomy by transversely incising the distal side of the loop. This transverse enterotomy should encompass at least half the circumference of the bowel wall. Place three-point sutures of 3-0 Chromic full-thickness through the free edge of the bowel, seromuscular through the bowel at the base of the stoma, and through the dermis. Place these sutures in the midline of the antimesenteric bowel wall and on each side near the stoma rod. While placing gentle tension on the sutures, evert the stoma by pushing the back of a forceps just under the free edge of the bowel. Tie the sutures down. Suture the distal bowel with interrupted 3-0 Chromic sutures between the full-thickness bowel wall and dermis. Place additional sutures between these initial sutures to fill in the gaps ([Fig. 15-29](#)).

**FIGURE 15-29** Use three-point sutures to evert the proximal limb of the loop ileostomy (inferior limb in this figure) so that the functional lumen is budded. The distal lumen (superior limb in this figure) can be at the skin level.

## COMPLICATIONS

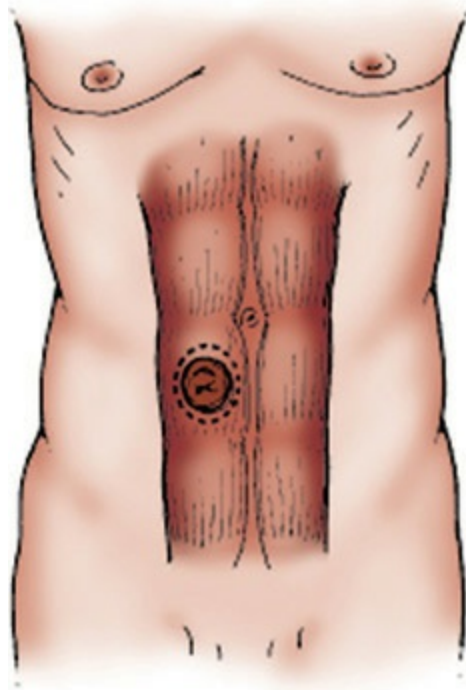

Patients with loop ileostomies are at particularly high risk for high stoma output and pouching difficulties. High stoma output is more likely when the stoma is proximal to the terminal ileum, as is the case for a loop ileostomy proximal to an ileoanal pouch, or a more proximal loop ileostomy in obese patients with thick abdominal walls and thick, foreshortened mesenteries that technically preclude the use of the terminal ileum. Patients with loop

ileostomies are more likely to experience pouch leakage due to the more liquid output of ileostomies, as well as the conformation of the proximal os, which may not be as centered as the os of an end ileostomy. An inferior tilt of the proximal os, especially combined with stomal retraction, causes the stoma effluent to run under the lip of the stoma appliance. Pouch leaks can lead to maceration of the peristomal skin, further aggravating the problem. We discuss the management of these complications in the next section.

## **CLOSURE OF LOOP ILEOSTOMY**

Closure of a loop ileostomy is usually performed at least 3 months after its creation, provided that imaging studies confirm that the distal pathology has resolved, or the colorectal anastomosis is patent and intact. While closing a loop ileostomy sooner than that may be feasible, some patients may still have dense scar tissue around the stoma. Dense adhesions increase the risk for injury to the small bowel or mesentery, and the need for laparotomy. Placement of an anti-adhesion barrier such as Seprafilm around the ileostomy at the time of its creation may reduce these risks.

Make a circumferential incision around the stoma, leaving a 3-mm rim of skin for retraction (Fig. 15-30). Sharply dissect the ileal loop free of the subcutaneous tissues and fascia. After completely mobilizing the bowel, carefully sweep around the anterior abdominal wall to check for additional adhesions, being mindful of the risk of inadvertent injury to small bowel. Successful mobilization of the ileostomy can usually be accomplished through the stoma defect (Fig. 15-31). However, some cases with dense adhesions may require a laparotomy, especially if injuries to the small bowel have occurred. The everted end of the bowel can be straightened with sharp dissection (Fig. 15-32). Infuse Betadine using a bulb syringe into the proximal and distal limbs of the loop ileostomy to detect serosal or full-thickness defects. Close any partial- or full-thickness defects transversely with interrupted 3-0 Vicryl sutures. If there are extensive bowel wall injuries, it may be necessary to resect a segment of small bowel.

**FIGURE 15-30** Make a circumferential incision around the ileostomy in the peristoma skin.

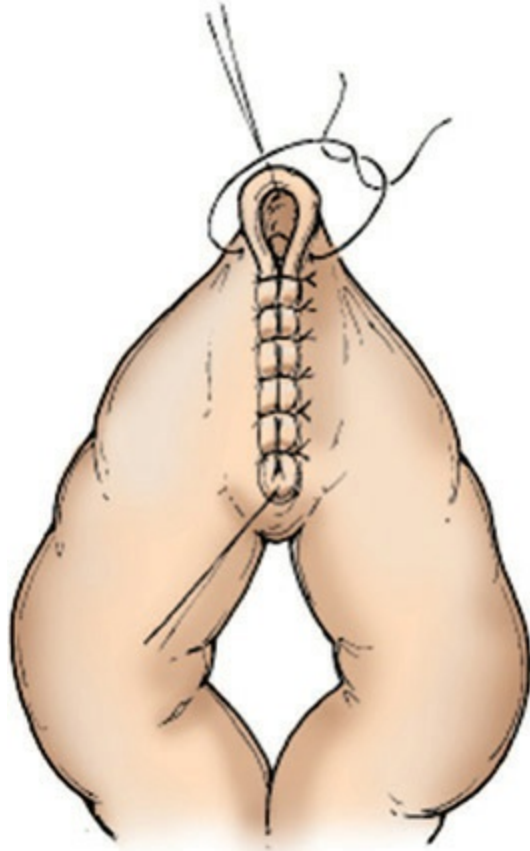

**FIGURE 15-31** Mobilize the ileostomy through the stoma defect.

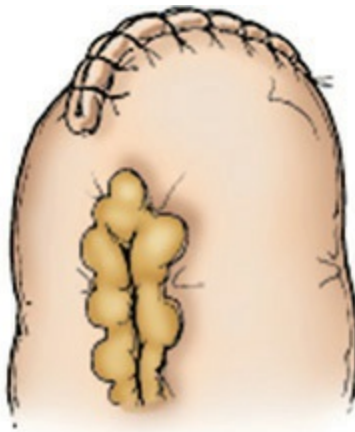

**FIGURE 15-32** Unevert the proximal limb of the bowel with sharp dissection, and check for any partial- or full-thickness defects of the bowel wall.

A sutured closure involves closing the defect in the antimesenteric bowel wall transversely with 3-0 Vicryl seromuscular sutures (Figs 15-33 and 15-34). A second layer of Lembert sutures may be used for reinforcement. If there is a size discrepancy between the proximal and distal limbs, then make a Cheatle incision on the antimesenteric bowel wall of the smaller side. If a small bowel resection was necessary, then perform a handsewn end-to-end anastomosis by approximating the mesenteric side of the bowel with interrupted sutures of 3-0 Vicryl that are full-thickness through the bowel wall, making sure that the mucosa is tucked into the lumen. Close the antimesenteric side of the bowel with interrupted seromuscular sutures of 3-0 Vicryl. In either case, the stapled option involves firing a linear cutting stapler down the proximal and distal lumens, creating a side-to-side anastomosis (Fig. 15-35). Fire a linear stapler to close the end of the anastomosis (Figs 15-36 through 15-39). Closure of the defect is as described for colostomy site closure.

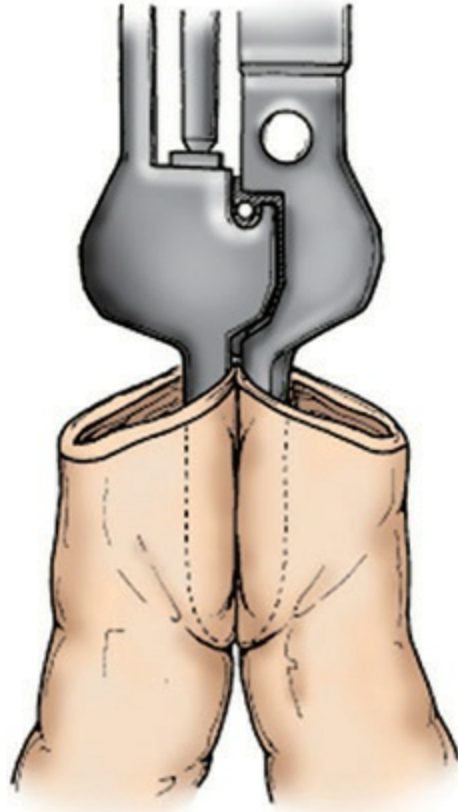

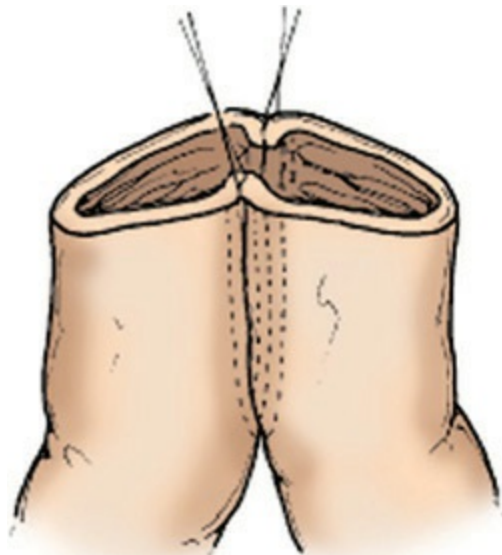

**FIGURE 15-33** Suture the defect closed in a transverse fashion.

**FIGURE 15-34** One or two layers of 3-0 Vicryl sutures are typically used.

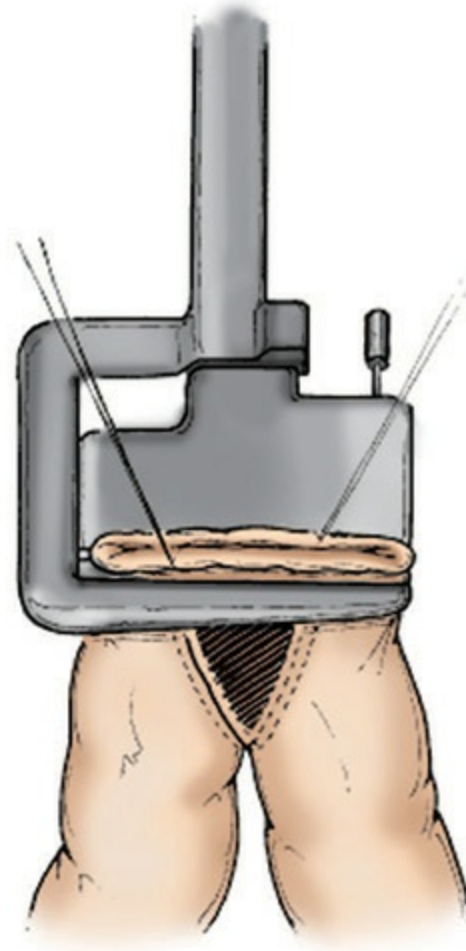

**FIGURE 15-35** A stapled side-to-side anastomosis is an option for ileostomy closure. Fire a linear cutting stapler down both lumens.

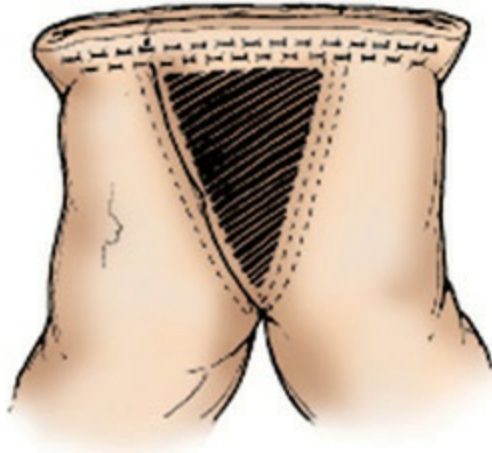

**FIGURE 15-36** The linear stapler creates a side-to-side anastomosis. Check the staple line for bleeding.

**FIGURE 15-37** Offset the linear staple lines before closing the end of the anastomosis.

**FIGURE 15-38** Close the end of the anastomosis with a linear stapler.

**FIGURE 15-39** Side-to-side stapled anastomosis.

## Loop-End Ileostomy

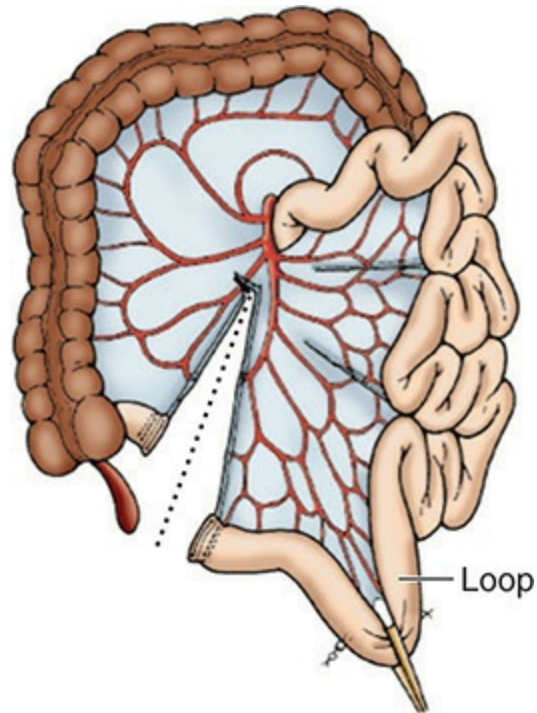

### INDICATIONS

A loop-end ileostomy is a good alternative to end ileostomy in the case of a thick abdominal wall or a foreshortened small bowel mesentery that prevents the end of the small bowel from reaching through the stoma defect. It is far better to create a loop-end ileostomy that is adequately everted than to create a suboptimal end ileostomy that is retracted or ischemic, resulting in pouching difficulties.

### TECHNIQUE

A loop-end ileostomy is created by first determining the most distal loop of small bowel that will reach through the abdominal wall. Place an umbilical tape through a defect in the mesentery at its junction with the bowel wall. Place orienting sutures marking the proximal and distal bowel (Fig. 15-40). Oversew the distal end of the bowel (Fig. 15-41). Create the stoma defect and bring the loop through the defect using the guidance of an umbilical tape or Penrose drain after wrapping the bowel with an adhesion barrier if the stoma is temporary (Fig. 15-42). Place a stoma rod through the defect in the mesentery where the umbilical tape was (Fig. 15-43). Transversely incise the distal side of the loop. Evert the proximal side by placing three-point sutures

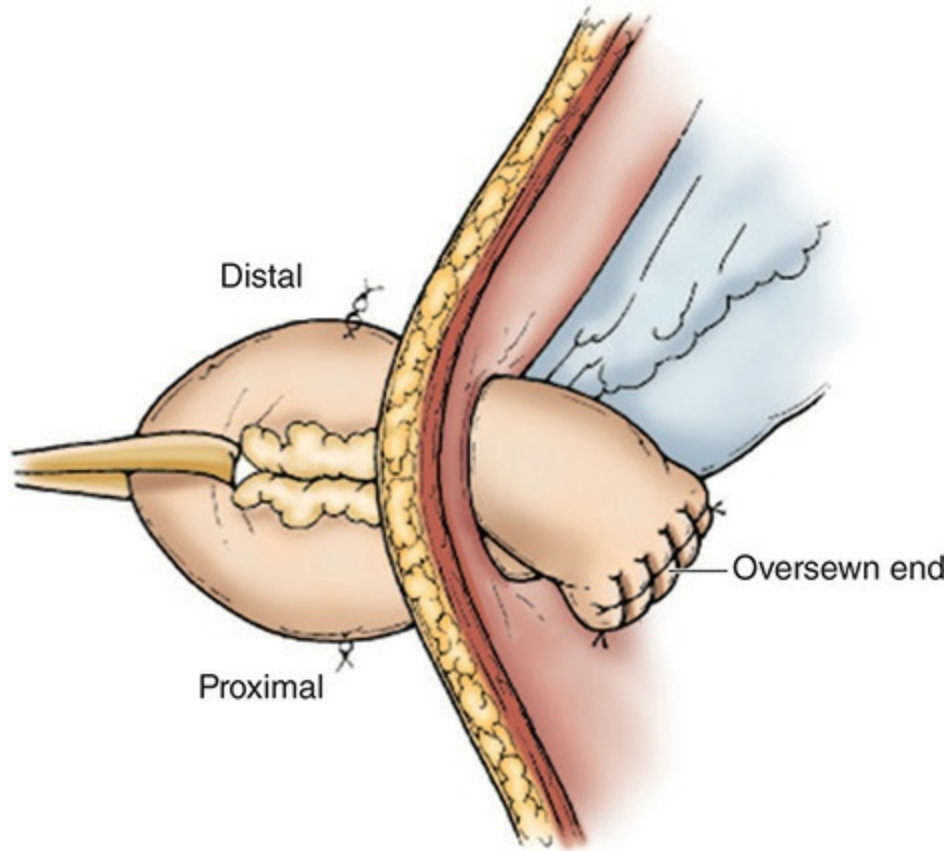

full-thickness through the bowel wall edge, seromuscular through the bowel wall at the level of the skin, and through the dermis. To mature the distal side, place two-point sutures full-thickness through the bowel wall edge, and through the dermis (Fig. 15-44).

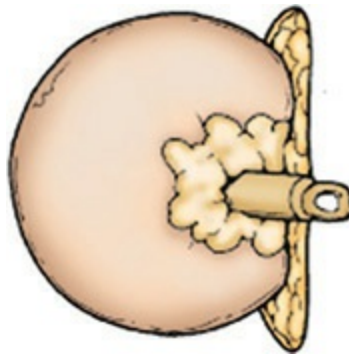

**FIGURE 15-40** Find the most distal loop of small bowel that will reach through the abdominal wall and place orienting sutures to mark the proximal and distal bowel.

**FIGURE 15-41** Oversee the distal staple line.

**FIGURE 15-42** Bring the loop of ileum through the stoma defect.

**FIGURE 15-43** Place a stoma rod through the mesentery at its junction with the bowel wall.

**FIGURE 15-44** Mature the loop-end ileostomy by incising the distal side of the loop transversely and everting the proximal side (inferior in this figure) using three-point sutures of 3-0 Chromic.

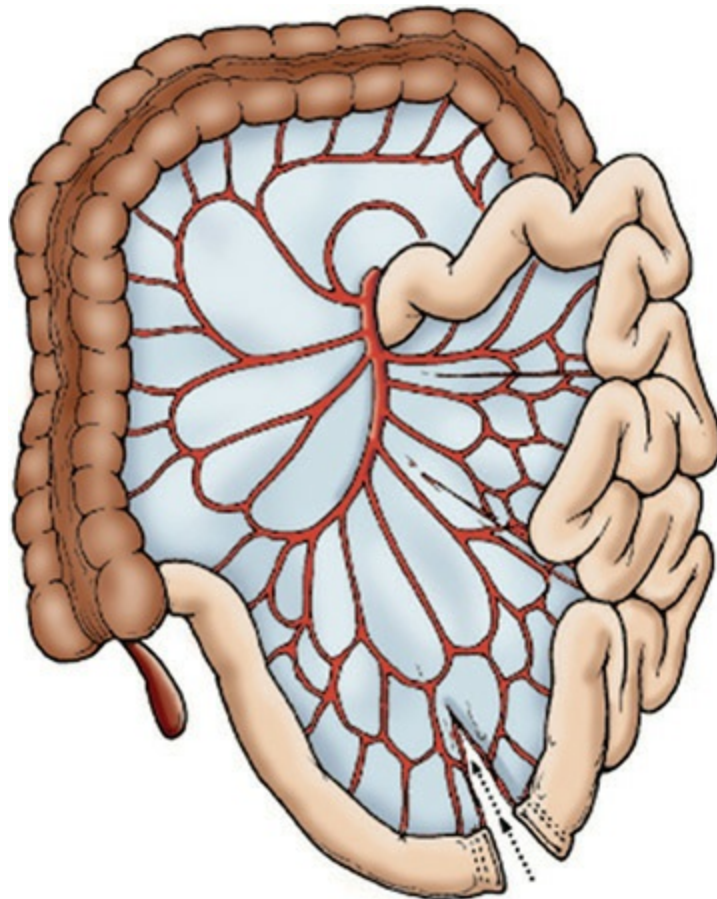

## Separated Ileostomy (Divided End-Loop)

### INDICATIONS

A separated ileostomy is useful in situations where complete fecal diversion is necessary, or if there is difficulty in bringing enough bowel through the abdominal wall.

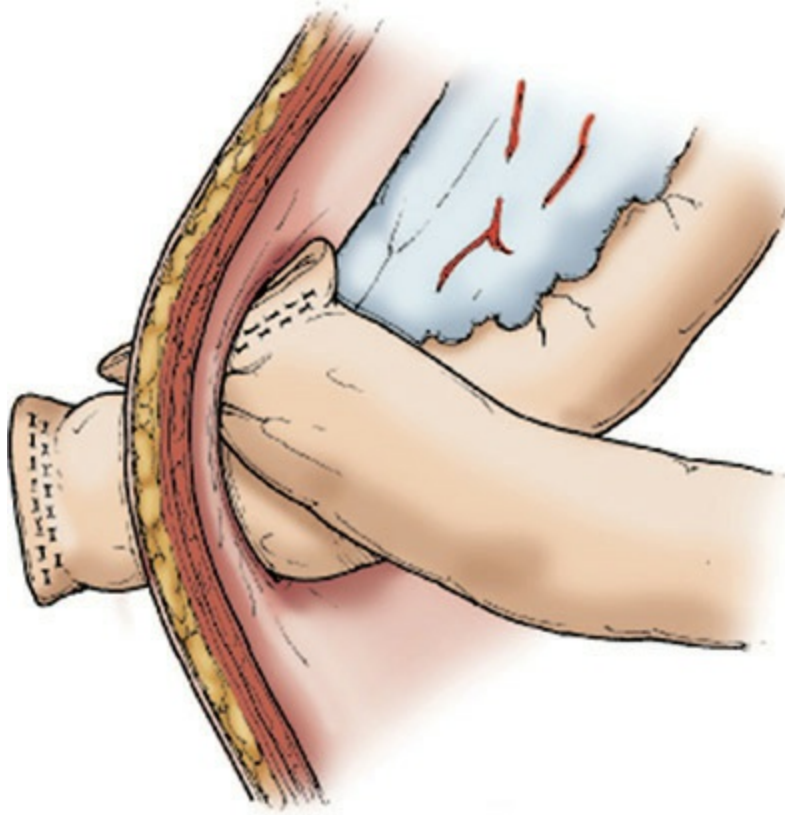

## TECHNIQUE

Divide the ileum with a linear cutting stapler, taking care to preserve all mesenteric vessels (Fig. 15-45). Create the stoma defect. Bring the proximal limb and the antimesenteric corner of the distal limb through the stoma defect (Fig. 15-46). Excise the antimesenteric corner of the distal limb and remove the end of the proximal limb (Fig. 15-47). Mature the proximal side using three-point sutures and the distal corner using two-point sutures (Fig. 15-48).

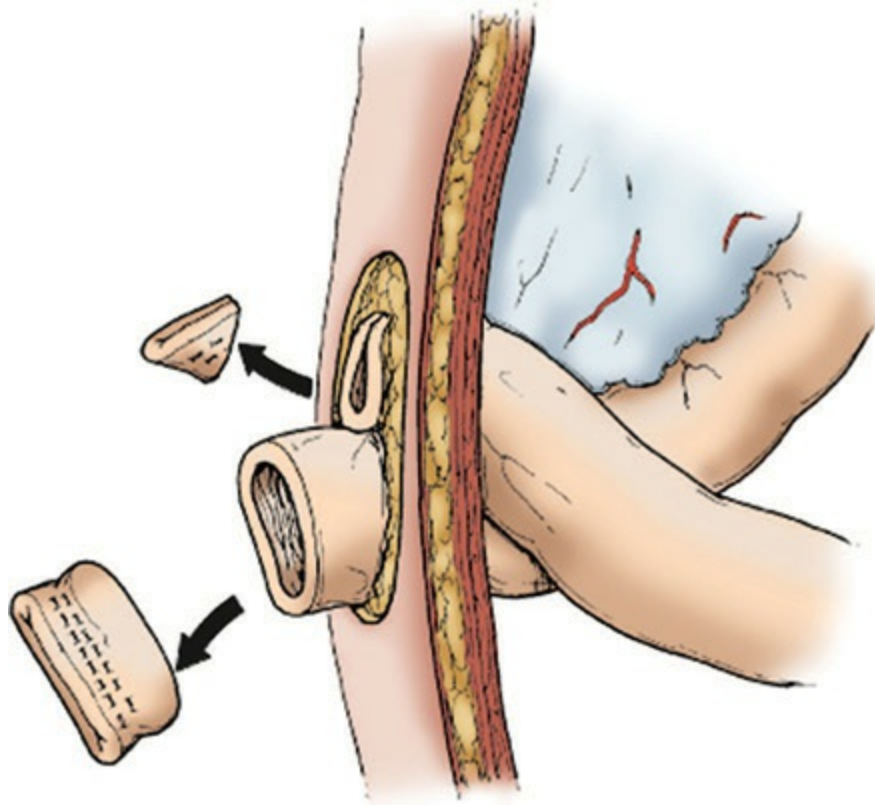

**FIGURE 15-45** Preserve the mesenteric blood supply when dividing the bowel.

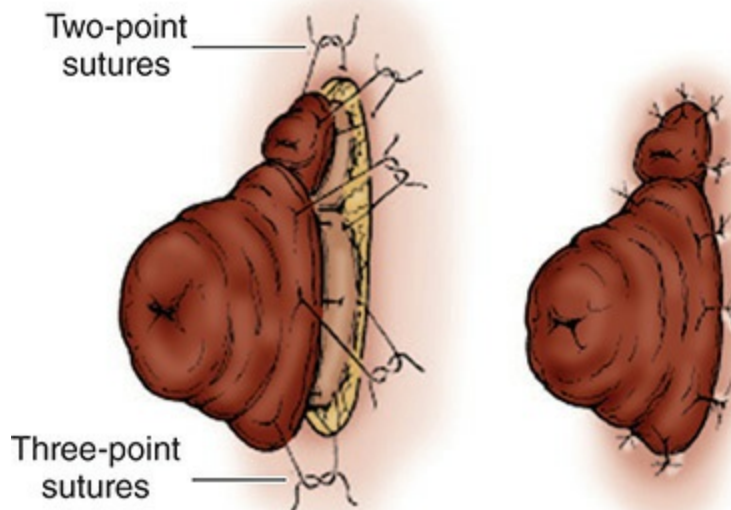

**FIGURE 15-46** Bring the proximal limb through the stoma defect, as well as the antimesenteric corner of the distal limb. In this figure, the proximal limb is inferior and the distal limb is superior but this configuration is not mandatory.

**FIGURE 15-47** Remove the staple line of the proximal limb (inferior in this figure) and the antimesenteric corner of the distal limb (superior in this figure).

**FIGURE 15-48** Mature the proximal limb (inferior in this figure) of the bowel by everting it with three-point sutures. The bowel edges of the

proximal and distal limbs that are adjacent to each other should be sutured to each other, and the rest of the distal limb should be sutured to the dermis of the stoma defect.

## **Ileostomy Care and Skin Complications**

A well-placed and well-constructed ileostomy should offer the patient a good quality of life, minimal restrictions on activity, and ability to enjoy a range of foods. Most patients use a two-piece ileostomy appliance system comprised of a faceplate with a skin barrier and a pouch. The stoma opening of the skin barrier must match the exact size of the ileostomy, so that all the peristomal skin remains protected from the ileostomy effluent. The faceplate typically lasts 3 to 5 days, but if the patient experiences leakage under the appliance, then it requires more frequent changes. Maintaining a good seal around the ileostomy is crucial for maintaining the integrity of the peristomal skin and quality of life. The chemical dermatitis caused by leakage of ileostomy contents onto the skin can be extremely painful and results in a vicious cycle in which maintaining an adequate seal between the faceplate and macerated skin is impossible, leading to more leaks and skin trauma.

A retracted ileostomy with an os at skin level, or a tilted ileostomy with an os pointing down, is likely to result in leaks and pouching problems. Loop ileostomies are more likely to be associated with pouching problems because the distal opening is flush with the skin, allowing mucus to seep under the faceplate and disrupt the seal.

## **Management of High-Output Ileostomies**

Many postoperative patients with new ileostomies experience a large volume of liquid output in the first few weeks after the operation. The daily volume of ileostomy output may be over a liter shortly after ileostomy creation, but should slow down to 500 to 800 mL after the small bowel has had a chance to adapt and increase its absorptive capacity. However, some patients may persistently have high output for various reasons including partial obstruction, short gut syndrome, or intrinsic bowel abnormalities.

The two main problems with high-output ileostomies are dehydration often accompanied by electrolyte abnormalities and pouching difficulties due

to the liquidity and volume of the effluent. The first step in the diagnostic workup is to rule out an underlying obstruction, which can cause the bowel proximal to the obstruction to secrete large volumes of fluid. Assess for an obstruction at the level of the fascia by inserting a finger into the stoma. A contrast study or ileoscopy through the ileostomy will demonstrate a more proximal obstruction.

Other possible etiologies include enteritis, short bowel syndrome, or inflammatory bowel disease. Most commonly, high ileostomy output is attributable to dietary indiscretion, and can be managed with a combination of diet changes, fiber supplementation, and medications. General principles for managing high ileostomy output are avoidance of concentrated sugars, hydrating with a combination of water and electrolyte beverages, and eating foods with a balance of protein, healthy fats, and soluble fiber (Table 15-4). Patients should be cautioned against drinking large amounts of water in an effort to keep up with the high volumes of watery ileostomy output they are experiencing, as this may exacerbate electrolyte deficiencies and will not help to slow the output. Rather, they should be counseled to eat as well as hydrate with a diluted electrolyte drink.

**TABLE 15-4: MANAGEMENT OF HIGH ILEOSTOMY OUTPUT**

### **Foods to slow down and thicken ileostomy output:**

- Peanut butter (creamy)
- Cheese
- Potatoes
- Bread
- Bananas
- Tapioca pudding
- Marshmallows
- Applesauce

### **Maintaining hydration and electrolyte balance:**

8–10 (8 oz) glasses of fluids per day

- Water

- Dilute fruit juices or sports drinks 1:1 with water, add a pinch of salt

- Coconut water (contains less sugar than fruit juice, and also contains sodium, potassium)

---

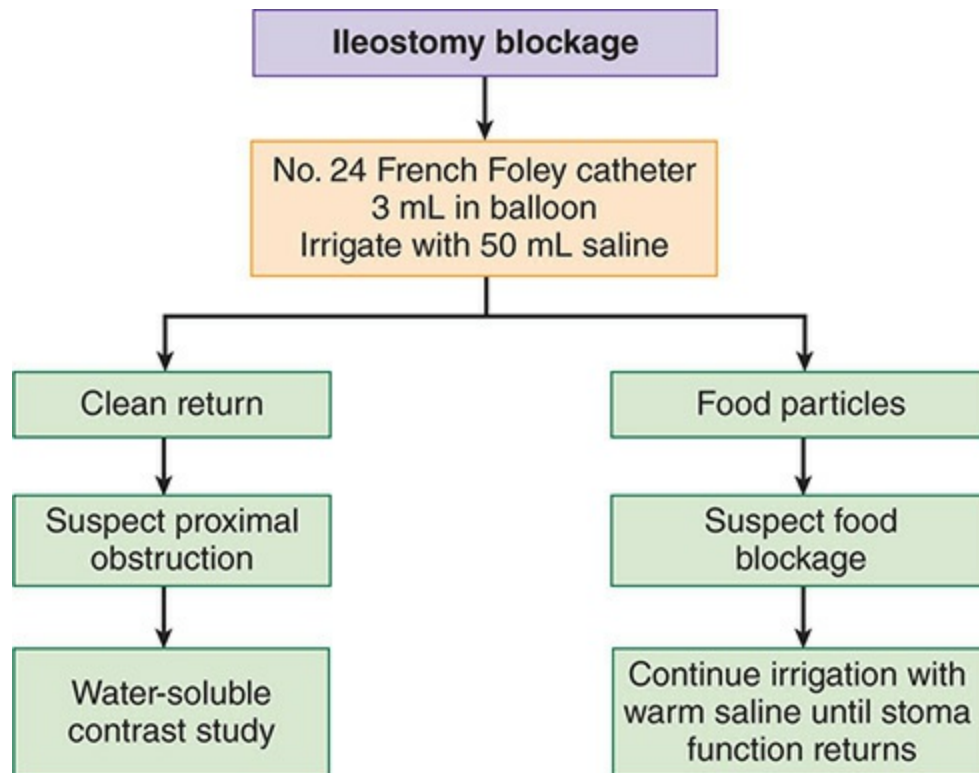

Fiber supplementation in the form of the soluble fiber pectin, powders dissolved in drinks, and fiber wafers are more effective than fiber pills. Medications such as loperamide, diphenoxylate-atropine, and tincture of opium can also be helpful in reducing the stoma output. Introduce one drug at a time and increase the dose as needed. Patients with fast transit may not absorb capsules or tablets, so elixir or orally disintegrating formulations may be more effective.

If all of these measures are unsuccessful at controlling the output and dehydration with electrolyte and/or nutritional deficiencies continues to occur, then the patient may require long-term parenteral replacement of fluids and electrolytes. Malnutrition due to poor absorption may require total parenteral nutrition.

## **Management of Ileostomy Obstruction**

If a patient with an ileostomy develops obstructive symptoms, the first step is to rule out an obstruction due to a food bolus by irrigating the stoma with saline via a Foley catheter. Food particles in the irrigant raise suspicion of a food bolus as the culprit, and continued irrigation with warm saline should resolve the problem. If there are no food particles in the irrigant, then the

obstruction may be due to other causes such as adhesions, volvulus of small bowel around the ileostomy, or parastomal hernia. Cross-sectional imaging or a water-soluble contrast study via the stoma is helpful in making the diagnosis (Fig. 15-49).

**FIGURE 15-49** Diagnostic and therapeutic algorithm for managing ileostomy obstruction.

## STOMA COMPLICATIONS

### Parastomal Hernia

Parastomal hernia occurs in up to 50% of patients. Risk factors of parastomal hernia include any condition that causes increased intra-abdominal pressure including obesity, chronic cough, chronic obstructive pulmonary disease, ascites, and straining behaviors. Other patient-related risk factors include older age, malnutrition, systemic steroids, and creation of the stoma during emergency operation. Technical factors that may reduce the risk of hernia are using an extraperitoneal route rather than a transperitoneal route, a smaller

trephine aperture for the stoma defect, and prophylactic mesh reinforcement of the stoma defect at the time of primary stoma creation.<sup>29,30</sup> Most parastomal hernias may be managed nonoperatively, but complications associated with parastomal hernia such as pouching difficulty, bowel obstruction, or incarceration are indications for surgical repair (Figs 15-50 through 15-52). The best treatment for parastomal hernia repair is restoration of bowel continuity, as the recurrence rate of parastomal hernia repair with mesh is as high as 17% in some series.<sup>31</sup> Primary suture repair has recurrence rates ranging from 46% to 100%, and there are few indications for this procedure. The use of biologic or prosthetic mesh is associated with a low incidence of mesh infection. Several options for mesh placement and surgical approach exist. An onlay mesh with a central defect for the stoma sits on top of the fascia. A sublay mesh with a keyhole opening for the stoma sits between the rectus muscle and the posterior rectus sheath. An underlay mesh sits posterior to the peritoneum. It may have a keyhole defect for the stoma opening, or it can be placed as a patch over the most distal intraperitoneal part of the colon. This Sugarbaker technique creates a short tunnel for the distal colon and has been found to have a lower recurrence rate.<sup>31</sup> The final option is stoma relocation with mesh repair of the other stoma defect. The success of stoma relocation is equivalent to that of mesh repair.<sup>32</sup>

**FIGURE 15-50** Patient with a large parastomal hernia, with pouching difficulties.

**FIGURE 15-51** This parastomal hernia was causing recurrent bowel obstructions due to the incarcerated loops of bowel in the hernia sac.

**FIGURE 15-52** Recurrent bowel obstructions and pouching difficulties are indications for parastomal hernia repair.

## **Stoma Prolapse**

Loop colostomies using the sigmoid or transverse colon have the highest risk of stoma prolapse. An accompanying parastomal hernia is common. If the prolapse is incarcerated but the bowel is not ischemic, then manual reduction should be attempted immediately. If the stoma is edematous, pour a generous amount of sugar onto the prolapsed segment and allow it to sit for at least 10 minutes. The sugar will induce an osmotic diuresis of the bowel wall, thus reducing the edema and increasing the chances of a successful reduction. Place a gauze sponge over the prolapsed bowel and apply gentle constant pressure to the os of the stoma. Giving the patient pain medication or muscle relaxant may aid in this process as well. If manual reduction is successful, then the patient may undergo elective repair.

Inability to reduce the stoma or ischemic bowel is an indication for emergent surgical intervention. Operative approach depends on whether the ischemia extends below the fascia. Most cases of incarcerated and ischemic stoma prolapse require resection of the prolapsed segment using the existing stoma site, with creation of a new stoma. A laparotomy is necessary if operating through the stoma site does not allow adequate access for resection of the ischemic bowel segment, or adequate mobilization of proximal bowel for a new stoma. Other indications for surgical management for a prolapsing stoma include pouching difficulty, obstruction, and pressure necrosis or bleeding due to a traumatized stoma.

## **Stomal Retraction**

Stoma retraction occurs when the bowel wall pulls away from the skin, causing the os of the stoma to sit below skin level. Risk factors for stomal retraction include inadequate mobilization of the bowel at the time of initial stoma creation, a thick abdominal wall, a short mesentery, and emergency surgery. This complication often occurs in the early postoperative period. If it occurs within a week of the initial operation, then it is worth considering reoperation for stoma revision to avoid the long-term sequelae associated with retraction. If it occurs more than a week from the time of initial operation, then reoperation may be ill-advised due to dense postoperative adhesions that are likely to preclude the additional mobilization that is needed to fix the problem. It is important to determine whether the bowel has

retracted below the fascia, as retraction below the fascia may cause intra-abdominal stool spillage and is an indication for operative intervention. If one encounters obliterative adhesions that preclude mobilization of the bowel, then a safer surgical strategy may involve bringing up a proximal loop stoma in a separate location.

If stoma retraction occurs too far after the initial operation to safely reoperate, and the distal end of the stoma is above the level of the fascia, then the mainstay of management is pouching strategies that will minimize damage to the peristomal skin and maintain a seal (Fig. 15-53).

**FIGURE 15-53** This patient had a retracted ileostomy that was very difficult to pouch, and as a result had caused significant peristomal skin irritation.

Prevention of stoma retraction involves mobilizing adequate bowel length at the time of initial stoma creation. As it may be very difficult to mobilize enough bowel and mesentery to bring the end of the bowel through a thick abdominal wall, especially if the mesentery is thick and foreshortened, a loop-end stoma can often be a good alternative that will reach through the abdominal wall without tension.

## Stoma Ischemia

Risk factors for ischemia of the stoma include a thick abdominal wall, small stoma defect size relative to the bowel caliber, and excessive dissection or tension of the mesentery. The bowel wall may not demonstrate obvious signs

of ischemia until several days after the operation. Similar to the case of stoma retraction, it is important to determine whether the ischemia extends below the fascia. If the ischemia only involves the bowel above the fascia, then the ischemic mucosa will slough off with time, and usually does not require reoperation (Fig. 15-54). Ischemia extending below the fascia is an indication for operative intervention. If the cause of ischemia is a tight stoma defect, then a local stoma revision to increase the size of the defect and bring up a healthier segment of bowel may be successful. Laparotomy will be necessary if mobilization of additional bowel cannot be performed through the stoma site. Often a loop-end stoma is necessary to preserve adequate mesenteric blood flow in the setting of a thick abdominal wall and a short mesentery.

**FIGURE 15-54** This stoma has mucosal ischemia that did not extend past the fascia, and therefore did not require reoperation.

## Stoma Stenosis

Stoma stenosis often occurs in conjunction with stomal retraction, which allows the skin of the stoma defect to close concentrically over the os. The most effective way to manage stoma stenosis is surgical revision, but patients who cannot undergo operative intervention may undergo stoma dilations.

Dilations can be performed in the office setting or under sedation in the operating room, depending on the patient's comfort level.

## Mucocutaneous Separation

Mucocutaneous separation, when the edge of the bowel wall separates from the skin edge at the border of the stoma, occurs as a result of poor wound healing (Fig. 15-55). The crevice that is formed by the separation presents a challenge for pouching, and patients may find it difficult to maintain an intact seal around the stoma. The key elements to managing this complication are to keep the peristomal skin in good condition, optimize nutrition, and to employ local wound care techniques to fill in the trough and induce granulation of the wound.

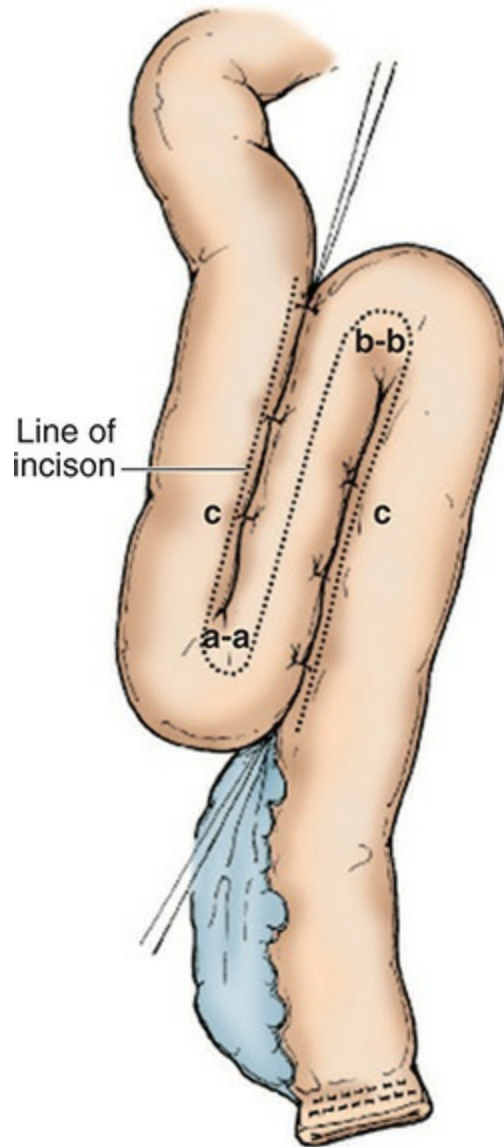

**FIGURE 15-55** This patient had underlying disease that precluded wound healing, and this led to severe mucocutaneous separation of the ileostomy.

## CONTINENT ILEOSTOMY

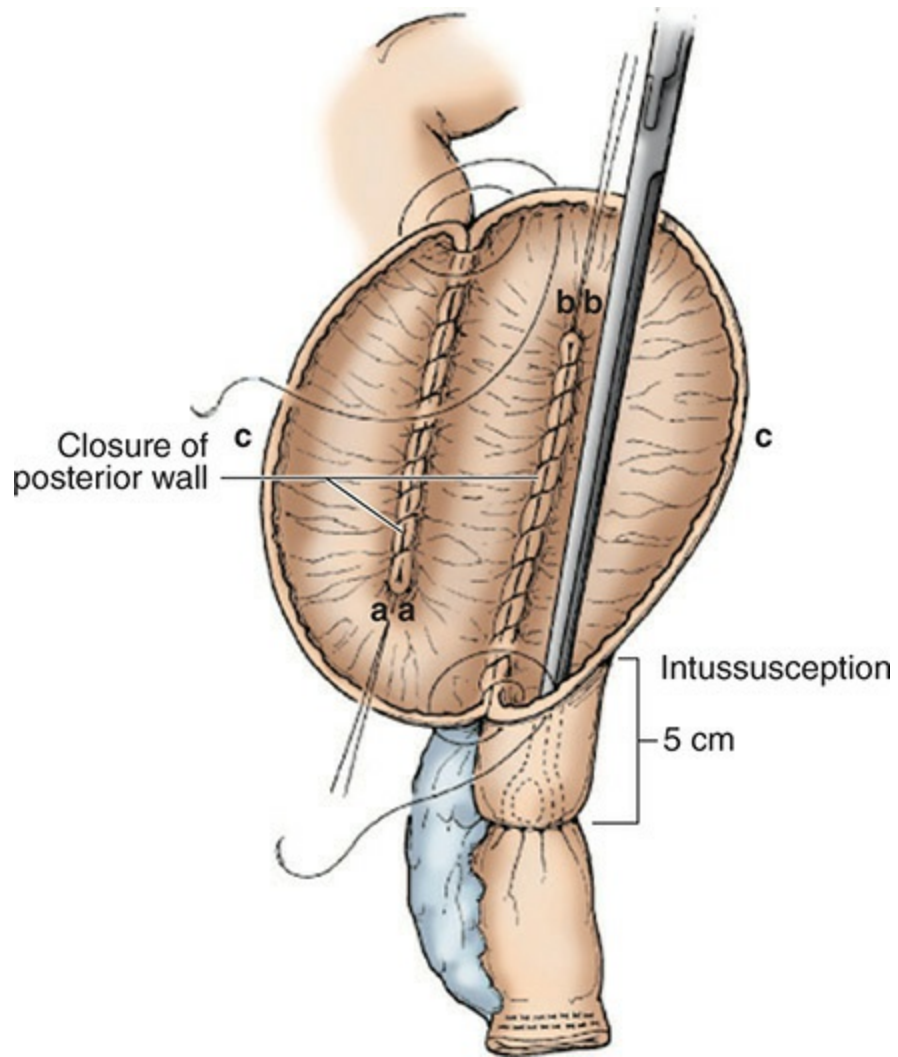

Continent ileostomy (Kock pouch) was introduced in 1969 and gained popularity throughout the 1970s.<sup>33</sup> Since the introduction of ileal pouch-anal anastomosis (IPAA), fewer continent ileostomies are being constructed because of their high complication and revision rates compared with IPAA.<sup>34–37</sup> Patients with medically refractory ulcerative colitis or familial adenomatous polyposis may still choose to have a continent ileostomy, often after having complications from IPAA that cannot be salvaged, or if end ileostomy presents particular challenges. Many patients who pursue continent ileostomy do so because of psychosocial considerations, and feel strongly

that their quality of life will be significantly improved, even with the potential of multiple complications. Contraindications for continent ileostomy include inability to learn how to reliably intubate the pouch, personal or family history of desmoid disease given the risk for multiple operations and thus surgical trauma, obesity due to the increased risk for valve slippage, and inadequate small bowel length. Continent ileostomy should only be offered to highly motivated and well-informed patients who understand the high risk for reoperation and pouch failure.

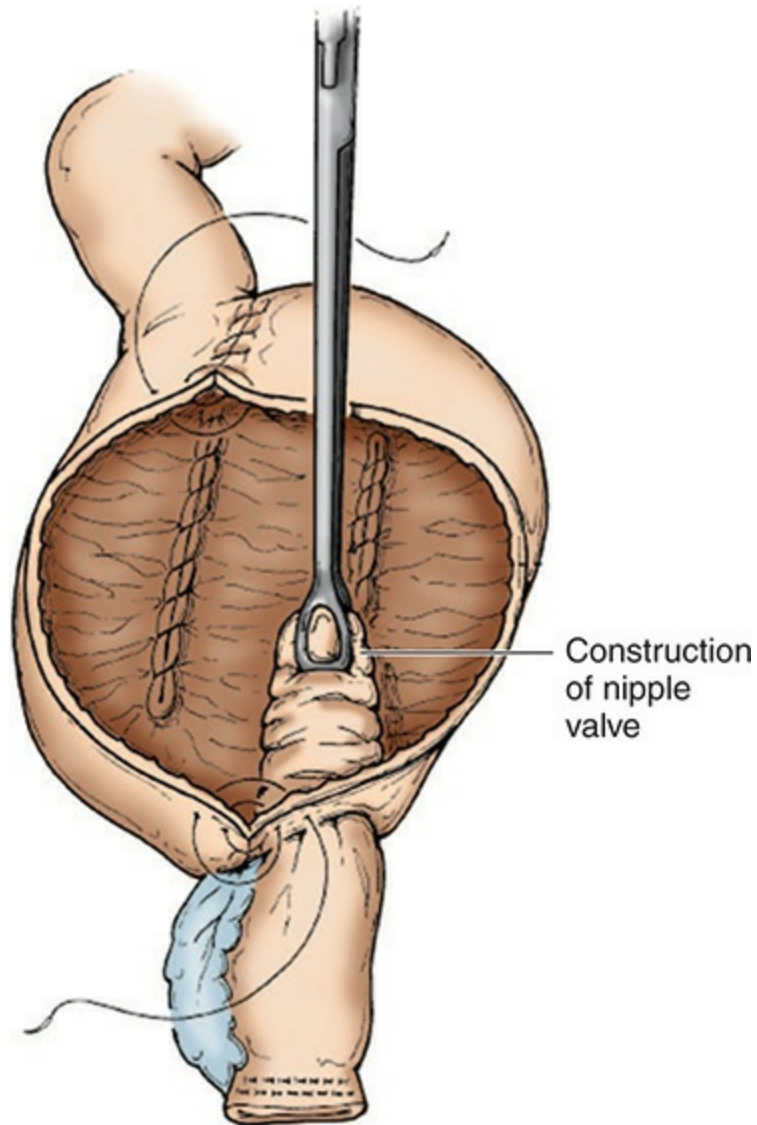

Several techniques for creating continent ileostomies have been described. The original Kock pouch design has been modified into a three-limbed S-pouch with a nipple valve created by intussuscepting a segment of the efferent limb. First, three 10- to 12-cm segments of small bowel are measured out and sutured together in an S-configuration, making sure to leave an additional 14 to 16 cm of small bowel distal to the pouch for the valve and outlet (Fig. 15-56). The antimesenteric side of all three limbs is opened with a longitudinal enterotomy. Another layer of sutures is placed in the back wall (Fig. 15-57). Intussusception of 6 cm of the efferent limb into the pouch forms the nipple valve (Figs 15-58 through 15-60). Before intussuscepting the bowel, the peritoneum of the small bowel mesentery is stripped, and cross-hatches in the mesentery can be created with electrocautery. These two techniques induce scar formation to hold the intussusception in place. The intussusception is fixed in place by firing a linear noncutting stapler along the length of the valve on either side of the mesentery (Fig. 15-61). The anterior wall of the pouch is closed in two layers. Before completing closure, the valve is fixed to the wall of the pouch with a third fire of the linear noncutting stapler. The valve's continence is tested after closure of the pouch by inserting a Medena catheter through the valve, infusing saline to fill the pouch, and removing the tube and ensuring that there is no leakage of saline from the pouch. Additional sutures are placed around the base of the valve where it enters the pouch, to further secure it from slipping. These sutures are used to affix the pouch to the abdominal wall at the planned stoma site (Fig. 15-62).

**FIGURE 15-56** Three 10- to 120-cm segments of small bowel are sutured together in an S-configuration.

**FIGURE 15-57** The antimesenteric sides of the S-configuration are opened, and a second layer of sutures is placed in the back wall of the pouch.

**FIGURE 15-58** Intussusception of a 6-cm segment of the efferent limb (distal to the pouch) forms the nipple valve.

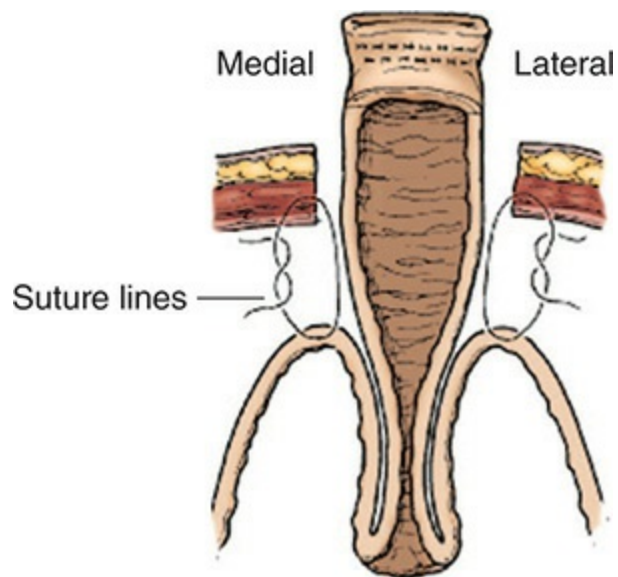

**FIGURE 15-59** The intussusception creates a continent valve.

**FIGURE 15-60** Intussuscepted nipple valve in a case of Kock pouch revision.

**FIGURE 15-61** The intussusception is stabilized by firing a linear noncutting stapler along the valve on either side of the mesentery.

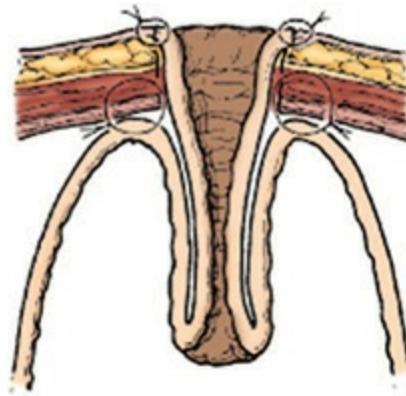

**FIGURE 15-62** Affix the pouch to the abdominal wall using sutures that have been placed around the base of the valve.

The site of a continent stoma is usually more inferiorly located than a

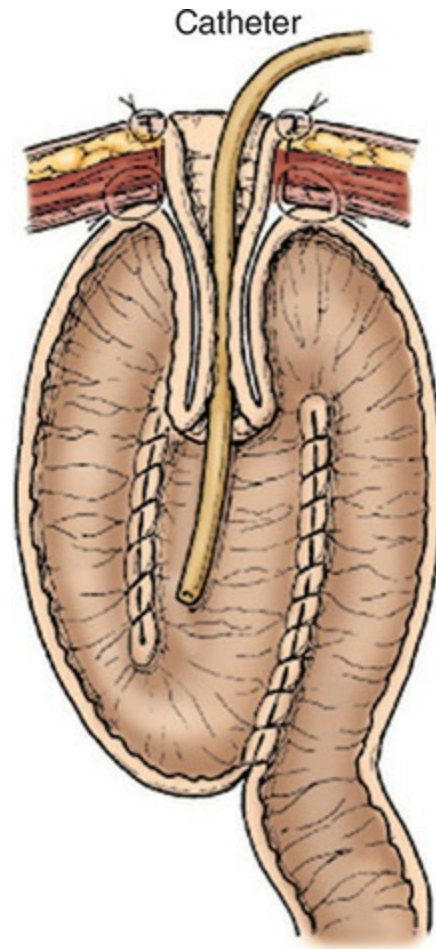

conventional ileostomy site. This allows the pouch to sit in the pelvis, and also allows the stoma site to be concealed below the beltline. The remaining length of distal small bowel is brought through the site, and a skin-level stoma is created by suturing the bowel wall to the dermis without eversion (Figs 15-63 and 15-64). A straight path for intubation from the stoma through the valve and into the pouch is paramount for a good functional outcome and minimizing the risk for repeated trauma to the valve or pouch from intubation (Fig. 15-65). Before abdominal wall closure, the ease of intubation and continence of the pouch is tested. The catheter remains in place within the pouch with regular irrigations for at least 2 weeks after the operation. Patients will then intubate every 2 hours for another week, then increase the time interval gradually until they are intubating every 4 to 6 hours.

**FIGURE 15-63** The stoma is brought through the stoma defect, which is located more inferiorly than a traditional ileostomy.

**FIGURE 15-64** The stoma is matured without eversion to create a skin-level stoma.

**FIGURE 15-65** A Medena catheter is typically used to intubate the stoma. It is important to ensure that there is a straight path from the stoma, through the valve, and into the pouch.

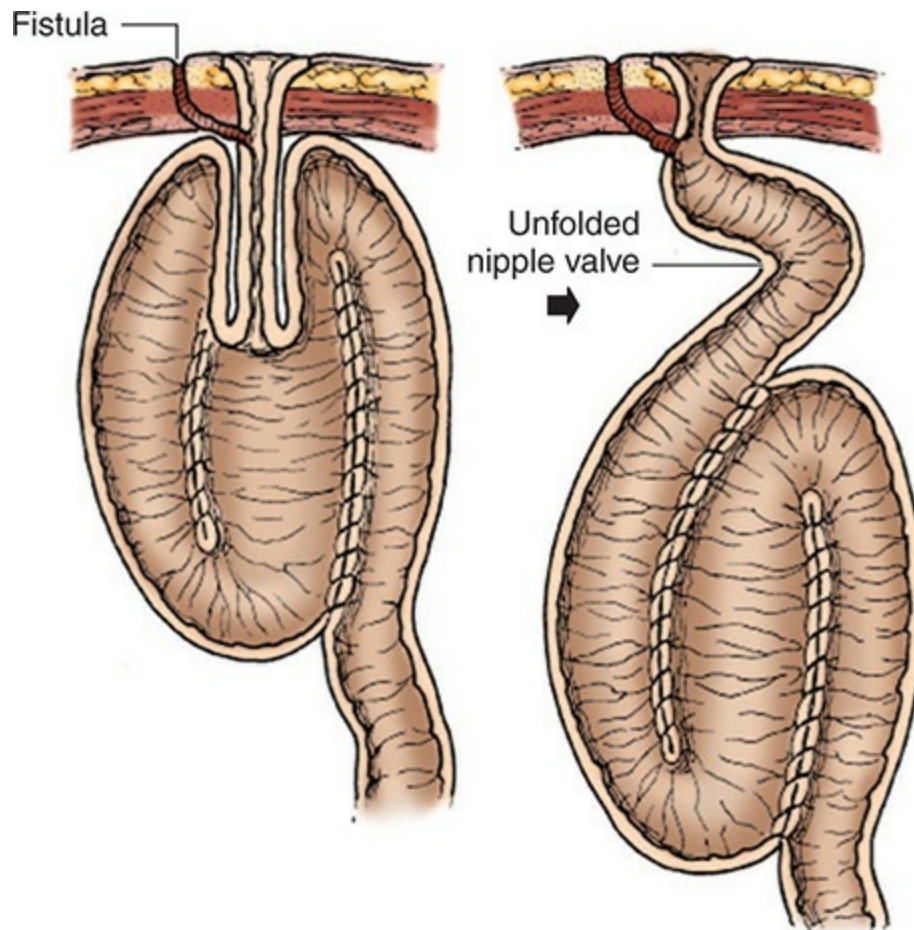

The Barnett Continent Ileostomy Reservoir is another method of continent ileostomy construction in which an antiperistaltic segment of the efferent limb is used to create the valve and stoma.<sup>38</sup> A segment of blind-ending efferent bowel coming off the pouch wraps around the valve, creating a living collar that distends as the pouch fills, thus closing off the valve. The afferent limb of bowel attaches to the apex of the pouch.

The T-pouch design was first used as a continent neobladder, and subsequently adopted for continent ileostomy.<sup>39,40</sup> This design also uses a separate segment of bowel to form the valve, but instead of intussusception, the valve consists of an antireflux mechanism using an ileal tunnel. The pouch is constructed of two limbs of small bowel. The antimesenteric side of the bowel is opened, and the edges along the valve are closed over the valve

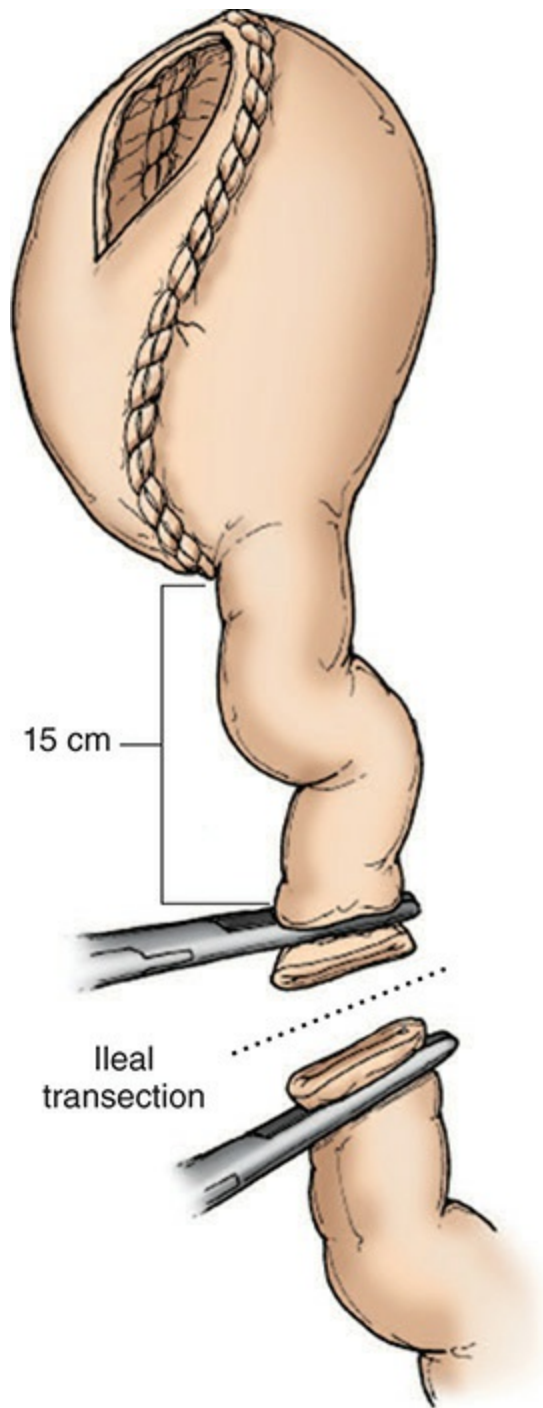

to form the ileal tunnel. The reservoir is then folded in half to close it.

Patients who have a well-functioning continent ileostomy enjoy excellent quality of life. Most patients intubate the pouch every few hours, depending on the volume of the output. Irrigation may be necessary depending on the consistency of the output.

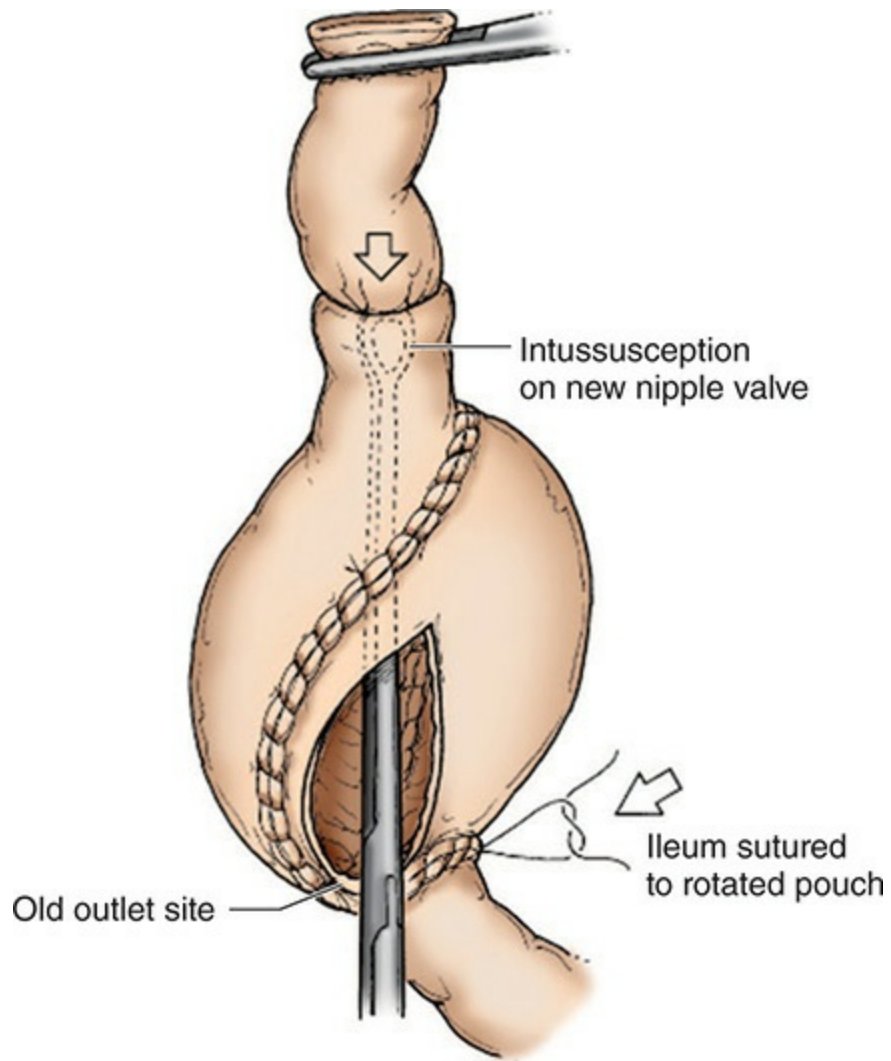

Early postoperative complications include leakage or bleeding from suture lines, or valve necrosis. Late complications include valve slippage, stomal stenosis, pouchitis, volvulus, and fistulas (Fig. 15-66). About 50% of patients will require at least one reoperation for revision of the pouch or excision of the pouch. Valve slippage can present as incontinence to gas or stool, or difficulty with intubation. Endoscopy confirms the diagnosis. Inability to intubate a still-continent pouch results in an obstruction, and decompression with endoscopy with placement of a catheter is the temporary treatment until surgical correction. Surgical management of a slipped valve or a valve fistula usually requires construction of a new valve using the efferent length of bowel just proximal to the pouch, 180-degree rotation of the pouch, and anastomosis of the new efferent bowel end to the opening where the old valve was (Figs 15-67 through 15-69). The highest rate of pouch reoperation is in the first 2 years, but in those patients in whom the pouch was salvaged, long-term durability and satisfaction were high.<sup>41</sup> Patients undergoing revision of a continent ileostomy must understand that the risk of pouch excision and conversion to a conventional ileostomy is very high—at least 50%. Many patients who face the chance of losing an imperfectly functioning continent ileostomy will prefer to live with incontinence rather than take the chance of losing the pouch completely.

**FIGURE 15-66** Late complications of continent ileostomy include fistula and valve slippage. Valve slippage presents as incontinence or difficulty with intubation.

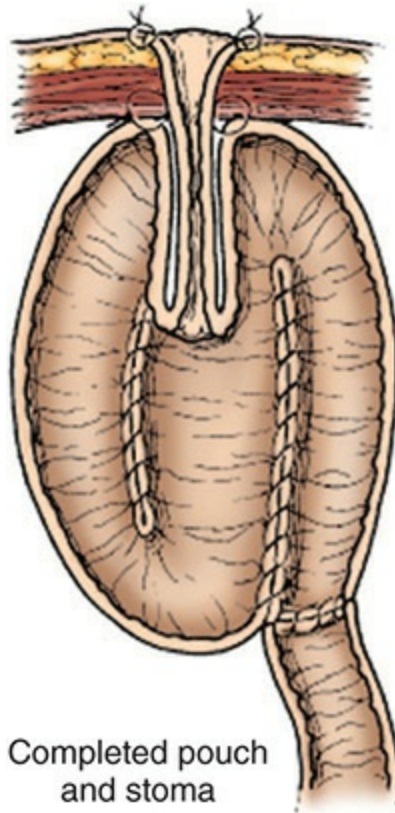

**FIGURE 15-67** Revision of a continent ileostomy for a slipped nipple valve can be performed by using the afferent segment of bowel for a new nipple valve. The ileum is transected about 12 to 15 cm proximal to the pouch.

180 degrees pouch rotation

**FIGURE 15-68** The pouch is rotated 180 degrees and the bowel is intussuscepted to form a new valve. The site where the old valve was is sutured to the proximal ileum.

**FIGURE 15-69** The valve is stapled and the pouch is completed in the same way as a new continent ileostomy.

## APPENDICOSTOMY

Appendicostomy with antegrade continence enema is an option for patients with fecal incontinence or medically refractory constipation due to colonic inertia. The cecum is plicated around the base of the appendix as an antireflux mechanism. The appendix is brought up to the umbilicus and the tip opened to create an inconspicuous stoma. The appendicostomy is intubated once a day for administration of an antegrade enema to clear the colon. In the long term, most patients experience improvement in symptoms but there is wide variety among studies.<sup>42,43</sup> It is not a commonly performed procedure, but may be successful for carefully selected highly motivated patients. Complications include stenosis of the stoma and leakage from the appendicostomy. A significant proportion of patients do not benefit from this operation so will need another operation to address the underlying problem.

## CONCLUSION

Intestinal stomas, if well-formed and well-placed, are compatible with a good quality of life for most patients, allowing them to return to normal activities. However, poorly constructed stomas, high-output stomas, and stomas located in suboptimal sites on the abdominal wall are associated with pouching difficulties, appliance leaks, skin breakdown, and poor quality of life. In many cases, a temporary or permanent stoma may be a major improvement to quality of life. For example, patients with severe medically-refractory inflammatory colitis usually find that having an end ileostomy is far superior to suffering with frequent, painful bloody bowel movements. In the decision-making processes that involve choices between options that result in a permanent stoma versus options that result in intestinal continuity, patients must be counseled that intestinal continuity does not always equal a better quality of life than a permanent stoma.<sup>44</sup> For example, patients undergoing operations for distal rectal cancer may find that a low pelvic anastomosis is extremely disruptive due to clustering of bowel movements, frequency, and urgency. In severe cases, a permanent colostomy may be preferable.<sup>45</sup> Specific scales to measure quality of life associated with a stoma have been developed, which will allow for more robust assessment of quality of life in future studies.<sup>46,47</sup> Surgeons must engage patients in a shared decision-making process to help make treatment decisions that will offer optimal quality of life outcomes.

# ABDOMINAL ABSCESS AND ENTERIC FISTULAE

*Joao B. Rezende Neto • Jory S. Simpson • Ori D. Rotstein*

## ABDOMINAL ABSCESS

### Definition and Etiology

Abdominal abscesses are well-defined collections of infected purulent material that are walled off from the rest of the peritoneal cavity by inflammatory adhesions, loops of intestine and their mesentery, the greater omentum, or other abdominal viscera. Abscesses may occur in the peritoneal cavity, either within or outside of abdominal viscera (extravisceral), as well as in the retroperitoneum.<sup>1</sup> Most relevant to the surgeon are extravisceral abscesses that usually arise in 1 of 2 situations: (1) after resolution of diffuse peritonitis in which a loculated area of infection persists and evolves into an abscess and (2) after perforation of a viscus or an anastomotic breakdown that is successfully walled off by peritoneal defense mechanisms. More than 80% of intra-abdominal abscesses occur in the postoperative period, the majority of which occur after pancreaticobiliary or colorectal surgery and are

usually related to anastomotic dehiscence.<sup>2,3</sup>

Occasionally, postsurgical abscesses result from infection of an intraperitoneal hematoma that develops following surgery. Less frequently, intra-abdominal abscesses are unassociated with previous surgery and are usually attributable to spontaneous inflammatory processes associated with a small, localized perforation, such as in appendicitis, diverticulitis, and Crohn disease.<sup>3,4</sup> Visceral abscesses are most commonly caused by hematogenous or lymphatic spread of bacteria to the organ. Retroperitoneal abscesses may be caused by several mechanisms, including perforation of the gastrointestinal (GI) tract into the retroperitoneum and also hematogenous or lymphatic spread of bacteria to the retroperitoneal space, where seeding of uninfected collections such as peripancreatic necrosis or hematomas may occur.

## **Pathophysiology of Abscess Formation**

After bacterial contamination of the peritoneal cavity, a complex series of events is initiated that, under ideal circumstances, effects complete eradication of invading bacteria. The 3 major defense mechanisms in the peritoneal cavity are (1) mechanical clearance of bacteria via the diaphragmatic lymphatics, (2) phagocytosis and destruction of suspended or adherent bacteria by phagocytic cells, and (3) sequestration and walling off of bacteria coupled with delayed clearance by phagocytic cells.<sup>5</sup> The first 2 mechanisms act rapidly, usually within hours. Egress of bacteria from the peritoneal cavity via the lymphatics is responsible for the early septic response due to bacteremia and initiation of the innate immune response to infection.

The initial peritoneal response to bacterial contamination is characterized by hyperemia, exudation of protein-rich fluid into the peritoneal cavity, and a marked influx of phagocytic cells. Resident peritoneal macrophages predominate early in the infection, but the rapid influx of neutrophils after a 2- to 4-hour delay makes them the predominant phagocytic cell in the peritoneal cavity for the first 48 to 72 hours.<sup>6</sup> The combination of resident peritoneal cells plus the migration of these cells into the peritoneum serves to propagate the initiation of the innate immune response, including the elaboration of inflammatory cytokines and the procoagulant response. In

humans with severe intra-abdominal infection, peritoneal levels of tumor necrosis factor-alpha (TNF- $\alpha$ ), interleukin (IL)-1, and IL-6 are higher than levels measured simultaneously in plasma.<sup>7,8</sup> Haecker and colleagues reported that TNF- $\alpha$  and IL-10 levels are increased and reach 100- to 1000-fold in the plasma following appendiceal perforation. In adult patients, a correlation between the magnitude of the cytokine response and outcome in infected patients has been demonstrated in several clinical studies.<sup>9</sup> Higher levels of circulating TNF- $\alpha$  and IL-6 have been recorded in patients who later die with intra-abdominal infection.<sup>7</sup> Interestingly, elevated peritoneal levels persist even after systemic inflammatory response has abated. This suggests that during resolving peritonitis, there is compartmentalization of the response with local cytokine elaboration, thereby promoting local resolution of infection.

Other cell types are likely important in the initiation of the local peritoneal response. Peritoneal mast cells and mesothelial lining cells have also been shown to be potent producers of a range of cytokines and procoagulants. Fibrin deposition appears to play an important role in this compartmentalization of infection, not only by incorporating large numbers of bacteria within its interstices<sup>10</sup> but also by causing loops of intestine to adhere to each other and the omentum, thereby creating a physical barrier against dissemination. Fibrin deposition is initiated after the exudation of protein-rich fluid containing fibrinogen into the peritoneal cavity. The conversion of fibrinogen to fibrin is promoted by the elaboration of tissue factor by both mesothelial cells and stimulated peritoneal macrophages.<sup>11</sup> In addition, generation of other inflammatory mediator molecules and components of the complement cascade (eg, C3a and C5a) further promotes the development of local inflammation. The net effect of these responses is the localization of the bacterial infection in the peritoneal cavity, wherein ultimate resolution can occur. However, a number of local factors thwart complete resolution and presumably establish the local environment for persistent infection and hence abscess formation. These include regional fibrin deposition that impedes phagocytic cell migration, factors that inhibit phagocytic cell function such as hemoglobin, particulate stool, low pH, and hypoxia.

On the microbial side, polymicrobial flora of these infections as well as the near ubiquitous presence of *Bacteroides fragilis* and its unique capsular

polysaccharide have been implicated in persistence of infection and abscess formation. Considered together, while the process of abscess formation represents a successful outcome of the peritoneal response to bacterial contamination of the peritoneal cavity, one is left with a residual infection that carries with it morbidity and potential mortality and must be actively managed.

## **Clinical Presentation and Diagnosis**

### **CLINICAL PRESENTATION**

Diagnosis of an intra-abdominal abscess is based on clinical suspicion complemented by radiologic confirmation of the presence of the abscess. High spiking fevers, chills, tachycardia, tachypnea, and leukocytosis, associated with localized abdominal pain, anorexia, and delay in return of bowel function in the postoperative patient, are the classic signs and symptoms associated with the presence of an intra-abdominal abscess. The presence of a well-localized tender mass on clinical examination is consistent with the presence of an abscess. However, there may be considerable variability in the clinical appearance of the patient with this infection, ranging from a relatively mild picture where the patient appears generally well but is “slow to recover” from his or her surgical procedure to those who manifest evidence of profound systemic inflammation. There may be no mass palpable on clinical examination. A number of factors may contribute to this variability, including patient factors such as age, immunocompetence, and concurrent use of antimicrobials, as well as abscess factors such location and size of the abscess and how well walled off the abscess is. For example, subphrenic abscesses can present with vague upper quadrant abdominal pain, referred shoulder pain, and occasionally hiccoughs but with no localized abdominal tenderness or palpable mass. By contrast, paracolic abscesses present with localized tenderness and may manifest as a palpable mass on abdominal examination. Pelvic abscesses may also cause local irritation of the urinary bladder, causing frequency, or of the rectum, resulting in diarrhea and tenesmus. Retroperitoneal collections, particularly psoas abscesses, can manifest as leg and back pain with muscular spasm and flexion deformity of the hip. In reality, with the ready availability of computed tomography (CT) scanning in most institutions, almost any deviation from the normal recovery

trajectory in the postoperative period will prompt a CT scan and possible early detection of the abscess.

## DIAGNOSTIC TESTS

Imaging provides the definitive evidence of the presence of an intra-abdominal abscess. Abdominal plain films can be helpful in identifying air-fluid levels in the upright or decubitus positions, extraluminal gas, or a soft tissue mass displacing the bowel. In the postoperative patient, however, extraluminal gas may be present for up to 7 days. Overall, plain radiography may suggest the presence of an abscess, but other imaging modalities have essentially replaced plain films in the evaluation of intra-abdominal abscesses.

CT scanning has emerged as the radiologic investigation of choice in the diagnosis of intra-abdominal abscess.<sup>12</sup> With its ready availability, it has essentially supplanted abdominal ultrasound (US) as the main diagnostic tool in this setting, mainly because of its accuracy, but also because its functionality is not impaired in the setting of ileus, wound dressings, stomas, and the open abdomen. The accuracy of the scan is improved if contrast is used. Intravenous contrast increases the accuracy of defining the presence of an abscess, while GI tract contrast helps to distinguish fluid-filled bowel loops from an abscess and, in addition, may detect the presence of an anastomotic leak. In a retrospective study that compared US and CT in diagnosing intra-abdominal abscesses, the sensitivity of US in 123 patients was 82% compared to 97% in 74 patients by CT, and the overall accuracy of US was found to be 90% versus 96% for CT.<sup>13</sup>

Criteria for identification of an abscess by CT have been well described and include identification of an area of low CT attenuation in an extraluminal location or within the parenchyma of solid abdominal organs. The density of abscesses usually falls between that of water and solid tissue.<sup>14</sup> Other radiologic signs of an abscess are mass effect that replaces or displaces normal anatomic structures, a lucent center that is not enhanced after the intravenous administration of a contrast medium, enhancing rim around the lucent center after IV contrast administration, and gas in the fluid collection (Fig. 16-1).

**FIGURE 16-1** Computed tomography scan shows a pelvic abscess in a 39-year-old woman 3 weeks after appendectomy. Asterisk indicates the abscess; open circle indicates the uterus; open triangle depicts the rectum. (Used with permission from Jo Hoeflok, Nurse Practitioner/Enterostomal Therapy Nurse, St. Michael's Hospital, Toronto.)

One of the major advantages of CT over US is the ability to detect abscesses in the retroperitoneum and pancreatic area. There are also some disadvantages to CT scanning. In the absence of contrast rim enhancement, gas, or visible septations, CT cannot distinguish between sterile and infected fluid collections. Occasionally, there may be a solid-appearing collection that is really an abscess with a high leukocyte and protein content. Septations and other signs of loculated abscesses can often be better visualized with US than CT. Finally, CT scanning is sometimes unable to differentiate between subphrenic and pulmonic fluid, a relatively common situation in abdominal surgery.<sup>15</sup> In these limited circumstances, US may be considered as a complement to CT imaging.

Other modalities include magnetic resonance imaging (MRI). While MRI can sometimes better delineate the extent of an abscess, particularly in relation to adjacent soft tissue structures such as muscles and major blood vessels, it does not clearly have advantages over CT scanning and its practicality may be limited in the sick surgical patient.<sup>16</sup> One area where US

and MRI may be relevant is in the investigation of the pregnant patient with abdominal pain.<sup>17</sup> US is particularly useful when appendicitis/appendiceal abscess is suspected, and MRI may be useful when localization is less clear. The roles of radiolabelled compounds in the diagnosis of abdominal abscesses are limited at present.<sup>18</sup>

## **Management**

The basic principles underlying the successful treatment of intra-abdominal abscesses are three fold:

1. Adequate resuscitation and support
2. Antimicrobial therapy
3. Source control/abscess drainage

### **RESUSCITATION AND SUPPORT**

In keeping with the variable presentation of patients with intra-abdominal abscesses, the initial approach to resuscitation and support will vary considerably. Attention to the ABCs (airway, breathing, circulation) while individualizing the intervention for each patient according to his or her deviation from normal physiology is appropriate. Particularly in the postsurgical patient, nutritional support should be considered.

When feasible, oral nutrition should be given in preference to total parenteral nutrition. Some patients are able to ingest food and/or supplements by mouth, while others might require an enteral feeding tube, due to anorexia, precluding adequate ingestion of nutrients. Systematic review of the literature suggests that infectious complications and cost are reduced in critically ill patients receiving enteral nutrition compared to parenteral nutrition.<sup>19</sup> One can presumably extrapolate to patients with intra-abdominal infection. When abscess formation occurs due to an anastomotic leak, there is a sense that this might preclude use of enteral nutrition. This concern is likely unfounded, unless there is profound ileus associated with the infection.

### **ANTIMICROBIAL THERAPY**

Considerations regarding antimicrobial use are based on the microbial flora

recovered from the infections. Over the past decade, there has been increasing appreciation that there is an evolution of the flora with increasing severity of abdominal infection.<sup>20</sup> For example, [Table 16-1](#) shows the bacteriology of peritonitis in patients with community-acquired peritonitis and those with postoperative peritonitis.

**TABLE 16-1: MICROBIOLOGY OF COMMUNITY-ACQUIRED PERITONITIS COMPARED TO HEALTH CARE-ASSOCIATED PERITONITIS**

Strain	Percent of Isolates of	
	Community-Acquired	Postoperative (Health Care-Associated)
Enterococci	5	21

Other	11	9

Reproduced with permission from Roehrborn A, Thomas L, Potreck O, et al: The microbiology of postoperative peritonitis, *Clin Infect Dis*. 2001 Nov 1;33(9):1513-1519.

The major pathogens in community-acquired intra-abdominal infections are coliforms (especially *Escherichia coli*) and anaerobes (especially *B fragilis*). As illustrated, while both are polymicrobial, postoperative peritonitis has a higher incidence of more resistant microbes. Aside from patients with postoperative peritonitis, other factors predict this shift in microbiology, including advanced age, severe physiologic derangement, immunosuppression, previous use of antibiotics, and residence in a health

care institution in hospitals and nursing homes.

Guidelines have been developed by the Surgical Infection Society and the Infectious Diseases Society of America regarding the use of antimicrobial therapy in intra-abdominal infection.<sup>21</sup> These authors have risk-stratified patients into 3 categories and provided recommendations for empiric antimicrobial regimens according to category. The 3 categories are (1) community-acquired infections of mild to moderate severity; (2) high-risk or severe community-acquired infections; and (3) health care–associated infections. Factors that dictate conversion from mild-to-moderate severity to high severity include severe physiologic derangement (eg, high Acute Physiology and Chronic Health Evaluation II [APACHE II] score), advanced age, or immunocompromised state. Our institution follows the best practice in general surgery guidelines of the University of Toronto–affiliated hospitals (Table 16-2). Even though these guidelines are readily applicable to decision making regarding patients coming to the hospital with abscesses, they are not to be considered a meta-analysis subjected to formal peer review process. It is noteworthy that while *Enterococcus* is frequently recovered in isolates in these infections, the evidence demonstrates no additional benefit to treating this microbe as part of empiric therapy.

**TABLE 16-2: RECOMMENDATIONS FOR ANTIMICROBIAL THERAPY IN THE COMMUNITY-ACQUIRED SETTING**

		Selection of Antibiotics			
Type of IAI	Examples	Spectrum of Activity	Recommended Antibiotics	Penicillin-Allergic Patients	Duration
Community-acquired IAI: uncomplicated Uncomplicated IAI	Nonperforated appendicitis	Enteric gram-negative bacilli and anaerobes	Cefazolin and metronidazole	Gentamicin and metronidazole	Preoperatively only
Perforation without established infection	Patients with perforations of stomach and duodenum and traumatic bowel perforations who are taken to the OR within 12-24 hours	Gram-positive cocci and aerobic/facultative anaerobes +/- anaerobes	Cefazolin and metronidazole	Gentamicin and metronidazole	“Ultrashort” 24 hours only
Community-acquired IAI: complicated Mild-to-moderate severity	Perforated appendicitis; perforated diverticulitis	Enteric gram-negative bacilli and anaerobes	Cefazolin (IV) or cephalexin (PO) and metronidazole	Gentamicin and metronidazole	3-7 days (until clinical signs of resolution)
High severity	Shock; new organ failure; ICU patient	Enteric gram-negative bacilli and anaerobes; possibly <i>Enterococcus</i>	Ceftriaxone and metronidazole (may consider piperacillin-tazobactam)	Gentamicin and metronidazole	3-7 days (until clinical signs of resolution)
Other risk factors for treatment failure	Age >70; immunosuppression; poor nutrition; delayed/inadequate source control	Enteric gram-negative bacilli and anaerobes; possibly <i>Enterococcus</i> in immunosuppressed	Ceftriaxone and metronidazole (may consider piperacillin-tazobactam)	Gentamicin and metronidazole	3-7 days (until clinical signs of resolution)

Abbreviations: IAI, intra-abdominal infection; ICU, intensive care unit; IV, intravenous; OR, operating room; PO, oral. Recommendations excerpted from the Best Practice in General Surgery's Management of Intra-abdominal Infection guideline. The full guideline can be found at [www.bpgigs.ca](http://www.bpgigs.ca). Best Practice in General Surgery is a quality initiative of the Division of General Surgery, University of Toronto.

When possible, switchover to oral agents is appropriate. Traditionally, the duration of antibiotics was based on resolution of the clinical signs and symptoms of infection, a period that usually ranged from 4 to 7 days. Should there be no resolution by this time, reevaluation of the patient for the presence of persistent infection in the abdomen and elsewhere is appropriate. A clinical trial randomly assigned 518 patients with complicated intra-abdominal infections to receive antibiotics until 2 days after the resolution of fever, leukocytosis, and ileus with a maximum of 10 days, or to receive a fixed course of antibiotics of  $4 \pm 1$  calendar days. Patients in both groups underwent adequate source control. The results of that study showed similar outcomes after fixed-duration antibiotics (approximately 4 days) compared to a longer course of antibiotics until the resolution of physiologic abnormalities (approximately 8 days).<sup>22</sup> This study successfully challenged the paradigm that discontinuation be based on clinical signs of infection and suggests that a shorter fixed duration of treatment may be acceptable therapy.

Patients who present in the postsurgical period fall into the category of patients with health care–associated infection. In these patients, empiric therapy should include agents with expanded spectra against gram-negative

aerobic and facultative bacilli, including meropenem, imipenem-cilastatin, doripenem, piperacillin-tazobactam, or ceftazidime or cefepime in combination with metronidazole. Table 16-3 shows the considerations regarding selection depending on local institutional microbial isolates. Empiric anti-enterococcal treatment should be given. Treatment of *Candida* with fluconazole when recovered from cultures and treatment of methicillin-resistant *Staphylococcus aureus* with vancomycin should be followed if the patient is colonized with the microbe.

**TABLE 16-3: RECOMMENDATIONS FOR ALTERATIONS OF ANTIMICROBIAL THERAPY IN THE HEALTH CARE–ASSOCIATED SETTING**

Organisms Seen in Health Care–Associated Infection at the Local Institution	Regimen				
	Carbapenem <sup>a</sup>	Piperacillin-Tazobactam	Ceftazidime or Cefepime, Each With Metronidazole	Aminoglycoside	Vancomycin
<20% Resistant <i>Pseudomonas aeruginosa</i> , ESBL-producing Enterobacteriaceae, <i>Acinetobacter</i> , or other MDR GNB	Recommended	Recommended	Recommended	Not recommended	Not recommended
ESBL-producing Enterobacteriaceae	Recommended	Recommended	Not recommended	Recommended	Not recommended
<i>P. aeruginosa</i> >20% resistant to ceftazidime	Recommended	Recommended	Not recommended	Recommended	Not recommended
MRSA	Not recommended	Not recommended	Not recommended	Not recommended	Recommended

Abbreviations: ESBL, extended-spectrum β-lactamase; GNB, gram-negative bacilli; MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*.  
 NOTE. “Recommended” indicates that the listed agent or class is recommended for empiric use, before culture and susceptibility data are available, at institutions that encounter these isolates from other health care–associated infections. These may be unit- or hospital-specific.

## SOURCE CONTROL

Source control is a term used to include all physical measures taken to control a focus of infection. Here we focus our discussion to abscess drainage, but adequate source control may also include debridement of necrotic tissue, surgical repair, resection, and/or exteriorization of the anatomic defect causing peritoneal contamination.<sup>23</sup>

Over the past 2 decades, percutaneous drainage of abscesses has become an established technique and a safe alternative to surgery. This evolution of care has not been based on a series of strong randomized trials showing equivalence or superiority of this approach. Rather, observational studies

from a number of centers have shown it to be a safe effective alternative to surgical intervention, with equivalent success rates, comparable mortality (10%-20%) and morbidity (~25%).<sup>24-26</sup> Combined with other advantages of percutaneous approaches including avoidance of general anesthesia, lower costs, and the potential for fewer complications, it has now become the default approach to abscess management. Prerequisites for catheter drainage include an anatomically safe route to the abscess, a well-defined unilocular abscess cavity, concurring surgical and radiologic evaluation, and surgical backup for technical failure. Multiple abscesses, abscesses with enteric connections as seen with enterocutaneous fistulas, and the need to traverse solid viscera are not contraindications. Indeed, as the technique has evolved over several decades, the barriers to accessing unusually positioned collections have disappeared with the use of unconventional routes (transgluteal, transvaginal, transrectal) and the advent of new technologies including endoscopic US.<sup>27,28</sup> Even the presence of septations and loculations has not precluded at least an attempt to use percutaneous drainage.<sup>29</sup>

Percutaneous drainage can be performed with US or CT guidance. CT provides for more precise identification of organs and bowel loops and is more accurate for planning of drainage route.<sup>15</sup> Once the abscess is identified, initial diagnostic aspiration should be sent for Gram stain and microbiological culture. The catheter used for drainage should be as small as possible for safety, yet large enough so that the tubing does not become obstructed. Most commonly used catheters range in size from 8 to 12 F. With appropriate catheter placement, the abscess cavity typically decompresses and collapses. Irrigation of the catheter should be done once daily to ensure tube patency. As catheter drainage decreases, repeat CT scanning can be performed to evaluate for residual contents. If drainage increases over time or continues at a steady rate, the development of an enteric fistula must be suspected. This may not have been unexpected when the catheter was initially placed near a perianastomotic abscess or an abscess adjacent to some underlying pathologic process. Potential complications of catheter placement include bacteremia, sepsis, vascular injury, enteric puncture, cutaneous fistula, and transpleural catheter placement.

Catheters should be maintained on closed drainage systems. There does not appear to be benefit to the use of suction or irrigation of these catheters, although flushing once per day with saline ensures patency. Patients should respond with defervescence of symptoms within 48 hours of catheter insertion. If

they do so, a repeat CT scan is done at approximately 5 to 7 days to ensure shrinkage of the abscess. Criteria for removal of the drain include (1) clinical resolution of septic parameters, including patient well-being, normal temperature, and leukocyte count; (2) minimal drainage from the catheter; and (3) CT evidence of the resolution of the abscess.

As noted previously, studies comparing outcomes of surgical and percutaneous drainage of intra-abdominal abscesses demonstrate comparable efficacy. In one study, patients were matched for age, abscess location, and etiology, and had similar APACHE II scores. There were no differences between percutaneous and surgical drainage in patient morbidity, mortality, or duration of hospital stay.<sup>25</sup> Furthermore, initial percutaneous drainage of abscesses in the context of diverticular disease allowed for subsequent definitive operative resection and primary anastomosis in 1 rather than 2 operations. Another group retrospectively examined postoperative intra-abdominal abscesses after laparotomy. This study similarly demonstrated that use of either form of drainage resulted in similar cure rates for postoperative intra-abdominal abscesses.<sup>26</sup>

With clear demonstration of its efficacy when compared to surgical drainage, percutaneous drainage should be considered the preferred approach in source control of abscesses. [Table 16-4](#) shows outcome of percutaneous drainage according to underlying pathologic processes. In general, one should predict a successful outcome in patients with a single, well-defined abscess with no enteric communication. The presence of enteric communication per se does not reduce the likelihood of success as it is defined by the resolution of the infection. In a postoperative abscess, following drainage of the infection, the underlying anastomotic defect will usually close. In other settings, there may be a requirement for subsequent surgery to manage the underlying disease process such as diverticular disease or Crohn disease. For example, in one study, approximately 75% of patients with large peridiverticular abscesses were drained percutaneously and then they underwent a single-stage sigmoid colectomy.<sup>29</sup> Other circumstances such as fungal abscesses, infected hematomas, peripancreatic necrosis, or necrotic-infected tumor have a lower success rate for percutaneous drainage and early consideration for surgical intervention.<sup>30</sup> CT features such as the presence of a “rind,” a sharp exterior margin, air-fluid levels, and septations do not predict outcome and therefore should not be determinants as to whether or

not initial percutaneous drainage should be used.<sup>31</sup> Finally, one should use clinical judgment as to the need for percutaneous drainage for small abscesses (<5-cm diameter) such as those that might occur with acute diverticulitis, Crohn disease, and interloop collections. These may respond well to antibiotics alone, and the use of percutaneous drainage may be meddlesome and potentially morbid.<sup>32</sup>

 **TABLE 16-4: DETERMINANTS OF OUTCOME FOLLOWING PERCUTANEOUS DRAINAGE OF ABSCESES**

Clinical Condition	Successfully Treats Abscess	Comment
Single, well-defined bacterial abscess with no enteric communication	Yes	
Abscess with enteric communication (eg, diverticular abscess or Crohn disease abscess)		May require subsequent surgery to treat pathologic process or residual fistula
Interloop abscess or other difficult-to-access abscesses (eg, deep pelvic)	Usually	Requires alternative approaches to access successfully, eg, transrectal, transvaginal, transgluteal, etc
Early postoperative diffuse peritonitis (eg, caused by anastomotic dehiscence or bile peritonitis)	Low	Inappropriate—needs surgery
Infected tumor mass	Low	Inadequate drainage
Fungal abscess		
Infected hematoma		
Pancreatic necrosis		
Small abscess (<4 cm in diameter)	Low	Difficult to drain; antibiotics alone may be suitable

There are circumstances where percutaneous drainage should be considered contraindicated. Most important among these is the circumstance where peritoneal infection is not localized, such as in the early postsurgical period where an anastomotic leak leads to diffuse peritonitis. Abdominal CT scans performed in this scenario may demonstrate 1 or more discrete fluid collections. When there is diffuse peritoneal irritation on clinical examination, fluid collections distant from the anastomosis, or the presence of massive intraperitoneal air, surgical intervention is clearly indicated. Attempts to manage such situations with percutaneous interventions invariably lead to delayed definitive surgical management and adverse outcome.

## SURGICAL DRAINAGE

As stated previously, percutaneous drainage is the procedure of choice for the majority of intra-abdominal abscesses, with the caveats being those indicated.

Specifically, when the infection is diffuse rather than localized, surgical intervention is clearly indicated. Second, when the content of the abscess is too thick for percutaneous drainage, an initial percutaneous attempt may be reasonable, but conversion to surgery early in the course is reasonable. Finally, when access is impossible, surgery is indicated. This last circumstance is increasingly rare.

The transperitoneal approach allows for examination of the entire abdominal cavity and allows for the drainage of multiple abscesses. Subphrenic abscesses and right subhepatic abscesses may also be approached by lateral abdominal incisions. Once abscess cavities are identified, they are entered and drained quickly to minimize spillage and contamination of the rest of the peritoneal cavity. The abscess cavity should then be widely opened. Specimens should be sent for Gram stain and culture. Copious warm irrigation must be used at the end of the operation to properly cleanse the abdominal cavity. Closed-suction drains should be placed in dependent positions to reduce the risk of reaccumulation. In extremely contaminated cases, the incision may be left open and packed to prevent wound infection.

## ENTERIC FISTULAS

### Definition and Etiology

A *fistula* is defined as an abnormal communication between 2 epithelial surfaces. Enteric fistulas may arise in a number of settings: (1) diseased bowel extending to surrounding epithelialized structures; (2) extraintestinal disease eroding into otherwise normal bowel; (3) surgical trauma to normal bowel including inadvertent or missed enterotomies; or (4) anastomotic disruption following surgery for a variety of conditions. The first 2 generally occur spontaneously, while the latter 2 occur following surgical procedures. For the surgeon, the latter 2 are generally more problematic, in part because they are iatrogenic complications of surgery, but also because their early management often requires treatment of the critically ill patient with sepsis.

While this chapter overviews general considerations regarding the pathophysiology and management of enteric fistulas, it focuses on postsurgical enteric fistulas, particularly fistulas to the skin, that is, enterocutaneous fistulas. In this particular patient population, the mortality

rate remains high, between 3 and 22% in series dating back 6 decades, largely due to the frequent complications of sepsis and malnutrition (Table 16-5). Successful outcome requires a multidisciplinary team of health care workers, including surgeons, infectious disease specialists, intensivists, radiologists, nurses, enterostomal therapists, and nutrition specialists. Management of these patients must also take into account the psychosocial and emotional needs of the patient and his or her family through a prolonged and often complex treatment course.

**TABLE 16-5: COLLECTED SERIES OF OUTCOMES IN PATIENTS WITH OPERATIVE REPAIR OF ENTEROCUTANEOUS FISTULAS**

Source	Period	No.(%)

<sup>a</sup>These deaths were "fistula related within 30 days of surgery."

<sup>b</sup>The number of deaths in patients who were operated on could not be determined in this study.

Adapted with permission from Brenner M, Clayton JL, Tillou A, et al: Risk factors for recurrence after repair of enterocutaneous fistula. *Arch Surg* 2009 Jun;144(6):500-505.

One of the challenges in attempting to discern optimal management of these patients relates to the quality of the medical literature. Most reports are retrospective reviews of large case series emanating from referral institutions. Notwithstanding this shortcoming, these series provide general approaches to therapy, which help to guide treatment.

## Classification

Fistulas involving the alimentary tract have traditionally been classified in 3 distinct ways: by the *etiology* responsible for their formation, that is, spontaneous versus postoperative; by the *anatomy* of the structures involved; and finally, by the *amount and composition of drainage from the fistula*. Such distinctions may provide important prognostic information about the physiologic impact of fistulas and the likelihood that they will close without

surgical intervention.

## **SPONTANEOUS VERSUS POSTOPERATIVE**

Enterocutaneous fistulas may be classified as either spontaneous or postoperative. Approximately three-quarters of fistulas occur in the postoperative setting, most commonly subsequent to procedures performed for malignancy, inflammatory bowel disease (IBD), or adhesive bowel obstruction.<sup>33</sup> These fistulas become evident to the surgeon in a number of different ways: (1) They may occur in the early postoperative period as a septic complication of surgery, sometimes with catastrophic physiologic deterioration. This is usually a result of uncontrolled diffuse intra-abdominal infection caused by anastomotic leakage, breakdown of enterotomy closure, or a missed enterotomy. (2) They may occur in a more delayed manner, following treatment of a postsurgical infection with percutaneous drainage of a deep abscess or opening of a superficial wound infection that may reveal an underlying connection to the GI tract as a cause. (3) They may occur very late after the surgery due to unanticipated injury to the GI tract. The development of a wound infection following use of mesh for hernia repair would fall into this category either through erosion of mesh into bowel or due to iatrogenic injury to the bowel as one attempts to debride infected mesh.

Overly aggressive management of an open abdominal wound can also lead to intestinal injury and fistula formation, underscoring the importance of early definitive closure of the abdominal wall, preferably within the first 8 days from the original laparotomy.<sup>34</sup> Fistulas have been reported to occur in up to 25% of patients during treatment with an open abdomen for abdominal sepsis.<sup>35</sup> Two easily avoidable causes of fistulas in open abdomens managed with vacuum-assisted closure devices are feeding tubes inserted through the bowel wall during surgery and manipulation of anastomoses during VAC dressing changes.

The remaining 25% of fistulas occur spontaneously, that is, without an antecedent surgical intervention. These fistulas often develop in the setting of cancer or inflammatory conditions. Fistulas occurring in the setting of malignancy or irradiation are unlikely to close without operative intervention. Inflammatory conditions such as IBD, diverticular disease, perforated ulcer disease, or ischemic bowel can result in fistula development.<sup>36</sup> Of these, fistulas in patients with IBD are most common; these fistulas may close

following a prolonged period of parenteral nutrition, only to reopen when enteral nutrition resumes.<sup>37</sup>

## **ANATOMIC CLASSIFICATION**

Fistulas may communicate with the skin (external fistulas: enterocutaneous or colocolocutaneous fistulas) or other intra-abdominal or intrathoracic organs (internal fistulas). Internal fistulas that bypass only short segments of bowel may not be symptomatic; however, internal fistulas of bowel that bypass significant length of bowel or that communicate with either the bladder or vagina typically cause symptoms and become clinically evident. Fistulas that occur in the absence of overlying soft tissue cover, known as enteroatmospheric fistulas, are among the most challenging types of fistulas. Identification of the anatomic site of origin of external fistulas may provide further information on the etiology and management of the fistula.

**Oral, Pharyngeal, and Esophageal Fistulas.** Radical resections and reconstructions for head and neck malignancy may be complicated by postoperative fistulas in 5% to 25% of cases.<sup>38</sup> Alcohol and tobacco use, poor nutrition, and preoperative chemoradiation all contribute to poor wound healing and increase the risk of fistula formation. Failure of closure of the pharyngeal defect at the base of the tongue most commonly leads to fistula formation, and free microvascular flaps are the preferred method for closure. Brown and colleagues reported a significantly decreased postoperative fistula rate in patients who underwent free flap closure versus those with pedicled pectoralis flap closure, 4.5 versus 21%, respectively.<sup>39</sup>

Most esophagocutaneous fistulas result from breakdown of the cervical anastomosis either following resection of esophageal malignancy or following esophageal trauma. Less common causes of oropharyngeocutaneous or esophagocutaneous fistula include tuberculosis, laryngeal or thoracic surgery, trauma, congenital neck cysts, anterior cervical spine fusion, and foreign body perforations.<sup>40-42</sup>

**Gastric Fistulas.** The most commonly reported procedure associated with gastrocutaneous fistula formation is the removal of a gastrostomy feeding tube, particularly in children. The duration of gastrostomy tube placement appears to be related to the likelihood of development of a fistula after tube

removal, with nearly 90% of children developing a fistula when the tube had been in situ for more than 9 months.<sup>43</sup> The rate of gastrocutaneous fistula following operations for nonmalignant processes such as ulcer disease, reflux disease, and obesity is between 0.5% and 3.9%.<sup>44</sup> The recent rapid increase in the number of bariatric surgical procedures was anticipated to lead to an increase in the incidence of gastrocutaneous fistula following surgery for benign disease, as the rate of anastomotic leakage after gastric bypass surgery is 2% to 5%. One study has reported that approximately 10% of patients with staple line leaks go on to form chronic fistulas, making the overall rate less than 0.5%.<sup>45</sup> Fistula formation following resection for gastric cancer remains a dreaded complication with significant mortality rates. Spontaneous gastrocutaneous fistulas are uncommon but can result from inflammation, ischemia, cancer, and radiation.

**Duodenal Fistulas.** The majority of duodenocutaneous fistulas develop after distal or total gastric resections or surgery involving the duodenum or pancreas. Inadvertent injury to or intentional excision of a portion of the duodenum during surgery of the colon, aorta, kidney, or biliary tract may also result in fistula formation. Spontaneous cases resulting from trauma, malignancy, Crohn disease, and ulcer disease account for the remaining duodenal fistulas.<sup>46,47</sup> Prognostically, duodenal fistulas segregate into 2 groups: lateral duodenal fistulas and duodenal stump fistulas. Some authors have reported a decreased spontaneous closure rate with lateral duodenal fistulas when compared to that with duodenal stump fistulas.<sup>33,48</sup>

**Small Bowel Fistulas.** Fistulas arising in the small bowel account for the majority of GI-cutaneous fistulas, the majority of which (70%-90%) occur in the postoperative period.<sup>37,49,50</sup> Postoperative small bowel fistulas result from either disruption of anastomoses (either small bowel anastomoses or small bowel to colon anastomoses) or inadvertent and unrecognized injury to the bowel during dissection or closure of the abdomen. Operations for cancer, IBD, and adhesiolysis for bowel obstruction are the most common procedures antecedent to small bowel fistula formation. As noted previously, spontaneous small bowel fistulas arise from IBD, cancer, peptic ulcer disease, or pancreatitis.

Crohn disease is the most common cause of spontaneous small bowel fistula. The transmural inflammation underlying Crohn disease may lead to

adhesion of the small bowel to the abdominal wall or other abdominal structures. Microperforation may then cause abscess formation and erosion into adjacent structures or the skin. Approximately half of Crohn fistulas are internal and half are external.<sup>51-53</sup> Crohn fistulas typically follow 1 of 2 courses. The first type represents fistulas that present in the early postoperative period following resection of a segment of diseased bowel. These fistulas arise in otherwise healthy bowel and follow a course similar to non-Crohn fistulas with a significant likelihood of spontaneous closure. The other group of Crohn fistulas arises in diseased bowel and has a low rate of spontaneous closure.

**Appendiceal Fistulas.** Fistulas of appendiceal origin may result from drainage of an appendiceal abscess or after appendectomy in a patient either without or with Crohn disease.<sup>54,55</sup> In the latter case, the fistula often originates from the terminal ileum, not the cecum. The inflamed ileum adheres to the abdominal wall closure and subsequently results in fistula formation.

**Colonic Fistulas.** While spontaneous fistulas of the colon may result from inflammatory conditions such as diverticulitis, appendicitis, and IBD, or from advanced malignancy, the majority of colocutaneous fistulas are postsurgical, usually secondary to anastomotic breakdown following colonic resection for 1 of these conditions. Preoperative radiation therapy reduces the risk of local recurrence and death from advanced rectal cancer and is an accepted practice.<sup>56</sup> However, radiation therapy contributes to both spontaneous and postoperative colocutaneous fistulas. Russell and Welch reported a 31% incidence of breakdown of primary anastomoses performed in irradiated tissues with resulting sepsis or fistula formation.<sup>57</sup>

**Enteroatmospheric Fistulas.** Enteroatmospheric fistulas tend to occur within the first week of the open abdomen. The incidence of these fistulas depends on the baseline abdominal problem. In trauma patients managed with open abdomen, the incidence of enteroatmospheric fistulas varies between 2% and 25%. The incidence increases to more than 25% in open abdomens for intra-abdominal sepsis, and up to 50% in the setting of infected pancreatic necrosis.

## PHYSIOLOGIC CLASSIFICATION

Traditionally, fistulas have been classified into high-output (>500 mL/d), moderate-output (200-500 mL/d), and low-output (<200 mL/d) groups. Enterocutaneous fistulas cause loss of fluid, minerals, trace elements, and protein, and, when improperly managed, they can result in profound irritation of the skin and subcutaneous tissues. Depending on the origin of the fistula and its anatomy, the amount of output and nature of the effluent may be estimated (Table 16-6). However, direct measurement of these parameters for an individual fistula allows for accurate replacement and an understanding of the physiologic and metabolic challenges to the patient. Classification of enterocutaneous fistulas by the volume of daily output provides information regarding mortality and has been used to predict spontaneous closure and patient outcome.<sup>33,58-60</sup>

**TABLE 16-6: PREDICTED OUTPUT AND ELECTROLYTE COMPOSITION OF FISTULAS ACCORDING TO LOCATION**

Source	Volume (mL/d)	pH	Na	K	HCO <sub>3</sub> <sup>-</sup>	Cl
Gastric	2000-2500	<4	60	10	—	90
		>4	100	10	—	100
Pancreatic	1000		140	5	90-110	30-45
Bile	1500		140	5	35	100
Small bowel	3500		100-130	15	25-35	100-140

In the classic series of Edmunds and associates, patients with high-output fistulas had a mortality rate of 54%, compared to a 16% mortality rate in the low-output group.<sup>33</sup> More recently, Levy and colleagues reported a 50% mortality rate in patients with high-output fistulas, while those with low-output fistulas had a 26% mortality.<sup>58</sup> Soeters and coworkers reported no association between fistula output and rate of spontaneous closure,<sup>37</sup> while multivariate analysis by Campos and associates suggested that patients with low-output fistulas were 3 times more likely to achieve closure without operative intervention.<sup>60</sup> The reason for these different closure rates most likely relates to the nature of the particular fistula, rather than the volume of output per se. If the fistula totally diverts flow, for example a pouting small bowel opening in the center of an open abdomen, it will be both high output

and unlikely to close, without these 2 factors being causally related. By contrast, a defect at a small bowel anastomotic site with a long fistula tract and no local infection will likely be walled off by surrounding tissues and close spontaneously. These fistulas, while initially high output, will often close because of favorable local conditions. In essence, prediction of closure should be based on the local conditions, and particularly the nature of the fistula rather than the output. To the extent that the output often reflects the nature of the fistula, it will then be predictive.

## Predicting Closure of Enterocutaneous Fistulas

Spontaneous closure of enterocutaneous fistulas without the need for major surgical intervention is clearly a desirable outcome for these patients. The precise probability of spontaneous closure is somewhat difficult to assess since the large series reporting management of fistulas are usually derived from specialty centers for fistula management and thus not only represent a biased sample but also reflect differences in referral practice. Thus, spontaneous closure has been reported to occur in 10% to 80% of patients.<sup>61-65</sup> Nevertheless, a number of factors have been suggested to be predictive of failure of spontaneous closure of fistulas (Table 16-7). Some of these factors are modifiable, for example, nutritional status, presence of local infection, and foreign bodies, while many are not, including location, proximal high output fistulas in the presence of an open wound, and the presence of distal obstruction. Knowledge of these factors should prove to be helpful in discussion of outcome with the patient and family members, as well as with the multidisciplinary team.

## **Risk Factors and Prevention of Enterocutaneous Fistulas**

The majority of enterocutaneous fistulas arise in the postoperative period, often related to leakage of small bowel/colonic anastomoses or enterotomy closure. A number of factors have been associated with postsurgical enteric leaks. These can be divided into patient factors such as old age, immunosuppression, malnutrition, emergency surgery, and peritoneal contamination, and surgical factors such as emergency surgery, level of anastomosis, preoperative radiation, duration of surgery, blood loss, tension on anastomosis, inadequate blood supply to anastomosis, and technical error in suturing or stapling.

A recent study showed that diabetes was not a significant predictor of anastomotic leaks. However, diabetic patients who developed a leak had a mortality rate 4 times higher than nondiabetic patients. Moreover, preoperative steroids were associated with increased rates of anastomotic leaks in diabetics.<sup>66</sup>

Use of mechanical bowel preparation, anastomotic technique (stapled vs hand sewn; single vs double layer), and omentoplasty has not been shown to

influence anastomotic integrity. A meta-analysis in 2008 of 13 trials and 4601 patients showed no difference in the anastomotic leak rate when a mechanical bowel preparation was used compared to when it was not used in elective colon resection.<sup>67</sup>

Clearly, optimization of modifiable factors will serve to reduce anastomotic leak. In the elective setting, operations may be delayed to allow for normalization of nutritional parameters, thus optimizing wound healing and immune function. In emergency operations, the luxury of optimizing nutritional status preoperatively is not possible. Instead, emphasis should be on adequate resuscitation and restoration of circulating volume, normalization of hemodynamics, and use of appropriate antibiotic therapy.

Once a patient has been optimized preoperatively, attention is then turned to operative techniques to minimize the development of a fistula. Performance of anastomoses in healthy, well-perfused bowel without tension provides the best chance for healing. Testing of the rectal and sigmoid anastomoses with intraoperative air insufflations has been shown to reduce “radiologic” leak rate through guiding placement of additional sutures as needed.<sup>68</sup> Careful hemostasis to avoid postoperative hematoma formation will decrease the risk of abscess, while inadvertent enterotomies and serosal injuries should be identified and repaired.

A recent meta-analysis based on 3 randomized trials showed that omentoplasty to buttress a colonic anastomosis did not reduce the rate of postoperative radiologic leaks, alter mortality, or change the need for reoperation.<sup>69</sup> However, while omentoplasty per se does not reduce the probability of anastomotic leakage, interposition of an omental flap to separate the anastomosis from the abdominal incision may lessen the probability of injuring the bowel during closure or of an enterocutaneous fistula should anastomotic leakage occur.

A recent study pooling the data from 5 European randomized clinical trials studying rectal cancer care demonstrated that diverting stomas reduced the rate of symptomatic anastomotic leaks and improved overall survival but had no effect on cancer-specific survival.<sup>70</sup> The differential survival was primarily attributable to early postoperative mortality. Proximal diverting colostomy or ileostomy may allow sufficient anastomotic healing prior to suture-line challenge by luminal contents.

## Approach to Management

An organized treatment approach is of paramount importance to ensuring the optimal patient outcome. [Table 16-4](#) lists overall mortality of patients presenting with enterocutaneous fistulas from a number of reports dating back 6 decades. Overall, the more recent studies appear to be associated with a lesser mortality rate, presumably a result of improvements in imaging, fluid resuscitation, antibiotic management, and intensive care support. However, the ultimate goals in treating patients with enterocutaneous fistulas are closure of the fistula with abdominal wall closure and return to baseline functioning level. Evenson and Fischer outlined 5 distinct phases of management that can be used to guide care of this patient population.<sup>71</sup> These phases are discussed in detail and also summarized in [Table 16-8](#).

**TABLE 16-8: APPROACH TO MANAGEMENT OF ENTEROCUTANEOUS FISTULAS**

Phase	Goals	Time Course
Recognition/ stabilization	Resuscitation with crystalloid, colloid, or blood Control of sepsis with percutaneous or open drainage and antibiotics Electrolyte repletion Provision of nutrition Control of fistula drainage Commencement of local skin care and protection	24-48 h
Investigation	Fistulogram to define anatomy and characteristics of fistula Other GI studies CT scan to define pathology Operative notes from prior surgery	7-10 d
Decision	Evaluate the likelihood of spontaneous closure Decide duration of trial of nonoperative management	10 d-6 wk When closure, unlikely or after 4-6 wk
Definitive management	Plan operative approach Refunctionalization of entire bowel Resection of fistula with end-to-end anastomosis Secure abdominal closure Gastrostomy and jejunostomy	Surgical intervention at 3-6 mo after patient stabilized
Postsurgical	Usual postoperative protocol Psychological and emotional support	Ensure access to ICU for management of potential complication Team approach to management facilitates recovery

Abbreviations: CT, computed tomography; GI, gastrointestinal; ICU, intensive care unit.

### PHASE 1: RECOGNITION AND STABILIZATION

**Identification and Resuscitation.** As noted in the introduction, the clinical presentation of patients with enterocutaneous fistulas depends on the

underlying pathophysiologic process. Invariably, the patient who develops a postoperative enterocutaneous fistula will do well clinically for the first few days after operation. Within the first week, however, the patient may suffer delayed return of bowel function, as well as fever and leukocytosis, together suggestive of intra-abdominal infection. This setting will usually prompt a request for an abdominal CT scan that demonstrates a perianastomotic abscess. Percutaneous drainage for therapeutic management of the abscess will serve to confirm anastomotic disruption, either immediately or a few days later when there is evidence of enteric content. Occasionally, erythema of the wound develops and opening the wound reveals purulent drainage that is soon followed by enteric contents. In both of these circumstances, the peritoneal host defenses have successfully walled off and contained infection. By contrast, in some patients, diffuse peritoneal contamination arising from a leaking anastomosis or enterotomy causes profound and rapid deterioration of the patient with diffuse abdominal tenderness, evidence of organ dysfunction, and hemodynamic instability. Usually, these patients exhibit signs of organ dysfunction in the days prior to their catastrophic deterioration, including reduced level of consciousness, tachycardia, and mild renal impairment. The diagnosis then becomes clear, and management shifts from routine postoperative care to the management of a potentially critically ill patient. As with all critically ill patients, attention should turn to management of the ABCs.

The patient with a localized collection or one that has necessitated into the wound can usually be managed on the ward, while the patient with a more significant septic response may require transfer to an intensive care unit (ICU) setting. In both scenarios, restoration of intravascular volume, usually crystalloid, is appropriate with or without inotropic support as determined by physiologic monitoring. A *Cochrane Database Systematic Review* showed no difference in outcome in critically ill patients managed with crystalloid versus colloid and therefore recommended crystalloid as the preferable resuscitation fluid.<sup>72</sup>

The initiation of broad-spectrum antibiotic therapy should occur early and be directed toward the most likely pathogens involved. Patients with postoperative peritonitis have increased probability of having multiresistant microorganisms and should receive broader-spectrum antibiotics. The consensus guidelines published by the Surgical Infection Society/Infectious Diseases Society of America address antimicrobial options for these severe

health care–associated infections (see [Tables 16-2 and 16-3](#)).<sup>21</sup>

**Control of Sepsis.** Uncontrolled infection with the development of a septic response and the concomitant fluid imbalance and malnutrition are the leading causes of mortality in modern series of enterocutaneous fistulas. The leakage of enteric contents outside of the bowel lumen may lead to a localized abscess or to generalized peritonitis. Percutaneous management of localized abscesses accompanied by appropriate antibiotic therapy and supportive measure is usually sufficient to resolve infection in this subgroup.

Diffuse peritoneal infection represents a much greater management challenge. In general, the generalized nature of the infection precludes successful therapy with percutaneous drainage, and therefore, an operative approach is indicated. Particularly in the early postoperative period, the surgeon should be wary of attempting to treat multiple intra-abdominal fluid collections observed on CT scan with percutaneous drains, when surgical intervention is required for definitive management.

**Surgical Approach.** The goals of operative management of peritonitis are to eliminate the source of contamination, reduce the bacterial inoculum, and prevent recurrent or persistent infection. The operative technique used to control contamination depends on the location and the nature of the pathologic condition in the GI tract.<sup>36</sup>

For patients progressing to diffuse peritonitis in the early postoperative period, the abdomen is usually reentered through the previous incision with the discovery of pus and enteric content. One should refrain from making small incisions in those conditions, thereby avoiding inadequate exposure. After aspiration of the fluid, an exploration to find the source of contamination is warranted. Anastomotic dehiscence/enterotomy should generally be managed by exteriorization of the affected bowel. Whether this is performed via a single stoma site or with separate stomas (ie, end stoma plus mucous fistula) depends on the specific scenario. Obviously, if one is able to exteriorize the intestinal defect, the likelihood of a postoperative enteric fistula is markedly reduced. It is attractive to hope that a surgically repaired enterotomy or leaking enterotomy might heal primarily, given the obvious simplicity of the procedure. However, this is rarely successful in the setting of diffuse peritoneal infection, and therefore, this approach is not recommended. Reoperation after this misjudgment is fraught with potential

difficulty, in that the surgeon is faced with the need to reoperate on the patient in the early postoperative period. This laparotomy is invariably more difficult and is often associated with bleeding, further enterotomies, and a bowel that is extremely difficult to exteriorize. Under these circumstances, there should be consideration of a proximal defunctioning stoma if technically feasible. These cases are frequently the ones associated with inability to close the abdominal wall.

A number of anatomical circumstances may also preclude exteriorization of a leaking anastomosis. The principle of “defunction and drain” is appropriately applied in this setting. Most important among these is the rectal or sigmoid anastomosis where the distal end can be neither exteriorized nor closed. Unless the anastomosis is greater than 50% disrupted, it is reasonable to defunction with an ileostomy or a colostomy upstream and drain the site of the hookup. This approach is preferred as it increases the probability of future restoration of the GI tract. This is particularly true of leaks below the peritoneal reflection.<sup>73</sup> If the anastomosis is almost completely disrupted, the surgeon is obliged to perform an end stoma and drain the pelvis, as the preserved anastomosis would stricture and preclude later stoma closure.

When a laparotomy is indicated for definitive source control in the presence of bleeding, massively damaged tissues, impeding physiologic exhaustion, and or abdominal compartment syndrome, a damage control approach is advisable. This strategy, frequently used in trauma patients, consists of abbreviating the laparotomy in lieu of performing a definitive operation. The initial aim is to establish control of hemorrhage and/or intra-abdominal infection, followed by a period in the ICU for stabilization prior to definitive management. Total operative time should be less than 90 minutes during this phase.

A similar approach can be used in patients with leaking enterotomy, anastomotic dehiscence, and generalized peritonitis found during a laparotomy. In that setting, bowel resection with the stapled ends left inside the abdominal cavity in discontinuity and abdominal washout are performed followed by temporary abdominal closure. In subsequent operations, anastomoses are completed and the abdomen closed definitively. That approach was investigated in septic patients with generalized peritonitis due to a perforated diverticulitis Hinchey score of III/IV.<sup>74</sup> In 9 of 15 patients, the local conditions and systemic state were considered adequate to perform primary anastomosis in the subsequent operation, hence avoiding a stoma.<sup>74</sup>

**Control of Fistula Drainage and Skin Care.** Concurrent with drainage of sepsis, a plan to control fistula drainage and provide local skin care will prevent continued irritation of the surrounding skin and abdominal wall structures. Obviously, fistulas created following percutaneous drainage of abscesses are usually well managed by the drain itself. Indeed, the drainage of a local infection is frequently sufficient to permit closure of the fistula. For small low-output fistulas, dry dressing may suffice. In less controlled circumstances, particularly in the setting of the open abdomen, control of the effluent is not straightforward and must be managed aggressively.

There are several resourceful techniques to manage a GI fistula in the setting of an open abdomen. The main goal in all of them is to isolate fistulous drainage from the open wound and the abdominal cavity, thereby obtaining adequate source control and preventing peritonitis. Those goals can be achieved with or without concomitant vacuum-assisted wound therapy techniques.

The method known as “floating stoma” consists of adapting an ostomy bag to an opening created on a plastic silo sutured to the abdominal wall. This method does not use vacuum therapy and is the basis for the other techniques.<sup>75</sup> At least 4 other methods use vacuum-assisted wound management in association with control of bowel effluent through the adaptation of different types of catheters/bags to the fistulous opening.<sup>76</sup> A skilled enterostomal therapist can often provide useful insight into these issues and should work in concert with a dedicated nursing team.<sup>77</sup>

The goals of therapy are to protect the skin, accurately monitor output, and minimize patient anxiety over effluent control. Use of a drainable pouching system that is tailored to the size of the open wound is effective. This is often combined with other ostomy-based accessories such as hydrocolloid sheets and paste to protect perifistular skin and to provide a base on which to secure the pouching system (Figs 16-2 to 16-5).

**FIGURE 16-3** The skin around of the wound is covered with an overlapping protective barrier (hydrocolloid sheets), and stoma paste is applied to the borders to prevent undermining of gastrointestinal contents. (Used with permission from Jo Hoeflok, Nurse Practitioner/Enterostomal Therapy Nurse, St. Michael's Hospital, Toronto.)

**FIGURE 16-4** The entire wound and the protective barrier are covered with a thin plastic film. A pouch with stoma paste is attached to an opening on the plastic film. [Used with permission from Jo Hoeflok, Nurse Practitioner/Enterostomal Therapy Nurse, St. Michael's Hospital, Toronto.]

**FIGURE 16-5** Photograph of the wound after 2 weeks demonstrates reduction in size and granulation tissue. *Top arrow: fistula. Bottom arrow: ileostomy.* (Used with permission from Jo Hoeflok, Nurse Practitioner/Enterostomal Therapy Nurse, St. Michael's Hospital, Toronto.)

Vacuum-assisted closure devices have been reported to aid in the care of these complicated wounds, including the promotion of closure. For example, Wainstein and coauthors reported promising results after reviewing their 10-

year experience with vacuum-assisted closure devices. In this study, fistula output was profoundly suppressed soon after commencing use of the device, and spontaneous closure was achieved in 46% of patients. The use of a vacuum-assisted device was also found to reduce the frequency of wound dressing changes and improve dermatitis in all cases.<sup>78</sup> These findings are consistent with most surgeons' anecdotal experience with vacuum treatment.

Some authors have reported a small number of patients developing new enteric fistulas with the vacuum device. Therefore, it is of utmost importance that a sheet of nonadhesive material is placed on top of the exposed viscera and beneath the peritoneum of the abdominal wall prior to any vacuum device in the open abdomen. It is also important to emphasize that when using vacuum-assisted wound therapy in the presence of GI fistula, the negative pressure should only be applied to the open abdomen surrounding the fistula. Otherwise, it will damage the fistulized bowel. Presumably, stable patients with some granulation overlying the exposed bowel have lower risk of fistulas.<sup>79,80</sup>

**Reduction in Fistula Output.** While fistula output does not correlate with the rate of spontaneous closure, reduction in fistula drainage may facilitate wound management and decrease the time to closure. Further, reduced output enhances the ease of fluid and electrolyte management and may make local wound care easier. In the absence of obstruction, prolonged nasogastric drainage is not indicated and may even contribute to morbidity in the form of patient discomfort, impaired pulmonary toilet, alar necrosis, sinusitis or otitis media, and late esophageal stricture. Measures to decrease the volume of enteric secretions include administration of histamine antagonists or proton pump inhibitors. Reduction in acid secretion will also aid in the prevention of gastric and duodenal ulceration as well as decrease the stimulation of pancreatic secretion. Antimotility agents such as loperamide and codeine may also be effective.

As inhibitors of the secretion of many GI hormones, somatostatin and octreotide were postulated to promote nonoperative closure of enterocutaneous fistulas. This had been challenged in the past.<sup>81</sup> However, a meta-analysis found that a significant number of fistulas did in fact close with somatostatin and somatostatin analogues when compared to a control group. In addition, the time to closure was also significantly faster.<sup>82</sup> Another systematic review and meta-analysis of 720 studies found similar results with

regard to the time to closure when compared to a placebo, with a weighted mean difference of 6.37 days. Hospital stay was also significantly decreased, but no mortality difference was observed.<sup>83</sup> Infliximab, a monoclonal antibody to TNF- $\alpha$ , has been shown to be beneficial in inflammatory and fistulizing IBD.<sup>84</sup> In a randomized trial of patients with chronic fistulas (duration >3 months), administration of infliximab resulted in a significantly increased rate of closure of all fistulas when compared to placebo.<sup>84</sup> Some evidence suggests a role for infliximab in treatment of fistulas complicating IBD, and its use has been reported to promote healing of persistent fistulae even in non-IBD patients.<sup>85</sup>

A number of other approaches to managing fistula output and promoting closure have been reported. These include endoscopic injection of fibrin glue into identified fistula openings,<sup>86</sup> radiologically guided percutaneous Gelfoam embolization of the enteric opening, and the insertion of an absorbable fistula plug using a combination of percutaneous and endoscopic approaches.<sup>87,88</sup> All 3 involve the “plugging” of the opening with a biological material, presumably with the expectation of tipping the local conditions toward healing. A study of 145 patients aimed at determining the efficacy and safety of autologous, platelet-rich fibrin glue (PRFG) found that time to closure was shorter (7 vs 23 days) and likelihood of closure within the first 28 days (77% vs 57%) and overall closure was greater with PRFG.<sup>89</sup> These low-morbidity techniques may therefore be considered as adjuvant considerations for fistula management. One would speculate that their greatest efficacy would be in the setting of a long tract, without epithelialization and with low output. Endoscopic insertion of a silicone-covered stent across the fistula opening related to gastrojejunal leak following gastric bypass surgery has been described as a means of allowing early feeding and promoting fistula closure.<sup>45</sup> One well-documented and potentially morbid complication of the stent use is its downstream migration with obstruction and erosion of the intestine. Clearly, no consensus regarding use of this approach has been achieved, given the small patient numbers described.

**Nutritional Support.** Malnutrition may be present in 55% to 90% of patients with enterocutaneous fistulas.<sup>37</sup> Even though provision of nutritional support and time may be all that are necessary for spontaneous healing of

enterocutaneous fistulas, normalization of nutritional parameters will optimize patients requiring a surgical intervention. However, malnutrition is a major contributor to mortality in that setting.<sup>37</sup> Patients with postoperative enterocutaneous fistulas are often malnourished due to a combination of poor enteral intake, the hypercatabolic septic state, and the loss of protein-rich enteral contents through the fistula and via the open abdominal wall.

The optimal route of nutrition in the management of enterocutaneous fistulas has not been critically studied. Parenteral nutrition has long been the cornerstone of support for patients with enterocutaneous fistulas.<sup>37,90-92</sup> This, in part, is related to the fear that early enteral feeds will exacerbate the fistula through increasing output and also that enteral feeds may not be an adequate form of nutritional support. Parenteral nutrition can be commenced once sepsis has been controlled and appropriate intravenous access has been established. Transition to partial or total enteral nutrition has been advocated in recent reports to prevent atrophy of GI mucosa as well as support the immunologic and hormonal functions of the gut and liver. In addition, parenteral nutrition is expensive and requires dedicated nursing care to prevent undue morbidity and mortality from line insertion, catheter sepsis, and metabolic complications. Thus, attempting enteral feeding is appropriate in most fistula patients. As achieving goal rates of enteral feeding may take several days, patients are often maintained on parenteral nutrition as tube feedings are advanced. Enteral feeding may occur per os or via feeding tubes placed nasogastrically or nasoenterically. Enteral support typically requires 4 ft of small intestine and is contraindicated in the presence of distal obstruction. Drainage from the fistula may be expected to increase with the commencement of enteral feeding, although this does not uniformly occur and is often dependent on fistula location and size of the fistula defect; however, spontaneous closure may still occur, often preceded by a decrease in fistula output. When parenteral and enteral nutrition are both options, the latter is preferred. It is far less expensive, safer, and is easier to administer (particularly if the intent is to manage the patient as an outpatient). A meta-analysis by Gramlich and colleagues<sup>19</sup> indicated that ICU patients receiving enteral feeds have a lesser infection rate than those receiving parenteral feeds.

In patients with high-output proximal fistulas, it has been suggested to provide enteral nutrition by a technique called *fistuloclysis*. In fistuloclysis, an enteral feeding tube is placed directly into the matured high-output fistula.<sup>93</sup> Teubner and colleagues reported on their experience using

fistuloclysis in 12 patients before reconstructive surgery.<sup>94</sup> Eleven of 12 patients were able to discontinue parenteral support, and nutritional status was maintained until surgery in 9 patients (19-422 days) and for at least 9 months in the 2 patients who did not undergo operative intervention.<sup>94</sup> Of note, surgeons in this study also reported improved bowel caliber, thickness, and ability to hold sutures in patients who had received enteral nutrition.<sup>94</sup> Other measures such as the use of recombinant human growth hormone on fistula patients have been examined. While able to promote intestinal mucosal epithelial cell proliferation; increase levels of total proteins, albumin, fibronectin, and prealbumin; and transfer and reduce nitrogen excretion, its clinical role has not been clearly defined.<sup>95</sup>

**Psychological Support.** Patients who develop postoperative enterocutaneous fistulas require considerable psychological support. They have sustained a major complication of surgery and are frequently faced with prolonged postoperative stay, excessive abdominal discomfort, and potentially 1 or more additional surgical interventions. In aggregate, all of these factors lead to psychological distress for patient and their families and should be addressed once the acute disease is dealt with.

## **PHASE 2: INVESTIGATION**

Once the patient has been stabilized with control of sepsis and commencement of nutritional support, early radiologic investigation may be of value. Abdominal CT scanning with GI contrast will help to discern whether there is residual local infection that requires drainage, will localize the level of the fistula and the amount of contrast flowing beyond the defect, and occasionally will indicate whether there is distal obstruction. Fistulograms down drainage tracts will elucidate the length, course, and relationships of the fistula tract. If the fistula is spontaneous, the nature of the local pathologic process from which the fistula arises may be determined. In the setting where the mucosal bud of the fistula is readily observed in the center of an open abdomen, aside from a CT scan to rule out distant infection, little further early imaging is required. Because patients with enterocutaneous fistulas are frequently referred to larger centers for management, it is essential that all notes, particularly operative notes, be obtained from the referring hospital. Personal communication with the surgeon may further

elucidate other factors in the patient's disease that are not readily evident from the notes.

### **PHASE 3: DECISION**

Spontaneous closure of fistulas restores intestinal continuity and allows resumption of oral nutrition. As noted previously, the rate of spontaneous closure varies considerably from series to series, with an average of approximately one-third of patients. This wide range likely represents patient selection in the various series, and in particular, whether the series emanates from a referral center where the patient population tends to be more complex. A number of factors predict spontaneous closure. These are listed in [Table 16-7](#). One might consider 2 case scenarios to illustrate these points. A long, narrow fistula tract originating from a small leak in a colonic anastomosis with no evidence of distal obstruction and a well-drained perianastomotic abscess is almost certain to close spontaneously. By contrast, a small bowel defect revealing itself as a mucosal bud in the middle of an open abdomen is unlikely to heal as the tract is short and epithelialized, in essence mimicking a stoma.

Fistulas associated with IBD often close with nonoperative management only to reopen upon resumption of enteral nutrition. These fistulas should be formally resected once closed to prevent recurrence. Fistulas in the setting of malignancy or irradiated bowel are particularly resistant to closure and would suggest the need for earlier operative intervention.

Most authors agree that once resuscitation, wound care, and nutritional support are established, 90% to 95% of fistulas that will spontaneously close typically do so within 4 to 8 weeks of the original operation.<sup>26,90</sup> In the absence of closure, there should be consideration of surgical closure. Like any surgical procedure, weighing of the risk and benefits of surgical intervention is critical prior to proceeding to operation. This is particularly relevant in this patient population where the surgical procedure is a major one and has a finite risk of recurrence. Some patients are perfectly well, tolerating a regular diet, and have fistula effluent that is trivial in volume and requires only coverage with dry gauze. The potential risks of a major operation in this type of patient might outweigh the ultimate benefit.

The timing of elective operative intervention for fistulas that are unlikely to or fail to close is extremely important. Early operation is only indicated to

control sepsis not amenable to percutaneous intervention. These early procedures are typically limited to drainage of infected fluid collections and defunctioning or exteriorization of the defect.

There is some controversy in the literature as to how long one should wait before attempting definitive elective closure of enterocutaneous fistulae. Very early closure appears to be contraindicated because the patient condition is generally not optimized. Further, from a technical standpoint, adhesions tend to be dense and vascular, therefore rendering the procedure difficult. In one retrospective study, Keck and colleagues observed that operative difficulty and denser adhesions leading to inadvertent enteromies were more common when patients were taken to surgery for reversal of a Hartmann procedure before 15 weeks compared to after.<sup>96</sup> Poor outcome when surgery is performed in the 2-week to 3-month window has been reported by several groups.<sup>97,98</sup> At least 2 reports suggest that a very long delay before definitive surgery (>36 weeks) might adversely affect outcome.<sup>99,100</sup> It is generally recommended that definitive surgery be considered in the window of 3 to 6 months after the patient is stabilized from the initial recovery from the procedure that led to the fistula formation. Various factors will influence where, in this interval, surgery is performed. Patient factors such as nutritional status, ease of managing the fistula, and family support may influence decision making. Some authors talk about the “soft” abdomen and prolapse of the fistula as being valuable clinical signs that peritoneal conditions are reasonable to proceed with surgery.<sup>101</sup> On occasion, there is intense pressure from the patient and family to reoperate and “fix” the fistula during this early period. This approach should be resisted.

## **PHASE 4: DEFINITIVE MANAGEMENT**

Operations repairing enterocutaneous fistulas may be complex and often lengthy. In addition to repairing the fistula, many of these patients require complex abdominal wall closures. Before definitive management, the patient should have achieved optimal nutritional parameters and be free of all signs of sepsis. Through careful management of fistula drainage, a well-healed abdominal wall without inflammation should be present. Given the complexity of these operations and importance of perioperative multidisciplinary care, surgical management in certain countries is dedicated to regional centers. For example, in the United Kingdom, 2 supraregional

centers are nationally designated. Having said that, Murphy and colleagues did demonstrate that surgical outcomes in regional units closer to home might be as successful with an appropriate dedicated multidisciplinary team.<sup>102</sup>

**Consent.** As for all operations, the patient should be fully apprised of the nature of the procedure and its potential for complications. Connolly and colleagues reported a very high incidence of complications following intestinal reconstructive surgery (82.5% of procedures) when one considered postoperative nosocomial infections including surgical site infections, respiratory infections, and central line sepsis together with postsurgical myocardial dysfunction, GI bleeding, and deep vein thrombosis.<sup>103</sup> In one of the larger studies by Owen and colleagues, 153 patients underwent definitive operative intervention for enterocutaneous fistulas. Of these, 88% were small bowel in origin and 52% of were high output. Successful closure occurred in 83% of patients; however, like previous reports, postoperative complications were high, occurring in 87% of patients, with a 30-day mortality of 3.9% and 1-year mortality of 15%.<sup>104</sup>

In discussions with patients and their families, the unique difficulty of these procedures should be raised, pointing out the potential for adhesions and therefore inadvertent injury and excessive bleeding. The fistula recurrence rate is also significant, with reported rates up to 33% (see [Table 16-5](#)), depending on the individual circumstance. The patient and relevant family members should know that the procedure may be prolonged and may require an ICU stay in the postoperative period. Some of the anxiety of the patient may be related to mistrust of physicians in general following a previously complicated operation. Clearly, the sensitive nature of reoperation for prior complications requires a strong physician-patient relationship to minimize patient anxiety prior to the planned procedure.

**Patient Preparation.** It is critically important for the operating surgeon to fully understand the nature of the patient's prior surgeries. Reviewing the previous operative notes as well as speaking with the original surgeon will consolidate one's knowledge of the initial pathologic process and the precise anatomy to be corrected in the reoperative setting. One should also be very liberal about using preoperative contrast imaging or endoscopy to completely define the anatomy. In the hypothetical case of reoperation after a colonic anastomotic dehiscence, the need for definition of the anatomy varies

according to the initial source control procedure. It is of utmost importance to confirm distal patency of the gut before any operation. In preparation for closure of a Hartmann procedure, the rectal stump should be routinely investigated by endoscopy. This may help with planning of the operation as well as locating the stump at surgery. Closure of a defunctioning ileostomy or colostomy should also be preceded by investigation of the downstream anastomosis. This is intended to rule out the presence of a stricture or persistent defect at that site, both of which would alter surgical approach. Finally, contrast studies are essential when complex fistulas exist and are to be treated by reoperative surgery.

The general principles related to preparation for any surgery should be applied to reoperation. These would include optimization of the general medical status of the patient, administration of subcutaneous heparin and/or other antithrombotic strategies, and initiation of measures aimed at reducing postoperative infectious complications. Orthograde intestinal lavage by mouth as well as distally via the defunctioned limb has been recommended for mechanical preparation of the bowel. However, the evidence underlying this recommendation is limited, and, in fact, studies show that mechanical bowel preparation for elective colon surgery does not improve outcome and may have some deleterious effects.<sup>68</sup> Our practice is to forego the use of mechanical prep unless reconstruction involves passage of stapling device transanally. Clearance of inspissated mucus in the rectal stump with an enema may facilitate advancement of the stapler proximally. Finally, prophylactic intravenous antibiotics with broad-spectrum coverage of both facultative gram-negative and anaerobic bacteria are indicated. Consideration of coverage of resistant microbes should be made.<sup>21</sup>

**Operative Intervention.** Patients should be positioned to permit optimal exposure to the field of surgery, to take into account potential requirements for extension of the operative field, and to facilitate optimal reconstruction of the GI tract and/or drainage of the operative field. In the majority of situations, the supine position is adequate. Concomitant lithotomy positioning is often helpful, particularly when reconstruction involves the left colon or rectum, where transanal access for endoscopy or stapling may be useful. When reoperation involves the upper GI tract, left lateral decubitus positioning will allow an initial thoracoabdominal incision or extension of an abdominal incision into the chest.

Careful planning of the location and type of incision are mandatory prior to making the initial incision. It is preferable to enter the peritoneal cavity through a previously unoperated area of the abdominal wall, thereby avoiding the areas where the most intense adhesions would be expected, that is, beneath the previous abdominal wall incision and in the region of the abdomen where the inflammation might have been the most severe. Inadvertent enterotomy is relatively common during reoperation, occurring in approximately 20% of patients, and is associated with a higher rate of postoperative complication and a longer postoperative hospital stay.<sup>105</sup> In addition, it is a frustrating beginning to an often long and tedious operation.

The use of the midline incision, beginning with entry either cephalad or caudad to this initial incision through an unoperated field, is the most common approach to reentering the abdomen. This approach provides broad access to the peritoneal cavity with opportunity for extension and is also readily closed. Other approaches may include unilateral or bilateral subcostal incisions, transverse incisions, flank incisions, or thoracoabdominal incisions. In general, these should be considered when a specific area of the abdomen is operated on, because they generally afford less access to the overall peritoneal cavity. When placing new incisions, care should be taken not to render intervening tissue bridges ischemic. This might occur when a midline incision is placed adjacent to a previous paramedian incision. It is preferable to use the previous paramedian incision with extension into the midline above or below. When the fistula opening is in the center of a reepithelialized section of the abdomen with no underlying fascia/muscle, one should preferably enter the abdomen as described above, either cephalad or caudad to the previously operated area. When this is not possible, one should consider placing the initial incision along the line of the fascial edge, rather than through the reepithelialized portion. In the latter operative field, the skin may be very adherent to the underlying bowel, therefore increasing the chance of bowel injury. This is particularly true when there is retained mesh, which may have contributed to fistula formation in the first place.

Upon entering the peritoneal cavity, adhesions between the anterior abdominal wall and the underlying omentum and bowel must be released. By 3 to 6 months following the initial surgery, adhesions are generally relatively filmy and readily divided using scissor or cautery dissection. Gentle traction on the bowel with countertraction on the abdominal wall will facilitate exposure of the appropriate tissue plane for division. A similar approach is

appropriate for dense adhesions, with some surgeons preferring knife dissection. During this dissection, it may be necessary to leave patches of abdominal wall (peritoneum with or without fascia) or even mesh adherent to bowel to avoid enterotomy. It is also noteworthy that enterotomies may be caused by traction on the bowel due to retraction on the abdominal wall. Clearance of the fascial edges along both sides of the entire incision is necessary to achieve adequate and safe closure of the abdominal wall.

Having successfully entered the abdominal cavity, one faces varying degrees of interloop adhesions. The degree to which these must be lysed depends on the particular operation to be performed. When one is operating on the colon for the purpose of stoma closure or reestablishment of colonic continuity, there is generally little need to exhaustively take down small bowel adhesions. The fact that the patient has been tolerating a normal diet preoperatively provides ample evidence that the small bowel adhesions are not of physiologic significance. However, care should be taken not to twist the gut when placing it in the abdominal cavity through small incisions. While not having to lyse all adhesions, it is necessary, however, to free small bowel loops from their attachments to the colon so that the latter might be adequately mobilized to permit easy closure or anastomosis.

On the other hand, when operating to close a small bowel stoma or to correct an enterocutaneous fistula, one should consider more comprehensive lysis of adhesions along the entire length of the small bowel, specially the distal small bowel. This approach is particularly important in the setting of a previous open abdomen with granulation tissue or reepithelialization of the abdominal wall. The presence of a stoma or fistula may serve to defunction a distal small bowel adhesive obstruction prior to surgery and may therefore preclude its recognition. The presence of a distal obstruction following upstream anastomosis could prove catastrophic in the postoperative period. Therefore, one should always confirm patency of the distal bowel before performing an anastomosis.

Adhesiolysis varies considerably in its degree of difficulty. Even when the reoperation is appropriately delayed from the initial operative procedure and vascularized adhesions are no longer present, the number and density of residual fibrous adhesions may still be significant and represent a significant technical challenge. As described for opening the peritoneal cavity, good lighting of the operative field, excellent surgical assistance, and a dose of patience are absolute requirements for this part of the operation. Two

experienced surgeons working together facilitate adhesiolysis. During lysis of adhesions, one should also be wary of encountering previous anastomoses. Adhesions may be particularly tenacious in these areas, particularly when the prior anastomosis was performed using a stapled technique. For side-to-side functional end-to-end stapled anastomoses, the crotch of the anastomosis may be mistaken for intense adhesions. Failure to recognize this may result in inadvertent enterotomy and the attendant increased morbidity.

When surgery has been timed appropriately, one usually finds the dissection distant from the fistula to be reasonably straightforward. As one approaches the fistula site, it becomes increasingly tedious with multiple adherent loops of bowel. We recommend that the fistula be addressed relatively late in the dissection, after most of the small bowel has been mobilized. This minimizes inadvertent injury to loops of bowel uninvolved in the fistula.

Several of the large case reviews address surgical technique and risk of recurrence.<sup>63,97,99,101</sup> In general, it appears to be preferable to locally resect the segment of small bowel bearing the fistula rather than simply closing the intestinal opening. The latter approach frequently fails. In the case of impossibly dense adhesions precluding mobilization and resection, one might consider the addition of a temporary proximal defunctioning stoma.

In the elective surgical setting, stapled anastomoses have been shown to be equivalent to hand-sewn anastomoses in terms of anastomotic dehiscence.<sup>106</sup> By contrast, in trauma patients, comparative and case-control studies (level of evidence 3) showed that hand-sewn anastomosis of the small bowel had fewer leaks and fewer intra-abdominal abscesses than stapled technique.<sup>107</sup> However, that finding was not reproduced in large bowel anastomosis in the same setting.<sup>108</sup> With respect to closure of enterocutaneous fistulas, hand-sewn appears to be the preferred approach to performing the anastomosis following resection. Whether 1 layer versus 2 layers of sutures or running versus interrupted stitching should be used has not been systematically addressed. Frequently, the chronically defunctioned bowel is atrophic, line-walled, and stiff. Under these circumstances, the stapling devices are unable to accommodate the pathologic nature of this bowel, where hand-sewing can better accommodate differences in size, thickness, and compliance of the intestine.

Wrapping of the anastomosis with omentum has been examined as a

means of preventing anastomotic leakage but has not proven to be effective.<sup>70</sup> However, placement of a flap of omentum between the fresh anastomosis and the abdominal wall closure may minimize recurrence of fistulization. Some have advocated the placement of a decompressive gastrostomy and/or the placement of a feeding jejunostomy, both of which may aid in the postoperative care of patients undergoing procedures of this scale.

As the cumulative experience with complex laparoscopic procedures has increased, several groups have reported laparoscopic approaches to enteric and enterocutaneous fistulas.<sup>109-114</sup> The largest of these series reported 73 procedures in 72 patients, 20% of which were enterocutaneous fistulas.<sup>113</sup> The authors reported a mean operative time of 199 minutes with a 4.1% conversion rate.<sup>113</sup> Because surgical procedures for the management of enteric fistulas are generally complex ones, a laparoscopic approach would seem appropriate only in the hands of a skilled and experienced laparoscopic surgeon and only in selected circumstances.

**Abdominal Wall Closure.** Results of a recently published systematic review and meta-analysis involving patients with open abdomens showed that the average primary fascial closure rate was 62%.<sup>115</sup> Therefore, after the fistula has been appropriately managed, one is left with the challenge of closing the abdominal wall. The complexity of this aspect of the operation varies depending on the preoperative state of the abdominal wall. Closure may be straightforward when the enterocutaneous fistula is along a previous drain tract or through necessitation of an abscess through an abdominal wound. By contrast, when the prior patient management involved an open abdomen approach with the fistula draining from the center of the wound, patients may present with large ventral hernias that are not amenable to simple fascial closure. In advance of surgery, it is essential that the surgeon consider management of the abdominal wall a significant part of the procedure and reflect upon the various surgical options. Included in these preoperative deliberations should be the proactive involvement of a plastic surgeon to aid in the assessment of options and to potentially prepare him or her for involvement in the operation. [Table 16-9](#) outlines the various approaches. Prior to beginning abdominal wall closure, it is desirable to debride/remove any residual infected foci, including chronically infected suture material and previously placed infected mesh. One should also attempt to position the intestinal anastomosis away from the closure and, if possible, to interpose

omentum between the anastomosis and the abdominal wall. Finally, it is generally considered that, in the setting of GI surgery where there is contamination of the surgical field, the use of nonabsorbable permanent mesh is contraindicated as it is associated with an increased risk of infection and refistulization.<sup>116</sup>

**TABLE 16-9: MANAGEMENT OF ABDOMINAL WALL FOLLOWING ELECTIVE CLOSURE OF GASTROINTESTINAL FISTULA**

#### **No Preoperative Fascial Defect**

- Primary closure with or without some fascial relaxation

#### **Preoperative Fascial Defect**

- Small defect (<5 cm)
  - Primary fascial closure with or without some fascial relaxation
- Large defect
  - Primary fascial closure using component separation technique
    - If very large, may be combined with prosthetic material
  - Coverage with vascularized flap
  - Use of prosthetic material
    - Nonabsorbable
    - Absorbable
      - Nonbiological
      - Biological

When no defect or a small defect in the fascia exists, primary closure is usually achievable. However, if primary closure is not achieved within the first 7 to 10 days, patients will likely require additional procedures to bridge the gap in the abdominal wall, since closure under tension can result in abdominal compartment syndrome, evisceration, and/or incisional hernias. In these circumstances, relaxing incisions placed in the aponeurosis of the external oblique muscle approximately 2 cm lateral to the edge of the rectus muscle may minimize any tension. Polydioxanone, a slowly absorbable monofilament suture material, appears preferable as it is equivalent to nonabsorbable monofilament suture in terms of recurrent hernias but has less wound pain and sinus formation.<sup>117</sup>

Various closure techniques have been proposed when primary fascial

closure is not possible.<sup>116,118-120</sup> There has been increasing enthusiasm regarding the use of the component separation technique as a means of achieving abdominal wall closure without prosthetic material. In brief, this approach involves the separation of the external oblique and internal oblique muscles bilaterally plus division of the posterior rectus fascia. Together, these accomplish up to 12-, 22-, and 10-cm advancements of the upper, middle, and lower thirds of the abdomen, respectively.<sup>118</sup> This approach has been reported for abdominal wall closure after trauma surgery, in patients with sepsis managed with the open abdomen, and in patients with enterocutaneous fistulas. Wind and colleagues examined the application of this technique in the presence of a contaminated abdominal wall defect, including during closure of an enterocutaneous fistula and/or stoma.<sup>119</sup> This study reported the feasibility of this approach in terms of achieving abdominal wall closure but noted considerable morbidity, including wound seromas, wound infections, and hematomas as well as recurrent abdominal wall hernias in approximately 22% of patients. Recurrence of the enterocutaneous fistula occurred in 25% of patients. In a small percentage of patients, the use of absorbable mesh was combined with the component separation technique, because the advancement of the abdominal wall alone was not sufficient to cover the defect.<sup>119</sup>

A new technique devised by our group incorporates 2 longitudinal incisions in the anterior and the posterior rectus sheaths, followed by abdominal wall reconstruction using 2 large synthetic meshes with antiadhesive coatings facing the abdominal cavity. This method creates 3 overlapping layers over the abdominal cavity and allows medialization of the rectus abdominis muscles as described by Lázaro da Silva.<sup>121</sup> Twelve patients with open abdomens underwent the procedure thus far; definitive closure was achieved in all cases. A follow-up at 36 months showed no incisional hernias or fistulas.<sup>122</sup>

Finally, absorbable prosthetics may be considered for management of the defect in a multistage reconstructive approach. Synthetic meshes such as polyglactin effect good initial coverage but have the anticipated long-term consequence of incisional hernia formation.<sup>103</sup> As an alternative, single-stage reconstruction with biological prostheses including porcine collagen mesh and acellular dermal matrix have been suggested with the potential advantage of increased resistance to infection. A recent study showed that despite

unquestionably lower complication rates with biological prosthesis compared to other materials, there was a 50% incidence of recurrent ventral hernia in the setting of infection within the first 3 years.<sup>123</sup> Moreover, the presence of enterocutaneous fistulas has also been linked to unfavorable outcomes.<sup>103,124</sup>

In summary, management of the abdominal wall following reoperative surgery in these patients may be a considerable challenge. The major objective is to prevent recurrent fistula formation and minimize postoperative infection. Prevention of late ventral hernia formation is a secondary goal. Involvement of a surgical team with expertise in the options, including the use of the component separation technique, would appear to broaden the clinical options for the patient.

## PHASE 5: POSTSURGICAL PHASE

The postoperative period can be divided into 2 parts: the early postsurgical recovery period and the later rehabilitation and convalescence phase. The former of these periods can be somewhat complex as postoperative complications are frequent, with up to 80% of patients having 1 or more complications.<sup>103</sup> In particular, these patients have a significant incidence of postoperative infection, both at the surgical site and at distant sites including lung and central venous lines. As shown in [Table 16-5](#), the incidence of recurrent fistulization following surgery is considerable and is associated with prolonged hospital stays and repeat admissions to the ICU as well as repeat interventions. Brenner and colleagues reported that recurrence of the enterocutaneous fistula in the postoperative period was the strongest predictor of mortality, invariably due to the development of overwhelming sepsis and organ failure.<sup>99</sup> Mortality is related to the presence of preoperative comorbidities.<sup>125</sup> Short of death, the recurrence of enterocutaneous fistula following surgery represents a major complication. Among those who survive this recurrence, only 50% to 66% go on to further surgery and successful closure, while the remainder live with a chronic fistula.<sup>97,99</sup> A number of factors predict recurrence ([Table 16-10](#)).

**TABLE 16-10: FACTORS PREDICTING RECURRENCE AFTER ELECTIVE REPAIR OF ENTEROCUTANEOUS FISTULA**

## **Patient Factors**

Open abdomen

Origin of fistula (small bowel > large bowel)

Underlying inflammatory bowel disease

“Frozen abdomen” or residual intra-abdominal infection

## **Surgical Factors**

Timing of surgery (<4 weeks, >36 weeks)

Multiple inadvertent enterotomies at reoperation

Oversewing of enteric defect, rather than resection and anastomosis

Use of stapled anastomosis, compared to hand-sewn anastomosis

Need to perform mesh closure of abdominal wall

---

By the time their fistulas have been surgically closed, these patients have often been undergoing medical care, usually both as inpatients and outpatients, for several months following the initial development of their enterocutaneous fistulas. By the end of this period, which may have included prolonged in-hospital stays, multiple surgical and radiologic interventions, frequent visits to health care facilities as outpatients, and an overriding focus on their medical disability, patients are invariably physically deconditioned and emotionally fatigued. The impact on the long-term quality of life, as measured by objective questionnaires, even in those treated, continues to be lower than matched controls, especially if there is a concurrent medical illness.<sup>126</sup> Physical and occupational therapists play a role throughout each patient’s hospitalization, but their efforts become even more important during the healing phase as the focus shifts to reintroducing the patient to normal activities of daily living. Involvement of case management staff early in the patient’s course will identify obstacles to the patient’s successful reintroduction to an active lifestyle, while use of psychiatric consultation-liaison services will identify and address issues of depression and adaptive disorders.<sup>127</sup>

Finally, active involvement by the senior surgeon responsible for the patient’s care to ensure clear communication to the patient and the family during what is invariably a prolonged convalescence and rehabilitation period is essential. Optimally, this physician-patient relationship would have begun early in the patient’s illness and would continue through until complete recovery occurs.

## CONCLUSION

Enteric fistulas, occurring spontaneously or in the postsurgical period, represent a significant management challenge. This chapter has focused predominantly on the postsurgical enterocutaneous fistulas, which may result in both morbidity and occasionally mortality for the patient. The care in these patients may be complex and has led to the establishment of specialized intestinal failure units, aimed at optimizing outcome. General principles of care include (1) early recognition and stabilization of patients with fistulas combined with control of sepsis and provision of nutritional support; (2) investigation of the anatomic and etiologic characteristics of each fistula, thus providing information about the likelihood of spontaneous closure or need for operative management; (3) decision making regarding the approach to management that includes the involvement of a multidisciplinary team, which will provide the best possibility of resolution of the fistula; (4) definitive surgical therapy in a controlled setting; and (5) postoperative care including physical rehabilitation and emotional support, which together help patients return to their premorbid condition.

## ACKNOWLEDGMENT

We thank Jo Hoeflok, Nurse Practitioner/Enterostomal Therapy Nurse, St. Michael's Hospital, Toronto, Ontario, Canada, for providing the photographs shown in [Figures 16-2](#) through [16-5](#).

# GASTROINTESTINAL BLEEDING

*Eric G. Sheu • Ali Tavakkoli*

## OVERVIEW

Acute gastrointestinal (GI) bleeding is a common problem causing significant morbidity and mortality. The source of GI bleeding can be anywhere in the GI tract, from the esophagus to the rectum. GI bleeding is classified into upper or lower bleeding based on the site of bleeding relative to the ligament of Treitz. Upper GI hemorrhage occurs from sites proximal to the ligament of Treitz and accounts for more than 80% of acute bleeding.<sup>1</sup> Lower GI bleeding originates distal to the ligament of Treitz, most commonly from the colon. The small intestine is the site of bleeding in less than 5% of patients.<sup>1</sup> Hemorrhage persisting or recurring after negative endoscopy is termed *obscure bleeding*. Occasionally patients present with *occult bleeding*, where there are no signs of overt bleeding but only symptoms of chronic blood loss anemia. In all cases, thorough investigation to localize the source of bleeding allows rapid and often definitive management.

## Incidence and Economic Impact of GI Bleeding

Acute GI hemorrhage is one of the most common problems prompting outpatient, emergency room (ER), and inpatient visits. In 2012, nearly 800,000 patients seen in the emergency department (ED) were discharged with a diagnosis of GI hemorrhage, or 254 visits per 100,000 adults.<sup>2</sup> Of those patients, 54.6% were admitted, and over 500,000 patients had GI bleeding as their principal diagnosis for admission in 2012, with an estimated cost of nearly \$5 billion US. The incidence of acute upper GI bleeding is estimated at 170 cases per 100,000 adults, and increases with age, affecting 1% of those older than age 85, and is more frequent than lower GI bleeding.<sup>3-6</sup> There are geographical variations in the GI bleeding incidence, with reported rates varying from 45 per 100,000 in the Netherlands to 172 per 100,000 in Scotland. This difference is likely related to differences in population demographics and prevalence of various etiological factors between the countries.<sup>7-11</sup>

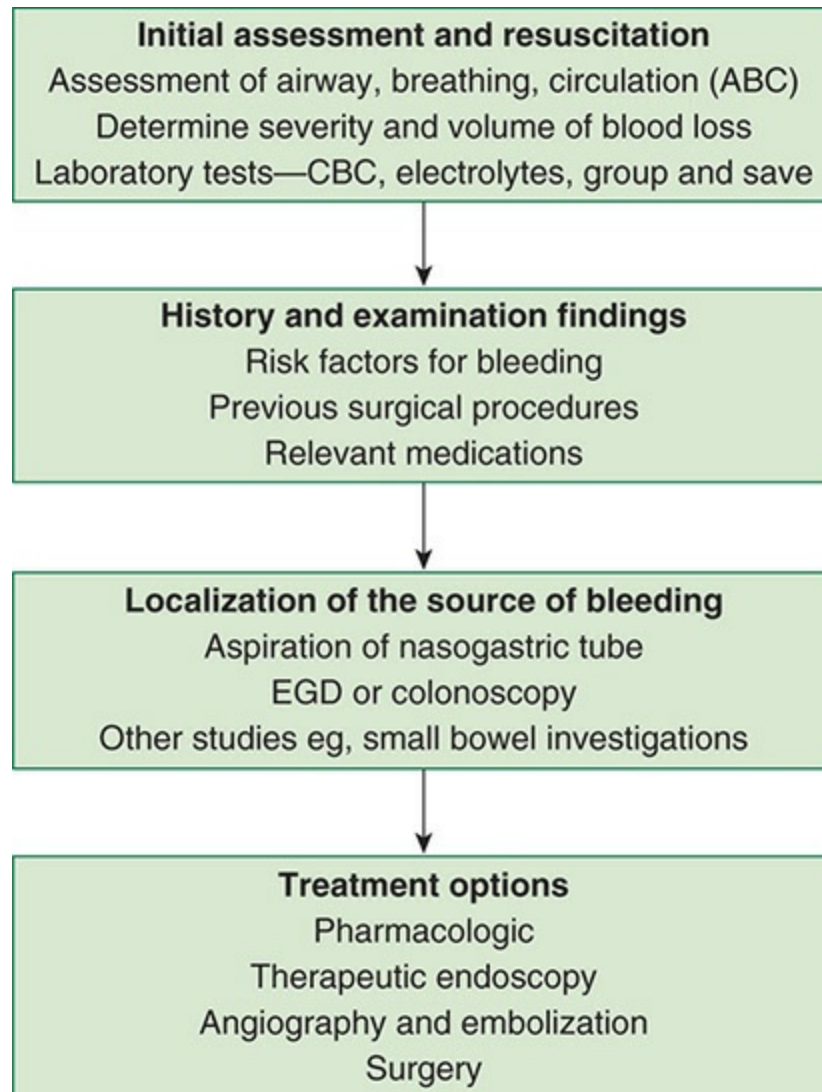

## Morbidity and Mortality

Despite advances in therapy, mortality from GI bleeding remains high. In hospital death from GI bleeding in 2012 occurred in 2.2% of cases, and is particularly high in the elderly.<sup>2</sup> Mortality from GI bleeding occurs frequently on presentation in the ED or early in hospitalization. Evidence suggests that upper GI bleed mortality rates have declined in the last 3 decades, with mortality rates based on the NHDS trending from 4.8% in 1979 to 1989 to 3.1% from 2000 to 2009, primarily due to reductions in early hospital mortality.<sup>5-6, 9, 12-13</sup>

## INITIAL ASSESSMENT AND RESUSCITATION

A structured approach is recommended in the initial evaluation and management of the patient with acute GI bleeding (Fig. 17-1). Early resuscitation with the aim of restoring hemodynamic stability is the initial priority, followed by a careful history and physical examination to help identify the etiology and source of bleeding. Particular attention should be paid to comorbidities and the drug history as this may further complicate

management. Diagnostic tests are subsequently performed to confirm the site of bleeding, and therapeutic interventions commenced to control active bleeding and prevent future recurrent hemorrhage.

**FIGURE 17-1** A brief overview of the management of gastrointestinal bleeding. (Reproduced with permission from Townsend CM, Beauchamp RD, Evers BM, et al: Sabiston Textbook of Surgery: *The Biological Basis of Modern Surgical Practice*, 18th ed. Philadelphia, PA: Saunders/Elsevier; 2008.)

## Initial Assessment

Management of resuscitation should follow the principles of A (airway), B (breathing), and C (circulation). Once airway and breathing have been

managed, adequate hemodynamic resuscitation is of the highest priority. In particular, the clinician needs to assess the amount of blood lost and the extent of ongoing bleeding. Initial evaluation should focus on rapid assessment of the magnitude of both the pre-existing deficits and of ongoing hemorrhage. This can be determined by history and examination of the presenting symptoms. In the majority of cases, a wealth of information can be obtained from simple clinical parameters such as consciousness level, blood pressure, and heart rate (Table 17-1), and further facilitated by measurement of urine output as a marker of end-organ perfusion. Not all patients will demonstrate a tachycardic response to bleeding, particularly in the elderly or those on  $\beta$ -blockers. Occasionally severe blood loss may cause vagal-mediated bradycardia. Depending on the hemodynamic status of the patient and existing comorbidities, more invasive forms of monitoring such as central venous monitoring may be required.

**TABLE 17-1: LEVELS OF SHOCK**

Class	Blood Loss (mL)	Blood Loss (%)	Heart Rate (bpm)	Blood Pressure	CNS Symptoms
I	<750	<15	<100	Normal	Normal
II	750–1500	15–30	>100	Orthostatic	Anxious
III	1500–2000	30–40	>120	Hypotension	Confused
IV	>2000	>40	>140	Severe hypotension	Oblunded

While initial blood tests including a complete blood count and a type and cross are important, a normal hematocrit in the early stages of bleeding may be falsely reassuring, as the hematocrit will only decrease following dilution of the blood volume with resuscitation.

## Resuscitation

The importance of adequate resuscitation cannot be overemphasized. The most important contributor to morbidity and mortality in acute GI bleeding is fulminant multiorgan failure from inadequate resuscitation. The critical care team should be involved early in the resuscitation process, as early intubation and ventilation will reduce the complications of any respiratory compromise. Large-bore venous access is crucial, particularly in the hemodynamically unstable. Fluid resuscitation should be commenced with an isotonic

crystalloid solution such as lactated Ringer's. Adequacy of resuscitation should be continuously assessed using clinical parameters such as heart rate, blood pressure, and urine output. A central venous catheter will facilitate assessment of preload in those with cardiac, pulmonary, or renal comorbidities and thereby facilitate more sensitive assessment of fluid balance. Basic laboratory tests including a complete blood count, basic metabolic panel, liver function test, coagulation profile, and type and cross should be obtained.

## **Transfusion**

Several factors need to be considered when deciding whether a blood transfusion is required. Of these, the most important are the presence and extent of ongoing bleeding and the response of the patient to fluid resuscitation. Other factors include the age of the patient and the presence of cardiopulmonary comorbidities that might compromise tissue perfusion. The suspected likelihood of rebleeding should also be taken into account; for instance, a transfusion is more likely to be required for esophageal varices, which have a high propensity for profuse rebleeding.

Packed red cells are the usual form of transfusion but are defective in clotting factors, calcium, and platelets. In patients with significant bleeding requiring massive transfusion (more than six units of blood), supplementation of red blood cell (RBC) transfusion with fresh frozen plasma, platelets, and calcium is important. In the trauma literature, use of a 1:1:1 ratio of RBC, plasma, and platelets to approximate whole blood in cases of massive blood loss has been associated with improved outcomes and may be applicable to similar situations due to massive GI hemorrhage.<sup>14</sup>

In cases of slower bleeding in the hemodynamically stable patient, hematocrit transfusion triggers have changed over time. There is literature from cardiac surgery and orthopedic surgery patients to suggest that a restrictive transfusion strategy may be linked to improved outcomes, primarily due to decreased infectious complications. A hematocrit less than 21 in the young and healthy patient is a threshold where transfusion should be considered, but in older patients with cardiac morbidity, transfusion is recommended at higher values. However, the decision to transfuse should ultimately be guided by the individual patient, taking into account factors such as the degree of ongoing bleeding, potential for recurrent bleeding, and

assessment of tissue perfusion.

## **Risk Stratification**

The development of risk stratification scores has facilitated prediction of mortality, risk of rebleeding, and triage for admission and timing of investigations. These scores help differentiate patients stable for outpatient investigation and those requiring admission and urgent endoscopy. The BLEED study identified ongoing bleeding, low blood pressure (systolic blood pressure less than 100 mm Hg), elevated prothrombin time (greater than 1.2 times control), erratic mental status, and unstable comorbid disease as risk factors for significantly higher rates of surgery, increased recurrent bleeding, and higher mortality.<sup>15</sup> Other studies have identified hepatic cirrhosis, high Acute Physiologic and Chronic Health Evaluation II (APACHE II) scores, active GI bleeding, hypotension, and end-organ dysfunction as independent predictors for the above outcomes.<sup>16</sup> These studies highlight the importance of comorbidities in determining the outcome of GI bleeding. For example, one study found a mortality rate of nearly 30% in patients with significant renal disease and 65% in patients with acute renal failure.<sup>17</sup>

## **HISTORY AND EXAMINATION**

A thorough history and examination can assist in diagnosing the cause of bleeding and identify comorbidities likely to influence outcome.

### **Important Characteristics of GI Bleeding**

Time of onset, volume, and frequency of bleeding are key aspects of the history in determining amount of blood loss. The character of bleeding is extremely important. Hematemesis is defined as the vomiting of blood, and usually represents upper GI bleeding (rarely bleeding from the nasopharynx or oropharynx). Hematemesis may be bright red when fresh, but older blood will resemble coffee grounds. Melena is defined as the passage of offensive, black, tarry stool, again usually due to upper GI bleeding. The appearance of the stool is a result of gastric acid degradation (which converts hemoglobin to

hematin), as well as the effects of intestinal enzymes and bacteria. Rarely, in cases of slow intestinal transit, blood loss from distal small bowel or the right colon may also present as melena. A guaiac test will allow differentiation of the tarry black stool of melena from the dark green stool of patients on iron supplementation (melena will test positive). Bright red blood per rectum is called hematochezia—this may represent blood on the tissue paper, blood around the stool, or blood mixed in with the stool—all important features to elicit on history-taking. Hematochezia usually results from bleeding from the distal colon, usually sigmoid colon or rectum, but may also occur from massive upper GI bleeds with rapid intestinal transit.

## Other Essential Features in the History

Other useful features to elicit in the history include antecedent vomiting (suggesting a Mallory–Weiss tear), recent weight loss or loss of appetite (suggesting malignancy), recent epigastric pain (possibility of peptic ulceration), and alcohol intake or liver disease (likelihood of variceal bleeding). Demographic data will assist in narrowing down the cause of bleeding—diverticulitis, angiodysplasias, malignancy, and ischemic colitis are likely culprits in the elderly. Younger patients are more likely to bleed from peptic ulceration, Meckel diverticula, hemorrhoids, or esophageal varices. In patients presenting with occult bleeding, the history may reveal syncope, angina, or myocardial infarction related to anemia. Previous abdominal surgery is relevant—previous aortic surgery in particular should raise suspicion of aorto-enteric fistula, and patients with gastrojejunal anastomosis, such as after gastric bypass, are susceptible to marginal ulceration. Drug history is particularly relevant in upper GI bleeding. Nonsteroidal anti-inflammatory drugs (NSAIDs) are a common cause of peptic ulceration, and similarly, salicylates and selective serotonin-reuptake inhibitors (SSRIs) are associated with upper GI bleeding.<sup>18,19</sup> Use of anticoagulants may require reversal with blood products.

## PHYSICAL EXAMINATION

Bleeding from the nasopharynx and oropharynx may occasionally present as GI bleeding, so these sites should be routinely examined. Pigmented lesions

in the oral mucosa suggest Peutz–Jegher disease—a rare cause of GI bleeding. The abdomen should be examined to identify any masses or hepatosplenomegaly. A tender epigastrium may suggest peptic ulcer disease. The neck and groins should be examined for lymphadenopathy suggestive of malignancy. The examination should include inspection for stigmata of liver disease. The jaundiced patient with ascites, caput medusae, and palmar erythema presenting with GI bleeding should raise suspicion for variceal hemorrhage. Rectal examination and anoscopy are other essential aspects of the examination to exclude rectal cancer or, more commonly, hemorrhoids.

## **IDENTIFYING THE SOURCE OF BLEEDING**

Performing a nasogastric (NG) tube lavage is an important diagnostic maneuver to help localize GI bleeding. An NG aspirate positive for fresh or old blood (either fresh blood or coffee grounds) confirms upper GI bleeding, aids in assessing the rate of bleeding, and allows removal of blood to facilitate endoscopic evaluation of the gastric mucosa during esophagogastroduodenoscopy (EGD).

A nonbilious, non-bloody aspiration of the stomach does not rule out bleeding from the duodenum, as a competent pylorus will prevent reflux of bile or blood into the stomach. A bilious aspirate without blood does suggest a lower GI source for the bleeding. However, a recent study showed that 20% of patients had a blood-free aspirate from the duodenum despite a diagnosis of upper GI bleeding.<sup>20</sup>

## **Endoscopy in Upper GI Bleeding**

EGD remains the gold standard investigation for the diagnosis and management of upper GI bleeding. EGD facilitates identification of the source of bleeding, determining the underlying etiology, achieving hemostasis, and providing prognostic information for risk stratification.<sup>21</sup> The timing of endoscopic assessment in patients with GI bleeding remains controversial. Although there is little doubt that early endoscopy in hemodynamically unstable patients is necessary, the ideal timing for endoscopic intervention in stable patients remains less clear. A review of studies examining the utility of early endoscopic intervention in upper GI

bleeding concluded that while endoscopy within 24 hours of presentation was of benefit in terms of aiding risk assessment and reduced length of hospital stay, earlier endoscopies (within 12 hours) offered no additional benefit. Indeed, endoscopy within 12 hours of presentation was associated with unnecessarily increased use of therapeutic endoscopy without any benefit in terms of rate of rebleeding or survival. Overall, these studies suggested that endoscopy should be performed within 24 hours of presentation, and in hospitals without a 24-hour endoscopy service, this should be offered to patients the following day.<sup>22</sup>

Other issues should be considered regarding the use of EGD in acute GI bleeding. First, the sensitivity of EGD may be reduced in the presence of active bleeding, as mucosal visibility is impaired. Also, endoscopic complications such as perforation and aspiration increase in the emergency setting. Similarly, sedative medications administered during endoscopy can exacerbate hypotension and hypoxemia. Resuscitative measures should not be delayed or paused for the endoscopic procedure. All patients undergoing urgent endoscopy should be continuously monitored, and consideration given to early anesthesia consultation.

## **Endoscopy in Lower GI Bleeding**

### **FLEXIBLE SIGMOIDOSCOPY AND COLONOSCOPY**

Colonoscopy is recommended over flexible sigmoidoscopy in lower GI bleeding with few exceptions. Colonoscopy has been deemed the most appropriate investigation in patients over 50 years of age with hematochezia or iron deficiency anemia. In younger patients, colonoscopy can be omitted if a convincing benign source of bleeding has been demonstrated on flexible sigmoidoscopy but should be pursued in cases of repeated bleeding.<sup>23</sup>

Colonoscopy has a diagnostic yield of 89% to 97% in the setting of acute GI bleeding.<sup>24,25</sup> Bowel preparation using polyethylene glycol with a prokinetic such as metoclopramide has been recommended to improve endoscopic visualization and thus diagnostic yield.<sup>23,26</sup> This step may have to be omitted in patients with severe ongoing GI bleeding, where there is insufficient time for a formal bowel preparation routine.

## Capsule Endoscopy and Deep Enteroscopy

Endoscopic access to the small bowel is difficult, secondary to the length of the small bowel, intraperitoneal location, and contractility. Capsule endoscopy has emerged as a suitable option for small bowel imaging, and is now the third diagnostic test in patients with obscure bleeding following EGD and colonoscopy.<sup>27</sup> Capsules are swallowed that contain a camera that visualizes mucosal surface as it travels the intestine, and wirelessly transmits images for later review. A device is available for patients with dysphagia, dysmotility disorders, and children to deliver the capsule directly to the duodenum. Capsule endoscopy has better yield than push enteroscopy or small bowel series, and an equivalent yield to intraoperative enteroscopy without the morbidity and mortality of the operative procedure.<sup>28,29</sup> Capsule endoscopy is unsuitable for imaging of the proximal duodenum due to poor visualization of the periampullary region, and should not be performed in those with bowel obstruction or strictures. Yield of capsule endoscopy is dependent on the experience of the reader.<sup>30,31</sup>

Techniques have been developed to allow endoscopy of the small bowel, including single balloon, double balloon, and spiral enteroscopy. The first two techniques use balloons to grip the intestinal wall and facilitate advancement of the endoscope through the intestine. Spiral enteroscopy uses a special overtube with helices at the distal end to pleat the small bowel onto the overtube, again allowing advancement of the endoscope through the intestine. The advantage of deep, or “push,” enteroscopy is the ability to perform biopsies, treat bleeding, and perform other therapeutic maneuvers.<sup>32</sup> The most significant disadvantage of deep enteroscopy over capsule endoscopy is the risk of perforation (0.3% to 3.4%), particularly in patients with inflammatory bowel disease, malignancy, and bowel anastomosis.<sup>31,33-36</sup>

## Angiography

Visceral angiography is a relatively insensitive investigation, able to detect bleeding only at a rate of 0.5 to 1 mL/min.<sup>37,38</sup> Although the specificity approaches 100%, the sensitivity varies from 47% with acute lower GI bleeding to 30% with recurrent bleeding.<sup>39</sup> Angiography has a role in patients with massive lower GI bleeding precluding endoscopic visualization or in

patients with negative endoscopies. Like endoscopy, angiography offers the advantage of potential simultaneous therapeutic intervention.

## **Red Cell Labeling (Nuclear Scintigraphy)**

Red cell labeling has been found to play a limited role in the diagnosis of GI bleeding and may be useful after other methods have failed. While sensitive (this method can detect GI bleeding at a rate of 0.1 mL/min), the site of bleeding is localized to an area of the abdomen rather than a portion of the GI tract. Intestinal motility can shift intraluminal blood away from the site of bleeding, resulting in incorrect localization. Specificity is improved when scans are positive within 2 hours after injection of labeled erythrocytes, as less transit through the bowel will have occurred, with accurate localization in 95% to 100% of cases. Correct localization falls to 57% to 67% when scans are positive more than 2 hours after injection.<sup>40</sup> Red cell scans are therefore more often used to identify a potential role for subsequent angiography. In patients with negative red cell scans or scans positive only after 2 hours, angiography is unlikely to be positive.

## **CT Angiography**

CT angiography (CTA) is a promising new technique that offers advantages compared to tagged RBC scanning. With the dissemination of high-resolution CT scanners, a CTA is available widely and at all times of the day and night. While nuclear RBC scanning takes hours to perform, a CTA can be obtained in minutes. A recent non-randomized retrospective study of patients who received either a tagged RBC scan or a CTA prior to visceral angiography showed that CTA was better at localizing the site of GI bleeding.<sup>41</sup> Despite increased use of IV contrast in CTA patients, no adverse impact on renal function was demonstrated. CTA has been reported to detect blood loss as low as 0.4 mL/min, which would make it less sensitive than nuclear RBC scanning. Further studies are still required to determine the role of CTA in assessing GI bleeding.

## **THERAPEUTIC OPTIONS**

## Pharmacologic Management

Pharmacologic management is unlikely to halt active bleeding but is aimed at preventing recurrent bleeding. Proton pump inhibitors, but not H<sub>2</sub> blockers, have been shown to reduce recurrent bleeding from gastric ulcers, as clot formation is stabilized in the absence of gastric acid. Octreotide is useful in variceal bleeding and may have an adjunctive role in other upper GI bleeds (see variceal bleeding below). Triple therapy treatment for *Helicobacter pylori* can prevent recurrent ulcers and bleeds.

## Endoscopic Treatment

Endoscopy remains the mainstay of investigation and therapy for most causes of upper and lower GI bleeding. Techniques used for control of hemorrhage include thermal coagulation, injection therapy, and mechanical devices such as metallic clips and band ligation. Thermal coagulation probes include bipolar, monopolar, and heat probes, with an overall perforation rate of up to 2.5%, particularly frequent in the thin-walled right colon.<sup>42</sup> Argon plasma coagulation is a means of non-contact coagulation with an almost nonexistent risk of perforation in the colon.<sup>43</sup> Laser-mediated coagulation (such as with the Nd:YAG laser) uses high-energy laser light to vaporize the tissue, producing deeper penetration than argon plasma coagulation but with a higher perforation rate.

Injection of a 1:10,000 dilution of epinephrine is an effective and inexpensive method of endoscopic treatment, causing vasoconstriction and physical compression of the vessel. Metallic clips, in both reusable and disposable forms, are used to control hemorrhage endoscopically. Rubber band ligation is frequently employed in lower GI bleeding due to hemorrhoids or rectal varices.

## Interventional Angiography

While initial attempts of embolization led to high rates of bowel infarction due to the use of large-bore catheters for cannulation, current approaches with microcatheters have produced success rates of 70% to 90% without significant complications, and recurrent hemorrhage rates of only 15%.<sup>44</sup>

Embolization materials include microcoils, gelfoam, and polyvinyl alcohol particles. Selective angiographic embolization has been shown to arrest life-threatening bleeding from gastroduodenal ulcers, with a low rate of early rebleeding and no late rebleeding, obviating the need for emergency surgery in high-operative-risk patients.<sup>45</sup>

Early bleeding recurrence is associated with coagulation disorders, longer time to angiography, higher preprocedural blood transfusion volume, two or more comorbidities, and the use of coils as the only embolic agent.<sup>46</sup>

Embolization has been shown to have 85% success rate in patients with diverticular lower GI bleeding, with higher efficacy in the left compared to right colon. Angiography is less efficacious in non-diverticular lower GI bleeding (eg, arteriovenous dysplastic lesions) with a greater than 40% rate of rebleeding.<sup>47</sup>

Angiography may also be coupled with selective infusion of a vasoconstrictor such as vasopressin, or the longer-acting analogue terlipressin. However, this strategy is associated with a 50% rate of rebleeding after cessation of the infusion.<sup>48</sup> The side effects of vasopressin and terlipressin, including abdominal pain and cardiac complications, have meant that this technique is now only rarely used.

## **Surgery**

Surgery is usually reserved for therapy when less invasive therapeutic modalities have failed and bleeding has been clearly localized. Surgery does remain the treatment of choice in patients with malignant or benign tumors, and may also be used as a last resort in patients with recurrent bleeding without a defined bleeding point or in fulminant hemorrhage. Further discussion of surgical options is detailed in relevant sections below.

## **UPPER GI HEMORRHAGE**

### **Causes of Upper GI Hemorrhage**

Causes of upper GI hemorrhage can be divided into variceal and non-variceal bleeding, which accounts for 80% to 90% of acute upper GI bleeding ([Table](#)

17-2).<sup>6-13</sup> Even in patients with portal hypertension, non-variceal bleeding is still more common. However, due to its morbidity and mortality, if suspected, variceal bleeding should be excluded first.

**TABLE 17-2: CAUSES OF UPPER GI BLEEDING**

	Causes	Frequency
<b>Non-variceal upper GI bleeding (80%)</b>	Peptic ulcer disease	40%
	Mallory–Weiss tears	15–20%
	Gastritis/Duodenitis	10–15%
	Esophagitis	5–10%
	Dieulafoy lesions	1.5%
	GAVE	4%
	Malignancy	2%
	Others:	7.5%
	Aorto-enteric fistula	
	Hemobilia	
Hemosuccus pancreaticus		
Iatrogenic bleeding		
<b>Portal hypertensive upper GI bleeding (20%)</b>	Gastroesophageal varices	>90%
	Gastric varices	Rare
	Portal hypertensive gastropathy	Rare

## NON-VARICEAL BLEEDING

**Peptic Ulcer Disease and Bleeding.** Gastroduodenal peptic ulceration accounts for 40% of all non-variceal upper GI bleeding.<sup>20</sup> The introduction of *H pylori* eradication therapy and proton pump inhibitors has reduced the incidence of peptic ulcer disease (PUD), leading to reduced rates of operation and mortality from PUD. However, the overall incidence of peptic ulcer bleeding remains high, with significant associated mortality and cost.<sup>49,50</sup>

A large proportion of PUD bleeding is linked to use of aspirin and

NSAIDs, and the majority of cases occur in the elderly (68% of patients are over 60 years of age and 27% over 80 years of age).<sup>51</sup> Ten percent to 15% of ulcers will bleed at some point during the course of the disease. Patients with bleeding ulcers commonly present with hematemesis and/or melena. History, examination, and investigations should proceed as outlined earlier (Fig. 17-2). Duodenal ulcers are more common, but gastric ulcers usually bleed more profusely. Ulcers involving an artery such as branches of the gastroduodenal or left gastric arteries can bleed significantly.

**FIGURE 17-2** An algorithm for the management of peptic ulcer bleeding.

Several risk stratification scores have been developed to assist in identification of patients who require close monitoring and are at risk of rebleeding. The two most commonly used tools are the Rockall score and the Blatchford score (Table 17-3). The Rockall score utilizes clinical as well as endoscopic findings to risk-stratify patients. The score ranges from 0 to 11, with a higher score indicating a greater risk of rebleeding or death.<sup>52</sup> The

Blatchford score incorporates clinical and laboratory values to produce a maximum score of 23, with higher scores again associated with a greater likelihood of rebleeding or death.<sup>53</sup>

**TABLE 17-3: COMPARISON OF THE BLATCHFORD AND ROCKALL SCORES**

Criteria of the Blatchford Score	Criteria of the Rockall Score
Systolic blood pressure	Age
Blood urea nitrogen	Shock
Hemoglobin	Coexisting illness
Pulse	Endoscopic diagnosis
Melena	Endoscopic stigmata of recent hemorrhage
Syncope	
Hepatic disease	
Cardiac failure	

The endoscopic appearance of a bleeding ulcer alone can also be used to stratify the risk of rebleeding using the Forrest criteria<sup>54</sup> (Table 17-4). High-grade lesions are those which are actively spurting or oozing blood, or have a non-bleeding visible vessel or adherent clot.

**TABLE 17-4: FORREST CLASSIFICATION FOR ENDOSCOPIC FINDINGS AND RISK OF REBLEEDING IN PU DISEASE**

Classification (Grade)	Endoscopic Finding	Risk of Rebleeding
Ia	Active, pulsatile bleeding	High
Ib	Active, nonpulsatile bleeding	High
IIa	Non-bleeding visible vessel	High
IIb	Adherent clot	Intermediate
IIc	Ulcer with flat, pigmented spot	Low
III	Clean, non-bleeding ulcer bed	Low

### **Medical Management**

STOP ANY CAUSES; EG, DRUGS. All ulcerogenic medication such as salicylates, NSAIDs, and SSRIs should be stopped and non-ulcerogenic alternatives prescribed. COX-2 inhibitors which initially showed promise as a gastroprotective alternative to NSAIDs have recently been shown to demonstrate cardiotoxicity without significant benefit on gastric mucosal protection and are therefore infrequently used.<sup>55</sup>

### **ERADICATION OF *HELICOBACTER PYLORI* AND LONG-TERM ACID**

**SUPPRESSION.** The association of bleeding with *H pylori* infection is not as strong as the association reported for perforated ulcers, with *H pylori* infection reported in only 60% to 70% of bleeding ulcers. However, recent data show that treating patients positive for *H pylori* with eradication therapy reduces the risk of rebleeding and obviates the need for long-term acid suppression, hence eradication with triple therapy is recommended in all bleeders infected with *H pylori*.<sup>56</sup>

Gastric acid has been shown to impair clot formation, promote platelet disaggregation, and increase fibrinolysis. In keeping with this, proton pump inhibitors have been shown to significantly reduce the risk of ulcer rebleeding, the need for urgent surgery and, in patients with high-risk stigmata who have undergone endoscopic therapy, mortality.<sup>57,58</sup>

**Endoscopic Management.** Patients with high-risk stigmata on endoscopy (active bleeding or non-bleeding visible vessel) require hemostatic intervention, such as injection or thermal or mechanical therapy, such as clips (Fig. 17-3). Addition of any one of these to adrenaline injection further reduces rebleeding rates, the need for surgery, and mortality.<sup>59-61</sup>

**FIGURE 17-3** Metallic clips to arrest bleeding from a duodenal ulcer. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Several factors are predictors of failure of endoscopic therapy for peptic ulcer bleeding, including previous ulcer bleeding, shock on presentation, active bleeding during endoscopy, ulcers >2 cm in diameter, a large underlying bleeding vessel  $\geq 2$  mm in diameter, and ulcers on the lesser curve of the stomach or the posterior or superior duodenal bulb.<sup>62</sup> Recent studies suggest that second-look endoscopy (within 24 hours of the initial endoscopic therapy) provided only a small reduction in the rate of rebleeding, is not cost-effective in the presence of acid-suppressing medication, and is overall not recommended.<sup>21,63,64</sup> Repeat endoscopy should only be considered in cases of recurrent hemorrhage or unsuccessful first treatment.

**Surgical Management.** Meta-analysis and surgical registry data show the rate of surgical intervention for bleeding peptic ulcers has decreased with time. An improved understanding of peptic ulcer disease as well as the development of newer pharmacologic and endoscopic treatments has meant that surgery is now employed not as first-line or curative treatment but instead only when other modalities have failed.

There are no consensus guidelines on the appropriate indications for surgery. In general, persistent blood loss with failure of endoscopic therapy and a blood transfusion requirement in excess of six units is often considered an indication for surgical intervention (Table 17-5). Similarly, hypovolemic shock associated with recurrent hemorrhage or slow continuous blood loss requiring ongoing transfusion are also considered indications. Shock on admission, an elderly patient, severe comorbidity, a rare blood type, refusal of transfusion, and bleeding chronic gastric ulcer with a suspicion of malignancy are considered relative indications for surgery.

 **TABLE 17-5: POSSIBLE INDICATIONS FOR SURGICAL INTERVENTION FOR PU BLEEDING**

Absolute indications	<ul style="list-style-type: none"> <li>Persistent blood loss refractory to endoscopic therapy</li> <li>Shock with recurrent hemorrhage</li> <li>Slow blood loss requiring more than 3 units blood transfusion per day</li> </ul>
Relative indications	<ul style="list-style-type: none"> <li>Shock on admission</li> <li>Transfusion in excess of 6 units</li> <li>Elderly patient</li> <li>Severe comorbidity</li> <li>Rare blood type/ refusal of transfusion</li> <li>Suspicion of malignancy in a gastric ulcer</li> </ul>

---

In stable patients with evidence of rebleeding, a second attempt at

endoscopic hemostasis is often as effective as surgery with fewer complications, and is the recommended management.<sup>65</sup> The aim of surgery in both gastric and duodenal ulcers is to arrest hemorrhage and perform an acid-reducing procedure if deemed necessary.

**Operative Procedure for Duodenal Ulcers.** A longitudinal duodenotomy or duodenopyloromyotomy provides good exposure of bleeding sites in the duodenal bulb, the most common location of duodenal ulcers. Direct pressure provides temporary arrest of the bleeding, and should be followed by suture ligation of the bleeding vessel. Four-quadrant suture ligation will achieve hemostasis in anterior ulcers. Posterior ulcers, particularly if involving the pancreaticoduodenal or gastroduodenal artery, will require suture ligation of the artery both proximal and distal to the ulcer for adequate control of hemorrhage, as well as placement of a U-stitch underneath the ulcer to control the pancreatic branches (Fig. 17-4).

**FIGURE 17-4** Suture control of bleeding duodenal ulcers. A longitudinal pyloric incision is made and figure-of-eight sutures are placed at the cephalad and caudad aspects of the ulcer to occlude the gastroduodenal artery.

The use of an acid-reducing procedure in duodenal ulcers remains a topic of debate, as theoretically arrest of hemorrhage and *H pylori* eradication is likely to be sufficient management. There is no good data on which to base recommendations, and currently the decision is left to the surgeon's

judgment, taking into account both individual patient factors and the surgeon's experience with these operations. Surgical options for acid reduction in bleeding duodenal ulcer management include pyloroplasty with truncal vagotomy, parietal cell vagotomy, or antrectomy with truncal vagotomy. Truncal vagotomy with pyloroplasty is most frequently employed, as it is facilitated by the duodenotomy already made to control hemorrhage. Experience with parietal cell vagotomy is limited in the current era. Antrectomy with truncal vagotomy may be considered in the stable patient with refractory PUD but is a more complex procedure with increased morbidity and mortality. Ulcer surgery is covered in greater detail in [Chapter 35, Stomach and Duodenum: Operative Procedures](#).

**OPERATIVE PROCEDURE FOR GASTRIC ULCERS.** Unlike the duodenal ulcer, gastrotomy with oversewing of bleeding is not adequate surgical treatment due to a high risk of rebleeding and underlying malignancy in gastric ulcers. A distal gastrectomy for ulcers of the antrum and distal stomach is the surgical treatment of choice. Resection of the ulcer alone is associated with a 20% rebleeding rate, but can be considered in combination with an acid-reducing procedure (eg, vagotomy and pyloroplasty) in patients who cannot tolerate a formal gastrectomy. Management of bleeding ulcers at the cardioesophageal junction and the proximal stomach is challenging. Formal resection with a proximal or near-total gastrectomy carries high morbidity and mortality in patients acutely bleeding. In these cases, less aggressive operations, such as distal gastrectomy with resection of a tongue of proximal stomach to excise the ulcer, wedge resection of the ulcer, or simple oversewing with a vagotomy and pyloroplasty, can be considered.

***Mallory–Weiss Tears.*** Mallory–Weiss tears are lacerations of the esophagus or stomach caused by severe vomiting.<sup>66</sup> With vomiting, the diaphragm moves abruptly upward, intra-abdominal pressure increases, and the gastric cardia is forced into the thorax through the diaphragmatic hiatus. Hiatus hernias coexist in more than 75% of patients with Mallory–Weiss tears, and the amount of herniated stomach determines the point of maximal dilatation (law of Laplace) and therefore the position of the tear.<sup>67,68</sup> Large hiatus hernias are associated with more distal tears, while in patients with small or absent hiatus hernias, tears occur at or below the gastroesophageal junction.<sup>69</sup> The majority of tears are situated within 2 cm of the gastroesophageal

junction on the lesser curvature.

The highest incidence of Mallory–Weiss tears occurs in patients between 30 and 50 years of age, and in males more than females. Forty percent to 75% of patients have a history of alcohol use and 30% have a history of aspirin use.<sup>68,70</sup> Patients typically present with a history of several episodes of vomiting or retching followed by hematemesis with fresh red blood. Ten percent of patients may present with only melena.

EGD usually identifies a single tear on the lesser curve of the cardia, or occasionally on the greater curvature of the cardia. Retroflexion during the endoscopic examination is an important maneuver in these patients to ensure the distal gastroesophageal junction and cardia are visualized. The majority of lesions heal spontaneously, hence management is largely supportive, with emphasis on antiemetic and acid suppression. Patients with persistent bleeding may require endoscopic or angiographic intervention. Surgery may be required should these options prove unsuccessful, and hemorrhage can be arrested operatively by a high gastrotomy and suture of the mucosal laceration.

***Cameron Lesions.*** A rare cause of upper GI bleeding is an erosion or ulcer of the stomach that occurs within a hiatal hernia. These have been reported to occur in up to 5% of patients with hiatal hernias, although they are overall an uncommon source of GI bleeding. Accurate diagnosis of a Cameron lesion requires an experienced endoscopist. The etiology of the ulcer is thought to be related to a combination of mechanical trauma of the gastric wall moving through the hiatus, exacerbated by reflux esophagitis. Treatment involves repair of the paraesophageal or hiatal hernia.

***Stress-Related Mucosal Bleeding.*** Critically ill patients are at risk for the development of diffuse mucosal injury of the stomach, resulting in upper GI bleeding with significant morbidity and mortality. This phenomenon, termed “stress-related mucosal bleeding” or “stress gastritis” is a result of a combination of mucosal ischemia and reperfusion injury and impairment of host cytoprotective defenses.<sup>71</sup> The most important risk factors for stress-related mucosal bleeding are prolonged mechanical ventilation (>48 hours) and coagulopathy. Other risk factors include shock, severe sepsis, neurological injury/neurosurgery, >30% burns, and multiorgan failure. Patients with these factors should receive prophylaxis with antacids, H2-

receptor blockers, proton pump inhibitors, or carafate.

The incidence of clinically significant stress gastritis, a previously common problem, has been reduced with introduction of proton pump inhibitor prophylaxis.<sup>71</sup> Acid suppression is often sufficient to control hemorrhage in stress-related mucosal bleeding. For persistent bleeding, options include selective infusion of octreotide or vasopressin via the left gastric artery, endoscopic measures, or angiographic embolization. Surgery is now rarely required, but if necessary, involves vagotomy and pyloroplasty with oversewing of discrete regions of hemorrhage or subtotal gastrectomy.

***Esophagitis.*** Esophageal bleeding is rare and most commonly occurs due to esophagitis. Gastroesophageal reflux disease (GERD) is the most common cause, with acid damage to the esophageal mucosa resulting in chronic inflammation and bleeding (Fig. 17-5). Other causes of esophagitis include Crohn's disease, drugs, radiotherapy, and infectious etiologies in the immunocompromised. Infective esophagitis is uncommon but may lead to torrential hemorrhage. Pathogens include herpes simplex, Candida, cytomegalovirus, HIV, Epstein–Barr virus, and secondary involvement of the esophagus in mycobacterial infection of adjacent lymph nodes.<sup>72</sup>

**FIGURE 17-5** Gastroesophageal reflux disease viewed on endoscopy.

Management, particularly of GERD-induced esophagitis, hinges on acid-suppressive therapy, occasionally requiring therapeutic endoscopy to arrest the bleeding. For infectious esophagitis, identifying and treating the underlying infectious cause is often successful at stopping bleeding.

**Dieulafoy Lesion.** Dieulafoy lesions are an arterial vascular anomaly featuring abnormally large (“caliber-persistent”) submucosal end arteries, likely congenital in origin, with the potential for massive, potentially life-threatening hemorrhage upon erosion of the overlying mucosa. These lesions are most commonly located in the stomach within 5 to 7 cm of the cardia, but may present in the small bowel and colon. They account for 1.5% of upper GI bleeding and are more common in men.<sup>73</sup>

Dieulefoy lesions appear as reddish-brown protrusions on endoscopy with no ulceration. Endoscopic therapy is often successful, with clipping or banding demonstrated to be superior to injections.<sup>74,75</sup> Angiographic embolization or surgery may be necessary for endoscopic failures. Prior

endoscopic tattooing facilitates identification of the site of the lesion for resection if surgery is necessary.

**Gastric Antral Vascular Ectasia.** Gastric antral vascular ectasia (GAVE), or “watermelon stomach,” is named for the dilated, tortuous mucosal capillaries and veins in the gastric antrum that converge onto the pylorus and resemble the surface of a watermelon (Fig. 17-6). This condition is more common in women and usually presents with occult blood loss and iron deficiency anemia. Argon plasma coagulation (APC) is the treatment of choice and may need to be repeated. Proton pump inhibitor cover is recommended for 1 month following treatment.<sup>73,76</sup> Patients refractory to APC should be considered for surgical intervention, usually an antrectomy.

**FIGURE 17-6** Gastric antral vascular ectasia (GAVE) can be seen in the gastric antrum, giving the stomach a watermelon appearance. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

**Malignancy.** Malignant upper GI lesions rarely present with significant overt hemorrhage, and more commonly present with hemocult-positive stool or

iron deficiency anemia. Endoscopy occasionally reveals a recurrent bleeding ulcer, a common feature of GI stromal tumors, which characteristically appears as a submucosal tumor with central umbilication and ulceration (discussed further in [Chapter 33](#), Gastrointestinal Stromal Tumors), and on occasion leiomyomas and lymphomas ([Fig. 17-7](#)). Surgery is the therapy of choice and may involve either curative resections or in unfit patients, palliative wedge resections.

**FIGURE 17-7** A gastrointestinal stromal tumor (GIST) of the stomach on endoscopy. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

***Aortoenteric Fistula.*** Aortoenteric fistula is an important clinical condition that can cause torrential GI hemorrhage. Primary fistulae are rare; fistulation occurs most commonly following a previous abdominal aortic aneurysm (AAA) repair, and is seen in approximately 1% of these cases. The pathophysiology behind this is likely to be infective in origin, leading to the development of a pseudoaneurysm at the proximal suture line with subsequent fistulization into the adjacent duodenum ([Fig. 17-8](#)).

**FIGURE 17-8** Intraoperative appearance of an aortoenteric fistula. The photograph demonstrates a large hole (black arrow) in the posterior aspect of the 3rd part of the duodenum after it was medialized and peeled off of the graft. The photograph has been taken from left side of the table with the patient in supine position. (Used with permission from Neal Barshes, MD, MPH, Brigham and Women’s Hospital, Boston, MA.)

Early diagnosis of this problem is critical but requires a high index of suspicion in patients presenting with GI bleeding with known aortic aneurysms or a history of aortic aneurysm repair. Often, patients present with smaller, self-limiting episodes of GI hemorrhage (“sentinel bleeds”). Urgent endoscopy at this stage is essential to preempt a subsequent torrential, often fatal bleed, and usually reveals bleeding at the third or fourth part of the duodenum (Fig. 17-9). CT with IV contrast is a useful adjunct in these patients, often demonstrating air within the aortic thrombus or around the graft (particularly in the context of an infected graft), and rarely a pseudoaneurysm or contrast within the duodenal lumen.

**FIGURE 17-9** Endoscopic view of the aortoenteric fistula on EGD showing the fistulous track (black arrow) into the aneurysmal sac from the 3rd part of the duodenum. (Used with permission from Neal Barshes, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

Surgical repair involves extra-anatomic bypass grafting and aortic ligation for primary aorto-enteric fistula. For secondary aorto-enteric fistula, surgery involves excision of the graft with extra-anatomic bypass or in situ aortic reconstruction. By necessity, these procedures are often performed in critically ill, septic patients and are hence associated with high morbidity and mortality. Endovascular stenting has been explored as treatment for aorto-enteric fistulas but has been linked to a high incidence of recurrent bleeding and infection, particularly in the presence of preprocedural infection.<sup>77</sup>

**Hemobilia.** Hemobilia is a rare cause of GI bleeding. Causes include trauma, hepatic neoplasms, instrumentation of the biliary tree, percutaneous radiofrequency liver ablation, and prior liver transplantation. A high index of suspicion is required in patients with these risk factors, as the classical presentation of hemorrhage, right upper quadrant pain, and jaundice is only seen in a minority of patients. Endoscopy may reveal blood at the ampulla,

but angiography and embolization remains the diagnostic and therapeutic modality of choice.

***Hemosuccus Pancreaticus.*** Bleeding from the pancreatic duct (hemosuccus pancreaticus) is another rare cause of upper GI bleeding, caused by fistulation of a pancreatic pseudocyst into the splenic or other peripancreatic artery.<sup>78</sup> A presentation of abdominal pain, hematemesis, and melena in patients with a previous history of pancreatitis should raise suspicion of hemosuccus pancreaticus. Angiography is again both diagnostic and therapeutic, although in some cases distal pancreatectomy may be necessary.

***Iatrogenic Bleeding.*** Prior endoscopic or surgical procedures are causes of bleeding. Common endoscopic procedures with bleeding complications include percutaneous gastrostomy tube placement, which carries a 3% rate of GI hemorrhage. Endoscopic retrograde cholangiopancreatography with sphincterotomy is associated with a 2% risk of bleeding. In many cases, bleeding can be controlled endoscopically with injection therapy, and surgical intervention is rarely required. Bleeding following upper GI surgery often occurs from suture or staple lines. These can occasionally be treated endoscopically, with care taken to minimize insufflation and torque to avoid disrupting fresh anastomosis.

## **VARICEAL BLEEDING AND PORTAL HYPERTENSION**

Portal hypertension is a serious cause of upper GI bleeding, often related to cirrhosis and chronic liver disease. The pathophysiology of portal hypertension is discussed further in [Chapter 61](#). Approximately 50% of patients with cirrhosis will develop gastroesophageal varices as a result of portal hypertension.<sup>79</sup> Variceal bleeding occurs in 30% of patients, and is one of the most important complications of hepatic cirrhosis. Variceal bleeding is associated with increased risk of rebleeding, higher transfusion requirements, greater length of stay, and higher morbidity and mortality compared with non-variceal bleeding.<sup>80</sup>

Gastroesophageal varices represent a rise as the portal circulation tries to decompress into the systemic circulation. Other sites of portal-systemic collaterals are the stomach, the umbilical region (caput medusae), and the distal rectum. Isolated gastric varices (IGV) can occur in the absence of

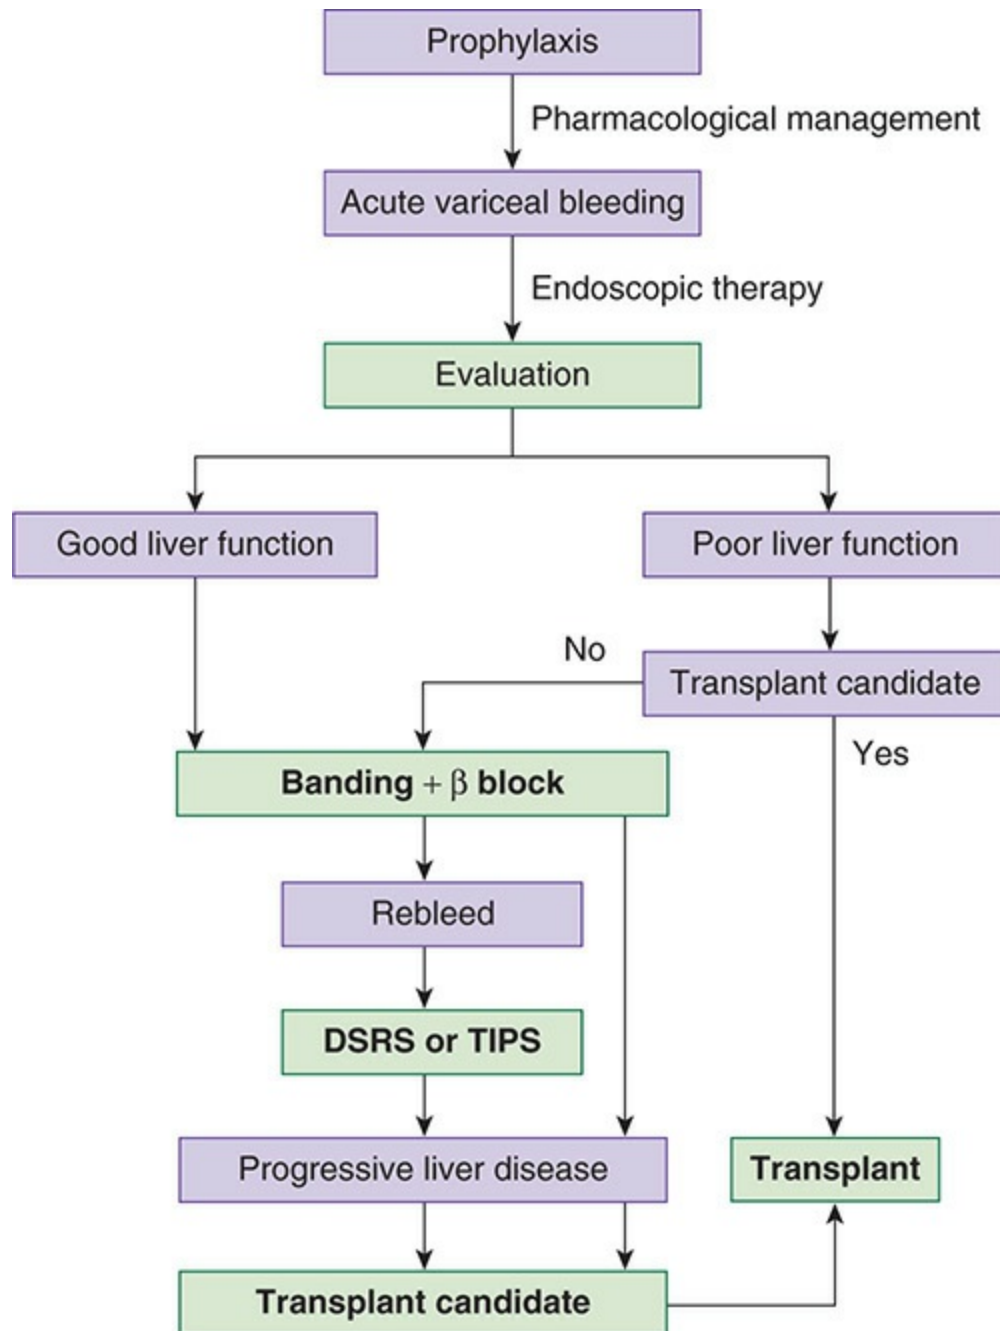

esophageal varices and are found along the gastric fundus (IGV1) or the body, antrum, or pylorus (IGV2).<sup>79</sup> Risk factors for gastric variceal bleeding include variceal size and the presence of a cherry-red spot (localized reddish mucosal area or spots on the mucosal surface of a varix).<sup>81</sup>

Besides varices, portal hypertension can lead to portal hypertensive gastropathy—the diffuse dilation of the mucosal and submucosal venous plexus of the stomach with overlying gastritis. The stomach develops a snakeskin appearance with cherry-red spots on endoscopy, and rarely may be the site of major hemorrhage (Fig. 17-10).

**FIGURE 17-10** Endoscopic view of portal hypertensive gastropathy. Note the snakeskin appearance of the stomach and the associated cherry-red spots. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Initial management of variceal upper GI bleeding follows the same principles as that of non-variceal upper GI bleeding, with emphasis on urgent resuscitation and therapeutic endoscopy due to the higher morbidity and mortality associated with variceal bleeds (Fig. 17-11). The diagnosis of variceal hemorrhage is based on meeting one of the following criteria: active bleeding from a varix, a “white nipple” overlying a varix, clots overlying a varix, or varices with no other potential source of bleeding.<sup>82</sup>

**FIGURE 17-11** An algorithm for the management of variceal bleeding.

## Management

**Medical.** Somatostatin or analogues such as octreotide should be administered immediately in cases where there is a high index of suspicion for variceal bleeding, and continued for 3 to 5 days after endoscopic confirmation of diagnosis.<sup>79</sup> Current recommendations are that any patients with cirrhosis and GI bleeding should also be given antibiotic prophylaxis against spontaneous bacterial peritonitis with a fluoroquinolone.

**Endoscopic.** In suspected variceal bleeding, endoscopy should be performed urgently, particularly in unstable patients.<sup>83,84</sup> Early endoscopy excludes non-variceal causes of bleeding, which occur in 15% of patients with varices.<sup>85</sup> Variceal ligation is the endoscopic treatment of choice, as it has lower rates of complications compared to sclerotherapy, which can cause perforation, mediastinitis, and stricture formation. Variceal ligation involves the placement of rubber bands to completely interrupt blood flow into the varix. The mucosa and submucosa eventually necroses, the rubber rings slough, and granulation tissue and scar replace the varix. Multiple sequential treatments may be required but will ultimately achieve control of variceal bleeding in up to 90% of patients.

Mechanical tamponade devices may be useful in temporarily controlling esophageal variceal bleeding when other methods have failed. The Sengstaken–Blakemore tube consists of an NG tube with gastric and esophageal balloons which are inflated to compress the esophagogastric venous plexus, arresting bleeding but at the risk of ischemic necrosis and perforation. Deflation of the tube leads to recurrent bleeding in 50% of patients; hence, this technique is reserved as a temporizing measure in massive hemorrhage before definitive therapy.

Gastric varices should be managed initially by pharmacotherapy. Endoscopic therapy is less successful with gastric varices due to the diffuse nature of portal hypertensive gastropathy. Patients with refractory bleeding should be referred early for decompressive therapy such as transjugular intrahepatic portosystemic shunt (TIPS) or shunting.

Isolated gastric varices, without associated portal hypertension, can occur in the setting of splenic vein thrombosis, often associated with pancreatitis.

Varices occur in the presence of normal central portal pressures due to left-sided hypertension, rerouted from the spleen to the short gastric vessels. While splenectomy relieves the hypertension, the risk of variceal bleeding in these patients is low and hence surgery is not routinely undertaken.<sup>86</sup>

**PREVENTION OF REBLEEDING.** Prevention of rebleeding is critical in this patient population. Rebleeding occurs in up to 70% of patients within 2 months in the absence of definitive therapy.<sup>87</sup> The greatest risk of rebleeding is in the first few days following the initial episode. A combination of nonselective  $\beta$ -blockers with isosorbide mononitrate has been shown to be more effective than  $\beta$ -blockers alone in preventing rebleeding.<sup>88</sup> The addition of prophylactic endoscopic band ligation to combination pharmacotherapy did not reduce the risk of rebleeding but instead was associated with more adverse events in a recent randomized controlled trial.<sup>89</sup>

**Radiologic or Surgical Portal Decompression.** In the approximately 10% of cases of variceal bleeding where endoscopic management fails, urgent decompression of the portal system is the next step. A TIPS procedure creates an artificial anastomosis between the hepatic and portal veins under fluoroscopic guidance with a covered stent, relieving portal pressure by shunting blood away from the hepatic sinusoids.<sup>90</sup> TIPS is associated with a 30-day mortality of up to 30% in the emergency setting, usually due to complications of hepatic encephalopathy.<sup>91</sup> Rebleeding may occur in 20% of patients and is often due to TIPS occlusion.

Surgery is another therapeutic option for decompression of the portal system. Surgical shunts, such as the selective distal splenorenal shunt (DSRS), have lower rates of rebleeding compared to endoscopic therapy but do not demonstrate any difference in survival.<sup>92</sup> DSRS patients have an in-hospital mortality of ~5%, a 5% to 8% rate of rebleeding, and a 75% to 80% 3-year survival.<sup>92</sup> A randomized controlled trial comparing TIPS with DSRS in patients who failed medical or endoscopic therapy showed no significant difference in the rate of rebleeding, hepatic encephalopathy, or overall survival. However, TIPS patients required close follow-up with a higher rate of re-intervention. DSRS may be a more suitable option in patients with limited access to health care facilities.<sup>93</sup> Further details on surgical decompression for portal hypertension are covered in [Chapter 61](#).

## LOWER GI HEMORRHAGE

Lower GI bleeding occurs most commonly from the colon but can arise from any site distal to the ligament of Treitz. Difficulty in diagnosis of lower GI bleeding stems from the large surface area of colon and small intestine, intermittent bleeding, occasional lack of visible mucosal lesions, and difficulties in endoscopic visualization from forward movement of blood. The majority of lower GI bleed patients experience self-limiting episodes; only 10% to 20% of patients present with massive unremitting bleeding. Most lower GI bleeding originates from the colon due to common entities such as diverticular disease and neoplasia (Table 17-6). Early identification of the cause of bleeding is essential for appropriate management, in particular for cases of malignancy.

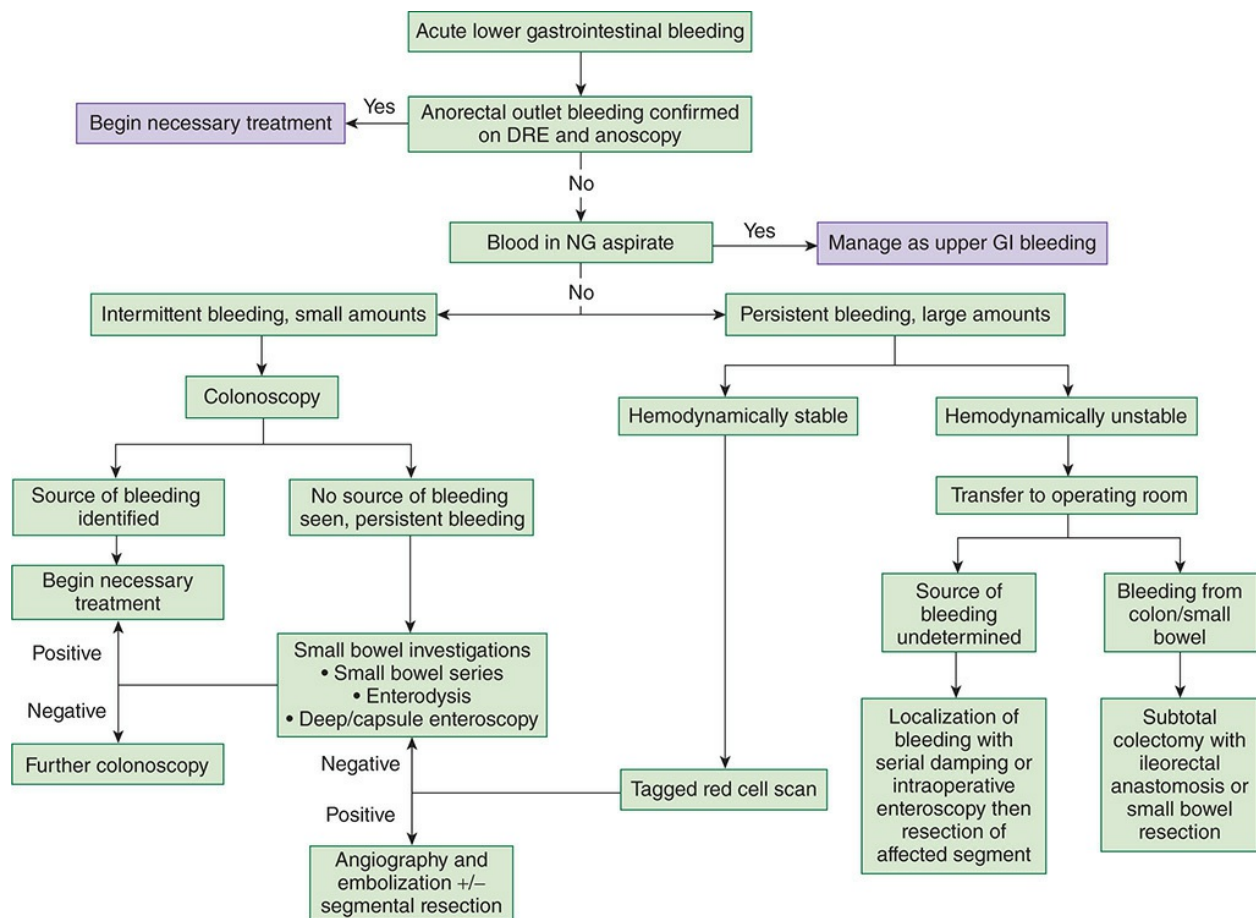

**TABLE 17-6: CAUSES OF LOWER GI BLEEDING**

	<b>Causes</b>	<b>Frequency</b>
Colonic bleeding (95%)	Diverticular disease	30–40%
	Angiodysplasia	40%
	Ischemia	6–18%
	Anorectal disease	6–16%
	Neoplasia	3–11%
	Infectious colitis	3–29%
	Polyps	5–13%
	Inflammatory bowel disease	2–4% 1–3%
	Radiation proctitis	1–9%
	Other	6–23%
Small intestinal bleeding (5%)	Unknown	
	Angiodysplasias	
	Neoplasia	
	Meckel diverticulum	
	Erosions/ulcers	
	Crohn's disease	
	Radiation	

# Management of Lower GI Bleeding

Lower GI bleeding is often less severe than upper GI bleeding; however, the same principles for initial evaluation and resuscitation should be followed (Fig. 17-12). Accurate identification of the source of bleeding can be difficult in patients with lower GI bleeding—more than one source for bleeding is found in 40% of patients, and in up to 25% of patients no source is identified. A management algorithm is outlined in Fig. 17-13. Hemodynamically stable patients with hematochezia should first undergo colonoscopy to identify a bleeding source. If a bleeding site is identified, endoscopic therapy should be attempted to control the bleeding. If no bleeding site is identified, an EGD should be performed followed by capsule or deep enteroscopy if this is unrevealing. Hemodynamically unstable patients should undergo EGD initially, as severe upper GI bleeding may present as hematochezia.

**FIGURE 17-12** An algorithm for the management of lower gastrointestinal bleeding. (Reproduced with permission from Townsend CM, Beauchamp RD, Evers BM, et al:

**FIGURE 17-13** An inflamed diverticulum with associated bleeding (black arrow) seen on colonoscopy. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Patients with bleeding refractory to endoscopic management or those with significant hemodynamic instability may require urgent operative intervention. In these patients, an exploratory laparotomy is performed with attempts made to determine the location of blood within the GI tract. The GI tract should be thoroughly examined for masses and diverticular disease, such as a Meckel diverticulum. On-table enteroscopy and lavage may allow localization of the bleeding source for segmental resection but is best attempted in stable patients who can tolerate the additional procedure length. A segmental bowel resection is appropriate in localized bleeding, and in relatively fit patients this may be combined with a primary anastomosis. In unfit patients with hemodynamic instability, an ostomy with or without a mucous fistula is a more appropriate option. Segmental colectomies should not be performed as “blind” procedures without localization of the bleeding

source, as these have been associated with high rates of mortality and rebleeding (up to 50% and 75%, respectively).<sup>94-96</sup> A better alternative in patients without localization of the bleeding source is a “blind” subtotal colectomy, with either an end ileostomy or a primary ileorectal anastomosis, which carries a <10% mortality rate and <10% rebleeding rate.

## Causes of Lower GI Hemorrhage

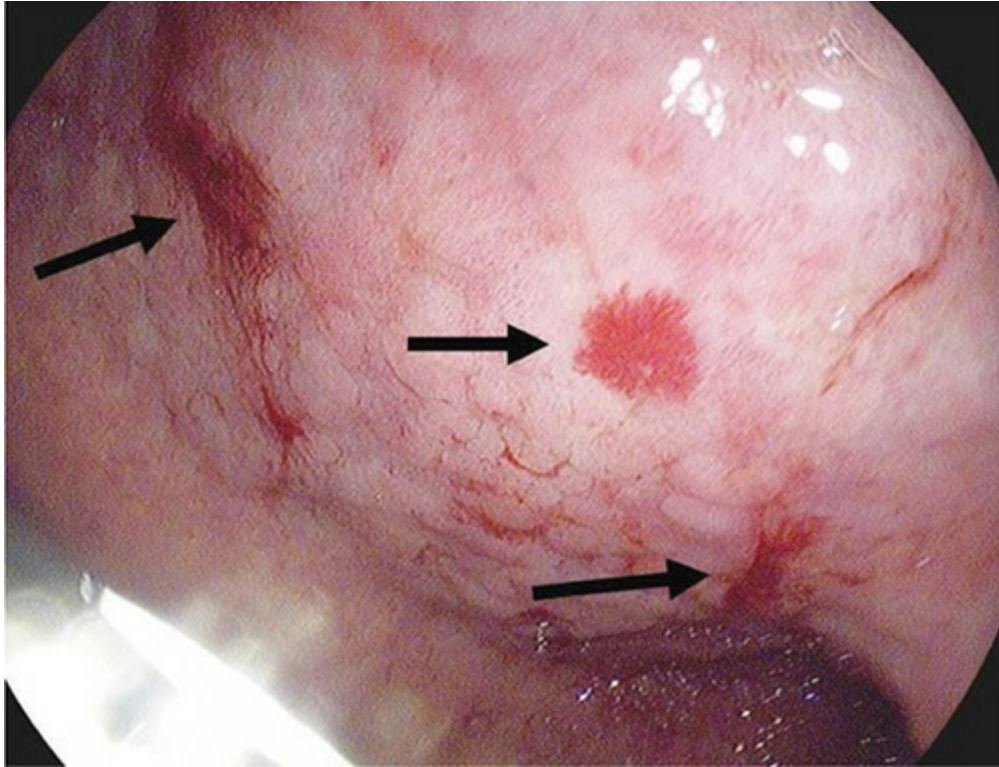

### DIVERTICULAR DISEASE

Diverticular disease is a common, often asymptomatic, disease of Western countries. The incidence increases with age; up to 60% of patients over 80 years of age have diverticulae.<sup>97</sup> In Western countries, 95% of diverticulae are in the sigmoid and left colon; however, in Asian countries, 70% of cases are in the right colon.<sup>98,99</sup> Colonic diverticulae are pulsion-type pseudodiverticulae—outpouchings of the mucosa and submucosa through the muscular layer of the bowel at the sites of penetration of the vasa recta. Only 4% to 17% of patients with diverticular disease develop symptoms of bleeding.<sup>100</sup> However, due to its prevalence, diverticular disease accounts for 30% to 40% of lower GI bleeding.<sup>101</sup> Eighty percent of diverticular bleeds stop spontaneously, but a small minority will require intervention. Ten percent of patients will rebleed within a year and 50% within 10 years.<sup>101</sup>

Colonoscopy remains the most useful diagnostic and therapeutic investigation for diverticular bleeding (Fig. 17-13). When colonoscopy fails, angiographic embolization can be successful in 85% of diverticular bleed patients.<sup>47</sup> Surgery is indicated for refractory bleeding, and colonic resection may be considered as a management option in patients with multiple episodes of self-limiting bleeding.

**Angiodysplasia.** Angiodysplastic lesions in the intestine are degenerative vascular lesions that develop as a result of progressive dilation of submucosal vessels. Bleeding from these lesions can account for up to 40% of lower GI bleeds.<sup>102</sup> Angiodysplastic lesions are frequently found in the elderly and associated with aortic stenosis and renal failure. The majority of cases present with anemia and cease bleeding spontaneously; however, 50% will rebleed in 5 years. Massive bleeding may occur in up to 15% of cases.

In the colon, angiodysplastic lesions are predominantly located in the cecum and ascending colon. Colonoscopy reveals red stellate lesions with a rim of pale mucosa. Angiographic features include early prolonged filling of the draining vein, clusters of small arteries, and a visible vascular tuft (Fig. 17-14). First-line treatment options include endoscopic or angiographic intervention. Bleeding refractory to these treatments requires a segmental colectomy, usually a right hemicolectomy.

**FIGURE 17-14** Telangiectatic lesions (black arrows) characteristic of colonic angiodysplasia, seen on colonoscopy. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

**Neoplasia.** Neoplasia is a rare cause of lower GI bleeding, accounting for only 2% to 9% of all hematochezia, but is significant due to the fairly high incidence of colorectal cancer in developed countries.<sup>95</sup> Neoplasia-induced hemorrhage presents as chronic painless bleeding, usually associated with iron deficiency anemia, often from tumors of the right colon.<sup>96</sup> Tumors of the left colon often present with obstructive symptoms but can also ulcerate to produce bright red bleeding (Fig. 17-15). Colonic polyps, especially those >1 cm in diameter, can bleed in 5% to 11% of patients and cause anemia in 3%

to 7% of patients (Fig. 17-16).<sup>102</sup> Treatment for bleeding tumors is usually surgical, following diagnosis and staging with colonoscopy, biopsy, and appropriate imaging. Colon tumors are covered in more detail in Chapter 49.

**FIGURE 17-15** Colonoscopic views of a large ulcerated neoplastic lesion. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

**FIGURE 17-16** Colonoscopic view of a large pedunculated polyp with associated bleeding. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Another common cause of lower GI bleeding is post-polypectomy bleeding, which can occur up to 2 weeks following polypectomy (Fig. 17-17). Risk of post-polypectomy bleeding is influenced by polyp size, inadequate electrocautery, comorbidity, bowel preparation, and experience of the endoscopist.<sup>103</sup> Delayed post-polypectomy bleeding is more frequent in large polyps, right-sided polyps, and in patients on anticoagulation.<sup>104</sup>

**FIGURE 17-17** Colonoscopic views of bleeding from the base of a polyp post-polypectomy. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

**Anorectal Disease.** Benign anorectal pathology can present as lower GI bleeding. History and physical examination can often confirm the diagnosis. Anal fissures cause pain with defecation and examination but rarely cause significant blood loss. Inspection of the anal margin is usually diagnostic and can be made painless following injection of local anesthetic. Bleeding from fissures usually stops spontaneously. Management includes the use of stool bulking agents, stool softeners, increased fluid intake, and topical nitroglycerin or diltiazem, which facilitate healing of the fissure by reducing sphincter spasm.

Hemorrhoids account for lower GI bleeding in 2% to 9% of patients.<sup>102</sup> Fresh red blood is seen on the tissue paper, in the bowl, and around the stool. Bleeding is often painless and from internal hemorrhoids. Management includes stool bulking agents and increased dietary fiber with hydration. Surgical treatments include rubber band ligation, injection sclerotherapy, infrared coagulation, and hemorrhoidectomy.

More unusual anorectal causes of bleeding include solitary rectal ulcers and anorectal varices. Solitary rectal ulcers are believed to arise as a result of

local ischemia and rarely bleed. In contrast, anorectal varices occur in up to 18% of patients with portal hypertension and can cause severe bleeding.<sup>105</sup>

It is important to note that benign anorectal diseases such as anal fissures and hemorrhoids are common findings, and particularly in the elderly, other sources of proximal bleeding, especially tumors, should be excluded. Benign anorectal conditions are discussed further in [Chapter 52](#).

## Colitis

***Inflammatory Bowel Disease.*** Lower GI bleeding occurs in the majority of patients with ulcerative colitis and in up to one-third of patients with Crohn's disease.<sup>106</sup> Most bleeding stops spontaneously, but 35% of patients will rebleed.<sup>107</sup> Both ulcerative colitis and Crohn's are associated with abdominal pain and increased bowel movements. Both Crohn's and ulcerative colitis are diagnosed on endoscopy and managed with 5-aminosalicylic acid (5-ASA) compounds, immunomodulatory agents, steroids, and antibiotics as needed ([Fig. 17-18](#)). Surgical therapy for ulcerative colitis is needed if the rare complication of toxic megacolon develops or in the event of refractory life-threatening hemorrhage. Surgery is avoided as much as possible in Crohn's disease due to the natural relapsing and remitting nature of the disease and the tendency of the lesions to affect any region of the GI tract. Crohn's disease and ulcerative colitis are discussed further in [Chapters 45](#) and [46](#), respectively.

**FIGURE 17-18** Colonoscopic view of Crohn's colitis. Note the cobblestone appearance of the mucosa and the associated edema and erythema. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

***Infectious Colitis.*** Causes of infectious colitis that may cause bloody diarrhea include cytomegalovirus (CMV) colitis, *Escherichia coli*, *Shigella*, *Salmonella*, and *Campylobacter* infection. Patients with infectious colitis typically present with bloody diarrhea with positive stool cultures. CMV colitis typically affects the immunocompromised.

Patients with HIV are particularly at risk of GI bleeding, and due to the immune deficiency, are particularly at risk for opportunistic infections. Causes of colonic bleeding in HIV-positive patients include CMV, lymphoma, histoplasmosis, Kaposi sarcoma, and bacterial colitis, with an overall average mortality of 14%.<sup>108</sup> Colonoscopy and biopsy confirm the diagnosis, and treatment should be commenced as appropriate.

***NSAID-Associated Lower GI Bleeding.*** NSAIDs can also induce and exacerbate lower GI bleeding. NSAIDs can themselves induce mucosa damage and colonic inflammation, erosions, and ulcers. In addition, they can

exacerbate existing colitis and increase the tendency of pre-existing lesions such as polyps or angiodysplasia to bleed. NSAID-induced lesions appear as flat, irregularly-shaped erosions and ulcerations with otherwise normal mucosa.<sup>95</sup>

**Radiation Proctitis.** Radiation therapy in the pelvic region is another cause of lower GI bleeding, producing a chronic radiation proctopathy due to the neovascularization resulting from radiation-induced endarteritis obliterans. Bleeding occurs in 4% to 13% of patients receiving radiation therapy for prostatic carcinoma.<sup>109</sup> Patients typically present with bloody diarrhea, crampy pelvic pain, and tenesmus. Endoscopy reveals multiple telangiectasias on an otherwise pale mucosa, and can be coupled with APC for treatment (Fig. 17-19). Other treatment options include antidiarrheals and hydrocortisone enemas. Ablation with 4% formalin solution may be considered for refractory bleeding.<sup>110</sup>

**FIGURE 17-19** Colonoscopic view of radiation-induced proctitis, with the characteristic appearance of multiple telangiectasia on a background of otherwise pale mucosa. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

**Ischemic Colitis.** Ischemic colitis, or mesenteric ischemia, results from a reduction in blood flow to the intestine due to either reduced blood pressure or vasoconstriction. Ischemic colitis occurs more frequently in the elderly and those with a history of cardiovascular disease. Other risk factors include recent abdominal vascular surgery, hypercoagulable states, and vasculitis. Patients on inotropes and vasoconstrictors are particularly prone to ischemic colitis due to splanchnic vasoconstriction. The splenic flexure of the colon and the rectosigmoid junction are vascular watershed areas and are especially susceptible to ischemia. Patients present with abdominal pain and bloody diarrhea. The diagnosis is suspected with the identification of a thickened bowel wall on CT, and confirmed on endoscopy showing bleeding, edematous mucosa with a demarcation between ischemic and normal bowel (Fig. 17-20). Ulcerations may appear on endoscopy in the later stages of disease progression. Despite the self-limiting nature of the disease in most patients, ischemic colitis is associated with a high morbidity and mortality.<sup>111</sup> Conservative management is usually employed, with bowel rest, intravenous antibiotics, and cardiovascular support to normalize hemodynamics. In 15% of patients, ischemia is followed by gangrene and perforation, requiring urgent laparotomy with resection of the ischemic bowel.<sup>112</sup>

**FIGURE 17-20** Ischemic colitis as viewed on colonoscopy, with evidence

of ulceration and submucosal hemorrhage. (Used with permission from Dr Frederick Makrauer, MD, Brigham and Women's Hospital, Boston, MA.)

## **OBSCURE LOWER GI BLEEDING**

Bleeding persisting or recurring after negative esophagogastrosocopy and colonoscopy occurs in approximately 5% of cases and is termed *obscure bleeding*, often the result of angiodysplastic lesions, Meckel diverticulae, Dieulafoy lesions, and small bowel neoplasms.<sup>113</sup> Bleeding in these cases may be visible (termed obscure-overt bleeding) or only detected by the presence of guaiac-positive stools (obscure-occult bleeding). Further investigation in the form of capsule enteroscopy, deep enteroscopy, angiography, or red cell labeling is often necessary in these cases.

**Angiodysplasia.** Angiodysplasia is the most common cause of small bowel bleeding, accounting for up to 40% of cases in elderly patients and 10% of cases in younger patients. The jejunum is the most common site for these lesions. Small intestinal angiodysplasias often present with obscure or occult bleeding. Unlike colonic angiodysplasia, angiography is rarely helpful in small intestinal angiodysplasias. Capsule or deep enteroscopy are the investigative modalities of choice. Optimal management involves segmental resection of the affected small bowel with on-table endoscopy as needed. However, it is important to note that a significant number of patients may spontaneously stop bleeding.<sup>114</sup>

**Meckel and Other Small Intestinal Diverticulae.** A Meckel diverticulum is the incomplete obliteration of the remnant embryonic vitelline duct that connects the yolk sac and fetal gut. Meckel diverticulum are true diverticula, occur in 2% of the population, are usually located within 100 cm of the ileocecal valve, and range from 1 to 10 cm in length (Fig. 17-21).<sup>115</sup> Up to 60% of Meckel diverticulae contain heterotopic mucosa, usually of gastric or pancreatic origin. Hemorrhage is a common complication of a Meckel diverticulum, occurring in 38% of adults and 31% of children, and results from ulceration of the normal mucosa adjacent to the acid-producing heterotopic mucosa.<sup>116</sup> Radionuclide scans may assist in the diagnosis of Meckel diverticulum, but are less accurate in adults than in children. Cimetidine slows the release of the pertechnate into the lumen and increases

the sensitivity of a Meckel scan.<sup>117</sup> Laparoscopy may be used for the diagnosis as well as the treatment of Meckel diverticulum. Operative management hinges on removal of the Meckel diverticulum and resection of adjacent affected bowel.

**FIGURE 17-21** Meckel diverticulum seen intraoperatively. The Meckel diverticulum (black arrow) can be seen on the antimesenteric border of the ileum.

The incidence of non-Meckelian intestinal diverticulosis is low, ranging from 0.06% to 4.6% on autopsy studies.<sup>118</sup> They are more common in the elderly but may present at any age. Small bowel diverticulae, like colonic diverticulae, are pseudodiverticulae involving only mucosa and submucosa. Most small intestinal diverticulae are found in the jejunum, where vasa rectae are more frequent. Upper GI contrast series or CT scans may reveal small bowel diverticulae but are not sensitive investigations. Enteroclysis can increase sensitivity for small diverticulae but are not a cost-effective first-line

study. The incidence of bleeding from jejunal diverticulosis ranges from 5% to 33%.<sup>118</sup> Enteroscopy (particularly deep enteroscopy) is suitable for diagnosis of diverticulae complicated by bleeding, inflammation, or obstruction, but laparotomy remains the gold standard for diagnosis and management, particularly in the unstable patient. Operative management involves resection of the affected segment of small bowel with a primary end-to-end anastomosis. Rarely, a large proportion of the bowel is involved (panjejunoileal diverticulosis), and conservative management may be trialed to avoid the need for massive small bowel resection. Selective mesenteric angiography and embolization may assist in the control of hemorrhage in these cases.

**Neoplasia.** Although small bowel tumors account for only 5% of all GI tumors, they are the second most common cause of small intestinal bleeding.<sup>119</sup> Patients present either with melena or occult bleeding. Leiomyomas and leiomyosarcomas are the tumors which most commonly bleed from tumor necrosis and mucosal ulceration. These are highly vascular tumors and hence angiography has an 86% rate of detection for these lesions. Other small intestine tumors include adenocarcinomas, carcinoids and lymphomas. Tumors can be diagnosed by enteroscopy, small bowel contrast series, or CT (Fig. 17-22). Treatment is surgical resection of the tumor.

**FIGURE 17-22** CT image of an ileal adenocarcinoma, obvious as a mass in the left mid-abdomen.

# LESIONS OF THE OMENTUM, MESENTERY, AND RETROPERITONEUM

*Tara A. Russell • Fritz C. Eilber*

## MESENTERY

The entire gastrointestinal tract is derived from a common dorsal mesentery. During development, as the mesentery fuses with the retroperitoneum, the remaining segments become the small bowel mesentery, transverse mesocolon, and sigmoid mesocolon. These mesenteries serve as the primary pathways to and from the bowel for arterial, venous, lymphatic, and neural structures.

The small bowel mesentery originates as the root of the mesentery, located at the fourth part of the duodenum and posterior border of the pancreas. It courses along the medial border of the jejunum and ileum in a fan-like projection. The transverse mesocolon connects the transverse colon to the retroperitoneum, and the sigmoid mesocolon connects the sigmoid flexure to the inferior retroperitoneum and pelvis.

## **Acute Mesenteric Lymphadenitis**

Acute mesenteric lymphadenitis (AML) is the marked focal inflammation of mesenteric lymph nodes and has been associated with viral illness and other infectious processes.<sup>1,2</sup> AML most commonly occurs in children, with an equal distribution in males and females. The most common presenting symptoms are abdominal pain, mild fever, nausea, and occasionally vomiting. Both laboratory and systemic symptoms are less severe in comparison to those seen with acute appendicitis.<sup>3</sup>

Given the young age at presentation, most children undergo ultrasound rather than computed tomography (CT) for diagnosis. Diagnostic criteria by either ultrasound or CT include clusters of enlarged (>5-8 mm) hypervascular mesenteric lymph nodes with a normal appendix.<sup>1,3</sup> While imaging findings are often suggestive, true diagnosis is often made at the time of negative appendectomy, when mesenteric lymphadenopathy is noted.<sup>1,4</sup>

When AML is suspected, one can proceed with supportive care, as the disease is self-limiting and typically resolves without invasive measures.<sup>1,3,4</sup> Given that the inciting agent is typically viral, there is no indication for antimicrobial agents.

## **Mesenteric Panniculitis/Sclerosing Mesenteritis**

Mesenteric panniculitis was first described in 1927 by Jura as an infiltration of plasma and polymorphonucleated cells into the mesentery.<sup>5</sup> The condition, now more vigorously investigated, has many names throughout the literature including sclerosing mesenteritis, retractile mesenteritis, and mesenteric lipodystrophy. The disease process of marked mesenteric inflammation and fibrosis more commonly affects the small bowel mesentery and can be asymptomatic or present as diffuse, nonspecific abdominal pain.<sup>6-8</sup> Most cases present in the sixth decade, with a slight male predominance.<sup>8,9</sup> The etiology is not well understood and has been related to various sources including autoimmune, infectious, ischemic, and traumatic causes.<sup>8-10</sup> In one study, 35% of patients with sclerosing mesenteritis were noted to have a history of abdominal surgery, and therefore, surgical trauma may be a predisposing factor.<sup>6</sup>

The inflammation and fibrosis originate at the root of the mesentery and

proceed to involve varying amounts of the mesentery. Histologically, the disease is classified into 3 stages, based on the relative proportions of fatty and fibrotic changes.<sup>6</sup> Mesenteric lipodystrophy has fatty predominance and is characterized by replacement of mesenteric fat by a layer of foamy macrophages. Mesenteric panniculitis, composed of both fatty and fibrotic changes, is marked by plasma and polymorphonuclear leukocytes as well as foreign body giant cells and foamy macrophages. Finally, sclerosing mesenteritis, or retractile mesenteritis, is marked by fibrotic changes with collagen deposition, fibrosis, and inflammations.<sup>7,11</sup>

This process is most frequently diagnosed by CT scan.<sup>8</sup> Findings often include an adiposidic mass, which often encases the mesenteric vessels and displaces but does not directly invade the bowel (*Fig. 18-1*).<sup>12</sup> Additional imaging with magnetic resonance imaging (MRI) may help with diagnosis, but this will not ultimately change management. Positron emission tomography (PET) imaging may be helpful in distinguishing mesenteric panniculitis from lymphoma or metastatic disease, as mesenteric panniculitis will have minimal PET avidity. While the majority of these cases can be diagnosed by imaging findings, if there is suspicion for malignancy or if surgical intervention is undertaken due to symptoms or obstruction, biopsy is warranted.

**FIGURE 18-1** Mesenteric panniculitis. **A and B.** Axial contrast-enhanced computed tomography images demonstrate peripheral curvilinear band of soft tissue attenuation (*arrows*) that separates the heterogeneous mesenteric mass from surrounding normal mesentery. (Reproduced with permission from McLaughlin PD, Filippone A, Maher MM: The “Misty Mesentery”: Mesenteric Panniculitis and Its Mimics, *AJR Am J Roentgenol* 2013 Feb;200(2):W116-W123.)

Mesenteric panniculitis is a self-limiting disease, and therefore, if it is

asymptomatic, it requires no intervention. Alternatively, for the >20% of patients who do report a debilitating course due to chronic abdominal pain, intervention is primarily medical and focuses on decreasing inflammation and fibrosis with a variety of therapeutic agents including corticosteroids, cyclophosphamide, or colchicine.<sup>7,8,10</sup> For patients who present with symptoms of obstruction and are refractory to medical management, surgical intervention may be warranted and should focus on relieving the area of obstruction with segmental resection of the involved mesentery and potentially segmental small bowel resection. If a patient does require surgical management, this should be followed by medical interventions, because surgery alone does not address the underlying problem.

## Mesenteric Cysts

Although the majority of mesenteric cysts are congenital, only 60% present during childhood, with up to 40% presenting during adulthood, most commonly in the fourth decade.<sup>13-15</sup> The overall incidence is estimated to be <1/100,000, and etiology varies from failure of mesenteric fusion to lymphatic malformation to trauma.<sup>10</sup> The majority of mesenteric cysts are asymptomatic, but patients can present with either a mobile abdominal mass or pain.<sup>16</sup> Abdominal pain typically arises secondary to rupture, torsion, or mass effect. On physical exam, palpable masses are frequently mobile in a single lateral direction (left to right or right to left), known as the Tillaux sign, and are not freely mobile, as is seen with omental cysts.

Ultrasound or CT is adequate for evaluating cystic lesions and delineating any solid components or septations.<sup>14,15</sup> The majority of lesions are located within the small bowel mesentery, are unilocular, and do not have a solid component. Identification of a solid component should raise suspicion for malignancy, which only occurs in approximately 3% of mesenteric cystic masses, and is typically sarcoma or rarely adenocarcinoma.<sup>15</sup>

More than 50% of the cystic mesenteric masses are lymphangiomas.<sup>11</sup> The majority of lymphangiomas present within the head, neck, or axilla, whereas small bowel mesenteric lymphangiomas account for <1% of all cases.<sup>17</sup> Lymphangiomas are classically solitary masses that develop due to congenital malformation of the lymphatic vessels, causing failure of the lymphatic channels to drain in the lymphatic system.<sup>17</sup>

Treatment of any mesenteric cyst requires surgical excision if the patient is symptomatic or malignancy has not been ruled out, with preference for a laparoscopic approach. Cysts should be excised in total because enucleation, marsupialization, internal or external aspirations, and drainage are associated with a high risk of recurrence.<sup>10,15</sup>

## Mesenteric Tumors

### MESENTERIC MESOTHELIOMA

Mesothelioma is the uncontrolled proliferation of mesothelial cells found in the serosal lining of the pleura, pericardium, peritoneal cavity, and mesentery.<sup>9</sup> Mesenteric mesothelioma accounts for 25% of all mesotheliomas and 6% to 10% of malignant mesotheliomas.<sup>18,19</sup> Among malignant disease, diffuse malignant peritoneal mesothelioma is the second most common site, with the most common site being pleural.<sup>19,20</sup> Malignant mesotheliomas can be classified as epithelioid, sarcomatoid, or mixed, with epithelioid type being the most common

Mesothelioma was poorly understood until its association with asbestos was reported by Wagner in 1960.<sup>21</sup> The incidence of all mesothelioma, including mesenteric, has been rising since 1970, with the rate in the United States continuing to rise through the 1990s and plateauing shortly thereafter.<sup>19</sup> The Surveillance, Epidemiology, and End Results database estimates that approximately 250 new cases of mesenteric mesothelioma are diagnosed annually.<sup>19,22</sup> Among all mesothelioma, mesenteric primaries account for 11% of diagnoses in men and 45% of all diagnoses in women.<sup>23</sup> This sex disparity has been debated in the literature, with the predominate theory indicating that the higher rate of female mesenteric primaries is due to the association of mesenteric mesothelioma with nonoccupation exposures, which often result in a higher dose and longer duration of exposure.<sup>22,23</sup>

Malignant mesenteric mesothelioma typically presents with abdominal pain and increased abdominal distention secondary to accumulation of both tumor and ascites<sup>19</sup> (Fig. 18-2). CT imaging demonstrates diffuse involvement of the peritoneal surfaces, innumerable nodules within both the abdomen and pelvis, and ascites.<sup>24,25</sup> Local invasion into the bowel and solid viscera can occur in advanced disease, and metastases are usually to regional

lymph nodes. Diagnosis requires either a CT-guided or laparoscopic biopsy, as diagnostic paracentesis has repeatedly been shown to have low diagnostic yield.<sup>19</sup>

**FIGURE 18-2** Diffuse malignant peritoneal mesothelioma.

Macroscopically, this disease is characterized by thousands of whitish tumor nodules of variable size and consistency that may coalesce to form plaques or masses or layer out evenly to cover the entire peritoneal surface. (Reproduced with permission from Munkholm-Larsen S, Cao CQ, Yan TD: Malignant peritoneal mesothelioma, *World J Gastrointest Surg* 2009 Nov 30;1(1):38-48.)

The treatment and management of malignant mesenteric mesothelioma are not well defined. Historically, this diagnosis is associated with very poor survival, frequently less than 1 year, secondary to progression, solid organ invasion, bowel obstruction, and malnutrition. Multiple therapies have been attempted in this rare disease including surgical debulking and intraperitoneal and intravenous chemotherapy. Although there is no consensus or level 1 evidence due to the lack of randomized controlled trials for this disease, large retrospective reviews have evaluated the impact of both cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) and advocate for a combined approach.<sup>21,25-28</sup> Cytoreductive surgery includes

removal of all visible tumor, peritonectomy, greater omentectomy with splenectomy, lesser omentectomy with cholecystectomy, and pelvic peritonectomy with rectosigmoid colonic resection. Completeness of the surgery is graded by the size of the largest remnant nodules (0 = no residual tumor, 1 = <2.5 mm, 2 = between 2.5 mm and 2.5 cm, 3 = >2.5 cm) and is the factor most strongly associated with posttreatment survival. Intraperitoneal chemotherapy regimens vary, but most commonly include cisplatin and/or doxorubicin and can be given intraoperatively at the time of surgery or at an interval after cytoreductive surgery. Studies evaluating the combined approach of cytoreductive surgery with HIPEC suggest there is a significant survival advantage, with one of the largest reviews reporting 81%, 60%, and 47% survival rates at 1, 3, and 5 years, respectively.<sup>27</sup> Therefore, in the setting of a diagnosis of mesenteric mesothelioma, referral to a specialized center is highly recommended.

## **DESMOIDS**

Desmoid tumors were first named by Muller in 1938.<sup>29</sup> Microscopically, they are composed of collagen, fibroblasts, and bundles of spindle-shaped cells, often with poorly circumscribed margins and no distinguishable capsule.<sup>9,29,30</sup> They are of mesenchymal origin and therefore can arise anywhere in the body. The most common sites include extremities, anterior abdominal wall, and mesentery. Within the United States, the annual incidence is 2.4 to 4.3 per 100,000.<sup>11</sup> Mesenteric desmoids account for only 8% of all desmoids tumors and most commonly develop in patients with familial adenomatous polyposis (FAP).<sup>6,9,31</sup>

FAP, which is classically associated with colonic polyposis and increased risk for colonic adenocarcinoma, has multiple extracolonic manifestations, including desmoid tumors. Patients with FAP have a 20% lifetime risk of desmoid tumor formation, of which 80% are intra-abdominal, 10% to 15% occur within the abdominal wall, and 5% are extra-abdominal.<sup>29</sup> Desmoids associated with FAP are considered to be more aggressive and have a higher risk of mortality due to local invasion, unlike desmoids of other anatomic locations that have no associated mortality.<sup>6</sup>

Although desmoid tumors can arise within a previous scar or incision, they may also occur sporadically. Mesenteric desmoids are more frequent after

abdominal surgery and, in FAP patients, after prophylactic colectomy.<sup>29</sup> Desmoids are locally invasive tumors that may invade surrounding structures or cause mass effect but do not metastasize. Therefore, clinical presentation is often due to a palpable abdominal mass or secondary mass effect and compression of intra-abdominal structures including ureters, pelvic vessels, or the bowel.<sup>29</sup>

Diagnosis is made by either CT or MRI, and need for intervention is based primarily on symptoms. Interestingly, the natural history of intra-abdominal desmoids tumors shows a unique pattern, in which approximately 10% resolve spontaneously, 30% undergo cycles of progression and resolution, 50% stabilize, and 10% progress rapidly.<sup>32</sup> Due to this indeterminate course, many recommend serial imaging with CT to characterize an individual tumor's propensity for growth.<sup>29,32,33</sup>

The treatment of desmoid tumors is best handled in the context of a multidisciplinary sarcoma program because there are a number of potential interventions, including surgical, medical, and radiation therapy. In particular, for small intra-abdominal desmoids that are slow growing and/or not in close proximity to vital structures, there is no clear indication for intervention, only serial monitoring with CT or intervention for symptoms alone.<sup>29,32</sup> For large masses or for those causing compressive effect, a multimodal approach is recommended.<sup>30,32,34,35</sup> Surgical resection requires complete en bloc resection of the mass. Because desmoids often have ill-defined borders, positive margins are not uncommon.<sup>36,37</sup> Unlike most sarcomas, re-resection of a positive margin or performing an extensive multiorgan resection for a desmoid is not done. Because mesenteric desmoids have a high recurrence risk and the required operation for complete resection is often highly morbid, medical therapies are now considered the treatment of choice.<sup>9,29,30,32</sup> A number of systemic treatment options are available, all of which have variable success rates and are best handled by an experienced sarcoma medical oncologist. The potentially effective systemic treatment options vary greatly in toxicity and include nontoxic agents (eg, nonsteroidal anti-inflammatory drugs, tamoxifen, hydroxyurea), marginally toxic treatments (eg, methotrexate and vinblastine), and more toxic traditional chemotherapy (eg, doxorubicin and dacarbazine).<sup>30,32,38</sup> There has been recent success with the newer targeted therapies, and currently, the Desmoid Tumor Research Foundation and the National Cancer Institute are running a

national trial using sorafenib based on recent success with this agent.<sup>39</sup> Although radiation therapy is often used in the treatment of extremity desmoids, it is generally avoided for intra-abdominal or mesenteric desmoids.

## **METASTATIC DISEASE**

Primary disease of the mesentery is rare, with the 2 most common forms discussed above. However, both systemic and metastatic disease can present within the mesentery, either due to symptoms of an abdominal mass or pain or as incidental imaging findings.

Lymphoma is the most common solid neoplasm identified within the mesentery.<sup>9,11</sup> While very few patients present with symptoms of a palpable mass, bulky adenopathy is frequently noted. On CT imaging, mesenteric lymphoma presents as an agglomeration of homogeneously enhancing lymphadenopathy that typically does not invade or obstruct the mesenteric vessels or the bowel.<sup>11</sup> The most common form of lymphoma to present with mesenteric lymphadenopathy is non-Hodgkin lymphoma.<sup>11</sup> Treatment is primarily nonsurgical, and therefore, these cases should be referred to a medical oncologist.

Metastases from other primary cancers are also common within the mesentery. Metastatic spread can occur through direct extension, intraperitoneal seeding, or hematogenous or lymphatic spread.<sup>6,9</sup> The most common primary tumors resulting in mesenteric metastases include ovarian, gastrointestinal, melanoma, breast, pancreatic, and bladder tumors.<sup>6,10</sup> Diagnosis typically includes additional imaging to identify a primary site and may require image-guided or laparoscopic biopsy for tissue diagnosis.

Furthermore, gastrointestinal primaries, including gastrointestinal stromal tumors (GISTs) and carcinoid tumors, may initially present as mesenteric disease due to local extension or invasion. These tumors should be treated as gastrointestinal primary tumors, and therefore, further discussion of diagnosis and management can be found in other chapters.

## **OMENTUM**

The greater omentum is a thin fibrofatty apron composed of 2 fused bilayers of peritoneum, with one bilayer originating along the greater curvature of the

stomach and a second along the transverse colon. These 2 bilayers fuse and then extend inferiorly and anteriorly over the small bowel and into the pelvis and laterally to the pylorus and gastrosplenic ligament. The lesser omentum is a smaller bilayer of peritoneum that extends from the liver to the lesser curvature of the stomach, including the hepatoduodenal and hepatogastric ligaments.

The omentum has many theoretic functions and was coined the “abdominal policeman” by the British surgeon Rutherford Morison due to its ability to wall off areas of infection and limit its spread.<sup>10,40</sup> The propensity for this policing arises due to the high concentration of tissue factor within the omentum, which assists with activation of coagulation and fibrosis at the sites of inflammation, infection, ischemia, and trauma.<sup>10</sup>

## Omental Torsion and Infarction

Omental torsion and infarction were first described by Eitel in 1899 and arise when a pedicle of omentum twists along its axis, compromising the vascular supply.<sup>41</sup> Such torsion then progresses from vascular congestion and thrombosis to arterial occlusion and ultimately necrosis of the omentum, with associated extravasation of serosanguinous ascites.<sup>42,43</sup> Cases of omental torsion are rare.<sup>40</sup> The majority of cases occur in male adults, typically in the fourth to fifth decade.<sup>42,44,45</sup>

Given the anatomic pattern of the omental sheet, torsions typically occur in the right or left lower quadrant and therefore may mimic the pain of other intra-abdominal pathologies including appendicitis, diverticulitis, ruptured ovarian cysts, and rarely cholecystitis. Clinical history often reveals localized pain without the presence of gastrointestinal symptoms such as nausea, vomiting, and diarrhea. Physical exam may reveal diffuse abdominal tenderness, mild peritoneal signs, and in some cases, a tender palpable mass. Approximately 50% of patients will have a low-grade fever and mild leukocytosis.<sup>43</sup>

Torsion can be either primary or secondary. Primary omental torsions arise due to anatomic abnormalities including tongue-like projections, accessory omentum, or anomalous vascular supply, whereas secondary torsions are associated with hernias, cysts, scarring, tumors, or foci of intra-abdominal inflammation.<sup>10,42,43,46</sup> Some reports have demonstrated an

increased risk associated with obesity, such that in one study >70% of patients with omental torsion were also obese.<sup>46</sup> This association is attributed to the increased density and thickening of the omentum acting as a lead point.

Additionally, infarction of the omentum can occur without preceding torsion. Omental infarction can be either idiopathic segmental infarction or secondary infarction. Secondary infarction occurs in the setting of systemic disease including vasculitis, hypercoagulability, or thrombi.<sup>40</sup> The presentation of isolated infarction or infarction secondary to torsion is similar.

Appropriate radiographic evaluation includes an abdominal and pelvic CT scan with intravenous contrast, which often demonstrates a localized inflammatory mass, with a whirl sign or concentric linear stranding.<sup>41,43</sup> Fat stranding in the area will be disproportionate to any adjacent bowel wall thickening, indicative of a pathologic process centered within the omentum rather than the bowel.<sup>42</sup>

If radiographic studies can conclusively exclude any bowel involvement, these patients can be observed clinically and managed supportively. Alternatively, if there is any clinical instability, pain does not improve within 24 to 48 hours, or other potential etiologies cannot be excluded (appendicitis), laparoscopic exploration with possible resection of the infarcted tissue should be performed.<sup>10,43</sup>

## Omental Cysts

Omental cysts, which arise due to peritoneal inclusions or lymphatic degeneration, are a rare condition, most commonly diagnosed in children.<sup>13</sup> On exam, these masses are freely mobile due to laxity of the omentum. Like other cystic masses, these can be imaged by ultrasound to exclude any solid component and are ultimately treated with simple excision or marsupialization.<sup>10,27</sup> Given the small risk of malignancy, these specimens should always be carefully reviewed with a pathologist.

## Omental Tumors

Primary omental tumors are exceedingly rare, with the majority of the literature composed of case reports and small series. Given that the omentum

is composed of various tissues, the origin of an omental mass can be very diverse, with tumors of mesenchymal origin being the most common. Benign tumors include lipomas, myxomas, leiomyomas, and desmoids.<sup>10</sup> Malignant tumors include leiomyosarcoma, liposarcoma, and mesothelioma.<sup>47</sup>

The omentum is also a site for distant metastatic disease, with ovarian cancer being the most common primary. Other primaries that can metastasize to the omentum include melanoma, uterine, renal cell, pancreatic, and gastrointestinal cancers.<sup>10</sup> Metastatic disease can present focally or in the form of omental caking, which is characterized by the diffuse thickening of the omentum and replacement of fat with metastatic islands.<sup>48,49</sup>

Of note, there are some infectious etiologies that may present with omental involvement, in particular tuberculous peritonitis, actinomycosis, and coccidiomycosis. The majority of these infectious etiologies are associated with additional systemic symptoms, and therefore, only rarely is an omental mass or thickening the first sign of disease.

While most masses of the omentum are diagnosed incidentally, patients can present with a focal mass or abdominal pain. Diagnostic workup includes CT imaging of the abdomen and pelvis, with some studies indicating increased diagnostic accuracy with the addition of CT angiography to delineate the presence of feeding vessels or to determine hypervascularity (favoring a malignant process).<sup>47</sup> If there is diffuse involvement of the omentum, which is more suggestive of metastatic disease, one should thoroughly evaluate for a primary tumor.

Given the wide differential upon identification of omental thickening or mass, further diagnostic workup is warranted. While open or laparoscopic biopsy has frequently been used for tissue diagnosis, multiple studies have demonstrated high sensitivity and specificity with large core needle biopsies of omental lesions, ranging from 89% to 93% and 86% to 100%, respectively.<sup>48</sup> Therefore, to rule out metastatic disease, it is recommended to initially proceed with ultrasound or CT-guided core needle biopsy for tissue diagnosis. Surgical biopsies should be only undertaken if an image-guided core needle biopsy is not diagnostic because surgery will only delay systemic treatment.

## **RETROPERITONEUM**

The retroperitoneum is defined as the space between the posterior aspect of the peritoneum and posterior abdominal wall. It is bounded by the diaphragm superiorly, spinal column and iliopsoas posteriorly, and levator ani muscles inferiorly. Within the trauma literature, the retroperitoneum is divided into 3 zones: zone 1 = central retroperitoneum, defined as the space between the renal hila containing the abdominal aorta, inferior vena cava, celiac axis, superior mesenteric artery, and proximal renal vasculature; zone 2 = lateral retroperitoneum, including all structures lateral to the renal hilum including the kidneys, adrenals, and proximal genitourinary tract; and zone 3 = pelvic retroperitoneum, bound superiorly by the bifurcation of the abdominal aorta and including the iliac vessels and their branches, rectum, and distal genitourinary tract.<sup>50</sup>

## Retroperitoneal Hemorrhage

Retroperitoneal hemorrhage can occur spontaneously or secondary to iatrogenic injury or trauma. The etiology of secondary retroperitoneal hematomas varies significantly and includes complications of femoral artery catheterization; pelvic or lumbar trauma; ruptured abdominal aortic, iliac, renal, or mesenteric aneurysms; or bleeding from any retroperitoneal structure (pancreas, adrenal glands, or kidneys).<sup>51,52</sup>

The presentation of retroperitoneal hematoma varies, but outside of traumatic injury, it is typically marked by clinical signs of hemorrhage, with relative hypotension and mild tachycardia. Some patients report back, lower abdominal, flank, or groin discomfort or swelling, and late signs, due to mass effect, may include neuropathy of the femoral nerve or iliopsoas muscle spasm.<sup>53-55</sup> In addition, patients may have cutaneous findings, including Grey-Turner sign, flank bruising, or Cullen sign, superficial edema, and bruising of the periumbilical tissue.

Spontaneous retroperitoneal bleeding has an incidence of 0.6% to 6.6% and most commonly occurs in the elderly, likely secondary to increased use of antiplatelet agents and anticoagulants in this population.<sup>51,53</sup> Spontaneous bleeds can arise due to underlying coagulopathy (factor IX or X deficiency, von Willebrand disease, or antiphospholipid syndrome), spontaneous hemorrhage (adrenal cysts), or vascular rupture. The pathophysiology of these bleeds is unclear, but it has been hypothesized that atherosclerosis and

vasculopathy affecting the small vessels of the retroperitoneum lead to increased friability and ultimate rupture.<sup>51</sup> It is clearly documented that all forms of anticoagulant and antiplatelet drugs increase the risk of hemorrhage, with unfractionated heparin having an elevated risk, estimated at 2 to 5 times that of warfarin.<sup>51,53</sup>

Iatrogenic retroperitoneal hemorrhage secondary to percutaneous vascular access was first described in 1963 in the setting of translumbar aortography.<sup>51</sup> Retroperitoneal bleeding occurring as a complication of femoral catheterization is one of the most common causes of secondary bleeding and arises from inadvertent puncture of the posterior wall of the femoral or iliac artery during cannulation. The incidence after cardiac catheterization is estimated at 0.15%, and the incidence after femoral artery catheterization for all purposes is 0.5%; yet some series report an incidence as high as 5% to 6%.<sup>51,56-58</sup> The range in incidence is likely due to differences in technique, equipment, and the number of punctures; use of vascular closure devices; concomitant use of anticoagulants and antiplatelet agents; and patient-specific factors.

Traumatic retroperitoneal bleeding typically arises in the setting of blunt pelvic trauma, although it may also occur with penetrating injuries. Blunt trauma, resulting in pelvic fracture, has a high risk of retroperitoneal hemorrhage due to the close anatomic proximity of the pelvis with the internal and external iliac arteries and their respective branches. Mortality secondary to pelvic fractures and retroperitoneal hemorrhage has improved with new techniques in resuscitation and endovascular therapy but still remains high (approximately 20%).<sup>59</sup> The majority of bleeding occurs due to lesions within the venous system, specifically the presacral and prevesical veins, yet those bleeds resulting in hemodynamic instability are more likely arterial in nature.<sup>59</sup> External pelvic stabilization has been shown to slow venous bleeding secondary to pelvic fractures in the setting of trauma and can be used as an adjunct while initiating hemostatic interventions. Surgical intervention is mandated in all zone 1 and penetrating injuries to the retroperitoneum to assess and control any potential vascular bleeding. Conversely zone 2 and 3 bleeds after blunt trauma should only be explored in the setting of pulsatile bleeding or rapid expansion.<sup>60</sup>

In addition to the clinical signs discussed previously, retroperitoneal hemorrhage or hematoma is typically diagnosed with imaging. While

ultrasound has been applied for evaluation of intra-abdominal fluid, it is not specific or sensitive for retroperitoneal bleeding.<sup>51,61,62</sup> Therefore, CT, preferably with intravenous contrast or angiography, is recommended.<sup>51,61</sup> On CT, retroperitoneal hematomas appear as abnormal soft tissue densities that compress adjacent normal structures. Contrast-enhanced imaging has the added ability to demonstrate extravasation of contrast and a layering effect within the hematoma. The further addition of angiography can help to isolate a feeding vessel, which is pertinent for any endovascular intervention.

In the setting of spontaneous bleeds attributable to anticoagulant therapy or coagulopathy, conservative management with intensive monitoring, fluid resuscitation, and correction of coagulopathy is advocated.<sup>51,53</sup> Surgical intervention with plans for evacuation of the hematoma risks alleviating any potential for tamponade and therefore is not advocated.<sup>58</sup>

There is growing evidence that, in cases with expanding hematomas either spontaneous or iatrogenic in origin, endovascular techniques with intra-arterial embolization or stent grafts can stop bleeding, without the associated risk of disturbing tamponade.<sup>51,58</sup> Recommendations for endovascular embolization advocate intervention for hemodynamic instability despite 4 or more units of blood transfusion within 48 hours or whenever clear arterial extravasation is identified.<sup>63</sup> As previously stated, surgical intervention for retroperitoneal hematomas is typically avoided unless there is severe hemodynamic instability, abdominal compartment syndrome, or femoral nerve compression. In this setting, the goals of open surgery would include control of any site of active bleeding, removal of the hematoma, and potentially packing the retroperitoneum for 24 to 48 hours.

## **Retroperitoneal Abscess**

Retroperitoneal abscesses arise secondary to an infection within an organ contained within or abutting the retroperitoneum. Common primary sources include diverticulitis, retrocecal appendicitis, Crohn disease, osteomyelitis, renal lithiasis, pancreatitis, or biliary tract disease.<sup>64</sup> Within the retroperitoneum, there are no anatomic boundaries that limit the spread of infection, except Gerota fascia surrounding the kidney; therefore, infections are often large and can be difficult to manage. They are most common in adults age 30 to 60 years, with no sex predominance.<sup>10</sup> Patients are typically

ill appearing and present with pain localized to the lower abdomen and flank, fever, nausea, vomiting, or changes in bowel habit, and potentially sepsis. In some patients, referred pain is present in the hips and lower extremities. Physical exam typically reveals abdominal tenderness, a palpable mass in some patients, and a positive psoas sign.

Diagnosis is made with abdominal CT scan, with a reported sensitivity and specificity ranging from 90% to 100% in multiple series.<sup>65-67</sup> Abscesses anterior to the pararenal space are often secondary to the retroperitoneal gastrointestinal organs, whereas the perirenal and posterior pararenal space abscesses are more likely secondary to kidney disease.

Management of retroperitoneal abscesses relies heavily on source control, drainage, and intravenous antibiotics. Cultures should be taken at the time of drainage to determine the appropriate directed antimicrobial therapy. *Proteus*, *Escherichia coli*, *Bacteroides*, and other gram-negative bacilli species are the most common given the proximity of the gastrointestinal tract, but other species, including gram-positive cocci, anaerobes, fungi (*Candida*), and tuberculous abscesses, have also been identified. Image-guided drainage is typically preferred over surgical interventions, as this provides a minimally invasive mechanism for decompression and continuous drainage without the added risk of surgery or dissemination due to violation of the retroperitoneum. Multiple case series have demonstrated high rates of success with percutaneous drainage and antibiotics alone, ranging from 45% to 100%.<sup>67-70</sup> In the event of failure to improve with conservative management or prolonged hemodynamic instability, surgical intervention is warranted. Overall mortality associated with retroperitoneal abscesses is high, estimated at 15% to 25%.<sup>10,65</sup>

## Retroperitoneal Fibrosis

Retroperitoneal fibrosis was first described by a French urologist Albarran in 1905 but was not recognized as a disease process until Ormond published the clinical course in 1948.<sup>71</sup> Retroperitoneal fibrosis is characterized by chronic inflammation and fibrosis entrapping the ureters, abdominal aorta, and other abdominal organs. The characteristic inflammation and fibrosis typically begin around the abdominal aorta and extend laterally to involve the ureters.<sup>10,72</sup> The disease is classified as either idiopathic or secondary.

Idiopathic retroperitoneal fibrosis has a reported incidence of 1.0 to 1.4 per 100,000, with a 2:1 male predominance.<sup>10,71</sup> Among all cases of retroperitoneal fibrosis, two-thirds are idiopathic, with no clear inciting agent or process.<sup>71</sup> Conversely, secondary retroperitoneal fibrosis occurs as an inflammatory reaction of chronic fibrosis in response to an inciting medication or inflammatory or malignant process (Table 18-1). The most common etiology is medications, with the greatest offenders being methysergide (semisynthetic ergot alkaloid used to treat migraines),  $\beta$ -blockers, hydralazine,  $\alpha$ -methyldopa, and entacapone.<sup>10,71,72</sup> Fibrosis occurring in the setting of malignant disease typically arises as a secondary desmoplastic reaction to retroperitoneal metastases or primary tumors (most commonly lymphoma). In addition, secondary retroperitoneal fibrosis has been associated with aortic aneurysm, pancreatitis, histoplasmosis, tuberculosis, actinomycosis, stromal and carcinoid tumors, and autoimmune disorders.<sup>10</sup>

**TABLE 18-1: MAJOR CAUSES OF SECONDARY RETROPERITONEAL FIBROSIS**

	<b>Examples</b>
Drugs	Methysergide, pergolide, bromocriptine, ergotamine, methyldopa, hydralazine, analgesics, $\beta$ -blockers
Malignant diseases	Carcinoid, Hodgkin and non-Hodgkin lymphomas, sarcomas, carcinomas of the colon, prostate, breast, stomach
Infections	Tuberculosis, histoplasmosis, actinomycosis
Radiotherapy	Testicular seminoma, colon carcinoma, pancreatic carcinoma
Surgery	Lymphadenectomy, colectomy, hysterectomy, aortic aneurysmectomy
Others	Histiocytoses, Erdheim-Chester disease, amyloidosis, trauma, barium enema

Retroperitoneal fibrosis typically begins just caudal to the renal arteries

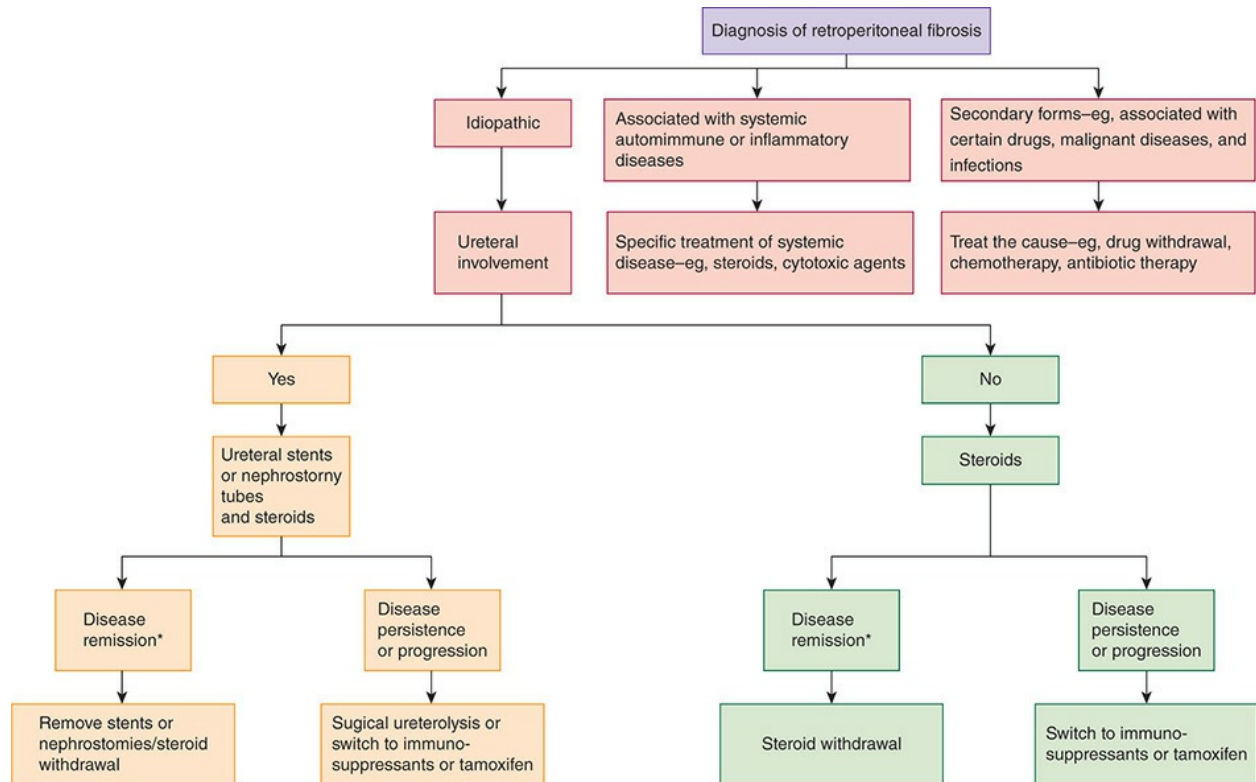

and gradually expands, encasing the ureters, inferior vena cava, abdominal aorta, mesenteric vessels, and sympathetic nerves. Macroscopically, this fibrosis appears as white, hard, sclerotic plaques. Microscopically, it is characterized by progressive infiltration of inflammatory cells, which are later replaced with collagen-synthesizing fibroblasts. Multiple mechanisms have been hypothesized, with the dominant being that of an inflammatory reaction to oxidized low-density lipoproteins found within the atherosclerotic plaques.<sup>71,73</sup>

Patients typically present with both localized and systemic symptoms. Localized symptoms arise secondary to mass effect or local invasion and include back, flank, or abdominal pain and lower extremity edema (secondary to either compression of the lymphatics or deep vein thrombosis). Systemic symptoms typically manifest as fatigue, low-grade fevers, nausea, anorexia, weight loss, or neuralgias. Eighty to 100% of cases are associated with ureteral obstruction; therefore, urinary complaints are also common.<sup>71,72</sup>

The diagnosis of retroperitoneal fibrosis has historically been made with intravenous urography, demonstrating the triad of medial deviation and extrinsic compression of the ureters and hydronephrosis. Yet, while this triad is useful in characterizing the ureteral involvement of the disorder, these findings may also be secondary to ureteral tumors, inflammatory processes, or adenopathy and are therefore not specific. The current recommendations for diagnosis include CT with intravenous contrast or MRI.<sup>72-74</sup> CT findings demonstrate an accumulation of periaortic soft tissue that encases the distal aorta below the renal arteries. To confirm the diagnosis of retroperitoneal fibrosis and rule out a retroperitoneal malignancy, a CT-guided biopsy should be completed.<sup>10,74,75</sup> In addition to imaging, laboratory tests will likely demonstrate an elevated erythrocyte sedimentation rate and C-reactive protein, which can both assist in diagnosis and be used for disease monitoring.<sup>71,73</sup>

The management of retroperitoneal fibrosis requires a combined medical and surgical approach (Fig. 18-3). Corticosteroids are the mainstay of medical management and can lead to either stabilization or regression of fibrosis; surgical intervention is then only warranted in rare cases and usually due to compression and obstruction of the ureters or vascular structures. For patients unresponsive to corticosteroids, both azathioprine and cyclosporine have been demonstrated to induce remission or regression of disease. In

addition, there are anecdotal reports of tamoxifen, colchicine, methotrexate, and mycophenolate being effective in disease stabilization or regression.<sup>10,71,72</sup> Overall long-term prognosis is good, with 5-year survival ranging from 90% to 100%.<sup>10</sup>

\*Defined on basis of clinical findings (remission of symptoms), normalisation of concentrations of acute-phase reactant, CT or MRI evidence of regression of retroperitoneal mass, or resolution of obstructive complications.

## Retroperitoneal Tumors

A variety of primary and secondary masses may present within the retroperitoneum. The majority of these masses are malignant, the most common of which are sarcomas, composing more than 50% of cases, followed by lymphomas and carcinomas.<sup>76</sup> Primary tumors arising from the retroperitoneal organs include renal cell carcinoma, colorectal and pancreatic adenocarcinoma, adrenal masses, and lymphomas. Lymphatic metastases are also a common retroperitoneal finding, particularly in gonadal cancers, which may present with large para-aortic lymph nodes. Lymphoma is associated

with systemic symptoms including fever, night sweats, and weight loss (>10% of body weight), whereas the majority of other primaries arising within the retroperitoneum are likely to present with minimal systemic symptoms and may only be associated with weight loss or changes in gastrointestinal or urinary function.

## RETROPERITONEAL SARCOMA

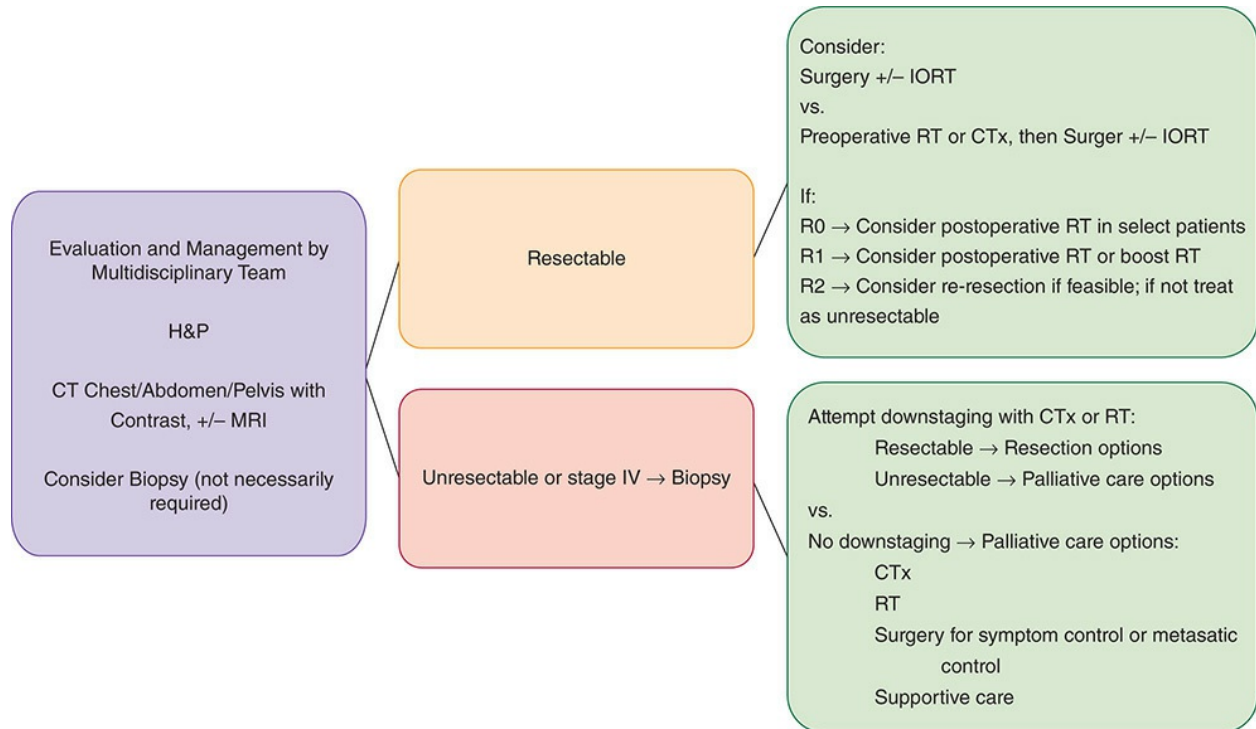

Retroperitoneal sarcomas account for more than half of all retroperitoneal tumors, with an annual incidence of 0.5 to 1 per 100,000 annually in the United States.<sup>77</sup> Soft tissue sarcomas are tumors of mesenchymal origin and include over 50 different histologic subtypes.<sup>78</sup> While the majority of soft tissue sarcomas arise within the extremities, the retroperitoneum is the second most common site of primary disease, and the most common histologic subtypes within the retroperitoneum include liposarcoma (41%), leiomyosarcoma (25%), and malignant fibrous histiocytoma.<sup>76,77,79,80</sup>

Retroperitoneal sarcomas typically present within the sixth to seventh decade, with no sex or racial predominance.<sup>79</sup> The majority of patients present with large tumors, with up to 50% of retroperitoneal sarcomas measuring over 20 cm at the time of diagnosis.<sup>79</sup> Patients often report vague symptoms such as abdominal fullness or distention; acute symptoms such as pain or obstruction are rare.<sup>76,81,82</sup> On physical exam, a palpable mass is often present.

Recently, several international sarcoma collaborative groups have developed guidelines for the diagnosis and management of retroperitoneal sarcomas, with the overarching recommendation that sarcomas be managed by an experienced multidisciplinary team with specialization in sarcoma (Fig. 18-4).<sup>77-79,83-85</sup> Preliminary workup includes a CT of the abdomen and pelvis with intravenous contrast, which can help with diagnosis as well as staging. CT can provide information on regional and distant metastases and suggest the histologic subtype. MRI has also been used and, in many cases, may more clearly define tissue planes when determining resectability. Upon identification of a retroperitoneal mass suspicious for sarcoma, an image-guided percutaneous coaxial core needle biopsy is strongly recommended.<sup>78,83,86</sup> Fine-needle aspirations are typically low yield and therefore not recommended. All tissue biopsies should be reviewed by an

experienced sarcoma pathologist, as 6% to 10% of cases originally designated as sarcoma are in fact not sarcoma and 14% to 27% are assigned the wrong histologic subtype.<sup>86</sup> After confirmation of diagnosis through a tissue biopsy, adequate staging should additionally include a chest CT to rule out pulmonary metastases.<sup>76,77,82,83</sup>

**FIGURE 18-4** National Comprehensive Cancer Network guidelines for management of retroperitoneal/intra-abdominal soft tissue sarcoma. CT, computed tomography; CTx, chemotherapy; H&P, history and physical examination; IORT, intraoperative radiation therapy; MRI, magnetic resonance imaging; RT, radiation therapy. Staging guidelines for sarcomas (both extremity and retroperitoneal) developed by the American Joint Committee on Cancer (AJCC) depend on grade, tumor size, tumor depth, and presence of lymph node or distant metastases. Unfortunately, the AJCC guidelines are poorly suited for soft tissue sarcomas in general, as the majority are >5 cm, rarely if ever develop nodal metastasis, and have significant heterogeneity due to the variability in site of primary disease and histologic subtype.<sup>78</sup> Several recent studies have

developed sarcoma-specific prognostic models or nomograms that provide a more accurate and patient-specific outcome prediction for patients with soft tissue sarcomas.<sup>33,87-89</sup> These nomograms have been further refined to be site and histology specific. The most comprehensive prognostic model or nomogram for retroperitoneal sarcomas was recently published by Gronchi et al<sup>90</sup> and is included in [Figure 18-5](#).

**FIGURE 18-5** Nomogram for 7-year overall survival (OS) in patients with retroperitoneal soft tissue sarcoma. Instructions: The nomogram allows the user to obtain the 7-year OS probability corresponding to a patient’s combination of covariates. For instance, locate the patient’s tumor size and draw a line straight upward to the “Points” axis to determine the score associated with that size. Repeat the process for the additional covariates. Determine the sum of the scores achieved for each covariate and locate this sum on the “Total Points” axis. Draw a line straight down to the “7-year OS” axis to find the predicted probability. DD lipo, dedifferentiated liposarcoma; FNCLCC, Fédération Nationale des Centres de Lutte Contre le Cancer; LMS, leiomyosarcoma; MPNST, malignant peripheral nerve sheath tumor; SFT, solitary fibrous tumor; UPS, undifferentiated pleomorphic sarcoma; WD lipo, well-differentiated liposarcoma. (Reproduced with permission from Gronchi A, Miceli R, Shurell E, et al. Outcome prediction in primary resected retroperitoneal soft tissue sarcoma: histology-

specific overall survival and disease-free survival nomograms built on major sarcoma center data sets, *J Clin Oncol*. 2013 May 1;31(13):1649-1655.)

Surgical resection remains the mainstay of treatment for retroperitoneal sarcomas. The rare cases that are classified as unresectable are typically due to extensive vascular invasion.<sup>86</sup> If a mass is deemed resectable, en bloc complete resection is recommended.<sup>77,78,83</sup> Multiple studies have demonstrated that the best, if not only, opportunity for curative resection is in the setting of primary disease. A thorough discussion of the extent of possible organ resection should be carried out with the patient prior to surgery. The most commonly resected organs include kidney (32%-46%), colon (25%), adrenal (18%), pancreas (10%-15%), and spleen (10%).<sup>76</sup> Due to poor outcomes associated with enucleation and partial resections, these procedures are not recommended and should not be done.

While there is some evidence of improved disease-free and overall survival in extremity sarcomas with multimodal therapy (neoadjuvant or adjuvant chemoradiation therapy), to date, there is no proven benefit of either neoadjuvant or adjuvant external-beam radiation or chemotherapy for the majority of retroperitoneal sarcomas.<sup>76,77,80,82</sup> Retrospective studies have demonstrated a decreased risk of local recurrence and a longer recurrence-free interval with neoadjuvant or adjuvant radiation therapy, but unlike the studies in high-grade extremity sarcomas, this has yet to be proven in a prospective manner.<sup>79</sup> At present, there is an effort by multiple cancer centers nationwide and the National Cancer Institute to evaluate the impact of radiation therapy and chemotherapy in the adjuvant and neoadjuvant setting for retroperitoneal sarcoma; the results are still pending. That being said, most experienced sarcoma centers tend to extrapolate the success of radiation therapy in extremity soft tissue sarcomas to retroperitoneal disease and therefore advocate for preoperative radiotherapy in high-grade lesions to reduce the radiation dose to visceral structures and improve resectability. In addition, certain histologic subtypes that are sensitive to systemic therapy do occur in the retroperitoneum (eg, pancreatic neuroendocrine tumors, gastrointestinal stromal tumors, myxoid round cell liposarcoma) and should be treated with the appropriate systemic agent. Regardless, preoperative and pretreatment planning is best handled in the context of a multidisciplinary sarcoma program.

Prognosis is influenced by many clinicopathologic factors as outlined in

the nomogram, with the 3 most influential being resection status (R0, R1, or R2), tumor grade, and histologic subtype.<sup>80,81</sup> Given the overall poor prognosis, there is no role for an incomplete resection of a retroperitoneal sarcoma. Similarly, patients with positive margins have reduced disease-specific survival and a much higher risk of developing metastatic disease. For patients with positive margins, median survival is approximately 18 months, equivalent to that of patients who do not undergo resection.<sup>80,82</sup> In those with negative margins, there is still a relatively high rate of recurrence, ranging from 40% to 91% in various studies, with median time to recurrence reported as less than 5 years.<sup>77,81,82</sup> Overall 5-year survival for patients with complete resection is 54% but is heavily influenced by grade, with reports of 74% for grade 1 and 24% for grade 2 or 3 disease.<sup>81</sup> Given that the risk of recurrence does not appear to plateau in series with long-term follow-up, it is recommended that patients be followed indefinitely. The current National Comprehensive Cancer Network guidelines for surveillance recommend follow-up with physical exam and imaging (CT of chest, abdomen, and pelvis) every 3 to 6 months for a period of 2 to 3 years and then annually.<sup>79</sup>

# ABDOMINAL TRAUMA

*L.D. Britt • Jessica Burgess*

## OVERVIEW

No anatomical region or cavity is exempt when addressing injuries sustained when managing multi-trauma patients, especially if the traumatic injury is the result of a blunt mechanism. This cornerstone principle is the paramount rationale for the two-tier, systematic approach for the injured patient. In most settings, the acute care surgeon (a specialist who has expertise in trauma, critical care, and emergency general surgical management) is heavily involved in every aspect of care of the trauma patient. Abdominal trauma, regardless of the mechanism of injury, can present many challenging situations, even for the most well trained and talented surgeon. With the pendulum continuing to move more toward nonoperative/selective management of abdominal trauma due to enhanced diagnostic modalities, the hazards of missed or delayed diagnoses are well known and equally well respected. The unevaluable abdomen in a patient who has an associated closed head injury or substantial intoxication with a depressed sensorium remains a perplexing dilemma, irrespective of an unprecedented myriad of advanced technology designed to detect the sequence of intra-abdominal injury.

In addition, there are special populations (the elderly, immunosuppressed, anticoagulated, morbidly obese, etc.) that pose unique management challenges. While the explosion of laparoscopic intervention has made an indelible imprint on practically every surgical discipline, its impact on trauma management has been mostly diagnostic in the hemodynamically normal patients, as opposed to therapeutic management of the injured patient. With the hemodynamically compromised patient being the prototypical individual who is taken to the operating room for exploration, a laparoscopic approach would be an absolute contraindication in that cohort of patients.

Traumatic injury remains the leading cause of death both in the United States and worldwide, resulting in enormous economic and societal losses. In many regions of the world, there is a significant shortage of surgical specialists and general surgeons. This is particularly problematic given the fact that it is the general surgeon specialist who still provides the bulk of emergency surgical care. Given the fact that there are many regions of the country and the world without established trauma systems, this chapter is as applicable to the general surgeon as it is to the trauma surgeon.

## **Initial Management**

Even though the abdomen remains one of the most critical and vulnerable anatomic regions in blunt trauma, a standard, systematic approach of the entire patient must always be conducted—without exception. An initial assessment of the entire patient is imperative before focusing on the specific anatomical region where there is an obvious traumatic injury. The concept of initial assessment includes the following components: (1) rapid primary survey, (2) resuscitation, (3) detailed secondary survey (evaluation), and (4) reevaluation. Such an assessment is the cornerstone of the Advanced Trauma Life Support (ATLS®) program.<sup>1</sup> Integrated into primary and secondary surveys are specific adjuncts. Such adjuncts include the application of electrocardiographic monitoring and the utilization of other monitoring modalities such as arterial blood gas determination, pulse oximetry, the measurement of ventilatory rate and blood pressure, insertion of urinary and/or gastric catheters, and incorporating necessary x-rays and other diagnostic studies when applicable, such as focused abdominal sonography for trauma (FAST) exam, other diagnostic studies (plain radiography of the spine/chest/pelvis and computed tomography [CT]). The initial assessment

essentially underscores the prioritization of patient management. Determination of the status of an airway and optimal oxygenation (airway [A] and breathing [B]) are inevitably the top priorities followed by assessing the adequacy of blood flow—circulation (C). For example, when an airway is believed to be inadequate, the establishment of a rapid-sequence translaryngeal endotracheal intubation might be indicated, or if circulation is deemed suboptimal and bleeding is suspected, an expeditious search for external or cavitory (peritoneum, thorax) source is conducted. Following the “ABCs” of the primary survey is a rapid assessment of the neurological status for gross disability (D)—including determining (1) the level of consciousness, (2) motor function (extremity movement), (3) sensory function, and (4) the presence of reflexes (pupillary, bulbocavernosus). This rapid neurologic assessment allows for the calculation of a Glasgow Coma Score (GCS). The last component of the primary survey is ensuring that full exposure (E) of the patient is achieved, along with environmental control, in order to lessen the chance of the patient becoming hypothermic.

The focus of the primary survey is to both identify and expeditiously address immediate life-threatening injuries. In addition to resuscitation, the necessary adjuncts to the primary survey (and secondary evaluation) include electrocardiographic monitoring, placement of urinary and gastric catheters (when appropriate and not contraindicated), along with the close monitoring of physiologic parameters such as respiratory rate, pulse rate, blood pressure, pulse pressure, arterial blood gases, body temperature, and urinary output. Only after the primary survey is completed (including the initiation of resuscitation) and hemodynamic stability is addressed should the secondary survey be conducted, which entails a head-to-toe (and back-to-front) physical examination, along with a more detailed history. Normalization of all vital functions should be evident before proceeding to the secondary survey.

## **PRIMARY SURVEY**

Only the emergency care disciplines of surgery/medicine have a two-tier approach to their initial assessment of the patient, with primary and secondary surveys being integral components. As highlighted above, the primary survey is designed to quickly detect life-threatening injuries. Therefore, a universal approach has been established with the following prioritization:

- Airway maintenance (with protection of the cervical spine)
- Breathing (ventilation)
- Circulation (including hemorrhage control)
- Disability (neurologic status)
- Exposure/environmental control

Such a systematic and methodical approach (known as the ABCDEs of the initial assessment) greatly assists the surgical/medical team in the timely management of those injuries that could result in a poor outcome.

- A. Airway assessment management (along with cervical spine protection):** Because loss of a secure airway could be lethal within 4 minutes, airway assessment/management always has the highest priority during the primary survey of the initial assessment of any injured patient, irrespective of the mechanism of injury or the anatomical wound. The chin lift and jaw thrust maneuvers are occasionally helpful in attempting to secure a patient airway. However, in the trauma setting, the airway management of choice is often translaryngeal, endotracheal intubation. If this cannot be achieved due to an upper airway obstruction or some technical difficulty, a surgical airway (needle or surgical cricothyroidotomy) should be the alternative approach. No other management can take precedence over obtaining an appropriate airway control. Until adequate and sustained oxygenation can be documented, administration of 100% oxygen is required.
- B. Breathing (ventilation assessment):** An airway can be adequately established and optimal ventilation still not be achieved—for example, when there is an associated tension pneumothorax. Other examples include a substantial hemothorax, open pneumothorax, or a large flail chest wall segment. Worsening oxygenation and an adverse outcome would ensue unless such problems are expeditiously addressed. Therefore, assessment of breathing is imperative, even when there is an established and secure airway. A patent airway but poor gas exchange will still result in a poor outcome. Tachypnea, absent breath sounds, percussion hyperresonance, distended neck veins, and/or tracheal deviation are all consistent with inadequate gas exchange. Decompression of the pleural space with a needle/chest tube insertion should be the initial intervention for a pneumo/hemothorax that compromises a patient's respiratory and/or

cardiovascular status. A large flail chest, with underlying pulmonary contusion, will likely require endotracheal intubation and administration of positive pressure ventilation.

- C. Circulation assessment (adequacy of perfusion management):** The most important initial step in determining adequacy of circulatory perfusion is to quickly identify and control any active source of bleeding, along with restoration of the patient's blood volume with crystalloid fluid resuscitation and blood products, if required. Decreased levels of consciousness, pale skin color, slow (or nonexistent) capillary refill, cool body temperature, tachycardia, or diminished urinary output are all suggestive of inadequate tissue perfusion. Optimal resuscitation requires the insertion of two large-bore intravenous lines and infusion of crystalloid fluids (warmed). Adult patients who are severely compromised will require a fluid bolus (2 liters of Ringer lactate or saline solution). Children should receive a 20 mL/kg fluid bolus. Blood and blood products are administered as required. Along with the initiation of fluid resuscitation, emphasis needs to remain on identifying the source of active bleeding and stopping the hemorrhage. For a patient in hemorrhagic shock, the source of blood loss will be an open wound with profuse bleeding, or within the thoracic or abdominal cavity, or from an associated pelvic fracture with venous and/or arterial injuries. Disposition (operating room, angiography suite, etc.) of the patient depends on the site of bleeding. For example, a FAST assessment that documents substantial blood loss in the abdominal cavity in a patient who is hemodynamically labile dictates an emergency celiotomy. However, if the quick diagnostic workup of a hemodynamically unstable patient who has sustained blunt trauma demonstrates no blood loss from an open wound in the abdomen or chest, then the source of hemorrhage would likely be from a pelvic injury, necessitating angiography/embolization of a probable arterial injury, if external stabilization (eg, a commercial wrap or binder) of the pelvic fracture fails to stop the bleeding. Profuse bleeding from open wounds can usually be addressed by application of direct pressure or occasionally ligating torn arterial vessels that can easily be identified and isolated.
- D. Disability assessment/management:** Only a baseline neurologic examination is required when performing the primary survey in order to determine neurologic function deterioration that might necessitate surgical intervention. It is inappropriate to attempt a detailed neurologic

examination initially. Such a comprehensive examination should be done during the secondary survey or evaluation. This baseline neurologic assessment could be the determination of the GCS, with an emphasis on the best motor or verbal response, and eye opening. An alternative approach for a rapid neurologic evaluation would be the assessment of the pupillary size and reaction, along with establishing the patient's level of consciousness (alert, responds to visual stimuli, responds only to painful stimuli, or unresponsive to all stimuli). The caveat that must be highlighted is the fact that neurologic deterioration can occur rapidly, and that a patient with a devastating injury can have a lucid interval (eg, epidural hematoma). Because the leading causes of secondary brain injury are hypoxia and hypotension, adequate cerebral oxygenation and perfusion are essential in the management of a patient with neurologic injury.

- E. **Exposure/environmental control:** In order to perform a thorough examination of a patient, he/she must be completely undressed. This often requires cutting off the garments to safely expedite such exposure. However, care must be taken to maintain normothermia and prevent the patient from becoming hypothermic. Adjusting the room temperature and infusing warmed intravenous fluids can help establish an optimal environment for the patient.

## SECONDARY SURVEY

As noted earlier, the secondary survey should not be done until the primary survey has been completed and resuscitation initiated, with some evidence of normalization of vital signs. It is imperative that this head-to-toe (front and back) evaluation be performed in a detailed and systematic fashion in order to detect less obvious or occult injuries. This is particularly important in the unevaluable (eg, head injury or severely intoxicated) patient. The management of blunt abdominal trauma continues to evolve more in the nonoperative arena, as opposed to surgical intervention. The workup has shifted largely from the use of physical exam, plain x-ray, laboratory findings, and diagnostic peritoneal lavage (DPL) to the extensive use of CT and ultrasonography. Treatment for visceral injury has traditionally been surgical, but many forms of solid organ injury can now be successfully managed nonoperatively or with minimally invasive and interventional radiology techniques. Management of the multiple injured trauma patient at

Level I trauma centers, with state-of-the-art techniques, has now conclusively shown significantly improved patient outcomes and survival.<sup>2</sup>

## Diagnostic and Imaging Techniques

### DIAGNOSTIC PERITONEAL LAVAGE

DPL has now been essentially supplanted by the adoption and now popularity of abdominal sonography. The utilization of DPL has diminished substantially. Originally described by Root in 1965, DPL was once a mainstay in the management of blunt abdominal trauma for over four decades.<sup>3</sup> Before the era of routine CT scanning, it was used as a screening tool to evaluate patients having blunt or penetrating abdominal trauma with an accuracy rate reported between 92% and 98%.<sup>4-9</sup> CT scans and FAST are now the diagnostic modalities of choice in assessment of the injured patient. However, DPL remains an excellent tool for further workup of occult bowel injury or in unstable patients when FAST is not available or has questionable findings. In the workup for occult bowel injury, traditional parameters (Table 19-1) should be used to guide therapy. In unstable patients and when FAST is not an option, a diagnostic tap is usually all that is necessary, and exploration is indicated when there is aspiration of greater than 10 mL of gross blood.

**TABLE 19-1: DIAGNOSTIC CRITERIA FOR A POSITIVE DPL**

<b>Any Viscus</b>	<b>Bowel</b>
10 mL gross blood	Bacteria
>100,000 red blood cell/ $\mu$ L	Bile
>500 white blood cell/ $\mu$ L	Food particles
>75 IU/liter amylase	

The pitfalls of DPL are a relatively high false positive rate, risk of creating visceral injury, and poor sensitivity for detecting injury to retroperitoneal structures such as the pancreas and duodenum.<sup>10-12</sup> Iatrogenic events are minimized if a Foley catheter and nasogastric tube are placed prior to the procedure. Patients with pelvic fractures and suspected retroperitoneal

hematoma or pregnant females should undergo a supra-umbilical approach. Visceral injury is less likely with an open approach but more time-consuming and invasive.<sup>13-16</sup> Checking amylase or lipase in the lavage sample, concomitant use of CT scan, and high index of suspicion are necessary to avoid missed retroperitoneal injury.

## **FOCUSED ABDOMINAL SONOGRAPHY FOR TRAUMA**

In the diagnostic assessment of the acutely injured patient, the bedside ultrasonography for detection of cardiac and intra-abdominal injury is considered the standard of care. Because focused abdominal sonography for trauma is of a noninvasive nature, this diagnostic modality allows the operator to perform an exam simultaneously during the initial resuscitation and stabilization of a multiple injured trauma patient. Due to the relative insensitivity of abdominal examination in the severely injured patient, this technique may provide evidence of significant hemorrhage early in the course of an evaluation. An ultrasound probe is used to examine four key windows for fluid; the subxiphoid area permits visualization of the pericardium, the left subcostal area visualization of the splenorenal recess, right subcostal area visualization of Morison pouch, and the suprapubic area visualization of the pelvic cul de sac (Fig. 19-1). The presence of fluid may indicate presence of cardiac tamponade (fluid in the pericardial space), intra-abdominal hemorrhage, hollow viscus perforation, hemoperitoneum, or ascites. False positive results secondary to preexisting ascites or false negatives due to operator error and/or body habitus are the main limitations. Scanning the suprapubic area with distension of the urinary bladder will enhance the sensitivity of the exam for the detection of pelvic fluid.

**FIGURE 19-1** Schematic showing sonographic windows for (1) subxyphoid, (2) left subcostal, (3) right subcostal and (4) suprapubic areas. Distension of the urinary bladder either prior to Foley catheter placement or by installation of 150 to 200 mL normal saline will enhance sensitivity. (Reproduced with permission from Rozycki GS, Ochsner MG, Schmidt JA, et al: A prospective study of surgeon-performed ultrasound as the primary adjuvant modality for injured patient assessment, *J Trauma* 1995 Sep;39(3):492-498.)

A threshold of at least 200 mL of fluid in the abdominal cavity is necessary for detection, and intra-abdominal injuries must be associated with the presence of this much free fluid for a positive finding.<sup>17</sup> Reported sensitivities range between 73% and 88% and specificity between 98% and 100%.<sup>18</sup> Accuracy rates range from 96% to 98%. FAST is an inexpensive, rapid, portable, noninvasive technique that can be performed in serial fashion if there is a change in patient stability.<sup>19–21</sup> In addition, it obviates the risk of exposing pregnant females to radiation. Positive findings in stable patients can be further evaluated with CT, while unstable patients with a positive finding should prompt the surgeon to take the patient to the operating room for emergent exploration. Workup of a patient with a reliable abdominal exam may be complete with a negative FAST in the absence of abdominal signs or symptoms.

## COMPUTED TOMOGRAPHY

Steady advances in the technology and speed of CT have continued to be an integral part of the diagnostic management of trauma patients. Multidetector scanners have drastically improved resolution and accuracy of these imaging studies. Negative predictive values as high as 99.63% have been reported for patients sustaining significant mechanisms of blunt trauma allowing the use of CT as a reliable and noninvasive screening tool for screening patients with blunt abdominal trauma.<sup>22</sup> In light of modern-day CT capabilities, prospective data have demonstrated that patients with a significant mechanism and a benign abdomen can be released from the emergency department if a CT scan of the abdomen shows no evidence of visceral injury provided that there are no other reasons for hospitalization.<sup>22</sup>

CT reliably identifies injuries in solid organs such as the spleen, liver, and kidney because of the associated vascular nature demonstrating disruption of normal architecture, associated free fluid, and the so-called vascular blush.<sup>23</sup> Established grading scales continue to be used for accurate classification and determination of management plan (Tables 19-2 through 19-4).<sup>23,24</sup>

**TABLE 19-2: SPLENIC INJURY GRADING SYSTEM**

	Grade <sup>a</sup>	Injury Description	ICD-10 <sup>b</sup>	AIS-90 <sup>c</sup>
I	Hematoma	Subcapsular, <10% surface area	S36.020A	2
	Laceration	Capsular tear, <1 cm parenchymal depth	S36.030A	2
II	Hematoma	Subcapsular, 10-50% surface area; intraparenchymal, <5 cm in diameter	S36.020A	2
	Laceration	1-3 cm parenchymal depth which does not involve a trabecular vessel	S36.030A	2
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma	S36.021A	3
	Laceration	Intraparenchymal hematoma >5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels	S36.031A	3
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)	S36.032A	4
V	Laceration	Completely shattered spleen	S36.032A	5
	Vascular	Hilar vascular injury which devascularizes spleen		5

<sup>a</sup>Advance one grade for multiple injuries, up to grade III.

Detection of bowel injury via CT scan in patients who are intoxicated, intubated, or who have associated closed head injury or other distracting injuries, can present a diagnostic challenge in the absence of a reliable abdominal exam. The incidence of blunt bowel injury varies from series to series but is generally reported in the 1% to 5 % range in all blunt trauma patients admitted to Level I trauma centers.<sup>25,26</sup> A high index of suspicion is predicated on mechanism of injury and physical exam findings, such as abdominal wall ecchymosis, tattooing, and/or seatbelt sign. CT findings may be overt such as extravasation of oral contrast or pneumoperitoneum, or more commonly subtle findings such as bowel wall thickening, stranding of the mesentery, or free fluid in the absence of solid organ injury. Indirect findings may be fairly nonspecific and secondary to bowel edema from resuscitation or preexisting ascites. Reproductive age females may have a small amount of normal or “physiologic” pelvic fluid present, sometimes adding to the complexity of the evaluation. Patients on positive pressure ventilation or with significant barotrauma may develop mediastinal or subcutaneous emphysema that can track through the peritoneum or retroperitoneum and give the appearance of free air. Great care in the radiologic interpretation and close clinical correlation are necessary in such cases. The liberal use of diagnostic modalities (eg, abdominal CT scan) in the hemodynamically normal injured patient may prevent nontherapeutic laparotomies. Obviously, when significant doubt remains, abdominal exploration may be required to confirm an injury.

The role of oral contrast in evaluation of the acutely injured patient has recently come under question. Little time is usually available in the

emergency setting to permit adequate opacification of the small bowel. Patients are further at risk for aspiration of the contrast media, and administration often requires placement of a nasogastric tube. There have been several reports that have shown that elimination of oral contrast media does not lead to an increased incidence of missed bowel injury.<sup>25-27</sup> Many centers have now safely eliminated the use of oral contrast media from their routine trauma protocols, expediting management and ease of patient care. Resuscitation edema may cause a hazy appearance around the head of the pancreas and duodenal c-loop, raising the question of a pancreas or duodenal injury. Further clarification in this situation can be obtained when it occasionally occurs via repeat CT scan with the administration of oral contrast and the injection of a 300- to 500-cc bolus of air down the nasogastric tube in order to make pneumoperitoneum obvious.

CT may also be of great importance in identifying patients with arterial hemorrhage related to pelvic fracture. CT imaging may demonstrate an arterial blush or large hematoma in the vicinity of a pelvic fracture indicating the need for pelvic arteriography or pelvic external fixation. A “CT cystogram” may also be helpful and eliminate redundancy of radiographic evaluation. The Foley catheter is clamped after placement in the trauma bay. Real-time interpretation of the CT scan is performed by the evaluating physician, which may dictate further delayed images or a formal three-view (anterior/posterior, lateral, and postvoid views) cystogram.

## **SPECIFIC CONSIDERATION FOR BLUNT TRAUMA**

### **The Bowel**

There is yet no place for nonoperative management of hollow viscus injury, and the nemesis of nonoperative management of blunt abdominal trauma is therefore the missed bowel injury and all its catastrophic consequences. Otherwise, most management is straightforward: debridement and primary repair for nondestructive injuries and resection with primary repair versus stomal formation for destructive injuries.

# RADIOGRAPHIC FINDINGS OF BLUNT BOWEL INJURY

There are two basic types of findings of bowel injury on CT scan: direct and indirect. Direct findings are usually straightforward *if* present and amount to extravasation of oral contrast (if administered) and free air, which have been reported to occur in 4% and 28% of the time, respectively. Little else can explain the first of these two entities, while free air from other sources such as extensive subcutaneous emphysema tracking through a diaphragmatic hiatus is unusual.<sup>28–30</sup> Such findings may be subtle and can vary in presentation depending on the quality of the scan. Indirect findings include mesenteric hematoma or contrast blush, bowel wall edema, unexplained free fluid, “fat streaking,” and bowel loops that do not opacify with intravenous contrast (Table 19-5).

**TABLE 19-5: CT SCAN FINDINGS OF BLUNT BOWEL INJURY**

<b>Direct</b>	<b>Indirect</b>
Oral contrast extravasation	Mesenteric hematoma
Free air	Mesenteric blush
	Bowel wall edema
	Unexplained ascites
	Fat streaking
	Unopacified (vascular contrast media) bowel loops

Mesenteric hematoma is nonspecific and can occur from associated injuries, such as pelvic fractures or renal injuries, with hematomas from these structures expanding into the bowel mesentery. However, a vascular blush in the leaves of the mesentery is indicative of active hemorrhage until proven otherwise, and generally is a determinant for immediate operative exploration. Bowel wall edema and ascites are common in blunt trauma patients, can occur from resuscitation of other injuries, and do not necessarily connote bowel injury. Free fluid in the absence of solid organ injury can be further evaluated with DPL if the abdominal exam is unreliable. Fat streaking can occur with mesenteric contusion and does not necessarily portend an operative indication. Unopacified bowel loops can indicate vascular

disruption of the mesentery or simply be due to poor contrast timing in an under-resuscitated patient. Evidence of these findings increases the likelihood of finding an injury at exploration when there is an increasing number of these findings.

## OPERATIVE MANAGEMENT

Appreciation of the American Association for the Surgery of Trauma (AAST) organ injury grading scale is helpful in describing wounds of the bowel.<sup>31</sup> Grade I injuries are contusions and partial thickness lacerations of the bowel wall without perforation. Grade II injuries are full thickness wounds involving less than 50% of the bowel wall circumference. Grade III are lacerations comprising greater than 50% of the bowel wall circumference without complete transection. Grades IV and V injuries represent complete transection of the bowel wall and transection with segmental tissue loss and/or devascularization of the mesentery, respectively. The terms destructive and nondestructive simplify the terminology; nondestructive wounds are those injuries that can be managed with debridement and primary-suture enterorrhaphy and are comprised of grades I through III.<sup>32</sup> Destructive wounds require resection of an entire segment of the bowel due to loss of colonic integrity or devascularization of the mesentery and encompass grades IV and V (Tables 19-6 and 19-7).

**TABLE 19-6: AAST SMALL BOWEL INJURY SCALE**

Grade <sup>a</sup>	Type of Injury	Description of Injury	ICD-10 <sup>b</sup>	AIS-90 <sup>c</sup>
I	Hematoma	Contusion or hematoma without devascularization	S36.429A	2
	Laceration	Partial thickness, no perforation	S36.439A	2
II	Laceration	Laceration <50% of circumference	S36.439A	3
III	Laceration	Laceration ≥50% of circumference without transection	S36.439A	3
IV	Laceration	Transection of the small bowel	S36.439A	4
V	Laceration	Transection of the small bowel with segmental tissue loss	S36.439A	4
	Vascular	Devascularized segment	S36.499A	4

<sup>c</sup>AIS, abbreviated injury score.

The distinction between destructive and nondestructive wounds is important in terms of the prescribed management. Nondestructive wounds of the large or small bowel can generally be repaired without further consideration. Most small bowel destructive injuries should be resected and reconstituted unless damage control conditions prevail. In contrast to the small bowel, the management of colon injuries has received great scrutiny. Ushering in the dawn of modern-day trauma surgery, the World War II military experience dictated that *all* colon wounds, destructive or not, be managed by colostomy. This philosophy remained surgical dogma until the 1980s.<sup>33,34</sup> In a comprehensive review of the literature since 1979, primary repair of the colon for nondestructive wounds was shown to have a leak rate of 1.6%.<sup>32</sup> Compared to patients receiving colostomy for similar types of wounds, the incidence of intra-abdominal abscess was 4.9% for primary repair and 12% for colostomy, and overall complication rate was 14% for primary repair and 30% for colostomy. Mortality rates were similar at 0.11% for primary repair and 0.14% for colostomy. These findings clearly show the superiority of primary repair for nondestructive wounds of the colon.

Several risk factors for anastomotic failure pertaining to destructive colon injury have been addressed in the literature: hypotension, shock, interval from injury to operation, amount of fecal contamination, associated organ injury, transfusion requirement, and comorbid disease.<sup>35</sup> No data have conclusively shown that any of these risk factors increase the likelihood of anastomotic failure. Patients with massive blood loss or shock may be better served by undergoing a damage control procedure, with delay of definitive repair.<sup>36</sup> Interval from injury to repair greater than 12 hours can be a relative contraindication to definitive repair if there is widespread (greater than one quadrant) fecal contamination. Greater than one or two organ system injury has been a concern, but this may just be a marker for degree of shock and overall physiologic derangement. Comorbidities, such as AIDS and cirrhosis,

deserve special consideration and these patients may be better off with the establishment of an ostomy diversion.<sup>37,38</sup> Patients with any of these risk factors have a higher incidence of intra-abdominal abscess and overall complication rates.<sup>32</sup>

Notwithstanding the caveats of these comorbidities, colonic resection and primary anastomosis for destructive wounds would be permissible in most trauma settings. In a collective review of 207 patients reported in the literature, management of destructive bowel injury with resection and primary anastomosis had a reported leak rate of 7.2%, with a mortality of 1.7% attributable to the colon wound.<sup>32</sup> In the largest single-institution experience, Murray showed a leak rate of 11% in 112 patients undergoing resection and primary anastomosis for destructive colon wounds, with two deaths related to leaks.<sup>39</sup>

In a multi-institutional trial, Demetriades reported 297 patients with destructive colon wounds in which 197 underwent resection and anastomosis and 100 underwent diversion.<sup>37</sup> The choice of operation was left to the discretion of the attending surgeon at the time of exploration. Not surprisingly, the patients with diversion were significantly more injured and critically ill than those undergoing reestablishment of intestinal continuity. The anastomotic leak rate was 6.6%, with one leak from the stump of a Hartmann pouch in the diverted group and four deaths related to anastomotic failure. Multivariate analysis showed no significant difference in mortality or abdominal complications between diversion and primary anastomosis groups. The authors concluded that “patients can be managed by primary repair regardless of risk factors.” This study certainly demonstrates a liberal use of resection and primary anastomosis in relatively sick and injured cohort of patients. However, the ultimate decision for the choice of operation was up to the discretion of the surgeon at the time of operation on a case-by-case basis—for which there is no substitute.

At laparotomy, the bowel should be examined in its entirety after all other sources of major bleeding are controlled. Small injuries should be noted and tagged with an identifiable suture for easy reference. Larger wounds contributing to ongoing soiling can be temporarily controlled with a whipstitch (quick running suture) or Babcock clamps. Mesenteric injuries are identified and active bleeding controlled appropriately. Attention should be directed to the location of the superior mesenteric artery for injuries

encroaching on the root of the mesentery. Mesenteric hematomas should be explored with ligation of injured vessels and mesenteric defects closed by careful reapproximation of the peritoneal edges so as not to compromise any associated vasculature. Bowel viability should be noted in relation to any mesenteric injury. Clusters of grade I through III injuries may be resected or individually repaired depending on the particular injury pattern. In blunt trauma, there are usually only one or two grade II or III wounds that can be repaired primarily or one or more devitalized segments that require resection.

Small, superficial grade I injuries can be left alone, while deeper, longer grade I injuries can be closed with a simple running suture or interrupted Lembert sutures. Grade II and III wounds should be debrided back to healthy, viable bowel and closed transversely, preventing narrowing of the lumen of the bowel. Single-layer running or interrupted closure is generally sufficient for repair of small bowel. When there is significant bowel wall edema, peritonitis, or soiling, a two-layer closure with a running inner layer and interrupted Lembert outer layer may be preferential. Grade I and II colon wounds may be managed with single-layer closure. However, grade III colon wounds should be closed in two layers for added protection.

The leak rate associated with stapled versus hand-sewn anastomosis for destructive wounds of the bowel has been an area of ongoing controversy. In a two retrospective studies totaling 284 patients undergoing stapled versus hand-sewn anastomosis, Brundage showed that hand-sewn procedures had lower leak rates.<sup>40,41</sup> Two other retrospective studies totaling 484 patients showed no difference in the leak rate of stapled versus hand-sewn procedures.<sup>42,43</sup> Brundage's two studies included 78 colon wounds, while the other studies were confined only to the small bowel. Stapled procedures may be a little quicker, particularly if there is more than one anastomosis. In general, the technique chosen according to the literature can be a matter of surgeon's preference. However, with edematous bowel, the hand-sewn technique is a more prudent approach.

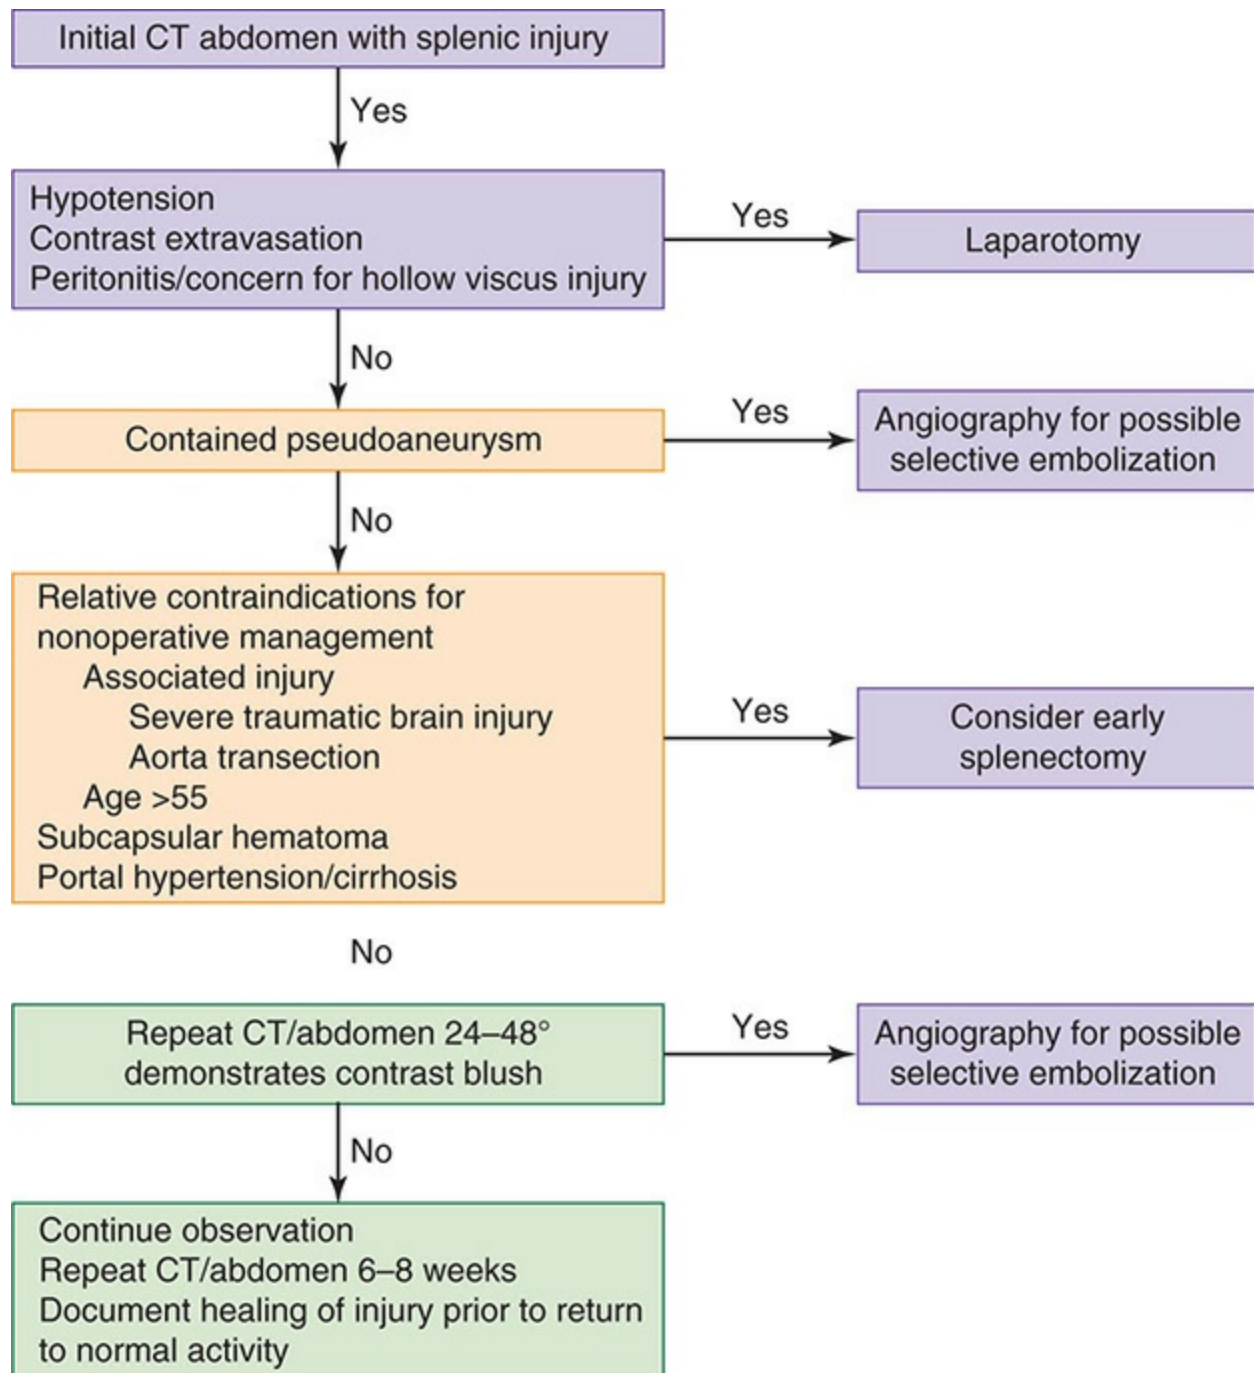

## **The Spleen**

The spleen is the most commonly injured intra-abdominal organ, followed by the liver and small bowel in blunt trauma patients. The spleen's location in the left upper quadrant lends susceptibility to injury from broken ribs,

deceleration, and blunt percussion forces. Clinically, patients with splenic injury may present with hypotension, left upper quadrant pain or tenderness to palpation, or diffuse peritonitis from extravasated blood. Referred pain to the left shoulder on deep inspiration in the face of splenic hematoma is known as Kehr sign.

## **NONOPERATIVE MANAGEMENT**

Most series indicate that approximately 60% to 80% of patients presenting with blunt splenic injury can be managed nonoperatively at Level I or II trauma centers.<sup>44–48</sup> Facilities without the resources and experienced of a bona fide trauma team may not safely meet the demands of nonoperative management and should consider patient transfer.<sup>49</sup> Patients selected for nonoperative management must have normal vital signs, be free of peritoneal signs or other concern for hollow viscus injury, and have no evidence of free extravasation of intravenous contrast from the splenic parenchyma (Fig. 19-2).

**FIGURE 19-2** Management algorithm for blunt splenic injury.

Considerable debate remains regarding risk factors for failure of nonoperative management. Higher AAST splenic injury grade, age greater than 55 years, moderate to large hemoperitoneum, subcapsular hematoma, and portal hypertension have all been suggested to increase the risk of failure. Early reports in the evolution of nonoperative management regarding AAST

grade did not demonstrate higher failure rates for higher-grade injury. More recent reports using high-resolution multidetector CT scanners allow better assessment of injury grade. The data from these studies show patients with injury grades III to V to be at increased risk for nonoperative failure.<sup>44,46</sup> Age continues to be controversial subject in the literature, with numerous reports claiming that age greater than 55 years either *is* or *is not* a risk factor for failure.<sup>44,46,50</sup> Documentation of a moderate or large hemoperitoneum is suggestive of a major injury and should be considered a significant factor in individual patient assessment.

Patients with splenic subcapsular hematoma or history of portal hypertension are specific subgroups of patients that deserve special consideration. This cohort of patients with subcapsular hematoma in our experience tend to ooze from the raw parenchymal surface and further disrupt the capsule, leading to more raw surface area to bleed. These patients are at increased risk for delayed rupture 6 to 8 days following injury and may already be discharged from the hospital if they have isolated injury. Furthermore, splenic embolization is not a very effective treatment for this condition because it usually necessitates coiling of the main splenic artery, which can lead to significant pain and abscess formation. History of portal hypertension or cirrhosis, while not an absolute contraindication to nonoperative management, certainly should serve as a caveat. The general risks of laparotomy in a Child–Pugh B or C cirrhotic patient need to be carefully weighed against the risk of ensuing and worsening coagulopathy. This scenario may indeed dictate the need for splenic artery embolization. None of these risk factors alone should dictate the decision to proceed immediately to operative intervention. Nonoperative management does reduce hospital length of stay and transfusion requirement; however, the morbidity of splenectomy should remain low in any surgeon's hands. Overall, the patient's condition, including comorbidities, coagulopathy, and other problems (such as traumatic brain injury, aortic injury, and suspicion for concomitant hollow viscus injury) factor into the decision-making process. No one should ever succumb to splenic hemorrhage that was undergoing nonoperative management.

Approximately 20% of patients initially undergoing nonoperative management of blunt splenic injury require further intervention. Failure has been associated with the presence of a contrast blush in up to two-thirds of these patients.<sup>51</sup> The presence of a contained contrast blush within the

parenchyma of the spleen represents pseudoaneurysm formation of a branch of the splenic artery. Angioembolization is now commonly used to selectively occlude the arterial branches containing these injuries.<sup>44,45,48,52,53</sup> Implementation of this salvage technique at centers that routinely screen for the presence of pseudoaneurysm has increased the success of nonoperative management to 90% or greater. Pseudoaneurysm formation has been observed in even grade I and II injuries, and may not be present on the initial imaging.<sup>44,47,53</sup> Therefore, follow-up CT scan is recommended on all patients with splenic trauma within 24 to 48 hours after injury. If these images show stable injuries without pseudoaneurysm formation, expectant management can continue.

Long-term data are unavailable concerning the risk of outpatient or delayed rupture, but the incidence is low and has been reported to be about 1.4%.<sup>54</sup> The average date to readmission for delayed splenectomy after discharge was 8 days in this study. Lower grade (I, II) injuries tend to heal more quickly, and most injuries are healed by 5 to 6 weeks.<sup>55</sup> However, approximately 20% of blunt splenic injuries will not show complete healing and may be at risk for pseudocyst formation. A CT scan should be repeated in 6 weeks for grade I and II injuries and 10 to 12 weeks in grades III to V before allowing the patient to return to normal activity.

## **SPLENECTOMY**

Patients requiring urgent or emergent intervention for splenic hemorrhage may develop hypothermia, coagulopathy, and visceral edema. The most expeditious and safest course of action under these conditions is removal of the spleen. The general assumption of abdominal exploration for trauma is that there are known, and possibly unknown, injuries. The operative approach is via a midline vertical incision that allows the best exposure and facilitates temporary abdominal closure should visceral edema or damage control measures be necessary.

With respect to performing a splenectomy, a self-retaining retractor can be used to expose the left upper quadrant. The spleen is retracted medially, with some downward compression, while taking down the posterior attachments with the cautery. Once these attachments are freed, the spleen can be mobilized medially for optimal exposure. The assistant stands on the left side of the table and supports the spleen while the surgeon ligates short gastric and

hilar vessels. Being careful to avoid the tail of the pancreas, a large clip, placed on the specimen side of the splenic hilum, will reduce back-bleeding and expedite the procedure. Once the spleen has been removed, the splenic fossa is meticulously inspected for further bleeding with a rolled laparotomy pad.

## **SPLENORRHAPHY**

Hemodynamically stable patients found to have small to moderate amounts of parenchymal hemorrhage at laparotomy may be candidates for splenic preservation. The spleen is mobilized into the wound using the same technique as for splenectomy. The injury to the spleen is assessed and decision is made whether to resect a portion if the parenchymal injury extends into the hilum or if arterial bleeding is coming from within the splenic laceration itself. If the decision is made to resect the upper or lower pole, the parenchyma is divided with the cautery and the associated hilar vessels are taken with clamps and ties. Any arterial bleeding from the parenchyma is controlled with suture ligature, and the cautery is used to control oozing from the parenchyma. A tongue of omentum is then sutured into the laceration or to the raw surface of the remaining spleen in the case of a partial splenic resection. Approximately 50% of the spleen is required to preserve adequate phagocytic and immunologic function. If this cannot be achieved, a splenectomy is probably the best option.

## **OVERWHELMING POST SPLENECTOMY INFECTION**

The incidence of overwhelming post-splenectomy infection (OPSI) following trauma is not well understood because it may not be appreciated when it occurs, along with the fact that it is not routinely reported. However, the reported incidence of OPSI in adult patients undergoing splenectomy for all causes is 0.9%, with a mortality of 0.8%.<sup>56</sup> The risk of OPSI in adults following trauma is felt to be lower than the incidence seen after splenectomy for hematological disorders such as idiopathic thrombocytopenic purpura (ITP), lymphoma, and thalassemia. Children are at greater risk for OPSI and should receive prophylactic penicillin V 125 mg twice daily until age 3 and then 250 mg twice daily until age 5. Currently, anyone greater than 2 years of age should receive the 23 valent pneumococcal vaccine and a one-time dose

of the *Haemophilus influenza* and meningococcal vaccine. A one-time booster dose of the pneumococcal vaccine is recommended 5 years after the original vaccine.<sup>57</sup>

## Hepatobiliary System

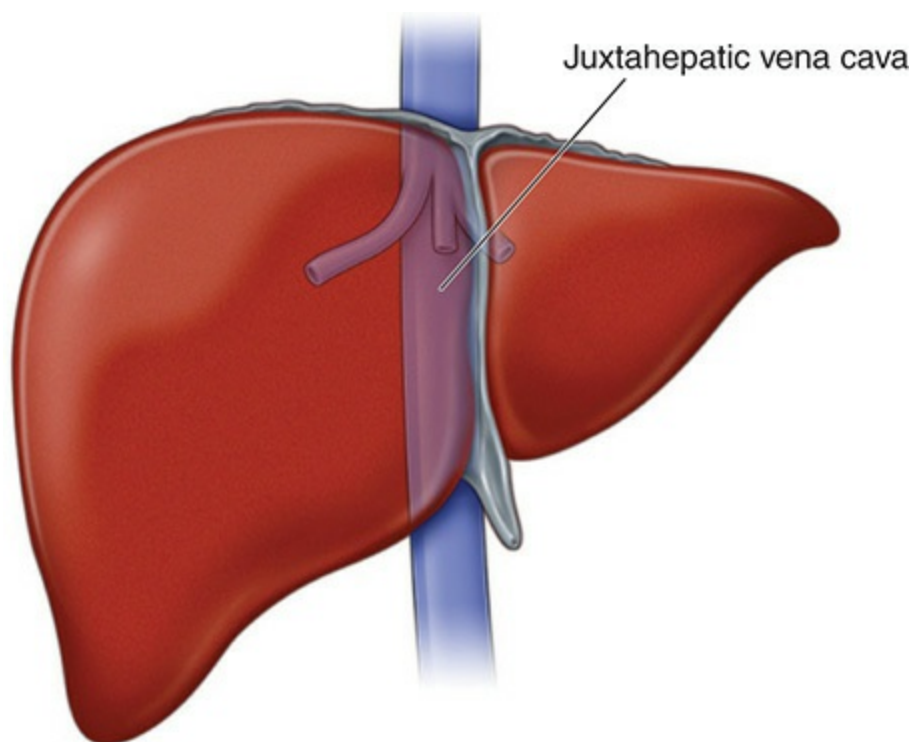

Blunt trauma contributes over 75% of mechanisms of injuries for most of the trauma centers in the United States. The liver, the largest solid organ in the body, is one of the most frequently injured abdominal organs by either blunt or penetrating mechanisms. Fortunately, the majority of hepatic injuries are not severe and require no surgical repair. These are low-grade injuries (Table 19-8). Suspicion of liver injury is predicated on several factors: clinical suspicion derived from the mechanics of the crash and the hemodynamic state of the patient in the field and upon arrival at the hospital along with findings obtained during abdominal examination obtained in the hospital (Fig. 19-3). High-energy crashes involving application of force to the upper abdomen or to the right thoracoabdominal area should arouse immediate suspicion of a possible hepatic injury. Hemodynamic lability, although not an exclusive feature of liver injury, mandates evaluation to exclude it as the source of the hemorrhage. Tenderness in the right upper quadrant in the absence of other signs can be suggestive of subcapsular hematoma requiring attention and further evaluation. Unfortunately, the physical examination is not perfect and has a false positive rate of approximately 50% and a false negative rate of 40%.

**TABLE 19-8: THE AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA (AAST) LIVER INJURY SCALE (1994 REVISION)**

Grade	Type of Injury	Description of Injury
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%-50% surface area Intraparenchymal <10 cm in diameter
	Laceration	Capsular tear 1-3 parenchymal depth, <10 cm in length
III	Hematoma	Subcapsular, >50% surface area of ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >10 cm or expanding
	Laceration	>3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%-75% hepatic lobe or 1-3 Couinaud segments
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
VI	Vascular	Juxtahepatic venous injuries, ie, retrohepatic vena cava/central major hepatic veins
	Vascular	Hepatic avulsion

**FIGURE 19-3** Juxtahepatic (or retrohepatic) vena cava is in direct contact with the posterior aspect of the liver.

Additional methods available to evaluate the abdomen include FAST, CT, and DPL. FAST has become a highly reliable test used when seeking to determine whether there is blood in the abdomen in a patient who is hemodynamically labile. In the stable patient in whom liver injury is suspected, the use of CT has become widespread. Several classification schemes have been described for liver injuries. There are inconsistencies in the terminology, but a grading scheme proposed by the AAST is now in wide

use (Table 19-8).

These diagnostic adjuncts are not intended to replace clinical judgment and examination by the surgeon. Whatever method is used for abdominal evaluation should be readily available, and the surgeon should be proficient in its use and interpretation.

## **APPROACH TO THE INJURED LIVER**

With hepatic injuries, the paramount decision is to determine if an intervention is needed to control hemorrhage. Hemodynamic instability mandates expeditious operative management or angiography/embolization (if the patient can be stabilized with volume resuscitation) in order to make transportation to the radiographic suite less risky for the patient. The hemodynamically stable patient may be evaluated by any of the methods noted earlier. Minor grade I or II injuries frequently require no operative intervention. When diagnosing by CT scan, the surgeon must be cognizant of the magnitude and anatomy of the liver injury. Contusion contained within the liver capsule or minor laceration, such as in grade I or II injuries, may be observed. These diagnoses together constitute most liver injury cases, accounting for 60% or 70%. Grade III injuries (deeper, larger wounds with more tissue destruction) occur in approximately 25% of cases. Grade IV and V injuries, involving large amounts of tissue destruction, have an incidence of 7% and 3%, respectively, and are highly lethal. It should be emphasized that evidence of blood in the peritoneal paracolic gutters, in the pelvis, or tracking along the periportal triads<sup>58</sup> is suggestive of a more significant injury than the liver anatomy may indicate and mandates exploration. In addition, the concomitant existence of hollow viscous injury occurs in 5% and 20% of major hepatic injuries.

It is important to be aware that massive parenchymal injuries can occur with surprisingly little bleeding and that minor lacerations may bleed profusely. An understanding of the tissue architecture of the liver is a prerequisite to successful management. Most blunt lacerations occur along segmental fissures, because the vascular and biliary duct structures are moderately shear resistant. This explains why a large stellate or “bear claw” laceration may be seen with little or no intraperitoneal blood in a hemodynamically stable patient. This can be managed nonoperatively with observation and repeated CT scan. Nonoperative treatment of the stable

patient sustaining a blunt liver injury is the management approach of choice today.<sup>59–64</sup> Table 19-9 highlights the reported failure rates for nonoperative management of hepatic trauma.

**TABLE 19-9: FAILURE RATES FOR NONOPERATIVE MANAGEMENT OF LIVER TRAUMA**

Study (year)	Number of Patients	Immediate Surgery (%)	Overall Failure Rate (%)	Liver Failure Rate (%)	Other Failure Rate (%)
Meredith (94)	116	48	3	3	0
Croce (95)	136	18	11	5	6
Pachter (96)	404	53	1.2	0.7	0.5
Malhorra (00)	661	15	7	3	4
Velmahos (03)	78	29 <sup>a</sup>	15	0	15
Christmas (05)	561	32 <sup>b</sup>	1.8	0.4	1.4

*Other Failure* refers failure due to injuries from other intra-abdominal organs such as the spleen, kidney, pancreas, or bowel.

<sup>a</sup>15% for liver bleeding

<sup>b</sup>13% for liver bleeding

Conversely, the deceleration forces are responsible for a shear effect that can result in avulsion of the hepatic veins from the vena cava or major branches of the portal venous or hepatic venous systems. Hemorrhage is devastating, difficult to control, and responsible for the high mortality rate seen with such injuries.

Penetrating injuries present their own set of difficulties; missile tracts may bleed profusely. The same elasticity that can protect the vascular structures from shear forces has little if any effect when confronted with a missile.

## INTRAOPERATIVE DECISIONS: GENERAL PRINCIPLES

Once the decision to operate has been made, the surgeon needs to proceed in an orderly fashion, to a fully equipped operative theater that includes the capabilities of invasive monitoring. Before opening the abdomen, the surgeons must ensure that there is optimal venous access. Large-bore central access is essential. The prudent, historic dictum is that access should be from the upper torso in the event there is a retrohepatic venacaval injury. The blood bank must be notified of the potential for massive transfusion of packed cells and blood components to treat the often associated coagulopathy. The development of blood salvage systems has greatly improved the care of these patients; shed blood from the operative field can

be washed and reinfused, provided there is no evidence of gastrointestinal contamination. Infusion systems are available that allow rapid delivery of large volumes of warmed fluid to help minimize hypothermia and hypovolemia. Hypothermia is a common cause of coagulopathy and must be aggressively defended against. Invasive monitoring capabilities are essential in the management of these critically injured patients.

Optimal surgical exposure is essential and starts with performing a midline vertical incision for expedient entry into the abdominal cavity. The incision should extend from the xiphoid process to the symphysis pubis. Such an approach allows, if necessary, relatively easy extension into the thorax through either a median sternotomy or a lateral thoracotomy.

Performing a celiotomy could potentially decompress the tamponade, thereby necessitating expeditious vascular control. The need to perform an emergency thoracotomy for vascular control of the aorta before opening the abdomen is rarely indicated. Such control of the bleeding can usually be obtained with the assistant's manual compression of the liver.

Once the abdomen is open, a rapid assessment of the injury is made and priority management begun. All clot is evacuated, and the four quadrants are packed to control bleeding. A sequential examination is then carried out with priority given to control of blood loss followed by control of any enteric content spillage.

The general approach to the liver injury requires adequate visualization of the anatomic features of the injury. This may require mobilization of the liver along the falciform and triangular ligaments. Full mobilization of the liver allows delivery onto the abdominal wall that can often facilitate suture repair of a hepatic wound in a difficult area. When mobilizing the liver, care must be taken that the hepatic veins are not injured. The coronary ligaments are in close proximity to hepatic veins. Also, the surgeon must be cautious during the mobilization of the liver that venous return through the vena cava is not obstructed for a prolonged period. Hemorrhage control during mobilization can often be done by the assistant's applying direct pressure with laparotomy packs, compressing the liver between the hands.

As noted earlier, most of the injuries encountered are grade I or II and require little more than simple suture repair. Grades III, IV, and V injuries require an organized approach for successful control of hemorrhage, which includes manual compression, direct ligation, or clipping of lacerated vessels along with sophisticated techniques for more complex wounds.

Vascular occlusion of the portal triad (performing the Pringle maneuver) is a useful method of controlling hepatic arterial and portal venous inflow to the liver. A noncrushing or vascular clamp can be applied to the porta hepatis and safely left in place for approximately 45 minutes, although the specific duration threshold is not known for the hemodynamically labile patient. An umbilical tape placed around the porta hepatis structures can also be used for such control. If this maneuver markedly reduces the liver's bleeding, the parenchymal injury can be assessed and a method of repair decided upon. However, if hemorrhage persists, then an intrahepatic portal vein injury or a major hepatic vein injury must be suspected.

Proceeding with hepatotomy for localization and control of hemorrhage requires fastidious cooperation between the surgeon and the first assistant. With the depth of the hepatic wound exposed, it is usually the first assistant who controls the bleeding. The finger-fracture technique for hepatotomy, with the first assistant compressing the liver, is very effective. The operating surgeon using his/her fingertips or the handle of a scalpel to separate the liver parenchyma and the assistant using a multiple loaded clip applier, made popular for laparoscopic cholecystectomy, ligate severed vessels. Nonabsorbable suture ligation can also be performed to control vessels as each is encountered. Knowledge of the anatomy of the liver (along with reported anatomic variants) is a prerequisite to this approach. The confluence of the left and middle hepatic veins must be kept in mind to avoid overzealous ligation (Fig. 19-4). Likewise, the position of the inferior vena cava and the hepatic veins to the caudate lobe should be noted to avoid unnecessary injury that may complicate surgical management. The placement of random deep sutures is fraught with difficulty. Failure of the abovementioned maneuvers to control hepatic bleeding means that the surgeon either has not adequately identified the source or is dealing with coagulopathic bleeding (or both).

**FIGURE 19-4** After obtaining the necessary exposure (thoracotomy, mediasternotomy), an opening—along with 2.0 Prolene purse-string suture—is created in the right atrial appendage (**A**) to provide the access needed for insertion of the atriocaval shunt (**B**), which is usually a No. 36 chest tube. An extra hole needs to be made at the level of the right atrium. With the chest tube holes being outside of umbilical tape occlusion, blood is directed from

the lower half of the body and the kidney through the atriocaval shunt.

Although ligation of the hepatic artery or portal vein branch supplying a specific portion of the liver is rarely needed, the suspected branch should be isolated, and its occlusion should control hemorrhage while the Pringle maneuver is released. If such is the case, then the identified branch should be ligated.

Liver injury rarely follows the anatomic lines of demarcation delineating the right and left lobes, or the segments. Anatomic resection, a once popular approach, has poor outcome with high mortality rates. This technique has essentially been abandoned. Resectional debridement of devitalized liver is not formal lobectomy but rather a completion of the injury to remove nonviable hepatic tissue and facilitate vascular control. This usually entails a degree of finger fracture through uninjured liver, which allows visualization of the bleeding raw surface and more direct control. Application of specific liver clamps, such as the Lin clamp, designed to aid in lobectomy, is difficult because of positioning of the injury laceration and maneuvering around the clamp.

Being able to perform a tractotomy of a missile wound should be in a surgeon's armamentarium when dealing with penetrating hepatic injury. In addition, a variety of methods designed for tamponade of the bleeding missile tract have been described, using various materials. Bluett et al.<sup>65</sup> described a tamponade device with multiple Penrose drains dragged through the liver tract. However, it is preferable to open the liver and suture or clip-control the bleeding site directly if possible.

Once the bleeding has been controlled, the large, raw surface of the liver can be problematic, as persistent oozing of bile or blood continues. A viable omental patch sutured to the liver bed is an excellent homeostatic agent and internal drain. Stone and Lamb<sup>66</sup> popularized the omental pack in their initial report. Fabian and Stone<sup>67</sup> reported 90% successful hemostatic control with this procedure. For large, raw liver surfaces resulting from debridement or tractotomy, the omental patch held in place with several liver sutures is an excellent hemostatic agent. Utilization of the argon beam coagulator is another option for addressing bleeding of raw liver surfaces. The argon gas removes the blood from the hepatic tissue, and ionizing energy is transmitted. A maximum of 110°C is achieved and an eschar is formed.

An alternative to surgical repair of the injured liver is a mesh wrap

intended to provide compression, control bleeding, and close parenchymal defects. Delaney et al.<sup>68</sup> reported success in six liver injuries controlled in this manner. Brunet et al.<sup>69</sup> reported 35 liver injuries wrapped for control. Sequential CT examination of the patients demonstrated progressive restoration of normal liver architecture.

The premise underlying much of the preceding discussion is that liver bleeding can be controlled. However, even when advanced techniques of liver control are used, hemorrhage control can be precarious at best. A critical error that can be made when dealing with major liver injury is to continue operative intervention in the face of a hypothermic (less than 32°C), acidotic patient who has developed coagulopathy. Although the specific time to make a decision to pack the liver and restore normothermia and coagulation factors is not always clear, the operating surgeon should always have a low threshold to incorporate packing and prepare the patient to be expeditiously transferred to the intensive care unit for aggressive resuscitation and monitoring. Once a patient has required a 10-U transfusion, packing should be seriously considered. Garrison et al.,<sup>70</sup> in a review in which they tried to predict the need for packing in severe abdominal injuries, noted that patients with severe injuries, hypothermia, refractory hypertension, coagulopathy, and acidosis need early packing. It needs to be emphasized that large-vessel bleeding must be controlled before packing can be effective.

Perihepatic packing was popularized during World War II. The high incidence of complications, plus the advent of more sophisticated techniques for control of liver bleeding, led to the demise of packing until its revival in the 1970s. Feliciano et al.<sup>71</sup> noted the major indications for perihepatic packing to be the postrepair coagulopathy that developed or an extensive subcapsular hematoma or capsular avulsion. They reported 57% survival rate in their series. Carmona et al.<sup>72</sup> reported similar success with perihepatic packing to control bleeding when other methods failed. Perihepatic packing is broadly embraced today. It is also a valuable adjunct to resectional debridement and tractotomy. Walt<sup>73</sup> has enumerated several guidelines regarding liver packing. The use of a folded, disposable plastic drape is helpful. It is placed against the liver and the packs placed on it, preventing the laparotomy pads from adhering to the liver and possibly minimizing the recurrent bleeding upon removal of the packs. Gauze packs are then placed in order to compress the liver. The packs should be placed at both the superior

and inferior surfaces of the liver. The packing should be tight enough to control the bleeding but not so tight that it unnecessarily compresses the renal vessels and possibly the inferior vena cava, resulting in intra-abdominal hypertension. Patients who have undergone packing will require continued sedation with mechanical ventilation until pack removal, because of the interference of optimal diaphragmatic movement. Abdominal wall closure is rapid and is performed by towel clips or by running nylon suture in the skin. Utilization of silo-like closures with sterile towels and plastic drapes should be used to minimize fluid loss and maintain abdominal pressure. In addition, there should always be a high index of suspicion for the development of intra-abdominal compartment syndrome.

Pack removal can be planned when the patient has regained normothermia and coagulation parameters have been normalized. This usually occurs within 24 to 72 hours. Packs are then removed during a second operation, and the surgical team again must be prepared to manage bleeding. Repacking at the second operation might be indicated. The complication rate of packing is appreciable. Ivatury et al.<sup>74</sup> noted an increased incidence of sepsis in a group of patients subjected to liver packing. An additional benefit of liver packing is that it may allow transport of a critically ill patient from one center to a definitive treatment center where the liver injury can be treated. Clark et al.<sup>75</sup> emphasized this point in the context of a trauma system, with a number of smaller, more rural hospitals transporting seriously injured patients to the tertiary center for definitive care.

## **JUXTAHEPATIC VENOUS INJURIES**

The lethality of juxtahepatic venous injuries in blunt hepatic trauma and the management challenges of definitively addressing such injuries have been well chronicled.<sup>76–80</sup> Fortunately, such liver wounds are seen infrequently. However, the downside is that very few acute care surgeons are familiar with and comfortable operating in this specific setting. Depending on the particular series, the mortality ranges from 50% to 80%, with massive hemorrhage being the overwhelming cause of death.

The deadly nature of this injury is a result of the difficulty in expeditiously getting access to the injury site. The retrohepatic vena cava and major hepatic veins are within the depth of the least mobile area of the liver—making exposure and direct control of bleeding very challenging. Attempting to

rotate the liver in an effort to access the injury can actually extend the wound and cause increased bleeding. Also, such a misguided effort could result in a fatal air embolus.

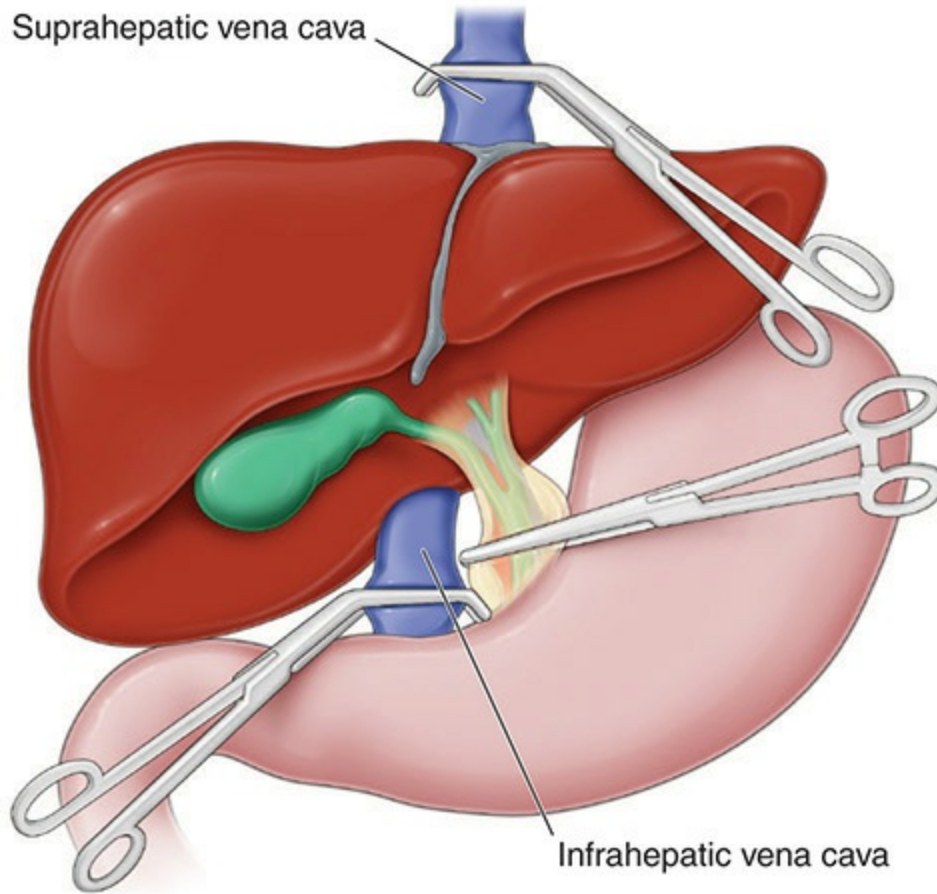

Detailed knowledge of the pertinent anatomy is imperative for any surgeon attempting an operative management strategy. The juxtahepatic vena cava, which is within the “bare area” of the liver, extends for approximately 7 cm and is bordered by the phrenic veins and right adrenal vein—cephalad and caudad, respectively. Approximately 3 cm above the most superior aspect of the retrohepatic vena cava, the inferior vena cava enters the right atrium. The retrohepatic cava is an extraparenchymal structure. The three major hepatic veins, along with their tributaries, enter directly into the anterior aspect of the retrohepatic vena cava. This anatomy is relatively constant, with major anomalies being uncommon. While the course of the extraparenchymal hepatic veins is short, the intraparenchymal veins have a long course. Substantial blunt trauma can lacerate/avulse either or both.

Probably because of their highly lethal nature, juxtahepatic venous injuries are infrequently managed. Surrounding structures can provide a tamponade effect and contain juxtahepatic venous hemorrhage. Such structures include the liver, the diaphragm, and the suspensory ligaments of the liver. Adequate containment of hemorrhage by these structures might allow an attempt at expectant or nonoperative management. However, if these supporting structures are disrupted, substantial bleeding will ensue. As a consequence, overly aggressive or injudicious hepatic mobilization can result in uncontrollable hemorrhage.

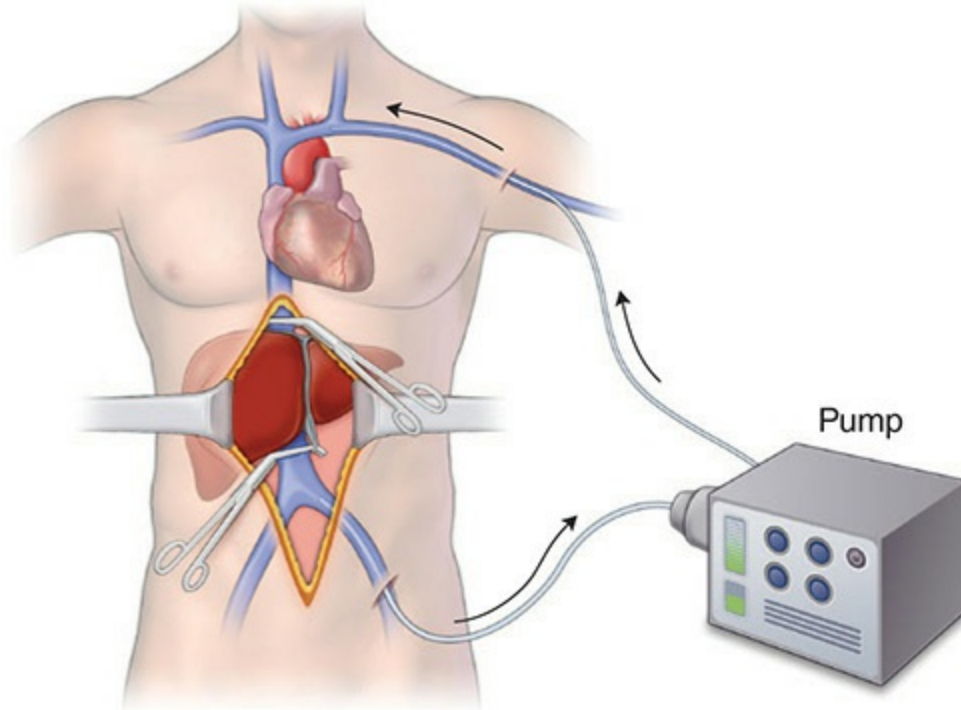

Juxtahepatic injuries, which can be caused by blunt or penetrating injuries, are often classified as type A or B, with the former being hepatic venous wounds that are intraparenchymal and the latter being extraparenchymal venous wounds. Both type A and B injuries can occur together. In addition, there can be associated injuries to the portal vein and its tributaries, which occur more frequently with type A wounds. Fortunately, the extraparenchymal hepatic venous or the associated retrohepatic caval injuries are infrequent. Penetrating wounds to this anatomic region or the sheer forces from blunt injury are the predominant mechanisms of injury. Irrespective of the reported series on the management of juxtahepatic venous injuries, the mortality rates are overwhelmingly high.

There are basically three operative approaches in the management of juxtahepatic venous injuries: (1) direct repair of the venous wound(s), (2)

surgical resection, and (3) pressure application (containment/tamponade measures) with reinforcement of the natural containment structures that have been disrupted. While there have been several reports of the specific strategy and efficacy of operative exposure and direct repair of juxtahepatic venous injuries, the success is sporadic and overall outcomes dismal.<sup>76-80</sup> In 1966, Feldman<sup>76</sup> was credited with reporting the first successful application of direct suture repair of a juxtahepatic venous injury. Schrock introduced, in 1968, the concept of vascular isolation with the utilization of an atriocaval shunt (Fig. 19-4).<sup>80</sup> However, the majority of surgeons have abandoned atriocaval shunting because of the challenges related to the technique and the overall dismal outcomes. The paramount or overarching principle in establishing vascular isolation is obtaining proximal and distal control of all vessels to totally isolate the liver. The Heaney maneuver advocates a more expedient approach to achieve vascular isolation (Fig. 19-5) to surgically address juxtahepatic venous injuries and other complex liver wounds. At all times, it is imperative that the patient is optimally resuscitated and closely monitored. Another alternative, with respect to achieving vascular isolation in an effort to access retrohepatic wounds, is the establishment of a venovenous bypass (Fig. 19-6). This approach necessitates cannulation of the femoral vein and the axillary vein in the upper arm. The cannulas are connected by a heparin-coated tubing, with a flow assisted by a centrifugal pump. Both supra- and intrahepatic clamps are required for the venovenous bypass. Along with inexperience in the above techniques, major blood loss with associated coagulopathy precludes successful utilization of any of the shunting interventions. Operative hepatic resection in an effort to access these retrohepatic wounds is associated with a high mortality rate and should not be attempted.

**FIGURE 19-5** The Heaney maneuver. Vascular isolation of the injured liver by applying vascular clamps to the suprahepatic and infrahepatic inferior vena cava, in addition to a Pringle maneuver.

**FIGURE 19-6** The venovenous bypass requires cannulation of both the femoral vein and the axillary vein. A heparin-coated tubing connects the two cannulas. Flow is assisted by a centrifugal pump.

Because of the inherent and overwhelming risks of surgical management of these complex injuries, tamponade with containment followed by angiography and possible embolization has become a viable option (when possible) in the management of juxtahepatic venous injuries. Such an approach often requires temporarily leaving the abdomen open. Although omentum has been proposed to create the tamponade effect, gauze packing is more expedient and effective. Pachter et al. described a “nonshunting approach” which consists of four components: (1) manual compression and aggressive fluid resuscitation; (2) prolonged portal triad occlusion (mean occlusion time, 46 min); (3) rapid and extensive finger fracture for vascular control, almost always through normal hepatic parenchyma to the site of injury; and (4) wide mobilization of the hepatic attachments with medial rotation of the liver to provide access to both the retrohepatic cava and the hepatic vein.<sup>81</sup> In their series, six of the nine “nonshunted” patients survived.

## **PORTA HEPATIS**

Injuries to the porta hepatis are rare, usually complex, and highly lethal. Review of the literature showed three large series that cumulatively report 180 patients treated between 1965 and 1994.<sup>82-84</sup> These injuries are usually penetrating, occurring in 50% to 100% of the populations reported. Isolated injuries to the portal structures occur and are far more survivable than are multiple injuries. Overwhelming hemorrhage is the usual cause of death in all reported series.

The porta hepatis is composed of the hepatic artery, extrahepatic bile duct system, and the portal vein. The proximity of these structures to other major structures, and their relatively difficult exposure, explains their high lethality. In the multi-institutional survey compiled by the Western Trauma Association and reported by Jurkovich et al.,<sup>84</sup> an overall 51% mortality rate was recorded. When broken down, the mortality rate in single-structure injuries is still 45%, whereas the mortality rate in multiple-structure injuries rises to 80%. This is in line with results in other reports in the literature.

## **PORTAL VEIN**

Injuries to the portal vein are responsible for most deaths ascribed to portal structures. Once identified and the bleeding controlled, the question of repair versus ligation must be addressed. Ligation of the portal vein can be tolerated, in that there will be decompression of the portal hypertension by collateral vessels. Unfortunately, in patients subjected to ligation of the portal vein, the mortality rate is as high as 90%. This is in disagreement with survival rates of 50% to 80% reported previously by Pachter et al.<sup>85</sup> and Stone et al.<sup>86</sup> Patients treated by ligation of the portal vein have greater circumferential disruption of the vein and overwhelming hemorrhage, and ligation is used as a rapid method of bleeding control. Repair of the portal vein is used with lesser degrees of injury—in circumferential injury less than 25%—and is reported to have increased survivability. Many of the deaths occur because of massive hemorrhage before a repair can be accomplished. When confronted with a portal venous injury, repair is preferable to ligation, although ligation is an acceptable option. Second-look laparotomy to check for bowel viability has been advocated when the portal vein has been ligated.

## **HEPATIC ARTERY**

The liver receives a dual blood supply from the hepatic artery and the portal vein, allowing ligation of the hepatic artery without absolutely compromising hepatic blood supply. Lobar artery ligation is well tolerated, but overall mortality rate remains in excess of 40%.

## **EXTRAHEPATIC BILIARY DUCTS**

Bile duct injuries are uncommon, even in this relatively uncommon injury cluster. Partial circumferential disruption can be treated by primary repair as well, as demonstrated from experience with iatrogenic bile duct injury at the time of cholecystectomy. Complex or complete disruption of the ductal tree is best managed by biliary-enteric anastomosis. End-to-end anastomosis has an excessive stenosis rate. Adequate drainage of the area is essential, because bile leaks can occur. On rare occasions, stenting and external drainage have been used in an unstable patient, with biliary reconstruction accomplished at a later date.<sup>87</sup>

The key to the diagnosis of bile duct injury is suspicion that the injury has occurred. Evidence of bile staining and the presence of a duodenal injury should prompt investigation that is best done by an intraoperative cholangiogram. Small injuries may be missed at initial exploration. Endoscopic retrograde cholangiopancreatogram with stenting may provide diagnostic therapeutic answers if a patient develops a biloma subsequent to a missed injury.

Once patients with operative hepatobiliary trauma sustain surgical hemostasis, they may become hypothermic and coagulopathic with bleeding occurring from nonsurgical sources, in particular the raw liver parenchyma. At this point, the liver and other sources of nonsurgical bleeding may be packed with laparotomy pads and a temporary abdominal closure performed.<sup>88-94</sup> Patients can then be transported to the intensive care unit where they may be further resuscitated and warmed. Take-back for removal of the packing and debridement of devitalized liver may generally be undertaken safely in 24 to 48 hours. Omental packing of the liver defect originally described by Stone may reduce the incidence of bile leak and abscess formation.<sup>95</sup>

## **SPECIFIC CONSIDERATIONS FOR PENETRATING**

## **ABDOMINAL TRAUMA**

The evolution in the management of penetrating abdominal trauma parallels the evolution of diagnostic modalities. In the 19th century, expectant (observation) management was the approach of choice worldwide. In the 1880s, Paule Recluse, a French surgeon, advocated supportive care only for penetrating abdominal injuries. Sir William McCormick, chief Army Surgeon during this same period, coined the McCormick aphorism regarding the management of gunshot wounds to the abdomen that stated “if a man undergoes surgery after being shot he dies and lives if left in peace.” Even with a mortality rate that was exceedingly high, such dogma was the standard of care during this era for any penetrating abdominal trauma. With predictably overwhelming morbidity/mortality associated with these injuries, it became apparent that a more aggressive, interventional approach was needed for penetrating injuries to the abdomen, and as a result, mandatory exploration, or celiotomy, became the prevailing management option of choice and essentially the standard of care.

Shafter and Nance’s landmark articles, which emphasized surgical judgment in the management of penetrating wounds of the abdomen, changed the approach to penetrating abdominal injuries from mandatory celiotomy to a more selective management.<sup>96,97</sup> Enhanced diagnostic imaging has greatly assisted in making the nonoperative/selective management a more reliable and acceptable treatment option in penetrating abdominal trauma.

### **Topography and Clinical Anatomy**

The abdomen is often defined as a component of the torso that has for its superior boundary the left and right hemidiaphragm, which can ascend to the level of the nipples (4th intercostal space) on the frontal aspect and to the tip of the scapula in the back. The inferior boundary of the abdomen is the pelvic floor. For clinical purposes, it is helpful to further divide the abdomen into four areas: (1) anterior abdomen (below the anterior costal margins to above the inguinal ligaments and anterior to the anterior axillary lines), (2) intrathoracic abdomen (from the nipple or the tips of the scapula to the inferior costal margins), (3) flank (inferior scapular tip to the iliac crest and between the posterior and anterior axillary lines), and (4) back (below the tips of the scapula to the iliac crest and between the posterior axillary lines). The

majority of the digestive system and urinary tract, along with a substantial network of vasculature and nerves, are contained within the abdominal cavity. A viscera-rich region, the abdomen can often be the harbinger for occult injuries as a result of penetrating wounds, particularly in the unevaluable abdomen as a result of a patient's compromised sensorium.

## Mechanism of Injury

In addition to the hemodynamic status of the patient, important variables in the decision-making regarding management of penetrating abdominal injuries are the mechanism and location of injury. The kinetic energy generated by hand-driven weapons, such as knives and sharp objects, is substantially less than that caused by firearms. Although not always evident, it is important to know the length and width of the wound along with the depth of penetration of the weapon or device that caused the stab injury. For example, a stab injury usually results in a long, more shallow wound that does not penetrate the peritoneum. Local wound management is the primary focus for these injuries with no concern for any potential intra-abdominal injury.<sup>98</sup> Although some stab wounds do not penetrate the peritoneal cavity, such cannot be assumed without some formal determination or serial abdominal examinations to assess for worsening abdominal tenderness or the development of peritoneal signs.

There is notable variability among the full spectrum of firearms in the civilian setting, with this arsenal including mostly handguns, rifles, shotguns, and airguns. The kinetic energy, which correlates with the wounding potential, is dependent on mass and velocity ( $KE = 1/2 mv^2$ ). Therefore, the higher the velocity, the greater the wounding potential.<sup>99</sup> Because the barrel is longer in a rifle than a handgun, the bullet has more time to accelerate—generating a much higher velocity. A high velocity missile is propelled at 2500 feet/second or greater. Airguns usually fire pellets (eg, BBs) and are associated with a lower velocity and wounding potential. Shotguns fire a cluster of metal pellets, called *shot*. The pellets separate after leaving the barrel, with a rapidly decreasing velocity. At a distance, the wounding potential is diminished. However, at close range (less than 15 feet), because of the increase in aggregate mass, the tissue destruction is similar to a high-velocity missile injury.

Although each injury should be handled on an individual basis, there are general principles that will provide some guidance in the management of penetrating injuries based on mechanism of injury. With respect to stab wounds, approximately one-third of the wounds do not penetrate the peritoneum, and only half of those that do penetrate require operative intervention. The number of organs injured and the intra-abdominal sepsis complication rate are significantly less than wounds caused by gunshots.<sup>100,101</sup>

## Physical Examination

A complete and thorough physical examination of the entire body is essential in the management of penetrating abdominal injury. There are some findings (Table 19-10) on physical examination that are absolute indications for operative intervention. The components of the physical exam should include careful inspection, palpation, and auscultation.

**TABLE 19-10: ABSOLUTE INDICATIONS FOR EXPLORATORY LAPAROTOMY IN PENETRATING ABDOMINAL INJURIES**

- A. Peritonitis
- B. Evisceration
- C. Impaled object
- D. Hemodynamic instability
- E. Associated bleeding from natural orifice
- F. Documented pneumoperitoneum

In addition to being able to determine the location, extent, and the number of wounds, inspection can sometimes determine the trajectory of the missile or other wounding agent, and consequently guide management decisions. For example, a patient with a documented, superficial tangential gunshot wound (low-velocity) with no other remarkable physical findings would likely be managed expectantly (observation). However, if a penetrating abdominal injury results in a patient presenting with an evisceration, exploratory laparotomy would be the management option of choice. Palpation will enable

the examiner to elicit abdominal tenderness or frank peritoneal signs, along with being able to detect abdominal distention and rigidity. On occasion, missiles can be palpated lodged in the soft tissue. Unless in a controlled and sterile setting such as the operative theater, probing of a wound should be avoided. Auscultation is also an important component of the physical examination. It can help determine diminished or absent bowel sounds that could be suggestive of evolving peritonitis. Also, auscultation could detect a trauma-induced bruit, suggestive of a vascular injury.

The examiner has to be keenly aware of the fact that there are situations in which the abdominal exam will be unreliable due to possible spinal cord injury or a patient's altered mental state.

## Diagnostic Studies

Even with penetrating injuries, the abdomen is notorious for hiding its secrets—occult injuries. Access to an extensive diagnostic armamentarium is imperative in the optimal management of these injuries. Strongly advocated by some for abdominal stab wounds, local wound exploration has the advantage of allowing the patient to be discharged from the trauma bay or emergency department if surgical exploration of the wound fails to demonstrate penetration of the posterior fascia and peritoneum. However, if the patient has to go to the operating room for other injuries, the local wound exploration should be done in the surgical suite, which will have better lighting and a more sterile environment. A positive finding during local wound exploration dictates a formal laparotomy or laparoscopy. However, even with local wound exploration as a guide, the nontherapeutic laparotomy rate can be high, given that only one-third of the patients with stab wounds to the anterior abdomen require therapeutic laparotomies.<sup>102,103</sup> In the patient who has an evaluable abdomen, serial abdominal examinations would be an acceptable alternative to local wound exploration in order to determine the need for operative intervention. Local wound exploration should only be done for stab wounds to the anterior abdomen. Such an approach is potentially too hazardous for thoracoabdominal penetrating injuries and back/flank wounds. Plain radiography (abdomen/pelvis/chest) can be pivotal in documenting the presence of missiles and other foreign bodies and determining the trajectory of the injury tract, particularly for wounds from firearms. Also, the presence of free air might be confirmed by plain radiography. Unless there is concern

about a retained broken blade, there is little utility for plain radiography for stab injuries.<sup>104</sup> DPL has never had a broad appeal in the diagnostic evaluation of penetrating abdominal wounds. Although some have advocated its use with tangential wounds of the abdominal wall, the technique has failed to receive widespread support.<sup>105</sup> Its reliability in detecting clinically significant injuries sustained as a result of penetrating abdominal injuries has been an ongoing concern.<sup>106–108</sup> The reported sensitivity and specificity of DPL for abdominal stab wounds are 59% to 96% and 78% to 98%, respectively.<sup>109</sup> Also, DPL is a poor diagnostic modality for detecting diaphragmatic and retroperitoneal injuries.

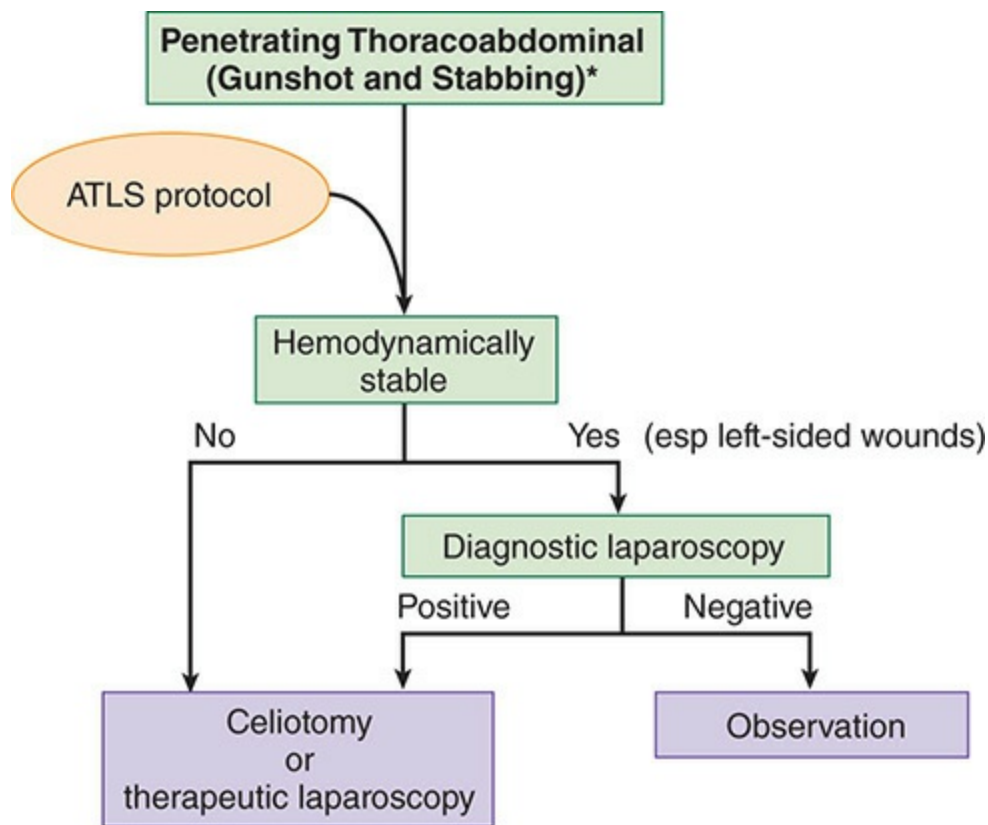

As with blunt trauma, diagnostic imaging has had the greatest impact in changing the face of trauma management, with CT taking the lead in this area. Its ubiquitous presence in the management of blunt abdominal trauma has been underscored. However, it is becoming an important diagnostic study in the evaluation of penetrating abdominal injuries. In addition to its excellent sensitivity in detecting a pneumoperitoneum, free fluid, and abdominal wall/peritoneal penetration, CT is helpful in identifying the tract of the penetrating agent. Hauser et al. recommended the use of “triple contrast” CT in the assessment of penetrating back and flank injuries.<sup>110</sup> CT scan evaluation is an essential diagnostic tool in the increasing advocacy for selective management of abdominal gunshot wounds obviating the need for mandatory surgical exploration.<sup>111</sup> However, there still remain two major limitations of CT: detection of an intestinal perforation and a diaphragmatic injury.

Unless the injury is confined to the solid organ of the abdomen, such as the liver or spleen, the matrix of intestinal gas patterns makes detection of penetrating injuries difficult. Kristensen, Buemann, and Kuhl were one of the first teams to introduce the role of ultrasonic scanning as part of the diagnostic armamentarium in trauma management.<sup>112</sup> Kimura and Otsuka endorsed using ultrasonography in the emergency room for evaluation of hemoperitoneum.<sup>113</sup> FAST does not have the same broad application in the evaluation of penetrating trauma as it does in blunt trauma assessment. Rozycki et al. reported on the expanded role of ultrasonography as the “primary adjuvant modality” for the injured patient assessment.<sup>114</sup> Rozycki also reported that FAST examination was the most accurate for detecting fluid within the pericardial sac. Such a finding would be confirmatory for a

possible cardiac injury and potential or existing cardiac tamponade, given a mechanism of injury that could result in a traumatic cardiac injury.

As a diagnostic modality, laparoscopy has been used by other specialists for several decades. However, it was formally introduced as a possible diagnostic procedure of choice for specific torso wounds when Ivatury et al. did a critical evaluation of laparoscopy on penetrating abdominal trauma.<sup>115</sup> Fabian et al. also reported on the efficacy of diagnostic laparoscopy in a prospective analysis.<sup>116</sup>

With there no conventional diagnostic tool that can conclusively rule out a diaphragmatic laceration or rent, diagnostic laparoscopy becomes the study of choice for penetrating thoracoabdominal injuries, particularly left thoracoabdominal wounds (Fig.19-7). Laparoscopy can also be used to determine peritoneal entry from a tangential penetrating injury.

\*Operative intervention is mandatory for all high-velocity injuries, irrespective of left or right.

**FIGURE 19-7** Management algorithm for penetrating thoracoabdominal injuries.

## **Penetrating Abdominal Injuries and the Hemodynamically Stable and Unstable Patient**

As highlighted above, the management principles in patients who sustain penetrating abdominal injuries and remain hemodynamically stable depend on the mechanism and location of injury along with the hemodynamic status of the patient. Irrespective of the patient's hemodynamic parameters, the ATLS protocol should be strictly followed upon arrival of the patient to the trauma bay.<sup>117</sup>

### **Trauma Laparotomy**

The operative theater should be large enough to accommodate more than one surgical team in the event the patient might require simultaneous procedures to be performed. In addition, the room should have the capability of maintaining room temperature as high as the lower 80s F plus range in order to avoid having a hypothermic patient. There should be a rapid transfusion device in the room to facilitate the delivery of large fluid volume and ensure that the fluid administration is appropriately warm.

Abdominal exploration for trauma has basically four imperatives: (1) hemorrhage control, (2) contamination control, (3) identification of the specific injury(ies), and (4) repair/reconstruction. The abdomen is prepared with a topical antimicrobial from sternal notch to bilateral mid-thighs and extending the prep laterally to the side of the operating room table, followed by widely draping the patient. Such preparation allows for expeditious entry into the thorax if needed and possible vascular access or harvesting. Exploration is initiated with a midline vertical incision that should extend from the xyphoid to the symphysis pubis in order to achieve optimal exposure.

The first priority upon entering the abdomen is control of exsanguinating hemorrhage. Such control can usually be achieved by direct control of the lacerated site or obtaining proximal vascular control. After major hemorrhage is controlled, blood and blood clots are removed. Abdominal packs (radiologically labeled) are used to tamponade any bleeding and allow for identification of any injury bleeding. The preferred approach to packing is to divide the falciform ligament and retract the arterial abdominal wall. This

will allow manual placement of the packs above the liver. Abdominal packs should also be placed below the liver. This arrangement of the packs on the liver creates a compressive tamponade effect. After manually eviscerating the small bowel out of the cavity, packs should be placed on the remaining three quadrants, with care taken to avoid any iatrogenic injury, especially to the spleen. During the packing phase after ongoing hemorrhage has been controlled, the surgeon should communicate with the anesthesia team that major hemorrhage has been controlled and that this would be an optimal time to establish a resuscitative advantage with fluid/blood/blood product administration.

The next priority should be control or containment of gross contamination. This begins with the removal of the packs from each quadrant—one quadrant at a time. Packs should be removed from the quadrants that you least suspect to be the source for blood loss, followed by removal of the packs from the final quadrant—the one that you believe is the area of concern.

After control of major hemorrhage has been achieved, any evidence of gross contamination must be addressed immediately. Obvious leakage from intestinal injury can be initially controlled with clamps (eg, Babcock clamp), staples, or sutures. The entire abdominal gastrointestinal tract needs to be inspected, including the mesenteric and antimesenteric border of the small and large bowel, along with the entire mesentery. Rents in the diaphragm should also be closed to prevent contamination of the thoracic cavity.

Further identification of any and all intra-abdominal injuries should be initiated. Depending on the mechanism of injury and the estimated trajectory of wounding agent, a thorough and meticulous abdominal exploration should be performed, including entering the lesser sac to better inspect the pancreas and the associated vasculature. In addition, mobilization of the C-loop of the duodenum (Kocher maneuver) might be required, along with medical rotation of the left and/or right colon for exposure of vital retroperitoneal structures.

The final component of a trauma laparotomy is definitive repair, if possible, of specific injuries. The status of the patient dictates whether each of the components of a trauma laparotomy can be achieved at the index operation. A staged celiotomy (“damage control” laparotomy) might be necessary if the patient becomes acidotic, hypothermic, develops coagulopathy, or is hemodynamically compromised.

# Definitive Management of Specific Injuries

## SMALL INTESTINES

Isolated small bowel enterotomies can be closed primarily with nonabsorbable sutures for a one-layer closure. If the edges of the enterotomy appear nonviable they should be gently debrided prior to primary closure. However, multiple contiguous small bowel holes or an intestinal injury on the mesenteric border with associated mesenteric hematoma will likely necessitate segmental resection and anastomosis of the remaining viable segments of the small bowel. The operative goal is always the reestablishment of intestinal continuity without substantial narrowing of the intestinal lumen, along with closure of any associated mesenteric defect. Application of non-crushing bowel clamps can contain ongoing contamination while the repair is being performed. Although a hand-sewn or stapler-assisted anastomosis is operator dependent, trauma laparotomies are time-sensitive interventions and expeditious management is imperative.

## COLON

The segment of injured bowel should be thoroughly inspected, particularly missile injuries that are most common—through-and-through enterotomies. This requires adequate mobilization of the colon in order to visualize the entire circumference of the bowel wall. Initially controversial, an enterotomy (right- or left-sided injuries) of the colon can be closed primarily, irrespective of contamination or transient shock state.<sup>118</sup> If the colon injury is so extensive that primary repair is not possible or would severely compromise the lumen, a segmental resection should be performed. Depending on the environmental setting, the remaining proximal segment can be anastomosed to the distal segment, or a proximal ostomy and Hartmann procedure can be performed. If the distal segment is long enough, a mucous fistula should be established. Documented rectal injuries below the peritoneal reflection should necessitate constructing a diverting colostomy and presacral drainage (exiting from the perineum). Such drainage is, however, not universally endorsed.

## STOMACH/DUODENUM

With respect to penetrating wounds of the stomach, the anterior and posterior

aspects of the stomach need to be meticulously inspected for accompanying through-and-through injuries. Penetrating injuries of the stomach should be repaired primarily after debridement of nonviable edges. The primary repair can either be performed in a single layer with nonabsorbable suture or as a double-layer closure with an absorbable suture (eg, Vicryl) for the first layer, the second layer being closed with nonabsorbable sutures (eg, silk). There are very few penetrating injuries of the stomach that would compromise the gastric lumen. Also, it is unlikely that primary repair of a through-and-through stomach injury would compromise the gastric lumen. Duodenal injuries can be repaired primarily in a one- or two-layered fashion if the penetration is less than half the circumference of the duodenum. However, for more complex duodenal injuries, an operative procedure is needed to divert gastric contents away from the site (where closure of the wound has been attempted). Performing a pyloric exclusion with the establishment of a gastrojejunostomy is such a procedure.<sup>119–121</sup>

## **PANCREAS**

Superficial or tangential penetrating wounds of the pancreas in which there is not an injury to the main pancreatic duct can be externally drained. However, a penetrating injury that transects the pancreas, including the main pancreatic duct, requires extirpation of the distal pancreas (distal pancreatectomy), particularly if the transection site is to the left of the superior mesenteric vessels. A more proximal penetrating injury that involves the main pancreatic duct, with associated complex duodenal injury (eg, injury to the ampulla), would likely necessitate a pancreatoduodenectomy. Unfortunately, because of the rich vascular network surrounding the pancreas, penetrating pancreatic wounds can be lethal injuries.

## **SPLEEN**

Most penetrating splenic injuries, particularly gunshot wounds, require a splenectomy. In order to visualize the entire spleen, it should be mobilized to the midline by dividing its ligamentous attachments. Superficial penetrating injuries of the spleen can sometimes be managed by either splenorrhaphy or application of a topical hemostatic agent. Splenorrhaphy can be done by a pledgeted repair or an omental buttress. However, complex repair of the

spleen is not a prudent approach in the always time-sensitive trauma setting.

## GALLBLADDER AND LIVER

Penetrating injuries to the gallbladder dictate the need for extirpation. There is no role for primary repair of a penetrating wound to the gallbladder.

Liver injuries are common in both blunt and penetrating trauma. The majority of injuries are superficial or minor and require no surgical repair. Simple application of pressure and/or a hemostatic agent or fibrin glue will constitute definitive management of the majority of these injuries. The argon beam coagulator, also a helpful adjunct in superficial hepatic injuries with persistent oozing, generates ionizing energy through an argon gas stream that causes rapid coagulation. The operative armamentarium for complex penetrating hepatic injuries is highlighted in [Table 19-11](#).

**TABLE 19-11: CONSIDERATIONS FOR HEPATIC INJURY**

- Portal triad occlusion (Pringle maneuver)
- Hepatic artery ligation
- Hepatotomy (sharp or finger fracture with distal vein isolation)
- Resectional debridement
- Omental buttress
- Intrahepatic balloon tamponade
- Atrial caval shunt (to the superior vena cava)
- Abdominal packing

## GENITOURINARY SYSTEM

Less than 10% of patients with penetrating abdominal wounds sustain genitourinary tract injuries. The majority of the injuries are renal. Penetrating injuries that result in a grade IV (cortical/calycal injury and associated vascular injury with contained hemorrhage) or grade V (shattered kidney and vascular avulsion) invariably necessitate a nephrectomy, particularly if there is a viable contralateral kidney. Lacerations or more superficial wounds of the kidney might require renorrhaphy, with approximation of the disrupted

capsule with pledgeted sutures or a prosthetic (mesh) wrap. Absorbable interrupted suture should be used, and all repairs should be drained. The injury pattern might dictate the need for a partial nephrectomy. Ureteral injuries can be extremely difficult to identify in penetrating wounds with an accompanying retroperitoneal hematoma. When possible, the ureter should be repaired primarily with interrupted absorbable suture over a double J stent. A complete transection of the ureter requires debridement of the nonviable edges, spatulation of the ends, and primary repair over a stent. All repair sites should be adequately drained. If the anastomosis cannot be performed in a tension-free fashion, a bladder flap (Boari) could be surgically constructed, with implantation of the proximal segment of the transected ureter into the flap. A psoas “hitch” might be required if there is any tension on the flap and the tunneled ureter.

Penetrating injury to the intraperitoneal bladder requires surgical repair. After confirming that there is no involvement of the trigone, the bladder should be closed with a two-layer closure with absorbable suture (the second layer incorporates Lembert sutures to imbricate the first layer). Suprapubic drainage should only be done selectively; however, a Foley catheter should be left in place.

## **Retroperitoneal Hematomas**

The retroperitoneum, an organ-rich region, has several vital structures that can be injured when its boundaries are penetrated. It can be a major potential site for hemorrhage in patients sustaining either penetrating or blunt trauma, due to the substantial vascularity along with bleeding that can occur from an associated solid organ wound (eg, kidney). In the central region (Zone 1) of the retroperitoneum resides the abdominal aorta, celiac axis, and the superior mesenteric artery, vena cava, and proximal renal vasculature. The lateral retroperitoneum (Zone 2) encompasses the proximal genitourinary system and its vasculature. The pelvic retroperitoneum (Zone 3) contains the iliac arteries, veins, and their tributaries. In addition to the vasculature and the kidneys (plus ureters), the retroperitoneum contains the second, third, and fourth portion of the duodenum, along with the pancreas, the adrenals, and the intrapelvic portion of the colon and rectum. [Table 19-12](#) underscores the management principles of trauma-related retroperitoneal hematomas. Ideally, proximal (and when applicable, distal) control needs to be achieved prior to

exploring any retroperitoneal hematoma. For retroperitoneal hematomas in Zone I, irrespective of a penetrating or blunt mechanism, mandatory exploration is required. Also, retroperitoneal hematoma in any of the three zones requires exploration for all penetrating injuries. For Zone II retroperitoneal hematomas resulting from blunt trauma, all pulsatile or expanding hematomas should undergo exploration. Gross extravasation of urine also necessitates exploration. Zone III (pelvic retroperitoneum) hematomas should be explored only for penetrating injuries to determine if there is a specific intrapelvic colorectal, ureteral, or vascular injury. However, such an approach should not be taken for blunt trauma, as the injury would likely be venous, and application of an external compression device would be the preferred intervention. An arterial injury could be addressed by arteriography/embolization.

## SPECIAL INTERVENTIONS

### Intra-Abdominal Packing and “Damage Control” Strategy

“Damage control” strategy, popularized by Rotondo et al., is a staged celiotomy strategy that was initially made operationally viable by Mattox and Feliciano and labeled the “Bogota bag” approach. Although this approach was not actually developed by them, Mattox and Feliciano popularized the technique and made it acceptable for use in this country.<sup>122–126</sup> Regardless of the name given to this strategy of surgically managing only immediate life-threatening injuries (along with intra-abdominal packing and rapid temporary closure of the abdominal cavity), the goal is the same—avoiding the potential irreversibility of sustained acidosis, hypothermia, coagulopathy, and

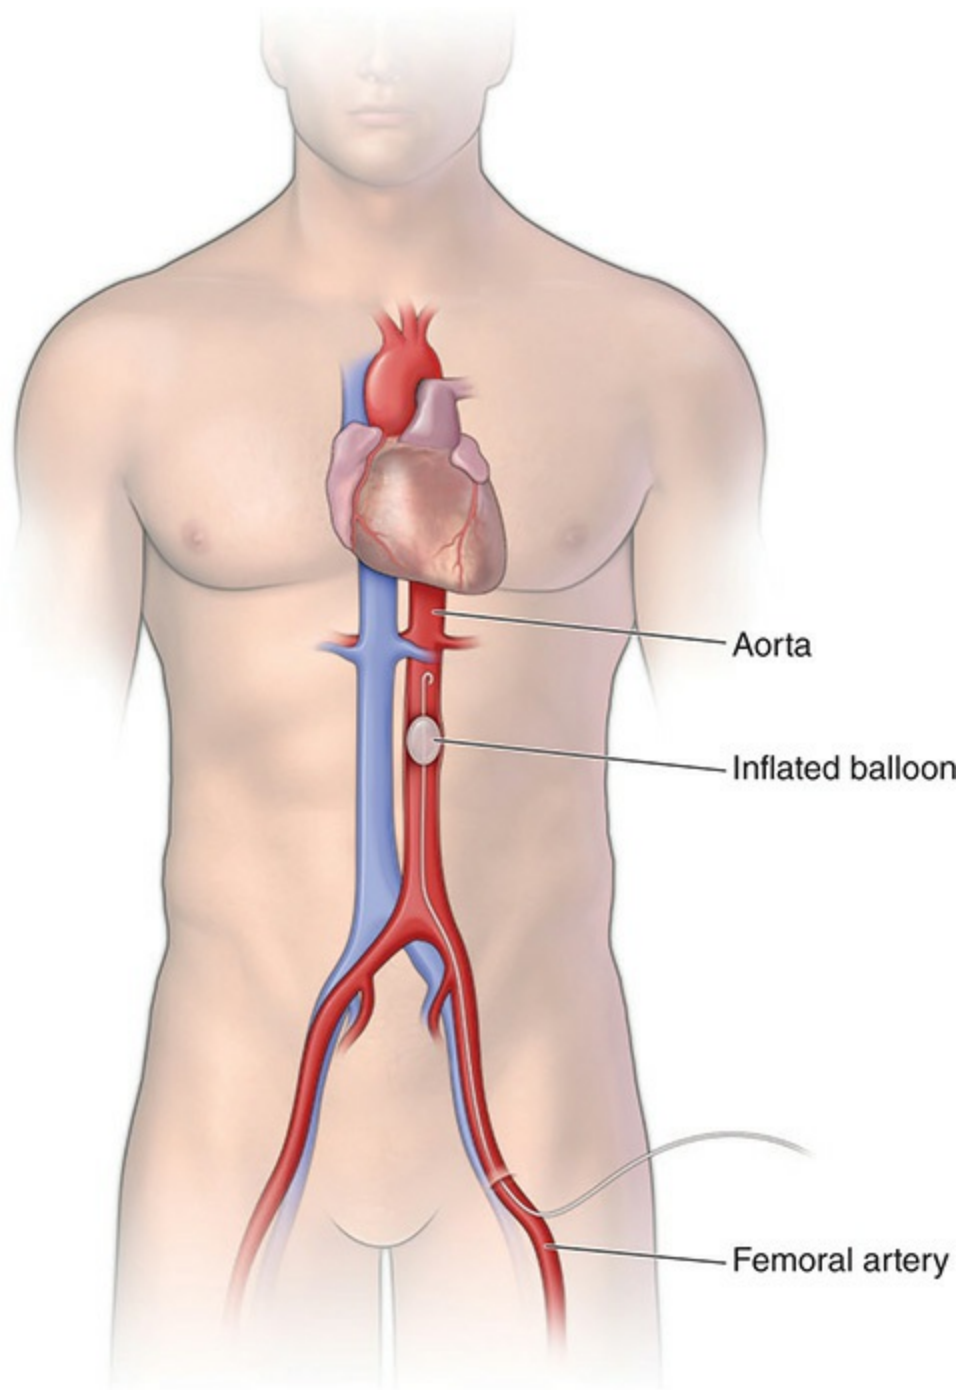

hemodynamic lability by delaying definitive operative management until the patient can be stabilized in the intensive care unit. Although “damage control” is most frequently used in association with severe hepatic wounds, other organ injuries, including vascular wounds, can necessitate this staged celiotomy approach with hepatic packing and a rapid, creative abdominal closure.

## **Resuscitative Endovascular Balloon Occlusion of the Aorta**

Bleeding remains the leading cause of preventable death in trauma patients that reach the hospital.<sup>127</sup> Both penetrating and blunt trauma can lead to life-threatening injury of the abdominal vasculature. Traumatic injury to vessels may occur via direct laceration and transection or blunt injury resulting in dissection or thrombosis. While endovascular treatment of abdominal vascular injuries has become increasingly utilized, the unstable patient with active hemorrhage will still require open surgical intervention.<sup>128</sup> Appropriate management of these patients centers on prompt recognition of the injury, rapid exposure, and control of hemorrhage. Prior to operative intervention, the use of permissive hypotension has been shown to improve survival and decrease hospital stay. The goal of permissive hypotension is to maintain perfusion to the vital organs while decreasing the amount of hemorrhage and clot disruption at the site of injury. Improved outcomes are thought to be due to the improved thrombus formation at the site of injury as well as a decrease in both dilutional and consumptive coagulopathy.<sup>129</sup> Despite advances in technology, mortality from abdominal vascular injury remains high, with mortality from penetrating injuries to the abdominal aorta approaching 80%.<sup>130</sup> Survival of these patients hinges on rapid exposure and control of the hemorrhage. Operative exposure of abdominal vasculature and surgical repair is described in detail [Chapter 20](#), Abdominal Vascular Emergencies. Resuscitative endovascular balloon occlusion of the aorta (REBOA) is gaining popularity as an adjunct for controlling major intra-abdominal hemorrhage. The technique was first described in 1953 during the Korean War by Dr. Lieutenant Colonel David Hughes on three soldiers in hemorrhagic shock. The surgeon placed a Foley through the femoral artery to provide proximal vascular control. Although none of the three patients

survived, Hughes noted temporary improvement with inflation of the balloon.<sup>131</sup> However, the procedure was not widely adopted during this time, likely due to concerns regarding the technical difficulty of the procedure and availability of the equipment needed. In 2000, Greenberg and colleagues first described the use of an aortic balloon occlusion device to control hemorrhage prior to endovascular repair for ruptured abdominal aortic aneurysms in three patients.<sup>132</sup> As the use of REBOA has continued to increase in the field of vascular surgery, it has also recently gained momentum as an effective method of obtaining proximal control in the setting of life threatening abdominal or pelvic trauma.

REBOA is currently indicated for refractory hemorrhagic shock due to abdominal or pelvic trauma. The goal of REBOA is to provide proximal control of abdominal vascular hemorrhage prior to transport to the operating room or angiography suite (Fig. 19-8). After the groin has been prepped, the common femoral artery is accessed with a standard hollow 18-gauge vascular access needle. It is important that incorrect placement, either too proximally into the iliac artery or too distally into the superficial femoral artery, be avoided. As many of these patients may not have a readily palpable femoral pulse, the artery can be accessed using standard anatomical landmarks, ultrasound guidance, or via direct exposure through an open cutdown. Once the artery is accessed, a 0.035-inch wire is fed through the needle in standard Seldinger fashion. Traditionally, a 6 Fr vascular sheath and dilator are placed and then upsized to an 11 to 14 Fr sheath depending on the size of the balloon being used; however, newer “one-pass” sheaths and dilators are currently in production for the trauma setting.<sup>133</sup> Once the appropriate size sheath is in place, a stiff Amplatz guidewire is placed through the sheath. The balloon device is then fed over the guidewire to the correct position.<sup>134</sup>

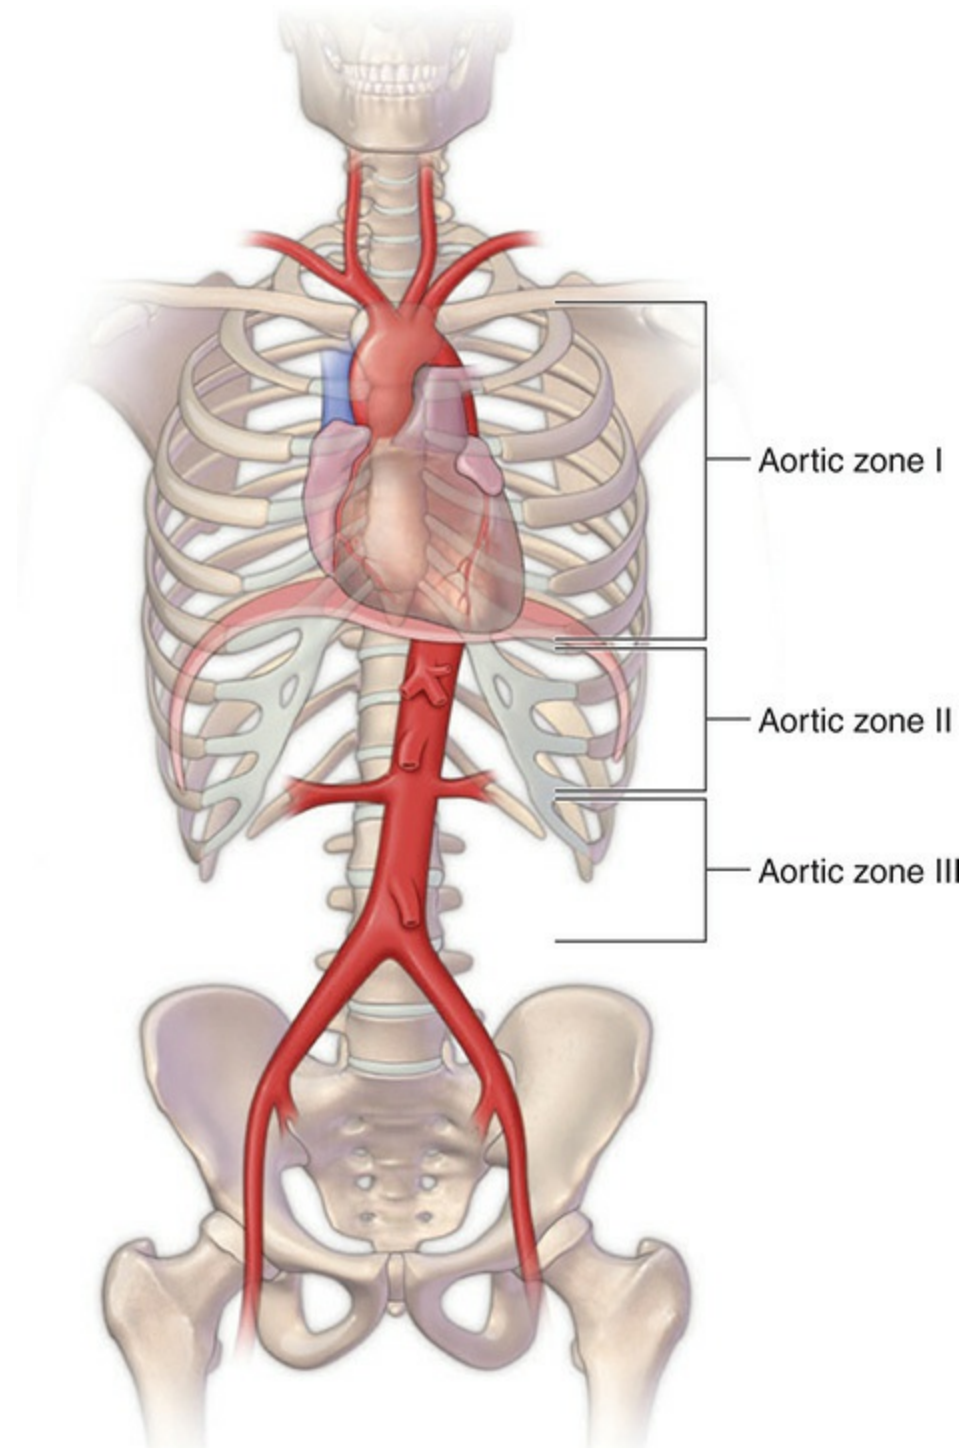

**FIGURE 19-8** Aortic balloon occlusion device (ER-REBOA).

The location of the balloon in the aorta is determined by the presumed location of the trauma, divided into three distinct zones (Fig. 19-9). Zone I is the proximal zone of the descending aorta between the left subclavian and celiac trunk. Placement of the balloon in this zone is recommended for

abdominal and visceral trauma. Zone II encompasses the abdominal vasculature from the celiac artery to the lowest renal artery. Placement of the balloon in Zone II is contraindicated, as it is possible to directly occlude the celiac artery, superior mesenteric artery, or renal arteries, resulting in organ ischemia. Zone III extends from the lowest renal artery to the aortic bifurcation. Positioning of the balloon in this zone provides proximal control for pelvic hemorrhage while still maintaining perfusion to the abdominal organs. Correct positioning of the balloon can be accomplished with either fluoroscopy, plain film radiograph in the trauma bay, or by physical landmarks.<sup>135</sup>

**FIGURE 19-9** Aortic zones for positioning of REBOA device. Zone I between subclavian artery and celiac artery, Zone II between the celiac artery and the lowest renal artery, and Zone III between the lowest renal artery and the aortic bifurcation.

Once positioned, the balloon is then inflated with either saline or a 1:1

mixture of saline and contrast if fluoroscopy is being utilized. Appropriate filling of the balloon can be confirmed by either visualization of the balloon flattening against the wall of the aorta if using fluoroscopy, or loss of a pulse in the contralateral femoral artery. Several animal studies have demonstrated that aortic occlusion times greater than 60 minutes may result in severe physiological derangement and irreversible organ failure, thus it is imperative that the surgeon be mindful of the duration of balloon inflation and should limit this to less than 60 minutes. After hemorrhage has been controlled, the balloon should be slowly deflated with ongoing communication between the surgeon and the anesthesiologist, as there may be abrupt periods of hypotension as the balloon is deflated. Prior to sheath removal, the common femoral artery should be exposed and the arteriotomy should be closed transversely with 5-0 or 6-0 monofilament suture.

Concerns regarding the use of REBOA focus on incorrect placement of the device, effectiveness in controlling hemorrhage, and potential for organ ischemia. One of the initial case series in 1989 documented the use of REBOA in trauma patients and found that trauma surgeons were able to appropriately position and deploy the balloon and the balloon was able to control hemorrhage in 11 out of 21 patients with refractory hemorrhagic shock.<sup>136</sup> Brenner and colleagues published a recent case series of six trauma patients with severe hemorrhagic shock in which REBOA was utilized prior to angiographic or surgical control of the hemorrhage. REBOA resulted in an average increase in systolic blood pressure of 55 mm Hg, and none of the patients died as a result of hemorrhage.<sup>137</sup> Additional studies have shown similar rates of successful placement and control of hemorrhage in patients with both blunt and penetrating abdominal trauma.<sup>138,139</sup>

While in many situations the most effective method to control hemorrhage will be direct control via laparotomy or embolization, REBOA is a technically feasible and potentially life-saving adjunct in the patient with refractory and end-stage hemorrhagic shock. As the technology for the REBOA devices improves and more clinical research is performed, REBOA will likely become more widespread as a rapid and effective method of hemorrhage control prior to definitive surgical repair for life-threatening abdominal and pelvic trauma.

## CONCLUSION

In addition to the management of abdominal trauma that has been described throughout the chapter for both blunt and penetrating trauma, there are several proposed treatment paradigms for many of the injuries sustained in trauma. However, the standard-of-care management for an individual is heavily dependent on the resources and personnel available, along with transport options, if any. Resource-rich trauma systems exist throughout the country, with highly qualified personnel. However, these systems are not uniform throughout the nation and the concept of regionalization has not been perfected for all regions. The overarching goal remains the same: optimal management for everyone, regardless of where the patient receives trauma care.

# ABDOMINAL VASCULAR EMERGENCIES

*John J. Ricotta • Cameron M. Akbari*

## INTRODUCTION

Among the many acute abdominal conditions that confront the general surgeon, disorders involving the vascular system are in the minority. Yet these conditions are often highly lethal if undiagnosed or inappropriately treated. Because operations involving vascular exposure, control, and repair are uncommon in the practice of most abdominal surgeons, a straightforward plan to identify and manage these conditions is required for optimal success. This chapter concerns itself with the general diagnosis of acute vascular abdominal conditions, principles of vascular control and repair, and a discussion of the management of the 3 most common types of vascular emergency: mesenteric ischemia, ruptured abdominal aneurysm, and abdominal vascular trauma. Whenever possible, emphasis is placed on general principles that can be applied to a variety of conditions. Acute pathology of the gastrointestinal tract that results in hemorrhage (eg, bleeding ulcer, esophageal varices, bleeding diverticula) is not considered within this chapter.

## GENERAL DIAGNOSTIC CONSIDERATIONS

Acute vascular conditions can be divided into those associated with hemorrhage and those accompanied by vascular thrombosis. The presentation within each of these 2 broad categories is generally distinct. Conditions associated with hemorrhage present with evidence of blood loss including shock. Hemodynamic alterations, for example hypotension and tachycardia, predominate over physical findings. Signs of an “acute abdomen,” specifically peritoneal irritation, are often absent. While abdominal pain is usually present, it is often focal and may be associated with a palpable abdominal mass. Signs of shock in the absence of generalized peritonitis or visceral perforation should prompt the consideration of a vascular emergency. In contrast, vascular thrombosis leads to intestinal ischemia and perforation. The clinical presentation of vascular thrombosis is often identical to that of other acute nonvascular abdominal conditions that cause an acute abdomen. Stigmata of cardiovascular disease, for example peripheral vascular occlusions, history of cardiac disease, atrial fibrillation, vascular bruits, and advanced age, should all increase the clinical suspicion of a vascular event as the underlying cause of symptoms. Nevertheless, thrombotic vascular complications often remain undiagnosed until the time of laparotomy.

While physical examination may help to identify patients with intra-abdominal or retroperitoneal bleeding (signs of hemorrhagic shock, absence of peritonitis), routine laboratory evaluations are less helpful. Acute hemorrhage may not result in changes in hemoglobin in its early stages. Laboratory studies are generally useful in excluding other acute inflammatory states, such as pancreatitis, and acute processes of the biliary tree or intestine. Plain films of the abdomen may reveal vascular calcifications or suggest hemorrhage (loss of psoas shadow) but are often nondiagnostic. Computed tomography (CT) scanning, when available, is the most useful preoperative diagnostic study ([Fig. 20-1](#)). With the addition of intravenous contrast, CT angiography (CTA) can identify vascular calcifications, aneurysms, and pseudoaneurysms; localize and quantify blood loss; and often identify thrombosis of major arterial and venous structures. Refinements in CTA, such as 3-dimensional (3D) reconstructions, have markedly reduced the need for diagnostic angiography and streamlined the evaluation of all patients with acute abdominal problems. In addition to visualizing vascular structures, nonvascular findings on CT scan may raise the suspicion of an acute vascular

emergency.<sup>1,2</sup> Thickening of the bowel wall and pneumatosis intestinalis may be present without an identifiable lesion in the mesenteric arterial or venous system. Evidence of visceral embolization, particularly in the spleen or liver, should suggest a proximal embolic source, most often from endocarditis. Evidence of a shrunken kidney is a sign of visceral atherosclerosis and, while a nonspecific finding, should increase suspicion of disease in other visceral beds.

**FIGURE 20-1** Noncontrast CT scan demonstrating calcium in the wall of the aorta (*dark arrow*) and retroperitoneal hematoma with fresh blood (*white arrow*) diagnostic of ruptured abdominal aortic aneurysm (AAA).

CT scanning cannot identify all acute vascular conditions, particularly when intravenous contrast is not administered, and scans may not be performed before laparotomy in a number of emergent cases. Under these circumstances, the diagnosis of an acute vascular emergency is made at the time of laparotomy. Most often this diagnosis is obvious on clinical grounds, identification of a mesenteric or retroperitoneal hematoma, presence of free

blood in the abdomen, or the presence of infarcted bowel without evidence of internal hernia.

## VASCULAR EXPOSURE AND CONTROL

Expeditious vascular exposure and control is essential for optimal management of vascular emergencies. The principles of operative vascular control are well established: proximal and distal control in a relatively normal area of the vessel. Proximal control should always be established before the lesion is addressed. When attempts to establish distal control would result in excessive dissection or cause damage to adjacent tissues and organs, the vessel is opened after proximal control is established and distal control established intraluminally by placing balloon catheters to control back bleeding. Increasingly, intraluminal techniques are being used for establishing proximal arterial control from remote access sites. *Antegrade* intravascular balloon control can be established without concern for balloon migration from arterial pulsation. A good example of this is placement of an arterial occlusion balloon in the suprarenal abdominal aorta through the arm vessels.<sup>3</sup> When the balloon catheter is placed from a site distal to the artery (retrograde control), the balloon must be buttressed to avoid migration as a result of the repetitive force of arterial pressure.<sup>4</sup> This can be done by supporting the catheter and balloon by a rigid sheath on which the balloon can rest. Balloon catheters can be used to tamponade proximal collateral bleeding if the main arterial inflow has otherwise been controlled. The most common example of this is the combination of supraceliac clamping coupled with placement of a Foley catheter to control collateral visceral back bleeding during repair of a ruptured aortic aneurysm.

In cases of active hemorrhage or when dissection is difficult, initial venous control is usually obtained by external pressure. Extensive venous dissection is usually avoided to reduce iatrogenic venous damage. Circumferential venous dissection must be meticulous because of the many venous tributaries and the fragility of the vein wall. Intraluminal balloons can be combined with external compression for both proximal and distal control in cases of venous injury, because this is a low-pressure system and catheter dislodgement is not a problem.

Endovascular techniques have been applied across all aspects of vascular

surgery, and management of abdominal vascular emergencies is no exception. However, the application of most of these techniques requires angiographic capabilities in the operating room and significant endovascular experience. In routine practice, the most expeditious way to achieve control remains open exposure. Endovascular techniques remain most useful when they replace extensive or dangerous open dissection. While endovascular options will be discussed within the context of each disease process, these approaches will not be described in detail within this chapter. What follows is a description of the open surgical approach to control of the major abdominal vessels.

## Exposure of the Aorta

### SUPRACELIAC EXPOSURE

Expeditious supraceliac control of the abdominal aorta is the most important and versatile technique in the management of abdominal vascular emergencies. While suprarenal, intrarenal, and occasionally supramesenteric controls of the aorta are all possible, there is no evidence that these prove superior to supraceliac aortic control as long as visceral ischemia is limited to 45 minutes or less. Supraceliac aortic control can be achieved rapidly with very little risk of damage to adjacent organs such as the intestines, pancreas, or vena cava or the visceral vessels. Finally, the supraceliac aorta is most likely to be free of either aneurysmal or atherosclerotic vascular disease. For this reason, exposure and control of the aorta at that level is easier and safer than control between the visceral vessels.<sup>5</sup> Supraceliac control of the aorta through a left retroperitoneal approach has been well described<sup>6</sup> but is not germane in this situation, because it precludes evaluation of the abdominal viscera. Therefore, only the transabdominal exposure of the supraceliac aorta is described.

The supraceliac aorta is approached through the gastrohepatic ligament, which is divided between clamps (Fig. 20-2A). The left lobe of the liver is mobilized by dividing its diaphragmatic attachments if necessary. Division of the gastrohepatic ligament brings one directly down on to the esophagus and aorta as they course through the diaphragmatic hiatus. The aorta lies to the right of the esophagus and should be easily palpable. In the event that the 2 organs are not easily distinguishable, a nasogastric or orogastric tube may be

placed in the esophagus to aid in distinguishing, but this is rarely required in our experience. Once the aorta has been identified, the key to obtaining control is complete division of the fibers of the left crus of the diaphragm as they cross the anterior aspect of the aorta (Fig. 20-2B). This can be done by placing either the index finger or a large-angled clamp between the aorta and the crural fibers as they cross over its anterior aspect. The fibers are divided, slightly to the left of the midline (“2 o’clock” position) to avoid bleeding, either with scissors or electrocautery. The phrenic arteries are identified and either clipped or, preferentially, spared. One cannot overemphasize the importance of completely dividing these fibers and clearing the anterior, medial, and lateral aspects of the aorta prior to applying the vascular clamp. If this is not done, any aortic clamp will slip anteriorly, resulting in loss of aortic control with disastrous results. Once the crura are divided, the aorta is encircled between the thumb and index finger of the operating surgeon’s right hand (Fig. 20-2C). The aorta is then lifted gently off the spine to be sure that it has been completely mobilized. A clamp can then be reliably placed across the aorta. More extensive dissection of the aorta is not required, and we avoid passing angled clamps and loops under the aorta to minimize damage to intercostal vessels. Use of the index finger and a straight aortic clamp are all that is required.

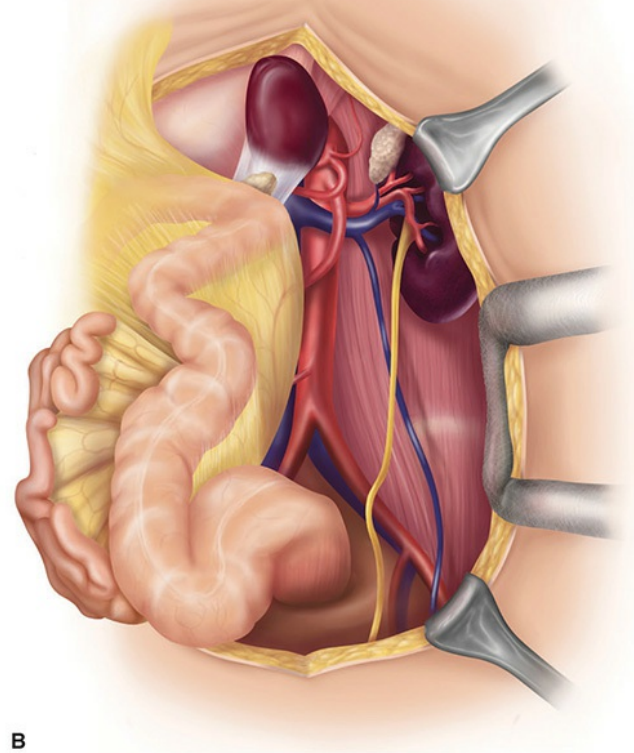

**FIGURE 20-2** Exposure of supraceliac aorta. **A.** Division of gastrohepatic ligament. **B.** Line of incision in left crus of diaphragm to expose aorta. This is facilitated by placing a finger or a clamp between aorta and crural fibers. **C.** The aorta is then encircled bluntly using finger dissection.

## EXPOSURE OF THE VISCERAL AORTA

This area of the aorta will rarely need to be exposed for acute vascular emergencies. Transperitoneal control of the visceral aorta requires a left medial visceral rotation.<sup>7</sup> The left colon is mobilized along Toldt's line (Fig. 20-3A), the retroperitoneal and phrenic attachments of the spleen are divided,

and the spleen, colon, and tail of the pancreas are reflected medially, leaving the left kidney down ([Fig. 20-3B](#)). This results in exposure of the anterior aspect of the aorta, and the origins of the renal, celiac, and superior mesenteric arteries (SMAs). If exposure of the posterior aspect of the aorta is required, the left kidney is elevated with the other viscera ([Fig. 20-3C](#)). Exposure of the visceral vessels more distally is described as follows.

**FIGURE 20-3** Left medial visceral rotation. **A.** Mobilization of the left

colon along Toldt's line. The spleen and pancreas are also mobilized. **B.** With reflection of the spleen, pancreas, and colon anteriorly toward the midline, the anterior aspect of the aorta is exposed along with the origins of the left renal, superior mesenteric, and celiac arteries. The aortic hiatus of the diaphragm may need to be incised to provide additional cephalad exposure. **C.** If access to the posterior aspect of the aorta is required, the left kidney is mobilized outside Gerota's fascia, along with the other viscera.

## **INFREARENAL AORTIC EXPOSURE**

This technique is familiar to most surgeons and involves incision of the ligament of Treitz and mobilization of the fourth portion of the duodenum superiorly and to the right (Fig. 20-4). When encountered, the inferior mesenteric vein may be divided between clamps. This sometimes improves exposure and is preferable to leaving an intact vein under tension with the risk of avulsion. The left renal vein serves as a reference to identify the superior extent of dissection. This vein almost never requires division. Should additional mobilization be required, the gonadal and lumbar veins can be divided for superior mobility and the adrenal vein is divided if the vein is to be retracted inferiorly. If these collaterals are divided and the renal vein is subsequently sacrificed, it should be repaired, either primarily or with an interposition graft. If the left renal vein is *not* encountered during this dissection, one must consider the possibility of an aberrant renal vein coursing posterior to the aorta, which occurs in 1% of patients.<sup>8</sup> In that case, the vein is at risk for damage during aortic cross clamping and particular care should be taken during the posterior dissection of the aorta.

**FIGURE 20-4** **A.** Exposure of the infrarenal aorta. The ligament of Treitz is divided and third and fourth portion of the duodenum are mobilized. The left renal vein is used to identify the superior extent of dissection. The inferior mesenteric vein may be divided. The more distal superior mesenteric artery (SMA) can also be exposed in this manner, although the origin of the vessel will not be reached (see Fig. 20-3). **B.** Exposure of the iliac vessels. The common iliac vessels and much of the right external iliac artery are exposed by continuing the mobilization of the small bowel and cecum medially and superiorly.

A 30-degree 5-mm scope is inserted and initial inspection commenced with attention to the presence of ascites, omental/peritoneal nodules, or liver masses. Next, additional trocars are placed in a manner that allows the region of primary interest to be examined with a head-on view and instrument ports to be aligned with the viewing angle (Fig. 7-1). The number and size of additional trocars will depend on the need for biopsies and other interventions, though a complete diagnostic laparoscopy with cup biopsies of the liver or peritoneum will generally require two additional 5-mm trocars. If peritoneal cytology is to be performed, it is done prior to manipulation or dissection of tissues by instilling 250 mL normal saline into each of the upper

quadrants and aspiration into a Lugol's trap.

Lymphatic and areolar tissue anterior to the aorta is cauterized or divided and ligated between clamps. It is better to ligate large lymphatics to prevent chyle leak postoperatively. As with the suprarenal aorta, the vessel is encircled using the thumb and index finger and lumbar vessels usually do not require division. We are more inclined to place a tape around the aorta in the infrarenal location, because visualization is optimal, but this is not required. As described previously, the aorta is circumferentially mobilized digitally, raised off the spine, and an aortic cross clamp is placed under direct vision (Fig. 20-5).

**FIGURE 20-5** Control of the aorta by finger dissection. The aortic neck can be elevated off the spine and a clamp applied.

## **Exposure of the Iliac Arteries**

The common and external iliac arteries are controlled after entering the retroperitoneum. For proximal iliac control, the small bowel mesentery is reflected to the right and the aortic bifurcation is exposed. For more distal control, particularly of the external iliac arteries, the right or left colon is

mobilized along Toldt's line and reflected toward the midline (Fig. 20-6). It is important to be mindful of the ureter as it crosses over the iliac bifurcation. Control of the iliac arteries at the aortic bifurcation can be dangerous because of the confluence of the iliac veins behind the right iliac artery. This is one of the most common sites of iatrogenic vascular injury during aortoiliac surgery. The venous structures are gently separated from the arteries by use of blunt dissection (sponge on stick, kitner dissector, or digital dissection). We avoid use of clamps to dissect around the iliac vessels whenever possible. Once the vessels are separated from the adjacent venous structures, they can be encircled with vessel loops and clamped. Relatively blind clamping of the iliac arteries without dissection away from surrounding veins is discouraged as venous injury may result with disastrous consequences.

**FIGURE 20-6** Exposure of the distal iliac vessels is performed by incising the lateral attachments of the sigmoid or cecum and retracting the bowel medially. Note the ureter as it crosses the iliac bifurcation.

The hypogastric arteries and distal external iliac arteries can be difficult to expose, particularly in a deep pelvis. The hypogastric artery in particular may present challenges with the risk of injury to deep pelvic veins. This artery can usually be controlled by retrograde balloon tamponade and oversewn. The very distal external iliac artery can be controlled with an intravascular balloon and, if necessary, oversewn. Vascular continuity can be restored by a bypass to the common femoral artery.

## **EXPOSURE OF THE CELIAC ARTERY AND ITS BRANCHES**

Exposure of the proximal celiac artery can be obtained through the gastrohepatic ligament, as described for the suprarenal aorta, or by left medial visceral rotation. We prefer the former approach whenever possible. The celiac artery is identified as it originates from the aorta at the diaphragmatic hiatus. Division of diaphragmatic fibers facilitates proximal exposure. More distal control is achieved by careful dissection along the anterior aspect of the vessel with caudal traction on the stomach and superior border of the pancreas. The tissue surrounding the vessel is carefully divided and ligated.

By opening the gastrohepatic ligament along the lesser curvature of the stomach, one can trace and isolate the common hepatic artery superior to the pancreas. The proper hepatic artery courses in the portal triad anterior and medial to the portal vein. The standard techniques for exposure of the porta hepatis will serve to identify and isolate this structure. The splenic artery is exposed by entering the lesser sac and reflecting the pancreas inferiorly and anteriorly. The multiple branches of this vessel that supply the pancreas must be ligated for adequate exposure. The distal splenic artery is best exposed by mobilizing the spleen as for splenectomy.

## **EXPOSURE OF THE SUPERIOR MESENTERIC ARTERY**

Transabdominal control of the superior mesenteric artery (SMA) at its origin requires medial visceral rotation of the left colon, spleen, and tail of the pancreas.<sup>7</sup> Exposure of the more distal SMA can be done through the base of the small bowel mesentery or by approaching the vessel on its posteromedial aspect after reflecting the small bowel mesentery to the right (as in standard aortic exposure). In the former approach, the transverse colon is elevated and the middle colic vessel is traced down to the SMA in the small bowel mesentery (Fig. 20-7). The anterior aspect of the vessel is cleared, taking care not to injure the adjacent vein. In the latter approach, the vessel is palpated in the root of the small bowel mesentery and dissection proceeds on the lateral aspect of the vessel (see Fig. 20-4A). In either case, dissection requires meticulous division and ligation of small venous, arterial and lymphatic branches, and the preservation of as many major arterial and venous branches as possible.

**FIGURE 20-7** Exposure of the superior mesenteric artery (SMA) through the mesocolon. The colon is lifted cephalad and the small bowel mesentery pulled caudally. The middle colic artery is identified and followed down to the SMA. Alternative SMA exposure is shown in [Fig. 20-4A](#).

## **EXPOSURE OF THE RENAL ARTERIES**

Transperitoneal control of the renal arteries can be achieved in a variety of ways, depending on the area of the artery to be controlled. The left renal artery is exposed in the same manner as the infrarenal aorta. The artery is usually superior and posterior to the left renal vein. The renal vein may require mobilization, including division of its lumbar, gonadal, or adrenal tributaries. Occasionally, the retroperitoneal attachments at the inferior border of the pancreas must be incised so the pancreas can be retracted in a cephalad fashion. The renal artery can be traced distally from its origin at the aorta. If the distal renal artery, near the hilum of the kidney, requires exposure, this is most easily done by mobilizing the left colon toward the midline. This may require mobilization of the splenic flexure and occasionally the tail of the pancreas, although this is not always the case. The proximal right renal artery can be exposed for a short segment between the aorta and inferior vena cava (IVC). The first part of the exposure is similar to that for the infrarenal aorta. Because the right renal artery runs *behind* the IVC, significant proximal exposure of this vessel requires mobilization of the vena cava and retracting it to the right. This requires careful division of 1 and often 2 sets of lumbar veins. Even with this maneuver, only the most proximal portion of the renal artery is exposed. As a result, the right renal artery is most often exposed by an extended Kocher maneuver; which reflects the duodenum, ascending colon and hepatic flexure toward the midline.<sup>9</sup> The artery again lies posterior and inferior to the renal vein, which often requires mobilization.

## **EXPOSURE OF THE VENOUS STRUCTURES**

The visceral veins are exposed by the same approaches as their corresponding arteries. Exposure of the vena cava and iliac veins requires some discussion. In general, these vessels are not involved in acute abdominal vascular emergencies outside the trauma setting. However, the vena cava is the vascular structure most commonly involved in penetrating abdominal trauma.<sup>10</sup> The IVC and confluence of the iliac veins are generally exposed by a right medial visceral rotation (Fig. 20-8). This involves mobilization of the right colon along with an extended Kocher maneuver rotating the duodenum and head of the pancreas when more proximal venous exposure is required. When exposing venous structures, one must be exceedingly cautious of the fragility of the vessel and, in particular, disrupting small, posterior, lumbar vessels. As a consequence and because the venous system is a “low-pressure”

system, compression plays a greater role in control of the vena cava and iliac veins than it does in exposure and control of the corresponding arterial segments. Circumferential mobilization of the veins is avoided if possible, as is the application of clamps. The use of blunt instruments such as sponge sticks can usually provide adequate hemostasis (Fig. 20-9). Fine clamps, such as Allis clamps, can be used to coapt cut ends of vessels and facilitate either suture or control by applying partial occlusion clamps. Whenever possible, only the anterior segments of the vein are exposed to avoid dissection around the lumbar vessels. Exposure of isolated posterior injuries involves significant mobilization and rotation of the vena cava and often requires ligation of multiple tributaries. Ligation is liberally applied in cases of extensive venous injury.

**FIGURE 20-8** Right medial visceral rotation. The right colon, duodenum, and head of the pancreas are mobilized to expose the vena cava, the iliac veins, and the right renal artery and vein. The renal artery is exposed by retracting the vein either cephalad or caudad.

**FIGURE 20-9** Control of vena cava. Pressure using digital compression or sponge sticks should be sufficient to control most venous injuries and avoids circumferential dissection.

## **PRINCIPLES OF ARTERIAL REPAIR**

Several factors dictate the approach to emergency arterial repair, including the extent of contamination, size of the arterial defect, and the adequacy of collateral circulation. The following are principles that should guide the choice of procedure:

1. When possible, primary repair is indicated. While most circumstances do

not lend themselves to this approach, lateral repair or primary end-to-end anastomosis, or even arterial reimplantation, is associated with good long-term results and avoids use of a conduit.

2. When adequate collateral circulation exists, ligation without repair is an appropriate option. This is the case with most splenic artery aneurysms and selected aneurysms of the hepatic and superior mesenteric arteries.
3. In the absence of contamination, prosthetic conduits provide the best choice for bypass of major intra-abdominal arteries. The high flow in the aorta and major visceral arteries along with their relatively large diameters is associated with good long-term patency of prosthetic bypass. Prosthetic conduits have the advantage of adequate diameter and ready availability, which makes them preferable to saphenous vein in the absence of any contraindication. Occasionally when reconstruction of a small to medium diameter (<6 mm) vessel is required, saphenous vein may be the preferred conduit.
4. In the presence of anything in excess of minor contamination, autogenous material should be used when vascular reconstruction is required. The risk of prosthetic graft infection with rupture argues against its routine use. For small- to medium-sized vessels (<6 mm), or when a patch closure is feasible, saphenous vein is usually adequate. For larger vessels, deep veins (femoral, popliteal, or jugular) should be considered. Short segment arterial repairs (eg, visceral and renal vessels) can be performed with hypogastric artery. Aortoiliac repair in the face of contamination should be performed with either deep leg veins, or more often arterial ligation and extra-anatomic bypass to restore perfusion. In the patient in extremis in whom obtaining autogenous conduit expeditiously is not an option, antibiotic-soaked prosthetic material can be used to salvage the situation, accepting an increased risk of infection and secondary surgery.

## **MANAGEMENT OF VASCULAR EMERGENCIES**

### **Acute Mesenteric Insufficiency**

#### **PRESENTATION**

Patients with acute mesenteric insufficiency generally present with abdominal pain out of proportion to their physical findings. However, if undiagnosed, acute ischemia will progress to intestinal infarction with the attendant signs of peritonitis. Laboratory investigations include complete blood count, electrolytes, lactic acid, liver panel, amylase, and lipase. In general, findings are nonspecific early in the course of the disease and consist of a leukocytosis and perhaps some evidence of hemoconcentration. Liver panel, amylase, and lipase are most useful to exclude other acute abdominal conditions. Elevated lactic acid is usually a late sign and associated with a poor prognosis. Plain radiographs are nonspecific. An ileus may be present and occasionally edema of the bowel wall (“thumb printing”) may be present. CT, with intravenous contrast, has emerged as the most useful imaging modality. CT scans can identify abrupt arterial cutoffs, particularly when 3D reconstructions are available. In addition, late-phase CT angiography is the most reliable means to identify mesenteric vein thrombosis. Occasionally, angiography may be required, particularly when nonocclusive mesenteric ischemia (NOMI) is suspected. In these cases, angiography may be both diagnostic and therapeutic.

Mesenteric ischemia results from a variety of conditions; the most common is arterial thrombosis, followed by arterial embolism, low-flow states, and mesenteric venous thrombosis.<sup>11–15</sup> Mortality is highest in low-flow (nonocclusive) ischemia and lowest in mesenteric venous thrombosis. Mortality of ischemia resulting from acute arterial occlusion remains 30% to 40%. Diagnosis is delayed in up to two-thirds of patients with mesenteric ischemia. Outcomes in acute mesenteric ischemia are related to the time to diagnosis,<sup>11,15</sup> and therefore effective treatment relies on prompt diagnosis and initiation of therapy before extensive bowel infarction occurs. This is dependent on a high index of suspicion. Prompt effective fluid resuscitation is important in all cases of mesenteric ischemia, along with the initiation of broad-spectrum antibiotics. Patients with signs of an acute abdomen should be taken to the operating room as soon as they have been adequately resuscitated. Beyond this, however, the specific management of each type of mesenteric ischemia differs somewhat according to the etiology. Therefore, they are discussed separately.

*Acute mesenteric embolization* presents with the sudden onset of severe abdominal pain in the setting of a relatively normal abdominal examination. Most emboli are of cardiac origin and the patient may have an irregular pulse,

cardiac murmur, or a history of prior myocardial infarction. Many patients may have a history of atrial fibrillation and/or prior embolic events. Because of the flow characteristics of the visceral vessels, most emboli preferentially go to the SMA. While some emboli lodge at the origin of this vessel, most end up distal to the first jejunal branches. An abrupt cutoff of flow in the SMA distal to the first jejunal branches on catheter angiography or CT angiogram is diagnostic of this condition (Figs 20-10 and 20-11). Treatment is generally laparotomy and embolectomy. Characteristically, the most proximal jejunum is viable in the case of SMA embolus, because the occlusion occurs distal to the first jejunal branches. This is a helpful, but not foolproof, way to differentiate mesenteric embolization from mesenteric thrombosis.

**FIGURE 20-10** Angiogram of superior mesenteric artery (SMA) embolus demonstrating an abrupt cutoff distal to a branch point. Note the replaced right hepatic artery (white arrow), a common vascular anomaly.

**FIGURE 20-11** CT Scan of superior mesenteric artery (SMA) embolus showing patent SMA (*right*) with more distal thrombosis (*left*).

As described earlier in this chapter, the SMA is exposed. The artery is usually soft and the site of the embolus is readily apparent. While a transverse arteriotomy with primary repair can be done, we prefer a longitudinal arteriotomy, and patch closure in most circumstances. The longitudinal arteriotomy can be extended if necessary and will allow thorough examination of the vessel and meticulous closure. It also facilitates bypass should this be required. Once the artery is opened, 3-F and 4-Fr embolectomy catheters are passed both proximally and distally to reestablish flow. If necessary, papaverine, 1 mg/kg, or 100  $\mu$ g of nitroglycerine can be instilled in the distal vessels to reduce vasospasm. When there is concern about residual distal thrombus, 250 mg of urokinase or 1 to 3 mg of tissue plasminogen activator (TPA) in 50 mL saline can be instilled in the distal vascular bed.<sup>16</sup> If there is clinical evidence of atherosclerosis in the artery, a longitudinal arteriotomy and patch closure are mandatory. If bowel resection is required, proximal saphenous vein should be used for arterial reconstruction.

In unusual circumstances, catheter-directed thrombolysis can be used as an alternative to open embolectomy.<sup>17</sup> The patient should have no signs of peritonitis and angiography should demonstrate distal emboli (not easily retrieved by an embolectomy catheter) or a partially occluding proximal embolus that permits distal flow to continue during thrombolysis. In these

rare circumstances, an infusion of TPA directly into the SMA can be attempted. Mechanical thrombolysis should not be attempted because of the danger of distal embolization. The patient must be observed carefully during lysis for signs of deterioration and any concern over bowel viability will prompt laparotomy. Best results are seen when symptoms show some resolution within 1 hour.<sup>18</sup>

The clinical signs of *acute mesenteric thrombosis* are indistinguishable from those of acute embolic occlusion; however, there are often differences in the history and some physical findings. History of arterial occlusive disease (stroke, claudication, myocardial infarction) is common, and atrial fibrillation or prior embolic episodes are less frequent. Careful questioning may elicit a history of chronic postprandial pain and weight loss, characteristics of chronic mesenteric ischemia. Physical examination often reveals stigmata of atherosclerosis, for example absent pulses and vascular bruits. Angiographic findings usually reveal diffuse atherosclerosis of the aorta and visceral vessels with multivessel involvement. When vascular occlusion occurs, it is usually at the origin of the mesenteric vessels (Fig. 20-12).<sup>14</sup>

**FIGURE 20-12** CT scan of superior mesenteric artery (SMA) thrombosis at the origin of the vessel. This is usually due to underlying atherosclerosis. Emboli lodge at the origin of the SMA in about 30% or fewer of cases.

The operative approach to acute thrombotic mesenteric ischemia differs from that of embolic occlusion. Mesenteric flow cannot be restored by a simple embolectomy and alternatives are required. The most common procedure required is bypass of the SMA usually from the infrarenal aorta or from one of the iliac arteries. While suprarenal bypass is preferred in elective surgery for chronic ischemia, an infrarenal origin of the bypass is more expeditious in the acutely ischemic patient and avoids the acute hemodynamic consequences of suprarenal clamping in a patient already acutely ill and often hemodynamically compromised. Because bowel resection is usually required, autogenous saphenous vein is the preferred conduit and should be harvested from the proximal thigh. When the bypass is performed, there should be sufficient redundancy to allow a “lazy C” loop, traveling from right to left in the abdomen to avoid sharp kinking (Fig. 20-13). The bypass is usually performed on the lateral side of the SMA slightly

posterior, so that it can lie without compromise when the viscera are returned to the abdomen. While it is tempting to use very short bypasses, these may be prone to kinking and perioperative thrombosis. In the acute setting, revascularization is usually restricted to the SMA alone.

**FIGURE 20-13** Retrograde bypass of superior mesenteric artery (SMA) occlusion. This can originate from the aorta or the right iliac artery. The “lazy

C” loop reduces the chance of graft kinking. The SMA anastomosis is on the posterolateral aspect of the vessel. While a prosthetic graft is pictured here, the saphenous vein should be used when contamination is a concern.

When there is no suggestion of intestinal necrosis and angiography reveals high-grade stenosis rather than vascular occlusion, an endovascular approach may be attempted.<sup>19,20</sup> Although an endovascular approach has been favored by many in patients with chronic mesenteric ischemia, it is more problematic in the acute setting. Endovascular recanalization is more dangerous when vessels are completely occluded because of the possibility of causing distal embolization. While the target lesion remains the SMA, it is reasonable to perform angioplasty of multiple visceral arteries if the patient remains stable. The visceral vessels may be engaged either transfemorally or more often via a transbrachial approach. The latter facilitates access to the origin of the vessel and passage of angioplasty balloons and stents as required. If there is any indication of intravascular thrombus, lytic infusion should be performed prior to any attempt at angioplasty to avoid the possibility of distal embolization. Once the possibility of thrombus is excluded, angioplasty with the placement of a balloon expandable nitinol stent is then performed. Use of a short (15-20 mm) 5- to 6-mm-diameter balloon-expandable stent allows precise deployment. The stent should completely traverse the area of narrowing and extend a few mms out into the aorta. This is important because the lesion in this case usually has its origin in the aorta. Selecting an endovascular approach does not mean that laparotomy is avoided, because bowel ischemia may be present. Any signs of peritonitis require prompt laparotomy and inspection of the bowel for viability.

Retrograde endovascular recanalization of a proximal SMA lesion has been reported at the time of celiotomy.<sup>21</sup> This technique involves a longitudinal arteriotomy made in the SMA and passing a wire retrograde into the aorta under fluoroscopic guidance. Balloon angioplasty of the proximal lesion is performed as an alternative to bypass, and the arteriotomy is closed with a patch. While reports are anecdotal, this procedure is of interest because it avoids the possibility of distal embolization and may be performed more expeditiously than a vein bypass.

*Nonocclusive mesenteric ischemia* (NOMI) may occur as the result of low flow, without evidence of acute arterial thrombosis or embolization. In one form of this condition, the colon, in whole or in part, is involved. The arterial

supply of the colon is less robust than that of the small bowel and, in elderly patients particularly, the inferior mesenteric artery (IMA) may be diseased or occluded. Systemic illness with reduced visceral blood flow, or abrupt interruption of the IMA, such as with aortic resection, may precipitate infarction of marginally perfused areas of the colon. This is most common in the sigmoid colon and the splenic flexure. The rectum is often spared in this process, because of its dual supply through the hemorrhoidal vessels. The small bowel is also usually spared. In these situations, resection of the infarcted colon, with exteriorization and diversion as necessary, is all that is required. The SMA and celiac arteries are usually normal, and no attempt at revascularization of the IMA is indicated.

Mesenteric ischemia without an underlying visceral lesion may also involve the SMA and celiac distribution. This has been called “nonocclusive mesenteric ischemia” (NOMI) and is associated with severe systemic illness, hypotension, and spasm of the mesenteric vessels without evidence of an obstructive lesion.<sup>22</sup> Patients with NOMI are often already in an intensive care unit (ICU) and have had a cardiac event requiring vasoactive drug infusions. Some patients may have been on digitalis preparations that themselves are known to reduce visceral blood flow. There have been some recent reports of NOMI following dialysis in patients with end-stage renal disease.<sup>23</sup> Angiography, when performed, shows “pruning” of the mesenteric vessels without discrete obstruction. Management of these patients is directed at overall cardiovascular support, treatment of the underlying acute condition(s), and broad-spectrum antibiotics. Intra-arterial papaverine may be administered to relieve vascular spasm, although this is not always effective and may be complicated by systemic hypotension. NOMI usually portends a bad outcome in general, which is related as much to the underlying illness as to mesenteric compromise. Laparotomy should be reserved for patients in whom intestinal infarction is suspected and who are deemed otherwise salvageable since it often will not influence the outcome in this disease.

*Mesenteric venous thrombosis* may result in acute intestinal ischemia, although this accounts for only about 5% of all cases. Patients are a distinct subgroup, being younger (30-50 years) and predominantly female.<sup>24-27</sup> Associated hypercoagulable state can be identified in more than three-quarters of patients and a history of prior venous thrombosis is not uncommon. Common inherited states include deficiencies of protein C, protein S, and antithrombin III; activated protein C resistance; factor V

Leiden mutation; and methylenetetrahydrofolate mutations.<sup>27</sup> Acquired prothrombotic states include profound dehydration, polycythemia, cancer, pelvic or abdominal inflammation, and hormone use. Mesenteric venous occlusion is most readily diagnosed by venous-phase CT angiography, which can demonstrate thrombus in the superior mesenteric vein and portal system (Fig. 20-14). Early diagnosis, and therefore a high clinical index of suspicion, and prompt initiation of systemic anticoagulation are critical to success. Operative findings suggestive of this condition are edematous beefy red bowel with thrombus in veins of the mesentery. The primary mode of therapy is anticoagulation; operative intervention is reserved for situations when bowel necrosis is suspected and resection is required. In those situations, limiting resection with a “second-look” laparotomy, along with ongoing anticoagulation, is the appropriate course. Most patients can be managed supportively, although significant volume resuscitation may be required. There are anecdotal reports of mesenteric and portal vein thrombectomy and thrombolysis,<sup>28-30</sup> but these do not reflect the standard of care for most patients.

**FIGURE 20-14** CT scan demonstrating thrombus in the superior mesenteric

vein. CT scan is the most accurate diagnostic study in this condition.

## **DETERMINING INTESTINAL VIABILITY: THE ROLE OF “SECOND-LOOK” SURGERY**

A major challenge in managing patients with intestinal ischemia is assessing the need for, and extent of, intestinal resection. Preoperatively, colonoscopy can be used to assess the viability of the large intestine in questionable situations. Friable red mucosa suggests viability and a grey mucosa that readily sloughs indicates the need for resection. Viability of the large bowel is difficult to judge from external appearance at the time of laparotomy, and in general, it is preferable to err on the side of resection in questionable circumstances, because maintaining large bowel length is not an absolute requirement for survival. Primary repair should not be undertaken after large bowel resection; diversion with secondary reconstruction is preferred.

When the small intestine is involved, the problem becomes more complex.<sup>31-33</sup> Every effort should be made to preserve as much small bowel as possible. Clearly necrotic segments of bowel and areas of perforation are excluded immediately to prevent contamination during vascular reconstruction and subsequently resected. Evaluation of the remainder of the small bowel is done after blood flow to the intestine is restored. The bowel is usually observed for 15 to 20 minutes after revascularization and warm lap pads are applied to the intestines to reduce any vasospasm. External inspection, with attention to color and peristalsis, is more helpful than in the large bowel. Doppler interrogation of the antimesenteric border for arterial flow is useful when positive. Use of fluorescein (1 ampule given intravenously) followed by inspection with a Wood's lamp, is the most sensitive means of determining perfusion. Viable bowel will be fluorescent yellow while nonperfused bowel will appear dark purple. When the extent of resection is minimal and the remaining bowel is clearly viable, anastomosis and abdominal closure is reasonable. When there are large areas of questionable bowel that might mandate extensive resection, an alternative approach is undertaken. Under these conditions, marginal segments of bowel are left in situ and their ends are simply closed over and returned to the abdomen. Plans for a second operation are made. Stomas are not performed at this stage to preserve intestinal length. Fluorescein is not used at this time but reserved for the second procedure. The abdomen is temporarily closed

using a “Bogotá bag,” polytetrafluoroethylene (PTFE) patch, or other temporary appliance (to minimize the chance of abdominal compartment syndrome) and the patient is returned to the ICU where resuscitation continues. A subsequent laparotomy is performed at 18 to 24 hours, after the patient has been stabilized. At this point fluorescein is injected and nonviable bowel is resected. Intestinal continuity is restored unless it is unsafe to do so. The abdomen often cannot be closed primarily at this point because of the danger of compartmental hypertension, and an “open abdomen” approach with delayed closure may be needed. Any deterioration in the patient’s subsequent hospital course should suggest breakdown of an anastomosis and prompt the appropriate therapy.

Despite increased clinical awareness and advances in diagnostic modalities and perioperative care, management of intestinal ischemia remains a significant challenge to the most experienced surgeon with continued high mortality and morbidity.

## **Management of Abdominal Vascular Trauma**

Vascular injuries occur in 10% to 15% of cases of blunt and penetrating trauma.<sup>34–38</sup> Associated nonvascular injuries are seen in over 90% of patients with vascular trauma, most commonly small bowel, colon, and liver.<sup>37</sup> Vascular injuries can be highly lethal when they occur and remain the most common cause of death following penetrating abdominal trauma. Arterial and venous injuries occur with equal frequency. The pattern of injury differs between blunt and penetrating injuries. In penetrating injuries, the most commonly injured vessels are the vena cava, followed by the aorta, iliac arteries and veins, and the SMA, and vein and multiple vascular injuries are common.<sup>10</sup> Vessels of the mesentery are the most commonly involved in blunt trauma. This section provides principles for management of injuries to the major arteries and veins of the abdomen and retroperitoneum. The reader is referred to the prior sections on vascular exposure for a description of how to obtain control of these vessels. The discussion here centers on management of specific injuries.

Overall, principles of trauma management including initial resuscitation of the patient, rapid evaluation and triage, and expeditious operation when indicated should prevail. Stable patients, particularly those with blunt trauma,

may undergo one or more diagnostic tests, including peritoneal lavage, “FAST” ultrasound examination, and, with increasing frequency, CT scan.<sup>39</sup> Many patients with penetrating trauma are taken directly to the operating room without further diagnostic evaluation. Consequently, in a significant proportion of cases, the extent of vascular trauma is not known preoperatively and must be assessed by the surgeon in the operating room.

Intraperitoneal hemorrhage is easily recognized and should be expeditiously controlled, by application of external pressure, vascular clamps, or intravascular balloon occlusion catheters. Once active hemorrhage is controlled, any visceral perforation is controlled by exclusion to prevent ongoing peritoneal contamination and any remaining solid-organ injuries (ie, liver, spleen, and pancreas) should be stabilized by packing. Definitive treatment of the vascular injuries should then receive priority over definitive visceral repair. The adaptation of a “damage control” approach to abdominal trauma has improved outcomes in abdominal trauma.<sup>40,41</sup> Vascular “damage control” involves the control of major venous injuries by ligation or packing and placement of temporary shunts to restore arterial continuity when arterial ligation will not be tolerated.<sup>42,43</sup> Shunts are most often used to temporarily restore flow to the extremities but are used less often in management of visceral injuries. In general, visceral vessels are either repaired or ligated during the initial operation. The end organ will either tolerate ligation because of collateral circulation or be sacrificed. The “damage control” concept combined with endovascular techniques may be of particular use when open vascular repair is exceedingly complex and associated with significant mortality. This is particularly true of contained retroperitoneal or hepatic injuries. Definitive treatment can be deferred at initial laparotomy in these cases and attempted in an imaging suite using endovascular techniques after the patient is stabilized. Examples of this include embolization of intrahepatic arterial injury and treatment of some contained retroperitoneal hematomas. This approach is in evolution and holds significant promise.

There are a number of situations in which the surgeon must make a decision about whether to explore a contained hematoma. In these cases, the risk of missing a major vascular injury is balanced against the morbidity of operative exploration. Classic trauma training requires exploration of all contained hematomas that result from penetrating injury. In the case of blunt trauma, central hematomas (zone 1) are explored because of the risk of injury to the aorta or vena cava, while lateral and pelvic hematomas are explored

only if there is active bleeding or expansion under observation.<sup>36</sup> If exploration occurs, it is important to obtain proximal and, whenever possible distal, arterial control outside the area of hematoma before proceeding. Venous control above and below the area of injury is desirable but may not always be obtainable. Approaches to vascular control, including endovascular techniques in various locations, have already been described. Intravascular occlusion catheters should be readily available for additional control as needed. Only after every attempt to control the arterial and venous ingress and egress to the hematoma has been made should it be entered.

The advent of endovascular techniques may be changing the classic paradigm of managing contained hematoma from either blunt or penetrating cause. The rationale for exploring nonexpanding hematomas of any type was based on the concern for occult vascular or visceral injury. The advent of CT angiography and the existence of sophisticated intravascular imaging in the operating room can facilitate evaluation of nonexpanding hematomas from both penetrating and blunt trauma without the need for operative exposure and its attendant blood loss. Furthermore, endovascular techniques such as covered stents or coil embolization will allow treatment of many vascular injuries from remote access with reduced risk of blood loss.<sup>44,45</sup> Such treatments are in fact preferred for trauma to branch vessels in the visceral, renal, or pelvic circulations. This potential change in paradigm suggests that the surgeon consider a form of vascular “damage control” in the case of contained hemorrhage, by considering an “endovascular first” approach for diagnosis and treatment of contained hematomas regardless of location. This area is currently evolving, and there is no consensus on the role endovascular techniques should and will eventually play. With these general comments in mind, a discussion of specific vascular injuries and their management follows.

## **INJURIES TO THE SUPRARENAL AORTA AND VENA CAVA**

These injuries as a group are highly lethal and management is difficult. They should be suspected in any patient with a central hematoma from either blunt or penetrating trauma. In the stable patient, CT scan with intravenous contrast can help to identify the area of injury. If CT scan is not possible

preoperatively, a clear plan of exposure and management is crucial before commencing any attempt at repair. Because of the advances made in endovascular techniques, patients should be treated in an operating room that has the capability of intraoperative fluoroscopic imaging and angiography whenever possible. If an injury to the aorta or vena cava is suspected and the patient is not exsanguinating, the surgeon should consider intraoperative angiography through the femoral artery or vein as appropriate to evaluate the location and extent of vascular injury and consider intravascular control. Following this, proximal and distal control should be established. Open exposure of the aorta at the diaphragmatic hiatus or endoluminal balloon control,<sup>3,4</sup> both described previously, can be performed. Injuries to the vena cava can initially be controlled by balloon tamponade, although this may reduce venous return to the right side of the heart. Open control of the vena cava is described in the following text.

## **OPEN REPAIR OF THE SUPRARENAL AORTA**

The visceral aorta is exposed by a left medial visceral rotation described previously. If access to the posterior aspect of the aorta is required, the left kidney should be elevated along with the other viscera; if access to the anterior aorta is needed, the kidney is left in its bed. Direct suture repair is undertaken whenever possible. Direct repair that does not narrow the lumen of the aorta more than 50% or impinge on a visceral vessel is well tolerated. Larger defects may require patch angioplasty using prosthetic material, arterial autograft, or arterial homograft. In the absence of significant contamination, prosthetic material provides a readily available, strong, and durable material for repair. In the presence of gross fecal contamination, biologic materials should be used if possible. Arterial homograft provides the most expeditious alternative both for size and durability, if available. Antibiotic-impregnated prosthetic material may be used, after extensive debridement of the area. In these cases, the repair should be wrapped in omentum and the patient should be placed on long-term, perhaps lifelong, antibiotic treatment. Saphenous vein is inappropriate in this circumstance due to concerns about strength and durability; deep veins of the leg have proven reliable substitutes for in situ aortic reconstruction in infected fields.<sup>46</sup> If appropriate, the aortic repair can be buttressed by an apron of omentum of some paraspinous muscle, to separate the suture line from any visceral

vessels. This should be done in the presence of associated visceral injury, particularly injury to the pancreas. Drainage is established as needed. If the damage involves the origins of one or more of the visceral vessels, these are ligated. Revascularization of these vessels can be performed as described in the following text. Damage control of the suprarenal aorta is not possible because of the mesenteric ischemia that would attend any such attempt.

## **ENDOVASCULAR REPAIR OF THE AORTA**

This emerging alternative should be considered in selected circumstances. In a stable patient with a contained injury, placement of a suitable covered stent can be combined with extra-anatomic debranching of 1 or 2 visceral vessels, as has been described for treatment of thoracoabdominal aneurysms.<sup>47</sup> This is most suitable when a single mesenteric vessel is involved, because the bowel will tolerate more prolonged ischemia than the kidney. Modification of the stent graft (“fenestrations”), to allow continued visceral perfusion, is possible.<sup>48</sup> This is most feasible when the aortic defect is posterior and relatively remote from the visceral orifices. More precise fenestrations, as required in suprarenal aortic repair, are currently beyond the capability of most surgeons in an acute setting. If a stent graft is selected, its diameter should be 110% to 115% of the normal aorta to allow for secure fixation. A variety of off-the-shelf aortic cuffs are available and their successful use has been reported in conjunction with thoracic aortic transection.

## **OPEN REPAIR OF THE SUPRARENAL INFERIOR VENA CAVA**

Open repair of injuries to the suprarenal vena cava is one of the most difficult of all abdominal vascular operations. Exposure of the infrahepatic suprarenal IVC is achieved by an extended Kocher maneuver and right medial visceral rotation. One cannot overemphasize the utility of intravascular balloon control in these cases to avoid hemorrhage. Balloon control can be combined with external pressure and the application of partial occlusion clamps to provide hemostasis. Fine Allis clamps are useful in coapting and controlling the cut ends of the IVC and are preferable to more traumatic attempts at control. Wounds of the infrahepatic suprarenal IVC are usually managed by

lateral venorrhaphy with running vascular suture. Narrowing the IVC 50% to 60% is often acceptable. If lateral venorrhaphy is not possible, patch repair using prosthetic or biologic material is acceptable. The use of anticoagulation in these circumstances is unsettled and is likely to remain individualized. Ligation of the suprarenal IVC should be avoided. Injuries to the retrohepatic vena cava, especially those that accompany blunt trauma, usually involve avulsion of the hepatic veins. Such injuries are highly lethal. Exposure of the retrohepatic IVC involves mobilization of the liver and anterior medial rotation of the right lobe.<sup>49-51</sup> Repair of retrohepatic venous injuries may require hepatic isolation (control of the aorta at the hiatus as well as the vena cava above and below the injury and occlusion of the portal triad), placement of an intraluminal shunt between the right atrium and infrarenal IVC or venovenous bypass with hepatic isolation. These techniques are only used in desperate circumstances when bleeding persists despite adequate perihepatic packing. In general, injuries in this area should initially be treated by packing, nonexpanding hematomas should not be opened, and the extent of injury should be defined and definitive repair planned after the patient has been stabilized.

## **ENDOVASCULAR TECHNIQUES IN THE SUPRARENAL IVC**

At this point, any endovascular approach would be considered experimental. The complexities of and poor results with open surgery in this area make an endovascular approach to suprarenal IVC injuries an attractive potential alternative. Remote access and control, facilitating exposure, along with limited occlusion of the IVC, are all points in favor of an endovascular approach. The size and distensibility of the IVC complicate the selection of an appropriate diameter endovascular graft. Patients with caval injury are often in shock and there may be external pressure on the vessel, both factors that cloud the estimation of caval diameter. No stent grafts have been made for caval use, and it is likely that aortic cuffs or short segment of grafts used for thoracic aortic repair would be most useful. Inadvertent coverage of the renal or hepatic veins represents a further potential complicating factor. There have been no reports of endovascular treatment of hepatic vein injuries. Nonetheless, the potential treatment of these injuries by remote rather than

direct access is appealing enough that it will undoubtedly be investigated in the future.

## **REPAIR OF THE INFRARENAL AORTA AND ILIAC ARTERIES**

Injuries to the infrarenal aorta and iliac arteries can be managed by a combination of open and endovascular techniques. Use of an endovascular balloon to achieve proximal arterial control, described for ruptured aortic aneurysm, should be considered as a part of management. These techniques require access to intraoperative fluoroscopy and familiarity with endovascular techniques. The balloon should be placed in the operating room before celiotomy if possible, either through the femoral artery with a supporting sheath or the left brachial artery, as previously described.<sup>3,4</sup> The balloon does not need to be inflated if the patient remains stable. Because concurrent visceral injury is common, laparotomy is almost universally required. After “damage control” of any gross intestinal spillage, attention is turned to the arterial injuries. Exposure of the aorta and iliac arteries has been described. When there is minimal enteric spillage, irrigation and repair with an in situ prosthetic bypass of appropriate diameter is the most expeditious approach. The repair should be wrapped in omentum if possible to separate it from the viscera. In the presence of significant contamination, the infrarenal aorta and/or iliac vessels should either be repaired primarily, ligated, or a temporary shunt inserted as part of a “damage control “strategy.”<sup>42</sup> If ligation is required, extra-anatomic (eg, axillofemoral or femoral) bypass with prosthetic material can be used to restore perfusion to the lower extremities. If the aortic bifurcation is preserved, a unifemoral bypass is possible. In cases where the aortic bifurcation is not salvageable, primary end-to-end anastomosis of the proximal ends of the common iliac arteries can be performed, followed by axillo-unifemoral bypass. If this is not possible, axillo-bifemoral bypass may be required.

Unilateral common iliac artery injuries may be ligated with subsequent cross femoral reconstruction using a prosthetic graft. Isolated external iliac artery injuries can be repaired in most cases with saphenous vein interposition. Internal iliac artery injuries should be ligated. In the absence of significant contamination, interposition graft replacement of the damaged

vessel with a prosthetic graft is preferred. There are advocates of in situ prosthetic bypass, even in the face of more significant contamination.<sup>52</sup> We prefer not to do this unless the situation is life threatening and prefer temporary placement of a shunt.

Endovascular repair of injured aorta and iliac vessels can be performed using techniques applied for repair of endovascular infrarenal aortic aneurysm repair. One must remember, however, that many of these patients are young and the durability of these repairs is unknown. In addition, most patients will require laparotomy for associated injuries. These 2 factors suggest a limited role for stent grafts in the treatment of traumatic lesions of the abdominal aortoiliac segment, as opposed to the more common use of stent grafts in traumatic rupture of the thoracic aorta. Endovascular repair has been used in treatment of traumatic dissection of the aorta or iliac arteries.<sup>53</sup> As previously noted, endovascular balloon tamponade is a valuable technique and endovascular coil embolization of difficult-to-access hypogastric artery branches can be employed with great success.

## **INFARENAL IVC AND ILIAC VEIN**

The principles of controlling venous injuries, including use of balloon tamponade and external pressure, have been previously described. The infrarenal IVC, iliac confluence, and right iliac vein are exposed through a right medial visceral rotation (see Fig. 20-8). The confluence of the iliac veins is obscured by the aortic bifurcation and right common iliac artery. If the aortic bifurcation cannot be sufficiently mobilized to provide exposure, the right common iliac artery should be mobilized or even transected for additional exposure. This is often required in any event because concomitant arterial injury is common. The more distal left iliac vein is approached on either side of the descending/sigmoid colon depending on the location of the injury.

As with the suprarenal IVC, lateral venorrhaphy is the preferred approach, with autogenous vein patch or ligation as alternatives. If needed, the infrarenal IVC and iliac veins can be ligated, due to the rather extensive collateral network that can develop within hours. While this may cause fluid sequestration in the lower legs, it is usually tolerated in the short term and is preferable to an attempt at repair in an unstable patient. In the rare case that

ligation results in extreme distal venous hypertension, a bypass graft is indicated. In patients who have been stabilized, we prefer venous repair, either with a vein patch or, when an interposition graft is required, a ringed prosthetic conduit. Successful venous repair must use a conduit of equal or slightly greater diameter than the native vein and should avoid any tension. Saphenous vein is of insufficient diameter for replacement of the iliac vessels and must be modified to be useful (“panel” grafts”). We find such panel grafts excessively time-consuming to construct in these critically ill patients and prefer externally supported PTFE of suitable diameter and length. This is usually done in situ but may be performed using an extra anatomic route. When short segments of prosthesis are used in the presence of distal venous hypertension, flow is usually sufficient to maintain patency without the need for anticoagulation or an adjunctive fistula. In our experience, when thrombosis of a prosthetic vein graft does occur, adequate collateral venous flow has invariably been present. The indication for caval filters in patients with venous injury is not clearly established and remains a matter of individual clinical judgment.

## **TREATMENT OF TRAUMATIC ARTERIOVENOUS FISTULA**

Fistula between the major arteries and veins can occur at any level, because the vessels are in close proximity throughout their course. It is important to realize that, while this may occur acutely, such a fistula rarely represents a true vascular emergency. Exsanguinating hemorrhage does not occur, because the arterial blood is decompressed into the venous system. Most of these patients present months to years after their initial injury. These patients may present with a continuous bruit, signs of lower extremity edema, and high-output cardiac failure.<sup>54</sup> Management depends on an accurate history of trauma, including prior surgery (particularly lumbar disc surgery) or endovascular manipulation. Detailed vascular imaging is essential. These patients are rarely in extremis, and an effort to delineate the problem and develop a careful plan of correction is time well spent. Repair can usually be delayed until the patient is stabilized and other acute problems are corrected.

Treatment is directed at repair of both the arterial and venous defects.<sup>54,55</sup> This is most often done by primary suture closure, although patch closure is

sometimes required. Proximal and distal arterial control is essential and is obtained using open or endovascular techniques as described previously. Proximal and distal venous control should be obtained when possible before opening the fistula. This can be done by external dissection, compression, or an intraluminal balloon. Central venous occlusion is important to prevent air embolization when the vein is opened. We generally avoid extensive venous dissection in close proximity to the fistula. On occasion, venous control can be obtained by placing a balloon catheter *through* the fistula from within the artery and then closing the communication with interrupted or running sutures. In the acute circumstance, the artery and vein may be separated, but this is more difficult in the case of a more chronic fistula and closure of the communication, by primary suture or patch, can be done from within the vessel. If this approach is chosen, it is important to be sure that the communication has been completely interrupted at the end of the procedure by use of intraoperative ultrasound or angiography. Appropriate flushing of both the arterial and venous sides is important to avoid embolization of debris or air into the central venous circulation.

Arterial-venous communications can also be approached endovascularly using covered stents.<sup>56</sup> The stent can be placed only on the arterial side of the defect if the site of injury is in a main artery and can be accurately identified. However, it is important to remember that the arterial injury may be in a branch of one of the iliac vessels, in which case placement of a stent graft in the main artery will not correct the abnormality. Detailed description of repair of these branch fistulae is complex and beyond the scope of this chapter. Suffice it to say that coil embolization can be particularly dangerous in these cases due to the high flow in the venous system and chance of central venous embolization. A variety of techniques can be employed to reduce this possibility. Endovascular treatment of these lesions should only be undertaken by those with significant experience in endovascular techniques. As with open repair, it is important to be sure that complete interruption of the fistulous communications has occurred using completion angiography.

## **TRAUMA TO THE MESENTERIC ARTERIES AND VEINS**

The origin of the celiac axis is exposed through the gastrohepatic ligament or

by a left medial visceral rotation as described earlier. While a short bypass from the aorta to the bifurcation of the splenic and hepatic arteries can be performed, the origin of the celiac artery can be ligated safely, if necessary, in most cases. This is preferable to attempting repair in a relatively confined space in an unstable patient. Collaterals through the pancreaticoduodenal and gastroduodenal are usually sufficient to preserve foregut flow. If there is any doubt, a bypass can be performed from the aorta to the common hepatic artery. The splenic artery can be ligated, as can the splenic vein. In the case of proximal injuries to the splenic vessels, the short gastric vessels provide adequate collateral flow. When the splenic vessels are injured close to the hilum, a splenectomy is usually the best approach. Injuries to the common hepatic artery may be ligated because of collateral circulation, while injuries to the proper hepatic artery are more likely to require repair. In order of preference, techniques are primary repair, interposition vein graft, and aortomesenteric graft using either saphenous vein or prosthetic. Two-thirds or more of hepatic flow is supplied by the portal vein, and, if this is intact, proper hepatic artery ligation is an acceptable option. Intrahepatic arterial lesions are generally treated with angiographically directed coil embolization unless massive exsanguination requires resection of the damaged area of the liver.

Injuries to the main trunk of the SMA should be repaired because significant loss of small bowel may result from sacrifice of the vessel. Ligation of proximal SMA aneurysms can be performed with acceptable results, due to the presence of collaterals from the celiac and inferior mesenteric arteries. However, in the trauma setting, integrity of collateral pathways from the pancreaticoduodenal and middle colic vessels is not easily ascertained and repair should be performed. Lesions at the origin of the vessel are best exposed by left medial visceral rotation and repaired with a short bypass originating from the aorta. More distal lesions are exposed through the base of the small bowel mesentery and can be repaired by patch angioplasty, interposition graft using saphenous vein, or proximal ligation and distal bypass arising from the aorta. In the trauma setting, the infrarenal aorta is preferred as inflow for the more distal SMA because supraceliac exposure and control is best avoided in patients who may be unstable and have multiple injuries. Saphenous vein is the preferred conduit. The details of SMA bypass have been described, including the need for proper length and orientation to prevent kinking. Trauma to the branches of the SMA is usually

treated by vessel ligation and any nonviable bowel is resected. Attempts to repair distal arterial and venous injuries in the mesentery are not rewarding. Mesenteric hematomas that are not expanding and are not associated with compromised bowel should be observed initially with angiography as necessary to identify vascular lesions. Attempts to explore stable mesenteric hematomas can lead to excessive blood loss and vascular compromise, resulting in more bowel ischemia.

Injuries to the splenic vein are treated by ligation, with or without splenectomy. There is often an accompanying injury to the splenic artery. In the rare instance of isolated splenic vein injury, consideration should be given to concomitant splenic artery ligation or splenectomy. Acute ligation of the splenic vein alone may result in sequestration of significant amounts of blood within the spleen and left-sided portal hypertension. This can be ameliorated by ligating the main arterial inflow to the spleen. Injuries to the main trunk of superior mesenteric vein should be repaired to avoid bowel ischemia secondary to mesenteric venous obstruction. If the vein cannot be repaired using a patch angioplasty or short interposition graft, a bypass from the superior mesenteric vein to the portal vein should be performed. This probably will require a large (6- to 8-mm) conduit of either reinforced PTFE or deep vein (jugular or femoral). Injuries to the portal vein should be repaired if possible, by lateral venorrhaphy, patch angioplasty, or interposition grafting, if the patient is stable enough to undergo repair. The retropancreatic portal vein is best exposed by transection of the pancreas (Fig. 20-15). Isolated injuries of the portal vein, with an intact hepatic artery, may be ligated if necessary to save the life of the patient, although significant hepatic dysfunction and acute massive bowel edema can be anticipated. This leads to significant fluid sequestration and may even result in bowel necrosis. Lesions of the hepatic artery and portal vein that are not immediately lethal should be repaired if possible.

**FIGURE 20-15** Exposure of the retropancreatic portal vein by division of the pancreas.

Injuries to the inferior mesenteric artery can usually be ligated, because adequate collaterals will exist from the arc of Riolan, the marginal artery of Drummond, and the hemorrhoidal vessels. If it appears that ligation will not be tolerated, reimplantation, a short bypass with the saphenous vein, and ligation with resection of any ischemic colon are all acceptable alternatives.

## **INJURIES TO THE RENAL ARTERY AND VEIN**

Management of renal artery lesions is dictated by the overall status of the patient, duration of ischemia, and presence or absence of a contralateral kidney. It is important to remember that after 60 minutes of warm ischemia time, most of the kidney's excretory function is lost. While some authors advocate renal vascular repair within the first 3 to 6 hours after injury, preservation of long-term renal function in these cases has been poor.<sup>57,58</sup> Therefore, situations in which there is nonvisualization of one kidney on a preoperative CTA or intravenous pyelogram (IVP) suggests that renal function will not be salvaged by revascularization. In most cases of arterial transection, ligation with nephrectomy is indicated. In cases of blunt trauma observation is usually indicated. In circumstances where the status of the kidney is unknown or when there is not a contralateral kidney, attempts at revascularization should be undertaken. The most expeditious approach is aortorenal bypass for lesions of the main renal artery, using saphenous vein with PTFE as a second choice. Lesions of the more distal renal artery, at or beyond branch points, are best ligated in the acute situation, unless they can be repaired with a simple vein patch, or if the injury is to a solitary functioning kidney. If there is doubt about contralateral renal function, the ipsilateral (damaged kidney) ureter can be clamped and indigo carmine administered intravenously. Appearance of dye in the urine confirms contralateral kidney function. Renal artery thrombosis due to blunt trauma, diagnosed as lack of perfusion on CT scan, can be treated by endovascular placement of a stent<sup>59</sup> if the patient is otherwise stable. However, salvage of a renal vessel in a patient with a contralateral functioning kidney remains a secondary priority in the trauma patient's overall management.

Lesions of the proximal renal veins may be ligated, as long as collateral flow through the gonadal, adrenal, and hypogastric veins is preserved. This works best on the left side. While it is known that some transitory renal dysfunction will occur after renal vein ligation, it is generally well tolerated. If inadequate venous collaterals exist or have been damaged during the course of the injury, a short bypass between the renal vein and the vena cava with 8- to 10-mm PTFE can be performed, although ligation and nephrectomy is appropriate if the patient is unstable. Under rare circumstances of injuries to the renal hilum, for example with a solitary kidney, nephrectomy with ex vivo repair and autotransplantation may be indicated. This extensive reconstructive surgery, however, is unwise in an unstable patient with a contralateral functioning kidney.

# TREATMENT OF RUPTURED ABDOMINAL AND VISCERAL ANEURYSMS

In the patient presenting with abdominal pain, pathology of the abdominal aorta and its branches should always be included within the differential diagnosis. Because of their rapidly catastrophic potential, prompt diagnosis and timely treatment for ruptured abdominal aneurysms are mandatory for patient survival and a successful outcome. While the most common aneurysms of the abdomen involve the abdominal aorta and iliac arteries, aneurysms of the visceral vessels may also rupture and present as abdominal emergencies.

## Ruptured Aneurysms of the Aorta and Iliac Arteries

Although historically called *atherosclerotic* aneurysms, the etiology of abdominal aortic aneurysms (AAAs) has come to be recognized as multifactorial.<sup>60</sup> This complex interplay, which includes elastin degradation, increased proteolytic activity, inflammation, matrix metalloproteinases, and other factors, leads to the ultimate development of aortic expansion and degeneration.<sup>61–63</sup> It is for this reason that the term *degenerative* aneurysm better describes the pathophysiology of AAAs. Familial<sup>64</sup> and sex-linked<sup>65</sup> factors also likely contribute: the incidence is several times higher in men, and the relative risk for development of AAA among first-degree relatives of affected individuals is increased 11-fold. The infrarenal aorta is the most common intra-abdominal location for aneurysmal degeneration; aneurysmal degeneration of the suprarenal aorta is much less common.

Despite advances in treatment and early diagnosis, AAAs continue to be a significant cause of death. In the United States, AAAs are the 15th cause of death overall and the 10th leading cause among men older than 55 years.<sup>66</sup> With improvements in the operative and perioperative management of *elective* AAAs, coupled with the introduction and refinement of endovascular techniques, *ruptured* AAAs overwhelmingly account for most of these deaths. Even among specialized centers, the operative mortality for ruptured AAAs remains high, between 35% and 50%, a range that has remained

constant over the past 3 decades.<sup>67</sup> When one also considers the proportion of patients who die without reaching the hospital, the mortality rate approaches 75%.<sup>68</sup> Accordingly, and because AAAs are notoriously asymptomatic until ruptured, much clinical research has centered on the natural history of the disease, specifically focused toward identifiable risk factors for rupture.

The absolute diameter of the aneurysm is the principal determinant of rupture risk. As the diameter increases, the risk of rupture increases nonlinearly, such that larger aneurysms have a significantly higher rupture rate. For example, AAAs 5 to 5.5 cm have an annual rupture risk of less than 5%, whereas those 6 to 7 cm in diameter have a 10% to 15% annual risk of rupture.<sup>69</sup> These “hinge points,” in which the rupture risk rises dramatically, are the basis for recommending elective repair for asymptomatic AAAs based on size alone (in general, >5.5 cm in average-risk patients).<sup>70</sup> Several other factors also independently predict rupture risk. The strongest risk factors are hypertension, chronic obstructive pulmonary disease (COPD), and family history of AAA.<sup>71,72</sup> Other possible risk factors include rapid expansion (>0.4 cm annually),<sup>73</sup> female gender,<sup>74</sup> and current smoking history.<sup>75</sup>

The classic presentation for ruptured AAA is abdominal or back pain, pulsatile mass, and hypotension; however, this complete triad is present in only a minority of patients. A large pannus or abdominal girth may preclude appreciation for a pulsatile mass; similarly, a blood pressure of 100 mm Hg systolic in an otherwise hypertensive individual may be mistakenly interpreted as “normotensive.” Pain is almost always a presenting symptom, and may include abdominal or back pain, groin pain, testicular pain, or flank pain. Less commonly, a patient with a large ruptured AAA may be obtunded and can present with hypotension only. The diagnosis of ruptured AAA must be included among the differential in every patient older than 50 years presenting with abdominal pain, abdominal pain and hypotension, or hypotension alone. When a pulsatile mass is also appreciated, the diagnosis of ruptured AAA is almost certain.

Much less commonly, an aortocaval fistula may arise from rupture into the adjacent IVC; signs and symptoms may include a bruit, distended veins, and acute heart failure. In general, these patients may be hypotensive but can usually be resuscitated. Because their treatment is different from that of a ruptured aneurysm, careful examination of the abdomen, with an effort to identify a thrill or bruit, will help in diagnosis.

## DIAGNOSTIC IMAGING

Ultimately, the role of imaging should depend on the patient's hemodynamic stability. Diagnostic imaging should not delay treatment. In the patient with abdominal pain and hypotension and a pulsatile abdominal mass, immediate transport to the operating room without imaging may be appropriate. In the more stable patient, in whom the diagnosis is in question, abdominal ultrasound or expeditious CT scan may be performed rapidly in the emergency room to identify AAAs. When performed expeditiously by an experienced ultrasonographer, the diagnosis of ruptured AAA may be rapidly confirmed sonographically. However, the technique is operator-dependent and accuracy may be limited by excessive bowel gas and obesity.

CT scanning is the most accurate and useful radiographic method in the evaluation of ruptured AAA (Fig. 20-16). The most common findings are retroperitoneal hematoma, an aneurysmal aorta, and retroperitoneal stranding of blood. With 100% specificity and a very high sensitivity,<sup>76</sup> CT can reliably confirm or rule out the diagnosis of ruptured AAA as well as identify alternative nonvascular causes of the patient's symptoms. It also yields important anatomical information about adjacent structures (such as a retroaortic left renal vein, horseshoe kidney, or concomitant iliac aneurysms) and about the aneurysm itself (such as an inflammatory AAA). CT scanning is particularly important if endovascular repair is contemplated. The newer-generation multislice scanners allow for complete chest and abdominal imaging to be completed in less than 5 minutes. Although intravenous contrast is very helpful in the planning for elective AAA repair, it is not required for diagnosis in the patient with suspected rupture and may exacerbate postoperative renal dysfunction. Even with an endovascular approach, thin slice (2 mm) noncontrast CT can provide sufficient information for repair.

**FIGURE 20-16** CT scan of ruptured abdominal aortic aneurysm (AAA) with retroperitoneal hematoma.

## **PREOPERATIVE MANAGEMENT**

Once the diagnosis of ruptured AAA is made, either by clinical presentation or radiographically, the patient should be taken immediately to the operating room. Large-bore intravenous access in the upper extremities (or central venous access), indwelling urinary catheter, type and cross-match for at least 6 units of packed cells, and chemistry and coagulation studies should all be performed. Because elevated blood pressure may lead to frank rupture of an otherwise contained leak, a strategy of permissive preoperative hypotension with minimal fluid resuscitation has been recommended. Although no rigid blood pressure parameter exists, most vascular surgeons would favor a minimum systolic pressure to maintain consciousness (usually around 80 mm Hg systolic).

## **OPEN REPAIR**

Open repair remains the most common and versatile approach to ruptured AAA. Because general anesthesia will lead to both generalized vasodilatation

and relaxation of the abdominal musculature, both of which can produce abrupt hypotension; the patient must be prepped and draped (“nipples to knees”) and the surgical team scrubbed prior to induction. A cell saver device should be set up and used when possible. A midline incision is performed for rapid access to the supraceliac aorta. In recent years, transfemoral placement of an occlusion balloon in the suprarenal aorta prior to induction of anesthesia has been proposed to facilitate rapid aortic control should the patient become hypotensive on induction.<sup>77</sup> Although this is a useful adjunct, it does require imaging capability in the operating room. After induction, the abdomen is opened from xiphoid to pubis. The abdomen and retroperitoneum are inspected. If a small or moderate retroperitoneal hematoma is found without intraperitoneal blood, the supraceliac aorta is controlled, as described earlier, but the artery is not clamped. If the juxtarenal aorta is spared of hematoma, this area may be dissected and a clamp applied directly below the renal arteries. Should bleeding develop during the course of this dissection, the supraceliac clamp is applied.

If intraperitoneal blood is present, rapid supraceliac aortic control is obtained, usually by manual compression at the diaphragmatic hiatus while the anesthesiologist rapidly continues resuscitation. The supraceliac aorta is then exposed as previously described and occluded with a vascular clamp. Once the cross clamp is placed, the distal aorta is palpated to confirm obliteration of the pulse and attention is turned to the aneurysm. In patients with massive rupture, bleeding, or hypothermia, in which coagulopathy is almost certainly present, heparin is not given. In such cases, thrombectomy of the distal vessels and vigorous flushing of the graft are necessary prior to restoring flow. In all other cases, we give a small dose of heparin, 40 to 50 U/kg.

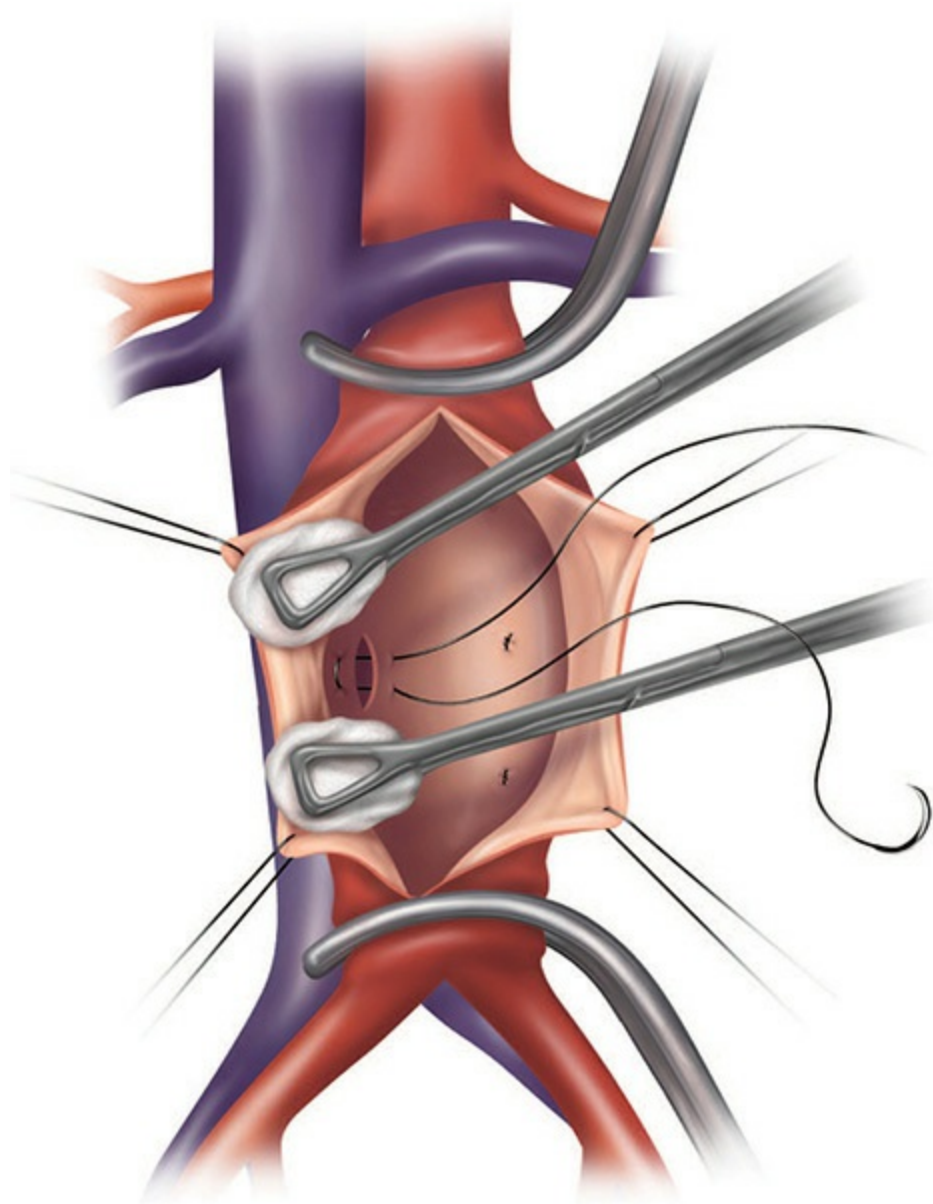

There is an increasing tendency to obtain intravascular supraceliac balloon control of the aorta prior to celiotomy. There is data that suggests this is superior to open aortic cross clamping.<sup>78</sup> This is performed by passing a wire and then a balloon into the supraceliac aorta via either a retrograde transfemoral or a prograde transbrachial approach, as described earlier in the chapter, before induction of anesthesia. This requires intraoperative fluoroscopic capabilities and catheter/guidewire skills. This approach provides less invasive and more rapid control of the supraceliac aorta and can facilitate resuscitation of the patient in circumstances of profound shock.

The aneurysm is approached by evisceration of the transverse colon and

omentum cephalad and the small bowel to the right. Care is taken not to injure the IVC or the inferior mesenteric, gonadal, or left renal veins. In most cases, the retroperitoneal hematoma facilitates the dissection. Efforts are made to identify an infrarenal neck of the aneurysm and place a clamp at this level. When there is a free rupture of the aorta, the surgeon can pass the fingers of one hand through the rupture into the aorta (after application of the supraceliac clamp) to help locate the proximal neck of the aneurysm. Bimanual palpation can facilitate the placement of a clamp above the aneurysm without extensive dissection. Once the aortic neck is controlled, the iliac vessels are dissected to allow for clamping and control. Because the iliac veins often adhere to the artery, circumferential dissection around the iliac arteries should be avoided to prevent vein injury. In most cases, the iliac arteries may be readily clamped with minimal dissection. However, if the dissection is difficult, as with a large distal hematoma, endoluminal control may be obtained using a number 5 occlusion balloon, placed in each iliac artery after opening the sac. Once the aneurysm has been isolated proximally and distally, the sac is opened longitudinally and thrombus evacuated. Bleeding from the lumbar vessels is controlled with direct suture ligation using a mattress suture (Fig. 20-17). Venous bleeding encountered inside the sac suggests an aorto caval fistula. In those cases the patient should be placed in mild Trendelenburg's position to reduce the chance of air embolus and the venous bleeding controlled by pressure. The defect is oversewn from within the aneurysm sac, with gentle digital or spongstick compression of the cava proximally and distally (Fig. 20-18). No attempt is made to clamp or mobilize the cava.

**FIGURE 20-17** Control of lumbar vessels from within the aneurysm using mattress sutures to encircle the vessel.

**FIGURE 20-18** Repair of an aortocaval fistula from within the aneurysm. Venous back bleeding is controlled with sponge sticks. This avoids dangerous dissection of the vena cava.

Because of the significant risk of colon ischemia following ruptured AAA repair, reimplantation of the IMA should be considered in cases of ruptured AAA.<sup>79</sup> Brisk back bleeding suggests adequate SMA collaterals and implantation is not required. If the IMA is *patent* and back bleeding is absent or sluggish, reimplantation of the IMA should be planned after aortic repair. In these cases, the IMA is controlled just outside the aneurysm sac with a small bulldog clamp, and after the aortic repair the IMA is reimplanted on the

aortic graft using a Carrel spatulated patch. An IMA that is obviously occluded at its origin is not reimplanted.

With the aneurysm opened and bleeding controlled, the graft may be sewn in place. When possible, this is done with an infrarenal clamp in place. It is absolutely mandatory that the proximal anastomosis be sewn meticulously into relatively healthy (nonaneurysmal) aorta. Poorly placed sutures in friable aorta will lead to proximal suture line bleeding once clamps are removed. If a secure anastomosis cannot be performed with an infrarenal clamp, the proximal anastomosis should be done with a suprarenal clamp in place. Tamponade of visceral back bleeding may be required while this is performed by placing an inflated balloon catheter through the aneurysm neck into the visceral aorta. Sutures must be placed in the aorta precisely and without tension or torsion of the needle. The proximal anastomosis may be reinforced with a Teflon felt pledget. Once the proximal anastomosis is completed and judged to be satisfactory, heparinized saline (5000 U/1000 mL saline) is flushed into the graft and the graft clamped. The distal anastomosis is then performed in a similar fashion. If heparin had not been given, a number 4 balloon thrombectomy catheter is gently passed down each iliac artery to extract thrombus. The graft should also be flushed to ensure adequate forward flow and the anastomosis is then completed ([Fig. 20-19](#)).

**FIGURE 20-19** Aortic tube graft in place for treatment of aortic aneurysm.

The anesthesiologist should be notified before release of the distal clamps. One leg should be perfused gradually, once the pressure has stabilized, the contralateral leg may be perfused. Pulses are checked at the femoral level and should be palpable; if not, thrombus or emboli are likely present and should be treated with thromboembolectomy. With the blood pressure stabilized and following a period of adequate perfusion, both feet should be assessed. Although palpable pulses may not be present, the feet should appear viable with reasonable capillary refill with Doppler flow.

Once adequate perfusion to the lower extremities has been achieved, the colon should be assessed. The colon should appear pink and Doppler flow should be present ideally at the antimesenteric border. If the colon appears ischemic, IMA reimplantation should be performed if not already done.

Hemostasis should be assured as best as possible prior to closure, and this may require infusion of additional clotting factors and protamine if heparin were given. The aneurysm sac is closed snugly around the graft with a running suture to obliterate the dead space and provide some hemostasis. The intestines should be excluded from contact with the graft as best as possible, usually by closing the proximal retroperitoneum or occasionally with a mobilized segment of omentum.

If the abdomen can be closed without tension, the linea alba is approximated and closed with a running suture. However, in many cases, the substantial hematoma precludes closure, and to prevent the development of abdominal compartment syndrome, the abdomen is left open with subsequent delayed closure several days later.

## **ENDOVASCULAR REPAIR**

Endovascular repair for ruptured AAA (rEVAR) was first reported almost 2 decades ago.<sup>80</sup> The early reports of decreased morbidity and mortality have been duplicated in other large single-institution series and large database reviews, with mortality rates for ruptured AAA ranging from 20% to 35%, compared with historical death rates for open repair of 50% or greater.<sup>80-83</sup> However, three prospective randomized trials have failed to show a benefit of rEVAR over open repair, with mortality rates slightly, but not significantly, lower in the rEVAR group, although one did show improved long term outcomes and cost effectiveness in the rEVAR group.<sup>84-87</sup> A meta-analysis of open and endovascular approaches to ruptured AAA showed that the benefit of rEVAR was lost when adjustments were made for the hemodynamic condition of the patient at the time of surgery.<sup>88</sup> It is important to note, however, that rEVAR was equivalent to open surgery in each of those trials and superior to open surgery in cases that were selected as suitable by the operating surgeon based on anatomic characteristics and hemodynamic stability. In addition recent large data base studies suggest superiority, particularly in elderly patients.<sup>89,90</sup> Therefore, it appears that rEVAR will have a place in the management of patients with ruptured AAA. It is currently

used in about one-third of patients with ruptured AAAs in the United States,<sup>82,83</sup> and there is reason to expect that this percentage might increase to 30% to 50% in the future.<sup>80,81,83</sup>

Successful endovascular repair of a ruptured AAA requires a dedicated team with experience in rEVAR for routine aneurysms, rapid imaging and triage by the emergency ward, 24-hour availability of imaging in the operating room, and a suitable stock of endografts. When these are in place, improvements in mortality can be expected in appropriately selected patients. It is important to note that rEVAR is associated with an increased risk of abdominal compartment syndrome, since the abdomen is not routinely entered with this technique and ongoing bleeding may be expected from lumbar and IMA back bleeding (type II endoleak) that may not be tamponaded in the absence of an intact aortic wall. Abdominal compartment syndrome may be seen in up to 20% of patients after rEVAR<sup>80</sup> and can be diagnosed by increased bladder pressures (>20 mm Hg), increased peak airway pressures with difficulty in ventilation, and reduced urine output. Treatment is laparotomy with decompression and control of any bleeding source.

The single most important consideration is the ability to expeditiously proceed with endovascular aortic control and suitable repair in the patient with a ruptured AAA before irreversible shock occurs. Multiple centers have described their techniques and operative strategy, and some variation exists; however, the fundamental principles are identical to our center's technique. The preoperative management and anesthetic considerations are the same as for open repair. Data have emerged indicating that endovascular balloon control, obtained under local anesthesia, reduces operative mortality, and this is preferred when possible.<sup>78,82</sup> In most cases, the repair is completed under general anesthesia to facilitate control of the patient's airway and minimize motion.

Access is obtained through both femoral arteries simultaneously. One artery may be accessed percutaneously with placement of a closure device. Once access is obtained by a Seldinger technique, bilateral 6-Fr sheaths are placed over floppy wires and subsequently exchanged for a stiff wire over a guiding catheter to the level of the proximal descending aorta. Contralateral to the side proposed for deploying the main body of the graft, the sheath is exchanged for a large sheath and a compliant 45-mm aortic balloon is introduced to the level of T12. Although a 12-Fr sheath is the minimum size

for the compliant aortic balloon, we prefer larger sheaths to allow for simultaneous pigtail catheter placement. If the patient is hemodynamically stable, the procedure can proceed with the balloon in place but not inflated. A marking pigtail catheter is introduced over a second floppy wire, aortogram is performed, and the position of the renal arteries marked. The main body graft is then introduced through the opposite femoral artery over the stiff wire and placed in appropriate position (Fig. 20-20). The deflated aortic balloon and its sheath are pulled back and the graft is deployed as is normally done for an elective rEVAR. The balloon is then removed from the contralateral limb and inserted through the main body of the graft into the suprarenal aortic position. The contralateral gate of the graft is then cannulated, and the contralateral limb is introduced and deployed. If the patient becomes unstable, the aortic occlusion balloon may be inflated in the suprarenal aorta.

**FIGURE 20-20** Intraoperative angiogram showing supraceliac occlusion balloon in place (*arrow*) and sheathed stent graft in position for deployment (*dotted arrow*). RA, right atrium.

The ipsilateral limb deployment is then completed and any ipsilateral limb extensions (if needed) are introduced and deployed. Once the endografting has been performed, all fixation sites are molded with the compliant balloon and a completion aortogram performed to document absence of endoleak ([Fig. 20-21](#)). A type I (attachment or perigraft leak) or type III endoleak (modular disconnection) warrants further repair before leaving the operating room, whereas a type II (branch endoleak) or type IV (graft porosity)

endoleak may be followed conservatively. All patients are watched closely for the development of abdominal compartment syndrome.

**FIGURE 20-21** Completed endograft for ruptured abdominal aortic aneurysm (AAA) showing complete exclusion of the aneurysm.

The femoral arteries are then closed primarily. If heparin had not been administered, inflow and back bleeding should be assessed prior to closure, and, if judged to be poor, a thrombectomy catheter may be passed gently to retrieve thrombus.

Although the above describes one approach for rEVAR, multiple options

exist, and the surgeon should be well acquainted with the options based on anatomic criteria should an endovascular approach be undertaken. These may include conversion to an aortouniiliac device with a femoral-femoral crossover graft or a proximal aortic extension in the case of a type I endoleak. It is anticipated that the future generation of endografts, along with greater surgeon experience, will lead to greater use of rEVAR for ruptured AAA.

## Results

Although some variation exists among individual series, pooled data suggest an overall perioperative mortality of approximately 50% after open repair for ruptured AAA.<sup>91</sup> Attempts have been made to correlate both pre- and postoperative variables with the probability of survival. Poor prognostic preoperative predictors include hypotension on induction (systolic blood pressure <90); age over 80 years, preoperative cardiac arrest, and low hematocrit.<sup>92</sup> Similar logistic regression analysis has identified postoperative myocardial infarction, respiratory failure, coagulopathy, and renal dysfunction as strong predictors of postoperative mortality; the probability of survival decreases dramatically with 2 or more complications or with the need for dialysis.<sup>93</sup>

Studies suggest that 40% to 60% of patients with ruptured AAA may be treated by endovascular means. As noted at the beginning of this section, rEVAR is associated with reduction in operative and hospital mortality of 20% to 30% in patients who are acceptable candidates for this approach. While it is unlikely that rEVAR will be applicable to all patients with ruptured AAA, up to 60% of patients may qualify for rEVAR in dedicated centers.<sup>83</sup> It is likely that increased dissemination of this technology will lead to a global decrease in the mortality from ruptured AAA.

## Visceral Artery Aneurysms

Aneurysms of the visceral arteries are uncommon, seen in 0.01% to 0.02% of autopsy studies.<sup>94</sup> However, the increased utilization of routine body imaging has resulted in greater recognition and discovery of asymptomatic visceral artery aneurysms, and thus their true prevalence is likely higher. The elective treatment of visceral aneurysms is outside the scope of this chapter. The

major complications of these aneurysms are rupture or distal embolization and prevention of these complications is the rationale for elective treatment. Recent reports on renal artery aneurysms suggest a low risk of rupture and slow growth, which has tempered previous enthusiasm for elective repair.<sup>95-97</sup> Indications for elective repair are unsettled but may include size over 2 cm, associated renal artery stenosis, and poorly controlled hypertension. Ruptured renal artery aneurysm is a rare entity, the treatment of which is outside the scope of this chapter. The remainder of this section will consider the management of a ruptured splanchnic artery. [Table 20-1](#) summarizes the relative frequency of these aneurysms, their estimated risk of rupture, and recommended treatment. Approximately 25% to 30% of splanchnic artery aneurysms are ruptured at the time of presentation<sup>98</sup> and about one-third are associated with aneurysms elsewhere in the arterial tree.<sup>99</sup> Endovascular techniques have been applied to elective and emergent treatment of splanchnic artery aneurysms with increasing frequency. In properly selected patients, these techniques, which include embolization and covered stents, appear to be associated with reduced mortality in the case of aneurysm rupture.<sup>100</sup>

**TABLE 20-1: SPLANCHNIC ARTERY ANEURYSMS**

Location	Frequency (%)	Risk of Rupture	Indications for Surgery	Type of Repair
Splenic	60	Low	Symptomatic; pregnant or childbearing age	Ligation; splenectomy; transcatheter embolization
Hepatic	20	High	Symptomatic; asymptomatic >2 cm (or all)	Ligation (common hepatic); endoaneurysmorrhaphy with arterial reconstruction; endovascular stent graft or transcatheter embolization
SMA	6	High	All	Ligation (with revascularization if compromised bowel)
Celiac	4	High	All	Ligation; resection with revascularization; aneurysmorrhaphy
Gastric/gastroepiploic	4	Very high	All	Ligation
Peripancreatic	Rare	High	All	Transcatheter embolization

## Splenic Artery Aneurysms

Splenic artery aneurysms are the most frequent visceral aneurysms (60%), are the only aneurysms with a female predominance (3:1), and have the lowest

risk of rupture. Splenic artery aneurysms have the lowest risk of rupture, perhaps no more than 10% overall and less than 2% in low-risk patients. However, the risk of rupture rises dramatically among pregnant patients, with maternal and fetal mortality rates of over 70%, and after liver transplantation,<sup>101</sup> which is the rationale for recommending repair of asymptomatic aneurysms in these groups.<sup>102</sup> Both arterial medial dysplasia (more common in females) and the underlying vascular effects of multiple pregnancies (both hormonal and hemodynamic) have been proposed as contributing factors.<sup>103</sup> Other possible etiologies include portal hypertension and splenomegaly, pancreatitis or pseudocyst-associated local inflammation, and trauma. Ruptured splenic artery aneurysm initially presents with abdominal pain referable to hemorrhage in the lesser sac without abdominal distention or shock. These signs may become apparent later after continued hemorrhage spills into the peritoneal cavity through the foramen of Winslow (“double rupture”).

In most cases, ruptured splenic artery aneurysms are treated by laparotomy and ligation. Restoration of arterial continuity is rarely necessary because of the collateral supply to the spleen, and therefore either open or endovascular obliteration of the aneurysmal segment is appropriate. Operative repair of proximal and midsplenic artery aneurysms entails exposure through the lesser sac, proximal and distal control, and simple ligation of the aneurysm without arterial reconstruction. It is important to ligate all feeding vessels; this may require opening the aneurysm and ligation from within the sac. Aneurysms of the splenic hilum require mobilization of the spleen and may be treated by ligation of all branches or splenectomy, if necessary. As in trauma, early control of the proximal splenic artery is important for the treatment of hilar aneurysms. While laparoscopic techniques have been reported for the elective resection of splenic aneurysms,<sup>104</sup> they have no place in the acute setting. Endovascular approaches have been used with increased frequency and are particularly useful in patients at high operative risk, including those with contained rupture, pancreatitis, advanced portal hypertension, or liver transplantation. In these cases, if the patient is stable, vascular access to the splenic artery is obtained through the celiac artery from a femoral or brachial approach. Using guiding sheaths and microcatheters, the splenic artery is engaged and coils are placed distal to the aneurysm, in the aneurysm sac and then proximal to the aneurysm. There is a 10% to 15% risk of rebleeding<sup>105</sup> using endovascular techniques, as well as a risk of splenic infarction when

hilar aneurysms are treated. However, the difficulties of open surgery in patients with pancreatitis or advanced liver disease justify attempts at endovascular treatment as a first effort. Endovascular stent graft placement has also been described<sup>106</sup> and may be particularly useful in certain subsets, such as patients in whom preservation of splenic blood flow need be maintained (as for portal-systemic shunts) or in high-risk patients with pancreatitis-associated aneurysms and severe inflammation.

## **Hepatic Artery Aneurysms**

Hepatic artery aneurysms, unlike splenic artery aneurysms, occur more frequently in men. There is some evidence that posttraumatic hepatic artery aneurysms are increasing in frequency. Etiologies include medial degeneration, atherosclerosis, trauma (up to 20% of cases), infection (usually secondary to illicit drug use), vasculitis, and as a consequence of orthotopic liver transplantation.<sup>107</sup> Hepatic artery aneurysms have a rupture risk of no less than 14%<sup>107</sup> and possibly higher.<sup>108</sup> About half the ruptured hepatic artery aneurysms present with signs and symptoms of intraperitoneal hemorrhage, while the other half will rupture into the biliary tract, manifesting as either hemobilia or gastrointestinal hemorrhage.

A variety of treatment options exist for hepatic artery aneurysms, including ligation, excision, repair with arterial grafting and reconstruction, hepatic resection, and endovascular approaches.<sup>95,107–109</sup> Treatment of ruptured hepatic artery aneurysms generally depends on their location and the status of hepatic blood flow. When feasible, preoperative arteriography is helpful in planning the operative approach. Arteriography can provide information on the collateral flow to the liver, demonstrate anomalies such as a replaced right or left hepatic artery, and identify multiple aneurysms, especially in the case of intrahepatic lesions.

Ruptured common hepatic artery aneurysms are treated by simple ligation and exclusion, unless the liver appears ischemic after clamping. Embolization of select common hepatic aneurysms may be considered in patients with a patent portal vein and good hepatic function. Collaterals from the right gastric and gastroduodenal arteries will maintain hepatic artery flow in most cases. Arterial reconstruction is indicated for most aneurysms of the proper hepatic artery and its extra hepatic branches unless the patient is too unstable to

tolerate attempts at bypass. In most instances, this requires interposition grafting (preferably with autologous saphenous vein) aneurysmectomy, or endoaneurysmorrhaphy. Because of their proximity to the bile duct and portal vein, dissection of the more distal hepatic or extrahepatic branch arterial aneurysmal segments may be tedious, and proximal and distal control may be easier from within the aneurysm itself. Ruptured aneurysms may require concomitant control at the supraceliac aorta level. If an interposition graft is not possible (as with distal common or proximal proper hepatic artery aneurysms), an aortohepatic bypass can be performed by exposing the right anterolateral border of the aorta through an extended Kocher maneuver and medial visceral rotation. The aortic anastomosis is performed first; the graft is tunneled retroduodenal to the porta hepatis and anastomosed to the hepatic artery after opening the aneurysm. If the patient is unstable, ligation of the hepatic artery, at any level, is acceptable as long as the portal vein is patent; the risk of hepatic infarction is low and is less than that of an extended procedure in a compromised patient.

Intrahepatic aneurysms are best treated by catheter-based embolization unless they are large. Options for endovascular treatment of hepatic artery aneurysms include both coil embolization and stent graft placement. Embolization has been most useful for small, saccular intrahepatic pseudoaneurysms, as may be seen following trauma or percutaneous biliary procedures with iatrogenic arterial injury. Large intrahepatic aneurysms may require liver resection. Endovascular approaches have also been described for extrahepatic aneurysms, including both coil embolization and the placement of endovascular covered stents.<sup>105</sup>

## **Superior Mesenteric Artery Aneurysms**

Superior mesenteric artery (SMA) aneurysms have been associated with an infectious etiology, dating back to DeBakey and Cooley's 1953 report of successful resection of a mycotic aneurysm,<sup>110</sup> and systemic infection (usually associated with endocarditis) continues to be a significant factor in their development. Other less common causes of SMA aneurysms include atherosclerosis, connective tissue disorders, vasculitis, and trauma. The risk of rupture of SMA aneurysms is in the range of 40% to 50%. The majority of SMA aneurysms occur in the proximal 5 cm of the vessel. SMA aneurysms are usually symptomatic, presenting with abdominal pain and sometimes

signs of intestinal angina. Treatment of ruptured SMA aneurysms is complicated by their frequent infectious etiology and difficulty with arterial reconstruction. Unlike the situation with trauma to the SMA, resection and reconstruction of aneurysms is often more difficult because the lesion is more extensive. While early teaching mandated proximal SMA reconstruction, larger, contemporary series suggest that ligation without revascularization can be considered in most patients.<sup>111</sup> In these cases, test occlusion of the vessel to assess the extent of intestinal ischemia is critical prior to a decision on the need for reconstruction. When collateral circulation from the celiac and inferior mesenteric arteries, through the pancreaticoduodenal and middle colic vessels, respectively, is sufficient to maintain intestinal viability after test occlusion of the SMA, ligation can be performed. If extensive intestinal ischemia is present after test occlusion, bypass grafting is required. This is usually performed as an interposition graft or a bypass from the infrarenal aorta, using autogenous vein. More distal aneurysms of the SMA can often be treated by ligation with resection of the compromised small bowel as needed. Access to the origin of the SMA is obtained by left medial visceral rotation. The more distal segments of the SMA are exposed by elevating the mesocolon and dissecting through the small bowel mesentery, using the middle colic artery as a guide.

Transcatheter embolization is usually reserved for multiple small bleeding aneurysms in a hemodynamically stable patient. Assessment of bowel viability by angiographic determination of collateral flow and celiotomy is mandatory after the procedure is completed.

## **Celiac Artery Aneurysms**

Medial degeneration is the most common etiology of celiac artery aneurysms. This is particularly true in those cases associated with anatomic anomalies such as a common celiomesenteric trunk.<sup>112</sup> On occasion, aneurysmal dilation occurs distal to compression by the median arcuate ligament, although the incidence of rupture in these cases is unknown. Atherosclerosis is also associated with celiac aneurysms. Ruptured celiac artery aneurysms are usually treated by ligation, which is generally well tolerated. In saccular or very focal aneurysms, aneurysmectomy, and arterial reconstruction may be considered.<sup>113</sup> In the patient with preexisting liver disease or evidence of

portal hypertension, reconstruction is indicated to maximally preserve hepatic nutrient flow. When necessary, arterial continuity may be established using either an aortoceliac bypass, originating from the supraceliac aorta or, less commonly, with an interposition graft. In some cases, the aneurysm may be confined to a portion of arterial wall; aneurysmorrhaphy may be accomplished with excision of that portion of aneurysmal wall provided the remaining wall is healthy. Exposure and control of the celiac artery is best obtained through a transabdominal incision and medial visceral rotation, allowing for visualization and subsequent division of the crura and median arcuate ligament. Alternatively, a direct approach through the lesser sac may be used.

## **Gastric, Gastroepiploic, Gastroduodenal, Pancreatic, and Pancreaticoduodenal Aneurysms**

Gastric and gastroepiploic aneurysms represent 4% of splanchnic aneurysms, the majority of which are solitary and involve the gastric artery. The etiology is undefined but likely results from either medial degeneration or an associated inflammatory process. These aneurysms have a very high incidence of rupture, either into the peritoneum or the gastrointestinal tract, and 70% present with gastrointestinal bleeding. These aneurysms are best treated by ligation, including resection of involved organs as necessary. The excellent collateral supply of the stomach and the urgent nature of the operation make reconstruction inadvisable.

Aneurysms of the gastroduodenal, pancreatic, and pancreaticoduodenal arteries are usually associated with either acute or chronic pancreatitis.<sup>114</sup> Occasionally these aneurysms are seen after liver transplantation or pancreaticoduodenectomy, particularly when complicated by postoperative pancreatic fistula. Most are symptomatic; rupture and gastrointestinal hemorrhage are common occurrences. Because of their association with pancreatic inflammation, gastroduodenal and pancreaticoduodenal aneurysms are best managed with transcatheter embolization and obliteration, especially in the setting of active hemorrhage.

## **Aneurysms of Mesenteric Branches and the Inferior**

## Mesenteric Artery

Jejunal, ileal, and colic branch aneurysms are usually small and often solitary.<sup>114</sup> These aneurysms are often identified during angiography to investigate gastrointestinal bleeding or on CT scans for evaluation of abdominal pain. The presence of multiple mesenteric aneurysms suggests a systemic pathology such as polyarteritis nodosa, septic emboli from bacterial endocarditis, or a connective tissue disorder. Rupture is most commonly seen in aneurysms involving colonic branches. Rupture most often occurs into the mesentery, although free intraperitoneal rupture can occur. Management is operative ligation, with resection of involved bowel as necessary. Transcatheter embolization has a very limited role, because laparotomy is required in any case to assess intestinal viability.

Aneurysms of the inferior mesenteric artery are exceedingly rare and little is known about their etiology or natural history. These aneurysms can usually be managed by ligation, with revascularization using autogenous vein if collateral circulation is inadequate.

## COMPLICATIONS AFTER RUPTURED ABDOMINAL AND VISCERAL ARTERY ANEURYSMS

Local and systemic complications are frequent after rupture of an abdominal aortic or visceral aneurysm. A high index of suspicion, prompt recognition, with early treatment of complications is mandatory for survival. Mortality rates range from 10% to 60% for ruptured visceral artery aneurysm and 40% to 75% ruptured aortoiliac aneurysms. Postoperative bleeding may occur as the result of ongoing coagulopathy (“medical bleeding”) or from a technical defect (“surgical bleeding”). Correction of hypothermia and coagulopathy (using blood component therapy) should be prompt, and abdominal reexploration, if bleeding continues, is mandatory. In the face of extensive blood loss and resuscitation, abdominal compartment syndrome may occur and should be promptly recognized. Abdominal compartment syndrome results in increased peak airway pressures, progressive hypoxemia, renal dysfunction and visceral ischemia from direct compression of mesenteric and hepatic capillary flow and venous compression, reduced cardiac output, and

increased intracranial pressure.<sup>115</sup> The diagnosis is suspected on clinical grounds and confirmed by bladder manometry. Bladder pressures that exceed 20 mm Hg should be treated with decompressive celiotomy. Once the edema has resolved (usually within 7 days), the abdomen is closed, either primarily or with mesh.

Residual visceral ischemia may occur after resection of aortic or visceral aneurysms. Patients who have persistent fever, leukocytosis, or ileus after surgery should be evaluated for residual visceral ischemia, pancreatitis, or intra-abdominal abscess. This is particularly true when resection of abdominal organs has been performed. Colon ischemia occurs in up to 30% of patients after ruptured AAA repair, with an associated mortality of more than 50%.<sup>116</sup> It occurs unpredictably, and can present with a range of signs and symptoms. Diarrhea, which may or may not be bloody, that occurs within 24 hours of AAA resection should raise suspicion of colonic ischemia; flexible sigmoidoscopy should be promptly performed in questionable cases. If the diagnosis of colonic ischemia is confirmed, differentiation between transmural and mucosal ischemia may be difficult, and the decision between nonoperative treatment (with broad-spectrum antibiotics, fluids, and bowel rest and repeat colonoscopy) or celiotomy and resection should be based on the patient's clinical course. In questionable cases, it is better to err on the side of operative intervention and colon resection.

Rupture of the aorta or a major visceral vessel often results in shock and multisystem organ failure. Cardiac (myocardial infarction, heart failure, arrhythmias) and respiratory (respiratory failure, adult respiratory distress syndrome) problems predominate. Renal dysfunction occurs in about one-third of patients undergoing ruptured AAA repair; the need for dialysis portends a poor prognosis, with mortality rates of greater than 75%.<sup>117</sup> Gastrointestinal and infectious complications may also occur, usually in the later stages of protracted convalescence. Finally, the culmination of these manifests as multisystem organ failure, which is the most common cause of death beyond 48 hours in patients with ruptured AAA.

Limb ischemia may be seen in patients after resection of ruptured AAA and is caused by distal embolization of aortic debris. If femoral or popliteal pulses are absent at the conclusion of surgery, prompt vascular exploration, usually by a groin incision, is indicated. In most cases the offending thrombus can be removed with an embolectomy catheter. If femoral and popliteal pulses are present, but pedal Doppler signals are diminished or

absent, more distal embolization has occurred. This sometimes manifests as “blue toes” and may be associated with microembolization of atherosclerotic debris to the buttocks, spinal cord, and sometimes abdominal and pelvic viscera. Treatment of this condition is generally supportive, because retrieval of microemboli is not feasible. Outcome depends on the severity and location of embolization and attendant ischemia and may range from full recovery to amputation and death.

**ESOPHAGUS**

# ESOPHAGEAL DIVERTICULA AND BENIGN TUMORS

*Marco E. Allaix • Marco G. Patti*

## ESOPHAGEAL DIVERTICULA

Diverticula of the esophagus are a rare entity, with a prevalence that ranges between 0.06% and 4%.<sup>1,2</sup> Esophageal diverticula are classified according to their location along the esophagus (pharyngoesophageal, midesophageal, or epiphrenic), and the mechanism of formation (pulsion or traction). Most common diverticula are those located in the pharyngoesophageal and epiphrenic locations. These are usually pulsion diverticula in which an increase of intraluminal pressure leads to herniation of mucosa and submucosa through the muscular layer resulting in a false diverticulum. Mid-esophageal diverticula are commonly traction diverticula. These are much less frequent and are the result of a focal traction of all layers (mucosa, submucosa, and musculature) of the esophageal wall by a periesophageal inflammatory process resulting in a true diverticulum.

# Pharyngoesophageal Diverticulum (Zenker Diverticulum)

## PATHOPHYSIOLOGY

Zenker diverticula are the most common diverticula of the esophagus. These arise in an area of muscular gap at the transition of the cricopharyngeal muscle and the inferior constrictors of the pharynx (Killian triangle) (Fig. 21-1), and are more frequently found on the left side of the esophagus due to the slight convexity of the esophagus to the left. Pathophysiologic mechanisms for this condition include muscular weakness and upper esophageal sphincter (UES) dysfunction. UES dysfunction is characterized by incomplete relaxation of the UES, increased intrapharyngeal pressure, and discoordinated pharyngeal contractions.<sup>3-5</sup> Gastroesophageal reflux is present in up to 95% of patients and may be related to esophageal longitudinal muscle reflex contraction and consequent widening of the gap between pharyngeal constrictors and cricopharyngeal muscles<sup>6</sup> or spasm of the UES.<sup>7</sup>

**FIGURE 21-1** Zenker diverticulum: anatomic and radiologic features. The radiologic image shows the presence of the pouch arising from the Killian triangle.

## **SYMPTOMS AND DIAGNOSIS**

Cervical dysphagia is the most common presenting symptom and is often associated with regurgitation, halitosis, choking, chronic cough, hoarseness, gurgling, or aspiration pneumonia. Findings on physical examination may include the Boyce sign (a neck mass gurgling on palpation) and weight loss. The presence of progressive dysphagia, odynophagia, hemoptysis, and hematemesis is more suspicious for a malignancy and may be a squamous cell cancer arising from the diverticulum (incidence up to 1.1%).

Diagnostic tools include:

1. Barium esophagram is performed to assess size and location of the diverticulum and the size of the diverticular neck. In addition, it determines the distance from the diaphragm, therefore giving the surgeon the possibility of choosing between a laparoscopic or thoracoscopic approach.
2. Upper endoscopy is mandatory in order to rule out the presence of cancer or other esophageal diseases and to evaluate signs of reflux
3. Esophageal manometry is important to define the underlying esophageal motility disorder. We usually obtain this test in all patients, even though some surgeons deem that it is not mandatory, in the belief that a primary esophageal motility is always present. The most common underlying disorder is achalasia, followed by diffuse esophageal spasm and nutcracker esophagus.

## **TREATMENT**

Main indication for treatment is to address the patient's symptoms from the diverticulum. The decision for intervention is made regardless of the size of the diverticulum, as it is mostly the underlying motility disorder that determines the symptom severity. However, some advice an operation also in the absence of symptoms to prevent the risk of aspiration.

Several treatment modalities directed at treating the motility disorder and

at managing the diverticulum have been proposed:

- Cricopharyngeal myotomy (CPM) alone
- CPM and diverticulectomy
- CPM and diverticulopexy
- CPM and diverticular inversion
- Diverticulectomy alone
- Diverticulopexy alone
- Diverticular inversion alone

In our experience, any procedure performed without a CPM results in an unacceptably high incidence of recurrent symptoms. Traditionally, these procedures have been performed through a left cervical incision. More recently, minimally invasive transoral endoscopic techniques have been developed.

**Open Transcervical Surgery.** This traditional approach is usually performed under general anesthesia, but can be accomplished with a cervical block and sedation. The diverticulum is either resected (diverticulectomy) or suspended and fixed to the prevertebral fascia (diverticulopexy), or invaginated into the esophagus.

In the past, *diverticulectomy* was performed with hand-sewn sutures, and was technically challenging with a risk of leak. The introduction of staplers has significantly reduced the risk of esophageal leak and mediastinitis (1.7%). Other risks of stapled diverticulectomy include recurrent laryngeal nerve injury, recurrence, and wound hematoma.<sup>8</sup> Most surgeons advocate the addition of a CPM to the diverticulectomy.<sup>9</sup>

*Diverticulopexy* consists of fixation of the sac of the diverticulum to the pre-vertebral fascia or pharyngeal muscles above the neck of the diverticulum. The advantage of diverticulopexy over diverticulectomy is that the hypopharyngeal mucosa is left intact, eliminating the risk of leakage, with shorter hospital stays.<sup>10</sup>

*Diverticular inversion* is an alternative technique: the diverticulum is invaginated into the esophageal lumen and the neck is closed by using a purse-string suture. As for diverticulopexy, the hypopharyngeal mucosa is not breached. Hospital stay is shorter and complication rate lower after inversion

than diverticulectomy.<sup>11</sup>

The rationale of performing a CPM is to relieve the functional obstruction distal to the diverticulum, thus reducing the risk of esophageal leak following diverticulectomy and recurrence of the diverticulum. The CPM is also critical to relieving the symptoms. This procedure is performed by gently incising the cricopharyngeal muscular fibers until reaching the underlying hypopharyngeal mucosa. The extension of CPM is debated,<sup>10,12,13</sup> but usually ranges between 3 and 6 cm below the cricopharyngeus muscle. Visualization of the muscular layers and mucosa may be enhanced by the placement of a bougie dilator in the esophagus prior to starting the myotomy. Perioperative complications include recurrent laryngeal nerve injury, pharyngocutaneous fistula, mediastinitis, and hemorrhage.<sup>8</sup>

Currently, there are no randomized controlled trials comparing the different open approaches to Zenker diverticulum. As a consequence, the evidence supporting one approach over the other is limited. Small (1-2 cm) symptomatic diverticula can be safely treated with CPM alone, since most of these resolve after myotomy. The choice of surgical treatment for larger diverticula (2-4 cm) is not standardized and is left to the surgeon's preference,<sup>14</sup> but most commonly includes a CPM with diverticulectomy or diverticulopexy. To date, a diverticulectomy performed using staplers in association with a CPM is considered the approach of choice for diverticular larger than 4 cm since this is associated with very low fistula rates (1%-1.7%).<sup>15</sup> Some would advocate resection to also eliminate the risk of cancer arising from the diverticulum.

**Endoscopic Transoral Surgery.** The goal of endoscopic transoral surgery is to sharply divide the common wall (septum) that separates the esophageal lumen and the diverticulum (diverticulotomy). A cricopharyngeal myotomy is automatically performed, since the common wall includes the cricopharyngeal muscular fibers. The first endoscopic approach to Zenker diverticulum with esophagodiverticulotomy was reported in 1917.<sup>16</sup> It was then abandoned due to the high rates of mediastinitis and death, until 1960 when Dohlman and Mattsson demonstrated very low rates of mediastinitis rate and recurrence by using electrocautery.<sup>17</sup>

Endoscopic diverticulotomy is accomplished under general anesthesia in patients with adequate oral access and the absence of both neck mobility

limitations and macroglossia. Endoscopic exposure is very limited in patients with a short neck, a short hyomental distance, and severe obesity, leading to a high rate of conversion to open surgery.<sup>18</sup> In addition, endoscopic diverticulotomy may result in incomplete myotomy in cases of small (<3 cm) diverticula, since only a few muscular fibers are contained in the short septum.<sup>15,19,20</sup> Some surgeons consider a very large diverticulum a contraindication to endoscopic diverticulotomy, since laser, argon plasma coagulation (APC), and diathermy are associated with higher risk of bleeding, and the use of several staple cartridges can lead to a higher risk of leak.

The endoscopic diverticulotomy can be performed by a flexible or rigid endoscope. Briefly, the endoscope is advanced down to the esophagus under direct vision until the septum is between the two valves of the endoscope. Four techniques have been described for the division of the septum for rigid diverticulotomy<sup>9</sup>:

- *Electrocautery*. The overall morbidity (subcutaneous emphysema and mediastinitis) and mortality rates reported in the literature are about 8% and 0.2%, respectively. Electrocautery has been replaced by CO<sub>2</sub> laser and stapler techniques.
- *CO<sub>2</sub> laser*. This technique is associated with limited focal tissue trauma. The reported complications and mortality rates are 9.3% and 0.2%, respectively. Most common complications are subcutaneous emphysema, mediastinitis, fistula, and bleeding.
- *Linear stapler*. The main limitation of this approach is the size of the diverticulum: poorer outcomes are reported in patients with diverticula smaller than 3 cm. The overall morbidity rate is 7.1%, while death is reported in 0.3% of cases. Most common complications are dental injury, esophageal mucosal injury, and esophageal perforation.
- *Harmonic scalpel*. This approach has been recently introduced in the clinical practice. It involves the use of ultrasonic energy to cut and seal tissues. Large studies are needed to validate this technique.

Flexible endoscopic diverticulotomy was first reported in 1995.<sup>21,22</sup> It can be performed under conscious sedation with no need for general anesthesia and neck extension. This approach is appealing in patients with comorbidities

that complicate general anesthesia and in patients with anatomical features that prevent good exposure.

The septum division can be achieved through four different techniques:

- Needle-knife incision
- Hook-knife incision
- APC
- Monopolar forceps

Repeat sessions are common to reduce the risk of perforation. Overall morbidity rate is 15% with no deaths reported in the literature. Complications include subcutaneous cervical emphysema, esophageal perforation, and bleeding.<sup>9</sup> Short-term studies demonstrate recurrence rates ranging between 0% and 35%; long-term studies are needed to understand the role and outcomes of this approach.<sup>9</sup>

To date, there are few studies (no randomized controlled trials) comparing open and endoscopic approaches. The results of these studies show that endoscopic surgery is associated with shorter operative time, lower morbidity, and shorter hospital stay than open surgery. Symptom relief rates are similar after both approaches.<sup>9,15,23–25</sup> However, the heterogeneity of these studies in inclusion criteria, sample size, and length of follow-up do not allow for any definitive conclusions.

In summary, several options are available for the surgical treatment of Zenker diverticula. Because each treatment option has advantages and disadvantages, patient selection is key to achieving satisfactory short- and long-term outcomes. In the absence of a high level of evidence, there is no consensus regarding the best approach, and a “tailored” approach is advocated.

## **Mid-Esophageal Diverticulum**

### **PATHOPHYSIOLOGY**

Mid-esophageal diverticula are a rare entity. They are often associated with mediastinal granulomatous disease, and these may develop secondary to traction exerted by inflamed mediastinal lymph nodes or malignancy.

## **SYMPTOMS AND DIAGNOSIS**

Mid-esophageal diverticula are often asymptomatic and incidentally diagnosed on a barium swallow or upper endoscopy. An esophageal manometry is usually obtained to assess the presence of an esophageal motility disorder, which is detected in about 90% of patients.<sup>2,26,27</sup>

## **TREATMENT**

While asymptomatic diverticula are not treated, symptomatic diverticula can be addressed with diverticulectomy or diverticulopexy. The decision for intervention is tempered by the underlying diagnosis that may take precedence. Diverticulectomy is the procedure of choice and it can be performed either by an open transthoracic approach or by thoracoscopy.<sup>26,28,29</sup> Even though the concomitant presence of a motor disorder implies the necessity to perform a myotomy below the diverticulum, there is no consensus regarding the indication to add a myotomy to the diverticulectomy.<sup>30,31</sup>

## **Epiphrenic Diverticulum**

### **PATHOPHYSIOLOGY**

Epiphrenic diverticulum of the esophagus is a rare entity. These are located in the distal 10 cm of the esophagus and in about 70% of cases arise on the right side of the esophagus (Figs 21-2 and 21-3). Even though most patients have a single epiphrenic diverticulum, two or more diverticula are found in about 15% of patients. A primary esophageal motility disorder, such as achalasia or diffuse esophageal spasm, is often present in patients with epiphrenic diverticulum and is thought to play a role in the development of the diverticulum and in the patient's symptoms.<sup>32-38</sup> The lack of coordination between the distal esophagus and the lower esophageal sphincter leads to increased endoluminal pressure with subsequent development of the diverticulum. Nutcracker esophagus and hypertensive lower esophageal sphincter are less frequently associated with epiphrenic diverticula. In some patients, the esophageal motility assessed by manometry is normal. This may be due to the intermittent nature of diffuse esophageal spasms for some

patients.<sup>39</sup>

**FIGURE 21-2** Barium swallow: epiphrenic diverticulum with a wide neck on the right side of esophagus a few centimeters above the gastroesophageal junction.

**FIGURE 21-3** Barium swallow: large epiphrenic diverticulum located on the left side of the esophagus with a fluid-air level; dysmotility of the distal esophagus.

## **SYMPTOMS AND DIAGNOSIS**

Most patients with epiphrenic diverticulum are symptomatic. The size of diverticulum does not correlate with the severity of symptoms,<sup>32,37,40</sup> since the underlying esophageal motility disorder is the cause of complaints rather than the diverticulum per se. Dysphagia, regurgitation of undigested food, and chest pain are the most common symptoms. The Eckardt score is the most common clinical scoring system for achalasia. It is the sum of the scores for dysphagia, regurgitation, and chest pain (a score of 0 indicates the absence of symptoms, 1 indicates occasional symptoms, 2 indicates daily

symptoms, and 3 indicates symptoms at each meal) and weight loss (a score of 0 indicates no weight loss, 1 indicates a loss of less than 5 kg, 2 indicates a loss of 5-10 kg, and 3 indicates a loss of more than 10 kg). The maximum score on the Eckardt scale is 12.<sup>41</sup>

Nocturnal cough, asthma, laryngitis, and recurrent pneumonia are secondary to aspiration of diverticular contents. Heartburn is less frequently reported, but may be due to stasis and fermentation of retained food in the distal esophagus.

The diagnostic workup includes

- Barium swallow
- Upper endoscopy
- Esophageal manometry

*Barium swallow* is the most important diagnostic test since radiological findings are useful for the planning of the surgical treatment. This test provides information about size of the diverticulum, length and width of the neck of the diverticulum, and location and distance from the gastroesophageal junction. *Upper endoscopy* should be routinely performed to rule out cancer of the distal esophagus as the cause of dysphagia, and any additional disease of the esophagus and the stomach. *Esophageal manometry* is performed to detect the presence of any underlying esophageal motility disorder. However, it is argued it could be omitted since it does not affect the management strategies. In fact, motility disorders are found in almost all patients and a normal manometry does not exclude the presence of esophageal dysmotility, such as diffuse esophageal spasm which can be episodic in nature.

## **TREATMENT**

The surgical treatment of epiphrenic diverticula consists of diverticulectomy, cardiomyotomy (to address the underlying esophageal motor disorder and to reduce the risk of staple line leak and recurrence of the diverticulum), and partial fundoplication (to prevent postoperative pathologic reflux). Even though some authors suggest treating asymptomatic patients in order to prevent the risk of aspiration, we believe that an operation should be performed only in symptomatic patients. The reasons for this policy are that

(1) symptoms will develop in less than 10% of asymptomatic patients and (2) surgery is burdened by significant morbidity and mortality even in referral centers.<sup>36,37</sup>

The last two decades have witnessed a shift in the surgical approach to symptomatic patients. While in the past the operation was performed with an open left transthoracic approach, nowadays laparoscopy is considered the approach of choice, as (1) single-lung ventilation is avoided, with no need for a chest tube at the end of the procedure, (2) it provides a better exposure of the distal esophagus, (3) it allows the introduction of the stapler parallel to the esophagus, and (4) it allows the addition of a partial fundoplication.<sup>42</sup> In addition, postoperative pain is reduced and the hospital stay is shorter after laparoscopic surgery. This operation brings relief of symptoms in 85% to 100% of patients.<sup>39</sup>

However, laparoscopic epiphrenic diverticulectomy is a challenging procedure. Staple line leaks occur in up to 23% of cases, pulmonary complications are observed in 8% to 10% of patients, and mortality rates range between 0% and 7%.<sup>14</sup> The main limitations of the laparoscopic approach are the distance of the diverticulum from the hiatus and the size of the diverticulum. The approximation of the muscular layers might be very challenging when the diverticulum is large and the diverticular neck is high in the mediastinum. In addition, a wide neck may require two or more cartridges of the stapler, thus creating a point of weakness where staple lines cross. Therefore, we suggest a tailored approach. When the upper pole of the diverticulum is too high to be safely dissected by laparoscopy or severe adhesions are present, the myotomy and the fundoplication can be completed laparoscopically, but the diverticulectomy may require a transthoracic approach.

Several factors, including distance of the diverticulum from the gastroesophageal junction, severe inflammation, and adhesions between the wall of the diverticulum and the pleura, might limit the feasibility of laparoscopic diverticulectomy.

We have recently reviewed our experience with 13 patients with symptomatic epiphrenic diverticulum who had undergone laparoscopic myotomy and partial anterior fundoplication.<sup>43</sup> In six patients the diverticulum was resected, while in seven it was left in place. In three patients the epiphrenic diverticulum was left in place because it was small

(between 2 and 3 cm) and in four patients because the upper border of the diverticular neck and the upper pole could not be safely dissected laparoscopically secondary to a long distance from esophagogastric junction, or severe adhesions. Follow-up of these patients revealed that similar Eckardt scores were reported in both groups, confirming that a myotomy alone can provide relief of symptoms and suggesting that the underlying motility disorder rather than the diverticulum may be the cause of symptoms. We recommend a second procedure through the chest no earlier than 4 to 6 weeks after the first operation in patients in whom the diverticulum is not resected for technical reasons but who still experience symptoms. An expectant strategy should be followed if the patient experiences resolution of symptoms.

**Technical Details.** Five ports are placed as described during a Heller myotomy for achalasia. The operation starts with the opening of the gastrohepatic ligament all the way to the right pillar of the crus, which is separated from the esophagus. The peritoneum overlying the esophagus is then transected, and the esophagus is separated from the left pillar of the crus. All short gastric vessels are taken down to the left pillar of the crus. Both the anterior and the posterior vagus nerves are identified and preserved. A Penrose drain is passed around the esophagus, incorporating the nerves. The surgeon then proceeds with dissection of the esophagus in the posterior mediastinum in order to bring the diverticulum as close as possible to the hiatus. The neck of the diverticulum, the lower and the upper pole, and the lateral aspect of the pouch are freed from surrounding structures. After passing a 56-Fr bougie down the esophagus into the stomach, the neck of the epiphrenic diverticulum is transected by using a linear Endo-GIA stapler with 3.5-mm staples. The staple line is covered by approximating the muscle layers with interrupted 2-0 silk stitches. A myotomy is performed in the 1 o'clock position, extending all the way to the level of the upper extent of the diverticular neck and about 2 cm onto the gastric wall. Finally, a Dor fundoplication is constructed to prevent postoperative reflux.

In conclusion, laparoscopic diverticulectomy, cardiomyotomy, and partial fundoplication are the procedure of choice for the treatment of symptomatic epiphrenic diverticula in most cases. Small diverticula can be left in place and the treatment should be oriented to treat the underlying motility disorder by myotomy and fundoplication. Large diverticula with wide neck require a

transthoracic approach.

## ESOPHAGEAL BENIGN TUMORS AND CYSTS

Benign tumors arising from the esophageal wall and esophageal cysts are rare (1%-2% of resected esophageal lesions).<sup>44</sup> Benign tumors can originate from each of the following layers of the esophageal wall: mucosa, submucosa, muscularis propria, and periesophageal tissues. They are classified according to the histologic tumor type and the location: *intramural* (leiomyoma [the most common], gastrointestinal stromal tumor [GIST], and schwannoma), and *intraluminal* (epithelial polyp, lipomatous polyp, fibrovascular polyp, papilloma, granular cell tumor, hemangioma).<sup>45,46</sup> Most of these tumors are diagnosed between the third and fifth decade of life. Children are more likely to present with symptoms secondary to cysts or duplications, which are discussed below.

### Benign Tumors

#### SYMPTOMS AND DIAGNOSIS

Benign tumors are asymptomatic and found incidentally in more than 50% of cases by upper endoscopy or other imaging tests obtained for other reasons. Presenting symptoms can be categorized as follows:

- Dysphagia secondary to obstruction by intraluminal tumor growth
- Pain and pyrosis
- Respiratory symptoms (more common in children) secondary to tracheal or bronchial compression
- Cardiac arrhythmia secondary to cardiac compression
- Ulceration and bleeding

The diagnosis of a benign tumor is frequently incidental. The evaluation of a patient with an esophageal benign tumor includes the following tests (Fig. 21-4):

**FIGURE 21-4** Esophageal leiomyoma. Barium swallow (A), endoscopy (B), and endoscopic ultrasound (C) show the presence of a mass arising from the submucosa of the esophagus that narrows the esophageal lumen.

- *Upper endoscopy* rules out the presence of cancer or other esophageal diseases and allows for biopsy of mucosal lesions. In addition, this test confirms the intact mucosa in the case of suspected submucosal tumors.
- *Barium swallow* helps to assess the location of the mass and identify other esophageal pathology.
- *Endoscopic ultrasound* provides information about (1) the layers of the esophageal wall that are involved by the mass, (2) the sonographic features of the mass that are often diagnostic, and (3) the size of periesophageal lymph nodes. In addition, needle biopsies of submucosal lesions can be taken under ultrasonic guidance with higher accuracy than endoscopic biopsy.
- *Chest computed tomography (CT)* helps define the relationships between the esophageal mass and periesophageal tissues and mediastinal organs.

## TREATMENT

Resection of the benign esophageal tumor is indicated in symptomatic patients and in the presence of masses suspicious for malignancy or with potential risk of malignant evolution (adenoma and gastrointestinal stroma tumors).<sup>47,48</sup> The excision can be accomplished by an endoscopic or surgical approach. The main indication for resection by endoscopic mucosal resection and endoscopic submucosal dissection are intraluminal lesions smaller than 2 cm and originating from mucosa or submucosa.<sup>48</sup> Most other lesions are now removed by minimally invasive resections (thoracoscopic or laparoscopic)

that are associated with low complication rates, excellent postoperative recovery, and low mortality rates.<sup>49–52</sup> Surgical enucleation is the most common procedure and is performed by laparoscopy or thoracoscopy according to the location of the mass.<sup>48</sup> Briefly, the surgeon first performs a longitudinal myotomy incising and splitting the muscular fibers, then bluntly dissects the tumor from the muscular layer and the submucosa, leaving the mucosa intact. The presence of mucosal injuries should be always checked with intraoperative endoscopy and air insufflation. Finally, the surgeon reapproximates the muscular edges to minimize the risk of diverticulum formation.

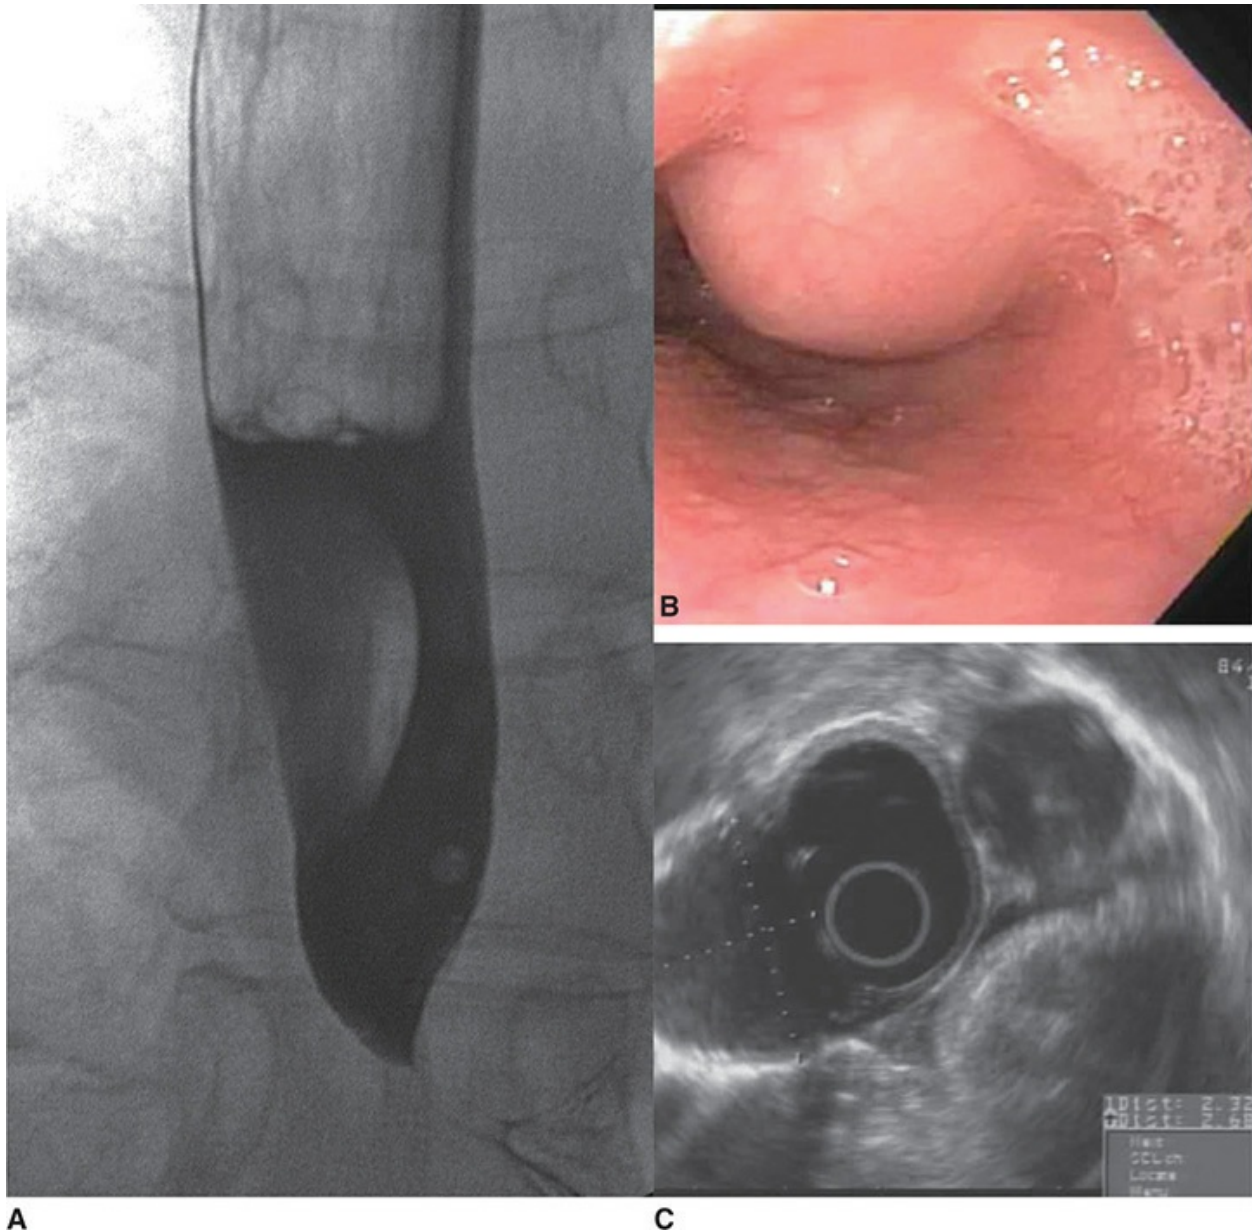

Esophagectomy is required in about 10% of patients, mainly those with leiomyomas larger than 8 cm involving the esophagus circumferentially, or with suspicion for leiomyosarcoma, and in patients with a GIST larger than 5 cm or other features of malignancy.<sup>48</sup>

## Cysts and Duplications

This group of esophageal diseases includes (1) congenital malformations that originate from aberrations of the development of esophagus or trachea and (2) inclusion and neuroenteric cysts. While esophageal cysts have muscular and epithelial layers and bronchogenic cysts include cartilage, inclusion cysts have an epithelial lining with no muscle or cartilage. Neuroenteric cysts are secondary to aberrant separation of the esophagus from the spinal column and are located on the posterior aspect of the esophagus.<sup>53</sup> These manifest with dysphagia, infection, or hemorrhage.

Diagnosis of an esophageal cyst is performed by upper endoscopy, barium esophagram, endoscopic ultrasound, CT scan, and magnetic resonance imaging (Fig. 21-5). Since the fluid-filled nature of the lesion is pathognomonic in most cases, biopsies are usually not necessary. Following identification, these malformations are resected through a thoracoscopic approach under endoscopic guidance. Both symptomatic and asymptomatic lesions are resected due to the risk of infection, mucosal erosion, and fistulization.<sup>54</sup> Cyst removal can be achieved by enucleation or esophageal resection in cases where the cyst is intramural and fused to the esophageal wall.<sup>55</sup> Previous biopsies and cyst infections might make the resection more challenging due to adhesion formation, and an open transthoracic approach

may be required.<sup>55</sup>

**FIGURE 21-5** Esophageal cyst. Barium swallow (A), endoscopy (B), and endoscopic ultrasound (C) demonstrate the presence of a fluid-filled cyst arising from the wall of the distal esophagus.

# ACHALASIA AND OTHER MOTILITY DISORDERS

*Jeffrey A. Blatnik • Jeffrey L. Ponsky*

## INTRODUCTION

Esophageal motility is a complex and multifactorial process that functions to pass food and liquid through the esophagus. Using systematic contractions in the esophageal body, combined with an appropriately timed relaxation of the lower esophageal sphincter (LES), the bolus is able to pass from the esophagus into the stomach. Errors in the process can occur anywhere along this chain of events and can lead to significant morbidity for patients. The constellation of presenting symptoms includes dysphagia, chest pain, and reflux. Due to these often vague symptoms, many patients undergo multiple other therapies prior to being diagnosed with an esophageal motility disorder and ultimately go on to further treatment. It is reasonable to start with a short course of acid suppression therapy in patients; however, when their symptoms fail to improve, this should prompt additional workup.

Achalasia is by far the most commonly diagnosed disease of esophageal motility; however, numerous other dysmotility patterns exist. The advent of high-resolution manometry has led to new understanding of esophageal

function. In addition, the information obtained from advanced diagnostics has led to improved patient selection for the various management options available. This chapter will review the common esophageal motility disorders, their diagnosis, and their management.

## **NORMAL ESOPHAGEAL FUNCTION**

A normal esophagus varies from 18 to 25 cm in length and serves to transport food from the oropharynx to the stomach. Structurally, the esophagus is made up of 4 primary layers, including the innermost mucosa, submucosa, muscularis propria, and adventitia. The muscle layer includes the innermost circular fibers and the outer longitudinal fibers, of which the upper third consists mostly of striated muscle, whereas the lower two-thirds are primarily smooth muscle. In addition to the circular and longitudinal muscles, the esophagus also contains 2 muscular sphincters. The upper esophageal sphincter controls the entrance of food to the esophagus from the oropharynx, whereas the LES prevents reflux of acid contents into the esophagus from the stomach.

Normal esophageal function is a complicated and well-choreographed event. When food is swallowed, the epiglottis moves backward to prevent aspiration and to direct food into the esophagus all while the upper esophageal sphincter relaxes. Primary peristalsis transfers the bolus down the esophagus by rhythmic contractions, which are controlled by excitatory activity in the vagal nucleus ambiguus, which releases acetylcholine.<sup>1</sup> In coordination and prior to the excitatory signal, inhibitory neurons (which release nitric oxide and vasoactive intestinal peptide) are activated by the preganglionic neurons and provide deglutitive inhibition. As one moves further down the esophagus toward the stomach, there is an increased inhibitory action called the latency gradient.<sup>2</sup> This delays contractions and allows the bolus to move forward toward the stomach. In contrast to primary peristalsis, secondary peristalsis is elicited by esophageal distension and is a local reflex that independently causes contraction of the esophagus. It is the relationship of inhibitory and excitatory signals along the esophagus that provides the coordinated forward movement of the food bolus. A disruption of this balance is thought to lead to esophageal motility disorders such as achalasia.<sup>3</sup>

# DIFFERENT TYPES OF ESOPHAGEAL DISORDERS

Esophageal motility disorders make up a broad spectrum of diseases with varied presentations and symptoms. Initial differentiation divides them into primary motility disorders versus secondary motility disorders that are manifestations of systemic diseases. By far, the most well-described primary motility disorder is achalasia, which results from failure of the LES to relax and causes varied esophageal contractions. Other primary motility disorders to be discussed in this chapter include diffuse esophageal spasm and nutcracker esophagus.

## ACHALASIA

### Epidemiology

Achalasia is the most well-studied esophageal motility disorder, with an estimated incidence of 1 per 100,000 worldwide.<sup>4-6</sup> However, achalasia is a chronic disease, and as a result, the prevalence is estimated to be between 9 and 10 per 100,000 people.<sup>5,7</sup> Sex and race do not appear to have a significant impact on the incidence of achalasia. However, there is increasing evidence supporting a genetic role.<sup>8,9</sup> This finding comes from twin and sibling studies and from association of achalasia with other diseases such as Parkinson disease and Down syndrome. However, genetic testing in achalasia is limited primarily to research studies with limited diagnostic utility.

### Pathophysiology

The cause of achalasia is felt to be the functional loss of myenteric plexus ganglion cells of the distal esophageal sphincter and lower esophagus.<sup>10</sup> This leads to a loss of inhibitory signals and eventually unopposed excitatory signals and the inability of the LES to relax. Although a definitive cause is unknown, most researchers feel that it is an autoimmune process that leads to loss of the myenteric plexus.<sup>11</sup> This is supported by histologic exam in which the ganglion cells that do remain are often surrounded by lymphocytes and

eosinophils.<sup>12,13</sup> In addition, some patients with achalasia also experience dysfunction of the upper esophageal sphincter, leading to difficulty with belching.<sup>14</sup> In unaffected patients, when gas from the stomach enters the esophagus, it triggers a relaxation of the upper esophageal sphincter. However, in some patients with achalasia, this reflex is lost presumably due to the loss of inhibitory neurons. This may also be a contributing factor to esophageal distension seen in patients with chronic achalasia. Finally, although rarely seen in Western countries, Chagas disease is a well-known cause of achalasia.<sup>15</sup> Secondary to an infection with the parasite *Trypanosoma cruzi*, Chagas disease leads to widespread myenteric plexus destruction and subsequently achalasia.

## Signs and Symptoms

For most patients, achalasia has an insidious onset with gradual progression of symptoms. Most commonly, this includes dysphagia that progresses from solids to liquids, and patients can often go years before seeking appropriate medical attention.<sup>16</sup> Patients frequently undergo therapy for other diseases such as gastroesophageal reflux disease before being diagnosed with achalasia.<sup>17</sup>

The most common symptoms associated with achalasia include dysphagia to solids (91%) and liquids (85%) and regurgitation of food and saliva (45%-75%; [Table 22-1](#)).<sup>18,19</sup> Although dysphagia is seen in nearly all patients with achalasia, it can also be observed in up to 4% of adults in the United States.<sup>20</sup> After dysphagia, additional nonspecific symptoms include chest pain, epigastric pain, weight loss, and odynophagia. Although not clearly diagnostic of achalasia, these symptoms are often part of the clinical picture.

**TABLE 22-1: RATES OF SYMPTOM PRESENTATION IN PATIENTS WITH ACHALASIA**

Symptom	Rate (%)
Dysphagia for solids	90
Dysphagia for liquids	85
Heartburn/reflux	75
Regurgitation or vomiting	45
Chest pain	20
Epigastric pain	15
Odynophagia	5

Respiratory symptoms are also occasionally seen in patients with achalasia and are thought to be related to chronic aspiration due to failed clearance of food and liquid from the esophagus. Symptoms including sore throat, hoarseness, or postnasal drip are seen in up to 71% of patients, and cough is seen in 61% of patients.<sup>21</sup> However, most patients who report respiratory symptoms often have had symptoms of dysphagia for 2 or more years prior to the onset of their respiratory symptoms.<sup>21</sup>

Finally, patient demographics may alter patient symptoms at presentation. Younger patients often present with symptoms of chest pain and heartburn more frequently than older patients.<sup>22</sup> In addition, older patients tend to be overall less symptomatic than their younger counterparts. Finally, obese patients with a body mass index  $\geq 30$  kg/m<sup>2</sup> often experience symptoms of choking and vomiting more frequently before myotomy compared with nonobese patients.<sup>23</sup>

## Diagnosis and Workup

Patients who initially present with complaints of dysphagia are often initially trialed on a course of a proton pump inhibitor (PPI). Although this is appropriate, when symptoms fail to improve after a 4 to 6 weeks, further evaluation is warranted. For most patients, the appropriate next step would be to proceed with an upper endoscopy with mucosal biopsy. This is crucial to rule out any underlying inflammatory ring, erosive gastroesophageal reflux, eosinophilic esophagitis, and esophageal cancer. The entity of an esophageal structural abnormality leading to achalasia symptoms is termed *pseudoachalasia*. Other endoscopic findings often seen in patients with

achalasia include a dilated and tortuous esophagus, residual food and fluid in the esophagus, and difficulty passing food and fluid through the LES (Fig. 22-1). Finally, patients with achalasia often develop *Candida* esophagitis secondary to the stasis.

A

B

**FIGURE 22-1** Example of retained food and saliva at the time of upper endoscopy in a patient with an esophageal motility disorder.

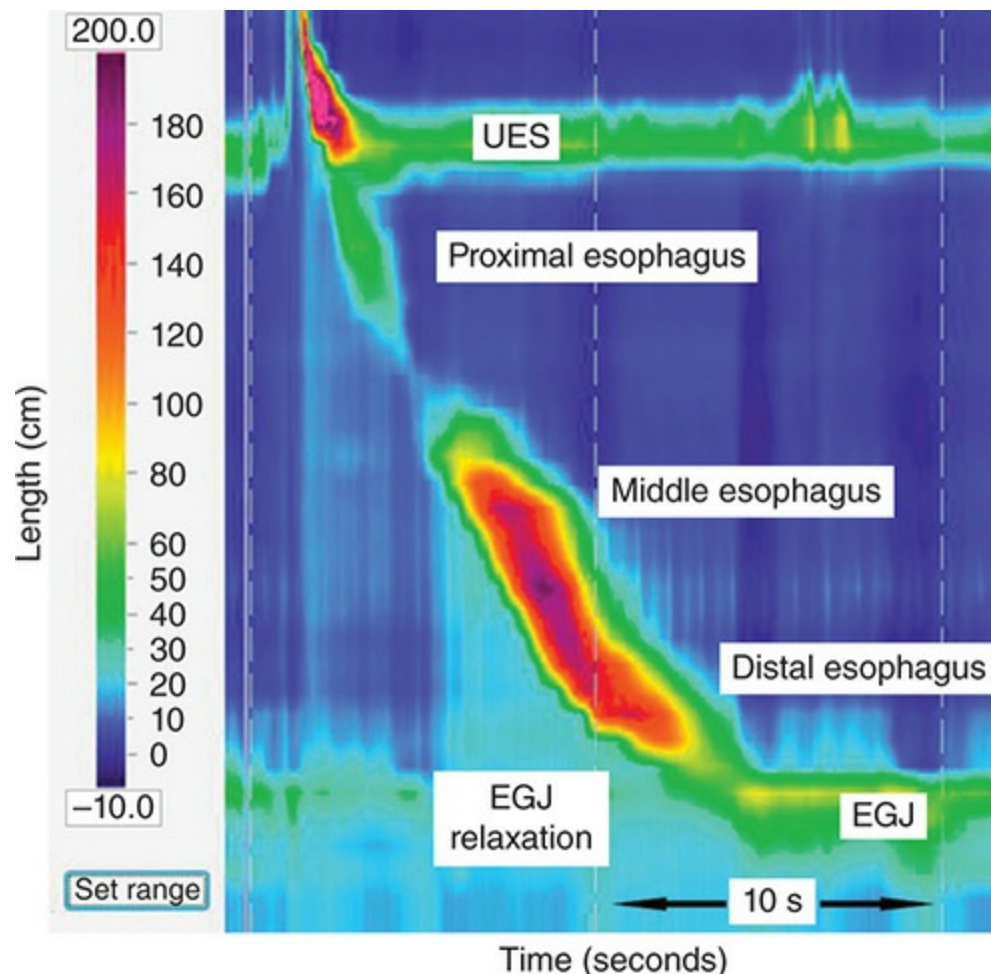

Although endoscopic findings can be suggestive of achalasia, additional evaluation with barium esophagram is recommended. This can provide details on both anatomy and function of the esophagus. A classic “bird beak” presentation ([Fig. 22-2](#)) can often be seen in patients with achalasia; other findings on esophagram include a dilated esophagus with aperistalsis and a corkscrew appearance in more severe cases. Similar to endoscopy, although these findings are suggestive of achalasia, they are insufficient for a definitive diagnosis. The next step in evaluation should include esophageal manometry.

**FIGURE 22-2** Barium esophagram in a patient with achalasia demonstrating narrowing of the distal esophagus at the lower esophageal sphincter in the classic “bird beak” pattern.

Traditional manometry, which includes water-perfused and strain gauge systems, has been for the most part replaced with more modern, reproducible,<sup>24</sup> and accurate<sup>25</sup> high-resolution manometry (HRM) catheters.

Specifically, HRM catheters have sensors spaced every 1 cm along the length of the catheter, in contrast to every 3 to 5 cm seen in traditional manometry. The result of the study is an esophageal pressure topography, which reports the pressure in a color scale compared with time and location within the esophagus (Fig. 22-3). These catheters are placed either directly or under endoscopic guidance (Fig. 22-4) through the LES and into the stomach to facilitate measuring the pressure of the distal esophagus and LES. Manometric findings consistent with achalasia include incomplete relaxation of the LES, which distinguishes it from other disorders associated with aperistalsis. In normal individuals, there is complete relaxation of the LES during a swallow (to a measured level  $<8$  mm Hg above gastric pressure). However, in patients with achalasia, the LES relaxation during swallow may be incomplete or absent all together. Additional manometric findings consistent with achalasia include an elevated resting LES pressure of  $>45$  mm Hg and aperistalsis in the distal two-thirds of the esophagus.<sup>26</sup>

**FIGURE 22-3** Sample normal high-resolution manometry. Vertical axis represents distance in centimeters, and horizontal axis represents time in seconds. The colors represented in the figure indicate the pressure, with blue being 0 and purple being the highest pressure. You can see the peristaltic contraction, the upper esophageal sphincter (UES), and the esophagogastric junction (EGJ).

**FIGURE 22-4** High-resolution manometry probe placed at the time of endoscopy. High-resolution manometry is critical for differentiating symptoms of dysphagia or chest pain in patients.

More widespread use and investigation of HRM have led to the ability to subtype achalasia based on the patterns of esophageal pressurization and the creation of a new classification scheme for motility disorders called the Chicago Classification.<sup>27</sup> The ability to subtype patients with achalasia has enabled the development of clinically relevant phenotypes.<sup>28</sup>

- Type I (classic) achalasia: Impaired LES relaxation, absent peristalsis, and normal esophageal pressure

- Type II achalasia: Impaired LES relaxation, absent peristalsis, and increased panesophageal pressure
- Type III (spastic) achalasia: Impaired LES relaxation, absent peristalsis, and distal esophageal spastic contractions

When evaluating the different subtypes, it has been found that type II patients were significantly more likely to respond to any therapy (Botox, 71%; pneumatic dilation, 91%; or Heller myotomy, 100%) than type I (56% overall) or type III patients (29% overall).<sup>28</sup> This information has improved our ability to discuss expected outcomes with our patients.

In cases without a clear diagnosis after endoscopy, barium esophagram, and manometry, there may be benefit from additional evaluation of the LES by endoscopic ultrasound<sup>29</sup> or timed barium esophagram to document contrast bolus retention.

## Treatment

There is no cure for achalasia; rather, treatment is aimed at palliating the symptoms that patients experience. Therapies are directed at reducing the contractility in the LES, thus allowing for adequate esophageal emptying. Overall, the goal is early diagnosis and therapy to prevent late complications while preserving esophageal function.

## MEDICAL

Medical therapy is the least invasive but also least effective treatment option for patients with achalasia, and as such, it is reserved for patients who cannot tolerate other treatments. Although initial response to medical therapy is approximately 50%, long-term success is limited by side effects, which include headache, orthostatic hypotension, and edema. The primary medical therapy for achalasia includes oral calcium channel blockers or nitrates, which can result in relaxation of the LES pressure in up to 47% to 64% of patients.<sup>30</sup> Nifedipine (10-30 mg administered 30-45 minutes before meals) and isosorbide dinitrate (5-10 mg administered 10-15 minutes before meals) are the 2 most widely used medical therapies; however, some studies suggest that isosorbide dinitrate may provide a more rapid response.<sup>31</sup>

Finally, phosphodiesterase-5 inhibitors, such as sildenafil, have also been used to treat patients with achalasia. They have been found to inhibit the contractile activity of the esophageal musculature in patients with achalasia, resulting in decreased LES tone.<sup>32</sup> Although initial studies have suggested some symptom improvement, long-term results are lacking.

## **BOTULINUM TOXIN**

Botulinum toxin therapy is considered for patients who are not good candidates for more definitive therapy such as pneumatic dilation or surgical or endoscopic myotomy. Under endoscopic guidance, botulinum toxin is injected into the LES and ultimately blocks the excitatory (acetylcholine-releasing) neurons that lead to the increase in the LES smooth muscle. The overall effect is a decrease in the resting pressure of the LES, allowing the esophagus to empty into the stomach. Initial symptom improvement rates of botulinum toxin are similar to those of pneumatic dilation and approach 70%.<sup>33</sup> However, patients tend to have more frequent recurrence of symptoms in as little as 6 months.<sup>34</sup> Finally, it has been found that repeated botulinum toxin injection may make subsequent myotomy more difficult and possibly result in worse outcomes compared to patients who undergo myotomy alone.<sup>35</sup>

## **PNEUMATIC DILATION**

Pneumatic dilation involves using a noncompliant cylindrical balloon to dilate the LES, essentially tearing its muscle fibers. The dilation should only be performed by an experienced endoscopist and is done under endoscopic and fluoroscopic guidance. Prior to proceeding with endoscopic dilation, patients should be considered appropriate surgical candidates due to the potential for esophageal rupture during dilation. Numerous studies have been done evaluating the efficacy of pneumatic dilation ([Table 22-2](#)), with short-term success rates ranging from 60% to 90%<sup>36</sup> and results generally sustained for up to 2 years. However, the number of patients who continue to have symptom relief wanes over time.<sup>37</sup> In addition, nearly one-third of patients will go on to require additional therapy after pneumatic dilation.<sup>38,39</sup> Despite this, pneumatic dilation is considered the most cost-effective treatment for achalasia and has the advantage of being less invasive than some surgical

options.<sup>40</sup>

**TABLE 22-2: RANDOMIZED CONTROLLED TRIALS OF PNEUMATIC DILATION VERSUS LAPAROSCOPIC HELLER MYOTOMY (LHM) FOR THE TREATMENT OF ACHALASIA**

Study	Year	Comparison	Sample Size	Findings
Persson et al <sup>37</sup>	2015	Pneumatic dilation vs LHM with posterior fundoplication	53	3-year treatment failure: 32% for pneumatic dilation vs 4% for LHM 5-year treatment failure: 36% for pneumatic dilation vs 8% for LHM
Boeckxstaens et al <sup>36</sup>	2011	Pneumatic dilation vs LHM and Dor fundoplication	201	Eckardt score $\leq 3$ at 12 months: 90% for pneumatic dilation vs 93% for LHM Eckardt score $\leq 3$ at 24 months: 86% for pneumatic dilation vs 90% for LHM
Novais et al <sup>72</sup>	2010	Pneumatic dilation vs LHM	94	3-month clinical response: 73.1% for pneumatic dilation vs 88.3% for LHM
Kostic et al <sup>73</sup>	2007	Pneumatic dilation vs LHM with Toupet fundoplication	51	12-month treatment failure: 23% for pneumatic dilation vs 4% for LHM

The greatest risk associated with pneumatic dilation is esophageal perforation after the procedure. This can range from small, clinically insignificant perforations managed with antibiotics, total parenteral nutrition, or esophageal stent placement to major disruptions requiring emergent surgical exploration and repair. The rate of esophageal perforation following pneumatic dilation ranges in the literature from 0% to 15%<sup>41,42</sup>; however, recent studies at high-volume centers place the rate at approximately 1% to 5%.<sup>36,43</sup> There are no predilation factors that have been found to be associated with a risk of perforation, but it is most likely due to an inappropriately positioned balloon. As a result of this risk, it is recommended that surgical backup be readily available when performing pneumatic dilation. The most commonly seen complication following pneumatic dilation is gastroesophageal reflux disease, with rates approaching 20%.<sup>44</sup> Symptomatic patients are often able to be successfully treated with PPI therapy.

Commercially available balloons come in 3 sizes (3.0, 3.5, and 4.0 cm in diameter); in comparison, the largest through-the-scope balloon is typically 2.0 cm. It is recommended to start with a 3.0-cm balloon that is confirmed to be in position across the LES by fluoroscopy or endoscopy. It is then insufflated with a hand-held pressure gauge for 15 to 60 seconds. After

dilation, all patients must undergo radiographic evaluation with a gastrograffin study, followed by barium esophagram to evaluate for esophageal perforation.<sup>45</sup> If patients fail to improve symptomatically, additional dilations can be performed with progressively larger balloons in 4 to 6 weeks. Long-term symptom improvement also appears to be improved with serial dilation compared with single pneumatic dilation.<sup>41</sup> Success following pneumatic dilation appears to be impacted by patient characteristics such as age (improved outcomes if >45 years), sex (improved outcomes in females),<sup>46</sup> esophageal diameter, and achalasia subtype.<sup>28,47</sup>

## **SURGICAL APPROACH**

The original surgical approach to achalasia involved division of the circular and longitudinal esophageal muscle fibers through a thoracotomy with overall good results.<sup>48</sup> However, this approach has been replaced by a minimally invasive, laparoscopic, transabdominal approach (Heller myotomy) with or without a fundoplication due to lower perioperative morbidity and faster recovery<sup>49</sup> compared with thoracotomy. Heller myotomy offers superior results when compared with single pneumatic dilation, with efficacy rates ranging from 88% to 95%.<sup>33</sup> However, this superiority is less evident when compared with serial and graded pneumatic dilation.<sup>33,36</sup> In addition, similar to pneumatic dilation, the efficacy of Heller myotomy can decrease over time, with symptom improvement decreasing from nearly 96% at 6 months to 57% to 92% at 6 years.<sup>37,41</sup>

Gastroesophageal reflux disease after surgical myotomy continues to be a frequent problem, with rates approaching 30%.<sup>33</sup> The addition of a surgical fundoplication has been found in a blinded, randomized controlled trial to reduce the rate of abnormal acid exposure in the esophagus from 47% to 9%.<sup>50</sup> As such, the Society of American Gastrointestinal and Endoscopic Surgeons currently recommends that a fundoplication be included following surgical myotomy to prevent reflux.<sup>51</sup> However, the preferred approach to fundoplication (anterior Dor vs posterior Toupet) remains uncertain.<sup>52</sup>

The procedure begins with a standard 4- to 5-port laparoscopic approach. After dividing the gastroesophageal ligament, the esophageal fibers are identified. Both the outer longitudinal and inner circular fibers are then divided either with blunt traction or the use of electrocautery for a distance of

4 to 6 cm proximal along the esophagus from the gastroesophageal junction and 2 cm distal onto the body of the stomach (Fig. 22-5). Following division of the muscle fibers, the fundoplication is then performed.

**FIGURE 22-5** Completed laparoscopic Heller myotomy prior to any fundoplication. The *arrows* point to the divided esophageal and gastric muscle, demonstrating a bulging mucosa between them. This step is then usually followed by either a Dor or Toupet fundoplication.

## **PNEUMATIC DILATION VERSUS SURGICAL MYOTOMY**

Initial studies comparing pneumatic dilation and surgical myotomy (Table 22-2) demonstrated that surgical myotomy was associated with improved long-term symptom improvement when compared with pneumatic dilation (68.2% vs 56.3%).<sup>33</sup> However, patients underwent only single pneumatic dilation, which is not the current recommendation. In one of the most referenced prospective, randomized trials comparing surgical myotomy and graded pneumatic dilation, no significant difference in success rates after 2 years of follow-up was found (92% for pneumatic dilation vs 87% for surgical myotomy).<sup>36</sup> Thus, it appears that laparoscopic surgical myotomy

and pneumatic dilation have comparable success rates.

## **PERORAL ENDOSCOPIC MYOTOMY**

Probably the most recent advancement in the management of achalasia comes in the form of peroral endoscopic myotomy (POEM). First described in 2010 by Inoue et al,<sup>53</sup> this procedure involves using a standard flexible gastroscope with a transparent cap to make a small cut in the esophageal mucosa approximately 14 cm proximal to the gastroesophageal junction. This is then used to enter into the submucosal plane and create a tunnel along the length of the esophagus and onto the body of the stomach. Following creation of the tunnel, it is then used to access and divide the esophageal muscle fibers using electrocautery. The final step involves closing the mucosal opening either with endoscopic clips or sutures (Fig. 22-6).

A

B

C

D

**FIGURE 22-6** The 4 key steps in performing a peroral endoscopic myotomy (POEM). **A.** After performing a submucosal injection, a mucosotomy is performed to gain access to the submucosal space. **B.** The submucosal tunnel is continued down the length of the esophagus and onto the stomach using intermittent injections of methylene blue solution and electrocautery. **C.** Following creation of the submucosal tunnel, the myotomy is performed. There are numerous variations on this approach; however, the ultimate goal is to divide at minimum the circular fibers on the esophagus and onto the stomach. **D.** Following completed myotomy, the mucosotomy created at the

beginning is then closed with either clips or endoscopic sutures.

Although long-term studies are lacking, many series report success rates of over 90% at 1 year follow-up.<sup>54,55</sup> A recent meta-analysis comparing POEM with surgical myotomy demonstrated equivalent short-term outcomes between the 2 treatments with comparable rates of complications. POEM is gaining increased exposure for the treatment of achalasia, but more long-term studies are needed. Similar to surgical myotomy, gastroesophageal reflux disease remains a common complication following POEM and is reported in 10% to 46% of patients.<sup>56</sup> For this reason, most patients are placed on PPI therapy after POEM until subsequent pH testing can be completed.

## **Follow-Up and Treatment Failures**

The rate of esophageal squamous cell carcinoma is increased in patients with achalasia compared to the general population (hazard ratio of developing cancer, 28).<sup>57</sup> There is also some concern for increased risk of adenocarcinoma; however, this risk is significantly lower than that for squamous cell carcinoma. The mechanism for increased malignancy is thought to be secondary to stasis within the esophagus and increased inflammation. Regardless, the risk is still low overall, and there are insufficient data to support routine endoscopic surveillance for patients with achalasia.<sup>58</sup>

The current management of achalasia is aimed at alleviating symptoms, but some patients go on to develop megaesophagus or “end-stage” achalasia. These patients present with a markedly dilated and tortuous esophagus. As such, pneumatic dilation is often unsuccessful, and patients require surgical myotomy<sup>59</sup> or POEM<sup>60</sup> with improvement in symptoms. However, some patients may ultimately require esophagectomy typically with gastric pull up for management of symptoms. Uncontrolled studies report that 80% of patients have improvement of their symptoms following esophagectomy, with mortality rates ranging from 0% to 5.4%.<sup>61</sup>

## **DIFFUSE ESOPHAGEAL SPASM**

Diffuse esophageal spasm (DES) is characterized by uncoordinated and

simultaneous contractions of normal amplitude within the distal esophagus. The contractions do not propel food effectively to the stomach, and patients tend to present with symptoms of dysphagia, regurgitation, and chest pain. On HRM, DES is characterized by  $\geq 20\%$  premature contractions within the esophagus (Fig. 22-7). In contrast to achalasia, DES symptoms are intermittent, and findings on HRM may not be present on every series of test swallows. In addition, unlike achalasia patients, DES patients usually have normal relaxation of the LES. Contrast esophagram may show a corkscrew esophagus or rosary bead esophagus (Fig. 22-8).

**FIGURE 22-7** Sample high-resolution manometry for a patient with diffuse esophageal spasm. The patient has evidence of a high-amplitude contraction occurring simultaneously. UES, upper esophageal sphincter.

**FIGURE 22-8** Sample barium esophagram of a patient with diffuse esophageal spasm (DES) showing the classic corkscrew pattern of the esophagus.

The pathophysiology of DES remains unknown but is thought to be associated with impairment of inhibitory innervation. An additional hypothesis is thought to be a dysfunction of endogenous nitric oxide synthesis within the esophagus. In one study reviewing patients presenting for evaluation of noncardiac chest pain and undergoing esophageal manometry, the prevalence of DES was 4%.<sup>62</sup>

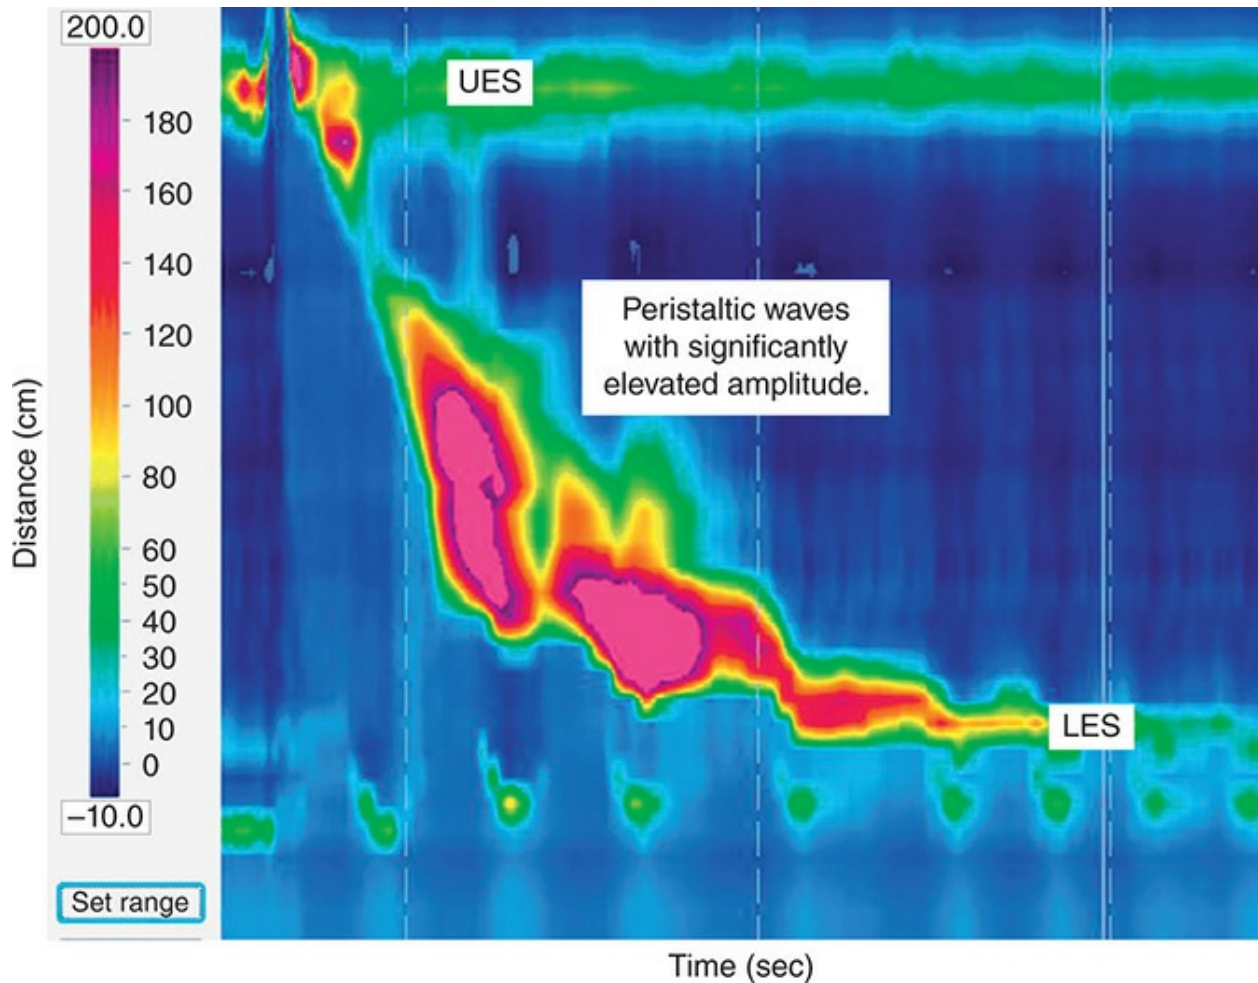

In patients diagnosed with DES, treatment is again focused on relieving symptoms. However, due to the intermittent nature of symptoms, no clear consensus exists on treatment algorithms. Medical management of DES is often focused on the primary symptom. In patients who present with dysphagia, therapy with a calcium channel blocker (diltiazem 60-90 mg 4 times a day) was found to reduce symptoms in select individuals.<sup>63</sup> For patients whose primary symptom is chest pain, calcium channel blockers and

tricyclic antidepressants (imipramine 50 mg/d) have been shown to be effective in small trials.<sup>64</sup> The use of pneumatic dilation for DES is not currently recommended due to the broad area affected. One small study evaluating the role of botulinum toxin injection for patients with DES found that the injection of botulinum toxin in 4 quadrants at 2 and 7 cm above the gastroesophageal junction improved total symptom scores.<sup>65</sup> The use of surgical myotomy has been evaluated for patients who are refractory to medical therapy with varied success rates.<sup>66</sup> Most recently, POEM has been evaluated for patients with DES. Using HRM to localize the extent of disease, POEM can be targeted to the affected area. In a small study of 5 patients who underwent POEM for DES, the overall rate of symptom relief was 71%.<sup>67</sup>

## NUTCRACKER ESOPHAGUS

In contrast to DES and achalasia, nutcracker esophagus (hypertensive peristalsis) is characterized by normal sequential esophageal contractions; however, they are of extreme amplitude or duration. Nutcracker esophagus on conventional manometry is defined as high-amplitude peristaltic contractions of >180 to 220 mm Hg in the distal esophagus. On HRM, the high-pressure contractions are measured as the distal contractile integral (DCI), with  $\geq 20\%$  of DCI measuring >8000 mm Hg·s·cm (Fig. 22-9).<sup>27</sup> In addition, many patients with nutcracker esophagus may also have a hypertensive or poorly relaxing LES, which can lead to some overlap in the diagnosis. Contrast esophagram in patients with nutcracker esophagus often shows a rosary bead pattern (Fig. 22-10).

**FIGURE 22-9** Sample high-resolution manometry in a patient with nutcracker esophagus. It demonstrates preserved peristaltic activity, but with significantly elevated amplitude. This is typically  $>180$  mm Hg of pressure. UES, upper esophageal sphincter.

**FIGURE 22-10** Barium esophagram of a patient with nutcracker esophagus demonstrating a rosary bead pattern. This is similar in appearance to a patient with diffuse esophageal spasm (DES) and requires the addition of high-resolution manometry to differentiate.

Patients with nutcracker esophagus tend to present more frequently with symptoms of chest pain rather than dysphagia due to the coordinated nature of the contractions. In addition, patient symptoms often do not correlate with the results of manometric studies. In one study evaluating 910 patients

referred for noncardiac chest pain, 12% were found to have manometry tracings consistent with nutcracker esophagus.<sup>68</sup>

Therapy for patients with nutcracker esophagus is similar to DES. One small randomized trial of 22 patients with nutcracker esophagus found that a calcium channel blocker (diltiazem 60-90 mg 4 times a day) significantly relieved chest pain when compared with placebo.<sup>69</sup> Also similar to DES, tricyclic antidepressants have shown limited success in alleviating symptoms.<sup>64,70</sup> Surgical myotomy has shown some success in relieving dysphagia symptoms; however, improvements in chest pain are less consistent.<sup>71</sup> The use of POEM has also found some initial success in patients with nutcracker esophagus, but ongoing investigation is still required before widespread acceptance.<sup>67</sup>

## CONCLUSION

In conclusion, esophageal motility disorders present with a complicated disease pattern that relies on a high index of suspicion. Patients often present with symptoms of dysphagia or chest pain and undergo other therapies prior to being diagnosed with achalasia or other motility disorders. POEM marks a new treatment option that is finding increasing applications for esophageal motility diseases. Further studies are needed to determine what the long-term outcomes will be for patients undergoing POEM.

# GASTROESOPHAGEAL REFLUX DISEASE, HIATAL HERNIA, AND BARRETT ESOPHAGUS

*Robert D. Bennett • David M. Straughan • Vic Velanovich*

## GASTROESOPHAGEAL REFLUX DISEASE OVERVIEW

### **Definition**

Gastroesophageal reflux disease (GERD) is a chronic disorder involving pathologic retrograde flow of gastric contents into the esophagus. In 2006, an international group of 44 experts known as the Montreal Consensus defined GERD as “a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications.”<sup>1</sup> This definition was chosen to allow for patients to be diagnosed independent of the technology used during evaluation. Nonerosive reflux disease (NERD) is defined as

classic GERD symptoms in the absence of mucosal complications, and may<sup>2-4</sup> account for 30% to 70% of patients presenting for endoscopy with reflux symptoms.

## **Epidemiology**

Until 2006, when the definition of GERD became more standardized, varying frequency rates were reported. A systematic review performed in 2005 identified a prevalence rate between 10% and 20% in Europe and the United States, and less than 5% in Asia.<sup>5</sup> These findings of regional variation were updated and confirmed in 2014 by the same group. Occurrence of at least once-weekly episodes of heartburn or regurgitation or a diagnosis of GERD as defined by the Montreal Consensus or a physician was found to be 18.1% to 27.8% in North America, 23.0% in South America, 8.8% to 25.9% in Europe, and 8.7% to 33.1% in the Middle East. In East Asian studies, prevalence of GERD ranges from 2.5% to 7.8% and 11.6% in Australia.<sup>6</sup>

Studies between 1992 and 2011 suggest that the prevalence of GERD may be increasing worldwide, but remains lowest in East Asia and highest in Western countries.<sup>5</sup>

## **Risk Factors and Associated Conditions**

Risk factors for the development of GERD include obesity, increasing age, and genetics (concordance rates are higher in monozygotic vs dizygotic twins). Behavioral factors may include alcohol consumption, tobacco use, and diet.<sup>5</sup>

The prevalence of GERD does not increase with age, but symptom intensity may decrease after age 50.<sup>7</sup> Prevalence of erosive esophagitis, however, does increase with age over 50.<sup>8</sup>

GERD is frequently associated with pregnancy, often presenting as heartburn. While onset can occur at any point during a pregnancy, the majority of cases begin in the first trimester (52%), with decreasing frequency of onset later in pregnancy (40% in the second trimester, 8% in the third trimester).<sup>9</sup> Overall prevalence of symptoms, however, increases throughout pregnancy, with up to 72% of pregnant patients reporting heartburn symptoms in the third trimester. Symptom severity also increases

as pregnancy progresses.<sup>10</sup>

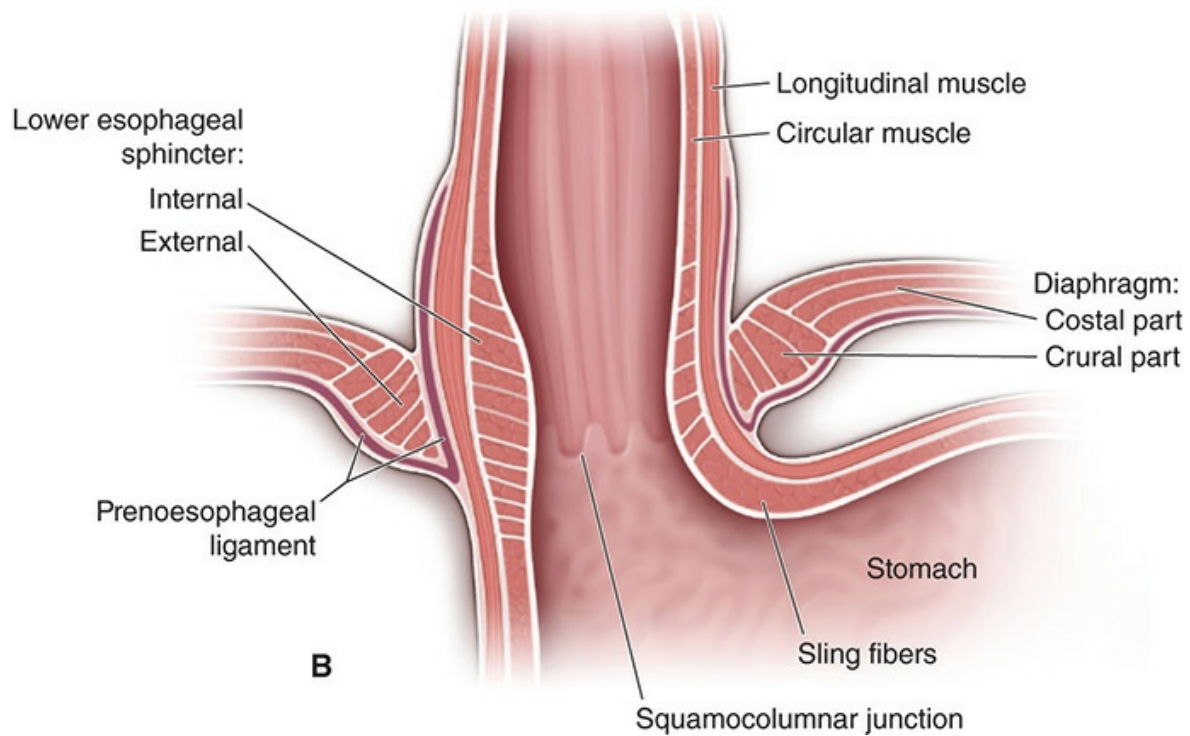

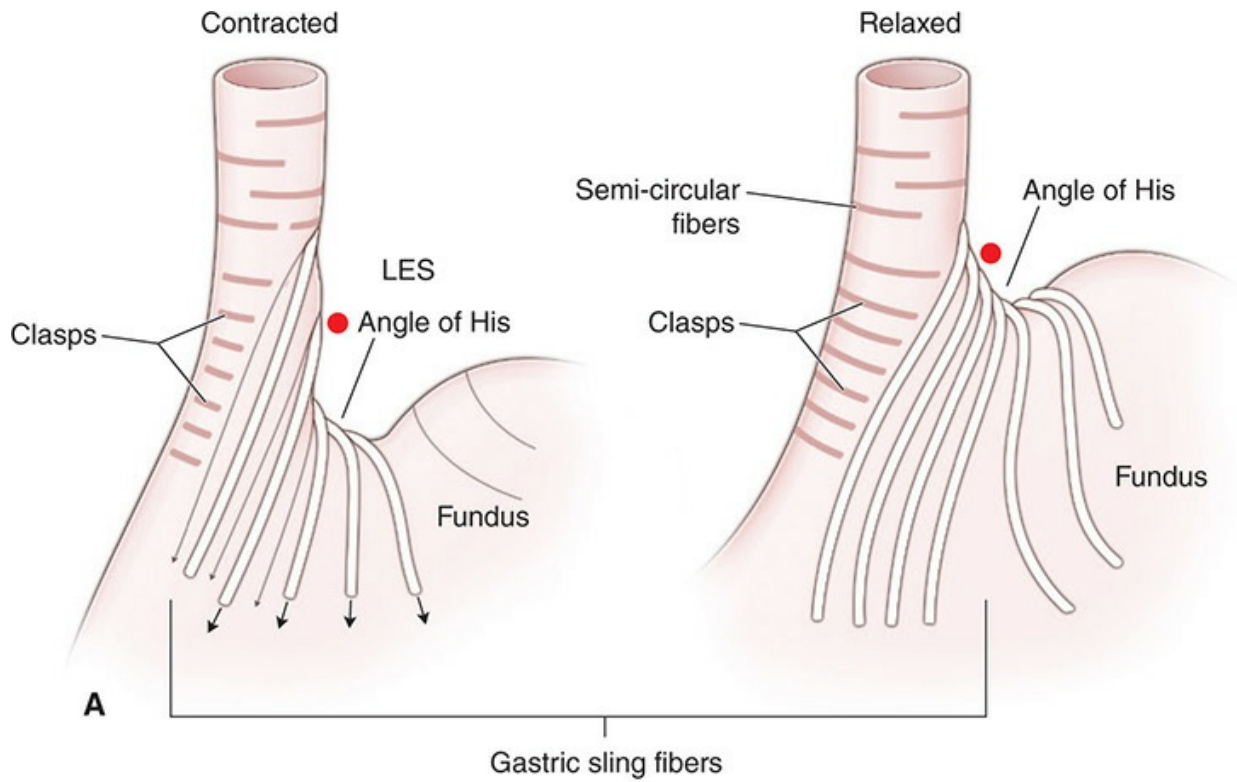

## PATHOPHYSIOLOGY

### Normal Lower Esophageal Sphincter Anatomy/Physiology

The lower esophageal sphincter (LES) is a physiologic high-pressure zone located just cephalad to the gastroesophageal junction (GEJ), which serves to prevent retrograde passage of gastric contents into the esophagus. The antireflux mechanism is supported by the lower esophageal musculature, interaction with the diaphragmatic hiatus, and maintenance of an intra-abdominal esophagus by the phrenoesophageal ligament. Any acid reflux that occurs is mitigated by neutralization of the gastric acid with alkaline saliva and minimization of contact of the acid with the esophageal mucosa by reflex clearing esophageal peristalsis.

The LES can be defined anatomically or physiologically. Anatomically, although difficult to identify clinically, the LES is composed of intrinsic and extrinsic contractile elements. The intrinsic contractile element is made up of circular, tonically contracted “clasp” muscle fibers within the distal esophagus, and diagonally oriented “sling” muscle fibers at the cardia-fundus junction (Fig. 23-1A). The extrinsic component is made up of crural fibers at the esophageal hiatus of the diaphragm, referred to as the diaphragmatic “pinch-cock” mechanism. Similar to the intrinsic component, these muscle fibers are in a state of tonic contraction, which contributes to the elevated resting pressure of the LES.<sup>11</sup> During inspiration, these crural fibers further contract, contributing to measured pressure at the LES. Lastly, the increased pressure of the abdominal cavity relative to the thoracic cavity also exerts increased transmural pressure on the intra-abdominal portion of the LES. Physiologically, the LES represents a region of relatively high pressure when compared to the esophageal body. Normally, the LES spans the esophageal hiatus, with half of the functional high-pressure zone present above the diaphragm in the thorax, and half below the diaphragm in the abdomen. It is normally fixed in this position by the phrenoesophageal ligament, which originates from the transversalis fascia of the diaphragm and has two leafs

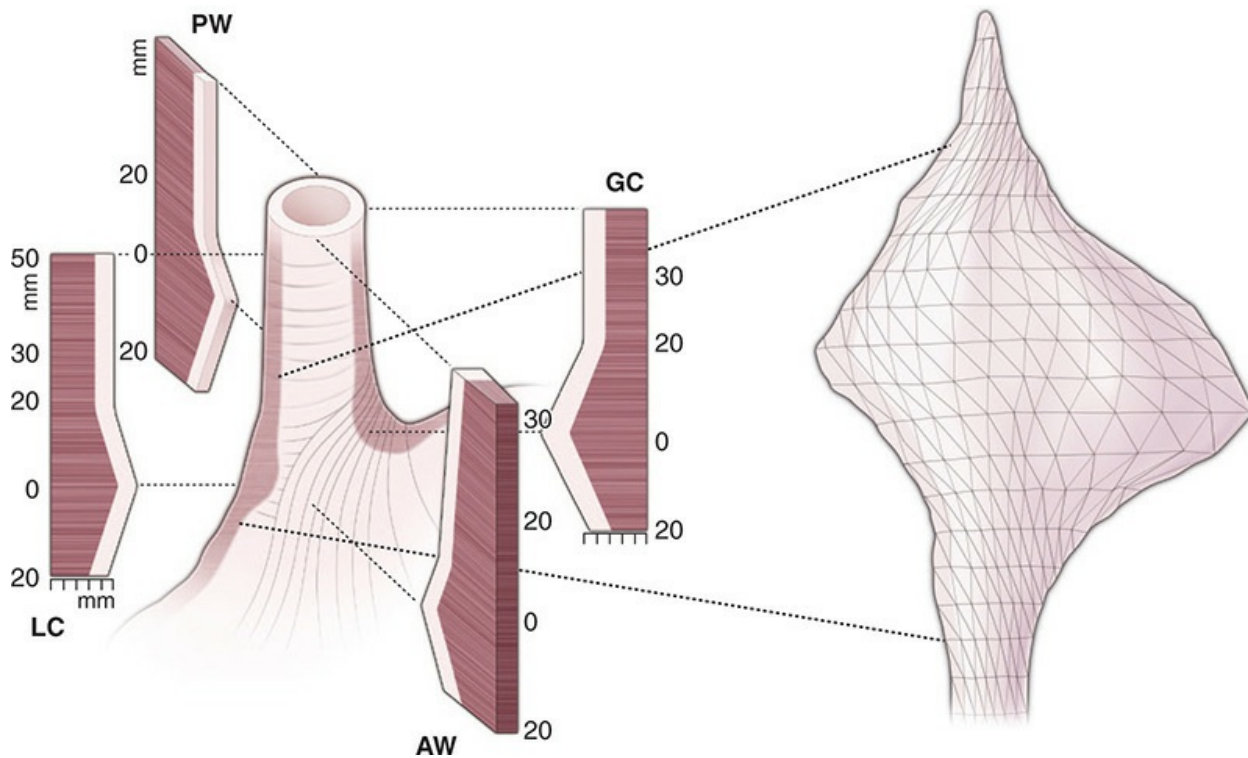

(Fig. 23-1B). The thin lower leaf attaches to the esophageal wall at the angle of His and a thicker upper leaf arises from the diaphragmatic fascia and attaches to the esophagus with collagenous extension.<sup>11</sup> Innervation to the intrinsic musculature of the distal esophagus contributing to the LES is primarily vagal in nature, with parallel excitatory and inhibitory pathways which lead to contraction and relaxation, respectively.<sup>12</sup>

**FIGURE 23-1** Anatomy of the gastroesophageal junction. **A.** The clasp and sling muscle fibers that make up the lower esophageal reflux barrier in the contracted and relaxed state, respectively. **B.** The anatomic relationship of the

gastroesophageal reflux junction, the phrenoesophageal ligament and the diaphragm. (Reproduced with permission from Swanstrom LL, Dunst CM: *Antireflux Surgery*. New York, NY: Springer Nature; 2015.)

The esophagus is classically described as being 10 inches, or 25 cm, in length.<sup>13</sup> Normal lower esophageal sphincter length is 2 to 4 cm, and the ratio of intra-abdominal to intrathoracic LES length (another way of expressing intra-abdominal length) is 1 to 1.2.<sup>13</sup> In healthy volunteers, normal resting LES pressure is approximately 20 mm Hg (15-29 mm Hg), and is dependent on whether the measurements are taken at end-inspiration, mid-expiration, or end-expiration.<sup>14</sup> The lower esophageal sphincter is maintained in a tonically contracted state by vagal innervations. LES pressure vectors are asymmetrical, with higher pressures anterior and medial and lower pressures posterior and lateral (Fig. 23-2).<sup>15</sup> Contraction and relaxation are primarily mediated by two neurotransmitters, acetylcholine (excitatory) and nitric oxide (inhibitory). Relaxation can also occur when tonic vagal cholinergic excitation is inhibited with deglutition.<sup>16</sup>

**FIGURE 23-2** Pressure vectors of the lower esophageal sphincter. (Reproduced with permission from Stein HJ, Liebermann-Meffert D, DeMeester TR, et al: Three-dimensional pressure image and muscular structure of the human lower esophageal sphincter, *Surgery* 1995)

## Pathophysiology of GERD

Gastroesophageal reflux occurs when LES pressure is less than that of intragastric pressure. This can occur under both normal and pathophysiologic conditions.

Immediately after swallowing, LES pressure decreases to allow food passage from the esophagus into the stomach. While normally maintained in a tonically contracted state, LES pressure also decreases temporarily, during transient lower esophageal sphincter relaxation (TLESR). This relaxation is a spontaneous, non-swallow-induced, vagally-mediated reflex associated with relaxation of the crural diaphragm.<sup>17,18</sup> When the gastric fundus is distended with gas, TLESR allows for belching to relieve elevated intragastric pressure. Increased frequency or duration of TLESR can predispose to reflux, accounting for up to 40% of abnormal reflux in patients with a normal LES.<sup>19</sup> The majority of reflux episodes occur during TLESR in the setting of normal resting LES pressure.<sup>18,20</sup> Most of the remainder of reflux episodes occur due to increased intra-abdominal pressure coupled with low resting LES pressure.<sup>18</sup> Increased gastric distention from largest intragastric volume, such as after a large meal, decreases LES length, thereby decreasing the pressure threshold required for pathologic reflux.

LES pressures naturally vary during the migrating motor complex while fasting.<sup>21</sup> LES pressure also drops frequently due to secretion of hormones secondary to food ingestion (cholecystokinin [CCK], secretin)<sup>22,23</sup> and pregnancy (progesterone).<sup>24</sup> The nature of food composition can also affect LES pressure. Substances known to cause decreases in LES pressure include chocolate, alcohol, caffeine, and fats.<sup>23,25-27</sup> Other lifestyle related considerations, including smoking, can also lower LES pressure and predispose to reflux.<sup>28</sup>

## Presentation

Symptoms of gastroesophageal reflux can be categorized as “typical” or “atypical.” Typical symptoms include heartburn, regurgitation, water brash, and, when advanced, dysphagia. While considered a typical symptom,

dysphagia warrants investigation for potential complications including an underlying motility disorder, stricture, ring, or malignancy. Atypical symptoms, on the other hand, include cough, globus sensation, hoarseness, throat clearing, asthma, aspiration pneumonia, pulmonary fibrosis, and atypical chest pain (Table 23-1).

**TABLE 23-1: PRESENTATION OF GERD**

Typical	Atypical
1. Heartburn Daily: 2-9% Weekly: 8-18% Monthly: 13-36%	1. Throat clearing
2. Regurgitation	2. Hoarse voice
3. Waterbrash	3. Chronic cough
4. Dysphagia <sup>a</sup>	4. Asthma
	5. Chest pain
	6. COPD
	7. Pulmonary fibrosis
	8. Aspiration pneumonia
	9. Globus sensation

## GERD and Quality of Life

In 1948, the World Health Organization (WHO) defined health as being more than simply absence of disease, recognizing that it incorporates not only physical but also psychological and social components. Quality of life (QoL) surveys reveal that GERD patients are equally or more impaired with regard to several aspects of QoL than patients with major medical comorbidities, including hypertension and diabetes, and more impaired with regard to bodily pain than patients with major depression.<sup>29</sup> Even in the absence of medical comorbidities, GERD results in impaired functioning and well-being when compared with healthy controls.<sup>30</sup> Health-related quality of life (HRQoL) models, designed to specifically examine the effect of a given disease state on a patient's well-being, support the notion that GERD has a significant impact that is not captured by traditional physiologic testing.<sup>31</sup>

Specifically, frequency and number of symptoms are inversely related to QoL scores. Timing of symptoms also correlates with QoL, with presence of nocturnal symptoms resulting in decreased reported QoL compared to patients with only daytime symptoms.<sup>32</sup> While symptom severity is not related to presence or absence of pathologic evidence of reflux, it is related to QoL. Correspondingly, QoL scores are not correlated with presence or absence of pathologic extent of disease.<sup>32</sup>

Considering the importance of QoL as demonstrated above, the primary goals of GERD treatment include symptom relief in addition to prevention of complications and healing of esophagitis. From a patient's standpoint, however, relief of symptoms may be considered paramount. Consistent with improvement in symptoms, medical therapy improves QoL scores in GERD patients irrespective of presence of pretreatment pathologic evidence of GERD. While medical treatment results in improved QoL scores, evidence for superiority of one medical modality over another is lacking. Similarly, surgical intervention has consistently, across numerous studies, been shown to improve QoL scores in patients suffering from GERD. In some studies, surgery has even resulted in QoL scores approximating those of healthy controls. Initial reports suggesting equivalence of open surgical intervention to optimal medical management for improvement in QoL have since been substantiated. Evidence for superiority of open surgery over medical therapy, however, is lacking. Laparoscopic surgery, on the other hand, has been shown to significantly improve QoL when compared to no treatment or proton pump inhibitor (PPI) therapy.<sup>32</sup> Laparoscopic fundoplication has been shown to be a very durable operation, with more than 90% of patients having excellent results for as long as 20 years after the operation.<sup>33</sup>

As QoL has a significant subjective component, and symptom severity is correlated with patient quality of life, it is imperative to consider QoL as a primary endpoint in GERD therapy, be it medical or surgical.

## **COMPLICATIONS**

Complications of GERD are classified as mucosal, extraesophageal/respiratory, or metaplastic/neoplastic. These complications are the direct result of mucosal or epithelial exposure to gastric contents (acid or alkali) and the host's natural response to the damage caused by that

exposure.

## Mucosal

Mucosal complications include esophagitis and esophageal stricture. Esophageal mucosa is damaged when exposed for prolonged periods of time to the contents of reflux of highly acidic or alkaline nature. Ingredients proposed to play a role in the process include gastric acid, pepsin, pancreatic enzymes, and bile acids. Prevalence of mucosal complications has been shown to be higher in patients with combined acid and alkaline reflux compared to those with only acid reflux.<sup>34</sup> The most severe injuries are reported in the presence of acid, pepsin, and bile salt exposure.<sup>35</sup>

Although not strong, there is some correlation with endoscopic esophagitis severity and symptom severity.<sup>36</sup> Acid exposure often leads to more pain but less mucosal damage, with alkaline exposure leading to more mucosal damage despite less pain.<sup>37,38</sup> Reflux of more than just acidic contents is more common in patients with mucosal and metaplastic/neoplastic complicated GERD, explaining why medical therapy with PPIs alone is not always effective.<sup>39</sup> Nevertheless, PPI therapy may improve esophagitis in up to 90% of patients, but relapse may occur in up to 80% within 1 year of medication discontinuation.<sup>40</sup>

The incidence of esophageal stricture in patients with esophagitis is 10% to 25%, with one large Veterans Administration (VA) study reporting a 14% incidence.<sup>41</sup> Treatment for patients with stricture should start with PPIs, but many patients require repeated esophageal dilations to control dysphagia. Stricture patients may benefit from antireflux surgery by decreasing the need for further dilations and dysphagia.<sup>42</sup> If a stricture is found on endoscopy, a biopsy should be obtained to rule out malignancy.

## Metaplastic/Neoplastic

Barrett esophagus (BE) is a metaplastic consequence of GERD involving a change from normal squamous epithelial lining to a segment of columnar epithelial lining that predisposes to the development of adenocarcinoma of the esophagus. This is discussed later in this chapter.

## **Extraesophageal Manifestations: Laryngopharyngeal Reflux and Pulmonary Consequences**

Many of the atypical symptoms of GERD, including cough, recurrent pneumonia, asthma, COPD, laryngitis, and pulmonary fibrosis, are secondary to the effects of reflux on extraesophageal aerodigestive tract. Up to 30% to 50% of patients with asthma, and nearly 90% of patients with pulmonary fibrosis, have objective evidence of GERD.<sup>43–45</sup> Gastric acid aspiration can be a mechanism for respiratory symptoms related to GERD.<sup>46,47</sup> Another proposed mechanism is vagally-mediated bronchoconstriction, in which acid exposure in the esophagus induces bronchoconstriction, possibly through vagal nerve networks innervating both the esophagus and bronchial tree.<sup>48</sup> A relationship between GERD and respiratory symptom severity has been established.<sup>43</sup>

Patients presenting with poorly controlled or adult-onset asthma may benefit from an evaluation for GERD as a potential underlying cause or exacerbating factor in their respiratory disease. Upper endoscopy and ambulatory pH monitoring should be performed to document mucosal evidence of GERD and to attempt to temporally correlate extraesophageal symptoms with reflux events. Multichannel intraluminal impedance-pH (MII-pH) shows some promise in the documentation of reflux and correlation with extraesophageal symptoms.<sup>38</sup> A trial of PPI therapy is a reasonable initial treatment for suspected GERD-related respiratory symptoms. If symptoms improve, this may strengthen the notion that GERD is at least partially responsible for the patient's symptoms. In general, however, it is difficult to establish the association of acid reflux to extraesophageal symptoms in the absence of the typical symptoms of GERD. Surgery for these patients should be approached with caution.

## **Mimics of GERD**

Typical symptoms of GERD, including heartburn, regurgitation, and dysphagia, are nonspecific and present in several pathologic conditions. Therefore, systematic evaluation of the patient presenting with esophageal

symptoms is necessary to achieve proper diagnosis and management. Optimal management of the patient with esophageal symptoms requires distinguishing those with GERD from those with esophageal motility disorders and functional esophageal disorders. However, the physician needs to be aware that there are nonesophageal causes of chest pain, the most concerning of which is cardiac ischemia, such as angina pectoris. Mediastinal inflammatory diseases and neoplasms occasionally present as chest pain. A careful history and physical examination can differentiate these processes.

Esophageal motility disorders encompass any abnormality of the usually coordinated peristaltic activity of the esophagus. They can be classified as primary or secondary based on the underlying cause of the abnormal motility. Primary esophageal motility disorders are the result of impaired excitatory or inhibitory innervations of the LES and body of the esophagus. These include achalasia, diffuse esophageal spasm, nutcracker esophagus, hyper- and hypotensive LES, ineffective esophageal motility, and nonspecific esophageal motility disorders. The most common symptoms of achalasia and other primary esophageal motility disorders are chest pain and dysphagia, which as mentioned earlier are also frequently seen as presenting symptoms in GERD. In fact, a large proportion of patients eventually diagnosed with esophageal motility disorders are initially presumptively diagnosed with GERD.<sup>49</sup>

Malignancy, while not a primary disorder of esophageal motility or LES function, can also present in similar fashion to GERD. While GERD and distal esophageal adenocarcinoma have a well-established relationship,<sup>50</sup> unrelated malignancies of the gastric cardia and more remote regions such as the pancreas, lung, and kidney can also produce a condition that may present in similar fashion to GERD. Pseudoachalasia, thought to be due to compression of the LES by tumor, infiltration of myenteric plexus and/or vagus nerves, and paraneoplastic neuropathy without direct infiltration, presents with progressive dysphagia to solids and liquids, as can also be seen as GERD symptoms.<sup>51</sup>

Functional esophageal disorders are a group of conditions marked by symptoms of apparent esophageal origin without objective evidence of esophageal pathology. They mimic GERD in esophageal symptoms, but diagnostic evaluation reveals normal endoscopy, manometry readings, and pH values by ambulatory or impedance pH testing.<sup>52</sup> As such, they remain a

diagnosis of exclusion after ruling out GERD, malignancy, and esophageal motility disorders by the aforementioned tests. The four currently recognized functional esophageal disorders, as outlined by the Rome III Consensus Criteria,<sup>53</sup> are functional heartburn, functional chest pain of presumed esophageal origin, functional dysphagia, and globus. Diagnostic algorithms have been proposed by multiple groups,<sup>52,53</sup> but generally involve a progression of objective tests, including endoscopy, esophageal motility studies, PPI trial, and pH monitoring to rule out other esophageal pathology. Initial tests should be directed by the presenting symptom, and subsequent testing guided by results of the previous test.

## Diagnostic Evaluation

Effective treatment of GERD, aimed at prevention of its complications and improvement in patient QoL, requires accurate diagnosis. Symptoms experienced by patients with GERD are not always specific, and could result in improper or ineffective treatment. Following a comprehensive history and physical examination, in patients with typical symptoms of heartburn but without “alarm” symptoms, a trial of PPI is reasonable.<sup>54</sup> The alarm symptoms of dysphagia, odynophagia, weight loss, anemia, or signs of bleeding require further evaluation. For those patients who have alarm symptoms or who are considering surgical intervention, mandatory objective testing includes upper endoscopy, esophageal manometry, and esophageal pH monitoring. Additional testing may include contrast esophagography, impedance pH monitoring, gastric emptying scintigraphy, laryngoscopy, and bronchoscopy.

The American College of Gastroenterology recently released a set of evidence-based clinical guidelines for the diagnosis and management of GERD. A presumptive diagnosis of GERD is often made based on a history of typical symptoms. However, the presence of heartburn and regurgitation symptoms had a sensitivity of only 30% to 76% and specificity of 62% to 96% for the presence of erosive esophagitis.<sup>55</sup> A PPI trial to “confirm” a diagnosis of GERD by symptom response increases sensitivity to 78%, with a specificity of 54%.<sup>56</sup> Chest pain, which can be the presenting symptom of GERD, should prompt an evaluation to exclude a cardiac etiology. Once a cardiac source has been eliminated and prior to PPI administration,

endoscopic evaluation and pH monitoring should be performed to document the presence of GERD, as PPI response compared to placebo is minimal in the absence of documented GERD.<sup>57</sup>

## **CONTRAST ESOPHAGOGRAPHY**

Contrast esophagography is a useful test to anatomically evaluate the esophagus and gastroesophageal junction. It can evaluate esophageal emptying and occurrence of reflux and detect the presence of hiatal hernia and the presence and location of complications such as strictures, webs, ulcers, or masses. It is a relatively poor test of esophageal motility. Contrast esophagography should be employed as the first step in evaluation of alarm symptoms such as dysphagia. Even high-quality esophagograms have been shown to have low sensitivity for detecting GERD and signs of esophagitis. It should be noted that GERD cannot be reliably ruled out solely by esophagography, but that it serves as a useful complement to other objective tests. Contrast esophagography is an excellent test to evaluate the presence and size of paraesophageal hernia.

## **UPPER ENDOSCOPY**

Endoscopic evaluation is the primary modality for evaluating esophageal mucosa and also allows for direct visualization of the stomach and duodenum. It can assess for structural issues such as size of a hiatal hernia or localization of pathology.

Presence and severity of esophagitis is most commonly graded according to the Los Angeles (LA) classification ([Table 23-2](#)).<sup>58,59</sup> LA grade A is considered to be the presence of one or more mucosal breaks that are less than or equal to 5 mm in length. Grade B is defined as the presence of one or more mucosal breaks longer than 5 mm. Grade C involves one or more mucosal breaks that are continuous between the apices of two or more mucosal folds, but that encompass less than 75% of the esophageal circumference. Lastly, LA grade D includes continuous breaks between mucosal folds encompassing greater than 75% of the esophageal circumference. In the presence of erosive esophagitis, when using LA classification, specificity of endoscopy for diagnosis of GERD is high, with good interobserver correlation.<sup>59</sup>

**TABLE 23-2: LOS ANGELES (LA) CLASSIFICATION OF EROSIVE ESOPHAGITIS**

Grade	Description
A	≥1 mucosal break ≤5 mm in length
B	≥1 mucosal break >5 mm in length
C	≥1 mucosal break continuous between apices of ≥2 mucosal folds, encompassing <75% of esophageal circumference
D	continuous breaks between mucosal folds encompassing >75% of esophageal circumference

Nonerosive esophagitis is more difficult to diagnose visually by endoscopy, but may be detected by microscopic findings on mucosal biopsy, including eosinophils, lymphocytes, polymorphonuclear leukocytes, and balloon cells. Biopsy has been found to have poor sensitivity (62%) and specificity (27%) when using a threshold of one or more histologic abnormalities consistent with esophagitis. Specificity is significantly increased (91%) and sensitivity decreased (31%) when using a threshold of three histologic abnormalities.<sup>60</sup> Despite the high specificity, routine use of esophageal biopsy in the face of endoscopically normal appearing mucosa is not currently recommended.<sup>57</sup>

Lastly, via retroflexion of the endoscope after passage through the GEJ, abnormalities of the LES flap valve can be identified and graded according to the Hill classification (Fig. 23-3).<sup>61</sup> Increasing abnormality of the gastroesophageal flap valve (increasing Hill grade) has been correlated with increased prevalence of a mechanically defective sphincter, abnormal esophageal acid exposure, erosive esophagitis, and BE.<sup>62</sup>

**FIGURE 23-3** Hill classification of the gastroesophageal junction. **A.** Grade I flap valve appearance. Note the ridge of tissue that is closely approximated to the shaft of the retroflexed endoscope. It extends 3–4 cm along the lesser curve. **B.** Grade II flap valve appearance. The ridge is slightly less well defined than in grade I and it opens rarely with respiration and closes promptly. **C.** Grade III flap valve appearance. The ridge is barely present, and there is often failure to close around the endoscope. It is nearly always accompanied by a hiatal hernia. **D.** Grade IV flap valve appearance. There is no muscular ridge at all. The gastroesophageal valve stays open all the time, and squamous epithelium can often be seen from the retroflexed position. A hiatal hernia is always present. (Reproduced with permission from Hill LD, Kozarek RA, Kraemer SJ, et al: The gastroesophageal flap valve: in vitro and in vivo observations, *Gastrointest Endosc* 1996 Nov;44(5):541-547.)

## ESOPHAGEAL MANOMETRY

Esophageal manometry is a catheter-based system to measure esophageal pressures. Manometry was originally developed using water-based hollow

catheters measuring pressure waves at distinct 5-cm intervals in the esophagus (Fig. 23-4). These measurements included the upper esophageal sphincter, points along the esophageal body, and the LES.<sup>63</sup> This older technology is now supplanted by high-resolution manometry (HRM). In HRM, a solid-state catheter with a sevenfold increase in the number of sensors at 1-cm intervals provides for a more “continuous” measurement of pressures along the length of the esophagus. These readings are converted by the system’s computer program into a color topography (Fig. 23-5).<sup>64</sup> Manometric evaluation is essential in the preoperative evaluation of any patient considering antireflux surgery. It will identify patients who may have symptoms suggestive of GERD but really are suffering from some other motility disorder, such as achalasia or scleroderma. This test may also help direct surgical approach, identifying patients who would be better candidates for partial, rather than complete, fundoplication, for instance in the case of manometric evidence of hypomotility.

**FIGURE 23-4** Esophageal manometry pressure waves.

**FIGURE 23-5** High-resolution manometry image.

LES competency has been defined based on comparative manometry studies of healthy volunteers and patients with GERD symptoms. The ability of the LES to properly function to protect the esophageal mucosa from exposure to gastric juice depends on its resting pressure, overall length, and the subcomponent of intra-abdominal length. Each HRM system will have slightly different normal pressure values, depending on the calibration of the system. However, an LES is considered to be incompetent if one or more of these anatomic components is abnormal, or more specifically, an average LES pressure less than 6 mm Hg, average overall length of 2 cm or less, and intra-abdominal length of 1 cm or less. Although a “hypotensive” LES supports the diagnosis of GERD, it is not essential. Many patients with pathologic reflux may have normotensive LES.

Measurement of esophageal body peristalsis is vital. A patient with normal peristaltic waves and pressures is the ideal candidate for a fundoplication. Ineffective esophageal motility is 30% or more swallows leading to failed peristalsis, or a mean wave pressure of less than 30 mm Hg (Table 23-3).<sup>32</sup>

Preoperative assessment of esophageal motility is vital in determining whether a fundoplication is appropriate, and may help in tailoring the type of fundoplication.

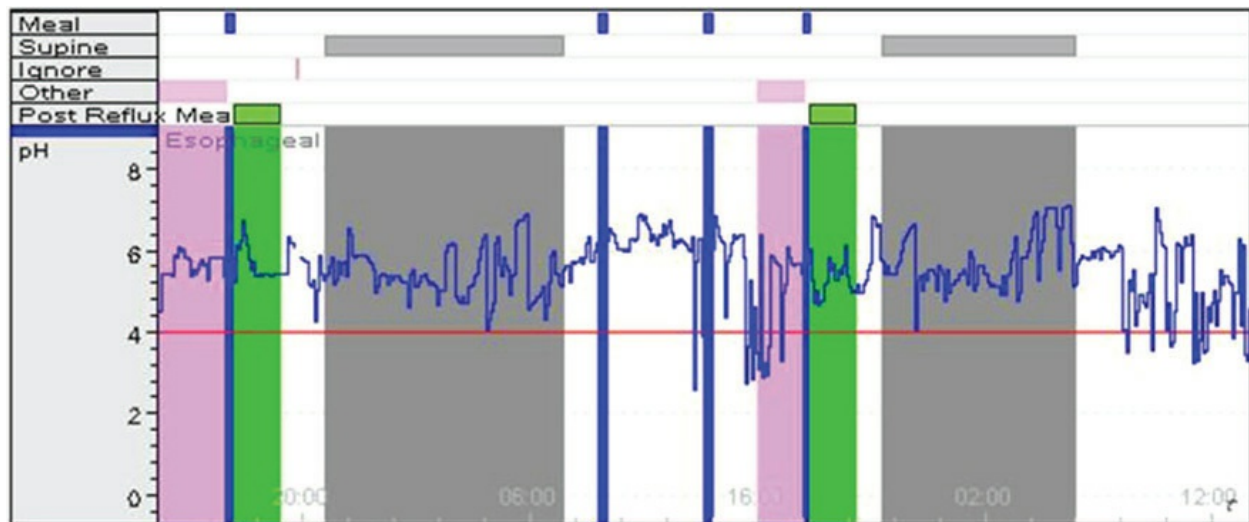

**TABLE 23-3: INFORMATION FROM HIGH RESOLUTION MANOMETRY WITH NORMAL RANGES**

Information	Normal Ranges

## AMBULATORY pH MONITORING

Ambulatory pH monitoring is the gold standard for diagnosis of GERD. It directly measures esophageal acid exposure, frequency and duration of reflux episodes, and concordance with the patient's symptoms (Fig. 23-6). Both 24- and 48-hour ambulatory pH monitoring tests have excellent sensitivity (77%-100%) and specificity (85%-100%) in the setting of erosive esophagitis. In patients without endoscopic evidence of erosive esophagitis, sensitivity is decreased to closer to 70%,<sup>65</sup> but is as high as 90% when

combined with impedance.<sup>66</sup>

**FIGURE 23-6** Twenty-four-hour esophageal pH monitoring.

Nevertheless, there are excellent positive and negative predictive values of 96%, and overall accuracy of 96% for 24-hour esophageal pH monitoring for the diagnosis of GERD.<sup>67</sup>

Patients should be counseled to discontinue any antisecretory medications 2 weeks prior to initiating pH monitoring to increase the ability to correlate symptoms with reflux events and grade the severity of disease. An abnormal pH test and good temporal correlation between symptoms and reflux episodes is the best predictor of successful outcome after antireflux surgery.

Early-generation esophageal pH monitoring devices involved passage of a catheter-based pH electrode transnasally. Patient comfort has been improved by the development of wireless pH capsules that transmit information to an external receiver.<sup>68</sup> Readings from the transnasal catheter can be negatively affected by the patient decreasing potentially provocative activities, leading to false negative results, and esophageal shortening during deglutition, noted to be up to 2 cm in length, can cause positional changes of the pH probe, leading to false positive results as the electrode moves closer to the GEJ.<sup>69</sup> However, non-acid reflux, known to be an important factor in development of esophagitis and other extraesophageal complications of GERD, is not detected by traditional pH monitoring. In addition, there may be an increase in acid exposure on day 2 of monitoring, thus potentially decreasing the sensitivity of 24-hour testing.<sup>70</sup> The development of wireless pH monitoring

systems has improved patient comfort and allowed for extension of monitoring to 48 hours or longer in some cases, increasing the sensitivity of the test.<sup>68</sup>

The DeMeester score (Table 23-4) has long been the standard by which results of 24-hour pH monitoring are reported.<sup>71</sup> The score is determined by six variables evaluating frequency and severity of reflux, and the ability of the esophagus to clear acid. These variables include total number of reflux events, percentage of total time spent in an acid environment with a pH less than 4, percentage of upright time spent in an acid environment with a pH less than 4, percentage of supine time spent in an acid environment with a pH less than 4, duration of longest reflux episode, and number of reflux episodes lasting more than 5 minutes.

**TABLE 23-4: INFORMATION FROM 24- OR 28-HR PH MONITORING**

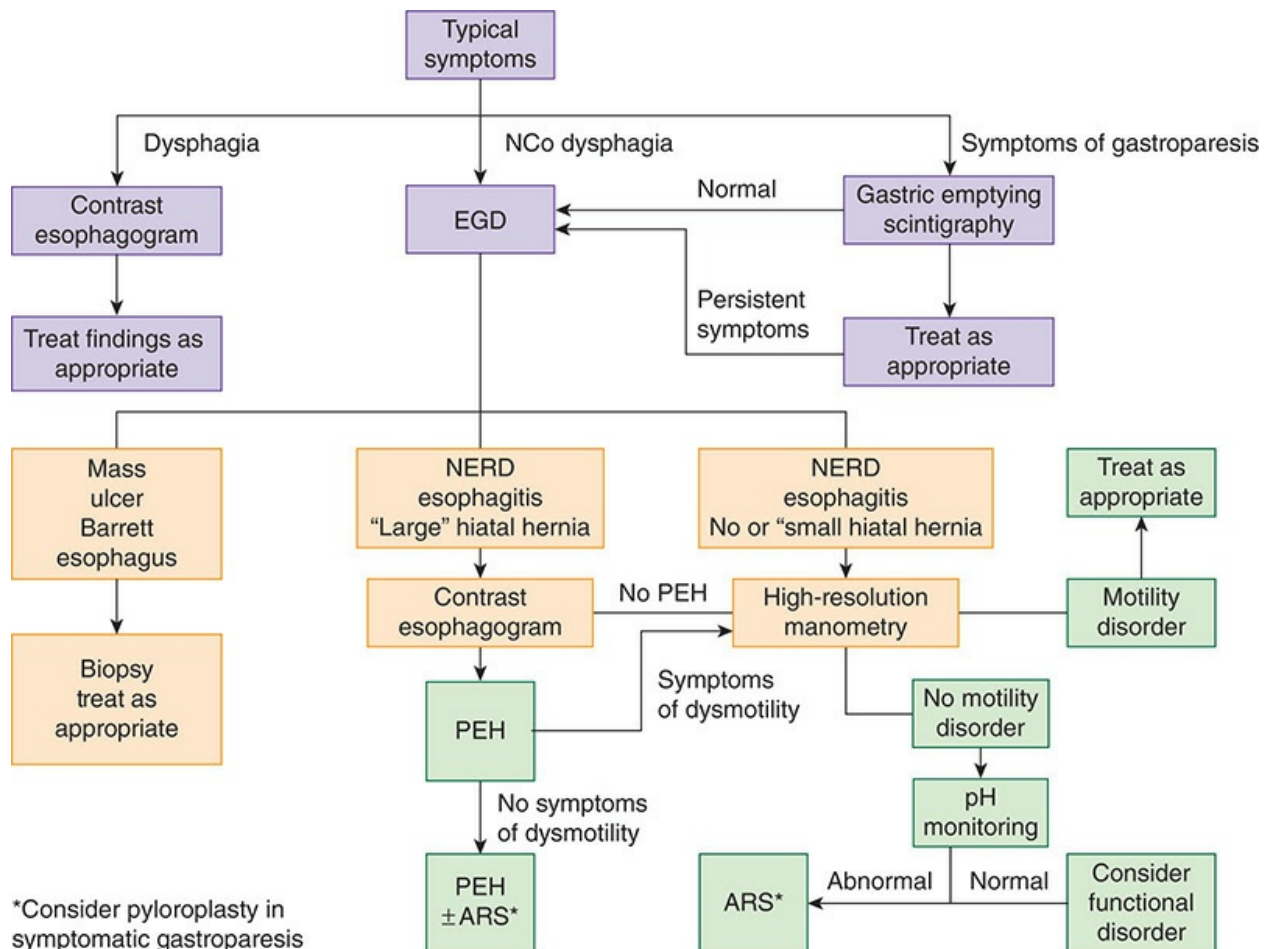

<b>Components Measured</b>	<b>Normal Values</b>
Total number of reflux events	104
Total time spent in an acid environment, pH<4 (%)	4.9
Upright time spent in an acid environment, pH <4 (%)	7.3
Supine time spent in an acid environment, pH <4 (%)	1.4
Duration of longest reflux episode (min)	16
Number of reflux episodes lasting more than 5 min	5
Composite DeMeester score	14.72

## **MULTICHANNEL INTRALUMINAL IMPEDANCE-pH MONITORING**

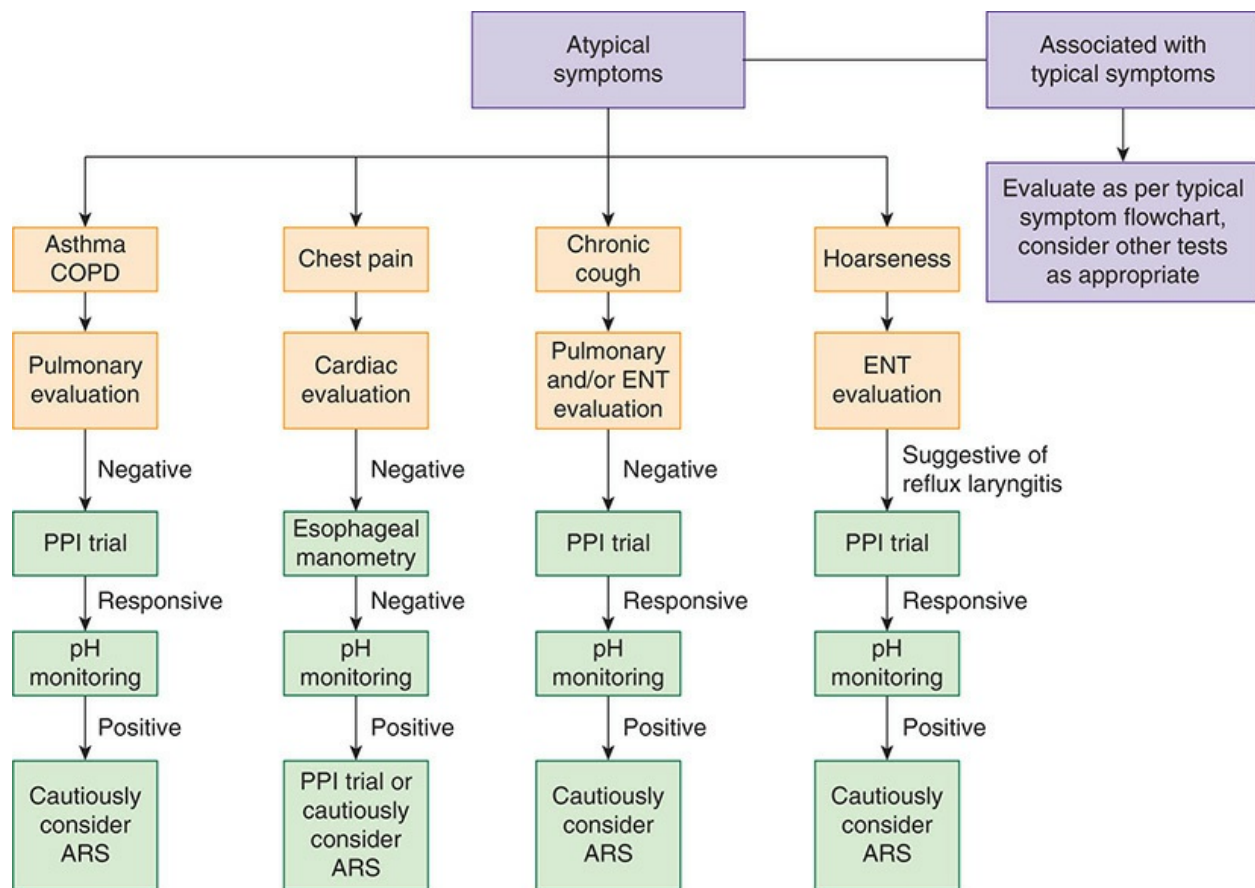

Similar to traditional 24-hour pH monitoring, MII-pH involves a transnasal catheter-based system and is thus often limited by patient comfort. This modality does, however, provide the benefit of allowing for concomitant measurement of bolus movement and pH by use of multiple electrodes

positioned serially along a catheter. By incorporating simultaneous pH and impedance monitoring, this modality allows for determination of the character of reflux episodes (acid vs non-acid), a measurement not possible with traditional catheter-based pH monitoring. While this theoretically provides a distinct advantage over other modalities, clinical advantages remain under investigation.

Figures 23-7 and 23-8 provide evaluation algorithms for patients with typical and atypical symptoms of GERD. Once again, it needs to be emphasized that antireflux surgery for patients with *only* atypical symptoms of GERD should be considered with extreme caution. There are many gastroenterologists and surgeons who would not offer these patients antireflux surgery under any circumstances.

**FIGURE 23-7** Evaluation of the typical symptoms of gastroesophageal reflux disease.

**FIGURE 23-8** Evaluation of the atypical symptoms of gastroesophageal reflux disease.

## Measuring Symptom Severity and Quality of Life

In typical practice, most clinicians simply enumerate the symptoms with quality descriptors of severity. Although this gives some impression of how GERD affects a patient, it does not quantitate the level of this affect. QoL and symptom severity instruments are used for this purpose.<sup>72</sup> In general, QoL instruments are divided into generic and disease-specific instruments.

### GENERIC INSTRUMENTS USED IN GERD

Generic QoL instruments are broadly applicable to a variety of disease processes. They measure different QoL domains. [Table 23-5](#) lists generic instruments that have been used in GERD patients with the domains they measure.

**TABLE 23-5: EXAMPLES OF QUALITY-OF-LIFE INSTRUMENTS USED TO MEASURE PATIENT-PERCEIVED EFFECTS OF GERD**

<b>Type of Instrument</b>	<b>Name of Instrument</b>
Generic	SF-36 Psychological General Well-Being (PGWB)
Disease-specific/symptom severity	Digestive Symptoms and Impact Questionnaire Gastroesophageal Reflux Disease-Health Related Quality of Life Scale Gastroesophageal Reflux Disease Symptom Assessment Scale GERD Symptom Frequency Questionnaire Heartburn Specific Quality of Life Instrument Nepean Dyspepsia Index Patient Assessment of Upper Gastrointestinal Disorders Symptom Severity Index Patient Assessment of Upper Gastrointestinal Disorders Quality of Life Gastrointestinal Symptom Rating Scale Quality of Life in Reflux and Dyspepsia Quality of Life Questionnaire in Gastroesophageal Reflux

## **DISEASE-SPECIFIC/SYMPTOMS SEVERITY**

Disease-specific instruments measure aspects of QoL that are specifically affected by the disease. For GERD, it may include such things as sleep, work, pain, eating habits, etc. Symptom severity instruments measure the symptoms specific for the disease. For GERD, this would include heartburn, regurgitation, dysphagia, etc. for typical symptoms, and hoarseness, cough, wheezing, etc. for atypical symptoms (Table 23-5).

Evaluation of studies of the treatments of GERD should include some measures of QoL and symptom severity, as most treatments are designed to improve symptoms. Some practitioners use these instruments routinely in clinical practice for both documenting the magnitude of change caused by an intervention and inpatient counseling.

## Management

Management of GERD can be broadly categorized into lifestyle modifications, medical, and surgical.

In 2006, a systematic review of the effect of lifestyle modifications on lower esophageal sphincter pressure, esophageal pH, and GERD symptoms revealed that intake of several products, including tobacco, chocolate, and carbonated beverages, led to decreased LES pressure.<sup>65</sup> Esophageal acid exposure increased with consumption of tobacco, alcohol, chocolate, and fatty foods, but cessation of tobacco and alcohol had no physiologic effect on LES pressure and did not lead to subjective symptom improvement. However, weight loss has been correlated with reduction in GERD symptoms.<sup>73,74</sup> Elevating the head of the bed leads to improvements in symptoms and pH monitoring values.<sup>75-77</sup> Aside from this, there is little evidence in support of lifestyle modification strategies as durable and effective antireflux therapy.

The success of medical therapy has made it a mainstay of treatment for GERD. For those failing lifestyle modifications alone, medical therapy can take the form of antacids, histamine receptor antagonists, or PPIs. PPI therapy has been shown to have higher rates of healing and decreased relapse rates when compared to histamine receptor antagonists in patients with erosive esophagitis.<sup>78,72</sup> In fact, meta-analysis has demonstrated healing of erosive esophagitis inclusive of all grades to be approximately 84% with PPIs, 52% with histamine receptor antagonists, 39% with sucralfate, and merely 28% with placebo.<sup>79</sup> While there are many currently available PPIs, no one drug is superior to any other for symptom relief.<sup>80</sup> Overall, partial relief of GERD symptoms has been found in 30% to 40% of patients after an 8-week trial of PPI therapy, without any difference shown between once- or twice-daily dosing.<sup>57</sup> Risk factors for poor response include hiatal hernia, extraesophageal symptoms, longer duration of symptoms, and lack of

compliance.<sup>81</sup> Sixty-six percent to 75% of patients with NERD, and 90% to 100% with erosive esophagitis, will demonstrate relapse of symptoms at 6 months after discontinuing PPI therapy.<sup>82,83</sup> Therefore, maintenance PPI therapy is recommended.

While medical therapy has proven fairly successful and leads to symptom improvement in a significant number of patients, it does not address the pathophysiologic component of a mechanically defective LES, a factor that can only be dealt with by surgical or endoscopic therapy.

## **SURGICAL THERAPY**

The history of antireflux surgery began in 1956 with the first report of successful operative intervention by Nissen.<sup>84</sup> Since this initial report, techniques and approaches to antireflux surgery have been modified several times and evolved along with surgical technology. After Nissen's original description, Dor<sup>48</sup> and Toupet<sup>85</sup> later developed and described variations of the procedure involving partial anterior and posterior funduplications to avoid bloating. Belsey developed a transthoracic partial repair, which required several modifications until settling on the Mark IV. Complete mobilization of the gastric fundus via division of the short gastric vessels was subsequently described by DeMeester et al. in 1986.<sup>86</sup> Finally, Dallemagne et al. in 1991 reported the first successful laparoscopic Nissen fundoplication.<sup>87</sup>

Indications for surgical therapy in GERD include incomplete symptomatic relief from medical therapy, desire to discontinue medical therapy, medical noncompliance, side effects of medical therapy, esophagitis refractory to medical therapy, presence of symptoms specifically related to a hiatal hernia, and esophageal and extraesophageal complications. Several studies have directly compared surgical and medical therapy for GERD (Table 23-6). The VA GERD Study Group Trial, a randomized controlled trial with 10-year follow-up, showed superiority of surgery over histamine receptor blockade and lifestyle modification for typical symptoms and esophagitis in the veteran population.<sup>88</sup> Another randomized controlled trial showed less acid exposure at 3 months and improved well-being scores at 1 year in patients undergoing surgical versus PPI therapy.<sup>89</sup>

**TABLE 23-6: MEDICAL VS SURGICAL THERAPY FOR GERD****Outcomes**

Authors	Year	Interventions	Findings
Spechler SJ <sup>88</sup>	1992	Continuous medical therapy Medical therapy for symptoms only Open Nissen fundoplication	Open Nissen fundoplication is superior to continuous or “as needed” medical therapy
Mahon D et al. <sup>89</sup>	2005	Medical therapy (PPI) Laparoscopic Nissen Fundoplication	Laparoscopic Nissen fundoplication is superior to PPI therapy by physiologic and QOL testing
Rickenbacher et al. <sup>91</sup>	2014	Meta-analysis of open or laparoscopic Nissen Fundoplication vs medical therapy	Surgical intervention led to more improved QOL vs medical therapy

**Cost**

Authors	Year	Interventions	Findings
Thijssen et al. <sup>90</sup>	2011	Systematic review of literature on cost of surgical (open or laparoscopic) vs medical (PPI)	Surgery is more expensive, but results in greater number of quality-adjusted life years, and is therefore more cost effective

Data concerning cost-effectiveness of surgical versus medical therapy remain inconclusive. A systematic review of Medline, EMBASE, and Cochrane databases published in 2011 revealed higher costs for surgical therapy, but two studies included in the review reported more quality-adjusted life-years with surgery.<sup>90</sup> Also of note, meta-analysis of health-related and GERD-specific QoL aspects from randomized controlled trials of surgical (open or laparoscopic) versus medical treatment of GERD showed less frequent symptoms and higher patient-reported levels of satisfaction after surgical intervention despite a significant proportion of patients requiring continued medical therapy after fundoplication.<sup>91</sup>

Surgical intervention for GERD is aimed at fixing the structural defects contributing to the pathophysiology while minimizing dysphagia, bloating, and vagally mediated adverse events. As such, the intervention must be designed to restore adequate LES pressure, the interaction between the esophagus and diaphragmatic hiatus and 2 cm of intra-abdominal length, while allowing for normal passage of ingested materials through the GEJ, and eventually from the stomach to the small bowel. This is generally accomplished by reduction of the intrathoracic portion of the stomach and esophagus with the hiatal hernia, repair of the diaphragmatic hiatal defect, and a fundoplication procedure in which the gastric fundus is used to create a “wrap” around the distal esophagus. The fundus creates a functional augmentation to the LES, as it is vagally innervated and will relax normally with deglutition in the absence of intraoperative vagal injury.

## PRIMARY ANTIREFLUX REPAIRS

**Principles.** Antireflux operations can be performed via a laparoscopic, open laparotomy, thoracoscopic, or open thoracotomy approach. Thoracic approaches are no longer routinely done, but may be needed for special circumstances. The 360-degree Nissen fundoplication is currently the most commonly performed antireflux procedure in the United States. Partial fundoplications are essentially variations of this procedure, but all must adhere to a certain set of key principles for successful outcomes. The first principle is dissection of the hiatus for adequate visualization of the left and right crura. The surgeon must take care to preserve the vagal nerves. The anterior vagal nerve generally lies adherent to the anterior surface of the esophagus, while the posterior nerve is a variable distance away in the fat posterior to the esophagus. The second principle is mobilization of the gastric fundus to provide for a tension-free fundoplication. Although this generally requires division of the short gastric vessels in the gastrosplenic ligament, this is not mandatory. The third principle is performing enough circumferential esophageal dissection to allow for mobilization of 2.5 to 3 cm of intra-abdominal esophagus. Fourth is posterior crural approximation to repair the hiatal hernia but allow for adequate esophageal expansion during swallowing. Lastly, the fundoplication itself should be constructed over a dilator of adequate size so that the fundoplication is floppy and about 2 cm in length.

**Laparoscopic and Open Nissen Fundoplication.** After induction of general anesthesia, the patient should be placed supine in a low lithotomy position, the so-called “French” position, with reverse Trendelenburg positioning employed as needed to allow the abdominal viscera to fall away from the surgical field. Although there are a variety of port placement positions depending on surgeon preference, the key is to allow for a camera port, liver retractor, two working ports, and a retraction port as needed. Our preferred port placement is shown in [Figure 23-9](#). If an open approach is required, our preference is an upper midline incision.

**FIGURE 23-9** Laparoscopic antireflux surgery port placement.

The surgeon operates from between the patient's legs while assistants are positioned to the patient's right and left. To gain access to the posterior mediastinum, the gastrohepatic omentum at the pars flaccida (the so-called "window of Heister") is first opened and divided from its attachment to the hiatus (Fig. 23-10). The right crus should be immediately identified. The phrenoesophageal ligament is divided to expose the esophagus, and this division is taken to the left to expose the left crus. The space between the esophagus and crus is developed posterior to the angle of His (Fig. 23-11). This dissection should be carried as posteriorly and inferiorly as possible to ease creation of the retroesophageal space. Similarly, the phrenoesophageal ligament is divided between the esophagus and the right crus and this space is developed. This allows for circumferential exposure of the esophagus at the hiatus. Care should be taken to identify the possibility of an accessory left hepatic artery branching from the left gastric artery to avoid injury. As the phrenoesophageal membrane is then opened on the right and dissection carried anteriorly, care must be taken to identify and avoid injury to both

anterior and posterior vagal branches. Posterior retroesophageal dissection is carried out until the union of the right and left crura is identified. At this point, the retroesophageal window is developed (Fig. 23-12). Once the posterior esophageal window is completed, a Penrose drain is passed posterior to the esophagus and the two ends secured (Fig. 23-13). The drain is used to manipulate the esophagus during the operation. Circumferential mediastinal dissection should be carried out until at least 3 cm of esophagus is present within the abdominal cavity without tension. If undue tension prevents adequate esophageal mobilization, a lengthening procedure such as a Collis gastroplasty, described later, should be considered. Once esophageal mobilization or lengthening is completed, the crura are approximated posteriorly using interrupted nonabsorbable sutures over Teflon pledgets, although the pledgets are not mandatory (Fig. 23-14). Crural closure should be up to the esophagus but allow for passage of a laparoscopic instrument or small dilator to minimize the risk of stenosis. The short gastric vessels are then divided along the greater curvature of the stomach from the inferior pole of the spleen, allowing for exposure of the posterior stomach and division of the posterior gastric vessels.

**FIGURE 23-10** Division of the window of Heister and phrenoesophageal ligament.

**FIGURE 23-11** Dissection of the plane between the left crus and esophagus.

**FIGURE 23-12** Development of the retrosophageal space.

**FIGURE 23-13** Use of a Penrose drain to encircle the esophagus.

**FIGURE 23-14** Closure of the crura to repair the hiatal defect.

Attention is then turned to creation of the fundoplication. The fundus is grasped on the posterior surface passed posterior to the esophagus through the retroesophageal window such that the greater curvature will become juxtaposed to the left side of the esophagus (Fig. 23-15). This allows for the fundus to be invaginated around the esophagus to avoid a “twisted” wrap. The surgeon may pull the fundus back and forth in a so-called “shoeshine maneuver” to ensure that the stomach is not twisted and that there is adequate mobility to create a tension-free fundoplication. A 56 to 60 Fr dilator should be passed through the gastroesophageal junction while creating the wrap to ensure that the wrap is not excessively tight. The anterior surface of fundus at the greater curvature is brought anterior to the esophagus. A fundoplication of approximately 2 cm in length is then created around the distal esophagus just superior to the gastroesophageal junction by securing the right and left limbs of the fundus anteriorly along the greater curvature using two pledgeted polypropylene sutures (although some surgeons prefer braided suture), incorporating full thickness stomach and partial thickness right lateral esophageal wall with each suture. The fundoplication should be pointed to the patient’s right, ensuring that there are equal lengths of the wrap anteriorly and posteriorly (Fig. 23-16). Special care should be taken to avoid incorporation of the anterior vagus nerve in the sutures. Finally, intraoperative upper endoscopy is performed to confirm proper position and construction of the fundoplication (Fig. 23-17).

**FIGURE 23-15** The gastric fundus being brought posterior to the esophagus.

**FIGURE 23-16** Construction of the Nissen fundoplication.

**FIGURE 23-17** Endoscopic view of completed Nissen fundoplication showing the normal “stacked coils” appearance.

**Collis Gastroplasty.** A Collis gastroplasty can be constructed if there is concern about a foreshortened esophagus. This is vital, as a foreshortened esophagus is a cause of recurrent transdiaphragmatic herniation. In this procedure, a continuation of the distal esophagus, or neoesophagus, is created from a tubularized portion of stomach. There are two methods of constructing a Collis gastroplasty.

In one method, an esophageal dilator is passed into the stomach along the lesser curvature. The anvil of an EEA stapling device is passed through the posterior surface of the stomach and then through the anterior surface about 2 to 3 cm from the angle of His at the left lateral border of the dilator. A gastric window is created in the fundus when the stapler is fired and the donuts removed. Through the window, a linear cutting stapler is then placed and

deployed parallel to the dilator. When fired, it creates a tubular esophageal extension from gastric tissue. The Nissen fundoplication is then performed around this neoesophagus (Fig. 23-18).

**FIGURE 23-18** Construction of a Collis gastroplasty using an EEA stapled technique. (Reproduced with permission from Horvath KD, Swanstrom LL, Jobe BA: The short esophagus: pathophysiology, incidence, presentation, and treatment in the era of laparoscopic antireflux

surgery, *Ann Surg* 2000 Nov;232(5):630-640.)

The other method of creating a Collis neoesophagus is the wedge gastroplasty. In this method, a triangle wedge of the fundus at the angle of His is excised by using a linear stapler to divide the stomach from the apex of the fundus to the dilator about 2 or 3 cm from the gastroesophageal junction. Another stapler is passed from the apex of the first staple line to the angle of His. When the stapler is fired, the neoesophagus is created. The fundus is then used for the fundoplication (Fig. 23-19).

**FIGURE 23-19** Construction of a Collis gastroplasty using a wedge gastrectomy technique. (Reproduced with permission from Terry ML, Vernon A, Hunter JG:

Stapled-wedge Collis gastroplasty for the shortened esophagus, *Am J Surg*. 2004 Aug;188(2):195-199.)

**Laparoscopic and Open Toupet Fundoplication.** Abdominal access for a Toupet fundoplication is similar to a Nissen fundoplication with respect to patient positioning and port placement. This is a 270-degree posterior fundoplication. The initial steps of the procedure are similar to a Nissen fundoplication for mobilization of the esophagus and repair of the hiatal hernia. The fundus is passed posterior to the esophagus in similar manner, but rather than a 360-degree wrap, each end of the fundoplication is sutured to the left and right anterolateral aspects of the esophagus with two interrupted nonabsorbable sutures for a 270-degree wrap (Fig. 23-20). To secure the wrap, the posterior gastric fundus is sutured to the right and left crus. As in the Nissen fundoplication, care must be taken to avoid injury to the anterior vagal trunk while suturing the fundus to the esophagus. This procedure is often employed in patients with esophageal motility disorders such as achalasia to prevent an outlet obstruction at the gastroesophageal junction.

**FIGURE 23-20** A completed Toupet fundoplication.

## **FAILURE RATES AND REOPERATION**

Failure rates for fundoplication have been reported to range from 2% to 17% for laparoscopic procedures to 9% to 30% for the open approach.<sup>86,92,93</sup> However, the overall reoperation rate after laparoscopic fundoplication is approximately 5%.<sup>94-97</sup> In a large retrospective database study of 13,000 patients over 15 years in the United States, reoperation most commonly occurred within the first year after initial surgery (1.7%), with a steady decline to 4 years, after which time it remained constant at approximately 0.5% per year.<sup>98</sup>

While initial antireflux operations have been shown to have the best chance at success, advances in surgical technique have allowed for improving results in redo surgery. Up to 84% of patients undergoing initial reoperation will have a good result.<sup>92</sup> Important principles of reoperative antireflux procedures include comprehensive reevaluation by objective testing (upper endoscopy, contrast esophagogram, manometry, pH monitoring, MII-pH, and gastric emptying studies) to properly identify the etiology of symptoms, complete reversal of any previous fundoplication to identify the natural anatomy, preservation of vagal nerves, identification of short esophagus, and proper approximation of the posterior crura prior to performing the new fundoplication. Redo antireflux surgery can be performed laparoscopically with excellent results.<sup>94,99</sup>

Nevertheless, patients who have undergone a redo fundoplication are at risk of yet another failure. Depending on operative findings, attempt at redo fundoplication may be appropriate. However, depending on findings of anatomic and physiologic testing, after the second or third redo fundoplication has failed, consideration should be given to resection. If esophageal function is adequate but gastric function poor, a total gastrectomy with long Roux-en-Y esophagojejunostomy may be appropriate. If esophageal function is poor, consideration for an esophagectomy may be appropriate.

## **Endoluminal Therapy**

Recently, there have been attempts to develop endoluminal treatments for GERD. These have centered on either endoscopic construction of a “valve” at the gastroesophageal junction or “augmentation” of the LES. It is beyond the scope of this chapter to provide a comprehensive review of these techniques

and devices, as many are now off the market. Nevertheless, we discuss two that are still commercially available and have data to support their use.

## **ENDOLUMINAL RADIOFREQUENCY APPLICATION**
